As experience with ceramic materials increased, care was taken to limit the number of blind alleys. This concept was supported by studies from Caplan and his colleagues showing that when porous ceramic cubes were implanted together with bone marrow-derived mesenchymal stem cells (MSCs) in muscle tissue, cells at the ends of blind alleys where oxygen tension was low differentiated into chondrocytes and adipocytes, whereas cells closer to the edges of the cubes where oxygen tension was high differentiated into osteoblasts.[38–40] The normal architecture of bone, particularly of trabecular bone, is one that provides for optimal exposure of osteoblasts to blood vessels. More recent ceramics have been designed to copy this architecture as much as possible. To accomplish this goal most effectively, manufacturers have used high temperatures to deorganify bovine bone, leaving the natural mineralized tissue architecture intact. At lower temperatures (300 °C), the mineral crystals also retain their physical properties (Bio-Oss, Geistlich Pharma Ag, Wolhusen, Switzerland), but there is also retention of minute levels of proteins including transforming growth factor β1 (TGFβ1) and BMP-2.[41] At higher temperatures (>1300 °C), the mineral becomes sintered and there is no retained organic component.[42]

6.617.2.2. Polymers

Nondegradable and biodegradable polymers are used for a variety of clinical applications today. Nondegradable polymers such as ultra high molecular weight polyethylene (UHMWPE) and poly methyl methacrylate (PMMA) are used as bearing surfaces in total joint arthroplasty and as acrylic cement for implant fixation, respectively. The success of these materials depends on osseointegration, and they are not intended to be replaced with bone.

Biodegradable polymers, depending on the clinical application, are replaced with bone, eliminating the need for an additional removal surgery, long-term biocompatibility issues, and the risk of stress shielding.[43] Biodegradable polymers used as suture materials[44,45] and as internal fixation devices[46] have been adapted for use in bone as 'bone void fillers,' which is a term used to define materials placed in bone voids that provide osteoconductive surfaces. Initial applications of these synthetic biodegradable polymers were in extraction sockets to stabilize the clot and facilitate bone growth.[47] More recently, they have been approved for use in orthopedic sites.[48,49] A goal of the biopolymers used as bone void fillers is that they degrade over the same time frame as new bone formation occurs. Polymers belonging to the polyhydroxy family including poly (L-lactide) and poly (D,L-lactide) (PLA), polyglycolide (PGA) and copolymers based on PLA and PGA, have been attractive because they degrade by hydrolysis, resulting in water and carbon dioxide. The degradation rates of PLA/PGA materials can be tuned by modifying the polymer chain length, the percent of each polymer type, the amount of cross-linking, and whether the L-form or the racemic mixture is used. There are two important drawbacks to PLA/PGA: the degradation products have the potential to acidify the local environment and cause inflammation, and the crystalline form of PLA may never completely degrade. These drawbacks have led investigators to develop alternative polymers for use in bone: polypropylene fumarate (PPF),[50] polycaprolactone (PCL),[51,52] tyrosine-derived polymers,[53] and polyanhydrides.[54]

6.617.3. Polymeric Bone Graft Substitutes to Tissue Engineering

Many of these materials were originally conceived in particulate form to be either space fillers or carriers of bioactive peptides. However, their polymeric properties were quickly co-opted as tissue engineering scaffolds, either as osteoconductive matrices or as substrates for *ex vivo* cell growth. Scaffold fabrication techniques such as gas foaming, phase separation, fiber meshing, three-dimensional (3D) printing (solid free form fabrication, SFF), and microsphere sintering have been reported in the literature.[55–58] These techniques permit controlling porosity and surface characteristics to target specific clinical use.

Hydrogels are a popular choice for tissue engineering scaffolds because their stiffness resembles that of biological soft tissues. They also provide highly swollen 3D scaffolds that allow diffusion of nutrients and cellular waste. Hydrogels can be made with flexible natural and synthetic polymers. Natural polymers used to make hydrogels include proteins (collagen, gelatin, and fibrin) and polysaccharides (hyaluronic acid, alginate). Synthetic polymers include poly (ethylene glycol) (PEG), poly (acrylic acid) (PAA), and polypeptides. Hydrogel scaffolds are being investigated for cartilage[59] and bone regeneration.[60]

More recently, composite materials that better simulate the intricate environment inside the host bone have been developed. These may include mineral plus a protein scaffold, a polymeric scaffold plus cells, a scaffold plus one or more bioactive agents, or a combination that has all three components. The goal is to achieve better integration and rapid and efficient bone regeneration. Gene therapy or the transfer of genetic information to cells can be done to enhance bone induction. In the next part of the chapter, we focus on the bone tissue engineering technologies that are currently being studied and reported in the literature.

6.617.4. Bone Tissue Engineering

Bone tissue engineering has evolved through the combination of biological and engineering approaches to overcome the shortages of existing bone graft materials. A critical consideration in developing effective 'new age' bone grafts is the diversity of biological, mechanical, and structural challenges that exist with each clinical application. For example, craniofacial reconstructions require a strategy that can conform to complex

geometries while matching the shape of the defect. Approaches for repairing nonunited fractures need to address excessive motion, fibrosis, and occasional infection. Spinal fusion needs to locally deliver osteoinductive signals to produce bone where none existed previously. Large segmental bone defects, >3 cm, are a particularly challenging problem and require consideration of high mechanical demands under complex load-bearing conditions, angiogenesis to address mass transport issues, and innervation. As a result of these distinct applications, it is unlikely that only one approach will be effective in replacing or regenerating all bone. Therefore, more than most other tissues substitutes, new age bone grafts will need to be tailorable for specific applications.

6.617.4.1. Tailoring Biomaterials for New Age Bone Grafts

An early clinical application of bone tissue engineering as we know it today was used to replace an avulsed distal phalanx of the thumb at the turn of the century.[61] Cells isolated from the periosteum were expanded, suspended in alginate, injected into a carved porous coral implant, and fixed with calcium chloride. Although the procedure demonstrated what the potential of combining cells and tailorable biomaterials can offer in improving bone replacement, preparing the engineered graft was more time consuming than a conventional bone autograft and was considered to be no more effective.[62] To make these kinds of implants effective clinically, engineers, biologists, and clinicians must consider the complexity of the final product, how quickly it can be assembled, and how difficult it is to use in surgery in addition to its ability to osseointegrate and regenerate the biomechanical and physiological properties of bone. Regardless of the approach, it is clear that tailoring biomaterials will play a critical role in achieving these goals. In the following sections, different adjustable properties and modifications of biomaterials for new age bone grafts are described, starting from macroscopic characteristics down to the cellular level.

6.617.4.1.1. Anatomically specific shape and architecture

Replication of the anatomical shape is a critical criterion for engineered bone grafts for craniofacial reconstruction and orthopedic applications where fitting the defect and joint conformity are required. Biomaterial architecture parameters such as pore size, density, and interconnectivity are also important as these have subsequent effects on local mechanical properties, mass transport, blood vessel invasion, and osteogenic behavior. Traditional methods of achieving appropriate shape and architecture have included carving, molding, and salt-leaching, but these methods can have minimal accuracy, reproducibility, or throughput. These shortcomings have led to significant interest in using medical imaging techniques such as magnetic resonance imaging and computed tomography to fabricate customized bone constructs. Recent advances in both computation topology design (CTD) and SFF have allowed for rapid prototyping of highly reproducible engineered bone grafts with a spatial resolution up to 25 μm.[63] SFF techniques build structures using a layer by layer additive process and have been used with a wide range of metals, polymers, and hydrogels. Scaffolds for engineered bone grafts can be fabricated directly or cast in a mold created with SFF techniques. Specific strut architectures and precise porosity have also been created with this technology to create desired anisotropic elasticity and permeability for new age bone grafts.[55]

Scaffold design has evolved to include components that mimic biological function. Electrospinning technology has made it possible to produce both random and oriented fiber polymer constructs that provide an ECM-like meshwork for cell attachment and differentiation.[64–66] These polymer meshes can also be made into fabric sheets that serve as a barrier, limiting epithelial cell down-growth in oral applications[67] or fibrous connective tissue ingrowth in segmental defect applications.[68] By combining a barrier with a biodegradable polymer scaffold, the tissue engineering application becomes one of guided tissue regeneration. This concept has been well accepted in dentistry and is now being adapted to orthopedic applications.

6.617.4.1.2. Mechanical properties

Because bone serves a dual function as a protective and weight-bearing structure, mechanical properties of new age bone grafts and how these properties change once implanted are critical considerations. Local mechanical properties such as modulus and viscosity are chosen not only to provide initial stability and protection to the damaged area but also to elicit the desired osteogenic response. Stiffer matrices facilitate stem cell differentiation down the osteogenic lineage, whereas softer matrices that mimic the mechanics of other tissues do not.[69] Therefore, scaffold mechanical properties can be varied by adjusting the local architecture or using different biomaterial compositions.[55,70] It is well established that bone remodeling is a function of mechanical loading due to Wolff's law, and effective bone regeneration strategies can take this attribute into account by mechanically stimulating viscoelastic tissue-engineered constructs under normal bone loading.[71]

6.617.4.1.3. Degradation

With the goal of new age bone grafts to increase the speed and quality of bone regeneration compared to traditional methods, the biomaterial used must eventually be replaced. To achieve this, the degradation rate must be such that cell migration, ECM remodeling, and tissue growth can occur while maintaining mechanical stability. The degradation products must also be biocompatible while eliciting minimal inflammation. Recent approaches have tried to tailor biomaterial degradation specifically to the expression profile of matrix metalloproteinase (MMP)-related and ECM-related genes during bone remodeling. This approach would allow scaffolds to better work temporally with resident stem cells and MMPs naturally expressed during bone regeneration by cross-linking a polymeric biomaterial with MMP-degradable peptides.[72,73]

New age bone grafts have also used scaffold degradation to control the release of stimulatory signaling molecules to promote bone regeneration.[74] BMPs have been released from solid constructs to enhance bone formation *in vivo*, and angiogenic factors have also been delivered to address mass transfer concerns.[75,76] Based on different scaffold degradation properties, the release kinetics of multiple factors can be manipulated to provide more robust tissue formation in new age bone grafts.[77]

6.617.4.1.4. Surface chemistry and topographical cues

Surface chemistry and roughness have well-defined influences on osteogenic behavior. Osteoblasts and stem cells respond to groves, ridges, wells, and other features at the micron and nanoscale.[78] For titanium implants and biomaterial surfaces, rougher hydrophilic interfaces elicit a stronger osteogenic response from osteoblasts[79,80] and MSCs,[81] whereas disordered nanotopographical features enhance stem cell spreading and subsequent osteogenesis.[82] New age bone grafts have focused on incorporating these findings into 3D scaffolds. HA-collagen and carbon nanotube polymer nanocomposities are examples of nanophase reinforcements that are able to increase bioactivity and mechanical properties of engineered grafts.[70] Other approaches aim to generate an enhanced osteogenic environment by recreating the topographical context of native ECM through engineered 3D nanofibrous matrices. Biological and synthetic polymers are electrospun into 3D matrices with high spatial interconnectivity, high porosity, and oriented fibers to direct cellular morphology and migration for *in vivo* bone regeneration.[70,83] Fiber diameter and alignment within these biomaterials can influence bone growth while mimicing the function of the periosteum.[84,85] The surface chemistry of these fibers can also be modified to promote direct nucleation and deposition of HA.[86] Surfaces of fibers and other biomaterials can be modified with other biological components such as glycosaminoglycans and heparin that can localize growth factors important for angiogenesis and bone formation.[70]

6.617.4.1.5. Cellular adhesion

Cellular adhesion via integrins not only influences osteoblast migration and spreading but also provides cellular signaling and influences cell behavior and osteogenesis. ECM components such as collagen and fibronectin are important in stimulating osteoblasts and directing bone growth. Although these proteins have been incorporated into various new age bone grafts, recent strategies have focused to mimic and enhance the therapeutic function of these tissue components. These biomimetic modifications of new age bone grafts have centered on creating peptide mimetics based on motifs found in collagen, fibronectin, and bone sialoprotein.[87–89] By adjusting the presentation and surface density of these peptides, osteoblast adhesion, migration, and differentiation can be tailored. These specific peptide sequences can also provide more direct stimulatory signaling while reducing infiltration of nonosteogenic-specific cells.

6.617.4.2. New Age Bone Graft Approaches

In 1989, a method was described to implant autologous marrow cells containing MSCs in combination with a porous ceramic material to repair large femoral defects in rats.[90] The addition of the marrow cells significantly improved bone formation over just the implanted ceramic alone and showed that delivering stem cells with biomaterials may have clinical applications in repairing bone defects. What is unknown is the mechanism these cells participated in to facilitate bone regeneration. The delivered marrow cells could have produced bone directly, attracted surrounding osteogenic cells to produce bone, or delivered soluble signals that initiated bone formation from uncommitted progenitor cells. It is also possible that the implanted cells would have performed even better if the cells and biomaterial were stimulated into producing tissue *in vitro* prior to implantation. In the years following, new age bone grafts have focused on using one or more of these distinct mechanisms to develop approaches that would better regenerate bone.

6.617.4.2.1. *Implanting* in vitro *cultured tissues*

Ideally, bone grafts that are optimized *in vitro* will be remodeled once implanted *in vivo*. Therefore, one approach has been to prime bone graft for quicker and enhanced osseointegration and bone regeneration. This has been particularly useful for graft integration where two tissues are involved, such as osteochondral grafts or tendon grafts. To improve osseointegration and graft function, current *in vitro* culture techniques aim to recreate the heterogeneous structure of bone interfaces such as the osteochondral transition and bone-soft tissue interfaces. To recreate these structures, mechanical, chemical, and biological gradients developed *in vitro* are often used. Perfusion and dynamic compression bioreactors have been created for anatomically shaped grafts to manipulate the local mechanical and chemical environment.[91] Controlled delivery of soluble factors from biomaterials and gradients of immobilized retrovirus can be used to recreate biological gradients.[75,92] These *in vitro* culture techniques act directly on seeded cells to enhance differentiation, proliferation, and subsequent tissue deposition and mineralization.

Interestingly, attempts to grow bone nodules *in vitro* for bone tissue engineering have been less successful. While it is possible to culture osteogenic cells on scaffolds in bioreactors, if the conditions support matrix mineralization, the constructs tend to form a calcified shell, resulting in a necrotic core.[93,94] This is due to reduced nutrient diffusion into the construct as well as reduced diffusion of waste products out of the construct. These tissue-engineered constructs may still have utility as mineralized templates as they present a 3D matrix containing bone-like HA.[95]

6.617.4.2.2. Delivering MSCs

Since Ohgushi *et al.*[96] showed that marrow cell delivery can improve bone formation over porous calcium phosphate, many new age bone grafts have attempted to deliver MSCs isolated from adult tissues to improve tissue regeneration. Although the exact mechanism of how these cells recreate bone *in vivo* is not completely understood, it is believed that these cells can either produce bone tissue directly or stimulate bone regeneration by recruiting surrounding progenitor cells. Adult stem cells for bone regeneration have been isolated from bone marrow, adipose tissue, synovium, and muscle[97]; they are able to modulate the immune response and have the ability to home to damaged tissues.[98] The effectiveness of stem cells in new age bone grafts can be enhanced by differentiating them toward the osteogenic lineage, genetic manipulation, and co-delivery with other cell types.[99,100]

6.617.4.2.3. Osteoconduction

As noted previously, osteoconduction refers to the ability of a material to serve as a scaffold on which bone cells can attach,

migrate, and grow and divide. Osteoconductive materials need to be adjacent to bone to 'conduct' bone cells and is generally reminiscent of electricity being conducted through conductive materials. Therefore, osteoconductive materials cannot form *de novo* bone at sites where bone previously did not exist such as the muscle. Current common clinical materials that actively use osteoconduction include terminally sterilized allografts and calcium phosphate synthetic substitutes.[101] New age bone grafts are able to tailor their osteoconductive properties by adjusting porosity, surface chemistry, topographical cues, and cellular adhesion sites.[70,78]

6.617.4.2.4. Osteoinduction

Osteoinduction is the process in which uncommitted progenitor cells in surrounding tissue are stimulated, undergo mitosis and osteogenesis, and form new bone. This process can occur not only in sites adjacent to the bone, but also in locations, such as the muscle, where the bone never existed previously. Because osteoconductive and osteogenic materials may have the same outcome as an osteoinductive material in the bone, the term 'osteoinductive' can only be applied to those materials that actually induce bone in nonbone tissues. Current clinical approaches that actively use osteoinduction include DBM produced by acid extraction of an allograft and recombinant human BMPs (rhBMPs)-2 and -7 on collagen sponges.[101] New age bone grafts aim to have biomaterials control the temporal and spatial delivery of osteoinductive factors like rhBMPs[75] or retroviral vectors increasing the expression of osteogenic genes[92] to provide a more localized bone formation while reducing the amount of osteoinductive molecules used.

6.617.5. Animal Models for Assessing Effectiveness of Bone Tissue Engineering Strategies

Bone tissue formation is mediated by a complex process orchestrated by osteoprogenitor cells and osteoblasts, which requires biochemical, biomechanical, and hormonal regulation by the body. Bone substitutes are used as treatments for bone healing and regeneration. Bone autografts are considered the gold standard to augment or enhance bone regeneration. However, autografts are limited by the size of the graft, in addition to high morbidity and painful extraction procedures and long recovery. Autografts, allografts, and xenografts usually result in an incomplete integration with the host tissue, mainly due to lack of vascularization. Infections and immune reactions are also associated with the use of allografts and xenografts.

Naturally derived and synthetic bone substitutes have been designed in order to avoid the limitations associated with standard treatments. Recently, tissue engineering has emerged with the potential to overcome the deficiencies that bulk materials have, integrating material science, mechanical engineering, and cell biology. These materials demonstrate biocompatibility and osteogenic potential in an *in vitro* environment. However, the complex cellular, biochemical, and systemic environments found in the body are impossible to replicate *in vitro*. Animal models are a powerful tool to evaluate bone grafting materials and their osteogenic potential, because the material will be exposed to several different cell types that can induce different tissue formations, encounter an aggressive local and systemic environment that may enhance graft outcome, and will experience a multitude of mechanical loads, factors impossible to reproduce *in vitro*.

The use of animal models to evaluate the potential healing capability of bone graft substitutes is critical in evaluation of their success. Mammalian animal species currently used in bone research include rat, rabbit, dog, sheep, pig, goat, and nonhuman primates, and some of the defect types commonly investigated include nongap fractures, segmental defects, cylindrical defects, and calvarial defects.[102] The numerous species and defect models available make selection of an appropriate defect model difficult. A number of factors need to be considered when choosing an *in vivo* model for research in bone tissue engineering.[102,103] Systemic factors such as age,[104,105] sex,[106] and hormone status[107] are known to play a significant role in bone repair and remodeling. It is therefore of importance to select a model that closely mimics both the physiological and pathophysiological conditions for the intended use.

Critical-size defects (CSDs) were originally defined as "the smallest size intraosseous wound in a particular bone and species of animal that will not heal spontaneously during the lifetime of the animal."[108] Later, this concept was redefined as "a defect that shows less than 10 percent bony regeneration during the animal lifetime."[109] A number of factors must be considered when selecting a specific animal species as a model system to evaluate bone substitutes. Selection criteria should include animal availability, size, age, sex, species phylogeny, metabolic and systemic conditions, cost of acquisition and care, size of operating field compared to size of defect, and postsurgery recovery time. Important factors for selecting the right CSD model are the anatomic location, bone structure, vascularization, presence of periosteum, physiological conditions, mechanical load, and pathophysiology.

6.617.5.1. Calvarial Defects

Calvarial defect models are important to test biomaterials and tissue-engineered constructs that will eventually be used in human defects in this area, common after trauma, degenerative diseases, or brain surgery. Age is particularly important, as it has been shown that the ability of animals to heal large calvarial defects is age-dependent.[110–112] Mice and rat models of calvarial defects are common, as they are easy to breed and husbandry is simple. However, they present a challenge due to a very small operating field and thin calvarial bones. Instead of surgical tools, dental burrs and drills are used to operate precisely in the confined space. An advantage of using these models is the availability of athymic models, which allow for study of materials from other species while limiting host graft rejection responses. Also, because of the ease of housing, these models are often used to examine the time course of bone formation and remodeling in the defect.

Defects in mice are typically 4 mm,[113–116] but smaller[117] and larger[117] defects can be found in the literature. In mice, a single defect is created in the center of the skull, although some studies have reported using bilateral parietal defects.[114] The size of the critical defect in mice varies widely depending on the age and strain used. Mouse models have been extensively used to characterize the ability of MSCs to repair calvarial defects. Bone marrow stromal cells with overexpression of

Runx2,[118] Osterix,[119] or BMP-7[117] have been used in this model, as have osteoblasts overexpressing Noggin.[120] The scaffolds used range from simple (gelfoam,[117] vitrigel,[121] or silk fibroin[117]) or more complex (combinations of RGD and MMP substrates in PEG hydrogels[113] or apatite-coated PLA/PGA scaffolds[120]). There is little uniformity in study endpoints, with the earliest ending after 2 weeks[116] and the longest extending to 6 months.[122] Most examine multiple time points, between 2 and 8 weeks.[114,120,121]

In rats, as in mice, there is no agreed-upon defect size. Defects used include 3.8 mm,[123] 5 mm,[124] 8 mm,[125,126] 8.8 mm,[127] and 9 mm.[128] Rats have also been used extensively for models of stem cell repair of calvarial defects, including muscle stem cells,[126] adipose-derived stem cells,[129,130] and MSCs.[125] Studies examine these cells grown on scaffolds such as polyglycolic mesh[126] or poly lactide-*co*-glycolic acid scaffolds.[130,131] Other studies focus on the effect of biomaterials on bone healing, using polylactic or polyglycolic acid[132,133] or bone substitutes (eggshell-derived,[134] bioactive glass[135]). A combination of scaffolds or cells and growth factors such as BMP-2[125,131,136,137] and VEGF[137] have also been studied using the rat calvarial defect model. Study endpoints vary, ranging from 4,[125] 6,[129] 8,[126] or 24,[127] but many studies examine bone formation at 12 weeks.[130,131,137] Experiments using the rodent models require inclusion of a control group as bone ingrowth occurs even in the absence of a scaffold or bone graft.[138]

Larger animal models are also used to test healing of calvarial defects. Rabbits are the most commonly used model in these types of defect studies, and study materials primarily in male animals. Defects are typically bilateral parietal circular or square defects between 10 and 15 mm.[139–141] Many materials have been examined in this defect, including PCL scaffolds,[142] resorbable polyethylene glycol hydrogels,[143] silica gels,[144] and bioactive synthetic bone and hyaluronic acid hydrogels.[145] Less commonly, a single mid-cortical defect is used,[146] but healing may be affected as this defect includes the sutures of the skull.

Dogs are less commonly used as experimental models in cranial defects. In one study, a 2 cm × 2 cm bone flap was created to test the efficacy of a mixture of β-TCP, calcium, collagen, and autologous bone fragments in bone healing.[147] The second study used combinations of DBM, platelet-rich plasma, and bone morphogenetic protein 2 to regenerate a 6 cm × 2 cm calvarial defect that crossed the sagittal suture.[148] Both studies examined bone formation 3 months after surgery.

Sheep defect models have a wide range of parameters. Some studies used 2 cm × 2 cm parietal defects,[149] one testing TCP-chitosan-collagen hydrogels and poly(L-lactide-*co*-glycolide).[150] However, usually multiple defects are created, which allows for testing of multiple substances in the same animal. A study testing HA composites[151] female, five 1.68 cm diameter defects-four in parietal, one in temporal bone, 1 year. In studies that specified sex, female animals were used. Studies examined healing time points of 6–14 weeks, up to 1 year.

Goats are a less-common large animal model, but one study examined healing of a single 2.2 cm diameter circular defect in the center of the cranial bone using poly lactide-*co*-glycolide/TCP/bone morphogenetic protein 2.[152]

Defects vary depending on the material, species, and location. A study outcome also depends on surgical technique. One study[123] demonstrated that the periosteum is crucial in bone repair; in that study, rat cranial defects did not heal from the defect edges but instead bone repair was found to originate from the periosteum. Another study found that as long as the periosteum is in contact with the implant material, the defect heals.[153] The question whether the defect involves only cranial bone or transverses sutures will also affect study outcome. For this reason, it is also important to accurately and thoroughly describe surgical procedures, as small variations in technique may influence experimental outcome.

6.617.5.2. Maxillary Sinus Augmentation

Sinus floor augmentations are used mostly to test particulate materials, including allogenic and autogenic bone, xenograft substitutes, synthetic biomaterials, or some combination of materials. More recently, growth factors have also been combined with these materials and examined in a sinus lift model.[154,155] Currently, autogenous bone is used as the gold standard as a bone substitute. The most common technique for animal models of maxillary sinus augmentation was described by Haas *et al.*[156] A crucial step in experimental design is the choice of the model. While larger species such as monkeys,[157–162] minipigs,[163] goats,[164] and sheep[165,166] have been used in such studies, they have several serious limitations. To achieve adequate statistical power, a large number of animals are necessary, and animal husbandry of these species is expensive. The majority of studies using this model only use a small number of animals, usually three to five animals per experimental variable, for their studies given these limitations. However, rabbits are a less costly alternative species and have been successfully used as a model in this type of defect.[167,168] Because of the ease of breeding and housing these animals, a larger sample size can be used for experiments. When larger animal models are used, bilateral defects are often created and both control and test materials implanted into the same animal. Typically, bone formation in maxillary sinus lift models is examined after periods ranging from 4 to 8 weeks, although some studies observe animals until 26 weeks postoperatively.[156]

6.617.5.3. Analysis Methods for Cranial Defects

Many studies examine the quality and quantity of new bone using histomorphometric analysis. Samples are either fixed in formalin and decalcified sections embedded in paraffin or undecalcified sections embedded in a plastic such as methyl methacrylate. Sections can be stained with hematoxylin and eosin to make quantitative measurements of defect area, total bone area, marrow area, fibrous tissue area, or void areas. Histological analysis is well accepted as an evaluation method for bone formation. However, it is limited in that many sections of each sample and many fields of each section must be analyzed in order to get an accurate representation of new bone growth. Sections can also be stained with antibodies conjugated to fluorescent molecules to determine the presence of several markers, including angiogenic factors. If cells are implanted, an *in vitro* imaging system can be used to track them after surgery. *In vivo* imaging systems can be used to quantify cells labeled with bioluminescence,[113,169] fluorescent proteins,[114,119,170] or quantum dots.[171]

For gross qualitative analysis, X-rays are used. However, images can only be related descriptively to one another. More recently, microcomputed tomography (μCT) has been used to quantify differences in bone formation. After the user determines a threshold of mineralization for bone, both 2D and 3D images are taken. This allows for calculation of bone volume density, bone surface density, and trabecular thickness. Additionally, contrast agents can be administered during the harvest process to quantify blood vessel formation. Studies comparing μCT and histology have found the results to correlate well.[172–174] The advantage of μCT is that it allows you to analyze the whole sample or a smaller portion of the sample nondestructively, leaving the bone intact for additional studies such as mechanical testing.

6.617.5.4. Critical-Sized Segmental Defect

One of the most commonly used animal models for bone tissue engineering research is the critical-sized segmental defect model. A CSD is defined as the minimum defect size that is incapable of complete healing without intervention.[103] Clinically, a defect is of critical size when complete healing has not occurred over a period of 6 months following injury. In general, the length of a critically sized defect should be at least 1.5 times the diameter of the selected bone,[175,176] although several studies indicate that a defect length of 2–2.5 times the diameter of the affected bone is necessary to create a critical-sized defect.[103]

Several animal species and anatomical locations are used in critical-sized segmental defect models. In the rat segmental defect model, a femoral defect between 5 and 10 mm is commonly used.[177] On account of the load-bearing nature of the rat femora, it is necessary to use either internal or external fixation to stabilize the defect. In rabbits, the defect sites typically used are the radius and ulna where fixation is not required and the typical critical-sized defect is 20 mm.[178] In canines, 20–25 mm defects of the radius, ulna, and femur are the most used.[179,180] In the large animal models of goats and sheep, the tibia is a common defect site and defect sizes in these animals range from 25 up to 50 mm.[181]

All of the aforementioned segmental defect models have been used to assess the bone-healing capability of various bone graft substitutes. Marks *et al.*[182] examined the healing capability of DBM in a rat segmental defect model and found that after 4 weeks, animals treated with DBM + antibiotic exhibited greater bone formation both radiographically and histologically compared to control animals and animals treated with antibiotic alone. Wojtowicz *et al.* coated PCL scaffolds with a short biomimetic peptide motif (GFOGER) and implanted coated and uncoated scaffolds into an 8 mm rat femoral segmental defect. After 12 weeks, it was observed that greater bone formation occurred in animals with GFOGER-coated PCL scaffolds compared to both empty defects and uncoated PCL scaffolds using both X-ray and micro-CT analysis techniques, although no difference in torsional strength of the newly formed bone was observed between the treatment groups.[183] Using a canine ulnar model, Itoh *et al.*[179] found that high doses of rhBMP-2 (160 or 640 μg) incorporated into PLGA/gelatin sponge scaffolds resulted in complete bridging of a 20-mm segmental bone defect 16 weeks postoperatively as assessed using radiographic and histological methods. The effect of a resorbable calcium phosphate paste on healing of a critically sized (30 mm) sheep tibial defect was examined by Bloemers *et al.*[184] Using both radiological and biomechanical torsion testing, it was found that at 12 weeks, animals treated with the resorbable calcium phosphate paste had more bone radiographically and exhibited a significantly higher torsional stiffness compared to animals that had been treated with autologous bone or with calcium phosphate particles.

These models have been referred to incorrectly as nonunion models because they fail to heal with bone. As they are used in the examples earlier, they are actually acute defects and as such, they test the ability of the tissue engineering approach to either enhance or retard the ingrowth of bone from the bone ends. This is particularly true if the preparation of the defect site includes removal of periosteum, thereby limiting the source of stem cells to the bone ends or to the muscle surrounding the defect. If the defect is allowed to heal in the absence of a graft, it will heal with fibrous connective tissue typical of nonunion, containing areas of fibrocartilage.[185] These chronic nonunions have also been treated effectively using injected MSCs[186] and injected BMP-7,[187] as well as by implanting PLA foams with adsorbed BMPs following resection of the nonbony tissue.[188]

Another model that is useful for the evaluation of the osteogenic capability of bone graft substitutes as well as their remodeling is the bone marrow ablation model. This model takes advantage of the rapid endosteal bone formation that occurs following injury to the marrow cavity of rat tibial bone.[189] In the rat ablation model, the bone marrows of rat tibias are flushed of cells. A blood clot and granulation tissue fill the marrow space over the first 3 days of healing. Primary bone begins to form on the endosteal surface by day 6 and eventually fills the marrow cavity. Remodeling of the newly formed bone occurs between days 12 and 25, resulting in resorption of the primary bone. By day 35 postablation, replacement of the primary bone with bone marrow is complete, resulting in the regeneration of normal tissue phenotype.[190] This process follows a well-documented timetable,[191,192] which makes it a very useful model for the study of normal bone repair and for the evaluation of extrinsic and intrinsic factors that may influence it. The enclosed environment of the marrow space restricts the distribution of test materials and localizes their effects, thus allowing the model to be useful for the study of the effects of biomaterials that have been designed for bone augmentation. Using the tibial marrow ablation model, our lab has found that hyaluronic acid in combination with DBM stimulates endosteal bone formation through increased vascularization of the ablated marrow space, suggesting that incorporation of hyaluronic acid with DBM may enhance osteogenesis in bone-healing applications (unpublished data). While the bone marrow ablation model can provide information on the rate of endosteal bone formation, its strength lies in the opportunity to assess graft remodeling.[190]

Glossary

Allograft A tissue or organ obtained from one member of a species and grafted to a genetically dissimilar member of the same species.

Autograft A tissue or organ that is grafted into a new position on the body of the individual from which it was removed.

Gene therapy The application of genetic engineering to the transplantation of genes into human cells in order to cure a disease caused by a genetic defect.

Tendinopathy Clinical syndrome encompassing overuse tendon injuries characterized by pain, swelling, and impaired function.

Xenograft A graft obtained from a member of one species and transplanted to a member of another species.

Abbreviations

ACL	Anterior Cruciate Ligament
bFGF	Basic fibroblast growth factor
BMP	Bone morphogenetic proteins
ECM	Extracellular matrix
GAG	Glycosaminoglycan
HA	Hyaluronan
IGF-1	Insulin-like growth factor 1
MCL	Medial Collateral Ligament
MMP	Matrix metalloproteinase
MSCs	Mesenchymal stem cells
PCL	Poly-ε-caprolactone, Poly(caprolactone)
PDGF	Platelet derived growth factor
PDLLA	Poly-D, L-lactic acid
PDS	Polydioxanone
PET	Polyethylene terephthalate

PGA	Polyglycolic acid
PLAGA	poly(lactide-*co*-glycolide)
PLA	Polylactic acid
PLGA	polylactic-*co*-glycolic acid
PLLA	Poly-L-lactide, Poly-L-lactic acid
PTFE	Polytetrafluroethylene
QLV	Quasi-linear viscoelasticity
RGD	Arg-Gly-Asp
SIS	Small intestina submucosa
TGF-β	Transforming growth factor beta
UHMWPE	Ultrahigh molecular weight polyethylene
VEGF	Vascular endothelial growth factor

6.618.1. Introduction

Tendon and ligament disorders represent a large subset of musculoskeletal injuries that cause pain and functional disability for millions of individuals and account for a significant portion of health care costs.[1] Thirty to fifty percent of injuries in athletes are diagnosed as soft tissue injuries,[2] and this number will likely continue to rise. For example, reconstruction of the anterior cruciate ligament (ACL) of the knee after rupture is one of the most common procedures performed by orthopedic surgeons. The number of patients undergoing ACL reconstruction is increasing substantially, and although considered a relatively safe procedure, the need for subsequent knee surgery in these patients is not uncommon, especially in young and female patients.[3] In addition to the large percentage of the young and active affected by tendon and ligament disorders, the current population continues to be active at older ages. Large increases in visits from active elderly patients for musculoskeletal problems are expected to be seen in sports and occupational medicine clinics. Soft tissue injuries, such as rotator cuff tears, are becoming increasingly common in individuals over the age of 40. This is not only important in terms of long-term pain and disability caused by these conditions, but treating these musculoskeletal injuries will put increasing financial pressure on health care providers worldwide.[4]

Tendons and ligaments are soft tissue structures that are frequently injured as a result of acute trauma or chronic overuse. Sudden, severe loading, which can occur with athletic injuries or motor vehicle accidents, can lead to rupture of tendons or ligaments. For example, sudden rotational force applied to the knee with the foot planted in the ground can lead to acute rupture of the ACL or medial collateral ligament (MCL), common injuries that occur in young, active individuals. Excessive and repetitive loading of tendons, such as the rotator cuff tendons of the shoulder, can similarly lead to rupture. In addition, tendons are often subject to overuse injuries, collectively referred to as tendinopathies. Repetitive tendon motion can lead to microtrauma and pathologic changes within the substance of the tendon. Historically, these changes were described by the term 'tendinitis,' implying inflammation of the tendon[5–8]; however, histopathologic studies have shown that these tendons have pathologic degenerative lesions in the absence of inflammation.[9–11] Therefore, 'tendinosis,' or degeneration of the tendon, or even the more general term 'tendinopathy' may be more appropriate to describe these overuse tendon injuries.

Our understanding of the pathogenesis of these common tendon and ligament conditions continues to improve. However, current treatment regimens formulated on evidence-based medicine are limited, and outcomes are often suboptimal. The preferred and accepted treatment for overuse tendinopathy is unclear. Tendinopathy was traditionally treated with corticosteroids, and nonsteroidal antiinflammatory medications for inflammation that later was found to be, if anything, only transiently present. Results of other treatment modalities such as shock wave therapy, physical therapy, and eccentric strengthening protocols have provided inconsistent results.[12] Neither ACL nor rotator cuff tendon injuries spontaneously heal after acute injury. Although these common musculoskeletal injuries have accepted standards for surgical treatment, many challenges remain in treating recurrent or recalcitrant cases. ACL reconstructions can successfully be performed with local autograft or allograft but are limited by the morbidity associated with local autograft and the immunogenic and infectious complications from allograft. Rotator cuff tears are typically treated with direct repair, but chronic or massive tears not amenable to direct repair pose a significant challenge to the orthopedic surgeon. Furthermore, these repaired tendons and ligaments do not return to baseline structural and mechanical function after injury, repair, and healing and can be complicated by rerupture. Restoring this normal mechanical function after injury, healing, and repair remains a significant challenge. This underscores the importance of developing new therapeutic approaches to treat these injuries.

Fortunately, with recent advancements in tissue engineering, novel strategies aimed at restoring native tendon and ligament structure and function show a lot of promise in their ability to address these challenging problems. As cellular and biochemical mechanisms for tendon and ligament healing continue to be elucidated, identification of therapeutic targets and manipulation of these biochemical mediators may prove useful in improving the healing potential of these structures. Recent studies have used gene therapeutic methods to introduce growth factors to improve tissue healing and remodeling, while others have used cell therapy and the introduction of mesenchymal stem cells (MSCs) in an attempt to improve healing. Furthermore, combinations of biocompatible scaffolds with appropriate cell populations and biologic growth factors are being investigated, with the hope that recreating or enhancing the mechanical and biological environment will lead to tendon and ligament properties similar to or mechanically stronger than native tissue. Tissue engineering is a quickly emerging field with great potential and could soon revolutionize the treatment for a number of musculoskeletal conditions.

The aim of this chapter is to concisely review the fundamental aspects of synthetic and natural biomaterials used in tendon and ligament repair. The first section of this chapter will review the basic biomechanical properties of tendons and ligaments. While similar in gross appearance and in general

load-transmitting capacities, these structures differ significantly in functional, compositional, and structural properties. Understanding basic properties of tendons and ligaments is crucial in the creation of novel biomaterials that reproduce and augment their native properties. The following sections will review various methods and techniques required to test tendons and ligaments, including methods of augmentation and factors involved in choosing an appropriate animal testing model. The primary section of this chapter will review individual biologic and synthetic graft materials and describe the primary characteristics that make each a suitable material for tendon and ligament repair and healing. Finally, the current clinical application and experience with these biomaterials will be summarized.

6.618.2. Basic Properties of Tendon and Ligament

Tendons and ligaments are dense fibrous connective tissue structures that assist in the complex mechanical functions of the musculoskeletal system. From an anatomical and functional perspective, tendons transmit forces from muscle to bone and allow for dynamic joint and limb motion, while ligaments connect two bony structures to serve as static stabilizers of joint movement. Tendons can center the action of multiple muscles across a joint (e.g., Achilles tendon), as well as distribute the pull of one muscle to several bones (e.g., posterior tibial tendon). They also transmit the force produced by large muscle bodies through narrow fibro-osseous tunnels and can change the direction of pull across a joint. Each tissue has structural and mechanical properties that are specific for its anatomic location and function and are composed of a unique combination of water, collagen, proteoglycan, and other constituents. Furthermore, tendons and ligaments have viscoelastic properties that allow for both smooth movement during normal joint motion and resistance to excessive or abnormal joint displacement at high loads. Also of importance is the ability of these structures to adjust their biomechanical properties in response to mechanical loading. Studies have shown that exercise-related loading can improve properties of tendons and ligaments. Immobility can lead to quick deterioration of properties, making these structures more susceptible to injury and pathologic change. Excessive or repetitive motions can lead to tendon and ligament injury or rupture as well. A series of coordinated responses occur after injury, leading to a structurally and mechanically inferior structure (see **Chapter 5.525, Tissue Engineering Approaches to Regeneration of Anterior Cruciate Ligament**).

6.618.2.1. Classification

Because tendons and ligaments have different structural and material properties based on anatomic location and function, these structures can be classified in many different manners. Tendons are commonly classified based on the presence or absence of a surrounding synovial sheath, as this characteristic affects the healing capacity and ultimate structural and mechanical properties of tendon after injury. The soft tissue envelope and vascularity of sheathed tendons are fundamentally different than unsheathed tendons. Sheathed tendons are relatively avascular and get nutrition from the synovium. In unsheathed tendons, a much richer blood supply is able to reach the tendon around its surface, and therefore, these unsheathed tendons have a greater potential to heal. Ligaments are similarly grouped into intraarticular or extraarticular location based on the presence or absence of joint synovial fluid surrounding the structure. Intraarticular ligaments such as the ACL of the knee are surrounded by synovial fluid and have poor healing potential because of the limited vascularity and nutrition available to the ligament. This is in contrast to extraarticular ligaments such as the MCL which have a more extensive blood supply and therefore can heal spontaneously.

6.618.2.2. General Structure

Tendons and ligaments are dense fibrous connective tissue structures that are composed of closely packed collagen fibers arranged in a hierarchical fashion. In the tendon, rod-like collagen molecules align in a quarter-stagger array parallel to the longitudinal axis of the tendon to form a fibril, the smallest tendon structural unit (**Figure 1**).[13] Collagen fibrils form fibers that are bound by endotenon, a connective tissue that contains nerves, blood vessels, and lymphatics. The hierarchial structure continues with a group of collagen fibers forming a fiber bundle, a group of fiber bundles forming a fascicle, and a group of fascicles forming the tendon. Contiguous with the endotenon is the epitenon which covers the tendon unit and similarly carries nerves, blood vessels, and lymphatics.[14] A third layer of thin connective tissue, the paratenon, also covers the tendon, and in some anatomical sites is the synovial sheath. The paratenon and epitenon together form the peritendon which provides protection and reduces friction to allow for smooth gliding of the tendon along the bone and other adjacent soft tissue structures as they pass through areas of high mechanical stress. The basic hierarchical structure of a ligament is similar to that of a tendon. The thin connective tissue covering of a ligament, the epiligament, is analogous to the epitenon in a tendon, and similarly carries vasculature, lymphatic, and nerves. In their relaxed state, the collagen fibers of both tendons and ligaments form a typical wavy pattern, also referred to as a 'crimp,' when viewed under a polarized light microscope. This contributes to the nonlinear mechanical properties for all collagenous tissues. One key difference between tendons and ligaments is that collagen fibers do not run as parallel to the longitudinal axis of ligament as they do in a tendon, and intertwining of collagen fibers is more common than in a tendon.

Common to both these structures is the tendon–bone or ligament–bone junction, also called the enthesis. This is a complex area of transition in tendons and ligaments that plays an important role in their structural and mechanical properties. The morphology of this enthesis is similar between the two structures and can take on two different forms, direct and indirect insertions.[15] Indirect fibrous insertions such as the femoral insertion of the MCL have collagen fibers that anchor the tendon or ligament directly into the bone through calcified collagen fibers, also called Sharpey's fibers.[16] In direct fibrocartilaginous insertions, such as the supraspinatus tendon of the rotator cuff, a continuous change in tissue composition occurs in four zones. The composition of the first zone is the same as the midsubstance of tendon composed of aligned collagen fibers. Toward the second and third zones, the collagen type changes with progressively more type II and III collagen in the

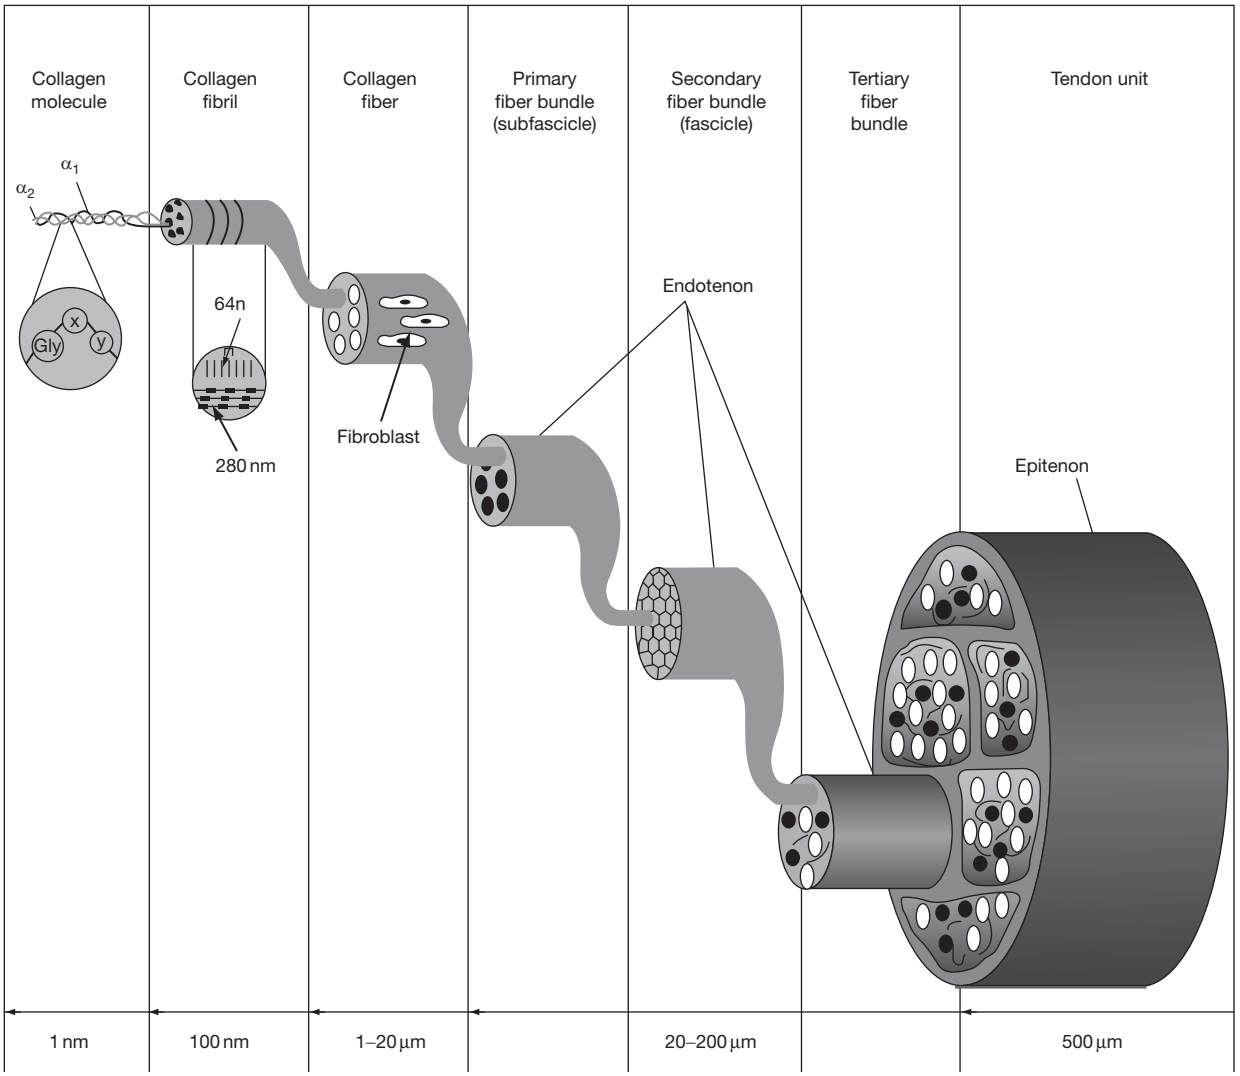

Figure 1 A schematic of multiunit hierarchical structure of the tendon. Reproduced from Wang, J. H. *J. Biomech*. **2006**, *39*, 1563–1582, with permission from Elsevier.

fibrocartilaginous second zone, and predominantly type II collagen in the mineralized fibrocartilage of the third zone. The fourth zone is bone and contains type I collagen and other minerals. This gradual transition and change in collagen composition helps to dissipate mechanical load at the enthesis, which is typically weaker in tension than the midsubstance of the tendon or ligament. On the opposite end of the enthesis in tendon is the myotendinous junction, in which collagen fibrils interdigitate with myofibroblasts, allowing for contractile proteins to exert their effect on tendon fibers.[17] This is the weakest point of the muscle–tendon unit.

6.618.2.3. Composition

Tendons and ligaments are composed of water, collagen, proteoglycans, glycoproteins, cells, and ground substance. Although the constituents are similar between the two structures, there are subtle differences that are important to differentiate in terms of their structural and mechanical properties. Water is the primary constituent of healthy tendon or ligament, accounting for about 60% of the wet weight. Of the dry weight, collagen is the primary component in both tendon and ligament and accounts for about 80% of the dry weight.[18] The content of water is lower and collagen is higher in tendon than in ligament. However, this varies not only between tendons and ligaments, but also between different anatomical and functional types of tendons and ligaments. Other constituents include elastin, proteoglycans, and a minimal amount of inorganic components. This overall composition allows these structures to have characteristics of tensile strength as well as elasticity.

Collagen contributes greatly to the tensile strength of tendon/ligament and comprises the majority of the dry mass of normal tendon. Individual collagen molecules consist of a triple chain helix with a characteristic tripeptide sequence which usually is glycine, proline, and hydroxyproline. These collagen molecules are synthesized in the endoplasmic reticulum of fibroblasts. They exist as procollagen chains which later

undergo multiple posttranslation modifications such as hydroxylation and glycosylation before reaching its typical triple helical structure. These collagen molecules are cross-linked by various enzymes in the extracellular matrix (ECM), such as lysyl oxidase.[19] This cross-linking increases the modulus of the tendon or ligament, and variations in cross-linking are responsible for the structural difference between the numerous different collagen types and their mechanical properties.[20] Both tendons and ligaments are primarily made of type I (> 90%) collagen, followed by type III and V collagen; ligaments contain more type III collagen than do tendons, which may be reflective of the increased metabolic activity in ligaments.[21] There are also minimal amounts of other collagen, notably type V collagen in vascular walls and type X collagen in mineralized fibrocartilage at the tendon/ligament enthesis. Type II collagen, predominantly found in cartilage, is also found in certain cartilaginous zones of tendons that undergo compression.

Glycoproteins are an integral part of the tendon and ligament ECM. Proteoglycans, which account for 1–5% of the dry weight of tendon and about 1% of the dry weight of ligament, are glycoproteins composed of a core protein attached to glycosaminoglycan (GAG) chains. GAGs are long linear carbohydrate side chains consisting of repeating disaccharide units. These side chains are highly negatively charged, a characteristic that is important in maintaining the hydration and viscoelastic behavior of tendon and ligament. The amount of proteoglycan present in these structures is largely dependent on whether the tendon or ligament is in a tension or compression-bearing location.[22,23] Proteoglycan content has been found to constitute a larger portion of the dry weight in compression-bearing regions than in tension-bearing regions. Larger aggregating proteoglycans, such as aggrecan, hold water within the fibrocartilage to resist compression, especially at the transition of ligament and tendon to bone.[22] Other smaller proteoglycans, particularly small leucine-rich proteoglycans such as decorin and biglycan, play a key role in the biologic activity and remodeling of tendons and ligaments.[24] Along with proteoglycans, there are numerous other glycoproteins in the ECM that contribute to the matrix structure. Elastin, which composes about 2% of the dry weight of tendon and a variable amount in ligament, is likely partially responsible for elasticity and return to a crimped configuration after loading.[25] Tenascin-C is a glycoprotein that interacts with collagen fibrils and is found in the tendon body as well as the enthesis and the myotendinous junction.[26] It is typically upregulated by mechanical loading of the tendon. Fibronectin is another important glycoprotein located on the collagen surface that attaches cells to various types of collagen and regulates cell migration and differentiation.[27] The role of these small and large proteoglycans and glycoproteins in tendon and ligament in the fundamental ECM processes continue to be elucidated.

Tendon fibroblasts, or tenocytes, and ligament fibroblasts represent the predominant cell type present in these structures, but like most types of connective tissue, these cells are few in number and not as abundant as the ECM. These spindle-shaped cells are oriented longitudinally between collagen bundles. Although tendons and ligaments have an overall low cellularity, these fibroblasts contain prominent cytoplasmic processes that allow for complex three-dimensional structural network and cell-to-cell communication via gap junctions with connexins 32 and 43.[28] As will be discussed in the following sections, tendons and ligaments respond to mechanical loading. The complex fibroblast structural network and cell-to-cell interactions are responsible for the changes in structural, compositional, and mechanical properties. When mechanically loaded, tendon and ligament cells alter gene expression and protein synthesis that lead to changes in ECM proteins such as collagen, proteoglycans, and other glycoproteins. Although the cellular mechanisms for mechanotransduction are still being elucidated, interactions between the actin cytoskeleton of fibroblasts, multiple cellular components such as integrins and membrane receptors, and the ECM help to detect changes in mechanical forces.[29,30] This leads to changes in gene expression and protein synthesis as a result of a cascade of cell-signaling events.[31] This complex array of interactions between tendon and ligament cells and their ECM allow these structures to respond and adapt to changes in mechanical loading conditions.

6.618.2.4. Biomechanical Properties

Tendons and ligaments must be able to transmit high tensile loads with minimal deformation. Structural properties describe the tensile capacity of the overall tendon structure and are therefore dependent on the size and shape of the tendon. Material properties, sometimes referred to as mechanical properties, describe the intrinsic quality of the tendon substance independent of its shape or size. These properties of tendon can be determined by mechanical tensile testing and are represented by the relationship between load and elongation (structural properties) and stress and strain (material properties).

Structural properties of tendon and ligament can be characterized by a load–elongation curve which typically has three major components. The toe region is the nonlinear portion at the base of the curve that is thought to be due in part to the recruitment and alignment of crimped collagen fibrils. The stiffness, defined by the slope of the curve between two defined points of elongation, increases throughout the toe region. Because collagen fibers are initially more highly aligned in the primary loading direction in tendon than in ligament, the toe region of the load–elongation curve for ligaments is typically larger, as more time is required to reorient the fibers in the direction of loading. Transition from the toe region to the linear region occurs as the tendon fibrils become aligned and oriented parallel to the longitudinal axis of the tendon. After the fibers are recruited and oriented in the longitudinal direction, the collagen fiber structure itself is being stressed. As opposed to the highly compliant toe region, the tendon exhibits much higher stiffness in the linear region of the curve. At a certain elongation, tearing of the collagen fibrils will begin to occur. This is represented by a reduction in the stiffness of the curve and signifies a transition from the linear region to the failure region. The highest load placed on the tendon before failure is the ultimate load, and the maximum elongation before failure is the ultimate elongation. Similarly, a stress–strain curve characterizes the mechanical properties of the tendon (Figure 2). Stress (the amount of force per unit of area) and strain (change in length relative to original length)

take geometry of the tissue into account. In a stress–strain curve, the elastic modulus is obtained by calculating the slope between two limits of strain. The tensile strength is the maximum stress achieved before failure, and the ultimate strain is the strain at failure.

An important characteristic of tendons and ligaments is their viscoelastic behavior, referring to the time and load-dependency of their mechanical behavior. This characteristic is thought to happen through the complex interaction of collagen, water, and other ECM constituents. These viscoelastic properties can be affected by changes in extracellular constituents, especially at low load stress states. Loading and unloading of the same specimen will result in different paths along a load–elongation curve (**Figure 3**). Hysteresis is a viscoelastic characteristic that refers to the amount of lengthening a tissue maintains during cyclic loading. On the curve, the hysteresis loop that is formed represents energy that is dissipated during the process. Two classic experimental characteristics of viscoelastic behavior are stress relaxation and creep. In a creep test, a specimen is subjected to a constant force and the deformation will gradually increase with time. In a stress relaxation test, a specimen is held at a constant elongation and the load will decrease with time as the tissue relaxes. A peak stress is still reached like in elasticity, but viscoelastic materials stress relax over time. Strain rate sensitivity is another characteristic of viscoelasticity. Tendons absorb more energy but are less effective in transferring load at low strain rates, but at high strain rates, tendons are less deformable and are more effective in moving large loads. This nonlinear behavior of tendon is important to take into account during experimental testing. Quasi-linear viscoelasticity (QLV) was developed as a method to model soft tissues such as tendons and ligaments. This model takes into account the nonlinear elastic response and time-dependency as separate functions in a general viscoelastic model. QLV is considered 'quasi-linear' as the material is assumed to be linear in its viscous time-dependent response; however, the deformation and instantaneous stress–strain behavior can be nonlinear. QLV can characterize the time-dependent and nonlinear behavior of tendons and ligaments and is an important tool in constitutive modeling in biomechanics of these structures.

6.618.2.5. Effect of Mechanical Loading

Mechanical and biochemical properties of tendons and ligaments have been shown to change in response to mechanical loading. Multiple studies have looked at the effect of mobilization and training while others have studied the effect of disuse and immobilization on tendon and ligament. In various investigations using mice, rabbit, and swine animal models, the structural and mechanical properties of tendon and ligament were higher in animals exposed to repetitive exercise compared to those that had no exercise.[32–36] Biochemical changes were evident as well, with increased collage deposition and upregulation of growth factors important in collagen synthesis and cell proliferation with exercise.[37,38] Repetitive and excessive mechanical loading, however, can become pathologic as evidenced by the clinical entity of tendinopathy. It is thought that repetitive loads lead to tendon microtrauma as well as production of inflammatory mediators, including PGE_2 and LTB_4.[39–41] Elevated levels of prostaglandins and leukotrienes produced in response to tissue damage contribute to further degeneration of tendon and tissue edema.[42,43] The effect of disuse on tendon is not so well studied, but the general conclusion from multiple studies is that immobilization of the tendon and ligament decreases stiffness and tensile strength, which occurs at a faster rate than the increase in structural properties seen with remobilization.[44–46]

6.618.2.6. Tendon and Ligament Injury and Healing

Following injury, tendons and ligaments undergo a reparative process that involves coordinated phases of inflammation, repairing/proliferation, and remodeling. The initial event in the inflammatory phase after injury involves the formation of a hematoma containing inflammatory cells, erythrocytes,

and platelets collected at the injury site. Resorption of necrotic debris ensues, and various chemotactic fibers recruit tendon fibroblasts to the area, and collagen synthesis and deposition begins as early as 3 days after injury. In the proliferative phase, these tendon fibroblasts continue to synthesize collagen as well as other ECM components into the wound site. The abundant amount of collagen tissue that is formed produces what appears like scar tissue by gross appearance between the two edges of the tendon or ligament. Histologically, the collagen matrix appears disorganized. Remodeling and realignment of fibroblasts and collagen fibers begins around three weeks after injury, presumably in response to stress along the longitudinal axis of the tendon. The end result is scar-like tendon tissue that is mechanically inferior to native tissue. Multiple studies have shown that after injury, these structures return to only a fraction of native strength.

Various growth factors and cytokines play a crucial role throughout this process. The primary growth factors that have been studied are insulin-like growth factor 1 (IGF-1), platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), and transforming growth factor β (TGF-β). During the inflammatory phase, high expression of IGF-1 leads to proliferation and migration of fibroblasts to the healing tendon or ligament, which leads to increased proteoglycan and collagen production. Injection of this growth factor has been shown to accelerate functional recovery in rat Achilles tendon. PDGF is also present during the inflammatory phase and plays a role in cell migration and proliferation; it increases DNA synthesis in tendon fibroblasts and is required for fibroblast division and replication. bFGF and VEGF regulate cellular migration and proliferation and also promote angiogenesis. TGF-β has three isoforms, TGF-β1, TGF-β2, and TGF-β3, that each plays varying roles in the inflammatory and repair phases of tendon healing. While TGF-β1 promotes tissue fibrosis when overexpressed, TGF-β3 has been shown to improve tissue scarring. The roles of each of these cytokines and growth factors on inflammation, angiogenesis, cell differentiation and proliferation, and ECM synthesis are still being elucidated.

As previously discussed, exercise has beneficial effects on tendon and ligament properties, but the effect of mechanical loading on tendons and ligaments during healing after injury is not as clear. This is in large part due to concerns that motion may compromise the healing process, particularly at the insertion site. Animal studies investigating the role of early controlled mobilization after flexor tendon repair have suggested increases in mechanical properties and improved tendon excursion,[47,48] but similar studies in looking at passive motion after rotator cuff repair show no difference in mechanical properties and a detrimental effect on joint range of motion.[49] In chronic tendinopathy models, mechanical loading is thought to stimulate fibroblast proliferation and collagen synthesis.[50] Further investigations into the role of immobilization and mechanical loading on the postoperative management of tendon and ligament repair are necessary. Understanding the complex interactions between cytokines, growth factors, and the response of fibroblasts to mechanical loading during healing is difficult but crucial in determining the optimal regenerative milieu for future biologic therapies.

6.618.2.7. Summary

A thorough appreciation of tendons and ligament properties and healing is necessary when attempting to replicate native tissue with tissue-engineered constructs. Knowledge of the basic structural and mechanical properties of tendons and ligaments is important in the development and testing of new constructs. Also, understanding the components and mechanisms behind tendon and ligament healing can be helpful in determining targets for novel therapeutics. Biocompatible scaffolds should mimic the collagen fiber structure, while combinations of specific cell lines with growth factors may be able to assist in recapitulating the dynamic interaction that occurs between cells, their ECM, and their response to mechanical loading and injury.

6.618.3. Augmentation of Scaffolds

While tissue-engineered constructs can help promote tendon and ligament healing, biomaterials alone are insufficient to restore tissue to its preinjured state. Augmentation techniques are used to manipulate or supplement biomaterials to help bridge the gap between engineered structures and natural tissue. *In vitro* studies are an excellent way to optimize augmentation techniques before investing in preclinical or clinical studies and therefore are imperative to the advancement of biomaterials research. Mechanical testing by simple tensile testing, cyclic fatigue, and creep and stress relaxation testing can be combined with biochemical testing such as cell proliferation assays, evaluation of cytotoxic properties, or bioresorption studies. By minimizing confounding variables introduced with *in vivo* studies, these studies can assist in determining the optimal environment for biomaterial integration. Outcomes from *in vitro* studies can then be used to transition these augmentation techniques into *in vivo* models. Two broad categories of scaffold augmentation include various methods of mechanical stimulation and chemical stimulation, such as cell seeding, growth factor implantation, gene therapy, and scaffold surface modification (see **Chapter 3.312, Cell Culture Systems for studying Biomaterial Interactions with Biological Barriers**; **Chapter 3.313, Histological Analysis**; **Chapter 3.316, Immunohistochemistry**; **Chapter 3.321, Microarrays in Biomaterials Research**; **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design**; **Chapter 5.502, Engineering Scaffold Mechanical and Mass Transport Properties**; **Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation**; **Chapter 5.506, Effects of Mechanical Stress on Cells**; **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**; **Chapter 5.507, Tissue Engineering and Selection of Cells**; **Chapter 5.508, Scaffold Materials for hES Cell Culture and Differentiation**; **Chapter 5.509, Cell Encapsulation**; **Chapter 5.510, Engineered Bioactive Molecules**; **Chapter 5.511, Rotating-Wall Vessels for Cell Culture**; and **Chapter 5.512, *In Vivo* Bioreactors**).

The incorporation of cells into biologic scaffolds can improve its composition, structure, and biomechanical properties. This technique requires selection of a particular cell type that has the desired properties. Once procured, these cells can be

purified, cultured, and then seeded onto a scaffold *in vitro*. In tendon repair models, scaffolds have been seeded with many different cell types including MSCs, dermal fibroblasts, and tendon and ligament fibroblasts.[51–53] Once implanted into the injury site, these cell-seeded scaffolds can provide additional signals to encourage cell proliferation and tissue regeneration; provisional mechanical support is provided by the scaffold while native tissue ingrowth occurs. MSCs have recently garnered much interest as a target for cell therapy because of their ability to differentiate into certain lineages of tissue, including tendon, with the appropriate conditions and stimulus.[52,54] Tenocytes, the primary cell type in tendons, have been shown to significantly improve the mechanical properties of scaffolds in tendon repair.[51] Other studies have focused on using tenocytes and dermal fibroblasts in cell therapy; dermal fibroblasts are an attractive option as they are more accessible than tenocytes or MSCs and could potentially achieve similar results. Multiple studies have shown a positive effect of cell therapy on the biomechanical properties of biologic scaffolds.[52,53]

Because adhesion of a large number of cells to the scaffolds is integral to cell therapy, multiple methods of encouraging cell integration have been investigated. Increasing the porosity and surface area to volume ratio of the scaffold, such as that seen in nanofibrous membranes, produces a more hydrophilic material and can increase the cell seeding efficiency.[55] Another commonly used method involves coating the scaffold with a material known to be involved in cell adhesion. For example, various ECM glycoproteins, such as fibronectin, vitronectin, and laminin, contain the RGD (Arg-Gly-Asp) tripeptide cell-binding domain that attaches to integrins on the cell surface. Coating the surface of scaffolds with these glycoproteins may enhance cellular attachment, and a positive effect on cellular response and tissue regeneration may be seen.[56,57]

Local delivery of growth factors can potentially improve tendon and ligament healing by enhancing migration and proliferation of cells as well as the synthesis of tissue. Growth factors that have been well-characterized in tendon healing include IGF-1, TGF-β, bFGF, PDGF, and VEGF. During the initial inflammatory phase, PDGF-BB and bFGF stimulate cell proliferation and mitogenic responses,[58] while multiple isoforms TGF-β aid in wound healing through matrix deposition; specific isoforms of TGF-β have opposing effects in tissue fibrosis and scarring.[59,60] Bone morphogenetic proteins (BMPs), a subgroup of the TGF-β superfamily, can affect tissue differentiation and induction into tendon- and cartilage-like phenotypes. For example, BMP-12 has been shown to increase proliferation and expression of type I and III collagen in healing tendon.[61] VEGF can stimulate endothelial cell proliferation and angiogenesis to improve the blood supply and nutrition to healing tendon. Although the effect of these specific growth factors on tendon and ligament healing has not been fully elucidated, manipulation and regulation of these growth factors have great potential for enhancement of tissue healing.

Gene therapy is a technique by which an exogenous gene can be transferred into a host genome, allowing for sustained expression of specific cytokines or growth factors.[62] This technique uses viral vectors, such as adenoviruses or retroviruses, or nonviral methods, such as naked DNA or liposome to incorporate a specific gene of interest from the carrier to the host genome. Tendon and ligament fibroblasts can be transduced with particular growth factors known to be important in the healing process, with the hope that overexpression will lead to enhanced structural properties. The increase in cellular activity from cytokines or growth factors could result in more robust tendon and ligament repair constructs. One of the main limitations to gene therapy is that certain methods, particularly the use of viral vectors, are immunogenic and can cause a toxic or inflammatory host response. Another concern in gene therapy is insertional mutagenesis, or the chance that a tumor could be induced with incorrect DNA placement within the host genome.

Cross-linking is another chemical method which can play a significant role in achieving desired structural and material properties. Cross-linking of collagen is a natural posttranslational process that occurs in the ECM of tendons and ligaments which provides additional mechanical integrity to the collagen fiber structure. Various chemical and physical treatment, such as genipin,[63] can be used *in vitro* to affect the intramolecular and intermolecular cross-linking of collagen, and therefore, the solubility of collagen[64]; insoluble fibrils will provide a much stronger structure biomechanically. Manipulation of these cross-links can be performed in an attempt to match the properties of native tissue and be more suitable for implantation. The enzymatic degradation of collagen fibers by collagenases can also be reduced or suppressed, resulting in a mechanically stronger structure with increased number of cross-links.

Scaffolds can also be augmented by fibrin-based materials to promote cell proliferation and differentiation. Fibrin-based biomaterials are biocompatible, biodegradable and have an inherent affinity for biological surfaces. However, because it is mechanically weak and does not maintain a desired shape after *in vivo* implantation, it is usually paired with more mechanically robust structures in scaffolds such as synthetic polymers and used as a cell delivery-system to expedite tissue healing.[65,66] These materials can be prepared using a solution containing fibrinogen, fibronectin, thrombin, factor XIII, plasminogen, and aprotinin. Fibrinogen is a glycoprotein that is converted to fibrin monomers by thrombin; these monomers are then cross-linked by activated factor XIII to form a network of fibers. The rate at which the fibrin scaffold will be absorbed *in vivo* is determined by the ratio of plasminogen to aprotinin.[66]

Mechanical stimulation is a vital component of engineering tendon and ligament repair structures. In order to form well-organized ECM in load-bearing tissues, tendon and ligament fibroblasts must set forth appropriate mechanotransduction mechanisms. These complex mechanisms affect the type and amount of ECM produced, the release of cytokines and growth factors, and the morphology of cellular structures. It has been shown that the fibroblast response is dependent on the type of mechanical stimulation (cyclic strain, uniaxial tension, biaxial tension, shear stress), as well as magnitude and duration of mechanical loading.[67] For example, although native tendon and ligament is composed of predominantly type I collagen, tendons and ligaments subjected to compressive loading modify ECM synthesis and processing, leading to an increase in type II collagen synthesis and a resultant fibrocartilaginous phenotype. Increases in collagen production due to mechanical stimulation are concomitant with increase in matrix metalloproteinase (MMP) activity. MMPs, and other enzymes, are also synthesized in response to mechanical stimulation to

maintain balanced ECM remodeling. MMP activity degrades randomly-oriented scar tissue, which can be replaced with oriented collagen matrix. In addition to ECM synthesis, specific cell-signaling mechanisms also are activated during mechanical loading that induce the cytoskeletal reorganization important in maintaining the baseline elongated, spindle-like morphology of the tendon and ligament fibroblasts.[67,68]

6.618.4. Animal Models in Tendon and Ligament Research

With tissue engineering becoming a large part of research that is conducted in the tendon and ligament field, establishing and utilizing appropriate *in vitro* and *in vivo* preclinical models is a necessary step in the development and testing of new materials and techniques. Research utilizing human tissue, while providing information that directly correlates with the human condition, is limited by timing and availability of obtaining such samples for analysis. Commonly, human tissue can only be obtained during the end-stage chronic pathology rather than throughout disease progression. In addition, the methods by which to obtain tissue are typically invasive. In humans, disease progression is often evaluated radiographically or clinically by functional deterioration, which may not always correlate well with the actual disease process. It is impractical to study disease pathogenesis and response to treatment well in humans. The use of animal models allows for invasive evaluation at the tissue, cellular, and molecular level and avoids the limited and invasive nature of conducting human tissue research. These animal models allow the safety and efficacy of new materials and techniques to be tested in an *in vivo* model before translation into human trials.

6.618.4.1. Choosing an Appropriate Animal Model

Choosing an appropriate animal model for testing biomaterials involves consideration of a number of conditions that most appropriately addresses the specific research question at hand. Therefore, there is no one best model when speaking in general. Determining the most appropriate model involves finding an optimal integration of similar tissue properties and anatomy, analogous injury characteristics, pertinent outcome measures, and appropriate feasibility and cost. Clearly, the appropriate tissue and anatomy must be reproduced. Although tendons and ligaments share similar properties, they do have fundamental differences that require differentiation of the two for modeling.[69] The fact that ligaments have two bony attachments while tendons have one bony and one muscular attachment has implications not just on basic mechanical properties, but also on the appropriate evaluation of those properties such as preparation and gripping of tendon samples for mechanical testing. Anatomic location is also crucial. As mentioned previously, the presence or absence of surrounding synovial fluid or synovial tissue has implications on healing properties of the respective tissues. Intraarticular ligaments and intrasynovial tendons are surrounded by synovial fluid, which provides lubrication and also limits the healing potential of these structures as a consequence of a limited blood supply. Some structures in their native form may be considered extrasynovial, but after injury, would be considered intrasynovial (e.g., supraspinatus tendon). As will be discussed, the surrounding specific bony and soft tissue anatomy may be an important factor, especially when choosing a model for tendinopathy.

The various types of injuries and methods to reproduce them must be taken into account when selecting an appropriate animal model. Partial injuries and complete tears can occur, and complete injuries can be further subdivided into those that have gap formation and those that do not. These characteristics have specific implications on the treatment modality. Partial tears and complete tears with no gap formation, such as a partial MCL, may be amenable to nonsurgical treatment. Therefore, an appropriate animal model would study direct healing of tissue and evaluate methods to accelerate tissue healing. On the other hand, some injuries involve complete disruption of the tendon or ligament and gap formation, such as complete tears of the ACL of the knee or rotator cuff of the shoulder. Unlike the MCL, these injuries do not commonly heal spontaneously; instead, they commonly require surgical intervention. Therefore, the purpose of an animal model would be to evaluate the role of various surgical techniques and/or tissue-engineered constructs on tendon/ligament with gap formation. In general, evaluation of surgical manipulation and techniques is more accurate in large animal models. Methods of inducing tendinopathy include mechanical and chemically-induced models. Choosing an appropriate animal model should take into account the time and labor-intensive nature of mechanical loading, which best simulates the human condition. Chemical induction of injury is less invasive and easier than mechanical loading. However, it is dissimilar to what is thought to cause tendinopathy in humans. The chosen technique of injury must be easy, consistent and reproducible.

As mentioned previously, tendons and ligaments have a complex response to different mechanical loading conditions. Many studies have shown that postoperative activity or immobilization has an effect of tendon, ligament, and tendon/ligament-to-bone healing. Therefore, the ability to control this condition should be considered. Protective immobilization after tendon repair, such as rotator cuff repair, has been shown to be beneficial, and exercise too soon after surgery can be detrimental. In other circumstances such as flexor tendon injuries of the hand, postoperative motion after repair is necessary to prevent adhesion formation that will limit gliding of the tendon. Smaller animals should be used when control of postoperative activity level is required, as controlling the activity of larger animals is difficult.

The specific outcome measures should be taken into consideration when deciding on an animal model. Tissue properties can be assessed in a variety of ways, and each method has implications on the animal model to be used. The structural properties of the target tendon or ligament are usually of primary concern given the primary function of these structures. Larger samples from large animals are typically easier to test mechanically. Gripping of the bone attached to the tendon/ligament is generally less problematic than gripping soft tissue structures, such as the musculotendinous junction of the tendon. Other tissue properties, such as biological, biochemical, and molecular properties, also need to be taken into account.

Size consideration is also of paramount importance when taking these into account. Histologic sectioning is easier done on smaller animals. On the other hand, obtaining adequate quantities of RNA in small animals can be difficult given the low cellularity of tendon and ligament. Dependent on the techniques used to handle DNA, small animal models may not be optimal for these types of studies. A significant limitation that must be considered is the gene sequence information available for specific species; only the mouse genome has been completely sequenced.

Lastly, the financial cost and resources required to manage the animals must be taken into account. In general, although large animal models may sometimes offer more accurate manipulation and offer a better parallel to human anatomy and disease, the cost and resources needed to care for these animals is significantly more than that needed for small animals. This must be balanced with the need for the desired study sample size, as the cost of obtaining a minimal amount of large animals for an adequately powered study may be prohibitory.

6.618.4.2. Animal Models of Tendon Injury

An important distinction that must be made before choosing an appropriate animal model for tendons is whether the tendon to be modeled has the presence or absence of a synovial sheath. Flexor tendons of the hand, as well as the long head of the biceps and flexors of the foot, are intrasynovial tendons that are commonly used in animal modeling. These tendons are present in sheaths containing lubricating and nourishing synovial fluid. This fluid surrounds the tendon, and therefore, the blood supply to the tendon is more limited than in extrasynovial tendons.

Research using animal models of intrasynovial tendons has typically focused on scar and adhesion formation after tendon injury and repair. These peritendinous adhesions limit the normal gliding motion of tendons and lead to pain and functional disability in the human. Many different animal models including the chicken, rabbit, and dog have been used to replicate the intrasynovial tendon healing environment. Historically, an extrinsic healing mechanism prevailed, and these adhesions were thought to be important in providing cells and factors important in the healing process based on studies in canine flexor tendon.[70,71] However, these tendons were found to also heal by an intrinsic mechanism marked by cellular proliferation from the epitenon and endotenon.[72] Studies using the flexor tendons of rabbits showed tenoblastic activity and tendon healing without formation of adhesions.[73] More recent studies have investigated the role of early postoperative mobilization as a solution to adhesion formation and maintenance of normal flexor tendon excursion. Most commonly used in the canine model, a passive motion machine has been used to test the effect of activity level on healing flexor tendon and the formation of peritendinous adhesions.[74–76] The chicken and the rabbit have accessible flexor tendons that have been used to test the effect of certain growth factors on flexor tendon healing and adhesion formation, both by local delivery and by gene therapeutic methods.[77–80] These various animal models have been instrumental in testing the effects of various mechanical and biologic factors that affect flexor tendon healing.

Extrasynovial tendons have an inherently different healing environment than intrasynovial tendons. Because synovial fluid does not surround the tendon, blood supply is not an issue. The rotator cuff tendons, patellar tendon, and Achilles tendon are the most common extrasynovial tendons that have been modeled. Previous work has shown that the rat shoulder joint has anatomic similarities with the human shoulder joint. The supraspinatus tendon passes below the coracoacromial arch, similar to that in humans, making it a suitable animal model for studying rotator cuff tendons (**Figure 4**).[81] This rat supraspinatus is a well-established model, and the surgical accessibility of this tendon makes it a good target for testing the effect of various rotator cuff repair techniques. Although the rat model is the most established model for rotator cuff tendinopathy, the rabbit is also another model that has been used to study the supraspinatus.[82,83] Because the required bony anatomical features of the Achilles and patellar tendons do not need to match the human as specifically as the bony features adjacent to the rotator cuff, there are numerous animals, including mouse, rat, and rabbit, that could be acceptable to model these tendons, depending on the particular research questions to be asked.

Multiple animal models have been used to better understand the etiology and pathology of tendinopathy. Tendinitis and tendonosis in animal models can be induced by mechanical and by chemical means. As previously mentioned, the anatomic relationship of the bony architecture and the rotator cuff tendons in the rat shoulder are similar to that in a human. By using this relationship and by running rats on a declined treadmill, supraspinatus tendon injury can be created and used as a model for rotator cuff tendinosis.[84] The contribution of extrinsic causes can also be tested in the model using various methods to decrease the space between the overlying arch and the supraspinatus tendon.[85,86] This overuse supraspinatus model in the rat is one of the few animal models that utilizes active mechanical overloading for inducing tendinosis. Other mechanical means of inducing tendonosis include passive participation methods, such as utilizing electrical stimulation to cause muscle contraction in rabbit Achilles tendon and dropping a weight on exposed rat Achilles tendon.[87] Chemical means of inducing tendinosis have also been widely used. Using collagenase in animal models can reproduce many of the important traits seen in clinical tendinopathy, such as matrix degradation, increased cellularity, and increased vascularity.[88,89] By using this method, the pathogenesis of tendonosis has been studied,[89,90] and the effects of various treatment modalities have been evaluated.[91,92] Since the enzyme is degrading collagen fibers rather than causing mechanical damage, debate exists about whether this is a valid model for tendinosis since tissues tend to begin to heal after the initiation of the injury, rather than continue with the tendinopathic condition. Corticosteroids,[93,94] cytokines,[95] and prostaglandins[40,96] have also been used as chemical means to induce tendinopathy. Further work in characterizing these various animal models will lead to improved treatments and outcomes for tendinopathy.

6.618.4.3. Animal Models of Ligament Injury

The MCL and the ACL are two commonly injured structures that are typically studied with animal models. Because the MCL is

J.; Carpenter, J. E.; Debano, C. M.; Banerji, I.; Moalli, M. R. *J. Shoulder Elbow Surg.* **1996**, *5*, 383–392, with permission from Elsevier.

extraarticular and the ACL is intraarticular, these two ligaments respond differently to injury. Smaller animals are typically used to model the MCL given its surgical accessibility. Larger animal models can be helpful in replicating the bony anatomic features that are important in the normal and reconstructed ACL.

The MCL is a structure that typically spontaneously heals in humans, and the response of ligament to healing and effects of growth factors on this healing are usually tested in animal models.[97,98] Testing the effects of growth factors on accelerating the healing process is also tested in animal models.[99,100] The rat and rabbit MCL have both been used as a model for MCL injuries due to low cost and ease of care, but some feel that the larger size of the rabbit allows for a more consistent and reproducible injury to the MCL.[98,101–103] Testing the effects of mobilization and immobilization on ligament healing has also been carried out using the rabbit model and has been significant in guiding the clinical treatment and rehabilitation after MCL injury.[46,104] The effects of various growth factors on the mechanical properties of the MCL are also commonly tested in this model. To show a clinically useful

result using the MCL, a significant improvement compared to a spontaneously healed ligament is necessary.

Animal models of the ACL, an intraarticular ligament, have typically focused on technical aspects of ligament reconstruction as well as tissue-engineered constructs to aide in ligament healing. Because ACL ruptures do not heal spontaneously and are not amenable to primary repair, the use of animal models to test new reconstructive techniques and novel biomaterials has grown. Collagenous or other biocompatible scaffolds with matrix amenable to cell seeding is a newer reconstructive option that is often tested in various models. Typically, larger animals are necessary to recreate the bony anatomy; in addition, a larger size is necessary to be able to consistently reproduce certain surgical techniques. The sheep, dog, and goat knee are often used to test new constructs, and results have been promising.[16,105–112]

6.618.5. Graft Materials

With the advent of tissue engineering, tendon and ligament grafts have transitioned from a primary role of mechanical stability to a multifaceted role integrating mechanical stability with active regeneration and incorporation of living tissue. Various biomaterials can act as scaffolds with properties conducive to cell infiltration and growth and can be organized into three main categories: biologic, synthetic resorbable, and synthetic nonresorbable. These scaffolds, regardless of type, must be nontoxic and biocompatible. Certain scaffolds possess specific characteristics, such as high porosity, which can be utilized to enhance cell infiltration and adherence. Other scaffolds have properties such as biodegradability that allow for temporary mechanical stability while functional remodeling of new tissue occurs around the scaffold. The goal of these constructs is to ultimately replicate the properties and characteristics of the native tissue particular to a specific anatomic site in a reliable and cost-effective manner (see **Chapter 4.401, The Concept of Biocompatibility**; **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing**; **Chapter 4.403, The Innate Response to Biomaterials**; and **Chapter 4.404, Adaptive Immune Responses to Biomaterials**).

6.618.5.1. Biologic Materials

Biologic materials are protein-based ECM components derived from human or animal connective tissues. Biological scaffolds are advantageous in that their components are similar to that of native tissue, and they usually contain surface proteins the host body is familiar with. Biologic materials are naturally porous and provide space for cell attachment, proliferation, and migration. This porosity allows biologic scaffolds to interact more rapidly with host tissue than synthetic materials (see **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**; **Chapter 2.208, Artificial Extracellular Matrices to Functionalize Biomaterial Surfaces**; and **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**).

6.618.5.1.1. Collagen derivatives

Collagen derivatives are a popular research target for tendon and ligament tissue-engineering applications. Since tendon and ligament ECM is composed primarily of type I collagen, scaffolds developed with collagen derivatives most closely replicate the structural and mechanical properties of native tissue. Collagen is nontoxic and has minimal immunogenicity. Additionally, collagen provides mechanical strength to the tissue and is a logical choice for a base scaffold support structure. Collagen derivatives support cell adhesion and cell proliferation, making them more attractive than some synthetic materials. Cells can be nested in these scaffolds *in vitro*, encouraging rapid synthesis and reorganization of the injured tissue when implanted. Collagen can be processed several ways leading to the following derivatives: porous sponges, gels, and sheets. This section will briefly describe both historical and more recent research in the field of engineering collagen derivative constructs for tendon and ligament applications (see **Chapter 2.212, Silk Biomaterials**; **Chapter 2.218, Elastin Biopolymers**; **Chapter 2.213, Chitosan**; **Chapter 2.214, Hyaluronic Acid**; **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**; **Chapter 2.216, Collagen–GAG Materials**; **Chapter 2.217, Fibrin**; **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**; **Chapter 2.221, Decellularized Scaffolds**; and **Chapter 2.222, Xenogenic Tissues and Biomaterials for the Skeletal System**).

Many studies have examined collagen gels as a potential scaffold material for tendon and ligament injuries. Collagen gels are usually seeded with cells and then cultured for a certain amount of time before implantation. MSCs are commonly used in collagen gel constructs but other cells such as dermal fibroblasts or tendon/ligament fibroblasts are also used. It has been observed that collagen gels encourage cell growth and that collagen substrates modify the morphology, migration, adhesion and differentiation of cells in certain conditions.[64] Cells seeded on collagen gels can cause contraction or shrinkage of the scaffold during culture. The amount of cell-induced gel contraction is dependent on the cell-to-collagen ratio.[113] The density of collagen is dependent on the amount of contraction. Fibroblast-seeded collagen gels can contract, causing the density of the collagen to drastically increase depending on the cell-to-collagen ratio. Gel contraction is thought to be the result of mechanical tension exerted by fibroblasts on collagen fibrils as opposed to cell–cell interactions.[64] Since the density of collagen is very high around cells and weak throughout the remainder of the gel, cell–collagen ratios are an important factor in designing appropriate scaffold materials. The rate and amount of gel contraction depends on a number of factors including quantity of serum in culture, number of cells, amount of collagen in cells, age of cells, and type of collagen.[64] Contraction can also be stimulated by growth factors or inhibited by excluding serum from culture. It is important to optimize culture conditions such as cell–collagen ratio before moving on to *in vivo* studies.

While collagen gels promote cellular activity, gels alone do not offer sufficient mechanical strength for effective repairs. In an attempt to increase the biomechanical properties of collagen gel structures, investigators began to add mechanical stimuli to collagen gels throughout the culture process. When cells are incubated in physically constrained collagen gels, they organize their ECM along the lines of tension created by the cell-mediated contraction of the gel.[54] It has been shown

that adding tensioned suture to the incubation setup aids in collagen gel attachment, contraction, and cell alignment.[113] Collagen gel contraction by cells significantly increases the structural biomechanics as well as the rates of improvement in material properties of repaired tendons in animal models.[54] This technique was later replaced with custom designed silicone dishes with anchor posts to replace the suture.[113] These anchor posts maintain axial strains on collagen gels[113] and the distance between the posts can be varied to allow for different gel aspect ratios. Larger aspect ratios demonstrate more highly aligned collagen gels.[114] Studies have also examined the effect of the cell-to-collagen ratios in gels and found that lower cell-to-collagen ratio constructs have a greater maximum force and maximum stress than repairs in rabbit patellar tendon defects using higher cellular concentrations.[115] Collagen gels can be integrated with other components or mechanically stimulated to improve mechanical properties of the scaffold and subsequently the repair constructs.

Collagen sponges are created by the lyophilization of collagen solutions and are porous three-dimensional structures. Before the lyophilization process, the size and structure of the pores can be modified by varying the pH concentration of collagen solution, temperature, or rate of freezing.[64] The porous nature of collagen sponges allows for better cell proliferation than collagen gels. Cell–sponge constructs can be created by applying the cell–collagen gel mixture to the surface of a type-I collagen sponge. These cell–sponge structures have been shown to improve the biomechanics and healing of tendon repairs in a rabbit patellar tendon model.[113,116,117] Constructs improve handling at the time of repair surgery, as they are much stiffer and have 10 times more collagen than previous collagen gel scaffolds.[116] These constructs significantly improve rabbit patellar tendon repairs along the range of *in vivo* loading when seeded with MSCs compared to the use of a gel–sponge composite alone.[116] The results from these construct studies are especially encouraging in that, for the first time, cell–gel–sponge repairs matched normal rabbit patellar tendon stiffness values up to peak *in vivo* forces.

Tensile mechanical stimulation has been applied to cell–sponge and cell–gel–sponge constructs in culture to try and improve repair mechanics. *In vitro* mechanical stimulation of cell–gel–sponge constructs significantly improved repair biomechanics after just 12 days in culture, despite the fact that collagen scaffold construct properties were not improved when tensile tested before implantation.[118] The tangent stiffness of cell–gel–sponge repairs have reached up to 25% beyond the threshold of normal rabbit patellar tendon peak *in vivo* forces, showing that mechanical stimulation in culture is an important tool in creating mechanically robust collagen biomaterials. A positive correlation has been demonstrated between linear stiffness and modulus for the in vitro collagen-derived construct and *in vivo* repair.[118] Further, the type, magnitude, and frequency of mechanical stimulation appropriate in culture for an optimized repair structure is dependent on the scaffold material. Additionally, some materials are more responsive to mechanical stimulation than others; cell–sponge constructs showed improved mechanical properties after being mechanically stimulated in culture, whereas cell–gel constructs did not.[119] This suggests that the collagen sponges, rather than collagen gel alone, facilitates cell response to mechanical stimulus.[119] Construct length has also been examined in both cell–gel and cell–sponge constructs. It was found that increasing construct length (distance between posts during cultures) increased construct linear stiffness and that longer, mechanically stimulated cell–sponge constructs had the highest *in vitro* stiffness overall.[114] *In vitro* studies can be used to optimize bioscaffold culture conditions such as mechanical stimulation, construct length, and aspect ratio. Many studies have demonstrated that it is possible to use *in vitro* predictors of *in vivo* outcome to expedite the development of biomaterial structures by reducing the time and cost of *in vivo* studies.

Growth factors can also be added to collagen-based scaffolds to encourage tissue healing. Specific growth factors can alter the biologic functions of cells seeded on scaffolds implanted in a tissue defect.[120] Growth factors accelerate many processes associated with healing including cell migration, proliferation, and collagen production in a scaffold that was originally mechanically weak. Specific dose–response relationships exist for each growth factor, so *in vitro* and *in vivo* studies are important in order to optimize the response desired for each implantation site.[120]

While there are many advantages to using collagen-derived constructs, they are not without their limitations. One disadvantage of collagen derivatives is the alteration of cell behavior. The different derivatives of collagen can have different effects on cell behavior, mechanical properties, and contraction. A disadvantage of seeding these collagen gels with cells is contraction or shrinkage of the scaffold during culture. Cells can reorganize collagen fibers in response to mechanical or chemical stimuli, causing scaffolds to shrink or lose their shape if the collagen is not stabilized throughout culture. Adding another material to improve mechanical properties or cell interactions with the collagen derivative can correct this limitation. Collagen-based constructs are subject to batch-to-batch variability, limiting the consistency and reproducibility of such structures. Collagen also does not offer comparable flexibility for modification as do biodegradable polymers.

6.618.5.1.2. Polysaccharides: Chitin, chitosan, alignate, and hyaluronan

Chitin is a one of the most abundant natural polysaccharides. It is a chemically inert linear polymer with high crystallinity.[121] It is plentiful, inexpensive, and biodegradable. Additionally, chitin has low immunogenicity and does not induce toxic reactions. Chitin enhances cellular proliferation and migration as well as accelerates wound healing.[122] Chitin scaffolds have also been shown to enhance collagen production at the repair site.[122] The pore size and thickness of the chitin fabric can be altered to control the mechanical strength of the construct. The diameter of fibers and density of chitin fabric can also be manipulated to control the degradation rate of the construct. Chitin is degraded by macrophages and decomposes more rapidly *in vivo* than other available scaffold materials. Since chitin fibers are partially absorbed early on and already possess low initial strength, chitin scaffolds must be supplemented with mechanically stronger materials in order to form an effective scaffold. For example, a braided combination of chitin and poly-ε-caprolactone (PCL) provides adequate initial strength to a rabbit Achilles tendon repair (see **Chapter 2.212,**

Silk Biomaterials; Chapter 2.218, Elastin Biopolymers; Chapter 2.213, Chitosan; Chapter 2.214, Hyaluronic Acid; Chapter 2.215, Collagen: Materials Analysis and Implant Uses; Chapter 2.216, Collagen–GAG Materials; Chapter 2.217, Fibrin; Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration; Chapter 2.221, Decellularized Scaffolds; and Chapter 2.222, Xenogenic Tissues and Biomaterials for the Skeletal System).[123]

Chitosan, alginate, and hyaluronan are resorbable polysaccharides with very similar properties to chitin. Chitosan is derived from chitin. Alginate is a nontoxic, noninflammatory polysaccharide derived from brown seaweed and can be processed in water. Hyaluronan (HA) is a repetitive linear GAG composed of *N*-acetyl-glucosamine and disaccharides of glucuronic acid. HA is a vital component of ECM, and its roles include interaction with proteoglycans and link proteins, facilitation of cell migration, differentiation, and adhesion, as well as eliciting electrostatic interactions with GAGs.[57] Like chitin, these materials produce a minimal foreign-body reaction and controllable mechanical and biodegradable properties. Chitosan, alginate, and hyaluronan alone possess low mechanical strength and can behave inconsistently with seeded cells. This problem may be ameliorated by combining them with other materials, or occasionally each other, to potentially increase strength and cell adhesion capabilities forming a more viable scaffold. For example, chitosan and alginate are commonly paired with agarose or hyaluronan to improve scaffold performance. Hyaluronan–chitosan scaffolds have also been shown to enhance fiber mechanical properties and improve adhesion to patellar tendon fibroblasts *in vitro* compared to chitosan scaffolds alone or a control group consisting of polyglactin 910.[124]

6.618.5.1.3. Silk

Silk is another potential biomaterial for tendon and ligament repair. It is biocompatible, degrades slowly and has attractive mechanical properties such as high strength and high elasticity.[125,126] The molecular structure and morphology of silk can be controlled through versatile processing and surface modification techniques.[125] Silk scaffolds can be made in many different shapes and forms. Silk grafts support cell adhesion, proliferation, and differentiation both *in vitro* and *in vivo* and promote tissue repair.[125] Additionally, woven silk scaffolds can be seeded with MSCs or modified with a peptide chain to increase collagen production. *In vitro* studies have shown that MSCs on silk scaffolds had robust proliferation and differentiation, while implantation of MSC scaffolds to repair ligament synthesized ECM and stimulated direct ligament-to-bone insertion.[112] Nanofibers or microporous silk sponges can also be incorporated into the silk mesh to prevent cells from leaking out of the scaffold.[112] This technique is exceptionally useful in that it creates a structure that mimics the ECM of ligament. Future studies will focus on increasing the strength and stiffness of these silk scaffolds (see Chapter 2.212, Silk Biomaterials; Chapter 2.218, Elastin Biopolymers; Chapter 2.213, Chitosan; Chapter 2.214, Hyaluronic Acid; Chapter 2.215, Collagen: Materials Analysis and Implant Uses; Chapter 2.216, Collagen–GAG Materials; Chapter 2.217, Fibrin; Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration; Chapter 2.221, Decellularized Scaffolds; and Chapter 2.222, Xenogenic Tissues and Biomaterials for the Skeletal System).

Hydrophilic silk scaffolds, comprising only protein and amino acids, have been used in some preclinical studies for ACL reconstruction.[127] The bundle size can be varied in hydrophilic scaffolds to allow differential diffusion of metabolites and nutrients with cell ingrowth, despite the lack of vasculature near the area of implantation.[127] In addition to supporting tissue ingrowth, hydrophilic silk grafts are mechanically strong and can be naturally resorbed by the body during tissue development. Small animal studies have shown that the bioresorption process of the hydrophilic silk is triggered by the ingrowth of cells as opposed to the presence of water in the case of the polyesters polylactic acid (PLA) and polyglycolic acid (PGA).[127] The stiffness of hydrophilic silk scaffolds is within the range of autograft and allograft tendons currently used for ACL replacements.[127] However, future work is still needed before this material can be implemented in the clinical setting, but *in vitro* and *in vivo* studies have demonstrated that hydrophilic silk scaffolds are mechanically robust and biocompatible.

6.618.5.1.4. Xenograft

Xenografts are transplantations of cells or tissues from one organism to another. ECMs derived from a variety of sources including small intestinal submucosa (SIS), dermis, and pericardium have been used as patches or grafts in tendon and ligament repair.[128] The most widely tested xenografts are the porcine SIS or porcine and bovine dermis. Because these xenografts can be highly immunogenic when implanted into the human body, these scaffolds must be processed thoroughly. This involves several steps including general cleaning, removal of lipid or fat deposits, disruption of cellular and DNA materials, cross-linking, and sterilization.[129] Any leftover noncollagen components may result in a host rejection response. These processes must be designed so that the natural collagen structure and mechanical properties of the tissue are not altered (see Chapter 2.212, Silk Biomaterials; Chapter 2.218, Elastin Biopolymers; Chapter 2.213, Chitosan; Chapter 2.214, Hyaluronic Acid; Chapter 2.215, Collagen: Materials Analysis and Implant Uses; Chapter 2.216, Collagen–GAG Materials; Chapter 2.217, Fibrin; Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration; Chapter 2.221, Decellularized Scaffolds; and Chapter 2.222, Xenogenic Tissues and Biomaterials for the Skeletal System).

6.618.5.1.4.1. Small intestinal submucosa

SIS biopolymer scaffolds are made up from the 100–200 μm thick interstitial ECM from the tunica submucosa layer. SIS scaffolds must undergo chemical processing to decrease cellular content before implantation. SIS is a thin translucent tissue that consists primarily of type I collagen and GAGs, such as chondroitin sulfate, heprain sulfate, and hyaluronan. It also contains growth factors such as TGF-β and VEGF which encourage growth and growth and differentiation of cells, while simultaneously providing integrity and strength to the scaffold throughout the healing process.[130] These scaffolds are mechanically strong, and their inherent porosity encourages a

reconstructive healing process by allowing cell infiltration. Mechanical studies have shown that porcine SIS scaffolds stretch considerably more than canine infraspinatus tendons before reaching maximum material properties and have linear moduli an order of magnitude lower than tendon.[128] Additionally, it has been reported that these scaffolds have a mean load to failure around 32–38 N.[131]

ECM scaffolds derived from porcine SIS have been used in a number of preclinical animal studies that have shown improvements in repair mechanical properties as well as formation of site-specific tissue.[132–136] Studies have shown that porcine SIS scaffolds can improve repair biomechanical and biochemical properties as well as histological appearance of a rabbit MCL and canine Achilles tendon.[132–134] Scaffolds rapidly degrade after implantation and are replaced by host tissue similar to that of normal uninjured tissue.[134] SIS grafts have also been used as interpositional grafts in canine infraspinatus, rat supraspinatus, and rabbit supraspinatus injury models with similar positive cell infiltration and tissue growth results.[128,135,136] Fibroblast-seeded, mechanically stimulated SIS scaffolds have induced changes in gene expression suggestive of tissue remodeling.[132] SIS scaffolds have also improved both the collagen fiber alignment and fibril diameter of repaired constructs.[137]

While some preclinical work has shown potential for these grafts, many animal studies have shown that porcine SIS grafts elicited a significant cellular and inflammatory response from the host and there is concern that SIS grafts do not possess adequate structural and material properties to support rotator cuff repairs.[138] Additionally, cross-linked SIS grafts have demonstrated delayed tissue degradation accompanied by repairs exhibiting little tissue organization, foreign-body giant cell presence, and a persistent inflammatory response.[128]

6.618.5.1.4.2. Dermis

Porcine and bovine dermis tissues have been used to create ECM grafts for tendon and ligament repair. Porcine dermal tissue grafts are acellular, cross-linked, collagen-based scaffolds. These scaffolds are primarily composed of type I collagen, some type III collagen, as well as a small amount of elastin. A porcine dermal scaffold was found to have a mean failure load of 128 N, bovine dermal grafts 70–76 N.[131] When implanted in a rat abdominal wall model, dermis xenografts were shown to cause low-grade chronic inflammation, fibrous encapsulation, and minimal scaffold degeneration.[128] After 112 days of implantation in mice, bovine dermal grafts were partially degraded, and the device had induced adipose connective tissue accumulation.[131] Porcine dermal grafts were not degraded at all after 112 days of implantation and were surrounded by thin, fibrous connective tissue.[131]

6.618.5.1.5. Autograft/allograft

An autograft is a tissue transplanted from one part of the body to another in the same individual. Autografts are appealing in that the use of the patient's own tissue eliminates the risk of rejection. Approximately 85–90% of ACL reconstruction patients have good-to-excellent results, with patellar tendon or hamstring autograft procedures currently being the most common choices for ACL reconstruction.[139] These grafts are chosen as they provide a high degree of stiffness and strength in the reconstructed structure. The main limitation to autograft is the associated donor site morbidity such as anterior knee pain after bone–patellar–bone autografts or weakened knee flexion with hamstring autograft. Allografts, or transplantation of tissue from a genetically nonidentical member of the same species as the recipient, are one potential solution. However, allografts have many complications including delayed biological incorporation, risk of disease transmission and tissue rejection. Human dermis and fascia lata have been used to create ECM grafts for rotator cuff repair augments. Human dermis is a highly elastic and tough layer of connective tissue located underneath the epidermis. Dermis is made primarily of type I and type III collagen, elastin fibers and contains growth factors, glycoproteins, and proteoglycans. Dermis can serve as a scaffold for tissue remodeling as its high collagen content provides a framework for tissue regeneration. Utilization of dermis requires processing to remove cellular components while preserving the native protein, collagen structure, vasculature, and biochemical composition before implantation.[129] Human dermis ECM grafts have been shown to stretch more than canine infraspinatus tendon before reaching its maximum material properties.[128] However, the linear region and elastic modulus of fascia lata ECM grafts are very similar to both canine infraspinatus and human supraspinatus tendons (see **Chapter 2.212, Silk Biomaterials**; **Chapter 2.218, Elastin Biopolymers**; **Chapter 2.213, Chitosan**; **Chapter 2.214, Hyaluronic Acid**; **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**; **Chapter 2.216, Collagen–GAG Materials**; **Chapter 2.217, Fibrin**; **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**; **Chapter 2.221, Decellularized Scaffolds** and **Chapter 2.222, Xenogenic Tissues and Biomaterials for the Skeletal System**).[128]

Human dermis grafts are thicker and stiffer than other ECM grafts currently on the clinical market and have superior suture retention characteristics compared to porcine SIS grafts.[128] They have failure loads in the range of 157–229 N.[131] Human dermal ECM grafts induced chronic inflammation up to 8 weeks after implantation and encourage only minimal cell infiltration and partial material degradation at 16 weeks after implantation in a rat abdominal wall model.[128] However, interpositional implantation of human dermis ECM graft in a canine infraspinatus tendon injury model reported a structure that resembled tendon morphologically at 6 months[140] and a mouse model showed that grafts induced dense, partially organized collagenous connective tissue formation and graft degradation at 112 days postimplantation.[131,138] Tendons repaired with dermis grafts were mechanically stronger than tendons repaired without a graft; however, repaired tendons still have lower biomechanical capabilities than control tendons.[140] Additionally, human fascia lata patches possess comparable mechanical, chemical, and ultrastructural properties to tendon.[141]

Although biologic scaffolds provide an excellent platform for cell infiltration, they also have many disadvantages. Most apparent is their inferior mechanical properties, which may result in early failure of the device or repair. In addition, the biocompatibility of the material is variable dependent upon the source of the biomaterial, and inflammatory responses or

implant rejection can occur in the host body. Because of the undefined rate of degradation of these materials, predicting the repair construct timeline when using biologic scaffolds can be extremely difficult.

6.618.5.2. Synthetic Materials

Although biologic scaffolds can undergo various augmentation techniques to improve mechanical properties, synthetic materials have superior initial mechanical strength. Their biocompatibility, however, is inferior to biologic scaffolds, as the debris caused by synthetic scaffolds can cause a foreign-body response and lead to long-term complications. Synthetic materials are manufactured from chemical compounds and their mechanical, physical, and chemical properties can be controlled to create stronger and more consistent quality materials. Biodegradable synthetic polymers provide immediate stabilization to the repaired tissue while simultaneously acting as a scaffold for ingrowth and, eventually, replacement of tissue cells. Synthetic grafts eliminate the problems of graft harvest, offer no risk of disease transmission, and are readily available for implantation. Synthetic polymers are also advantageous in that they provide the ability to tailor mechanical properties and degradation kinematics to suit specific site requirements. They can also be fabricated into various shapes with a range of porosities. Current studies are investigating the use of synthetic grafts carrying cells, ECM or growth factors to promote tissue healing through a biodegradable scaffold (see **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**).

6.618.5.2.1. Resorbable polyesters

Polyesters are tough plastic materials with excellent fatigue and tear strength. This material is frequently used for tissue-engineering applications as it does not elicit a permanent foreign-body reaction and is reabsorbed into the body and replaced by natural tissue gradually. Additionally, the degradation products of many polyesters such as PGA, PLA, and polylactic-*co*-glycolic acid (PLGA) are naturally present in the human body. These polyesters also have good mechanical properties and many have been shown to improve tendon healing. However, future investigation is needed, as each polyester induces a different cellular response and has a different degradation profile.

6.618.5.2.1.1. Polyglycolic acid

Polyglycolide or PGA is the simplest linear, aliphatic polyester. PGA is a rigid material with high crystallinity, which is not soluble in most organic solvents. It is a biogradable polymer whose fibers exhibit high strength and modulus. PGA can be processed by extrusion, injection, or compression molding, similar to most polyesters. However, given its high sensitivity to hydrolytic degradation processing, conditions must be carefully monitored.[142] Processing techniques determine properties and degradation characteristics of PGA scaffolds. The degradation product, glycolic acid, is a natural metabolite but if absorbed at high concentrations, can cause local acid concentration accumulation, which may result in tissue damage. The rate of degradation in polyesters is determined by many factors including copolymer ratio, crystallinity, molecular weight, porosity, site of implantation, amount of residual monomer, configurational structure, morphology, and stresses.[142] PGA has an approximate strength of 7.0 GPa and degradation time of 6–12 months.[142] PGA can be woven or unwoven; however, woven scaffolds are more robust.[57]

Several *in vitro* and *in vivo* studies have suggested that both PGA and fellow polyester PLA are sufficiently biocompatible, but other studies have shown that PLA–PGA scaffolds may cause systemic or local reactions.[142] The main cause of concern for these polyesters is the potential for local reactions to acidic degradation and the release of small wear particles. Cell-seeded PGA scaffolds formed repair structures with adequate mechanical properties when implanted subcutaneously in nude mice.[143] A PGA–PET device has also been shown to provide adequate strength to use for tendon repairs, but have not demonstrated any notable advantages to currently available materials.[62]

6.618.5.2.1.2. Polylactic acid

Poly(L-lactic acid) (PLLA) has an approximate strength of 2.7 GPa and degradation time of over 24 months.[142] Lactic acid exists in two steroisomeric forms and the polymer derived from active L monomers are semicrystalline. The L-PLA isoform or PLLA is a slowly degrading and biocompatible polymer. The L-PLA isoform is more commonly used since its hydrolysis yields the L (+)-lactic acid which is a naturally occurring stereoisomer of lactic acid. L-PLA also has a higher mechanical strength and toughness than the D-PLA form. PLLA scaffolds have been used for rotator cuff repairs in animal models as interpositional devices for irreparable tears, reinforcement of suture repair line as well as augmentation with tendon–bone repair.[144] When used as an augmentation device, PLLA scaffolds reduced tendon retraction distance and improved stiffness and ultimate load of an infraspinatus tendon repair in a canine model at 12 weeks.[145] Felt PLLA grafts also improve tensile recovery of repairs[146]; however, PLA patches did not significantly improve ultimate strength in a goat model.[147]

6.618.5.2.1.3. Polylactic-co-glycolic acid

The material and degradation properties of polyesters can be altered by creating copolymers. PLGA, a copolymer composed of PGA combined with the more hydrophobic PLA, is very common. The hydrophobic nature of PLA limits the water uptake of the copolymer and reduces degradation. No linear relationship exists between the ratio of polyesters and physicomechanical properties of copolymers. The changes in copolymer properties are the result of changes in the rates of hydration and hydrolysis. This means that 50:50 copolymers will degrade more rapidly than either polymer individually.

The hydrophilicity of PLGA can be improved by plasma treatment or gelatin coating the scaffold.[148] PLGA and PCL (described below) have been coated with a gradient of calcium phosphate to augment tendon to bone healing in some studies and this form of augmentation will be discussed further in the following section. PLGA fibers braided together to form an ACL graft have demonstrated biocompatibility, healing and long-term mechanical strength when implanted in a rabbit model.[149,150] A scaffold consisting of three different continuous phases has recently been developed to mock the multitissue native insertion site and improve ligament-to-bone healing.[149,151–153] Phase A of the scaffold is composed of a

10:90 PLGA mesh for fibroblast culture and soft tissue formation, Phase B consists of 85:15 PLGA microspheres and is intended for fibrochondrocyte culture, while Phase C is composed of sintered PLGA 85:15 and bioactive glass microspheres for osteoblast culture and bone formation.[153,154] It has been shown that the innovative triphasic scaffolds form a fibro-cartilage-like interface and demonstrate the feasibility of the stratified scaffold for promoting ligament-to-bone healing.[153] Because the tendon and ligament enthesis is often the weakest area of a surgical repair and is most prone to fail, further investigation into using these multiphasic scaffolds to improve upon insertion site healing is of particular clinical importance.

6.618.5.2.1.4. Poly(caprolactone)

Poly(caprolactone) (PCL) is a semicrystalline polymer that degrades at a much lower rate than PLA. PCL is very popular as a base polymer for long-term drug delivery applications as it has a degradation time of two to three years.[142] The degradation rate can be altered by adding other copolymers and is one strategy for improving its potential as a bioscaffold. PCL is considered to be nontoxic. PCL has an approximate strength of 0.4 GPa and a degradation time of over 24 months.[142] PCL scaffolds have been developed that possess a calcium phosphate gradient between the top and bottom surface of the mat. A gradient in mineral composition within the construct has functional consequences in PCL and PLGA scaffolds, which lead to spatial gradients in mechanical properties and cell proliferation.[148] Mineralized PLGA scaffolds have lower strain in the loading direction at the mineralized end of the scaffold than the unmineralized end.[148] These graded constructs could significantly enhance tendon to bone healing, which remains a major obstacle in tendon and ligament healing in sites such as the rotator cuff and ACL.

6.618.5.2.1.5. Summary and general observations in polyesters

Current polyester biomaterial research for tendon and ligament applications is focused on finding the balance between scaffold degradability, rate of cell matrix production, structural integrity, and overall scaffold mechanical properties. Polymer composition and surface modification can have significant effects on both mechanical properties and degradation rates of scaffolds.[149] Changes in these properties also result in consequences for cell attachment morphology and growth rate.[149] Additionally, comparisons between polyesters found that braided PGA was the strongest scaffold followed by PLLA and poly(lactide-*co*-glycolide) (PLAGA).[149] It is important to remember that choosing an appropriate polyester scaffold material should be based on the intended target tissue's mechanical properties instead of simply choosing the strongest material available.

Studies have looked at augmenting polyester scaffolds by modifying the biomaterial surface with cell adhesion molecules to combat the hydrophilicity of polyesters that naturally support low levels of surface cell adhesion. Adding components such as fibrin or fibronectin to polyester scaffolds may increase the possibility for cell adhesion and organized tissue growth. Cells can be seeded onto a three-dimensional polyester scaffold to homogenously proliferate inside the graft and secrete their own ECM to form repair tissue. The biomaterial surface can be modified by precoating braided scaffolds with fibronectin in order to increase cell attachment efficiency and overall cell proliferation.[149] However, the magnitude of property changes after culture is dependent on the polyester material.[149] Fibronectin has a positive effect on matrix production and improved cell attachment on PLLA and PLAGA scaffolds. The mechanical strength of fibrin sponges increased after they were combined with cell-seeded PGA scaffolds.[155] Fibrin naturally encourages cell infiltration, but the addition of PGA increased resistance to compression in addition to forcing more free space inside the fibrin sponge allowing for increased cell infiltration.[155]

Cell-seeded polyester scaffolds have been shown to improve tendon and ligament repairs. In particular, knitted polyester scaffolds seeded with a cell–gel mixture can improve tissue repairs.[156] bMSCs can also be fabricated into a cell sheet and assembled into a knitted PLLA scaffold to create an incorporated structure that is stronger and more stretchable than previous structures.[156] The novel cell sheet technique was designed to improve the efficacy of cell seeding, as well as reduce inflammatory response of the polyester biomaterial. Growth factors can also be used to influence the maturation and homeostasis of the healing response in tendons and ligaments with polyester scaffolds. Further, growth factors can have an effect on cell division and even enhance tissue-healing response.[139]

Polyester scaffolds are not without their limitations. While the resorbable nature of polyesters is attractive, the concentration of degradation products is a major concern. Although the degradation products of polyesters are natural metabolites, a large concentration could cause adverse local or systemic reactions. Cell adhesion is vital to the engineering and repairing tendons and polyester's hydrophobic nature impedes this process. One potential solution to this limitation is surface modification with adhesive agents.[57]

6.618.5.2.2. Nonresorbable materials

Many attempts at synthetic grafts, composed of carbon fibers or bundled polyester fibers, have been characterized by chronic foreign-body inflammation, particle wear shedding into adjacent lymph nodes, graft rupture, and particle-induced synovitis. Synthetic nondegradable scaffolds provide a backbone to promote surrounding tissue ingrowth. These scaffolds use open fiber weaves in the hope that surrounding tissue would grow and incorporate into the scaffold forming a functional graft. Unfortunately, many studies using nondegradable synthetic scaffolds have shown that they cause significant inflammatory reactions and frequently rupture and fail.[143] In attempt to reduce the inflammatory response, fibroblasts were seeded on synthetic scaffolds, but with limited results.[143] The following briefly describes some studies on nonresorbable materials for tendon and ligament applications.

6.618.5.2.2.1. Carbon

Flexible carbon fiber implants were one of the initial attempts to step away from auto/allografts. Initial studies that used flexible carbon implants found that carbon fiber scaffolds induced the formation of tendon.[157] Carbon fiber grafts cause a reduction and even distribution of stress between the graft and soft tissue attachment and encourage ingrowth of

collagen into the implant. However, carbon wear particles migrate into the joint space and throughout the body after implantation of carbon scaffolds. Attempts were made to coat carbon structures with polymers or collagen to combat this problem with minimal success. A PLA coat was found to protect the graft from implantation but, the carbon implant stretched and ruptured, leading to poor long-term functional outcomes.[157] Focus has since shifted to other materials.

6.618.5.2.2.2. Polyethylene terephthalate

Polyethylene terephthalate (PET) implants are composites of four tightly woven polyester strips wrapped in a sheath of loosely woven velour and act as a scaffold for fibrous tissue ingrowth. The polyester coating of these scaffolds is designed to protect the graft from abrasion. PET has been used as a tendon graft in the form of suitably sized knitted velour prosthesis for implantation in the rat patellar ligament and tail tendon.[158] Implanted PET constructs are characterized by infiltration of large numbers of macrophages and foreign-body multinucleated giant cells.[158,159] Additionally, a capsule of fibrous tissue characterized by low collagen solubility has been found surrounding the PET structures. These grafts possess short-term strength initially but lack long-term stability.[139] Tissue repaired with PET grafts is more reminiscent of scar tissue formation than neoligament and exhibits disorderly collagen fibers.[158,160] Studies suggest that PET alone may not be suitable for ligament replacement.

PET has also been used in a graft attempting to combine the properties of permanent synthetic prothesis and a tissue-promoting scaffold. This graft consists of a PET mesh-like structure to promote tissue ingrowth through the intraarticular and extraarticular sections of ligament which is anchored between two bone plugs.[139] This graft has impressive maximum tensile strength; however, a study implanting the scaffold in ovine ACL found a large number of long-term graft ruptures.[161] Another two-part PET implant has been designed in an attempt to mimic the natural structure of ligaments. The intraosseous part of the graft is made of longitudinal fibers bound together by a transverse knitted structure while the intraarticular part comprises longitudinal parallel fibers twisted at 90°.[162] The twisted fibers should provide protection from shear forces by preorienting them in the appropriate direction for a right or left limb. This novel structure was designed to encourage tissue ingrowth from the porosity of PET fibers, ideally contributing to the viscoelasticity of the structure and providing protection from friction.[162] While this design has many promising features, no long-term data on its viability over time exist.

6.618.5.2.2.3. Polytetrafluoroethylene

Polytetrafluoroethylene (PTFE) grafts are composed of a single long fiber of expanded PTFE arranged into loops. The ultimate tensile strength of PTFE is about 3 times that of human ACL and extensive mechanical testing has shown it is one of the strongest potential synthetic graft materials in terms of material stability.[139] PTFE grafts are typically fixed at both ends and have been used to provide stability to ACL-deficient knees. Unfortunately, fixing the graft at both ends causes the graft to stress-shield the ligament. Stress-shielding prevents the ligament from developing proper mechanical strength. While these structures may provide positive short-term results, the long-term consequences will be poor due to wear and potential for rupture of the prosthesis.[139]

PTFE felt is made from 100% virgin PTFE fluorocarbon fiber and is acid-bleached. The cytotoxicity, haemolysis, and dissipation of material have not been shown to be different than currently used nonresorbable materials. It has adequate thickness and flexibility to be used in rotator cuff repairs.[163] PTFE felt has been used for covering irreparable tears of the rotator cuff and has been found to be effective for pain relief.[163] A study using PTFE to reconstruct defects in the infraspinatus tendon of beagle dogs found an ingrowth of fibrous tissue between PTFE fibers and adequate mechanical recovery of the tendon.[164] Foreign-body reactions were found at the margin of the PTFE-bone interface and remain a concern in using this material.

6.618.6. Clinical Application

Tissue engineering is an emerging field with considerable potential for the development of new therapeutics for tendon and ligament disorders. Rupture of the rotator cuff of the shoulder and ACL of the knee are two injuries which are attractive targets for tissue-engineered constructs. A biocompatible scaffold, responsive and robust cells for proliferation, and appropriate growth factors to stimulate reparative mechanisms are each important constituents for successfully developing an engineered ligament.[165] So far, *in vitro* and *in vivo* animal studies have been promising, but continued efforts are needed to translate these into clinically applicable solutions.

6.618.6.1. Rotator Cuff

Despite advances in surgical treatment and rehabilitation for rotator cuff tears, significant challenges still remain in the treatment of this disorder. Moderate to large rotator cuff tears do not heal spontaneously. Recurrent and chronic rotator cuff tears are difficult to treat, with limited options such as debridement with partial repair or muscle transfers as salvage procedures. Furthermore, failure rates after repair of large, chronic rotator cuff tears remain relatively high.[166–169] The recent development of synthetic and biologic augmentation devices and interpositional scaffolds are intended to improve and expand upon the current treatment options. The indications for use of these devices are not yet clearly defined but, in general, are limited to cases in which there is a high probability of suboptimal healing after primary repair, such as chronic or massive tears. They also can be used as interposition grafts for large tears in which only partial repair is attainable. These devices, typically made from ECM materials, provide a temporary mechanical support and act as a biologic scaffold for cellular proliferation. By mechanisms similar to the natural tendon healing response, these devices are remodeled by the host body and become incorporated into native healthy tissue. Many of these materials, including biodegradable polymers,[145,147,170] ECM[140,171] including SIS,[135,172–174] and chitin and chitosan-based material[124,175] have been tested in animal models with varying results.

Only a few devices, listed in **Table 1**, have been transitioned into the clinical setting, with devices composed of porcine

Table 1 List of commercially available bioabsorbable graft materials

Product	*Company*	*Type*	*Cross-linked*	*Irradiation*
Restore	DePuy (Warsaw, IN)	Porcine SIS	No	Electron beam
GraftJacket	Wright Medical (Arlington, TN)	Human dermis	No	N/a
TissueMend	Stryker Orthopaedics (Mahwah, NJ)	Fetal bovine dermis	No	N/A
CuffPatch	Arthrotek (Warsaw, IN)	Porcine SIS	Yes	Gamma
Permacol	Zimmer (Warsaw, IN)	Porcine dermis	Yes	Gamma
BioBlanket	Kensey Nash (Exton, PA)	Bovine dermis	Yes	Gamma
OrthoADAPT	Pegasus Biologics (Irvine, CA)	Equine pericardium	Yes	N/A

SIS most extensively studied.[128] This material is composed of 90% collagen, 5–10% lipids, and a small amount of glycoproteins and TGF-β.[136,176] Processing of porcine SIS has been studied extensively in *in vitro* and *in vivo* animal models to reduce the host cellular response.[177] Mechanical studies have shown that these grafts stretch considerably more than canine infraspinatus tendon before reaching maximum material properties and have linear moduli an order of magnitude lower than tendon.[128] Despite encouraging animal studies using porcine SIS, several studies have investigated the use of this material in augmentation devices for massive rotator cuff tears clinically with mostly unfavorable results. In a series of eleven patients using SIS as an augmentation device for massive rotator cuff tears, ten of eleven repairs were found to have failed by magnetic resonance imaging at 6 months.[178] Similarly, a prospective, randomized, controlled trial of 30 chronic two-tendon tears found a higher rate of failure in repairs using SIS as an augmentation device than those repairs with no augmentation.[179] Also, the porcine cellular elements in the porcine SIS devices used in these studies are thought to be the cause of a noninfectious inflammatory reaction that occurred in some patients in which the device was used.[174,179,180] Experience with human dermis ECM has been more favorable. When used as an interposition graft for massive rotator cuff tears, patients had significantly higher functional scores.[128,181] MRI scans showed failure of the graft in only three of the sixteen patients in the study. In another study of 17 patients with massive rotator cuff tears, human dermis ECM was used to augment repair. Similarly, patients had significantly improved functional scores, and three had recurrent tears. No patient had any adverse inflammatory reaction. These studies are promising but are limited by lack of proper controls. Further investigations are needed to determine whether rotator cuff regeneration and improved clinical outcomes is feasible using these materials.

6.618.6.2. Anterior Cruciate Ligament

Rupture of the ACL is one of the most common injuries to the knee, leading to pain, knee instability, and early arthritis. Ruptures of the ACL do not heal spontaneously, and in contrast to the rotator cuff tendon, the ACL is usually not amenable to direct repair. In appropriate patients, reconstruction of the ligament is performed. Various options are available to the surgeon for reconstruction of the ACL, the most common being local hamstring or bone–patellar–bone autograft and allograft.[182] Although results of ACL reconstruction using these tissues are generally favorable,[183,184] there are complications such as donor site morbidity using autograft, and immunogenic and infectious complications using allograft.[185,186] Because the prevalence of ACL injuries is expected to continue to rise, effort has gone into finding a suitable tissue-engineered construct to improve the reconstructive procedure and decrease the number of complications.

Currently, there have been no tissue-engineered constructs that have been tested *in vivo* in humans. Collagen has been the most widely studied material as a biocompatible scaffold[187,188] but has been found to have mechanical and immunogenic limitations.[189–191] Synthetic materials including silk[126,192] and biodegradable polymers[193] have also received attention as an attractive options due to their low cost and biocompatibility. Other modified biologic materials such as hyaluronic acid, chitosan, and alginate have been proposed as potential scaffold options.[194,195] Matching an appropriate cell source with the biocompatible scaffold is also important. ACL and patellar fibroblasts have been tested with various scaffolds,[187,188] but recently bone marrow stromal cells have presented themselves as an attractive candidate due to their relatively easy accessibility, robust renewal, and potential to differentiate.[196] Lastly, appropriate growth factors such as PDGF, TGF-β, FGF, and IGF-1 are important in stimulating cellular response and inducing collagen and proteoglycan synthesis. A number of these growth factors have been tested in various animal ACL models[197–199] as well as *ex vivo* in human tissue.[120,200]

6.618.6.3. Suture Anchors

The current standard for surgical repair and reconstruction of rotator cuff tears and ACL ruptures involves minimally invasive arthroscopic techniques. The role for arthroscopic fixation devices has expanded greatly. Options for suture anchors include metal and biodegradable materials, with the current trend leaning toward the use of biodegradable polymers.[201] The most common polymers currently used in suture anchors include PLLA, poly-D, L-lactic acid (PDLLA), PGA, polydioxanone (PDS), or a combination of these biomaterials. The material properties and rate of degradation and strength loss are the most clinically relevant characteristics of these materials. PGA degrades by both hydrolysis and enzymatic activity and when used *in vivo*, degrades more rapidly than PLA. The use of PGA has been thought to lead to inflammatory and lytic changes due complement cascade activation after enzymatic degradation, and therefore, has been used less in the clinical setting.[202,203] However, case reports of inflammatory reactions to PLLA anchors have also been reported.[204]

Current arthroscopic techniques also demand high strength suture material. Sutures using braided polyester or degradable PDS have been popular options, and new high strength sutures incorporating ultrahigh molecular weight polyethylene (UHMWPE) are available. The failure strength of these suture materials far exceeds the requirements to secure tissue into bone. Some sutures have been developed with a combination of materials to optimize properties of each. For example, UHMWPE and PDS have been used in combination – after degradation of the PDS, the material strength of UHMWPE remains, but with a lower profile. Although studying the properties of these suture and suture anchors is important, many other factors such as suture size and number, anchor design, and surgical technique ultimately dictate the final clinical outcome.

6.618.7. Summary

Tissue engineering has the potential to revolutionize the way we treat tendon and ligament disorders. Currently, autograft and allograft are most widely used in the augmentation or replacement of injured tissue. However, these options are not without associated morbidity and complications, therefore continued effort has been dedicated to applying biomaterials and tissue-engineering techniques to the enhancement of tendon and ligament healing. This requires a thorough understanding of the fundamental structural and material properties of these tissues. The effect of various chemical and mechanical manipulations on tendon and ligament properties and healing is important in creating and modifying novel biomaterials that best recreate native tissue properties. A multitude of mechanical, biochemical, and histologic assays can assist in testing the basic properties of materials *in vitro* and can assess various material augmentation methods. Once basic *in vitro* testing identifies an optimal combination of a specific material and augmentation methods, transitioning these biomaterials to a clinical setting requires preclinical studies utilizing animal models. Numerous animal models exist, and many factors must be taken into account in order to choose the animal model which best recreates the clinical scenario in a reproducible and cost-efficient manner. These include size of animal, anatomic similarity with the human, ability to recreate the injury, postoperative/injury management, and cost. Only after preclinical studies show encouraging results with regards to safety and efficacy can a device advance to clinical trials.

A wide variety of materials can be used in constructing a device to augment or replace tendon or ligament tissue. The chosen material not only needs to provide initial mechanical integrity, but should also function as a scaffold that is conducive to cell infiltration. Multiple methods of chemical and mechanical augmentation can then enhance the properties of these scaffolds, which must provide adequate initial strength before degradation in the body and replacement with native tissue. Biologic materials such as collagen most closely replicate the structural and mechanical properties of native tissue, and processing of these materials can reduce antigenicity and resultant inflammatory response. Many synthetic materials such as resorbable polyesters and other nonresorbable materials provide greater initial mechanical strength but are generally less biocompatible. Combinations of different materials based on their specific mechanical and biologic properties can enhance the overall structure and biologic response once implanted.

In general, clinical application of these devices has been limited. Chronic or massive rotator cuff tears and ACL tears are both common clinical problems that have been targets for healing enhancement with tissue-engineered constructs. Multiple preclinical animal studies using biodegradable polymers, ECM materials, and biologic implants have been promising, but the utility of these devices has yet to be proven in the clinical setting. Continued efforts into manipulating and enhancing these materials to improve cell infiltration, tissue proliferation, and mechanical integrity should be expected to result in the production of clinically successful devices capable of mimicking the mechanics and biologics of native tendon and ligament.

Glossary (from Laney[1])

Abutment Tooth, tooth root, or implant component that serves as support and/or retention for a dental prosthesis.

Bacterial leakage Colonization and release of bacteria at the interface of an oral implant abutment and implant.

Cutting torque Turning or twisting force produced by a rotary device (i.e., dental handpiece) to cut through a material such as bone.

Early implant loss Loss of an implant that occurs prior to implant osseointegration.

Early implant placement Early implant placement takes place 4–8 weeks following tooth extraction, providing sufficient time for soft tissue healing.

Early loading Placing of an implant into function or a load-bearing situation following a reduced period of healing after the initial placement. It is generally considered to be loading more than 48 h but less than 3 months after implant placement.

Immediate implant placement Implant placement immediately following extraction of a tooth.

Immediate loading Application of functional or nonfunctional load to an implant at the time of surgical placement or shortly thereafter; that is, generally considered to be loading within 48 h of implant placement.
Implant–abutment interface Surface forming a common boundary between the abutment and the implant (microgap).
Late implant loss Outcome related to the loss of an implant that occurred after implant osseointegration.
Late implant placement Implant placement at least 6 months following tooth extraction. The chosen time period should allow for sufficient bone regeneration of the extraction socket, and consequently, implant placement without bone augmentation procedure. Late implant placement bears the risk of bone atrophy in the orofacial direction, particularly in the anterior maxilla.
Microgap Microscopic space between two components, specifically between an implant and an abutment. It is usually considered to be a source of chronic irritation or contamination creating an inflammatory response.
Nonsubmerged healing Implant placement procedure incorporating a transmucosal extension for healing guidance. A special healing cap is required to extend the implant shoulder above the soft tissue level, allowing the suturing of wound margins around the implant neck/healing cap. This approach does not require a second surgical procedure and is often used in posterior implant sites. (One-stage implant placement).
Osseointegration Direct structural and functional connection between ordered, living bone and the surface of a load-carrying titanium implant.
Peri-implantitis Condition of inflamed peri-implant soft tissues, bone loss, and increased probing depth combined with exudation.
Permucosal seal Seal or tissue barrier at the base of the peri-implant sulcus provided by the epithelial tissue prevents the penetration of chemical and bacterial substances from the oral cavity to the internal environment of the peri-implant tissues.
Primary stability Clinically, implant immobility at the time of surgical placement, resulting from intimate contact of the implant with the bony walls of the osteotomy. Primary stability decreases with time as osseous remodeling occurs. It is distinct from secondary implant stability, which is the result of new bone formation and osseointegration.
Secondary stability Implant stability within its prepared bony site, created by osseointegration and the formation of new bone subsequent to loss of the bone initially in contact with the implant at the time of placement.

6.619.1. History and Development of Dental Implantology

The possible use of biomaterials in Oral and Maxillofacial Surgery dates back to pre-Christian times.[2,3] Early attempts to anchor 'artificial' teeth into the jaw bone are discussed in controversy.[4] The first trusted use of a biomaterial for the functional replacement of a tooth was performed by Maggiolo in 1807, who inserted a root form gold implant into an alveolar socket.[5] This procedure was repeated in 1887 using a platinum implant.[6] Younger was the first to describe the idea of the implant bed generation by transplanting teeth into artificially created bone cavities in 1886.[7] In his important work, Greenfield in 1913 described some principles of bone implant contact (secondary stability), and thus started with the idea of 'osseointegration'.[8]

At this time, some authors started to test different metals in animal experiments, first using histology to test biocompatibility[9]; the results for titanium in 1940 were described as positive.[10] In 1951, Leventhal[11] endorsed titanium as an ideal metal for use in fixation of bone fractures. He described what Brånemark later called 'osseointegration' when he placed titanium screws in rat femurs: 'At the end of 6 weeks, the screws were slightly tighter than when originally put in; . . . and at the end of 16 weeks, the screws were so tight that in one specimen the femur was fractured when an attempt was made to remove the screw.' Clinically in 1937, Strock used cobalt–chromium–molybdenum alloys ('vitallium') for tooth replacement[12] in alveolar sockets. His contribution was a description of a staged approach with a secondary fixation of the crown and an idea of the theoretical background of mechanical stability (primary stability) at the metal–bone interface. Despite various successful reports, these efforts remained case reports with unpredictable clinical success rates. During these times, many of the failures might have been caused by early loading or excessive mechanical stress and not by the material or the surgical technique that was used.

The replacement of a tooth by an artificial implant at the start of the last century was marked by the empirical search for the best implant area (subperiostal vs. enossal) and the best implant shape (extension vs. rotational-symmetric). Greenfield's cage-like implants in 1913[8] suffered from low surface contact with the bone. Dahl's subperiostal implants in 1948 led to excessive bone loss and have not been supported since the 1980s.[13] Blade implants were introduced by Linkow and Roberts[14] and became very popular for almost two decades. However, systematic research on long-term success rates was lacking. The majority of the blade implants were one-piece (implant and abutment), and had to be immediately loaded. This led to the clinical phenomenon of a peri-implant radiolucency called fibro-osseous integration. In these days, the majority of implant surgeons believed that a fibro-osseous connection had a 'shock-absorbing capacity' similar to the periodontal ligament around a natural tooth. At that time, advances in the understanding of implant biology were hampered by undeveloped histological methods. Beginning in 1976, Schroeder demonstrated that the pseudoligament was not the perpendicular orientation of fibers that is found around a natural tooth.[15] Thus, peri-implant radiolucencies were termed fibro-osseous encapsulation, indicating a pathological rather than an anatomical variation.

The scientific quantum leap is contributed to the orthopedic surgeon P. I. Branemark. In the 1950s, he performed vital blood flow microscopy in animals. The titanium cylinders he used were so difficult to remove from bone, that he thought they might withstand occlusal forces. He called this phenomenon 'osseointegration'[16] and developed the concept of unloaded healing of smooth titanium implants. On the basis of extensive preclinical and clinical experiments, he developed a helical implant, which had predictable success rates.[17,18] Characteristics of this system were a standardized surgical procedure, unloaded subgingival healing, and a helical implant with a smooth surface. The landmarks of the Branemark group consisted of the description of a standardized approach and the documentation of the long-term clinical outcome. This is an approach that continues to shape the academic work in implant dentistry and has led to the development of the so-called Branemark Implant System.

Almost simultaneously with the 'discovery' of osseointegration, Schroeder described the similar effect in transgingival, rough implants as 'functional ankylosis'.[19] Out of these results, a cylindrical implant with transgingival healing and a rough surface was developed,[20] known as the ITI implant (former bone fit implant), which also showed predictable implant success rates.[19,21–27] The primary clinical indication of these implants has been the functional rehabilitation of the edentulous mandible with implant placement in the regio interforaminalis.[17] The success of these systems in early days was partly based on the good bone quality in this area.

The first systematic approach to single-tooth replacement came from the University of Tubingen with a modification of the implant material. Two-piece aluminum oxide ceramic implants were used for immediate implantation.[28] After first positive results with respect to osseointegration,[29] fractures occurred, which led to the ceramic implant material being changed to metal titanium.[30,31] The implant has been widely used as the Frialit II implant.[29,31–34] The IMZ system (intramobile cylinder implant) played a key role in the systematic development of implantology. The basis of this system was the imitation of natural tooth mobility. Together with the Branemark system, it was one of the first implant systems with subgingival healing and with standardized, innercooled bone bed preparation.[35,36] Long-term studies with realistic assessment of success rates and a critical assessment of marginal bone remodeling/bone loss were available.[37–42]

So, in the early seventies of the last century, a treatment alternative with predictable and acceptable success rates for the restoration of edentulous jaws was available for the first time. This is reflected by several consensus statements in the description of the implant as a scientifically documented therapeutic option.[43–45] The goal of creating a means for a possible long-term oral, endosteal implant option on endosseous anchorage had been largely achieved. Only much later, the purely empirically verified, good success rates of implants in edentulous mandibles and for the single-tooth replacement were transferred to other indications. With the widening of the localization into the cancellous maxillary and vertically limited lateral mandible, the way was paved for masticatory rehabilitation of complex cases like severe atrophy or large jaw defects due to trauma or tumor.

6.619.2. Indication and Procedure for Dental Implants

6.619.2.1. Functional Goal of Dental Implants

The general property requirements for dental implants can be subdivided into biological and mechanical aspects:

- Biological properties (biocompatibility)
  - Nontoxic, noncancerogenic, nonteratogenic
  - Nonantigenic
  - Noninfectious, possibility to be sterilized
  - Biological stability
- Mechanical properties
  - Form stability
  - Mechanical toughness
  - Radio-opacity

Experiences from the last years have shown that dental implants have to be produced (and sold) at a market-adequate price. The ability to produce two-piece systems (endosseal part and supraconstruction) allows for unloaded healing and high flexibility regarding the prosthetic solutions. Prefabricated parts allow for high precision coupling of the elements during the entire process.

6.619.2.2. Typical Indications

6.619.2.2.1. Edentulous jaws

The first successful steps in dental implantology were initiated to rehabilitate patients with edentulous mandibles,[16,17,19,38,46–50] because in this situation, the classical denture often is insufficient due to progressive bone atrophy (**Figure 1**).[51] For these patients, implants help to 'carry' and stabilize the removable denture and are thought to prevent further progression of bone atrophy.[52,53] In the rehabilitation of the edentulous mandible, implants have already demonstrated very high survival rates of above 98% over 10–20 years and are promoted as the rehabilitation of choice compared to a conventional denture as a preventive measure for further bone loss.[54–58] Owing to the anatomical position of the inferior alveolar nerve, they are positioned in the interforaminal (anterior) region of the mandible. Earlier studies used six to four implants to support the denture. Quality of life (QoL)

Figure 1 Two implants in an edentulous mandible supporting a complete denture with a locator abutment.

studies have shown that patients already have a clear benefit with two implants supporting a mandibular overdenture compared to a conventional denture[59–66]; four implants compared to two implants do not change the QoL significantly.[67] Thus, the two implant rehabilitation of the mandible supporting an overdenture can be stated as a 'classical' solution nowadays. More comfort for the patient is provided by a fixed denture, which requires four to six implants.[68,69] Besides the higher number of implants needed for a fixed restoration compared to a removable one, this technique is more sensitive to patient-related factors and more cost intensive.[70] Prospective studies have shown that patients choose fixed or removable implant-supported prostheses for specific reasons, and that it is important to consider patient attitudes at the beginning of the therapy (**Figure 2**).[71]

The edentulous maxilla represents a far more complex situation. The anatomical proximity to the nasal cavity and the maxillary sinus limits the available bone area for dental implants. Esthetic demands and speech requirements are important for the planning of shape and position of the rehabilitation. This often makes the realization of a fixed solution more critical.[59,72–78] Owing to the increased bone softness of the maxilla, implant failure rates with smooth implant surfaces have been not as high as in the mandible.[79] Besides the speech and esthetic outcomes, palatal coverage is a crucial question for patients wearing a complete denture. In contrast to the high gain of QoL by restoring the mandible with two or more implants, the gain is less pronounced for the maxillary implant rehabilitation.[73]

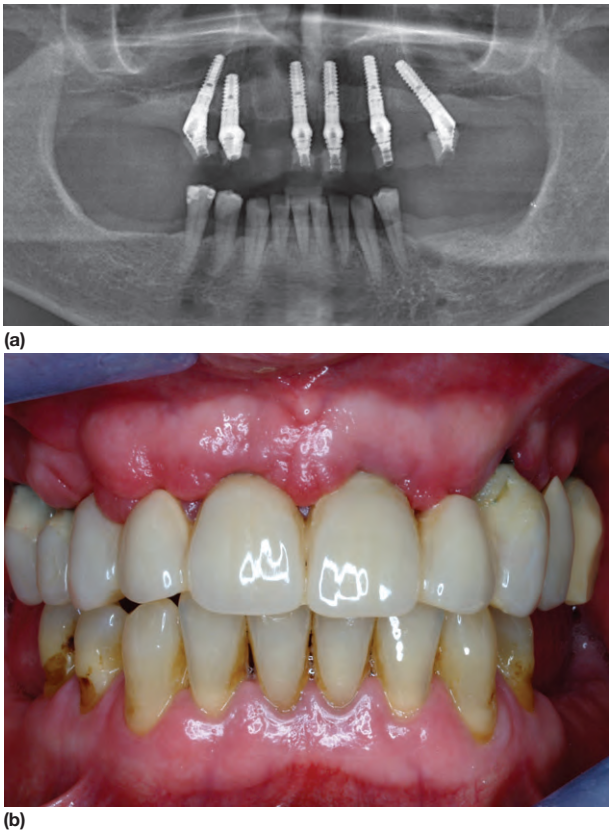

Figure 2 (a) Panoramic X-ray of six tilted implants in the maxilla to support a fixed denture and allow immediate loading; (b) intraoral situation with the provisional immediate restoration at the 6-month follow-up.

To overcome the limits of the anatomy in the maxilla as well as the mandible, tilted or angulated implants have been used to generate a larger area of support for the prosthesis by many groups using different implant systems.[80–91] The data on long-term outcomes of tilted implants, however, are still missing.[92]

A clear trend is seen in the indication 'edentulous mandible' for the use of small-diameter implants, but long-term data on low-diameter implants are rare[93–95] and the best supraconstruction in these cases still remains unclear.[65]

6.619.2.2.2. Fixed partial denture

The rehabilitation of single or more tooth gaps using implants requires different prerequisites in diagnosis, planning, and therapy compared to the fully edentulous jaw. In edentulous situations, bar constructions often allow mediation between the denture and the implant position, whereas in partial dentures, the direct connection of the implant to the crown using an abutment requires perfect positioning of the implant with respect to the future supraconstruction. Thus, especially in esthetically demanding cases, so-called backward planning is recommended; meaning that, after the planning of the supraconstructions (e.g., a wax up of the crowns), the ideal implant position is planned. Missing bone in this situation should be augmented.[96,97] Nevertheless, implants are overwhelmingly selected over a fixed bridge for the replacement of a single-tooth unit.[98]

The restoration can be either screwed on or cemented on the abutment. By using cemented crowns, the risk that residual cement in the crestal area leads to inflammation and bone loss may increase.[99] The increased possibility of removing the supraconstruction for cleaning and maintenance is an advantage of the screw-retained dentures.[100] Owing to the superior esthetical possibilities using full ceramic crowns, cementing is increasingly chosen by the dentists and has become more and more widespread.[101]

One open question in this field is the necessity to splint implants via supraconstructions together or to restore the crown individually. Especially when short implants (<8 mm) are in use, splinting seems to be preferred.[102] In many centers, the idea of splinting teeth to implants is still not followed, due to the fact that both have different mobility. The IMZ implant with its intramobile element was initially designed to overcome this problem.[42,50] Studies with other implant systems have shown that splinting teeth and implants together is possible, but a higher number of technical complications have to be expected.[103,104] Some systematic reviews have addressed the question of a possible distal cantilever in fixed partial denture.[105,106] Although some researchers are very cautious regarding this technique,[105] newer studies seem to indicate that despite minor technical problems such as screw loosening, the concept is rated a 'valid treatment modality'.[106,107]

6.619.2.2.3. Special indications

For the rehabilitation of tumor defects, extraoral anchorage of epitheses is needed. In these situations, dental implants inserted into extraoral bone sites have proven to be useful.[108–110]

The reported success rates in these indications are favorable, but extraoral skin seems to be more prominent for dermatitis than intraoral one for mucositis.[111–113] A well-established example is the implant-retained anchorage of hearing aids.[114] In concordance with the extraoral skin-penetrating epithesis implants, peri-implant abutment infections are known for this indication.

Particularly in the last years, skeletal orthodontic anchorage using dental implants or miniscrews has become an important issue. Positive results have been reported for short implants placed into the palate, which undergo classical Osseointegration.[115–117] The reported survival rates for miniscrews, which work with the principle of primary stability seem to be a little bit lower.[118–120] The potential of orthodontic anchorage continues to be a promising development.

6.619.2.2.4. Implant survival and success criteria

Several suggestions have been proposed on the question regarding how implant success can be obtained. The most tangible and objective criterion is implant survival (*in situ*), which is used in many studies, and therefore is a candidate for meta-analyses.[121] Implant survival rates of 90–100% are available for some systems for the last 10–20 years.[48,74,122–129] From a clinical point, it is clear that an implant can be *in situ*, but not successfully. Pain, persistent inflammation, progressive bone loss, probing depth, and mobility have been discussed as indicators of failure. Consequently, several respective criteria for success have been introduced, and at least one of them has been reported in a clinical study.[130,131] In more recent times, a critical discussion on these criteria has started. One major question is whether bone loss of 0.2 mm $year^{-1}$ is acceptable, and whether bone loss during the first year should be excluded.[130] Still no modern, fully accepted score for implant success is available. Rating implant outcomes seems to underestimate the prosthodontic outcome. Thus, reporting technical versus biological complications in conjunction with survival rates has increased.[100] Particularly in the anterior esthetically demanding zone, the esthetic outcome is of major importance. The former papilla score by Jemt[132] has been replaced by the more complex pink esthetic score,[133] which rates mucosal parameters, and the white esthetic score, which rates the crown esthetics.[134]

6.619.2.3. General and Local Risk Factors

As reported above, promising long-term results for well-established treatment sites with optimum bone quality, such as the interforaminal region of the lower jaw,[135] have led to a continuous expansion of indications and introduction of more aggressive treatment protocols like:

- implantation into augmented areas,
- immediate implantation following tooth extraction and/or,
- immediate loading of dental implants,

thereby defining potential risk factors for dental implant success.[136–139]

Furthermore, patients with limitations of tissue homeostasis and integrity, such as that which occurs after radiation therapy to the head and neck region or with impaired bone remodeling, and repair capacity under systemic medication (e.g., bisphosphonates) have been identified as challenging collectives for the treatment with dental implants.[140,141] Table 1 provides a synopsis over patient-related general and local risk factors affecting dental implant success.

Table 1 Dental implant success: patient-related parameters

Local factors	*Extended local factors*	*General constitution*
Bone parameters	Smoking	Diabetes mellitus
Quantity, quality	Radiation therapy	Immunodeficiency
Horizontal versus vertical deficit	Pathogenous microflora (parodontitis)	IL-1 polymorphism
Local versus augmented bone	Bad mouth hygiene, noncompliance	Systemic bisphosphonate medication
Alloplastic bone substitutes	Malocclusion, habits	
Soft tissue parameters		
Fixed versus mobile mucosa		

For instance, patients with generalized aggressive periodontitis showed higher implant failure rates (20%) when compared to healthy subjects (2%) or collectives with only chronic periodontitis (4%).[142] Another potential risk factor is diabetes mellitus (DM). In a recent systematic review, Javed and Romanos concluded that long-term high glucose levels (not well-adjusted DM) impair dental implant healing and successful osseointegration with higher failure rates, which could be avoided by correct adjustment of serum glucose levels.[143] To date, no serious scientific data provide evidence for higher implant failure rates in an osteoporotic collective.[144] However, concomitant bisphosphonate medication should be taken into account when an implant therapy is planned for these patients.[145,146]

Another potential risk factor for implant loss is radiation therapy. A recent systematic review by Ihde *et al.* identifies radiation therapy to the head and neck as a potential risk factor for implant failure.[147] The authors detected a 3–12-fold increased risk for implant loss when inserted into irradiated bone. They also defined a 'threshold' value above 50 Gy as a significant higher risk for subsequent to implant loss. In this study, no difference between the sequence of implantation and radiation could be observed.[147] Nevertheless, patients with considerable intraoral defects after ablative tumor surgery significantly benefit from functional rehabilitation through dental implants.[148–150] Other authors identified the time interval between radiation therapy and dental implantation as a potentially important cofactor for implant success. Schliephake and coworkers opine that radiation therapy has no relevant impact on implant success if dental implantation takes place at least 1 year after completing radiation therapy.[151] According to Jacobsson and coworkers, functional self-regeneration of the damaged tissue would provide sufficient implant healing and osseointegration capacities of the bone 1 year after radiation therapy.[152,153]

As a conclusion, the described host tissue limitations require an optimal treatment protocol as well as optimized implant properties to promote the endosseous healing cascade in order to achieve timely and stable osseointegration.

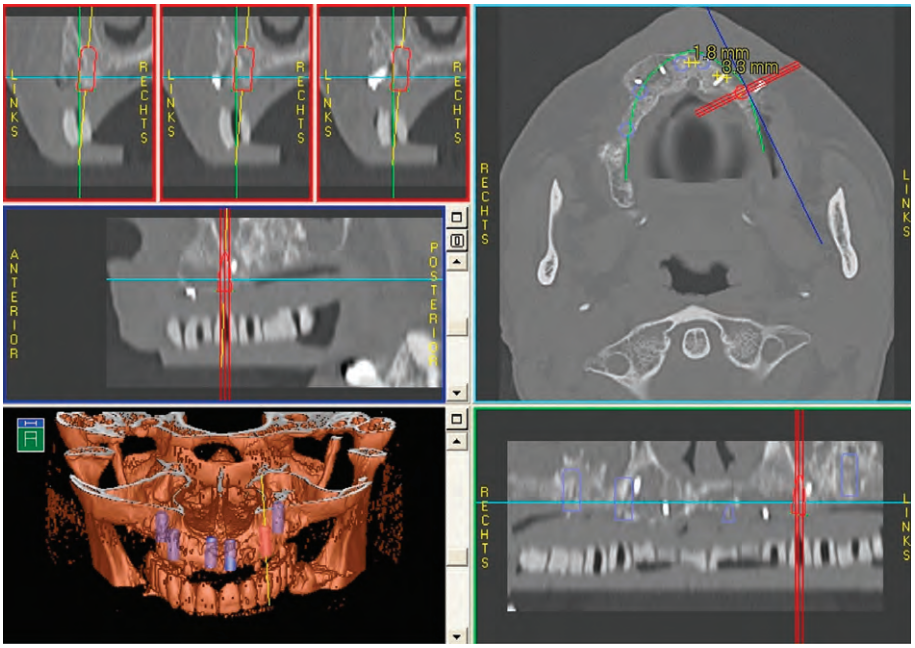

Figure 3 Example of a PC-based 3D planning tool showing the planning of six implants in the edentulous maxilla after lateral augmentation and sinus floor elevation.

6.619.2.4. Surgical Procedure

6.619.2.4.1. Presurgical considerations

After clinical and radiologic planning, there is a general consensus nowadays that before implant placement, prosthodontic planning should be done as well. This means that the type and details of the final restorations should be considered prior to implant placement (top–down planning). During the planning procedure, 3D-imaging and PC-based planning systems have become more and more important.[154–157] The assessment of the available alveolar bone prior to surgery particularly helps to plan augmentation procedures.[158] For this purpose, three-dimensional (3D) radiology or mechanical ridge mapping is used (**Figure 3**). Inactivity of the jaw bone after tooth extraction leads to resorption, which as a consequence leads to the necessity of bone augmentation before or at implant insertion.[51] The resorption processes immediately following tooth extraction have been a strong research focus. The major loss in alveolar crest width occurs within the first months after extraction.[159] In animal experiments, it was possible to prove that the bone adjacent to the sharpey fibers, which are connected to the tooth, is part of the periodontium. If the tooth is extracted, the periodontal structures, including this bundle bone, disappear.[160,161] Particularly, the thin buccal bone wall is susceptible to this physiologic remodeling (**Figure 4**).

To overcome this physiologic process, two options are currently being discussed: immediate implantation into the fresh extraction socket or early implantation after soft tissue healing (6–8 weeks).[162] Animal experiments show that the implant itself is not able to prevent buccal bone remodeling.[163] The dimension of the alveolar ridge and the implant diameter seem to be more important for the outcome than implant macro- or microstructure.[164–166] Perfect esthetic results after immediate implantation are possible but also depend on mucosal thickness,

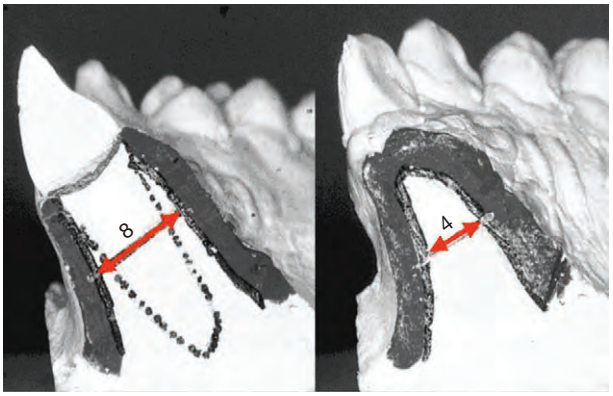

Figure 4 Model of the alveolar ridge remodeling after extraction with the typical loss of the buccal wall.

implant type and dimension, and implant positioning.[167,168] Systematic reviews show similar survival rates for immediate and early placed implants of about 95%, but early implant placement seems to be associated with a lower frequency of mucosal recession compared to immediate placement.[162]

6.619.2.4.2. Surgery

Under sterile conditions, a local anesthesia is applied and the crestal bone is exposed subperiostally. The setting includes a sterile drape for the patient's head and torso, sterile gloves for the surgeon, and a sterile rinsing/cooling solution; a full sterile draping of the patient and sterile gown do not seem necessary.[169] Using a drill guide as a direction indicator, the position of the implant in relation to the restoration (supraconstruction) can be controlled (**Figures 5–8**). In recent times, 3D-radiographic data are used to fabricate PC-planned

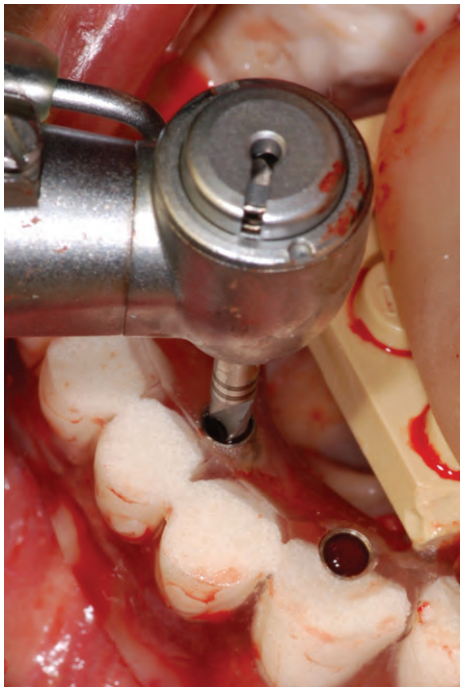

Figure 5 Use of a drill guide during implant insertion.

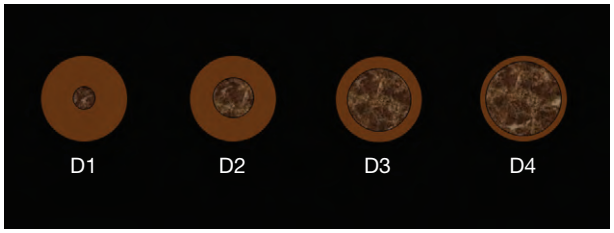

Figure 6 Bone classes in relation to the amount of cortical bone. Reproduced from Lekholm, U.; Zarb, G. A. In *Gewebeintegrierter Zahnersatz*; Branemark, P. I., Zarb, G. A., Eds.; Quintessenz: Berlin, 1985; pp 195–205.

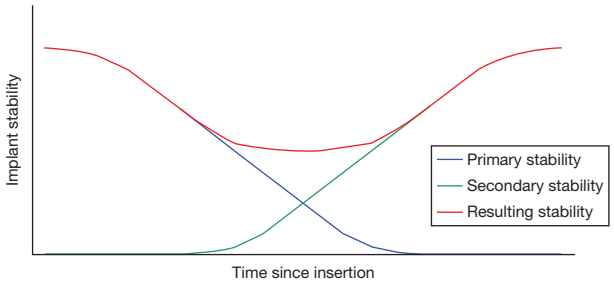

Figure 7 Time course of mechanical primary stability followed by biological secondary stability with a stability 'dip' within the first weeks.

surgical splints, thus allowing a more accurate realization of the preoperative plan and a reliable protection of critical anatomical structures.[170] It should, however, be noted that the deviation of the implant at the entry point into the bone can be up to 1–2 mm at the apex.[171]

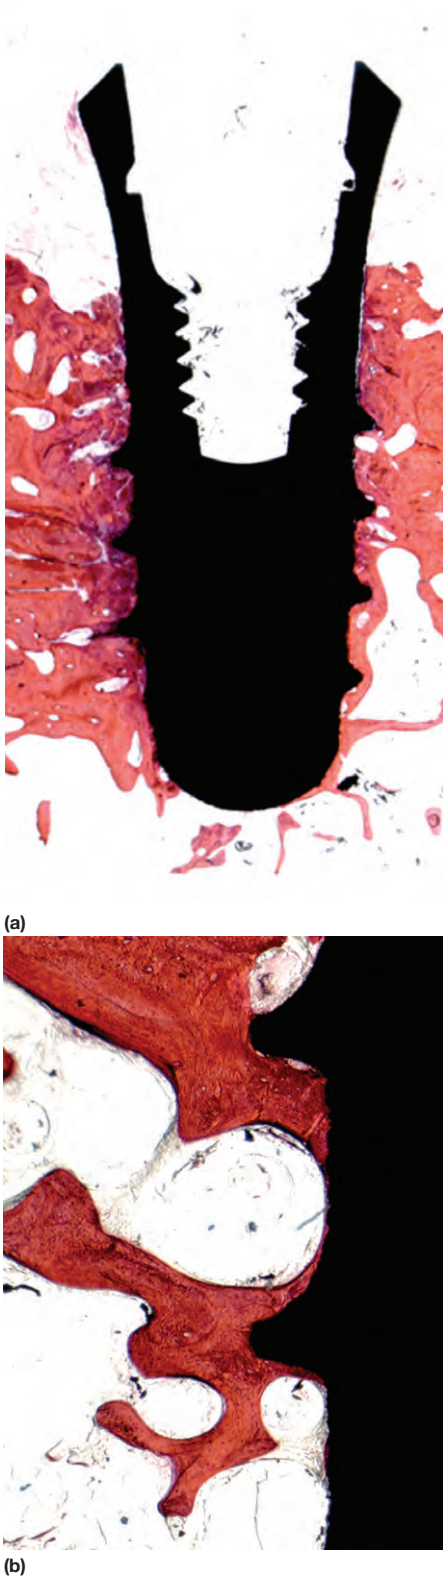

Figure 8 HE staining of an implant with sand blasted and etched surface showing osseointegration as a direct contact of bone to the biomaterial in the loaded situation. (a) Full aspect of the implant. Note that the typical bone implant contact area is 60–80%. (b) Detail showing the effect of loading on osseointegration with a dense contact in the thread area.

The drilling of the implant bed is done with increasing drill diameters until a congruent implant bed is prepared. *In vitro* studies indicate that cooling of the site is important,[172] especially if a surgical stent in 'modern' guided surgery is used.[173] Internal cooling was suggested by some researchers but does not seem to contribute to better outcomes.[36] The drills are either single or multiple use. It should be noted that heat production and signs of wear after sterilization and multiple use differ between the implant systems.[174,175] For some implant systems, zirconium drills are available. Recently, piezoelectric surgery has been used to prepare the implant bed, with positive results on early implant healing in animal models.[176] As one of the most important goals is achieving a sufficient primary stability, the last drilling steps mainly depend on the type of bone. The histology-based classification of bone 'quality' ranges from the types D1–D4 and is mostly concordant to the 'drilling feeling'.[177] Thus, the surgeon selects an adopted drilling procedure after the initial pilot drill, which is used for the full length of the planned implant. In hard bone, a nearly congruent bone bed will be prepared. Some implant systems allow tapping; in soft bone, underdimensioned drilling is used.[178,179] This adoption seems necessary, as missing primary stability of the implant leads to micromotions with impairment of sufficient osseointegration. On the other hand, exceedingly high primary stability (>50 N cm) is suspected to harm the crestal bone and lead to early implant failures or early crestal bone loss. This theory is challenged by the finding that rotationally unstable implants may osseointegrate despite the lack of primary stability,[180] and that some implant systems work with exceedingly high primary stability (<70 N cm) without overloading the crestal bone.[181] As primary stability is a prerequisite for early and immediate implant loading, future research on thread design and drilling procedure seems promising.

6.619.3. Tissue Reaction on Dental Implant Material

6.619.3.1. Bone (Enossal Part)

The term 'osseointegration' refers to successful, long-term endosseal dental healing. Per-Ingvar Brånemark defined osseointegration as "*direct* and *functional* apposition of *vital* bone at the implant surface under functional loading without establishment of a fibrous interface with maintenance of this connection under function."[17,182–184]

Successful osseointegration of a dental implant is a long-lasting *dynamic* process. After *de novo* bone formation at the dental surface ('modeling'), a lifelong physiologic turnover ('remodeling') takes place under functional implant loading.[185] Obligate preconditions for osseointegration are (1) careful surgery with minimal violation of the surrounding host tissue, (2) establishment of high primary stability with (3) prevention of infections and micromovements during the implant healing period, and in particular, (4) high biocompatibility of the dental surface with osteopromotive properties.[186] During or directly after implant insertion, the so-called primary stability is verifiable and depends on (1) mechanical bone quality, (2) bone quantity, (3) implant(macro-)design, and (4) insertion torque. High primary stability is a precondition for treatment strategies in the field of immediate or early loading.[187,188]

The healing cascade leading to stable osseointegration directly takes place at the implant surface by means of 'contact-osteogenesis'.[189,190] During surgical preparation of the implant cavity, the integrity of the bone is interrupted, which leads (after placement of the dental implant) to a defined sequence of biological events, resembling fracture healing. In detail, these events can be subdivided into

- hemorrhage into the defect with (unspecific) protein adsorption by the dental surface,
- platelet activation and degranulation,
- inflammation,
- recruitment, migration, and adhesion of osteogenic progenitor cells (*osteoconduction*),
- osteogenic proliferation,
- osteogenic differentiation with
- matrix synthesis,
- calcification (*de novo bone formation*), followed by lifelong
- bone remodeling at the implant surface.

This itemization implies that some fundamental processes with conditioning of the implant surface precede the adhesion of osteogenic cells at the implant surface.

6.619.3.1.1. Early interaction with noncellular components of the extracellular milieu

Initially, the implant surface interacts with blood components. For titanium (Ti) surfaces, H_2O molecules can lead to hydration of the titanium dioxide. Both anorganic compounds and proteins like fibrin or albumin are absorbed at the implant surface, thus modulating its biological response to the surrounding tissue. Protein interactions with the dental implant surface depend on their concentration, size, on the surrounding pH value, temperature and result in characteristic adsorption and desorption kinetics. Changes in protein conformation could result in impaired biological activity.[191,192] Both protein type and its conformation play a crucial role in modulating, for example, permissive cell adhesion via specific interactions with adhesion receptors as well as activation of further intracellular signal cascades.[191] **Chapter 4.405, Leukocyte–Biomaterial Interaction *In Vitro*** deals with the respective presentation of functional, adhesive RGD sequences.[193–196] As a short summary, proteins from the extracellular milieu serve as essential mediators of early biomaterial–host tissue interactions; initially, vitronectin, fibrinogen, and particularly fibronectin (FN), as well as the von Willebrand factor (vWF) seem to be of great importance.[192]

6.619.3.1.2. Platelet activation and cytokine release

Later in the process, an early, transient organic matrix is established on the biomaterial surface which is supplemented by further acellular and cellular blood components like fibrin (ogen), albumin, erythrocytes, and platelets. Particularly Ti surfaces as well as certain surface modifications bear highly thrombogenic properties.[197–199] Surface–platelet interactions play a crucial role in early biomaterial healing, as platelets are the first cellular components to interact with the above described transient matrix at the implant surface, and platelet activation with cytokine release[200] serves to promote biomaterial healing by stimulation migration, proliferation, and differentiation of osteogenic cells.[201,202] Well-investigated cytokines and growth factors are, for example, platelet-derived

growth factor (PDGF), vascular endothelial growth factor (VEGF), transforming growth factor beta (TGF-β) as well as vasoactive substances like serotonine and histamine.[203] Membrane-bound receptors interact with proteins absorbed at the implant surface, such as fibrin or vWF which are derived from vascular endothelial cells. These have an impact for platelet aggregation at the biomaterial surface with consecutive activation and degranulation. From the integrin receptor family, glycoprotein (gp) Ib-receptor modulates platelet binding at vWF and gpIIb/IIIa-receptor modulates platelet binding at fibrinogen/fibrin.[204] GpIIb/IIIa-mediated platelet interactions with fibrin absorbed at the implant surface are of especially great importance and can be further enhanced by chemical and structural implant surface modifications.[205] Respective investigations have shown that a rather rough microtopography of implant surfaces resulted in enhanced fibrin adsorption as well as enhanced platelet adhesion, aggregation, and activation.[197–199]

The above-mentioned cytokines PDGF and VEGF are stored in the platelet a-granules and released into the extracellular milieu after platelet activation.[206] Both cytokines (representing an abundance of other important mediators) are highly biologically relevant for implant and biomaterial healing. Especially for dental implant healing in compromised bony tissue (general and local risk factors), simultaneous neoangiogenesis plays a crucial role and is an obligate precondition for sufficient osteogenesis and osseointegration.[207,208] Furthermore, these cytokines are indispensable for osteogenic cell activation with subsequent osteoconduction and osteoinduction. Vascular endothelial growth factor-A (VEGF-A) stimulates early angiogenesis and osteogenesis by recruitment and activation of relevant hematopoietic and osteogenic cell populations.[208,209] Furthermore, VEGF promotes differentiation of osteogenic precursors,[210] not at least by stimulating the production of bone morphogenetic protein-2 (BMP-2) by endothelial cells.[211–213] A systematic review by Keramaris and coworkers emphasizes the value of VEGF for the treatment of critical size bony defects.[214]

Besides chemoattractive properties, PDGF stimulates proliferation of endothelial cells and osteogenic cells as well as osteogenic cell differentiation.[215–217] Successful treatment of periodontal defects with recombinant human PDGF has led to to its subsequent approval by the US Food and Drug Administration (FDA).[218] Finally, VEGF- and PDGF-mediated effects on osteogenic cells seem to be synergistic ones.[219,220] As already stated, platelet activation with consecutive degranulation and cytokine release can be modulated by surface properties like (micro-)topography, chemical composition, and surface charge.[221,222] Hong *et al.* identified titanium (Ti) as a highly thrombogenic substrate with enhanced platelet activation and PDGF release.[197] Further studies from Park and Kikuchi showed that a rough implant surface microtopography has a higher impact on platelet activation rather than the presence of calcium or phosphate ions.[199,223,224]

6.619.3.1.3. Inflammation period, chemotaxis

The implant surface maintains close contact with the blood coagulum, consisting of a loosely, 3D fibrin meshwork which directs both angiogenesis and osteogenic cell recruitment.[189,225] During the inflammation period, inflammatory cells like leucocytes migrate out of postcapillary venoles into the blood coagulum. Leucocytes, as well as the activated platelets and endothelial cells already mentioned, liberate cytokines, which promote the recruitment of further inflammatory cells. Low oxygenation of the early peri-implant compartment can serve as a chemotactic signal for mesenchymal and endothelial cells as well.[226,227] During the first 24–48 h, neutrophilic cells dominate, followed by monocytic cells like macrophages. As for platelets, rough titanium surfaces showed higher monocyte adhesion *in vitro*.[228]

6.619.3.1.4. Osteoconduction and matrix synthesis, functional remodeling

Finally, the liberated or secreted cytokines and growth factors such as VEGF, PDGF, and TGF-β[224,229] promote chemoattraction and recruitment of osteogenic cells,[202,230] which migrate from the local bone border through the peri-implant blood coagulum and the fibrin meshwork to the implant surface. This process of recruitment, migration, and adhesion of osteogenic cells is also called 'osteoconduction'[189] and plays a key role during implant healing. Initial osteogenic cell adhesion predominantly occurs at sites where fibrin adsorption on the implant surface has taken place. Later, osteogenic cells can produce their own adhesive environment (structural proteins like collagen type I α). Osteogenic cell adhesion is followed by cell proliferation and differentiation into mature, postmitotic osteoblasts. Osteoblasts produce a primarily nonmineralized organic bone matrix. The subsequent process of implant healing is referred to as '*de novo* bone formation' and results in calcification of the primary bone matrix via deposition of anorganic substrates and finally in a stiff connection between implant and surrounding bone.[189,231]

The initial deposition of vital bone at the implant surface is followed by early functional bone remodeling; multiple stress-induced adaptive cellular activities and interactions at the implant–bone interface result in directed formation of trabecular structures and in final bone maturation. This lamellar bone adapts to functional implant loading (chewing) and other peri-implant stimuli. At the end of this process, the osseointegration defined above occurs, with definitive close functional union between implant and bone. As vital tissue, peri-implant bone undergoes a permanent, lifelong functional remodeling.[232] **Figure 1** provides a schematic illustration of the activities of osteogenic cells and bone tissue during implant healing.

6.619.3.2. Soft Tissue (Mucosa and Epithelium)

In contrast to the extent of the literature regarding the bony healing, only few results on peri-implant soft tissues are published. There is, for the passage point of the implants through the mucosa, evidence that a higher roughness promotes plaque accumulation with bacterial invasion, thereby endangering the long-term development of a soft-tissue infection and subsequent lesion. A rather smooth surface, on the other hand, hinders epithelial cellular adhesion at the implant neck. It is postulated that cells adhere to the implant/abutment in the form of hemidesmosomes.[233] In cell culture experiments, both primary and secondary cultured gingival keratinocytes show an advantageous adhesion to smooth (polished)

compared to rough surfaces.[234,235] Only a few studies report on the basic material properties of the mucosal portion of dental implants.[236] Although the macroscopic structures of soft tissue seal at the implant and tooth are very similar, their morphology as well as the defense mechanisms are fundamentally different.[237] Micromorphologically, comparing the tooth and the implant's structural features, only the presence of hemidesmosomes, although to a lesser extent than the dentogingival seal, is described.[238] In contrast to the radial arrangement of collagen fibers in the cement at the attachment of natural teeth, collagen fibers at implants are found only circularly arranged with significantly fewer blood vessels.[239,240] As the epithelium junction around implants offers only a partial barrier against the penetration of bacteria from the oral cavity, perhaps due to functional adaptation, increased inflammatory cells, including T-cells, are found.[241,242] Similar to the bony attachment, glycoproteins seem to be important for the implant–mucosa connection.[243] The exact mechanism of the postulated soft tissue attachment has not yet been resolved. *In vitro* research of the fundamental mechanisms is difficult, as cell culture models do not allow mimicking of the complex structure of the epithelium and fibrous tissue.[244,245] Increasing evidence has been found that the soft tissue thickness has an influence on the bone remodeling around dental implants.[246]

6.619.3.3. Experimental Methods

6.619.3.3.1. Mechanical testing and modeling

Mechanical testing of dental implants has two central objectives. One is to study the influence of the implant macrostructure on primary stability in various bone densities, and the other is the stability of the implant abutment connection. The latter one classically is studied by mechanical testing.[247] The accepted method of fatigue testing is described in ISO/FDIS. 14801:2007 (**Figure 9**).

One method to determine the influence of the thread design on primary stability is photoelastic analysis. It helps to visualize critical stress points using a photoelastic, homogeneous, isotropic material. By studying the fringe pattern of polarized light, one can determine (visualize) the state of stress at various points in the material.[248,249] Photoelastic stress analysis was introduced into dentistry to evaluate different types of orthodontic movements.[250] Since then, the application of this method has started to be used in different areas of dental research, focusing on stress distribution.[251] It is an important tool for visualizing stress points. The main and inherent limitation of the method is its capacity to model the nonhomogeneous and anisotropic characteristics of bone and its limitation to qualitative data.[248]

The application of strain-gauge method on dental implants is based on the use of electrical resistance strain gauges. A strain gauge utilizes the property of electrical conductance's dependence on not only the electrical conductivity of a conductor, but also the conductor's geometry.[252,253] It mainly provides *in vitro* measurement strains under static and dynamic loads. *In vivo* studies were also developed to quantify the degree of stress that occurs in the bone around implants associated with fixed partial denture,[254] to measure strains involved in connecting implants to a natural tooth,[255] and to measure the force

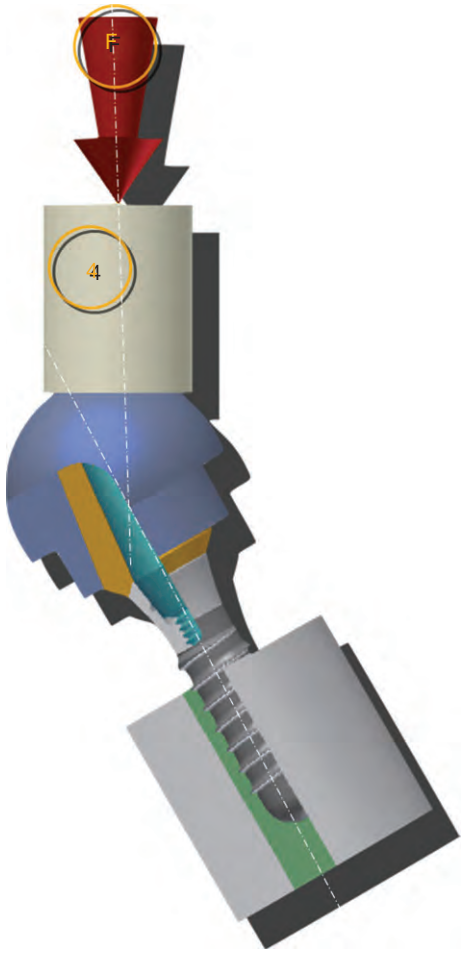

Figure 9 Schematic drawing of the fatigue testing setup due to ISO 14801 (4 = loading device, F = force applied in 30°.)

transmission onto implants supporting overdentures.[256] The limits of the *in vivo* use of the strain-gauge method are obvious, as it provides only the data regarding strain at the gauge.

The finite element analysis is based on the idea that a complex situation is divided into small elements which allow an estimation of the solution. Thus, it is a method whereby instead of seeking a direct solution function for the entire domain, one formulates the solution functions for its finite elements and combines them properly to obtain the solution to the entire structure.[257] By using computer-aided design software and engineering experience, the power of the finite element method is its versatility. The anistropic structure of bone and the wish for a 3D model, which are the limit of the method, are frequently solved by improved PC possibilities. The model is used for a variety of questions in dental implantology.[248]

6.619.3.3.2. Cell culture methods

Biocompatibility of various surface properties is primarily tested using cell culture models. They consist of cell (mainly osteogenic cells) visualization on the biomaterial surface employing methods based on scanning electron microscopy

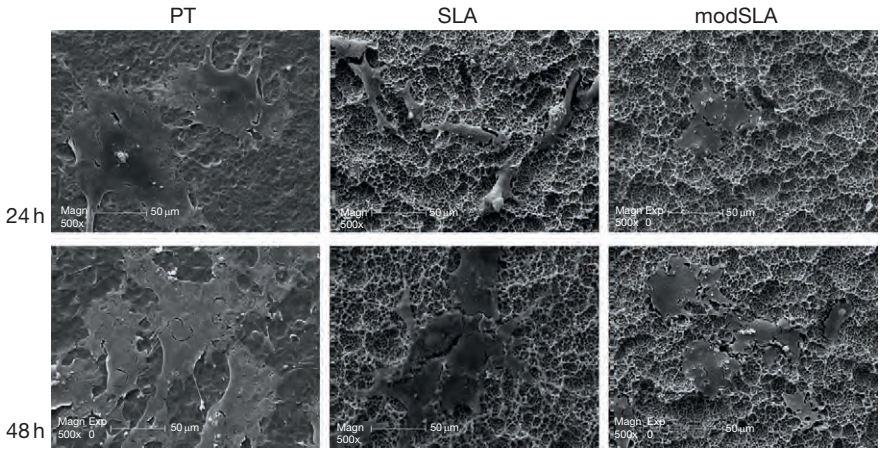

Figure 10 SEM image of osteoblast-like cells on different titanium surfaces (PT = machined; SLA = sandblasted & etched; modSLA = sandblasted & etched, hydrophilic) (Prof. Konerding, Department of Anatomy, University Medicine Mainz).

(SEM, Figure 10) or vital stainings. The interpretation of the cell shape provides first hints on the biocompatibility of the material. Visualization is completed by proliferation assays.[258] Different surfaces are tested using different cell populations like fibroblasts, chondrocytes, and osteoblast-like cells of different origin. The different origins of osteoblasts might be one cause for divergent results of these experiments. MG-63 cells have become a widely used cell line for these experiments.[259–266] The quantifications of osteogenic cell markers like osteocalcin, osteopontin, and alkaline phosphatase permit a conclusion as to the state of differentiation of these cells. Some groups are working on coculture models which might help to understand important interactions between the different cell types.[267,268]

6.619.3.3.3. Animal models

A better understanding of the human *in vivo* effects can be drawn from animal models.[269] Small animal models where implants are implanted into the tibia help to understand basic principles of the interactions between *in vivo* material and bone.[270–288] The results are based on histomorphometry, where bone–implant contact rates are measured after the classical sawing and grinding technique.[289] However, due to the mesenchymal bone and cortical structure of the bone, only minimal generalization to the human situation is possible. Moreover, it should be kept in mind that the unloaded situation does not really reflect the definition of osseointegration of a loaded implant. Another type of results is drawn by biomechanical testing of the implant–bone interface using reverse torque measurements.

Larger animal models allow simulation of a loading condition and are more similar to the clinical situation. Some groups are promoting a sheep model.[269,290–299] The majority of groups prefer a dog model, where the implants are inserted into the premolar region (Figure 11).[163,165,166,240,300–331] Quantification of the bone-to-implant contact is mainly done using the sawing and grinding technique followed by conventional staining. SEM analysis,[332] confocal laser scanning microscopy (CLSM),[331] and *in vivo* sequential staining are more rare.[333] More recently, µCT has been introduced as an additional method to study the bone–implant interface.[286] Direct comparison of conventional histology and micro-CT indicates a superiority of conventional histomorphometry over micro-CT, as the latter is hampered by deficits in the discrimination at the implant–tissue interface.[334] Noninvasive methods such as resonance frequency analysis[335] have been applied in animal models but seem not to reflect the clinical situation.[331,336–338] The classical bone-to-implant contact measurement shows the deficit of a static situation. To overcome this situation, bone ingrowth models[339] or dehiscence defect models[328,329] are common for some questions.

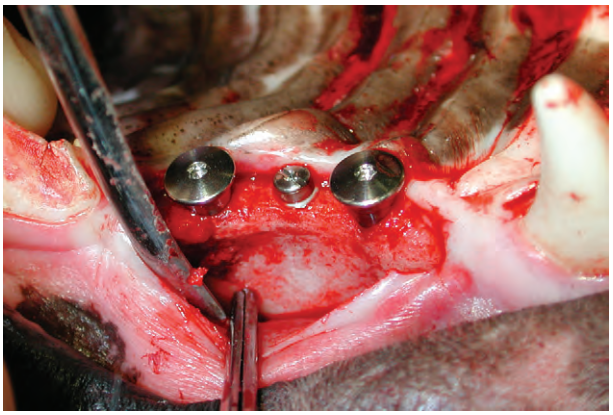

Figure 11 Intraoperative situs of the typical premolar area in a dog model. Note the narrow alveolar ridge after extraction of the premolars which allows the insertion of 3–4 small diameter implants.

6.619.3.3.4. Human histology

Human histologic specimens are rarely available. Some researches use retrieved implants in prospective studies,[340] which from an ethical point of view, might be considered drawing criticism. Implants retrieved from a clinical cause also allow long-term studies of dental implants in the human situation.[341] These results show a bone-to-implant contact area of about 60% for functioning implants (Figures 12 and 13).

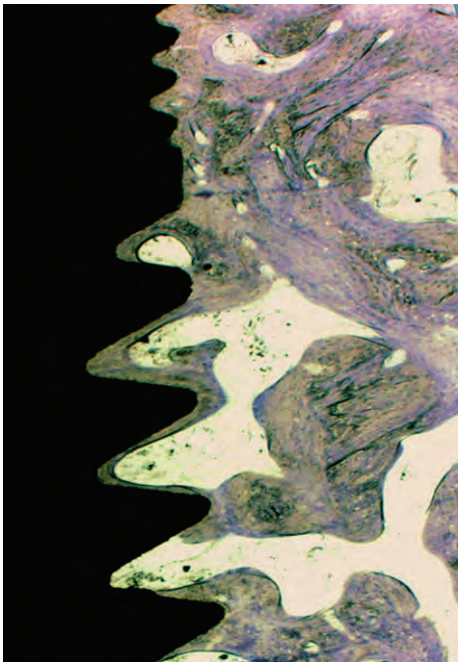

Figure 12 Human histology (toluidine blue) of a loaded TiO_2-blasted, fluoride-containing implant surface, which shows the dense contact in the microthreaded cortical area and a osseoconduction in the area of cancellous bone.

6.619.4. Implant Materials

6.619.4.1. Metal

Despite the variety of materials used as biomaterials, titanium has been clinically established for use in dental implants. This is mainly due to its good tensile strength with relatively low weight and excellent corrosion resistance and because of the spontaneous formation of a passivating oxide layer. Both pure titanium and, more rarely, titanium alloys (Ti–6Al–4V and Ti–6Al–7Nb) are in use. Cp titanium and the alloy are defined by the American Society for Testing and Materials (ASTM F67). In older cell culture studies comparing alloy and pure titanium, no essential difference could be identified.[342] In a more recent work, when utilizing human osteoblasts on pure titanium in contrast to the alloy (Ti–6Al–7Nb), an improved proliferation rate and a higher activity of alkaline phosphatase as a measure of cell differentiation was reported for the pure Ti.[343] This is complemented by results from several *in vivo* studies, which demonstrate a superiority of the pure titanium on the osseous healing.[276,284,344] Titanium alloys are mainly used for diameter-reduced implants and orthodontic mini-implants.[345]

TiAlNb alloys are currently under investigation in preclinical studies.[346] Other alloys studied in animal models are Ti-75 (AlMoZrTi)[347] and TiAlNb[332] with positive results, and nitinol (Ni–Ti)[348] with negative results for osseointegration. In contrast to these experimentally used alloys, TiZr alloy is already commercially available for dental implants. This Ti alloy containing 50% zirconium is significantly harder and more tensile than the hardness of pure titanium and pure zirconium.[349] In a chondrocyte culture, TiZr showed positive results.[350] In a rat model, lower toxicity and higher biocompatibility of TiZr compared to Ti was reported,[351] which is also seen in a larger animal model.[352,353]

Regarding bone–implant interactions, currently the material 'Titan' and the macrostructure 'screw type' have been established clinically, whereas the microstructure and nanostructure are at the center of current research. In recent publications, the role and prevalence of Ti allergies have been discussed. The authors estimate a prevalence of 0.6% and propose cutaneous testing in patients who presented allergic symptoms after implant placement or suffered from unexplained implant failures.[354] However, the existence of Ti allergies and the role of testing are not generally accepted.

Tantalum (Ta) is one of the few nontitanium metals, which has been investigated for osseointegration in dental implantology. It has been shown to be bioactive and biologically bonds to bone. However, the relatively high cost of manufacture and an inability to produce a modular, pure Ta implant have limited its acceptance. Tantalum, especially porous variations, have been studied for use in orthopedics,[355] and positive findings for Ta have been seen in the cell culture.[356] TiTa alloys show promising biocorrosion parameters *in vivo* and would be more easy to produce.[357] Additionally, a Ta coating on Ti seems to increase biocompatibility in a cell culture.[358] Other metals have not yet revealed promising results; for example, CoCr implants show lesser osseointegration than TiAlV.[359]

6.619.4.2. Ceramics

Early and promising systematic data in implantology were derived from the Tuebinger immediate implant, which was made of aluminum oxide ceramic.[28,29] Despite its favorable osseointegration characteristics, fracture events after long-term use have outdated its use as dental implants. Because of this negative experience, for many years only metal implants were in use. However, in recent years, a recurrence of ceramic dental implants of favorable (white) color has taken place. Zirconium dioxide (zirconia) has shown favorable results in the osteoblastic cell culture.[360] The ceramic composite of zirconia–hydroxyapatite (TZ–2Y/25HA) has also been investigated in a single animal model.[361] The first *in vivo* experiments and clinical studies were done with single-piece implants with a rather smooth surface, as it was difficult to generate surfaces comparable to Ti on zirconium oxide.[362] As known from endodontic apical cones, the osseointegration was comparable to Ti or aluminum oxide.[363] The material primarily used is Y-TZP (tetragonal zirconia polycrystal), which is stabilized by yttrium oxide. In the unloaded animal experiment, the osseointegration of these rather smooth implants was positive.[281] By sandblasting the surface, the osseointegration of zirconia in a large animal model after loading is comparable to that of titanium.[364] This result has been reported by several other groups using different surface treatments, with the conclusion that in animal models, surface-modified zirconia implants can reach firm stability in bone.[282,293,365–371] As most of these implants are single-piece implants (with abutments directly connected to the implant), it is often necessary to reshape them. Despite some concerns about this procedure, Crown preparation did not influence the reliability of the one-piece ceramic implant from a mechanical point of view.[372] It should, however, be stated that in the clinical setting the success rates vary between 84% and 99%.[373–375] To date, no controlled clinical studies in humans regarding clinical outcomes or osseointegration are available. Thus, most researchers agree that zirconium oxide implants, although now available as two-piece implants with a rough surface, still cannot be recommended for routine use.[376] Y-TZP implants may have the potential to become an alternative to titanium implants, but long-term data in this field is lacking.[377]

6.619.5. Surface Structure and Modifications

6.619.5.1. Macrostructure

Macrostructures of dental implants have been developed empirically. Rotational symmetric screw and cylindrical designs have been favored by the clinicians. Finite element analysis is classically used to model stress distribution around different implant designs. In these models, screws have shown a more favorable stress distribution than cylinders.[378] One of the early ideas was that the design of the implant should not overload the crestal bone, thereby leading mechanical load to the apex of the implant. This has led to the progressive thread design of the Ankylos implant (formerly NM implant).[379,380] Another way to solve the problem of crestal overloading was the lack of threads in the neck region of the first-generation Astra standard implant.[122,381–383] The more or less rough 2D FEM analysis has been replaced by 3D models which include several material parameters of bone and implant.[384,385] Using these techniques, it is possible to optimize implant geometry with respect to platform shift and thread design.[386] It has been shown that the majority of stress distribution happens in the crestal part of the bone,[387] which promotes the use of short implants. On the other hand, clinical studies have shown that loading the crestal bone with microthreads leads to less pronounced bone remodeling in this area.[388,389]

As one major goal during implant insertion is to reach mechanical primary stability, the implant threads of modern dental implants are receiving more attention. The primary stability, especially in situations of critical bone quality, has been attempted to be optimized by modification of implant design. One suggested approach to enhance primary stability in critical bone quality is to choose a conical implant for insertion into a standard parallel-sided hole (underdimensioned drilling). The idea behind this approach is to induce controlled compressive forces in the cortical bone layer, as the implant is inserted.[390,391] Modern thread types are often intended to reach high primary stability even in soft bone.

6.619.5.2. Physical Modification (Roughness)

The implant surface is the area that is in direct contact with the body and is therefore mainly involved in implant healing. Therefore, one key target of various modifications is achieving high levels of biocompatibility. A prominent role is played by the already mentioned above. Owing to its high surface passivation by establishing an oxide film, corrosion resistance of titanium is achieved; this reduces the detachment and diffusion rate of ions or molecules on the surface and thus guarantees high chemical stability. In addition, it affects the adhesion and stability of coatings in the context of surface modification.[392] The 3–7 nm thick film consists mainly of TiO_2, but small amounts of TiO and Ti_2O_3 are also included.[393,394] After implant insertion, the oxide layer is modified in thickness, composition, and microstructure. In addition to the spontaneously formed natural oxide film, a variety of optional processing steps allow for more targeted modification of the implant surface. Primary surface treatments can be grouped into three methods[395]:

(a) Machining processes
The surfaces are macroscopically smooth; microscopically small groves can be seen along the working direction.

(b) Additive procedures
Application of material onto a surface is done either in the form of coatings with ceramic materials (mostly hydroxyapatite or calcium phosphate (CaP)) or produced by titanium plasma spray coating. This procedure gives a rough, relatively irregular shape with increased surface area. Other approaches closely related to biofunctionalization exist in the coating with functional protein ligands or cytokines (e.g., collagen or BMP and chemical modifications such as fluoride[396] or magnesium application).[288]

(c) Ablative procedures

These procedures include blasting the surface and/or acid treatment. For blasting, mainly Si, Al-(Al_2O_3), or titanium (TiO_2) particles are used. The surface is roughened with plastic deformation, and some small particles are embedded into the material. The size of the irregularities depends on various factors such as blast pressure, distance, time, and particle size. Acid etching also serves to increase the surface area or an increase in roughness. It leads to a more porous, but regular structure. It also adds to the process of cleaning the surface and the removal of blast residue. The extent of the etching process depends on the type and concentration of acid (H_2SO_4, HNO_3, HF, HCl), as well as temperature and duration time.[397]

The chemical composition of the surface results from both intentional and unintentional actions, and is also influenced by the various manufacturing and steps: often there are several organic pollutants such as hydrocarbons, fatty acids, or silicones. These come mainly from cleaning solutions or adsorbed molecules from the air. Etching, and grinding and abrasive residue, such as silicon, aluminum, or titanium, may also influence the chemical composition. Furthermore, increased temperatures, taking as an example, occur in the heat treatment effect on the elemental composition.[397]

6.619.5.3. Chemical Modifications

Anodic oxidation of titanium surfaces leads to different thickness of the oxide layer and a characteristic surface topography.[398] Animal experiments revealed positive bone reaction for these types of surfaces.[399,400] In comparison to an etched surface, the anodic oxidation revealed faster bone healing,[401] which has led to the development of two commercially available implant surfaces, which allow faster bone healing.[402,403]

Other experimental studies had focussed on the influence of surface hydrophilicity, for example, maintained by UV treatment.[326,339,404] Hydrophilic surface modifications show potential to support tissue integration of titanium dental implants.[405] Other groups have demonstrated positive osseocondictive effects for fluoride-modified surfaces.[325] Both hydrophilic and fluoride modifications are commercially available. Incorporation of Mg also seems to be favorable.[288]

6.619.5.4. Clinical Impact of Surface Modifications

A huge number of the experimental investigations have demonstrated that the bone response was influenced by the implant surface topography.[271,272,326,331,406–415] Smooth ($Sa < 0.5\,\mu m$) and minimally rough ($Sa\ 0.5–1\,\mu m$) surfaces showed less strong bone responses than rougher surfaces. Moderately rough ($Sa > 1–2\,\mu m$) surfaces showed stronger bone responses than rough ($Sa > 2\,\mu m$) in some studies. Owing to the various definitions of 'smooth' and 'rough' used by the different authors, it is very difficult to compare the results directly. The authors of a recent review conclude: "Surface topography influences bone response at the micrometer level. Some indications exist that surface topography influences bone response at the nanometer level. The majority of published papers present an inadequate surface characterization. Measurement and evaluation techniques need to be standardized. Not only height descriptive parameters but also spatial and hybrid ones should be used".[416] Interestingly, animal models demonstrate that in the presence of loading, the topographic dependency of the osteogenic activity at the interface is overruled by the loading-related bone response.[285,331,417]

Presuming optimal bone quality and healthy patients, dental implants with both minimally rough and rough surfaces have shown very high long-term survival rates.[25,79] However, in the compromised situation (e.g., following radiation therapy, bone augmentation, class D4 bone), the implant survival rate of machined implants is lower,[418] and it is still unclear which surface modification may lead to a higher clinical success rate.[25,122] Besides this aspect concerning the implant bed, surface topographical properties are a prerequisite for reduced healing time and are thus within the scope of *in vivo* studies.[402,419–425] The potential influence of a modified microstructure may be reflected by the high number of surface modifications which are commercially available. On the other hand, the clinical impact of these modifications is far from being clinically proven.

6.619.5.5. Biofilm and Peri-implantitis

The stable functional bone remodeling in the crestal part of the implant as a physiologic reaction ('biologic width') must be distinguished from a pathological loss of bone due to peri-implant inflammation. There is consent for the following definitions[426,427]:

Peri-implant disease: Collective term for inflammatory reactions in the tissues surrounding an implant.

Peri-implant mucositis: Presence of inflammation in the mucosa at an implant with no signs of loss of supporting bone.

Peri-implantitis: Besides inflammation in the mucosa, loss of supporting bone is found.

The diagnosis is made using probing (depth, the presence of bleeding on probing, suppuration) and radiographs to evaluate supporting bone levels around implants. There is strong evidence that poor oral hygiene, a history of periodontitis, and cigarette smoking are risk indicators for peri-implant bone loss due to peri-implant disease.[427] The prevalence of peri-implant disease is astonishingly high. In a systematic review, peri-implant mucositis occurred in approximately 80% of the subjects and in 50% of the implants. Peri-implantitis was found in 30–60% of the subjects and in 10–40% of implant sites.[426] The association with periodontitis is very important, as it is known that aggressive periodontitis[142] and bone loss[428,429] have a direct influence on peri-implant disease. Implants become colonized by periodontal pathogens originating from intraoral sources shortly after insertion.[430,431] However, *Staphylococcus aureus*[430] and Candida group[432] are also found at implants with peri-implant disease. Soft tissue integrity is a prerequisite to prevent bacterial colonization[433] but cannot prevent subgingival colonization.[434] The surface seems to have an effect on peri-implant disease as there is limited evidence showing that implants with relatively smooth (turned) surfaces are less prone to bone loss due to chronic infection than implants with rougher surfaces.[435] The current state of literature is more descriptive, rather than providing strong data, because animal models, such as the ligature model, are limited by the nonhuman flora in the mouth of the beagle dog.[436] *In vitro*,

it has been shown that an increase in surface roughness and surface-free energy facilitates biofilm formation on dental implant and abutment surfaces,[404] but does not directly lead to peri-implant disease in the human *in vivo* situation.[437] Surface chemistry and the design features of the implant–abutment configuration also play a significant role in biofilm formation.[438] The 'classical' process of biofilm formation on biomaterials plays an important role in this aspect. It includes an initial physicochemical interaction phase and a late molecular and cellular one.[439] Extensive work has been done in the theoretical background of this field, but few clinical steps to modify implant neck and/or abutment are available. One experimental way is to produce different surface types to prevent peri-implant disease, such as shaping memory alloys to prevent microleakage at the implant–abutment gap,[440] surface polishing,[441] ZrN coating,[442] and UV irradiation.[443] The other concept is disinfection or antibacterial coatings of abutments: Decontamination of the internal implant parts using 1% chlorhexidine gel seems to be effective for a 6-month period.[444] Experimental antibiotic delivery using different antibiotics and methods of delivery are also under investigation.[445–448] The possible role of biofunctionalization using different proteins in this context yet is unclear.[449,450]

6.619.5.6. Biofunctionalization

Because of its high biocompatibility and adjustable physicochemical properties, titanium (Ti) serves as a particularly favorable substrate for developing and testing new surface modifications.[190,451,452] As already stated above, current literature indicates that modifications of surface topography on a micrometer-scale supports both osteogenic cell activity *in vitro*[453,454] as well as bone response *in vivo*.[455] In some publications, alterations of surface-free energy with enhancement of hydrophilicity and consecutive *unspecific* protein precipitation also proved to enhance osteogenic cell response and osseointegration of dental implants.[339,456–458] In this context, *specific* biofunctionalization of dental implant surfaces with functional ligands has been identified as a consequent next step, but has yet only reached the level of *in vitro* or animal studies.[459] The biological value of functional extracellular matrix (ECM) ligands and solitaire cytokines/growth factors for bone regeneration and implant healing is beyond doubt (see **Chapter 4.403, The Innate Response to Biomaterials**). For respective clinical applications, cell adhesion peptides, such as collagen, FN, and RGD-sequences, and growth factors, such as members of the TGF-β superfamily (including the BMP family), are of special interest.[460]

In general, various approaches to immobilize biomolecules onto titanium surfaces exist.[460] *Physical adsorption* is a rather simple method with ideally no changes of protein conformation (and biological effects, respectively), but shows the disadvantage of an uncontrolled desorption from the surface. *Physical entrapment* strongly depends on the quality of the employed barrier system and bears the disadvantage of tearing or eroding with loss of biomolecules. *Covalent attachment*, for example, via silane chemistry, is sophisticated and time-consuming, but results in dense surface loading with low protein loss. However, changes in protein conformation could result in decreased presentation of functional receptor binding sites with consecutive impaired biological effectiveness.

As stated above, functional, biological ligands can be subdivided into *adhesion molecules* and into *cytokines or growth factors* such as BMP-2.[459]

Promising coatings to enhance *cell adhesion* are ECM peptides like collagen and FN, or ECM-peptide sequences such as the RGD (Arg-Gly-Asp) sequence, which directly affect osteogenic cell response via integrin-mediated signaling pathways.[460–463] The presentation of these biomolecules at the implant surface aims to accelerate peri-implant bone formation, to bridge small remaining gaps between implant and bone, and to improve the remodeling process.[464–466] In contrast to cytokines, where a rather transient immobilization with subsequent controlled release into the peri-implant environment might be favorable, adhesive molecules generally require long-term immobilization on the implant surface.[460] Another important issue in biomimetic implant coating is the preservation of the native protein conformation and biological activity. General approaches of biofunctionalization with adhesive molecules imply either physisorption directly on the metal surface or chemisorption over linker molecules.

Analogous to adhesion molecules, the estimated clinical benefit of (appropriate applied!) locally acting *cytokines or growth factors* at the bone–implant interface is beyond doubt.[467–470] Owing to its high osteoinductive potential, BMP-2 as a potent candidate for implant surface modifications is in the focus of intensive research activities.[471,472] However, ambiguous results of implant surfaces loaded with BMP-2 have at least challenged the clinical feasibility of various BMP-2 concentrations, delivery systems, or coatings.[473–476] The mode of immobilization on the implant surface as well as consecutive delivery from the implant surface are of particular significance for the biological effects of BMP-2. On the one hand, the concentration of BMP-2 must exceed the threshold levels for cellular activity;[190] on the other hand, the effectiveness of BMP-2 is strongly dose-dependent.[467,475] An overdose in the environment can trigger adverse effects like bone resorption or peri-implant inflammation.[473–475] It is known that BMPs also stimulate osteoclast recruitment, proliferation, and differentiation,[477] and that high dosage may result in local overexpression of BMP inhibitors such as noggin.[478]

For instance, Wikesjö *et al.* observed the effects of rhBMP-2 coated onto titanium porous surfaces. Different concentrations were used. On the one hand, rhBMP-2 *coated* surfaces resulted in significant higher vertical bone regeneration; on the other hand, the mean bone-to-implant contact was significantly higher for uncoated surfaces. Furthermore, high rhBMP-2 concentrations resulted in rather immature bone, peri-implant seroma formation, and extensive peri-implant bone remodeling.[475] Schliephake *et al.* found no additional benefit of BMP-2 *coated* onto collagen-modified titanium surfaces.[476] In a substantial study, Liu and coworkers assessed different BMP-2 delivery modes. The authors concluded that osteoconductivity was impaired when BMP-2 was present only as *superficially adsorbed* depot on CaP-coated or -uncoated surfaces.[473] An investigation by Becker *et al.* showed the highest bone-to-implant contact values for covalently immobilized rhBMP-2, followed by noncovalently immobilized rhBMP-2 and BMP-free surfaces.[468] As conclusion, an optimum modus of BMP-2 immobilization on the surface and delivery (if necessary at all) into the peri-implant environment still has to be clarified.

The review of the experimental surface alterations revealed that thin CaP coating technology can solve the problems associated with thick CaP coatings, while they still improve implant bone integration compared with noncoated titanium implants. Nevertheless, there is a lack of human studies in which the success rate of thin CaP-coated oral implants is compared with just roughened oral implants. No unequivocal evidence is available that suggests a positive effect on the implant bone integration of peptide sequences or growth factors coated on titanium oral implants. In contrast, the available literature suggests that BMP-2 coatings might even impede the magnitude of implant-to-bone response.[479]

6.619.6. Implant Design

6.619.6.1. Principles in the Endosseal Part

Successful treatment with dental implants is indispensably linked to a vital adjacent tissue situation. Both primary implant stability and a stable secondary osseointegration require a quantitatively and qualitatively sufficient hard tissue supply. Furthermore, high-leveled bone around the dental implant serves as a basis for a tight soft tissue margin fit with high esthetic implications ('soft tissue follows hard tissue'). On the other hand, well-placed and functionally loaded implants bear the potential of respective tissue maintenance or even regeneration and counteract atrophy and resorption kinetics.

As stated above, a mandatory precondition for successful dental implant healing is sufficient primary stability, which depends on implant macrodesign, mechanical bone quality, and adequate preparation of the implant bed. Secondary stability or osseointegration rather depends on implant surface microdesign, surface composition, and biological bone quality.

Conical implant designs as well as extended implant threads aim to increase primary stability especially in spongy D4 bone like in the maxillary side region. However, the insertion of conical implants requires more experience than the insertion of cylindrical-shaped ones. A practical compromise represents so-called 'hybrid-shaped' implants with a cylindrical apical part and a conical crestal part.

In a systematic meta-analysis by Kotsovilis *et al.*, the authors investigated the influence of implant length on implant survival.[121] They included eight studies on fully edentulous patients with overall implant survival rates of 97% for implants <8 mm, 95% for implants 8–10 mm, and 100% for implants >10 mm. They also included 12 studies on partly edentulous patients with overall implant survival rates of 97% for implants <8 mm, 97% for implants 8–10 mm, and 98% for implants >10 mm. As a result, it is admissible to insert dental implants <8 mm in clinical routine. However, the authors did not address the impact of different implant designs and abutment connections on the peri-implant bone loss with consecutive reduction of the functional length of a dental implant.

The impact of the ratio between length of the (inserted) implant and length of the prosthetic crown on peri-implant bone loss was analyzed in a systematic review by Blanes.[480] Two studies were included with a total number of over 450 investigated implants.[125,481] No negative impact of larger crown dimensions could be observed; generally, a crown to implant ratio up to two seems to be unproblematic.

An important criterion to assess implant success or to improve established implant systems is the stability of the crestal bone level. After insertion of a dental implant, certain clinically asymptomatic crestal bone defects are characteristic and occur in almost all cases.[482–484] Generally, these crestal bone changes occur during the early healing phase after implant placement.[485,486] These defects have to be differentiated from bone loss due to peri-implant inflammation. In addition to assessment of probing depth, radiographic evaluation is well employed to monitor marginal bone loss, resulting in differential success criteria. According to an older definition of Jahn and d'Hoedt, the mean mesial and distal angular bone defect should not exceed 30% of the endosseous part of the implant.[487] According to Albrektsson, after higher initial bone loss rates within the first year, additional vertical bone loss should be less than 0.2 mm year^{-1}.[488]

A variety of external, implant-related parameters to modulate alveolar peri-implant bone loss have been discussed. Both histomorphometric and radiographic analysis of animal models as well as recent clinical and radiographic observations of human collectives reported no significant differences in implant survival rates and marginal bone changes between submerged and nonsubmerged implant healing.[485,486,489–491] A variety of recent investigations identified the presence and location of an interface between implant and abutment (microgap) as an important variable for biological width and resulting crestal bone changes. Generally, changes of the marginal bone level are determined and initiated during the early healing phase after implant placement for one-piece nonsubmerged implants, or after abutment connection for two-piece implant configurations.[485,492] Furthermore, crestal bone changes around two-piece implants are significantly influenced by possible movements between implants and abutments, but not by the size of the microgap.[492,493] Finite element analysis revealed that the design of the implant–abutment interface has a profound effect upon the marginal bone stress state with advantages of conical interfaces compared to flat top interfaces.[494] In a histomorphometric study, Weng *et al.* could identify an internal taper abutment connection as advantageous for peri-implant crestal bone morphologies, compared to an external hex abutment connection.[495]

Another explanation for marginal bone loss could be bacterial colonization of the microgap.[496] Broggini and coworkers showed a significantly increased number of inflammatory cells for subcrestal located interfaces compared to supracrestal interfaces. Moreover, inflammatory cell accumulation below the original bone crest was significantly correlated with bone loss.[497]

In a canine animal model, for all two-part implants, nonsubmerged and submerged, the most coronal bone-to-implant contact was consistently located approximately 2 mm below the microgap.[486] As a clinical implication, supracrestal positioning of the microgap would minimize the amount of crestal bone loss.[485,498] Another strategy known as platform switching also yielded similar results. Platform switching involves repositioning the outer edge of the implant–abutment interface horizontally and inwardly by using healing abutments of a smaller diameter.[499–506]

The benefit of microstructured rough implant surfaces for the promotion of dental implant osseointegration and to sustain high-bone contact levels is well known.[507–510] Accordingly, subcrestal positioning of the border between the rough and smooth implant surfaces resulted in higher crestal bone loss.[485,511] Additional macroscopic modifications such as microthreads at the implant neck have been proven to maintain primary marginal bone levels.[388,389,512–514]

As a conclusion, adjustment of biological width with related crestal bone changes after dental implantation essentially depends on the following characteristic implant properties: macrodesign and surface microstructure as well as existence and positioning of the implant–abutment interface (microgap).

6.619.6.2. Future Developments

One clear clinical development is the challenge to avoid bone augmentations by using short or diameter-reduced implants.[515] The critical length of the implant in the bone (functional implant length) still has to be estimated. Clinical studies with 4- and 6-mm implants are ongoing. Reduced diameter implants are becoming more and more interesting, not only for the rehabilitation of the edentulous mandible,[516] but also in more challenging areas. Titanium alloys like TiZr will allow diameters smaller than 3.0 mm for use in the lower frontal area or the lateral incisor. In the esthetic area and for patients with concerns about metal, zirconium oxide implants will find their niche. Additionally, the development of custom-made CNC zirconia abutments is becoming more and more common. Three-dimensional imaging (cone beam CT) and the use of these techniques will allow better bidirectional planning, including the available bone volume and the planned supra construction. As long-term stability is a clear clinical goal, the 'fight' against peri-implantitis is an important topic. Modified abutments including better adhesion to the soft tissues and/or antibacterial properties are underdevelopment. Bone loss due to peri-implantitis is very difficult to be regained. Reosseointegration of the contaminated titanium surface is an issue of future research.

6.620.1. Introduction

The use of oral implants has become a common treatment to replace missing or lost teeth.[1,2] When teeth are missing, the surrounding bone and soft tissue is challenged as a result of the natural resorptive process subsequent to extraction. Furthermore, the prosthodontic requirements for the design of the implant superstructure (rather than the bone volume available) dictate the position in which the dental implants have to be placed. This has been called 'restoration-driven' implant placement.[1,3–5] Consequently, resorption of the alveolar ridge after tooth extraction frequently mandates site development by augmentation before implants can be placed.[1,6–8]

The current gold standard for bone reconstruction in implant dentistry and craniomaxillofacila surgery is the use of autogenous bone grafts.[9–15] Among the various techniques to reconstruct or enlarge a deficient alveolar ridge, the concept of guided bone regeneration (GBR)[12] has become a predictable and well-documented surgical approach.[11] The need for localized ridge augmentation prior to the placement of dental implants has been one of the clinical indications for GBR.[12] At present, autogenous bone grafts are preferably combined with barrier membranes.[9,11,16] These autografts have been used to reduce the defect volume, thereby stabilizing the blood clot,[17] and to support the membrane as a space-maintaining device,

thus preventing their collapse into large defects.[12,13,18,19] Furthermore, augmentation of the maxillary sinus floor with autogenous bone grafts has become a well-established preimplantology procedure for alveolar ridge augmentation of the posterior maxilla.[20,21] The main disadvantages of autogenous bone grafts have been the need for an additional surgical site, increased donor site morbidity, insufficient volume of (intraorally) harvested bone, and the need to use general anesthesia for extraoral bone harvesting.[15,22–25] Using biodegradable bone substitutes as a membrane-supporting device would simplify GBR, as it avoids second-site surgery for autograft harvesting.[9,13] This is also true for sinus floor elevation procedures.[22,23,25] On account of the significant increase in dental implants placed and also in alveolar ridge augmentation procedures performed over the last two decades, there also has been an ever-increasing demand for adequate bone grafting materials for implant dentistry.

These bone substitute materials should undergo remodeling and substitution by newly formed functional bone tissue in view of placing dental implants in such augmented sites.[9,26–33] Bioactive calcium phosphate ceramics and bioactive glasses are candidate biomaterials which qualify as bone substitutes for this kind of application, as they are widely used in orthopedics.[34–38] Alloplastic bone substitute materials are superior to freeze-dried human allografts due to their safety in terms of disease transmission and immunological aspects.[9,24,39]

Among the ceramics most commonly investigated for use in bone regeneration are β-tricalcium phosphate (β-TCP),[36,37,40] hydroxyapatite (HA),[37,41–44] and bioactive glass.[34,35,45] All of these materials are biocompatible[37,38] and osteoconductive.[33–35,37,46–51] However, they differ considerably in the rate of resorption and in the rate of bone formation at their surface. Dense HA ceramics resorb very slowly compared to β-TCP[37,42,52] and bioactive glass.[34,35,50,53]

6.620.2. Categories of Dental Grafting Materials

As mentioned earlier, the majority of the dental grafting materials are calcium phosphate-based. Various HA- and TCP-based dental grafting materials[40,54–62] as well as bioactive glasses and glass ceramics[63–65] have been investigated and proposed as therapies to augment alveolar bone and to promote periodontal regeneration since the 1970s.

6.620.2.1. Hydroxyapatites

Numerous HA-based grafting materials were developed over the last decades. These include HAs, fluorohydroxyapatites, and apatites of coralline origin,[27,28,66–84] synthetic HAs[41] including nanocrystalline HAs such as an aqueous paste of synthetic nanoparticular HA[85–87] as well as bovine deproteinized bone xenograft particles.[88–94]

Most of these materials have been shown to be osteoconductive.[85–87,93,95,96] However, none of these materials exhibit a high biodegradability.[85–87,9697] Typical studies report excellent osteoconductivity.[18,30,70,71,86,87,93,97–110] In this regard, one of the porous bovine-derived HAs that closely resembles HA of bone, namely Bio-Oss™, has been extensively reported in the scientific literature. Its morphology resembles that of cancellous bone. Its excellent osteoconductive properties have been described in numerous *in vivo* preclinical and clinical studies.[18,30,70,71,93,97–112] It has been shown, however, that biopsies sampled 20 months after implantation in the human sinus floor still consisted of 29% residual grafting material, which showed close apposition to the newly formed bone.[97] With this material also three-dimensional (3D) cancellous blocks are available for the purposes of bone tissue engineering.

Various HA block grafts have also been proposed for reconstruction of contour and discontinuity defects in maxillofacial surgery by transplantation of HA-bone composite grafts[113–115] and for use as scaffolds in bone tissue engineering procedures.[116,117]

More recent developments include a peptide-modified HA[118–121] named PepGen P-15. P-15 is a highly conserved linear peptide with a 15 amino acid sequence identical to the sequence contained in the residues 766–780 of the α-chain of type I collagen. PepGen P-15 (Dentsply Friadent, Mannheim, Germany) is a combination of a bovine bone-derived hydroxypaptite with P-15. This material has been shown to accelerate bone formation at its surface at the early stages of wound healing; however, after 6 months, no difference compared to the native HA was noted.[120]

Another development is the use of a nanocrystalline HA embedded in a silica matrix, which is a synthetic HA produced by a sol–gel process in the presence of SiO_2. The use of this material is being advocated as a dental graft material, as it has been shown to exhibit good osteoconductivity and to support neovascularization.[85,122–125] However, it displays a limited biodegradability.[85]

6.620.2.2. TCP Ceramics

While early β-TCP ceramic products were plagued by insufficient phase purity and inhomogenous solubility characteristics, which led to varying biological and clinical outcomes, more recent improvements in β-TCP ceramics include products with a high phase purity (>99%) and homogenous solubility characteristics, so as to prevent premature separation of microparticles from the structural compound.[126] In the past, these types of microparticles have been shown to elicit inflammatory tissue responses.[126] Furthermore, the use of TCP particles with increased porosity (65% vs. 35% porosity) has been proposed in order to increase the biodegradability.[126–132] These particles exhibit a material structure with pores on different length scales micropores (size: <50 μm), mesopores (size: 50–100 μm), and macropores (size: 100–500 μm), designed to enhance the degradation process. This structure allows for a reduced bulk density. The microporosity allows circulation of biological fluids, increases the specific surface area, and thus accelerates the degradation process. The interconnectivity of the pores creates a capillary force that actively draws cells and nutrients in the center of the particles. The macroporosity is created to encourage the ingrowth of bone by permitting penetration of cells and vascularization.[126] Over the last decade, numerous studies have been published regarding the *in vivo* preclinical and clinical performance of TCP ceramic granules in implant dentistry, confirming the excellent osteoconductivity of various TCP ceramic products (**Figure 1**).[9,13,33,46,47,50,98,127,128,132–154] Long-term results in human patients were shown to be equal to those of autogenous bone grafts.[140,155] Recent developments also

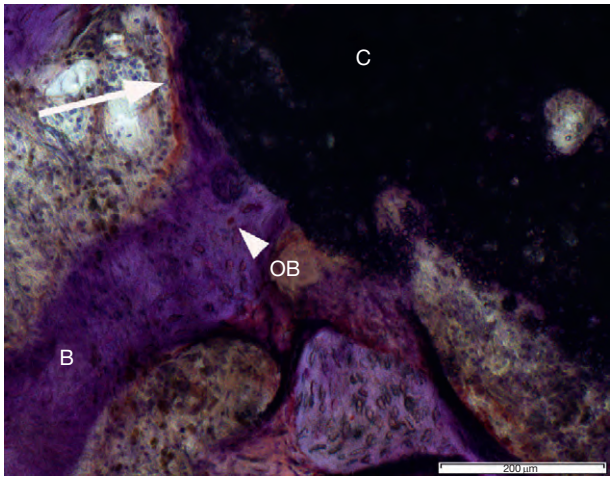

Figure 1 Resin-embedded human biopsy stained immunohistochemically for osteocalcin after deacrylation. The biopsy was sampled 6 months after augmentation of the sinus floor with β-tricalcium phosphate (β-TCP) particles (C) with 35% porosity. Intense staining of cells and unmineralized fibrous matrix (of the osteogenic mesenchym) lining the newly formed bony trabeculae (B) that are in contact with the TCP particle (C) is evident (arrow). OB (arrow head) – intensely stained osteoblast. These findings demonstrate the good bone-bonding properties of TCP. Furthermore, 6 months after implantation, bone formation and matrix mineralization are still actively progressing in the tissue surrounding the TCP particles. Undecalcified sawed section counterstained with hematoxylin. Bar = 200 µm.

include the clinical use of β-TCP block grafts in implant dentistry and maxillocraniofacial surgery.[156] Furthermore, the use of TCP ceramics with zinc or silica additives has been proposed with the goal to further enhance the osteogenic effect of TCPs as well as their mechanical properties.[157–159] Even more recently, a TCP putty-like material with kneadable properties has been introduced. It consists of pure, synthetic β-TCP granules of a wide range of particle sizes in a fermented sodium hyaluronate carrier. This material, however, does not set *in situ*, but with respect to surgical handling is advantageous over granules for a number of surgical uses. Furthermore, autologous blood or its derivates, bone marrow aspirate or bone chips as well as antibiotics can easily be added to the material prior to the surgical application (**Figure 2**).

6.620.2.3. Bioactive Glass 45S5

Bioactive glass (BG45S5) granules have been used for alveolar ridge augmentation and periodontal repair for more than a decade, and their excellent osteoconductivity, bone-bonding properties, and stimulatory effect on bone formation have been demonstrated by numerous *in vivo* preclinical and clinical studies since.[34,35,50,53,64,129,130,136,146,160–174] Among the various bone grafting materials used in implant dentistry, BG45S5 granules of a narrow size range were the first material, for which extensive and comprehensive histological data regarding their biodegradability derived from human biopsies were reported.[50,136,146] These biopsies were sampled at implant placement in clinical studies. Furthermore, the use of preexcavated granules has been proposed in order to even further enhance the osteogenic effect of BG45S5 granules of a narrow size range.[175]

6.620.2.4. Calcium Carbonate

Over the last two decades, a madroporic coralline calcium carbonate material (product name: Bio-coral) has been proposed as bone grafting material in implant dentistry, periodontology, and oral and maxillofacial surgery.[176–190] This material has been shown to exhibit good osteoconductive properties in combination with a limited biodegradability.[178,182] Furthermore, promising long-term clinical results have been demonstrated with respect to bony regeneration of infrabony periodontal defects.[189] More recently, this material has also been used for fabricating scaffolds for cell seeding and tissue engineering.[190,191]

6.620.2.5. Biphasic HA TCP Materials

Over the last 5 years, the use of synthetic biphasic HA TCP materials has been introduced for alveolar ridge augmentation. For these materials, a decreasing biodegradability has been demonstrated with increasing HA content.[192] A fully synthetic biphasic calcium phosphate consisting of a mixture of 60% HA and 40% of β-TCP (product name: Straumann Bone Ceramic) has been examined in *in vivo* animal and clinical studies. This material has been shown to display good osteoconductivity and support new bone formation.[100,103,192–196] Although this material has been shown to be not fully resorbable, it exhibited greater biodegradability than the bovine-derived HA material Bio-Oss; this, however, was associated with a less favorable bone-bonding behavior.[100]

6.620.2.6. Demineralized Freeze-Dried Bone Allografts and Mineralized Freeze-Dried Bone Allografts

Demineralized freeze-dried bone allografts (DFDBAs) and mineralized freeze-dried bone allografts (MFDBA) have been proposed as substitutes for autologous bone in implant dentistry, periodontology, and oral surgery for more than two decades.[162,164,168,197–230] These materials are inferior to synthetic materials in terms of risk of disease transmission and immunological challenges.[9,24,231] They have been widely used in the United States, while in several European countries, their use has not been approved for dental applications. Furthermore, conflicting results regarding their osteoconductivity and potential to support new bone formation in clinical settings have been reported.[199,218,223,225,228]

Schwartz *et al.*[223] showed that a wide variation in commercial bone bank preparations of DFDBA existed and that the ability to induce new bone formation also varied widely. In addition, commercial DFDBA differed in both size and ability to induce new bone formation, but the two were not related. The authors also pointed out that methods or assays for evaluating the ability of DFDBA to induce new bone should be developed and standardized.[223] In addition, these materials are not fully resorbable, even 4 years after implantation, residual grafting material was present in the human case.[225]

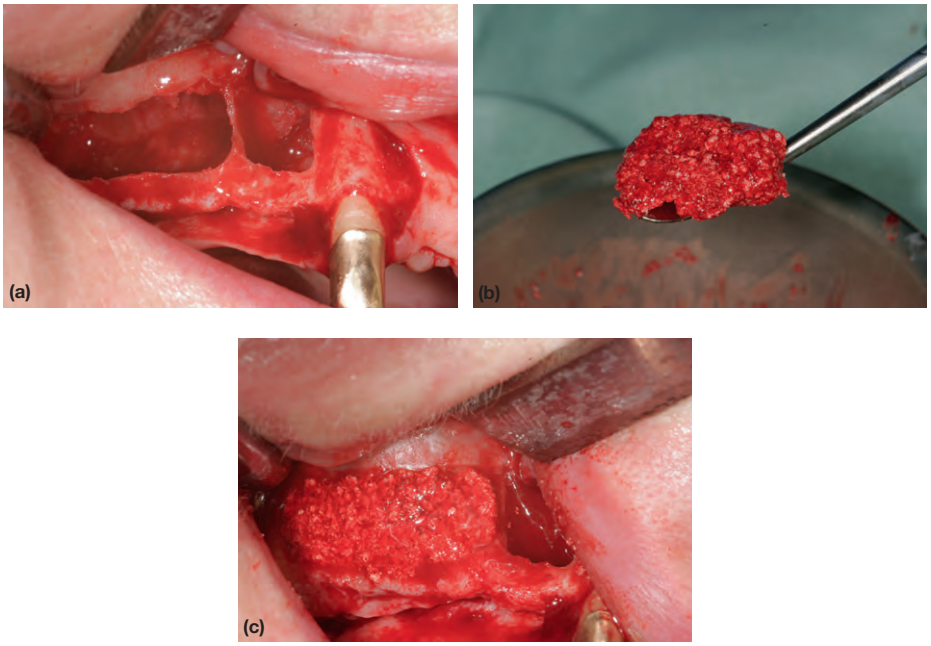

Figure 2 Clinical image of maxillary sinus floor augmentation using a tricalcium phosphate (TCP) putty material (a) sinus floor prior to augmentation, (b) TCP putty material which has been mixed with veinous blood, and (c) sinus floor after application of the TCP putty material.

6.620.2.7. Polymer-Based Scaffolds for Craniofacial Tissue Engineering

Over the last two decades, there have been increasing efforts to develop adequate scaffolds and concepts for bone-tissue engineering in the craniomaxillofacial domain.[232] However, only few of these concepts have reached the clinical arena so far.

In 2001, the 'bioseed oral bone' concept was introduced. Cell-fibrin constructs, that is, pellets made from polylactide, polyglycolide, and/or poly-*p*-dioxanon, which were coated with fibrin glue and cultured for 4–6 weeks with autologous periost-derived osteoblasts, were used for sinus augmentation of the severely resorbed posterior maxilla.[233–235] In clinical studies, this approach resulted in the formation of lamellar bone within 4 months after sinus floor augmentation, thereby providing a reliable basis for dental implant placement. The drawbacks of this approach were the high costs involved and the 4–6 week waiting period between the harvesting of the periosteum and the delivery of the cell-seeded pellets for sinus floor augmentation surgery. This concept, however, is one of the few tissue engineering approaches that has found somewhat wider clinical use in implant dentistry so far.

Hollister *et al.*[236–238] developed an image-based and integrated approach for engineering craniofacial scaffolds. This design/fabrication approach can create scaffolds with designed porous architecture to match craniofacial anatomy. These scaffolds were also designed to support bone regeneration for craniofacial reconstruction and, furthermore, to exhibit mechanical properties in the range of those of craniofacial tissue. Using image-based design (IBD) and computer software, precisely sized and shaped scaffolds created via selective laser sintering of polycaprolactone were developed for osseous tissue regeneration.[239] This way, polycaprolactone was used to create a condylar ramus unit (CRU) scaffold for application in temporomandibular joint (TMJ) reconstruction. These scaffolds were used successfully for the reconstruction of the mandibular ramus and TMJ in minipigs.[239] IBD and solid free-form (SFF) fabrication was also used to generate scaffolds that are load bearing and match patient and defect site geometry. Using this methodology, poly-L-lactic acid/HA composite scaffolds which were differentially seeded with fibroblasts transduced with an adenovirus expressing bone morphogenetic protein-7 (BMP-7) in the ceramic phase and fully differentiated chondrocytes in the polymeric phase were developed in order to regenerate osteochondral defects and, ultimately, the TMJ.[240]

3D polycaprolactone scaffolds with controlled microarchitecture were developed for fabricating customized cell-polymer constructs for the repair of calvarial defects using calvarial osteoblasts and mesenchymal progenitor cells in combination with these scaffolds and fibrin glue.[241,242] Furthermore, bone-marrow-coated polycaprolactone scaffolds were successfully used for the reconstruction of orbital and craniofacial defects in pigs.[243,244] More recently, polycaprolactone-20% TCP scaffolds were utilized in a pilot study in combination with platelet-rich plasma for the treatment of critical-sized defects of the mandible.[245] Also, a polycaprolactone-TCP/collagen scaffold loaded with recombinant BMP (rhBMP) was developed for the repair of calvarial bone defects, and the stimulation of healing within a rat calvarial defect was demonstrated.[246] Moreover, very recently, successful use of a customized polycaprolactone TCP scaffold fabricated by the rapid prototyping technology fused deposition modeling (CAD/CAM) for calvarial reconstruction in a human case was described.[247]

Hydrogels were proposed as scaffolds for craniofacial bone tissue engineering and delivery of stem cells and growth factors.[248–251] Very recently, calcium cement scaffolds with mesenchymal stem cells were developed for craniofacial tissue

engineering.[252,253] Furthermore, the use of rhBMP-2 loaded porous calcium phosphate cements was proposed for craniofacial tissue engineering.[254]

With most of these tissue engineering approaches, however, controlled clinical studies will have to follow for these concepts to proceed to the clinical arena.

Current research efforts in craniofacial tissue engineering also deal extensively with biomaterial matrices and scaffolds with controlled release of signaling cues for stem cells, and integrated tissue engineering approaches[255] as well as with 'guided interplay' between biomaterial scaffolds, growth factors, and local cell populations toward the restoration of the original architecture and function of complex tissues.[256,257] Furthermore, various approaches to pursue adequate vascularization of bioengineered constructs for repair of extensive discontinuity bone defects are being investigated.[258–263] This is in addition to optimizing pore-size distribution and pore-geometry of various scaffolds.

6.620.2.8. Bone Grafting Cements

To fill bone defects, currently available calcium phosphate bone grafting materials are mainly applied as granules. Bone substitutes with improved surgical handling properties include injectable and moldable calcium phosphate cements in paste or putty form that can be introduced into a bony defect with a spatula or injected with a syringe; they subsequently set *in situ*. These properties make this an intriguing group of materials for bone reconstruction, as by this way, these materials exhibit advantageous surgical handling properties for a number of surgical applications. Consequently, over the last two decades, the use of calcium phosphate-based cements and in a few cases, that of polymer-based cements, have been proposed for craniofacial bone grafting.[264–288] With most currently available cements, however, HA or calcium-deficient HA[289–292] is formed during setting, which limits their biodegradability.[289] This has initiated efforts to develop resorbable cements with improved biodegradability which form TCP or calcium alkali orthophosphates during setting.[261,293–298]

6.620.2.9. Combination of Bone Grafting Materials with Platelet-Rich Plasma

Numerous clinical and animal studies have explored the combined use of bone grafting materials and platelet-rich plasma [PRP] with the intent to enhance bone regeneration. The majority of the studies, however, failed to demonstrate an additional benefit when platelet-rich plasma [PRP] was used in addition to various bone grafting materials. As such, these studies did not show a significant improvement of clinical and histological outcomes.[279,280,299–302]

6.620.2.10. Combined Use of Grafting Materials and Growth Factors or Other Biologicals

6.620.2.10.1. Growth factors

Over the last two decades, numerous preclinical studies have explored the use of rhBMP-2 and -7 for bone regeneration in craniomaxillofacial applications.[254,303–321] Furthermore, absorbable collagen sponges and collagen sponges with incorporated HA and TCP particles were proposed as carriers for recombinant human BMP-2, -7, -10 as well as nerve growth factor β for use in craniofacial bone regeneration.[322–330] In addition, the use of recombinant human platelet-derived growth factor BB (rhPDGF-BB) and transforming growth factor β (TGF-β) have been investigated.[254,331]

Preclinical studies have shown that rhBMP-2 and -7 induces normal physiologic bone in clinically relevant defects in the craniofacial skeleton. The newly formed bone develops properties similar to those of the adjacent resident bone and allows placement, osseointegration/re-osseointegration, and functional loading of endosseous implants. Over the last 6 years also, some clinical reports and studies have been published.[263,303,304,332–337] A very visible report in this regard was the use of rhBMP-7 for preparing a customized vascularized tissue-engineered mandible, with the patient being used as a living bioreactor.[263,335] In this case, rhBMP-7 was combined with bovine-derived HA xenograft particles, bone morrow aspirate, and a titanium mesh shaped after the patient's mandible. However, further clinical studies optimizing dose and delivery technologies,[338,339] including the development of scaffolds with controlled release properties, as well as optimizing conditions for stimulation of bone growth, are needed. The use of rhBMP-2 and -7 for craniomaxillofacial application only received approval in Europe and by the US Food and Drug Administration (FDA) in 2005.[340] Furthermore, the aspect of the high costs involved in the use of these growth factors has had a somewhat limiting effect with respect to achieving wide clinical use in implant dentistry and other craniomaxillofacial applications.

In 2008, the FDA[341] published a safety review communication regarding the use of a PDGF-containing product 'Regranex' in cancer patients. An epidemiologic study that was performed to investigate the possibility of an increased risk of cancer in patients with diabetes who applied the product 'Regranex' (a topical medicine) directly to their foot and leg ulcers showed that the risk of death from cancer in patients who used three or more tubes of Regranex was 5 times higher than in those patients who did not use Regranex. However, the risk of getting new cancers among Regranex users was not increased compared to nonusers. As BMPs also enhance the vascularization of the regenerated tissue similar to PDGF, this FDA safety review communication raised major concerns with respect to the use of growth factors such as BMPs and PDGF for bone reconstruction and bone tissue engineering in tumor patients. It is useful to point out that tumor patients with major squamous cell carcinomas comprise a major patient population in maxillofacial surgery. This group of patients requires extensive surgery for bone reconstruction of the bone discontinuities arising from tumor resection in major portions of the mandible or maxilla. Thus, the question whether the use of growth factors for bone tissue regeneration in tumor patients increases the risk of relapse or metastases, warrants further investigation.

In 2008, the FDA[342] published a public health notification regarding life-threatening complications associated with recombinant human BMP application in cervical spine fusion, which involved airway obstruction and compression of major blood vessels and nervous structures in the head-neck region caused by extensive swelling, thereby resulting in patient

fatalities. Consequently, preclinical and clinical studies are needed to ensure that this type of complication can reliably be avoided when using BMPs for major mandibular or craniofacial bone reconstruction.

Recently, a β-TCP coated with recombinant human growth and differentiation factor 5 (rhGDF-5) was developed, and the results of a prospective, randomized multicenter clinical trial were recently reported. The authors investigated the potential benefit of rhGDF-5 coated onto β-TCP (rhGDF-5/β-TCP) to support bone formation after sinus floor augmentation.[343] rhGDF-5/β-TCP was found to be as effective for sinus floor augmentation as the control treatment with autologous bone, which was mixed with β-TCP. As very low amounts of anti-rhGDF-5 antibodies were transiently detected in some patients who received rhGDF-5, further investigations regarding efficacy and safety will be carried out in larger patient populations.[343]

6.620.2.10.2. Enamel matrix derivative

Some clinical and preclinical animal studies examined the combined use of various bone grafting materials and an enamel matrix derivative (EMD) for bone and periodontal regeneration.[221,331,344–346] In these studies, a trend was observed toward more bone formation and improvement in clinical outcomes, when EMD was combined with freeze-dried bone allograft, bovine-derived bone xenograft, and bioactive glass.[221,331,344–346] However, larger prospective controlled clinical trials are needed to confirm these findings.[221,345,346]

Evaluation of various dental grafting materials by comparing them with one another is fraught with uncertainty, as there are only few comparative animal and controlled clinical studies that compare several of these materials in the same study or in studies using identical study designs.[347] Furthermore, in order to ultimately prove the superiority of any of these materials or any of these tissue engineering approaches to any other materials/approaches or to autogenous bone graft as the gold standard, long-term, that is, 2-, 5-, and 10-year data from prospective controlled clinical studies would need to be provided, which is a gargantuan task. Such studies would need to show greater regenerated bone volume and higher survival rates for dental implants placed in areas augmented with these grafting materials or tissue engineering approaches, in comparison to areas in which autogenous bone, any other grafting material, or any other tissue engineering approach was used.

6.620.3. Requirements and Novel Developments for Dental Graft Materials

6.620.3.1. Requirements for Dental Graft Materials

As outlined earlier, over the last decade, the use of TCP and BG45S5 particles as alloplastic bone graft materials for alveolar ridge augmentation and sinus floor elevation procedures has received increasing attention in implant dentistry.[33,46,47,50,136,146,150,151,155] As also outlined earlier, the same is true for bovine deproteinized bone xenograft particles (product name: Bio-Oss®) that closely resemble the native HA of bone, have excellent osteoconductive properties, and exhibit a limited biodegradability.[18,30,70,71,97–110] Even with β-TCP, biodegradation has been reported to be incomplete 9.5 months after grafting in the human mandible.[47] Histologic examination of these biopsies revealed that 34% of the biopsy consisted of mineralized bone tissue and 29% of remaining β-TCP.[47] Biopsies sampled at 8 months after sinus floor augmentation consisted of 20% mineralized bone and 44% remaining β-TCP.[47] With respect to BG45S5 particles of a narrow size range, Tadjoedin *et al.*[50] reported that after grafting in the human sinus floor, BG particles appeared to resorb within 1–2 years. This was by dissolution rather than by osteoclastic activity.[50] It is useful to consider, though, that at those time points, these particles are no longer original glass, but calcium phosphate formed *in situ* out of the glass. When using mixtures of 80%, 90%, and 100% BG particles and 20%, 10%, and 0% autogenous bone, histomorphometric analysis of biopsies harvested at 4, 6, and 15 months showed that the grafts consisted of 27% mineralized bone tissue at 4 months, 36% bone at 6 months, and 42% bone at 15 months. The volume of the biologically transformed BG particles in the biopsies decreased from 29% at 4 months to 15% at 6 months and 8% at 15 months.[50] Thus, compared to the bone substitute materials which are currently clinically available,[47,50,85,97,100,136,146] there is a significant need for bone substitute materials that degrade more rapidly but still stimulate osteogenesis at the same time.[9,26–32] Particularly in non-load-bearing applications such as alveolar ridge augmentation, a biomaterial used as a bone substitute should be a temporary material serving as a scaffold for bone remodeling. The material must degrade in a controlled fashion into nontoxic products that the body can metabolize or excrete via normal physiological mechanisms.[37] Moreover, this substance should be resorbable and should undergo remodeling and substitution by newly formed functional bone tissue in view of placing dental implants in such augmented sites.[9,26–33] This has initiated an ever-increasing search for bioactive, rapidly resorbable bone grafting materials that exhibit good bone-bonding behavior by stimulating enhanced bone formation at the interface in combination with a high degradation rate. Another important consideration when using grafting materials for sinus floor and alveolar ridge augmentation is the stability of the height and volume of the regenerated bone over time. Consequently, with an ideal grafting material, reduction in height and volume should be minimal and should not exceed that in the presence of autogenous bone grafts. Furthermore, as outlined previously, dental graft materials have been most widely used as granules. However, because of the increasing number of surgical techniques and procedures used for bone regeneration in oral and craniomaxillofacial surgery, there has been a growing demand for resorbable bone grafting materials that can be either injected into defects in paste form or applied as putty that sets *in situ*. In addition, there is equal demand for biodegradable 3D blocks and scaffolds for bone tissue engineering purposes.

6.620.3.2. Novel Developments for Dental Graft Materials

6.620.3.2.1. Calcium alkali orthophosphate materials

Thus, considerable efforts have been undertaken to produce rapidly resorbable bone substitute materials that exhibit both excellent bone-bonding behavior by stimulating enhanced

bone formation and a high degradation rate. This has led to the development of a series of novel, bioactive, rapidly resorbable, glass ceramic calcium-alkali orthophosphate materials.[348–350] These are glassy/crystalline calcium alkali orthophosphates which exhibit stable crystalline $Ca_2KNa(PO_4)_2$ and $Ca_{10}[K/Na](PO_4)_7$ phases.[348–351] These materials were designed to exhibit a higher degree of biodegradability compared to TCP[348,349,352,353] and therefore could serve as excellent alloplastic materials. In fact, these materials have a higher solubility than TCP. Another approach to increase the solubility and biodegradability of calcium-orthophosphates is by adding diphosphates ($Ca_2P_2O_7$). Diphosphates have a higher solubility than orthophosphates and they are transiently formed *in vivo* during the mineralization process of the bone matrix. A number of *in vitro* and *in vivo* studies, which examined calcium phosphates to which diphosphates were added, yielded encouraging results.[354–357] This prompted Berger to synthesize a calcium alkali orthophosphate ceramic with a small portion of diphosphates.[358] He reported that there was an additional effect on the dissolution rate compared to that of the calcium-alkali-orthophosphate. At this time, 3D scaffolds have been fabricated from these calcium alkali orthophosphate ceramic materials, opening interesting perspectives for their use as tissue engineering scaffolds.

6.620.3.2.2. The effect of calcium-alkali-orthophosphate ceramics on the expression of the osteoblastic phenotype in vitro

In recent years, several studies examined the effect of rapidly resorbable calcium alkali orthophosphate bone substitute materials on the expression of osteogenic markers characteristic of the osteoblastic phenotype and compared this behavior to that of the currently clinically used materials β-TCP and BG45S5.

These studies showed that several calcium alkali orthophosphate materials supported osteoblast differentiation to a greater extent than did TCP.[128,290,291,359]

The composition of four of these calcium alkali orthophosphate grafting materials studied, GB14, GB9, GB9/25, and 352i, whose main crystalline phase is either the phase $Ca_2KNa(PO_4)_2$[348,349,351] or $Ca_{10}[K/Na](PO_4)_7$[358], is indicated in Tables 1 and 2. Glass ceramics GB14, GB9, and GB9/25 contain the crystalline phase $Ca_2KNa(PO_4)_2$.[348,349] They contain an amorphous phase, silica phosphate (GB9 and GB9/25), or magnesium potassium phosphate (GB14), respectively. Crystallization occurs spontaneously from the melt, and thus, these bioceramics can be fabricated easily. The dissolution rate of the calcium-alkali orthophosphates depends on the amount of added ions such as Na, K, or Mg. Importantly, GB 9/25[358] also contains a small portion of diphosphates ($Ca_2P_2O_7$), unlike GB9, which does not. This further increases the dissolution rate in comparison to this previously described GB9.[290,348,349,360]

More recently, it was demonstrated that the glass ceramic calcium alkali orthophosphate material GB9 had a significantly greater stimulatory effect on osteoblastic proliferation and differentiation when compared to β-TCP, preconditioned BG45S5, and other calcium-alkali-orthophosphate materials of varying composition, that is, GB14, GB9/25, and 352i (Table 1).[128,290,359] 45S5 discs were preconditioned by a two-step procedure, which resulted in the transformation of the BG surface into a crystalline, carbonated calcium phosphate apatite onto which serum proteins were adsorbed in a second step. Hence, the conditioning treatment of BG produced an *in situ*-formed calcium phosphate surface layer. Figure 3 shows that osteoblastic cells grown for 14 days on GB9 expressed significantly higher levels of the osteogenic markers type I collagen, alkaline phosphatase, osteopontin, osteonectin, and bone sialoprotein than when the same

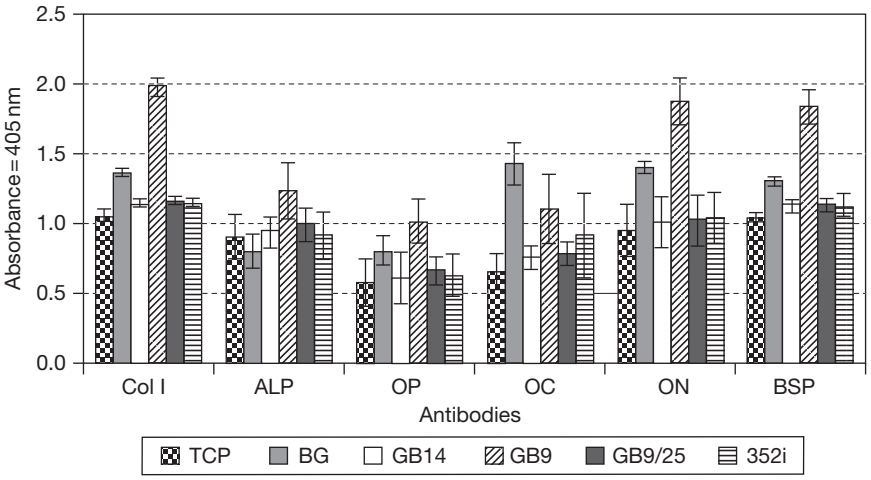

Figure 3 The temporal expression of osteogenic proteins by osteoblasts cultured on different calcium phosphate materials for 14 days. Intracellular protein expression by human osteoblasts is at 14 days of culture on tricalcium phosphate (TCP), bioactive glass 45S5 (BG) GB14, GB9, GB9/25, and 352i. Results are normalized to the internal control β-actin protein for each substratum. All values are mean±standard deviation of eight measurements. Col I, type I collagen; ALP, alkaline phosphatase; OP, osteopontin; OC, osteocalcin; ON, osteonectin; and BSP, bone sialoprotein.

cells were grown in parallel on β-TCP and BG 45S5. Furthermore, BG 45S5 and GB14 induced significantly greater expression of the majority of these osteogenic markers when compared to β-TCP.[128,163]

6.620.3.2.3. The effect of calcium alkali orthophosphates on bone formation and osteoblastic phenotype expression in vivo

Correlating *in vitro* data with *in vivo* phenomena is important in order to test the hypothesis that enhanced osteoblastic cell differentiation *in vitro* leads to more and more expeditious and more copious bone formation at the bone–biomaterial interface *in vivo*. This includes (1) correlating quantitative expression of the osteogenic markers *in vitro* with the amount of bone formed after bioceramics implantation and (2) quantifying the expression of these markers in histological sections obtained from *in vivo* experiments in comparison to the expression of the various markers *in vitro*. To this end, a study was performed in which the effect of the same selection of bioactive ceramics (Table 1) on the expression of osteogenic markers was studied *in vitro* as well as *in vivo*.[128–131,163,361] This required the development of an adequate hard tissue histology technique. Histological evaluation of the bone–biomaterial interface requires undecalcified poly(methylmethacrylate) (PMMA) sections. While various assays have been developed which permit studying the effect of calcium phosphate biomaterials on the expression of osteogenic markers *in vitro*,[290,291,359,362] there have been considerable difficulties to visualize the expression of these markers in undecalcified implant material containing sections of bone obtained from *in vivo* studies.[363] In recent years, a new technique has been developed that facilitates immunohistochemical analysis of osteogenic markers on undecalcified sawed sections of bone which contain ceramic implant materials.[129,364] This rendered it possible to study the effect of ceramic bone substitute materials on osteoblast differentiation and tissue maturation on *ex vivo* specimens by visualizing active osteoblasts in their different stages of differentiation at the bone–biomaterials interface. This experimental capability was in addition to visualizing the expression of various osteogenic markers in the mineralized and unmineralized extracellular matrix components.[129,130] Utilization of this hard tissue technology rendered it possible to study the effect of identical bioactive ceramics on the expression of osteogenic markers *in vitro* and *in vivo* and to test the aforementioned hypothesis.[130,163,298,361,365–367] In this study, calcium alkali orthophosphate ceramic bone substitute materials (Table 1) were implanted in the sheep mandible and sinus floor and compared to currently clinically used synthetic bone substitute materials (β-TCP, BG 45S5).[130,131,163] These materials were selected, because previous *in vitro* studies demonstrated that they stimulated greater differentiation of osteoblasts compared to cells grown on TCP ceramic.[128,290,359]

The various calcium phosphate materials with a particle size range of 300–355 μm were implanted in the sheep mandible for 1, 4, 12, and 24 weeks with the goal to regenerate critical size membrane-protected defects as described by von Arx *et al.*[9] Autogenous bone chips and empty defects, which were filled with collagen sponges, served as controls.[130,163,361] This study examined the aforementioned calcium alkali orthophosphate materials GB9 and GB14. As described previously, GB9, followed by GB14, displayed a significantly greater stimulatory effect on osteoblast proliferation and differentiation *in vitro* compared to TCP, BG 45S5, and other calcium alkali orthophosphates.[128,290,359] It was found that the *in vitro* findings correlated with enhanced bone formation and bone-particle-contact (i.e., bone-bonding behavior) *in vivo* (Figure 4(a) and 4(b)). This in its turn was associated with enhanced expression of type I collagen, osteopontin, osteocalcin, osteonectin, and bone sialoprotein *in vivo* (Figure 5(a) and 5(b)).[130,361] This was associated with a significantly greater decrease in particle area fraction over time, that is, a significantly greater biodegradation (Figure 4(c)).[130,361] Staining for tartrate-resistant

acid phosphatase showed that biodegradation of the various calcium alkali orthophosphates as well as TCP occurred by dissolution rather than by osteoclastic activity.[130,163,361] Furthermore, it is noteworthy that GB9 displayed a significantly greater bone-particle-contact than all other calcium phosphates after only 4 weeks (Figure 4(b)). By 12 weeks, the defects that were augmented using GB9 showed greater bone formation in comparison to those defects that were augmented with autogenous bone chips.[130,163] These findings are clinically very significant, by virtue of autogenous bone being the gold standard. BG 45S5 and TCP displayed good bone-regenerative capacities and bone-bonding behavior (Figures 4(a,b) and 6). However, the biodegradability was lower in comparison to GB9 (Figure 4(c)).[130,163]

With respect to augmentation of the ovine sinus floor, the materials GB9/25 and 352i were studied and compared to TCP. Among these materials, GB9/25 facilitated the greatest extent of bone formation (Figure 7(a)) in combination with the highest biodegradability (Figure 7(b)). This finding was in addition to a more enhanced effect on osteogenic marker expression (Figure 8).

The studies summarized here demonstrate that among the various bioceramic bone grafting materials studied, the calcium alkali orthophosphate material GB9 displayed the greatest stimulatory effect on osteogenesis *in vitro* and *in vivo*, in combination with a high biodegradability, and that in this it was followed by the materials GB14 (Figure 9) and GB9/25.

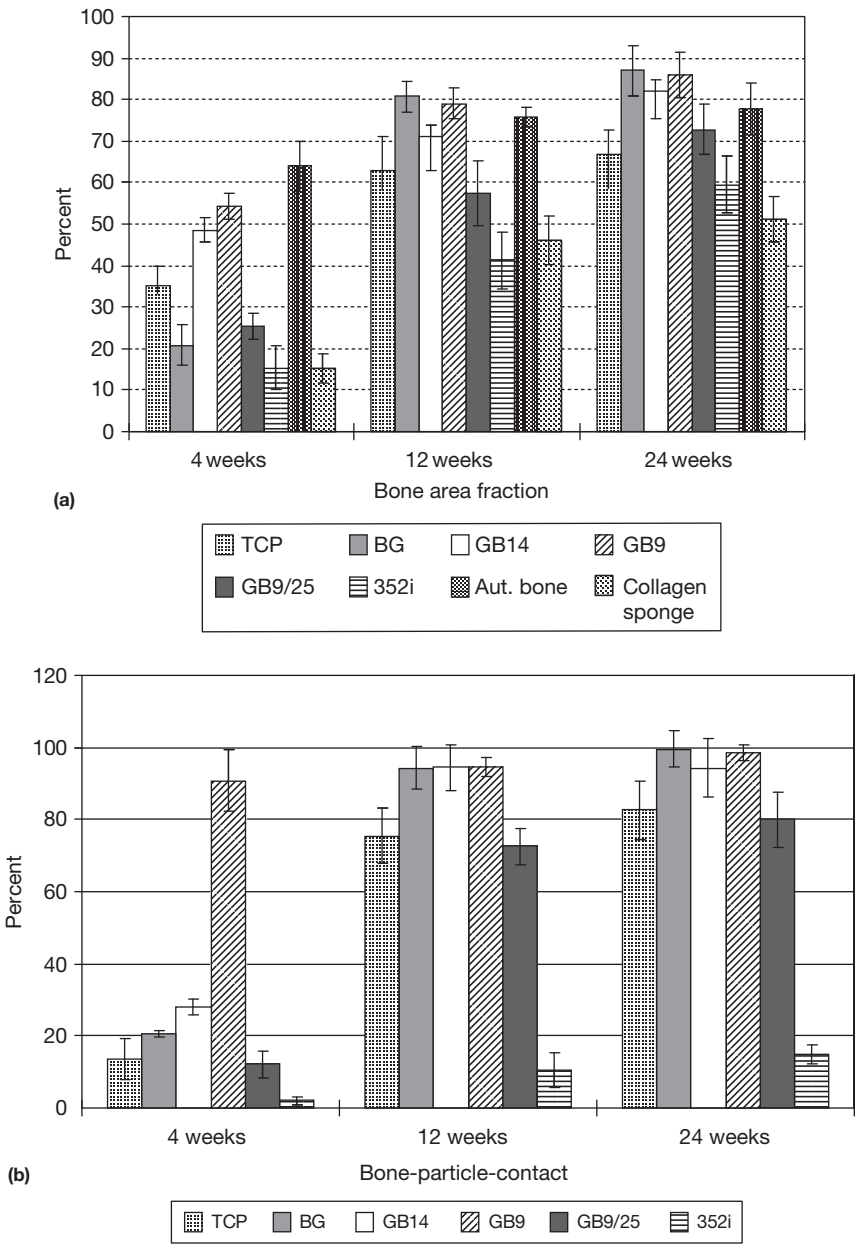

Figure 4 *(Continued)*

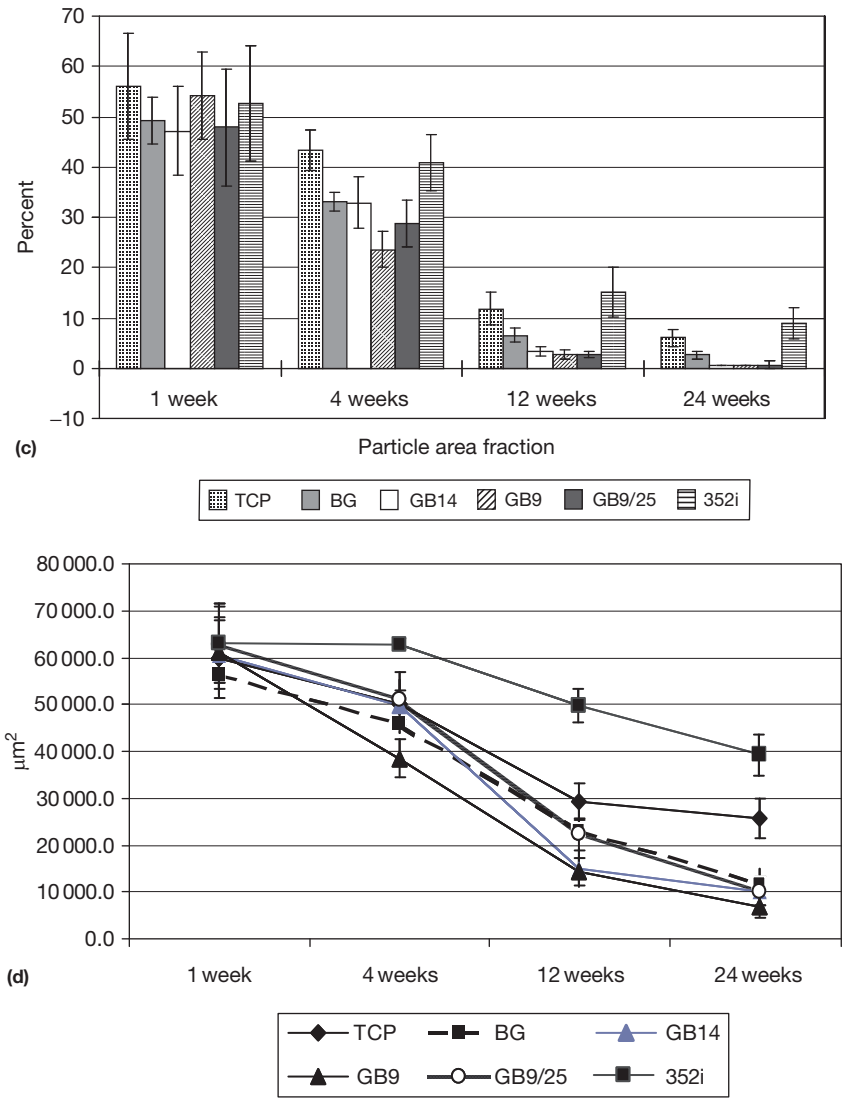

Figure 4 Histomorphometric results of mandibular defects augmented with various calcium phosphates after 1, 4, 12, and 24 weeks of implantation: (a) bone area fraction in the augmented defect area and (b) bone-particle-contact after 1, 4, 12, and 24 weeks of implantation. (c) Particle area fraction and (d) particle size. All values are mean±standard deviation of five measurements. TCP, tricalcium phosphate; BG, bioactive glass; aut. bone, autogenous bone chips; collagen, empty hole defects filled with a collagen sponge.

6.620.3.2.4. The effect of calcium alkali orthophosphate ceramics on cell adhesion and intracellular signaling mechanisms

Cell adhesion and intracellular signaling events which are associated with this stimulatory effect of some of the calcium alkali orthophosphate materials on osteogenesis *in vitro* and *in vivo* are not yet fully understood. Developing this understanding has been hampered by the inadequacy of the experimental techniques that could be used. Recently, however, new molecular biological methods have been brought to bear on similar problems of osteogenesis and they have been combined with insight generated using powerful surface analysis techniques. Consequently, we performed a series of experiments to study the mechanisms by which these novel bioactive bone substitutes stimulate the intracellular signaling pathways that regulate osteoblast differentiation and cell survival.[131,163,298,366,368] This included investigating (1) solution-mediated surface transformations, (2) serum protein adsorption events, (3) integrin-mediated cell adhesion mechanisms, and (4) intracellular signaling mechanisms. These studies are described in greater detail in **Chapter 1.114, Bioactivity: Mechanisms** to which the interested reader is referred here.

6.620.3.2.5. The effect of calcium alkali orthophosphate-based bone substitute cements on bone formation and osteogenic marker expression in vivo

Bone substitutes with improved surgical handling properties include moldable calcium phosphate cements in paste form that can be either introduced into a bony defect with a spatula or injected with a syringe; they subsequently set *in situ*, which makes them an attractive group of materials for bone reconstruction.[163,295] Over the past decade, various bioactive

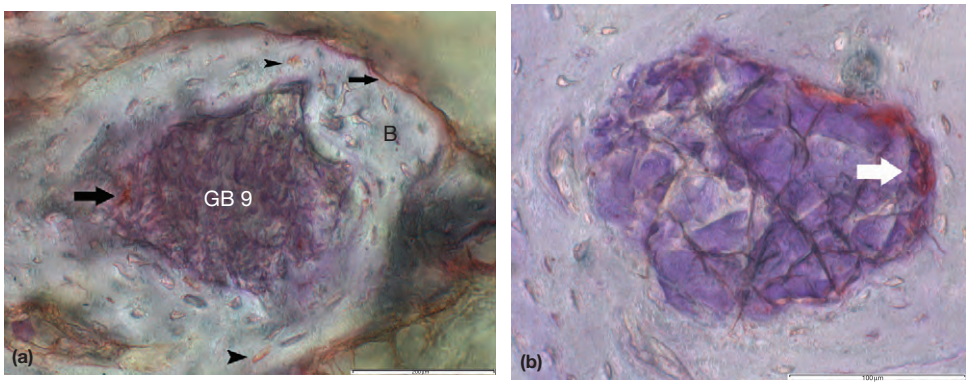

Figure 5 (a) Histomicrograph of GB9 particle 4 weeks after augmentation of a critical-size defect in the sheep mandible with GB9. Immunodetection of type I collagen in deacrylated sawed section of mandibular defect. Already after 4 weeks, the GB9 particle is almost fully covered by newly formed bone tissue. Strong staining of the newly formed bone matrix (B) in contact with the particle is present (block arrow). In addition, moderate cellular staining of osteocytes is visible (arrow heads). Moreover, strong staining of the osteoid and bone matrix lining the periphery of the newly formed bone is evident (small arrow). This is indicative that bone formation and matrix mineralization are actively progressing both at the surface of the degrading particle and on the periphery of the newly formed bone. These findings demonstrate the excellent bone-bonding and bone-regenerative capacities of the calcium alkali orthophosphate material GB9, which is capable of stimulating bone formation at its surface as early as 4 weeks after implantation. Undecalcified sawed section counterstained with hematoxylin. Bar = 200 μm. (b) Immunodetection of osteocalcin in deacrylated section of mandibular defect 12 weeks after implantation of GB9. Histomicrograph of residual GB9 particle fragment and surrounding bone tissue. In general, only very few particle fragments are present at 12 weeks. Areas with strong osteocalcin staining of cells and mineralized bone matrix (arrow) in contact with the degrading particle which displays new bone formation in its center are present. These findings show that after 12 weeks, bone formation, matrix mineralization, and particle degradation are still actively progressing at the surface of this degrading particle. Undecalcified sawed section counterstained with hematoxylin. Bar = 100 μm.

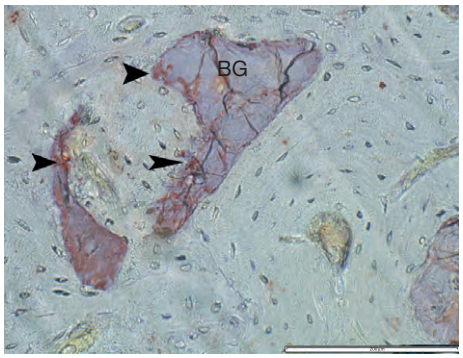

Figure 6 Immunodetection of bone sialoprotein in deacrylated section of mandibular defect 24 weeks after augmentation of a critical-size defect in the sheep mandible with BG45S5. Histomicrograph of residual excavated BG45S5 particle and surrounding bone tissue. Areas with strong osteocalcin staining of cells and mineralized bone matrix in contact with the particle are present (arrowheads). This shows that bone formation, matrix mineralization, and particle transformation are still actively progressing at the surface of the degrading particle 24 weeks after implantation. Undecalcified sawed section counterstained with hematoxylin. Bar = 200 μm.

calcium phosphate cements have been developed. In most cases, HA is formed during setting, which limits their biodegradability. More recent developments include cements which form calcium alkali phosphates during setting, which, as outlined previously, have been shown to have a stimulatory effect on osteogenesis *in vitro* and *in vivo*.[128,130,163,290] These cements are designed for higher biodegradability.[295] Thus, an animal study was performed to evaluate the effect of four calcium alkali orthophosphate cements as compared to TCP particles on osteogenesis *in vivo* after implantation in critical size effects in rabbit femora for 1, 3, 6, and 12 months.[261] Of the various bone substitute cements studied, the GB9 cement showed the best bone-bonding behavior and had the greatest stimulatory effect on bone formation and expression of osteogenic markers, while exhibiting the highest biodegradability.[261] After 12 months, the original trabecular structure of the rabbit femur was almost fully restored (Figure 10). The biodegradability of the GB9-cement, however, was lower than that of the TCP granules.[261] Hence, current efforts deal with increasing the porosity of the cement during setting in order to accelerate the biodegradation and studying moldable calcium-alkali-orthophosphate-based putty-like cements for restoring outer bony contours.[261,294]

6.620.3.2.6. The effect of β-TCP particles with varying porosity on osteogenesis after sinus floor augmentation in humans

By virtue of the importance to correlate findings from preclinical (animal) studies with data from clinical studies, a study was conducted in which the effect of various TCP particulate bone grafting materials with varying porosity on bone formation and osteogenic marker expression was examined in biopsies sampled 6 months after sinus floor augmentation in patients.[129,132,163] These studies demonstrated that greater porosity of the TCP particles (65% vs. 35% porosity) resulted in greater bone formation and particle degradation.[129,132,163] Moreover, 6 months after implantation of both types of β-TCP particles, bone formation and matrix mineralization was still actively progressing in the tissue surrounding the particles (Figure 1). Both TCP materials supported bone formation and exhibited excellent bone-bonding behavior (Figure 1).

Figure 7 *(Continued)*

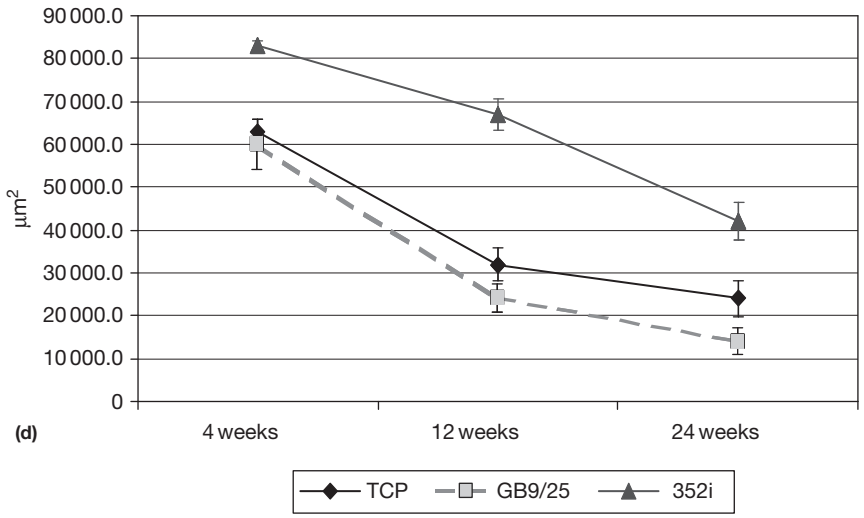

Figure 7 Histomorphometric results of the ovine sinus floor augmented with various calcium phosphates after 1, 4, 12, and 24 weeks of implantation: (a) bone area fraction in the augmented sinus; (b) bone-particle-contact after 4, 12, and 24 weeks of implantation; (c) particle area fraction; and (d) particle size. All values are mean±standard deviation of five measurements. TCP, tricalcium phosphate.

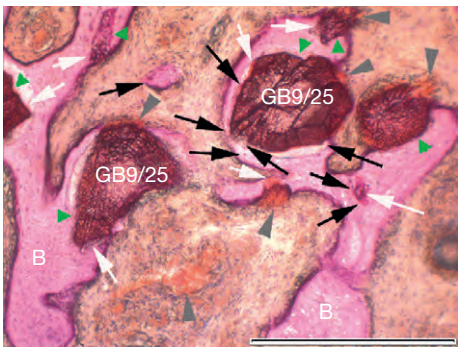

Figure 8 Histomicrograph of GB9/25 particles 3 months after implantation in the ovine sinus floor directly underneath the Schneiderian membrane. Immunodetection of osteopontin (OP) in deacrylated sawed section of the sinus floor. After 12 weeks, new bone formation (B) is visible at the surface of these particles (GB9/25) in combination with strong expression of OP in the mineralized bone matrix (white arrows) at the particle surface as well as in the not-yet mineralized fibrous matrix (gray arrowheads) in contact with the degrading particles and particle fragments. In addition, osteoblasts with strong OP expression (black arrows) are visible at the surface of these particle fragments which show excellent bone-bonding behavior (green arrowheads). These findings demonstrate the excellent bone-bonding and bone-regenerative capacities of the calcium alkali orthophosphate material GB9/25, which is capable of stimulating bone formation at its surface in this location underneath the Schneiderian membrane, that is, at a great distance from the original resident bone of the sinus floor. Undecalcified sawed section counterstained with hematoxylin. Bar = 320 µm.

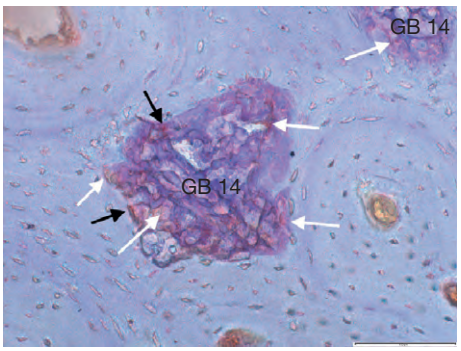

Figure 9 Immunodetection of bone sialoprotein in deacrylated section of mandibular critical-size defect 12 weeks after augmentation with GB14. Histomicrograph of residual GB14 particle fragments and surrounding bone tissue. Strong staining of osteoblasts (black arrows) is present at the particle surface in combination with moderate staining of the mineralized matrix (white arrows) in contact with these particles. This is indicative that after 12 weeks of implantation, bone formation, matrix mineralization, and particle degradation are still actively progressing at the surface of the degrading particles. Undecalcified sawed section counterstained with hematoxylin. Bar = 100 µm.

With the more porous particles, however, bone formation, osteogenic marker expression, and particle degradation had already reached a more advanced stage at 6 months. Consequently, a greater porosity appears to be advantageous for enhancing bone formation and particle degradation.[129,163] These studies provide a valuable insight into the performance of synthetic bone graft materials in the human case and can form the basis for designing controlled clinical studies and selecting appropriate model parameters. Such studies are needed to advancing new bone grafting materials to the clinic in an evidence-based fashion. This clinical study also confirms the validity of any animal model by correlating *in vivo* animal findings to those obtained from human biopsies. In fact, excellent correspondence between animal data and clinical findings suggests comparable *in vivo* response, a useful finding for any animal study.[129,130,163]

Current research efforts focus on dealing with efforts toward personalized medicine questions, in that the influence of age, gender, and hormone status-related parameters in 120 bone-regeneration patients (after sinus floor augmentation with TCP

bone grafting materials) are examined. Such studies have the potential to provide powerful predictive tools toward the therapeutic outcome in any future patient and thereby facilitate tailoring individual bone augmentation treatment regimens for individual patients. Additional research involves computed tomography (CT) and Synchroton-CT methodology for volumetric determination of the newly formed bone and the residual grafting material after sinus floor and alveolar ridge augmentation.[132] This is described in greater detail in **Chapter 3.304, Developments in High-Resolution CT: Studying Bioregeneration by Hard X-ray Synchrotron-Based Microtomography**.

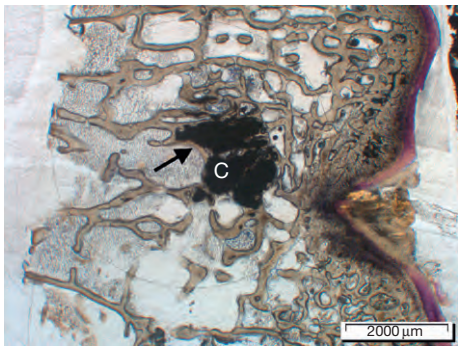

Figure 10 Histomicrograph of GB9 calcium alkali phosphate cement after 336 days after implantation in the rabbit femur. The defect area is circled. The highly cancellous original bone structure or the rabbit femur has been widely restored with only a very small amount of residual cement (C) being present which displays high bone-cement contact (arrow), that is, excellent bone-bonding behavior. Undecalcified sawed section stained with Giemsa surface staining. Bar = 2000 µm.

6.620.3.2.7. Three-dimensional calcium-alkali-phosphate-based scaffolds for bone tissue engineering

Current research also deals with optimizing 3D calcium-alkali-phosphate-based scaffolds[350] in which mesenchymal stem cells are cultured under perfusion bioreactor conditions for bone tissue engineering purposes, that is, repair of large segmental defects. This includes various approaches to achieve adequate angiogenesis. These scaffolds are fabricated from calcium alkali orthophosphates using a free form fabrication technique, that is, 3D printing as well as a method utilizing combustible polyurethane sponges as temporary templates (Schwartzwald–Somers-technique) (**Figure 11**).[350]

6.620.4. Summary

Insertion of dental implants has become a common treatment in modern dentistry. However, the resorptive processes following tooth extraction often mandate site development by alveolar ridge augmentation before implants can be placed. Although the current gold standard, namely autogenous bone grafts, serves this function, there has been an ever-increasing search for excellent synthetic bone grafting materials, in order to avoid second-site surgery for autograft harvesting.

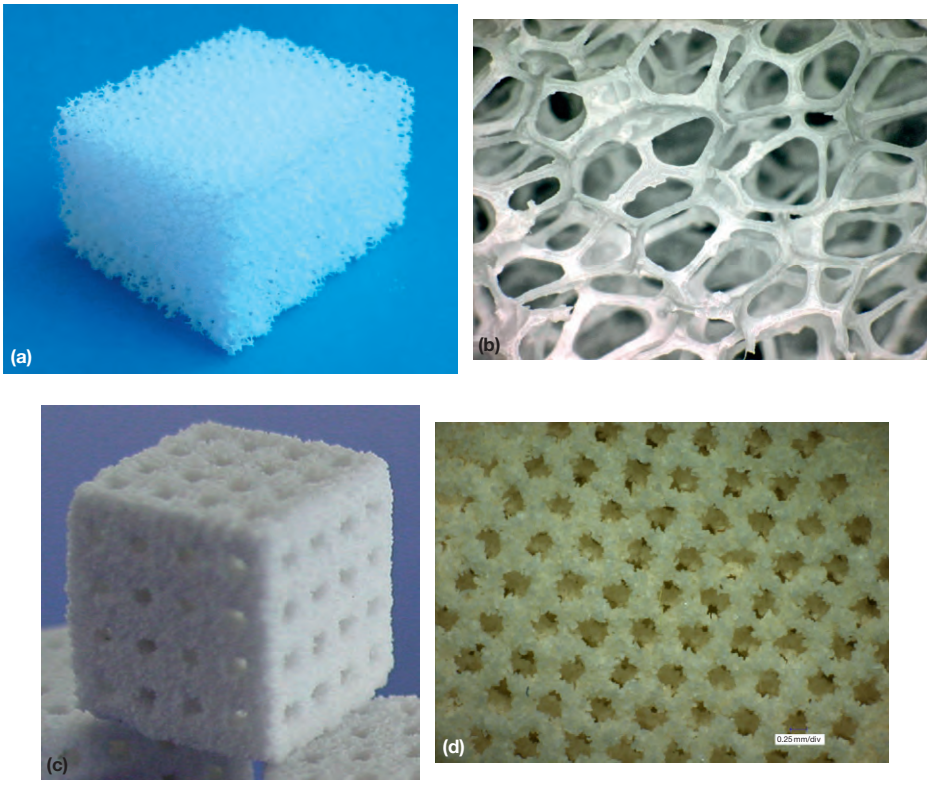

Figure 11 (a, b) Three-dimensional calcium-alkali-orthophosphate-based scaffold fabricated utilizing the Schwartzwald–Somers-technique, (magnification 50×), (c, d) 3D calcium-alkali-orthophosphate-based scaffold fabricated by 3D printing.

Furthermore, the significant increase in the number of dental implants placed and alveolar ridge augmentation procedures performed over the last two decades resulted in an ever-increasing demand for adequate bone grafting materials for implant dentistry.

Numerous bone grafting materials have been developed and studied since the late 1970s. The majority of these grafting materials are calcium phosphate-based materials. Various HA- and TCP-based dental grafting materials, as well as bioactive glasses and glass ceramics have been proposed for use in therapies to augment alveolar bone and to promote periodontal regeneration. These materials include synthetic as well as coralline and bovine-derived HAs, nanocrystalline or peptide-modified HAs, TCP ceramics, biphasic HA-TCPs, calcium carbonates, BG45S5, glass ceramics, and DFDBAs. Most of these materials have been shown to be osteoconductive but exhibit limited biodegradability. DFDBAs are inferior to synthetic materials in terms of the risk of disease transmission and immunological challenges. While for these DFDBAs a wide variation in commercial bone bank preparations of DFDBA and conflicting results regarding their osteoconductivity and potential to support new bone formation have been reported in combination with a low biodegradability, excellent osteoconductive properties have been demonstrated by numerous *in vivo* and clinical studies for one of the porous bovine-derived HAs that closely resembles the native HA of bone and whose morphology, in addition, resembles that of cancellous bone. This material, however, also exhibits only limited biodegradability. For other HAs, varying degrees of osteoconductivity and bone-bonding behavior have been reported. Both TCP ceramics and BG45S5 have been shown to possess excellent osteoconductivity, bone-regenerative capacity, and bone-bonding behavior in combination with a higher biodegradability than various HAs. More recently, injectable and moldable resorbable bone substitute cements as well as scaffolds for craniofacial bone tissue engineering have been developed. Furthermore, the combination of grafting materials with growth factors and other biologicals has been explored.

Compared to the bone substitute materials which are currently clinically available, there is a significant need for bone grafting materials that degrade more rapidly but at the same time stimulate osteogenesis. This prompted a search for bioactive, rapidly resorbable bone grafting materials that exhibit good bone-bonding behavior by stimulating enhanced bone formation at the interface. They also exhibit a high degradation rate. This led to the development of calcium alkali orthophosphate materials. Current research efforts include the optimization of resorbable bone grafting cements and of scaffolds for various tissue engineering approaches that integrate concepts to achieve adequate vascularization when restoring large segmental defects.

Abbreviations

AATB	American Associate of Tissue Banks
ADRC	Adipose-derived regenerative cells
ASTM	A consensus standards organization, formally known as the American Society for Testing and Materials, but now referred to as ASTM International
BMPs	Bone morphogenetic proteins
CaHa	Calcium hydroxyapatite
CP	Commercially pure, used to designate a type of titanium
CT	X-ray computed tomography
DBM	Demineralized bone matrix
ECM	Extracellular matrix
ePTFE	Expanded polytetrafluoroethylene polymer
Et2Zn	Zinc(II) diethyldithiocarbamate, a catalyst used in polymerization of *p*-dioxanone
FDA	Food and Drug Administration
HA	Hyaluronic acid
HDPE	High-density polyethylene polymer
HTR	Hard tissue replacement, a copolymer of polymethylmethacrylate and polyhydroxymethylmethacrylate with a calcium phosphate coating
IGF-1	Insulin-like growth factor 1
IMF	Intermaxillary fixation
ISO	The International Standards Organization
MM	Methyl methacrylate
MMF	Mandibular-maxillary fixation
MRI	Magnetic resonance imaging
ORIF	Open reduction internal fixation
PDS	Polydioxanone polymer
PGA	Polyglycolic acid
PLA	Polylactic acid; can exist in dextrorotary (D) or levorotary (L) or racemic (equal parts D and L forms) stereoisomer forms; designated as poly-D-lactide, poly-L-lactide, and poly-DL-lactide, respectively
PLDA	Copolymer of poly-L-lactide and poly-D-lactide isomers

PLDLA	Copolymer of poly-L-lactide isomer and poly-D,L-lactide racemic forms
PLLA	Polymer or all poly-L-lactide isomers
PMMA	Polymethylmethacrylate
PRP	Platelet-rich plasma
SR	Self-reinforced polymer; special designation that refers to 70:30 PLDL copolymer that is specially processed to have highly oriented crystalline fibers in a polymer matrix
TGF	Transforming growth factor
VEGF	Vascular endothelial growth factor

6.621.1. Introduction

Since the origins of the specialty, craniomaxillofacial surgeons have relied on various biomaterials to stabilize, augment, repair, and replace biological tissues of the head and face. Materials currently used range from simple stainless steel wire to complex biological compounds that are designed to modulate cellular biology. While the application of various materials depends on the particular need and use, all of them share two general requirements. First, they must be biocompatible. Second, inorganic or alloplastic products must be prepared in a sterile environment or have the capacity to retain their physical properties when subjected to current sterilization procedures. These two basic requirements limit the number of materials that can be considered for use in craniomaxillofacial reconstruction.

Materials can generally be categorized into organic, that is, those deriving from a living organism, and inorganic. This clarity in material categorization has been blurred by the manufacture of synthetic 'organic-like' compounds that seek to replicate or stimulate living tissues. Organic material can be subclassified into autografts, allografts, and xenografts. An autograft is autologous tissue (i.e., self-derived) harvested and grafted on the same patient. In terms of reconstructive purposes, autogenous tissue is ideal for craniomaxillofacial surgery as it is biocompatible and inexpensive, and often possesses properties nearly identical to those of the deficient tissues. Autogenous material can be transferred without a vascular supply (graft), attached to a vascular pedicle (e.g., rotational flap), or be attached to a new blood supply (free tissue transfer). One of the advantages of autogenous grafts and flaps is that they become vascularized and fully incorporated into the recipient. This makes autogenous tissues durable and resistant to infection. Unfortunately, there is a limit to the quantity of autogenous tissue available. Furthermore, there is limited functional redundancy, and borrowing tissue from another area can have deleterious aesthetic and functional implications.

Allograft, or biological material from the same species, is an alternative to autogenous tissue. Allograft retailers capitalize on an economy of scale, enabling them to provide an almost unlimited supply of material. An allograft can become vascularized, although it tends to be less well vascularized and to incorporate to a lesser degree into recipient tissues than autografts. Thus, allografts serve as an option only when autograft is not available. Also, allografts have biocompatibility issues and will be rejected by the recipient's immune system unless they are decellularized. In addition, disease transmission (i.e., virus, prions, etc.) remains a concern. These significant issues have been addressed by altering or negating allograft tissue immunogenicity, or by modulating the host's immune response. Processed allograft materials are widely used in craniofacial reconstruction and will be reviewed later. Host immune modulation forms the basis for modern transplant surgery, the most recent application of which is facial transplantation; facial transplantation is beyond the scope of this text and will not be discussed. Recombinant technology allows the production of purified human proteins that have little immunologic reactivity and no risk of disease transmission.

Xenografts are biological materials derived from other species. Because sources of xenograft products are plentiful, they are an attractive option for reconstruction. However, the immune response to xenografts can be pronounced, and these tissues require processing to eliminate antigenic epitopes. In spite of xenogenic tissue processing, some patients experience a significant immune response to these materials. Moreover, xenogenic tissue processing can, unfortunately, alter the properties of the tissue and lessen its usefulness.

Nonorganic biomaterials also play an important role in craniomaxillofacial surgery. Some clinical needs, such as mandibular osteosynthesis, require material properties not found in biological tissues. In addition, there are many clinical applications where nonorganic products can effectively substitute for organic tissues. Biocompatible, nonorganic products must be nontoxic, nonimmunogenic, noninflammatory, and sterilizable. Additional specific considerations for nonorganic biomaterials to be used in craniomaxillofacial applications include modulability/flexibility to be shaped to meet the necessary geometry, potential to be stabilized/fixed in position, ability to restore proper tissue volumes for function and aesthetics, and capacity to resist infection. These materials include metals and alloys, plastics, and various synthetic polymers, and they have some distinct advantages over organic substrates. First, there is no concern regarding disease transmission. Second, the materials are plentiful. Third, the strength, contourability, and material properties can be engineered to fit the reconstructive needs. However, one major disadvantage of these materials is their inability to revascularize or fully incorporate into the host tissues; this results in an increased risk of infection and stress fracture. The choice of material depends on the application for which it is to be used.

6.621.2. Biomaterials and Implants in Craniomaxillofacial Surgery

6.621.2.1. Skeletal Fixation/Stabilization

Bone stabilization and osteosynthesis are fundamental to craniomaxillofacial reconstruction. Over the last three decades,

techniques have shifted from semirigid fixation using wires and suture, to rigid fixation using various plating systems. This transition has been propelled by the speed and ease of plate application as well as reduction in the incidence of nonunion and infection. Both metal and resorbable materials are now used for osteosynthesis.

Reported outcomes and rates of complications for metal and resorbable systems are similar. Nevertheless, resorbable plates are often used in pediatric patients to avoid plate migration as the craniofacial skeleton grows. For example, resorbable plates have largely replaced metal ones for craniosynostosis procedures for infants after several reports of intracranial migration after growth. However, the strength of metal systems may still be required for adult mandibular repair. Dorri *et al.* recently reviewed multiple clinical studies to compare resorbable and metal craniomaxillofacial implant systems for fracture management. The authors noted that there were no published randomized controlled clinical studies, that there was insufficient evidence for the effectiveness of resorbable systems over conventional titanium systems, and that trials needed to be undertaken.[1]

Implant materials must conform to certain basic requirements (e.g., adequate function, minimal side effects, and biocompatibility). Less obvious is the need for appropriate handling qualities, and the selection of the material and implant design depend on it. The plating system has five different functions: (1) protection, (2) compression, (3) tension band, (4) bridging, and (5) buttressing. Many different materials have been proposed to provide these functions and avoid implant failure under high mechanical load. Surgeons generally select the smallest plating system that will provide stable fixation under functional loads during the healing period. Larger plates are used when the fracture occurs across a longer osseous lever arm (e.g., the mandibular angle compared to the mandibular body), or in areas of comminution where bone contact or compression cannot be applied.

Miniplate osteosynthesis emerged in the late 1960s and capitalized on dynamic compression.[2] Analysis of the biomechanics and principles of tension banding in extremity fractures demonstrated that elevated tensile stress along the mandibular alveolar ridge could be neutralized by miniplates.[2] Champy described his method of mandibular fixation, which involved applying small plates to the superior border of mandibular angle fractures to offset tension stress, and in the neutral zone and body.[3] Stainless steel plates were later changed to titanium to improve strength.

With regard to the midface, small metallic plates have proved to have better potential to reestablish bony contours compared with direct wiring or suspension wiring techniques. Miniature and microplate systems have been developed with biocompatible metals such as titanium alloys. These plates have greatly facilitated reconstruction of comminuted, unstable fractures and reestablished normal facial projection and contour.[4] These plating systems have specialized instruments to assist in bending the plates; an improperly bent plate can exert undesirable forces on the bone and lead to loosening or malunion.

Oblique fractures can be stabilized without plates by placement of screws using a lag technique. Ideal situations include mandibular symphysal or oblique fractures of the zygoma.[5,6] This technique uses differential hole size – the hole in the near fragment is as wide as the outer thread diameter, while the hole in the distal fragment is the diameter of the screw body. Thus, the screw glides easily through the near fragment hole and begins to engage as it passes into the distal fragment. This creates progressive compression across the fracture as the screw is tightened.

6.621.2.1.1. Metals and alloys

The most common implant metals used for craniomaxillofacial fracture fixation are the alloys, 316L stainless steel, Co–Cr–Mo (Vitallium), and titanium.[7] They are biocompatible and strong, and can be contoured and shaped. Consequently, they have been used extensively for many applications in the head and neck. The composition, physical, mechanical, and corrosion properties are covered in detail in other chapters. A brief summary is provided here.

316L stainless steel is an iron-based alloy consisting of the following major elements: 17–19% Cr, 13–15 wt% Ni, 2.25–3.0 wt% Mo, 2.0 wt% (max) Mn, and 0.03 wt% (max) C. The 'L' designation refers to the low (< 0.03 wt%) carbon content of the alloy in comparison with the conventional 316 grade (0.08% C). The alloy is also referred to as ASTM F138 by ASTM International Standards Organization or as ISO 5832-1 [ASTM, ISO] by the International Standards Organization, ISO.. Chromium provides a corrosion-resistant chromium-oxide surface layer, and the addition of molybdenum enhances the oxide's resistance to chloride attack. While stainless steel, applied as plates and screws, was used in early craniomaxillofacial fracture fixation, it is not widely used currently for the same application. This is primarily because its high modulus ($E = 190$ GPa) makes it difficult to bend and contour it to fit complex craniofacial geometries.[7,8] Poor adaptation of the plates to the underlying bone makes them easily visible and palpable beneath facial soft tissues. Additionally, while stainless steel is highly corrosion-resistant, it shows some susceptibility to pitting corrosion *in vivo* as compared to either the Co–Cr–Mo or titanium alloys, despite the fact that the addition of Mo to the alloy composition is specifically intended to alleviate this issue. Stainless steel wires are still used though for temporary external fixation.[9] One early and still used method of bone stabilization after open reduction has been the placement of direct interosseous wiring (**Figure 1**). Wire osteosynthesis provides only semirigid fixation but has found use nearly everywhere in the craniofacial skeleton.

Co–Cr–Mo alloy (Vitallium® or ASTM F1537 or ISO 5832-12) is a high modulus alloy ($E \sim 230$ GPa) with a nominal composition of 26–30 wt% Cr, 5–7 wt% Mo, and the balance Co. Chromium alloy provides a highly corrosion-resistant chromium-oxide surface layer and exhibits higher corrosion-resistant properties than 316L stainless steel. This combination of high mechanical strength and excellent corrosion resistance make it useful in mandibular fixation where high fracture loading is typical. The high modulus of elasticity and strength of Co–Cr–Mo has also led to the development of micromesh sheets, which allow for versatility of design and coverage for large cranial defects.[10] However, the stiffness of the alloy also makes it difficult to shape and contour. Thus, special tools are required to fit plates and meshes to complex mandibular and cranial sites.[10] Potential for metal

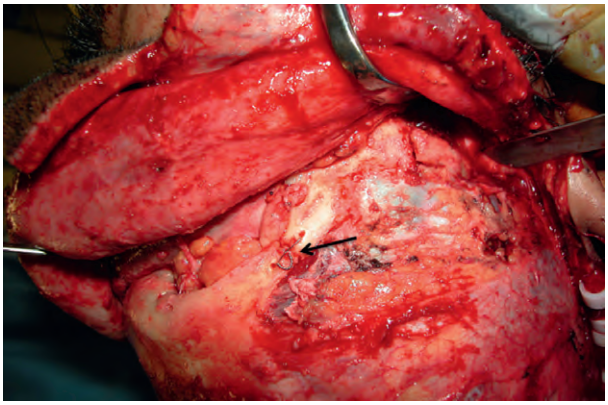

Figure 1 A 54-year-old man with orbitozygomaticomaxillary fracture. Intraoperative superior view of an interosseous wire placed across the frontozygomatic fracture (arrow). The placement of direct interosseous wires for bone stabilization provides only semirigid fixation. Note: A fracture of the zygomatic arch can also be seen.

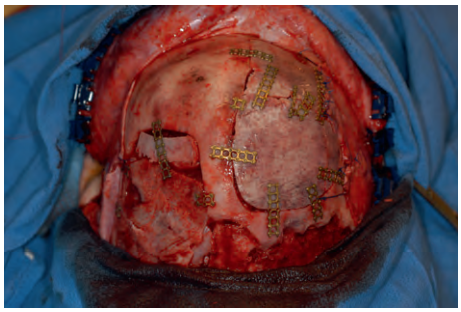

Figure 2 A 24-year-old man with titanium plates stabilizing a cranioplasty. Intraoperative view of various titanium plates holding multiple cranioplasty bone segments to the patient's skull.

hypersensitivity reactions to Co and Cr degradation/corrosion products has been a concern.[11]

Commercially pure (cp) titanium and titanium alloy (Ti–6Al–4V) are the predominant alloys used today in craniomaxillofacial bone fixation (Figure 2). These metals have a significantly lower modulus (E = 100–120 GPa] than stainless steel or Co–Cr–Mo alloys, making them much easier to shape and contour. CP Ti (also known as ASTM F67 or ISO 5832-2) is subcategorized into 4 grades depending on the content of oxygen, iron, and other trace elements. Higher grades depict increasing levels of oxygen (0.18–0.4 wt%), iron (0.2–0.5 wt%), and other trace elements, and are correlated with increasing mechanical strength (e.g., Grade 1 tensile strength = 240 MPa; Grade 4 tensile strength = 550 MPa). The Ti–6Al–4V alloy (ASTM F136 or ISO 5832-3) has a composition of 5.5–6.5 wt % Al and 3.5–4.5 wt% V. The addition of the Al and V alloying elements increases the modulus and high-cycle fatigue properties as compared to cp Ti. Titanium has a high affinity for oxygen, which results in the formation of a titanium oxide surface layer that has exceptional corrosion resistance and ability to osseointegrate.

Current craniomaxillofacial bone fixation systems come in a range of sizes that are generally referenced to diameter of screw (Figure 3). For example, a 2 mm plate is a plate that is

Figure 3 A 32-year-old man with midfacial fractures. Intraoperative view of a bioresorbable polymer plate across a midfacial fracture. The high-molecular-weight poly-a-hydroxy ester plates have been successfully used throughout the craniomaxillofacial skeleton. Note: metal arch bars have been temporarily placed on the teeth to restore normal occlusion.

used with 2-mm diameter screws. The thickness of the plates can range from <1.0 mm to >2.5 mm. Generally, larger diameter screws and thicker plates (e.g., >2 mm) are used for the highly loaded applications such as fractures of the mandible. These are still referred to sometimes in the literature as 'miniplate and screw' systems. The smaller diameter screws and thinner plates (e.g., <2.0 mm) are typically used in low load regions, such as the midface, orbit, and cranium, to limit palpability. Such thin plates and small diameter screws are still referred to sometimes as 'microplate and screw' systems in the literature. However, it is important to note that these designations are not standardized and there is significant variability among manufacturers.

Metal-based plate and screw systems are sometimes contoured to match craniomaxillofacial bone geometries with the aid of Al templates. The templates are pressed against the bone at the fixation site, and then using the molded template as a guide, the final fixation plate can be bent to the appropriate geometry.[10] Fixation systems for larger bones or bones that endure significant load, such as the mandible, often have screws that require tapping prior to insertion.[12] These tapped screws are typically used when bone thickness is >3 mm and biocortical fixation is required. In such applications, the excessive force and frictional heating that would occur without tapping the hole could lead to bone necrosis. Self-tapping screws are more applicable to bone <3 mm thick such as in the orbital rims, midface, and craniofacial skeleton. The thin bone in these regions coupled with the sharper threads on the self-tapping screws reduces the concern regarding frictional heating with insertion. It has been reported that non-self-tapping screws may be reinserted into their tapped holes without compromising stability, while self-tapping screws should not be reinserted if plate position requires adjustment.[12,13]

6.621.2.1.2. Resorbable polymers

Bioresorbable polymers are commonly used in the craniomaxillofacial region to effect bone stabilization or fracture fixation (Figure 4). These high-molecular-weight poly-alpha hydroxy esters include polylactic acid (PLA), polyglycolic acids (PGAs) and their copolymers, and polydioxanone. These materials have been successfully used as bioresorbable sutures or staples for upward of three decades.[14,15] The polymers degrade first

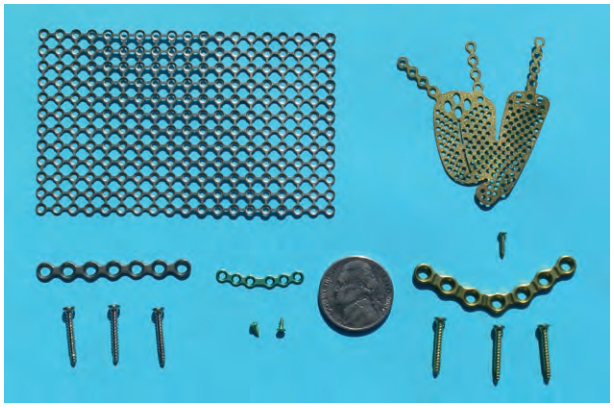

Figure 4 Plate and screw fixation system. Current titanium plate and screw systems for craniomaxillofacial bone fixation come in a range of sizes that are generally referenced to the screw diameter. (Plate and screws were kindly provided by BIOMET Microfixation, Jacksonville, FL, USA.)

by hydrolysis and then through metabolic processes. Once implanted, water and body fluids penetrate the implant and cause bulk hydrolysis of ester bonds in polymer chains, resulting in a decrease in polymer molecular weight, followed by a loss in mass and in mechanical properties. As hydrolysis continues, the material disintegrates/fragments and is ultimately metabolized into carbon dioxide and water or excreted in urine.[14–16]

Lactic acid is chiral and it exists in sterioisomeric forms that give rise to distinct polymers: poly-D-lactide, poly-L-lactide, and poly-D, L-lactide (racemic form from a mixture of D and L lactic acid). The D or L polylactides are optically active semicrystalline polymers, while the poly-D,L-lactide is optically inactive and amorphous. These sterioisomers may also be combined to form various copolymers such as poly-L-lactide–poly-D-lactide (poly (L/D) lactide or PLDA) or poly-L-lactide–poly-D,L-lactide (poly(L/DL) lactide or PLDLA). The pure poly-L-lactide (PLLA) can have high crystallinity, characterized by high strength (bending strengths of 240 MPa) and degradation times of three or more years.[14–16] When implanted as plates or screws, swelling and discharge from under thin subcutaneous tissues can occur.[17] The D,L-lactide polymer has low strength and degrades rapidly within a few months.[14,15] The combination of L-lactide and D,L- lactide make a copolymer with good strength with an intermittent degradation rate. For example, the 70:30 PLDLA polymer is 100% amorphous, and retains approximately 70% of its strength after 9 months, approximately 50% after 12 months, and undergoes complete degradation within 1.5–3 years.[15] Subjected to a solid-state extrusion process at 150 °C, the 70:30 PLDL material develops highly oriented crystal fibers within the polymer matrix, which increase its initial mechanical properties. This 'self-reinforced' (SR) polymer is reported to maintain its strength for 12–18 weeks, and be totally resorbed within 3 years.[18] Several commercial bioresorbable plates, screws, and mesh products are marketed based on the 70:30 PLDLA copolymer: MacroPore, Medtronic, MN; LactoSorb, Biomet Inc., IN; Fixsorb, BioPlate Inc., CA; Bionix, Bionix Development Corp, OH; Isosorb, Aesculap Implant Systems Inc. PA; Synthes Resorbable Fixation Systems, Synthes GmbH, Switzerland.

The PGA polymer is characterized as being highly crystalline, with a high melting temperature (~230 °C), good mechanical strength (~330 MPa), and low solubility in organic solvents. PGA suture, commercially available under the trade name Dexon™ S (Covidien, MSA), has been used since the 1970s. These sutures degrade rapidly and lose their mechanical strengths within 2–4 weeks after implantation.[14] Screws made of PGA were reported to lose their mechanical strengths within 6 weeks and to be completely resorbed within 1 year.[17,19] However, high rates of adverse tissue reactions to pure PGA materials, such as swelling, tissue drainage, and osteolysis have been reported as resulting from rapid degradation and buildup of acidic by-products.[17,19] PGA can be copolymerized with PLA to slow down the degradation rate compared to pure PGA; doping PLA into PGA, however, reduces the crystallinity and mechanical strength. The 82:18 PLLA/PGA copolymer (LactoSorb, Biomet) is reported to retain 70% of its strength for approximately 8 weeks and to be completely resorbed within 1 year.[19] An 85:15 PLLA/PGA copolymer has also been reported to have controlled rapid degradation properties with sufficient strength for pediatric craniofacial applications.[15] It is important to note that physicomechanical properties of PLA–PGA copolymers do not follow a linear relationship.

Polydioxanone, PDS, is a homopolymer of *p*-dioxanone prepared by polymerization in the presence of a Zinc(II) diethyldithiocarbamate, Et2Zn, catalyst.[14] It is considered a modification of PGA created by replacing one ester linkage for an ether linkage. This molecular alteration provides increased material flexibility while retaining good degradability. As a monofilament suture, it exhibits minimal to no tissue reaction. It loses 40% of its strength after 4 weeks, exhibits complete loss of mechanical properties after 8 weeks, and is totally resorbed by 4–6 months.[14,16] It has been used as fixation pins for unloaded fractures.

Resorbable plate and screw systems have screws that require tapping since the polymers are not as hard as bone. This can add time to surgery, and because pretapping does not always engage bone as well as self-tapping screws, fixation may not be as good in small mobile bone segments.[20,21] To overcome this issue, bioresorbable tacks have been developed.[22–24] The tacks may be placed by hand, or with a mallet or an automatic driver. However, if repositioning of plate and screws is needed, new drill holes may be made in the plates to allow screws to be optimally placed in bone. Also, if screws are damaged or broken during placement, they can be removed by burring through remnants and replaced with a new screw.[16] To adapt plates to bone geometries, they are heated above their glass transition temperatures (~55–70 °C) in water baths, with heat packs or other heating devices. *In situ* contouring may be achieved using electrocautery or thermal scalpels.[13]

6.621.2.1.3. Clinical application

6.621.2.1.3.1. External fixation

Initially, craniofacial surgeons used sutures, wires, occlusal splints, external fixators, and creative bone cuts to provide rigid fixation. For example, Gilmer first introduced his technique of mandibulomaxillary fixation in 1887 and the materials used were basic.[25] Wire ligatures were passed around the neck of available teeth and twisted clockwise until tight. By

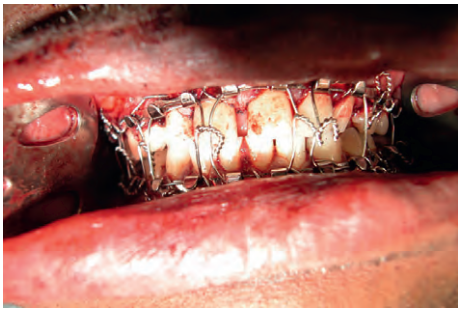

Figure 5 A 28-year-old man with maxillary and mandibular fractures. Erich arch bars can be secured to the upper and lower dental arches by passing wires around the neck of the available teeth and twisting clockwise until tight. Then, wires can be passed from the upper arch bar to the lower arch bar to establish centric occlusion.

attaching the upper wire to the lower wire, centric occlusion could be established (**Figure 5**).[25] The eyelet technique emerged as another technique of IMF. This method used a 24- or 26-gauge wire twisted around an instrument to make a loop.[27] A continuous wire loop has also been used. The technique of intermaxillary fixation used most commonly today uses stainless steel arch bars and wire. The stainless steel arch bar is contoured to the dental arch and affixed onto the dentition using 24-gauge wires that are twisted around individual teeth. One bar is placed on the lower and upper arch. Once the occlusion is set, the two bars are then tethered together by a series of wire loops placed between them. If there are not enough teeth, or if additional stability is needed, one can connect wires to the skeleton by passing the wires around the mandible, the zygoma, the pyriform rim, nasal spine, and infraorbital rim; this technique can be used anywhere in the face to provide additional bone stabilization.[28]

Closed reduction, particularly in edentulous patients, may be facilitated using intraoral splints. A Gunning splint is a prosthesis fabricated from models of edentulous maxillary and mandibular arches and aids in reduction and fixation of a fracture. Acrylic splints can be made by obtaining impressions of the arches. Using a stone model made from initial impressions, the model of the fractured side is sectioned and fit to the other side. The acrylic splint can now be made off these models. Holes are drilled so that it is wired to teeth, and reduction is achieved.[9]

External pin fixation is an effective method of fracture stabilization. It can be used in cases where there is significant bone loss, such as gun shot wounds, where bone grafting has been performed, or where rapid fixation is needed. Two or more pins are placed in the proximal and distal bone fragments and joined together using locking plates and bars.[28]

6.621.2.1.3.2. Open reduction internal fixation

Rigid internal fixation is designed to offset or negate functional forces that may impede fracture healing. Materials used for this application need to demonstrate durability, malleability, and biocompatibility. Metal wires, arch bars, and splints are still used as external fixation devices to stabilize fractures (i.e., nondisplaced or nongrossly comminuted fractures)[29] in combination with internal fixation systems. These internal fixation systems use a range of materials, from metals to resorbable polymer plates, screws, and mesh and pin systems.[18]

Carl Hansmann was the first to present a procedure for subcutaneous fixation of mandible bone fragments with a plate and screw system.[30] These were nickel-coated, came out through the skin, and were removed 4–8 weeks later. In 1907, Lambotte coined the term 'osteosynthesis.' He invented external fixation and many screws and plates made from silver, copper, brass, and aluminum.[31] Sherman is credited with applying the first self-tapping machine cut threads.[32] Although these plating systems were novel, mandibular-maxillary wire fixation (MMF) systems were still preferred because they had a lower incidence of pseudoarthrosis and they avoided the infections that were common with the internal fixation devices.[2]

One explanation for the increased complication rate with early plating systems is that they did not allow adequate approximation of the bone fragment. Collins was the first to develop a plate that allowed the fracture ends to be approximated.[33] The first true compression plate of the mandible was presented by Luhr.[26,34] The plates were Vitallium® and shaped like a half pipe around the lower body of the mandible. Compression plates allow a lateral moment of force that compresses the fracture together. The resultant frictional forces and load sharing reduce the size of the plate that is needed for stability. Spiessel of the Swiss Association for Internal Fixation modified plates of stainless steel, vitallium, and titanium.[35] Spiessel established a system that involves bicortical screws, an eccentric compression plate at the inferior border of the mandible, and a tension band at the superior border.[35]

Raveh introduced a locking plate system in 1980. Composed of titanium, the heads of screws locked into the holes of the plate. It was named the Titanium-coated Hollow Screw and Reconstruction Plate System.[36] The head of the screw was hollow, and a second smaller screw was inserted that pressed against the plate. This construct allowed the bone fragments to be stabilized without pressure from the plate. This technique has been replicated in other systems.[37]

With rigid internal fixation techniques, the need for MMF is limited. Rigid fixation is preferred in fractures with an unfavorable alignment, such as those at the angle of the mandible where the masseter and medial pterygoid cause displacement of the proximal mandible. Rigid fixation is also valuable when a patient has a condylar fracture and contrecoup fracture because it enables early mobilization. As a result, patients with condylar fractures and body fractures can start moving early toward ankylosis.

Numerous studies support the clinical benefits and relatively low complication rates with metallic and resorbable systems for craniofacial bone fixation.[15,19,21,38–43] In a comprehensive review, Rubin and Yaremchuk reported a low 6.6% incidence of infection and a 2% exposure rate from five clinical studies comprising 880 patients who received midfacial metal plates and screws.[39] Prominence (0.9%), pain (1.3%), and an overall 10.1% removal rate due to implant complications were reported. Studies on mandibular fracture plates also reported a similarly low 6.1% infection rate and very low incidence (<0.5%) of plate fracture loosening.[44] Infection and exposure rates increased to 14.3% and 14.9%, respectively, when plates were used for mandibular reconstruction after tumor resection

and adjuvant chemotherapy and/or radiation. Combined midfacial and mandibular data for 2659 patients reported an overall infection rate of only 7.4% and an exposure rate of 3.3% for metal fixation systems. Jack and coworkers reported similar complication rates (14%) in a series of 54 patients treated for more complex facial fractures with titanium plates and screws. Potter *et al*. observed that materials used for orbital reconstruction rarely became infected. The authors noted only one infection of metal meshes in two studies totaling 66 patients, and aesthetic outcomes were considered very good to excellent.[40]

While metal fixation systems provide excellent osteosynthesis, they can cause artifact with CT or MRI imaging, have been hypothesized to impair growth when used in children, and do not have sufficient long-term outcomes.[18,21,25] The artifacts created during radiological imaging or external radiation therapy for malignancy can be problematic, but they are fewer with titanium devices than with stainless steel or Co–Cro–Mo.[18] In children, it is unclear if the metal fixation devices interfere with bone and or brain growth. Additionally during this rapid growth period, the calvarial vault undergoes resorption from the inner aspect and deposition on the outer aspect. As this process occurs, there is a propensity of fixation plates to migrate or translocate from the ectocranial to the endocranial surface.[18,21] While the clinical consequences of this have not been noted, concern still exists about the long-term effects of deep metallic implants.[21] Other potential negative consequences include palpability, thermal sensitivity, and the need for subsequent removal of devices.[16,21]

Degradable implant systems were developed to overcome many of the issues related to metallic implants. The advantages of the degradable systems include the lack of need for device removal (especially for children) and, presumably, the lack of growth disturbance. Early resorbable plates and meshes were made of 100% PLLA, but their long degradation times (3–6 + years) and sterile foreign body were problematic.[45,46] Today, most common degradable systems are based on the PLLA-PDLLA or PLLA-PGLA systems. Agrawal *et al*. recently reported on a review of 19 clinical studies using resorbable mandibular plate systems. The studies comprised a total of 326 patients with 70:30 PLLA-PDLLA plates and screws, and 112 patients with screws only.[43] They noted that while the overall rate of removal for the resorbable devices (2–3%) was lower than that for metal devices, the former exhibited a 4–5% infection and were more likely to lose fixation and result in malunion than the latter. Eppley and Reilly[20] reported on 18 pediatric patients with facial fractures treated with 82:12 PLLA–PGLA (LactoSorb) systems. All of them healed with no complications and with total resorption of implants within 1 year. Yerit *et al*.[47] observed similarly good results in 13 pediatric patients treated with SR PLLA–PDLLA devices. Several studies found good clinical results with resorbable PLLA–PDLLA meshes in orbital rim repair, although some inflammation was noted even after 11 months due to the need to fold the mesh to obtain sufficient strength.[38] Bell and Kindsfater[21] retrospectively reviewed 59 patients with resorbable plates and found an overall complication rate of 6% (16 patients); this included 8 patients with infections (13%), 4 with malunions (7%), 2 with nonunions (3.3%), 3 with alterations in eyeball position (5%), and 1 patient with sterile abscess at 1 year. Holmes and coworkers reported an overall 12.8% (n = 14) complication rate in 164 patients treated with 70:30 PLLA–PDLLA devices.[15] This included 2 patients with minor erosion, 4 with intraoral exposure, 3 with fracture, and 5 with temporal or fronto-orbital swelling, which resolved over 3 months. They noted that improvements in surgical techniques may substantially reduce complication rates. They further suggested that good clinical and aesthetic outcomes had been obtained in preliminary studies using other implants such as a customized PLLA–PDLLA mesh for cranial repair, PLLA–PGLA tacks, and 85:15 PLDA–PGA fast resorbing screws and plates for pediatric patients.

Certain clinical situations clearly favor the use of either resorbable systems (e.g., pediatric stabilization) or metallic systems (e.g., mandibular stabilization). However, the advantages of one system over another are less clear for many applications. Dorri *et al*. recently published a Cochrane Database Systemic review of clinical studies to compare resorbable and metal craniomaxillofacial implant systems for facture management.[1] In their meta-analysis, the authors concluded that the lack of level I datas and randomized trials prevents adequate comparison between resorbable systems and conventional titanium systems. The lack of trials in their systematic review may be partly because of the ethical and methodological limitations of conducting such trials on humans. Fedorowicz and coworkers[48] carried out a similar Cochrane review to compare the effectiveness of bioresorbable fixation systems compared to titanium systems for orthognathic surgery. Based on their assessment of published clinical studies, they were also not able to determine any advantage of the resorbable systems compared to the titanium systems. These authors advised some caution in the interpretation of their results mainly because of the methodological limitations and poor reporting of the results of the trials. The best available studies seem to suggest that both fixation systems are similarly effective.

6.621.2.1.3.3. Extracellular matrix and growth factor-coated implants

The application of growth factors, such as bone morphogenic proteins (BMPs), to plating surfaces has shown promise with regard to improvement in bone healing.[49] BMPs are members of the TGF family of proteins, and there are at least 30 BMPs. BMPs are complex, and some studies have shown that BMPs also stimulate osteoclasts. Therefore, the net bone formation may be less with BMPs and it may be dose-dependent.[50] Other growth factors that have been tested on titanium implants include growth hormone, platelet-derived growth factor, and insulin-like growth factor.[51] This developing and promising area of implant technology is beyond the scope of this treatise.

6.621.2.2. Skeletal Replacement and Augmentation

Autogenous bone is a standard to which all biomaterials are compared.[52] Many of the most influential surgeons in the field continue to feel that autogenous bone is the best biomaterial for craniofacial reconstruction.[53,54] Advances in surgical technique have led to a decrease in morbidity and an increase in ease of harvest. Nevertheless, there are limitations to autogenous bone grafting. The most common bone graft donor sites are cranial bone, iliac bone, ribs, and tibia, and harvest of bone from these areas is associated with added operative time and

donor site morbidity. In addition, autogenous bone can be difficult to mold to meet the requirements of the craniofacial skeleton, and there can be significant and unpredictable resorption over time. Lastly, the supply of autogenous bone is limited, particularly in the pediatric population.

Given the limitations of autogenous bone graft, biomaterials have assumed a central role in oral and craniofacial bone replacement and augmentation. The most common recipients of facial implants are the cheek (malar, submalar, and midfacial), nose, jaw, and chin regions. While existing implants for these anatomic areas are biologically inert and nonbiodegradable, and elicit little inflammatory response, they tend to lack the plasticity for custom molding to fit the contours of the face.

6.621.2.2.1. Methyl methacrylate

First used in World War II for craniofacial reconstruction, poly (methylmethacrylate) (MM) is an acrylic-based resin that is strong and resistant to resorption.[55] MM is a colorless, odorless liquid that is made into a polymer. It is biologically inert. It has significant applications in the construction industry today, being used for casting, molding, and paints. It is inexpensive and easily accessible. Because MM does not integrate with the surrounding bone or develop a blood supply (**Figure 6**), it does not grow with the surrounding bone, can become dislodged if exposed to load, and is prone to infection.[56] Marchac *et al*. describe their experience with the use of MM in 98 patients over 21 years.[57] They document an infection rate of 9%, requiring removal of implant, with good or excellent results at long-term follow up of 85 out of 98 patients. Infection rates were higher when the nasal or frontal sinus was in contact with the implant during the operative procedure. Blum *et al*. noted a 23% complication rate with the use of MM. These complications were also noted in defects that communicated with the frontal sinus, were very large, or were associated with a history of infection or postoperative radiotherapy.[58]

6.621.2.2.2. Silicone implants

Silicone is a polymer of Si molecules described in the chapter by V. Hasirci. Implants designed from this material were used for cheek augmentation in the 1960s.[59] Silicon implants are inert and resist tissue ingrowth; instead, they become surrounded by a fibrous capsule.[60] Once formed, this capsule helps to maintain implant position.[61] Also, silicone is easy to handle, has minimal complications, and good overall patient satisfaction.[59] A recent study on techniques and materials used in rhinoplasty found that surgeries using silicone implants had overall shorter operation times compared with autologous grafts.[62] Another investigation recommended that silicone implants should not be used to create a caucasian nose in an Asian patient as this can cause protrusion of the implant.[63] Silicone implants have also been shown to be effective treatment options when reconstructing the orbital floor.[64]

While there are many benefits to silicone implants, they are not without limitations and problems. Silicone implants may be associated with increased bone resorption. Silicone implants used in mandibular reconstruction can cause a decrease in the volume of bone beneath the implants, possibly as a result of diminished circulation.[65] Further, it should also be noted that silicone implants can be associated with benign granulation which may be falsely diagnosed as a malignant tumor by radiograph.[66] Given this information, a physician should always question whether a patient has previously undergone any silicone implantation when interpreting radiographic images. Finally, silicone can degrade and fracture over time (**Figure 7**).

6.621.2.2.3. Hard tissue replacement (HTR)

Hard tissue replacement (HTR) is a porous polymeric composite of polymethylmethacrylate and polyhydroxyethyl methacrylate with a calcium hydroxide coating that acts to promote tissue ingrowth for implant stability. It has a 20–30% material porosity (150–350 μm), holds a negative surface charge (−8 to −15 mV), and has a compressive strength of 50 000 lb in^{-2} in particulate form and 5000 lb in^{-2} in molded form.[67] Porosity allows for some tissue ingrowth that helps stabilize the implant and prevent migration/dislodgement.

Eppley used a rabbit model to demonstrate osseous ingrowth into inlay implants extending up to 2000 μm.[68]

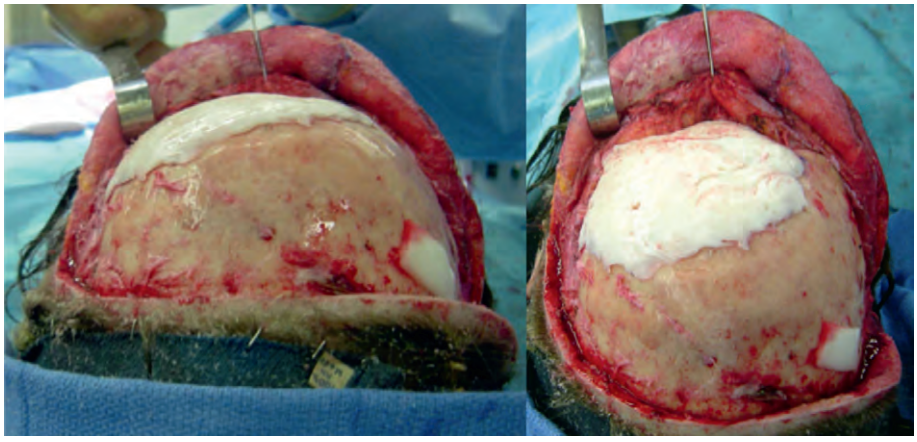

Figure 6 A 42-year-old female with left-sided coronal craniosynostosis. Intraoperative views of methylmethacrylate monomer applied to the frontal bone to correct forehead asymmetry. Methylmethacrylate is a colorless, odorless liquid that polymerizes into a strong inert solid that is resistant to resorption and does not incorporate into the bone.

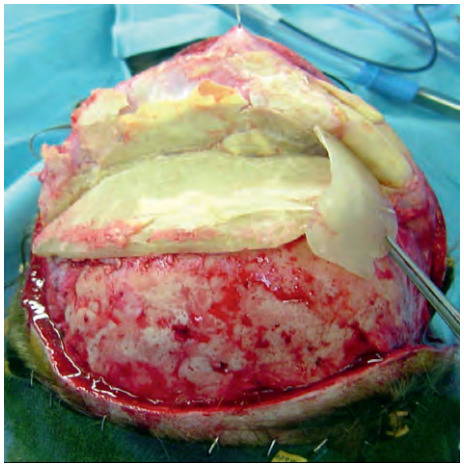

Figure 7 A 47-year-old female with a silicone implant placed 20 years earlier for correction of forehead contour deformity. Intraoperative view of a silicone implant 20 years after its placement showing the aging and fracture of silicone over time.

The onlay implants, however, exhibited more limited bony ingrowth, extending only up to 100–200 μm into the material. The material is considered osteoconductive and appears to resist infection. Guyuron reported good results using HTR to augment the orbit and temporal region in four patients to correct an hourglass facial deformity.[69] Eppley used prefabricated HTR from a computer-generated model in 14 patients to reconstruct large cranial defects (greater than 150 cm^2) with excellent results. In all these cases, the procedure was delayed for debridement and treatment of all sources of infection, and the frontal sinus was cranialized using pericranial flaps.[70]

6.621.2.2.4. Porous polyethylene (MEDPOR™)

MEDPOR™ Surgical Implants are manufactured from linear high-density polyethylene. MEDPOR™ allows for tissue growth into its interconnecting open pores. The average pore size is around 100 μm, and pores make up approximately 50% of the total implant volume. The firm material can be carved with a sharp instrument without collapsing the pore structure (**Figure 8**). Dougherty *et al.* reported ingrowth of vessels into the implants within 1 week and peripheral integration with bone at 3 weeks.[71]

Yaremchuk reported on a series of 370 porous polyethylene implants in 162 patients.[72,73] These implants were fixed in the subperiosteal plane with titanium screws. All implants were incorporated onto the native tissues without incident, and there was no implant extrusion or capsule formation. Reoperation rate was 10% and the infection rate was 3%. Porous polyethylene has found application in microtia reconstruction, nasal reconstruction, and throughout the craniofacial skeleton.[74] Like HTR, porous polyethylene molds can be made to fit the defect using CT imaging. It is considered osteoconductive due to the tissue and bone ingrowth into the material.

6.621.2.2.5. Hydroxyapatite and bioactive glass

Hydroxyapatite is a calcium phosphate ceramic, as is bioactive glass. These materials are described at great length in other chapters in this publication. Herein, we briefly describe their utility in craniomaxillofacial surgery. Hydroxyapatite is chemically similar to the mineral component of bone and hard tissues in mammals. It is a bioactive material that will support bone ingrowth and osseointegration. It has been used in orthopedic, dental, and maxillofacial applications and can be replaced with bone formation via osteoconduction.[75] This material is radiolucent and biocompatible. Hydroxyapatite cement consists of a calcium phosphate preparation comprised of tetracalcium phosphate and dicalcium phosphate anhydrous powders. When mixed with water, it isothermically forms a hydroxyapatite paste that can easily be shaped during application. The mixture sets in approximately 15–20 min and converts into a microporous material in 4 h.

Figure 8 Porous polyethylene chin implant. The firm nature of porous polyethylene allows intraoperative shaping without collapse of the pore structure. Note: The pore structure allows for some bony ingrowth.

Because it mimics the mineral component of the bone, this material has been made in various forms and has been extensively used in craniofacial surgery. It is important to keep in mind that dense hydroxyapatite does not have the mechanical strength, especially the fracture toughness, to allow its use in long-term load-bearing applications. Jackson *et al.* successfully used dense hydroxyapatite without complication to fill contour irregularities in 20 patients.[76] Burstein and coworkers have reported on 61 patients in whom hydroxyapatite was used for secondary craniofacial reconstruction: 31 for secondary orbitocranial defects after surgery for synostosis, 7 after surgery for hypertelorism, 10 for posttraumatic skull defects, and 13 for a variety of other facial skeletal defects. There was a 11% complication rate (four seroma, one drain cemented), but an excellent overall retention of implant volume with no recurrence of contour defects.[77] Byrd and colleagues reported the use of porous hydroxyapatite granules to augment the craniofacial skeleton in 200 patients over 8 years. They found favorable results in augmenting the perialar, maxilla, and glabellar area.[78]

Synthetic bioactive glass is a compound consisting of silicon oxide, sodium oxide, calcium oxide, and phosphate. Glass particles in various size ranges have been used: a size range from 300 to 355 μm and another from 90 to 710 μm.[79–83] Through a complex set of surface- and solution-mediated reactions, bioactive glass stimulates cell function, including the stimulation of osteoprogenitor cells to produce TGF-β, which makes the material osteogenic at the surface of glass particles.[84–86] Bioactive glass mixed with autogenous bone has been used in orbital floor fractures, maxillary sinus augmentation, and frontal sinus obliteration with promising results.[87,88]

It has proved useful to augment bone in preparation for titanium plating. Unfortunately, prefabricated bioactive glass ceramic implants made to date have not been proven to be more advantageous compared to other implants mentioned earlier, and are not widely used.[89]

6.621.2.2.6. Demineralized bone

Demineralized bone matrices (DBMs) are osteoinductive and, thus, can stimulate bone formation de novo. This material is prepared by acid demineralization of allograft bone. The remaining collagen and noncollagenous proteins, including growth factors and BMP, contain the osteoinductive components. DBMs are available in two different forms, as a paste or in small chips. Several different DBMs are commercially available, but each product has been shown to have a distinct osteoinductivity potential as a result of the differences in the preparation methods, storage, and donor specifications.[90] DBM is very pliable and can be easily molded to accommodate most defects. Based on their clinical observations, Salyer *et al.* conclude that demineralized perforated bone implants serve as osteoinductive centers.[91] These authors found that cortical demineralized perforated bone matrix caused no adverse tissue reactions and was capable of stimulating bone formation and remodeling. In large calvarial reconstructions, some areas had not been populated by living bone cells, although there were no signs of osseous resorption.

6.621.2.3. Cartilage Replacement

Autologous cartilage grafts are not new. Autologous cartilage harvested from the costal margin has been utilized in the treatment of microtia for decades.[92] Because the quantity of autogenous cartilage is limited, some researchers have focused efforts on manufacturing cartilage using cultured autologous human chondrocytes.[93] Yanaga and colleagues described a procedure where a 1 cm portion of the auricular concha was taken from a patient and placed in a serum that stimulates cell proliferation.[93] After only 4 weeks, cell counts were noted to be 1000 times larger than the number originally harvested. The autologous cells were then placed in a gel matrix and injected subcutaneously into areas requiring augmentation.[93] Surprisingly, cultured chondrocytes can be used to reconstruct complicated shapes.[94]

6.621.2.4. Soft Tissue Replacement and Augmentation

Reconstruction of the craniomaxillofacial soft tissue must be functional and aesthetic. Surgeons have used autologous grafts, allografts, and synthetic materials to reconstruct soft tissue defects. Depending on the type of defect and the size, as well as the patient preferences, one or multiple techniques may be required to address the soft tissue problem.

6.621.2.4.1. Collagen

Collagen is the most abundant protein in humans and the main structural support of the skin.[95] Collagen also acts as a scaffold for cell differentiation and proliferation. In the skin, fibroblasts secrete collagen and other proteins that form networks of extracellular matrices (ECMs); these ECMs are constantly being remodeled by collagenase and protease activity.[96] Many different physiologic changes occur in the skin during aging. One study suggested that advance-glycolitic end products, such as carboxymethyllysine, accumulate in the ECM and stimulate apoptotic pathways in fibroblasts, effectively reducing their cell count.[97] With fewer fibroblasts available, future collagen deposition is diminished and the overall thickness and strength of the ECMs is decreased. Aged or damaged fibroblasts have also been shown to produce up to 20% less collagen, further decreasing overall skin thickness and strength.[95] Thus, exogenous collagen augmentation may help restore soft tissue volume in aging skin and other conditions associated with soft tissue volume loss.

In the mid-1980s, bovine-derived collagen gained approval from the US Food and Drug Administration (FDA) for the correction of contour deficits in soft tissue.[95] Bovine collagen injections have been used to help correct wrinkles, such as glabelar lines, perioral lines, horizontal forehead lines, and crows' feet.[98] Despite its proven effectiveness in correcting contour defects in the aforementioned areas, bovine-derived collagen has unwanted side effects and relatively poor longevity. One problem is that compounds containing bovine-derived collagen can cause allergic reactions. Thus, it is suggested that a patient should have at least two allergy tests spaced 2 weeks apart before having bovine collagen treatment.[99] Furthermore, the life of a given treatment has been reported to be only a few months.[100] Zyplast™, a bovine collagen that is chemically cross-linked, is reported to last about 6 months due to its greater resistance to endogenous collagenases.[101] Chemically cross-linked bovine collagen has significantly better longevity and can last up to 24 months.[102] Recent advancements in collagen treatments have focused on human[103] and porcine-[104] derived collagen. While these options are reportedly less immunogenic than their bovine counterpart, the overall retention of the material is still quite limited. The poor longevity of injected collagen materials has prompted a move toward longer lasting dermal fillers, such as hyalorunic acid, calcium hydroxyapatite, and polylactic acid, in recent years.[105]

6.621.2.4.2. Dermal substitutes

Acellular human dermis is donated human skin that has been aseptically processed to remove the epidermis and the cells (that can lead to tissue rejection and graft failure) while preserving and stabilizing the remaining biochemical components and dermal matrix. This resulting framework (composed of collagen, elastin, protein, hyaloronan, proteoglycans, fibronectin, and vascular channels) is an intact acellular matrix of natural biological components that promotes rapid cellular repopulation and vascularization. The cadaver skin undergoes a strict comprehensive series of procedures as directed by the FDA, the American Association of Tissue Banks (AATB), and other regulatory bodies to assure its safety. The skin donors are prescreened and tested for transmissible diseases, and the grafts are harvested at the time of death. Microbiological cultures are performed on the tissue to assure the absence of bacterial and fungal pathogens. Once processed, histology and immunohistochemistry are performed on the dermal matrix to confirm that the material is acellular, has an intact basement membrane complex, and has retained most of the native collagen.

Acellular human dermis was originally developed and approved by the FDA as a skin substitute for burn victims. Nevertheless, it is now used more frequently for off-label uses in dental, orthopedic, urogenital, and plastic surgical reconstructive procedures. Currently, there are multiple commercially available acellular human dermis products, but the literature most commonly refers to Alloderm® (Lifecell, Branchburg, NJ).

6.621.2.4.2.1. Alloderm®

Since 1994, more then 1 million Alloderm® grafts have been implanted. This tissue has been used to repair soft tissue defects and is reported to support the revascularization and regeneration of tissue (www.lifecell.com) (**Figure 9**). Alloderm® has a shelf life of 2 years when stored at 1–10 °C and requires about 30 min for rehydration. Currently, it is used in many different reconstructive procedures, including implant-based breast reconstruction after mastectomy, abdominal wall reconstruction, and oncological head and neck reconstruction. Sclafani *et al*. compared the clinical results and longevity of Alloderm® to those of bovine cross-linked collagen, Zyplast® (Collagan Corp, Palo Alto, CA). These authors measured the persistence of the materials at 1, 3, 6, and 12 months after subdermal implantation (behind the ear) and found statistically better retention of Alloderm® (82.8%, 48.3%, 21.9%, and 20.2%, respectively) compared to Zyplast® (26.6%, 8.0%, 1.1%, and 0.9%) at all times. Biopsies taken at 12 months showed extensive ingrowth of mature blood vessels and fibroblasts in the Alloderm® specimens, but almost complete resorption of Zyplast® had occurred by 3 months. Although the volume retention of Alloderm was excellent, the authors still recommended overcorrection, given the observed loss of volume.[106]

The use of acellular dermal matrix has become increasingly popular as a substitute for donor connective tissue in oral surgery. Conventional wisdom now dictates that one should assess the quality of the underlying gingiva at the recipient site prior to hard tissue augmentation of autologous bone graft.

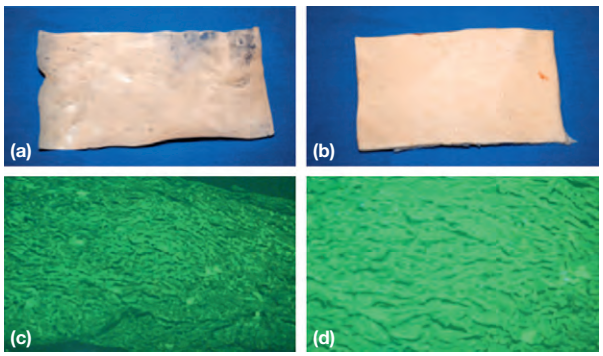

Figure 9 Gross and histologic images of Alloderm™ dermal matrix. Alloderm™ is human skin that has been aseptically processed to remove the epidermis and the cells (thereby reducing immunologic reaction) while preserving and stabilizing the remaining collagen components of the dermal matrix. (a) Dehydrated Alloderm™ (b) Alloderm™ after hydration (c) Alexa fluor stained Alloderm™ showing its intact acellular matrix of natural biological components serving as a framework for rapid cellular repopulation and vascularization (10×). (d) Higher power view of alexa fluor stained Alloderm™ (20×).

Alloderm® has been shown to improve graft survival and diminish the risk of graft exposure when used for soft tissue reconstruction of the gingival defect 12 weeks prior to the bone graft.[107]

The use of Alloderm® for secondary nasal reconstruction was successfully reported by Gryskiewicz in 2004. Nasal augmentation is important for correcting secondary deformities. The gold standard has been autogenous cartilage graft, but this technique has the drawback of donor site morbidity and irregularity of the cartilage graft, especially in patients who have had prior nasal procedures. In one report, 25 patients underwent dorsal augmentation of the nose using Alloderm® placed over autogenous cartilage grafts, including those used to reconstruct the nasal tip.[108] There was good patient satisfaction and only one patient had a partial extrusion. There was no resorption at 1 year, although nearly half of the patients had partial graft resorption (<50%) at 2 year follow-up. The latter observation led the authors to recommend overcorrection, particularly on the bony dorsum. Jackson *et al*. showed similar results using Alloderm® in secondary rhinoplasty to create a smooth nasal dorsum.[109] Sudarsan and coworkers used Alloderm® in combination with BioOss® (inorganic bone material) to treat Siebert's class I ridge deficiency.[110] Alloderm® acts as a barrier membrane to prevent the gingival tissue from contaminating the wound space and interfering with osteogenesis. This combination showed an increase in both bone and soft tissue volume after 6 months and 9 months of study.

Lastly in 1999, Rubin *et al*. showed that Alloderm® could be successfully used as a barrier and a reconstructive grafting material in occuloplastic interventions.[111] These authors used Alloderm® as a scaffolding for primary and secondary implant coverage, as a lid spacer graft, and for volume augmentation of the superior sulcus and other periorbital defects. Unpredictable resorption of the material did result in multiple revisions for some patients.

6.621.2.4.2.2. DermaMatrix

DermaMartix® (Synthes, West Chester, PA) is another acellular human dermis product available. DermaMartix® can be stored at room temperature and has a shelf life of 3 years and a rehydration time that is 10 times shorter than that required for Alloderm®. Nevertheless, Alloderm® seems to have a better elasticity than DermaMatrix®, making it more popular in breast reconstruction. Becker and coworkers compared DermaMatrix® and Alloderm® in immediate expander-based breast reconstruction procedures.[112] At 6 months, both materials were well incorporated into host tissue (grossly and histologically) and had equal vascularization. The most common complications were wound infection and the formation of seroma, although the complication rates were similar.

DermaMatrix® has been used in oculoplastic surgery. Lee *et al*. reported the use of DermaMatrix® for eyelid (lower eyelid retraction repair) and anophthalmic socket reconstruction.[113] The success of the surgery was gauged by the improvement of symptoms as well as the anophthalmic patient's ability to wear a prosthesis. Ten of the 13 patients were successfully treated in one operation; the remaining 3 patients had complex reconstructive needs that required more than one operation. At 3 months, the graft (typically 1×4 cm) demonstrated

neovascularization. The authors concluded that DermaMatrix® was a viable alternative to Alloderm® for oculoplastic surgery.

6.621.2.4.3. Hyaluronic acid

Hyaluronic acid (HA) is a polysaccharide and the most prevalent glycosaminoglycan in human dermis.[114] Therefore, this material would be a natural candidate for use as a dermal filler. Currently, HA is the most commonly used dermal filler, ranked second only to Botox™ in 2007 for its use in minimally invasive cosmetic procedures.[105] Age and sun damage decrease the amount of endogenous HA.[115,116] Restoring or replenishing HA can help correct volume deficits. A highly hydrophilic molecule, HA can bind many times its weight in water, further increasing the effective volume of the given treatment. HA was first approved by the FDA for use in correction nasolabial folds, but it has since been used to correct other areas prone to volume deficits such as the glabela crease, mental crease, ocular sulcus, and tear trough region.[105,117]

Despite the reported efficacy of HA to correct nasolabial folds and other facial volume deficits, HA too has been shown to have only temporary results. A recent study found that volume improvement from HA injected around the eye was evident even after 24 months and, in some cases, up to 36 months.[118] The longevity of HA has increased over the years by the creation of compounds of different molecular weights (1.5–2 million Da to 4–6 million Da) and different types of cross-linkages (e.g., 1,4-butandiol diglycidyl ether or divinyl sulfone).[114] There have been reports of allergic reactions to HA treatment, but this can be treated with injections of hyaluronidase to break down the HA.[119] This method can be used to correct misplacement or overinjection of HA.[120]

6.621.2.4.4. Polymethylmethacrylate

ArteFill™ is an injectable material that comprises 30–50 μm polymethylmethacrylate (PMMA) spheres suspended in bovine-derived collagen. This was the first permanent injectable filler approved by the FDA to improve nasolabial folds.[121] Once injected into the skin, PMMA cannot be broken down by enzymes or phagocytosis. Thus, PMMA treatment can persist for many years. Further, PMMA components are described to be completely encapsulated and do not migrate or spread apart.[122] Once injected into the subcutaneous tissue, PMMA microspheres promote fibroblast activation and act as a scaffold for collagen deposition.[123] Since obtaining FDA approval in 2006, PMMA treatment has proved to be a versatile dermal filler. It has been used to correct nasolabial folds, horizontal forehead lines, glabellar frown lines, shadowed lower lids, crow's feet wrinkles, facial wasting and cheek depressions, acne scars, traumatic scars, nose irregularities, lip enhancement, nipple augmentation, hand rejuvenation, and many other dermal lines and wrinkles.[121]

While the benefits of using permanent dermal fillers are obvious, the resulting complications may be as permanent. Unlike temporary and semipermanent fillers, permanent fillers and their complications are long-lived. Errors in technique, most notably, misplacement of the PMMA treatment (either too deep or too shallow), are common and can require subsequent treatments to amend the mistake. Also, permanent scarring, nodule formation, and granuloma formation is possible, albeit rare, following PMMA treatment.[121] Thus, the possibility of an uncorrectable negative result complicates the decision between temporary and permanent treatment options. Every patient should discuss his or her own goals and fears with the physician before deciding on a particular treatment option.

6.621.2.4.5. Poly-L-lactic acid

Poly-L-lactic acid (PLLA) is a synthetic biodegradable compound that has been approved by the FDA for use as an intradermal filler to help correct soft tissue defects associated with HIV. HIV-associated lipodystrophic syndrome is described as either a soft tissue volume loss or a soft tissue rearrangement and is a common and noticeable side effect of long-term antiretroviral drug use.[124] One study reported that lipodystrophy occurs in 20% of individuals using antiretroviral drugs and the most affected areas include the face, the buttocks, the legs, the arms, and the abdomen,[125] While both permanent and nonpermanent fillers have been used in the treatment of HIV-associated lipodystrophic syndrome, PLLA is one of the most promising. While results may still be seen in patients with severe facial lipoatrophy, the best results are reported in both younger and less lipoatrophic patients.[126] These results, and other similar findings, argue that patients should begin PLLA treatment on or before the first signs of facial lipoatrophy.[127] PLLA has also been shown to be a promising polymer for use in reconstructive surgery.

While it has not yet been approved in the United States, the use of PLLA as a cosmetic filler has gained popularity in Europe in recent years. As such, PLLA has been used to correct facial volume loss associated with the aging face.[128] Specifically, nasolabial folds and other age-related creases of the face have been the focus of PLLA treatment studies, with improvements lasting up to 25 months posttreatment.[129] Products such as New-Fill™ and Sculptra™ are being used to stimulate neocollagenesis and improve facial contours and folds. In a recent study, PLLA was found to have positive cosmetic results. Surgeons rated 55% of patients to have had good to excellent results, while 75% of the patients self-reported their results as good to excellent. There were a few negative findings, with 12.5% of patients reporting palpable nodules in their hands and 7.2% of reporting palpable nodules in their cheeks; however, these nodules were almost entirely nonvisible. Although only 68% of the patients in the aforementioned study would repeat the procedure again, PLLA appears to be promising for use in cosmetic surgery.[130]

PLLA is injected intradermally every 4–6 weeks to increase fibroblast number and collagen deposition.[131] Overall, PLLA injections are reported to be well tolerated, and there is little evidence of acute inflammation, tissue necrosis, or abscess formation. PLLA injections are associated with an increase in mononuclear macrophages, well-vascularized beds, and proliferating fibroblasts, findings that suggest an environment of remodeling and collagen deposition. As the PLLA polymer is broken down by the body, collagen deposition and overall volume have been shown to increase significantly.[132]

6.621.2.4.6. Calcium hydroxyapatite-based dermal filler

Radiesse™ is an aqueous gel of suspended calcium hydroxyapatite (CaHa) microspheres that has been approved by the FDA as a dermal filler. Radiesse™ has gained popularity in recent years as a nonsurgical treatment for nasolabial folds and for

improvement in volume loss in the face and hands.[133] Because this treatment is associated with some pain, the area is infiltrated with local anesthesia.[134] Some authors suggest premixing CaHa with lidocaine to reduce discomfort during and after injections.[135] Once injected into the treatment area, the aqueous gel is resorbed by the body. The resulting precipitating CaHa forms a matrix onto which new collagen deposition can take place. Histologic evaluations have demonstrated that the persistent localized CaHa lattices initiate an early macrophage response that is followed by a fibrotic response that lasts for up to 6 months after treatment. After 6 months, the CaHa matrix begins to lose form.[136] Another study reported obvious CaHa resorption and shape loss by 9 months and near complete resorption by 12 months.[137] One investigation compared CaHA to hyaluronic acid (HA) at 6, 9, and 12 months posttreatment. At 12 months, 79% of the CaHa treatments were still evident compared to the 43% of HA treatments. This study also showed that 30% more HA volume was needed to elicit the same results as the CaHa treatment.[138] While most of the literature supports treatment longevity of around 12 months, one study observed histologic remnants of CaHa injection up to 6 years after the treatment.[139] This information proves promising for the possibility of a longer lasting CaHa treatment. Caution must be exercised when examining patients who have previously had CaHa-based dermal fillers to prevent false interpretation of radiographic calcifications as evidence of malignancy.[140]

6.621.2.4.7. Fat

A great deal of the recent literature has focused on autologous fat grafting for the management of soft tissue volume depletion. Given its relative abundance and proximity to the surface of the skin, adipose tissue is thought to be an ideal filler for both age-related and pathologic volume deficits. This autologous tissue obviates the negative psychological impressions associated with synthetic implants and xenogenic fillers.[141] Furthermore, because the fat is harvested from and grafted into the same individual, there is no potential for immune rejection that can be associated with exogenous grafts (**Figure 10**). One of the major issues regarding fat grafts is the highly variable rate of resorption. Studies performed throughout the 1990s reported retention rates consistently in the range of 20–90%.[142–144] A more recent study in 2008 used computer topography to quantify cheek volume before autologous fat transfer and at 2 and 12 months posttreatment in HIV-positive individuals.[145] This population is reported to have minimal endogenous subcutaneous fat; therefore, possible biases are removed when evaluating treatment efficacy. This study found a significant increase in mean cheek volume after 2 months (2.93 cm^3) compared to mean pretreatment volume (1.57 cm^3). Interestingly, the study also reported an average increase of 0.33 cm^3 between 2 and 12 months. This study demonstrates that a single treatment with autologous fat can sustain for a minimum of 12 months and suggests that even at 12 months, there is little likelihood of resorption. While these

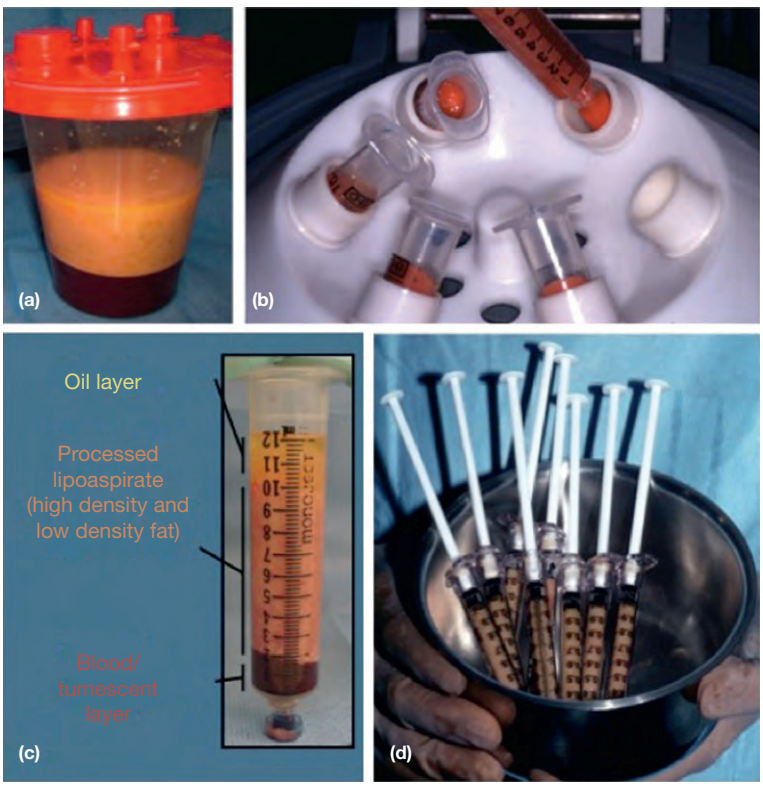

Figure 10 Human fat harvest and processing. After liposuction or syringe aspiration (a), centrifugation is used to separate the viable cell fraction (high-density cells) from nonviable cells (low-density cells) and oil as well as blood contained in the lipoaspirate (b). Following centrifugation, a gradient of lipoaspirate can be seen (c). The blood tumescent layer is discarded and the oil layer wicked away, leaving the processed lipoaspirate to be loaded into a 1-cm^3 syringe for reinjection (d).

results are impressive, other recent literature has not reported the same conclusion.[146] In 2009, Meier *et al*. injected 10.1 cm^3 into the midface region in eight patients. By 16 months post-treatment, on average there was only 3.3 cm^3 of grafted fat remaining (average graft retention was 31.8%).[147] Thus, more research in the field of fat grafting is needed to improve graft retention and equilibrate outcomes. The current literature focuses on the enhancement of grafting techniques, the addition of graft supplements to stimulate adipogenesis and increase individual cell size, and improvement in graft perfusion to prevent necrosis.

- Harvesting techniques

Techniques to harvest and implant fat vary greatly. While liposuction may take less time, it is generally agreed that syringe aspiration produces less trauma to the adipose tissue and improves cell survival.[148,149] The techniques for handling and implanting the lipoaspirate are less defined. The harvesting and processing techniques described and advocated by Coleman have gained wide acceptance in recent years; he harvests adipocytes using syringe aspiration and then uses centrifugation to separate the viable adipose cells (high-density fat) from nonviable cells (low-density fat), oil, and blood contained in the lipoaspirate. Studies using this technique report a greater number of total viable adipocytes and improved grafts survival after implantation.[150] Proper implantation of the fat is equally important and smaller grafts survive better than larger grafts.[151] As such, it is suggested that small droplets of fat are added through a cannula to different locations and in different planes of the subcutaneous space. A conservative approach should be taken, with small augmentations performed serially over time, to yield the most effective results.

- Improvement of fat graft survival

The physiologic demands of adipocytes require a critical amount of perfusion to prevent graft necrosis. Consequently, researchers are exploring ways of improving fat graft perfusion. The fate of an individual graft is determined in part by its ability to stimulate angiogenesis (the process of developing new vasculature from an existing vascular network) and vasculogenesis (the de novo creation of new vascular network).[152] Thanik and coworkers showed that human fat cells injected into the dorsum of nude tie2/lacz mice have both angiogenic and vasculogenic properties.[153] The presence of human-specific cytochrome c oxidace expression suggested that the perigraft vasculature was a human derivative and not merely a murine infiltrative vasculature. Although fat grafts are capable of creating their own vascular network, the size of any single fat droplet must be kept smaller than a specific radius to limit the likelihood of poor perfusion and graft necrosis. Thus, each fat droplet should optimally be limited to the size of a pea.[154]

Many studies have found promising results in augmentation of graft retention rates through the supplementation of different materials such as adipose-derived regenerative cells (ADRCs),[155] platelet-rich plasma (PRP),[156] and insulin-like growth factor (IGF-1).[157] The choice of the additive depends on the desired effect. For example, graft size and graft viability are both contingent upon the presence of a large population of viable mature adipocytes. Insulin, IGF-1, and other specific growth factors have been used to stimulate adipogenesis, the transformation of immature adipocytes to mature adipocytes.[157] To improve graft retention, additives that augment the mechanisms of angiogenesis and neovasculogenesis can be used. ADRCs contain populations of cells that are both multipotent and capable of secreting growth factors, such as VEGF, that have been proved to increase graft perfusion and survival.[155] Further research is needed to determine which of these combination treatments will yield higher rates of fat graft retention.

6.621.2.4.8. Expanded polytetrafluoroethylene implants

Another implant material that has been in use for several decades is expanded polytetrafluoroethylene (ePTFE). ePTFE is an ethylene monomer attached to four fluorine monomers. It has a more spongy feeling than denser silicone implants.[59] While technically simpler to use than silicone, ePTFE used for forehead reconstruction has been reported to have a relatively high rate of infection.[158] ePTFE has also been used to reconstruct the oral and maxillofacial region,[159] and the nasolabial fold and malolabial groove.[160] Surgeons like the pliability and durability of this material, and its ability to provide a solid anchor for soft tissue growth in the midface[161] While some studies support ePTFE for facial implantation, others have reported less favorable outcomes. One study that used ePTFE in the perioral region found the patients only moderately satisfied at a mean follow-up of 23 months: only 63% of these patients stated that they would have ePTFE for additional implants, and only 51% of these patients would recommend this type of implant to other patients. Further, the authors noted that there was histologic evidence of chronic inflammation in the ePTFE implants that were removed.[162] Another study in 2005 also surveyed patients about their ePTFE facial reconstructive experiences.[163] This study found that 10 of the 12 patients were satisfied with their ePTFE facial implant in all areas of the face but the lips. Furthermore, revision rates in the lips ranged from 1% to 100%. Redbord and colleagues found that 11 of the 85 ePTFE implants (33 patients) required removal – 4 were replaced with bigger ePTFE implants and 7 were completely removed for reasons such as malposition, localized swelling, or unnatural feel.[164] Reported complications with ePTFE implants include inflammation, extrusion, migration, shrinking, and hardening.[165] Thus, the suitability of ePTFE as a facial implant material is still debatable. The patient's goals and expectations, the area of restoration, and potential complications should be addressed before deciding on a ePTFE-based reconstruction.

6.621.2.4.9. High-density polyethylene implants

High-density polyethylene (HDPE) implants are firm, yet flexible, plastic that has pores to allow for some soft tissue and minimal bone ingrowth.[59] This material has been advocated for the correction of maxillonasal dysplasia (Binder's syndrome),[166] traumatic nasal deformity,[167] nasal valve collapse,[168] mandible reconstruction,[72,73] orbital trauma,[169] ear construction,[170] and other facial reconstruction. Because of its porosity, HDPE is more prone to infection than ePTFE or silicone. Consequently, preoperative antibiotic impregnation may be considered.[59] A recent study found that HDPE may not be as biologically inert as previously thought, and that a mild inflammatory response can occur.[171]

Cleft lip nasal reconstruction has also been successfully performed with HDPE. The characteristic spongy nature of this material allows tissue and vascular ingrowth, with good aesthetic outcomes and minimal complications.[172] A rabbit study demonstrated improved integration of HDPE into the host bed through the addition of basic fibroblast growth factor and epidermal growth factor.[173] These authors found a synergistic improvement in both the fibrous and vascular ingrowth into the HDPE implant, and noted very few complications.

6.621.3. Considerations and Future Applications

There are a wide array of treatment options for bone and soft tissue reconstruction. We have reviewed the basic principles and practices used in craniofacial reconstruction, and this treatise is by no means exhaustive. There is no one best solution for bone and soft tissue repair. Instead, physicians must devise a treatment plan that carefully weighs the benefits and pitfalls inherent in each surgical alternative and balances these considerations with the patient's condition and goals. Further research and biomaterial development should lead to better operative outcomes and the creation of more effective, safe treatment options to correct tissue losses associated with trauma, disease, and aging.

6.622.1. Introduction

The first events after an implant comes in contact with tissues are due to interactions of the biological environment with the implant surface. Upon implantation, the implant surface is coated with an adsorbed layer of proteins, ions, sugars, and lipids present in the blood and tissue fluid. The onset of the biological reactions, as well as the particular response pathways in the bone surrounding the implant, depends strongly on a variety of surface properties, including topography, chemistry, charge, and tension (Figure 1). This chapter focuses on the role that the microtopography of the surface has in modulating cell behavior at the bone–implant interface.

It has been understood for some time that bone tends to form on rough surfaces, whereas fibrous connective tissue forms on smooth surfaces.[1–5] To capitalize on this empirical observation, implant manufacturers designed surfaces that had porous coatings with the intent to promote bony ingrowth. The results have been less than anticipated, in part because the microtopography of the surface that was sensed by individual cells was perceived by them as smooth.[1] More recently, investigators have examined microroughness effects and have noted that R_a values of 4–5 μm tend to enhance osteogenic differentiation both *in vitro*[6] and *in vivo*.[7]

In general, dental implants are produced by machining titanium rods. Machined surfaces are macroscopically smooth, although microscopic irregularities exist. These microscopic grooves and pits are the result of the machining operation and have dimensions in the micron range. Although there are minor differences in the microroughness and appearance of machined surfaces,[8–10] they have not been proved to be of clinical significance.[9]

In order to increase the implant surface in contact with bone and interaction with the bone formation process, most manufacturers modify the titanium surfaces, applying several surface treatments or coatings (see Chapter 1.112, Calcium Phosphate Coatings and Chapter 1.113, Bioactive Layer Formation on Metals and Polymers). One approach is to increase the surface roughness by grit blasting.[11] Implants can be blasted with silica, alumina, glass, or titanium particles, which erode the substrate and form an irregular surface with pits and depressions of various sizes.[12] The size of the irregularities depends on various factors such as the size and material of the blasting particles, the pressure used, the blasting time, and the distance from the blasting nozzle. Some blasted particles can remain embedded in the implant surface. This is an undesirable occurrence as the embedded particles can be released later in the biological environment, causing activation of phagocytes. To minimize this occurrence,

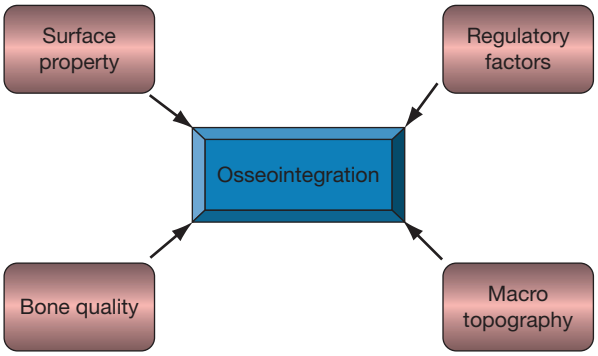

Figure 1 Schematic illustrating the various surface features that influence osseointegration.

meticulous postblasting cleaning procedures are used, such as chemical etching.[13]

Chemical etching is also used to increase the surface roughness of oral implants.[14] It can be applied after machining or grit blasting, further increasing the complexity of the surface microstructure.[15,16] While most chemical etching uses one acid, a dual etching procedure using HCl and H_2SO_4 has also been used.[17] This treatment results in small regular pits on the implant surface, doubling the surface area of the implant.[17]

Another treatment that increases surface microroughness is plasma spraying. In this process, individual titanium particles are suspended in a plasma torch and projected onto the implant.[18,19] During this process, local melting typically occurs, resulting in a surface that is characterized by depressions and protrusions with extremely irregular regions as well as relatively smooth areas.

Not only does the surface topography at the micron and submicron scale affects cell response, but features at the nanoscale have also been demonstrated to influence cell behavior (see **Chapter 4.409, Surfaces and Cell Behavior** and **Chapter 1.129, Engineering the Biophysical Properties of Basement Membranes into Biomaterials: Fabrication and Effects on Cell Behavior**).[20–23] The primary nonmineral component of bone, type I collagen, consists of fibers of approximately 300 nm in length and 0.5 nm in width. The mineral hydroxyapatite crystals in bone are generally around 50 nm in length and 5 nm in diameter.[24] Research suggests that features at the nanoscale may in fact aid in new bone formation at the tissue–implant interface. In one study, it was shown that composite materials possessing nanophase surface structural features comparable to natural bone (i.e., grain sizes in the nanometer range) support greater osteoblast adhesion and mineral deposition compared to conventional ceramics.[25]

To understand the role of surface microroughness on osseointegration, *in vitro* studies have been conducted to evaluate the mechanisms by which the micron-scale topographical features of an implant mediate their effects on bone cell behavior. *In vivo* studies have been conducted to determine if surface microarchitecture has an effect clinically on the relative success of a particular implant design. Investigators have begun to resolve the difficulties in characterizing implant surfaces where nanostructure is imposed upon microscale topography,[26] but it is not yet understood what influence features at this level will have on cell and tissue response.

6.622.2. *In Vitro* Studies

Osteoblast attachment to materials, and their proliferation, extracellular matrix synthesis, and differentiation are sensitive to the microtopography of the surface.[27] On titanium surfaces with microrough rugosities, osteoblasts assume a more differentiated morphology. Attachment is reduced on these surfaces in comparison with tissue culture polystyrene or smooth titanium surfaces. In addition, those cells that do attach exhibit reduced proliferation. In contrast, these cells show increased markers of osteoblastic differentiation. The cells exhibit increased levels of alkaline phosphatase-specific activity and osteocalcin, and they produce factors that are known to modulate osteoclastic activity,[28] as described below. Moreover, osteoblast phenotypic expression and the levels of regulatory factors in the conditioned media are modulated by the vitamin D metabolite $1\alpha,25(OH)_2D_3$ ($1\alpha,25$-dihydroxy vitamin D_3) in a manner that is synergistic with surface roughness.[29] Osteoblast response to BMP-2 also depends on surface features[30] and fetal rat calvarial cells are regulated by BMP-2 and dexamethasone under similar culture conditions.[31] Moreover, normal human osteoblasts are regulated by 17β-estradiol in a roughness-dependent manner.[32]

These observations indicate that the microstructural features of an implant surface modulate bone formation, and suggest the hypothesis that microtopography might be a factor regulating osteogenesis on bone surfaces as well. Studies examining the response of human MG63 osteoblast-like cells to the surfaces of dentin and bone wafers support this observation (see **Chapter 2.210, Bone as a Material**). When these cells are cultured on dentin or bone wafers, they exhibit reduced proliferation and increased differentiation in comparison with cells grown on tissue culture polystyrene.[33,34] This surface effect is further enhanced when the wafers are treated with osteoclasts. It is clear that part of the effect of osteoclastic resorption is due to biochemical conditioning of the surface and not simply to removal of mineral. If only 3% of a dentin surface is removed via osteoclastic resorption, the effect on osteoblasts is greater than that caused by demineralization of the entire surface with tetracycline. It has been shown that osteoclasts deposit attachment factors during the resorptive process.[35] However, at least part of the osteoclastic response is microtopography dependent. Resorption of mineral leaves a complex micro- and nanotopography that can be modeled using titanium substrates (**Figure 2**).

Surface-dependent changes in osteoblast physiology can result in altered paracrine regulation in peri-implant tissues (**Figure 3**). Many of the factors produced in increased amounts by osteoblast-like cells grown on microrough titanium surfaces are known to regulate bone remodeling by differentially affecting osteoblasts and osteoclasts. As surface microroughness increases, levels of PGE_1 and PGE_2 in the conditioned medium also increase.[36] The amount of PGE_2 produced also appears to be sensitive to the method used to fabricate microtextured surfaces[37] and to the osteoblast-like cell model.[38] Monocytes also exhibit increased PGE_2 production on Ti surfaces in comparison with plastic, but increases due to LPS stimulation are not dependent on microarchitecture.[39]

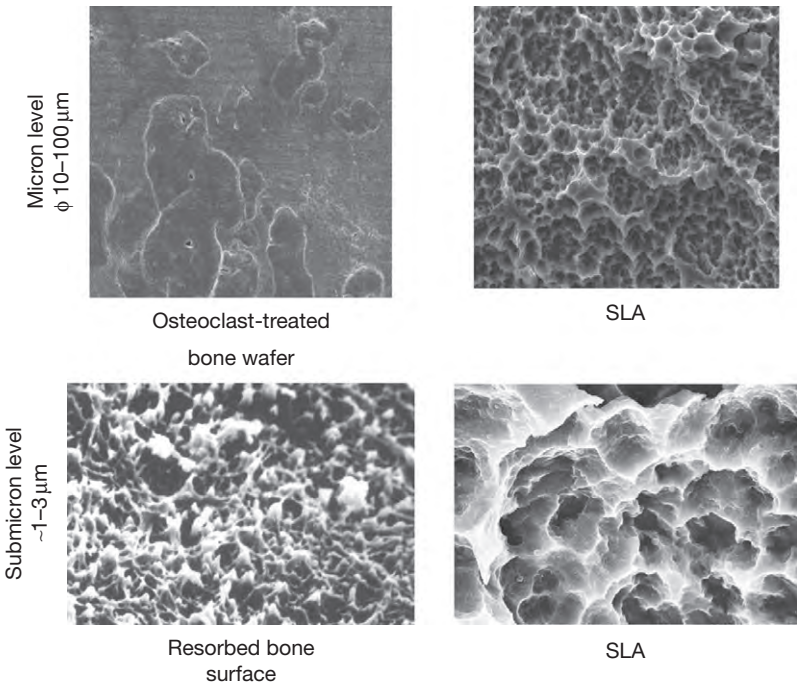

Figure 2 Scanning electron micrograph images showing the similarities between osteoclast resorbed bone surfaces and sandblasted, acid-etched titanium surfaces. Figure 3 Processes involved in osseointegration. Events at the implant surface, including osteoprogenitor cell attachment, proliferation, and differentiation, lead to release of local regulatory factors in the peri-implant space. These factors contribute to the recruitment of osteoblast-progenitors on the endosteal bone surface and suppression of osteoclast formation and activity. Studies also show that implant materials placed at one site in bone can affect bone formation at distal sites, supporting the hypothesis that factors are released locally that become systemic.

PGE_2 stimulates osteoclastic activity at high levels, but it is required at low levels for osteoblast activity.[40,41] The elevated prostaglandins that are seen in cultures grown on rough microtopographies appear to be required for enhanced osteogenesis as inhibition of prostaglandin production by indomethacin blocks the increase in osteoblast phenotypic expression on these substrates.[42] Moreover, $1\alpha,25(OH)_2D_3$ stimulates PGE_2 production by MG63 cells only when they are grown on the rougher surfaces and this stimulatory effect is dose dependent and synergistic with the surface effect.[43]

Growth factor production and storage are regulated as well, as shown in studies using TGF-β1 as a model. TGF-β1 stimulates proliferation of mesenchymal cells and enhances the production of extracellular matrix, particularly of type I collagen.[36] It is synthesized in latent form and stored in the extracellular matrix together with a binding protein termed latent TGF-β binding protein. When MG63 cells are cultured on Ti surfaces of increasing roughness, most of the TGF-β1 produced is in latent form, and the amount increases on surfaces with rough microtopographies.[36] The regulation of TGF-β1 production on Ti surfaces depends on the osteoblast-like cell model used.[37,38] In studies using MG63 osteoblast-like cells as the model, the distribution of TGF-β1 between the matrix and the conditioned media of the cells is affected. On rougher surfaces, there is a greater incorporation of TGF-β1 into the matrix.[44] This is important for later bone remodeling because osteoclasts release TGF-β1 during the resorption phase and activate it. Once activated, TGF-β1 can act on the osteoclast to downregulate its activity.

The amount of TGF-β1 produced by osteoblasts cultured on Ti is modulated in a surface-dependent manner by factors that regulate osteogenesis and subsequent bone resorption. 17β-Estradiol has no effect on the TGF-β1 content of the media of MG63 cells grown on smooth Ti surfaces but when these cells are cultured on rougher microtopographies, 17β-estradiol causes a dose-dependent increase in the levels of TGF-β1.[33,34] The vitamin D metabolite $1\alpha,25(OH)_2D_3$ causes a similar effect.[29] $1\alpha,25(OH)_2D_3$ does not alter TGF-β 1 levels in cultures grown on smooth Ti, but it increases TGF-β1 levels in the media of cells grown on rougher surfaces and the effect is dose dependent.[29]

In vivo, it is likely that immune cells interact with implant surfaces before osteoblast-progenitor cells migrate onto the implant surface (see **Chapter 4.403, The Innate Response to Biomaterials**). Ti surface topography affects these cells as well. Macrophage and monocyte attachment and spreading, and BMP-2 expression are increased on microrough titanium.[39,45] Thus, the behavior of cells grown on surfaces with rough microarchitectures is altered both with respect to their basal production of autocrine factors and with respect to their ability to produce these factors in response to hormonal regulation. Moreover, the response is to increase production of factors that promote early stages of bone formation and retard osteoclastic resorption.

These studies suggest that other factors that modulate osteoclastogenesis might be modulated as well. To test this, an examination of osteoblast-dependent regulation of osteoclasts via receptor activator of nuclear factor κ B (RANK) ligand (RANKL) was initiated (see Khosla[46] for a review of the RANKL regulatory system). Osteoblasts retain RANKL on their plasma membranes. When RANKL binds its receptor RANK on osteoclasts, osteoclastic resorption is activated. To control this phenomenon, osteoblasts also produce a decoy receptor termed osteoprotegerin (OPG), which binds to RANKL, preventing it from interacting with RANK. If the regulatory stimulus now favors osteoclasts but excess OPG is present, the osteoblast may also produce soluble RANKL (sRANKL), which can then bind the OPG, leaving membrane-associated RANKL to interact with RANK on the osteoclasts. Thus, excess OPG would favor osteogenesis over bone resorption. When grown on titanium substrates with rough microtopographies, MG63 cells produce higher levels of OPG and this is further increased by $1\alpha,25(OH)_2D_3$ in a synergistic manner, but no change occurs in the expression of sRANKL.[47]

In addition to regulating osteoblast attachment, morphology, differentiation, and local factor production, Ti implant roughness also modulates the production of angiogenic factors by osteoblasts.[48] Clinically, the success of implanted materials in orthopedics and dentistry is dependent not only on bone apposition at the implant–tissue interface, but also on the establishment of a vascular supply in the peri-implant bone to allow for the delivery of oxygen and nutrients, as well as systemic hormones and osteoblast-progenitor cells. Angiogenesis, the sprouting of new capillary blood vessels from the preexisting vasculature, is a critical process during embryonic development and in several physiological conditions, including the formation of new bone and bone fracture healing,[49,50] as well as during bone regeneration and osseointegration of implanted materials.[51] This suggests that materials that support peri-implant bone formation may support angiogenesis as well as osteogenesis.

Both MG63 cells and normal human osteoblasts secrete several proangiogenic growth factors into their conditioned medium, including vascular endothelial growth factor A (VEGF-A), basic fibroblast growth factor (FGF-2), and epidermal growth factor (EGF).[48] When these cells are cultured on smooth Ti, secretions of VEGF-A, FGF-2, and EGF are increased compared to cells cultured on tissue culture polystyrene. On microrough Ti substrates, there is a further increase in secretion of these proangiogenic growth factors. The production of angiopoietin-1 (Ang-1), a marker of later stages of angiogenesis, was not affected by Ti implant microtopography. The increased production of proangiogenic growth factors by MG63 cells cultured on Ti substrates with a rough microtopography resulted in increased endothelial tubule formation in both Matrigel® and fibrin gel angiogenesis assays,[48] suggesting that implant surface roughness may directly enhance neovascularization as well, potentially resulting in greater clinical success of implanted materials. Recently, it was found that the receptor $\alpha_2\beta_1$ integrin regulates the expression of proangiogenic growth factors.[48]

Most studies examining the osteogenic potential of implant surfaces *in vitro* have used cells that are either immature osteoblasts or osteoblast cell lines.[52–54] However, the first group of mesenchymal cells to colonize the implant surface must be able to migrate through the peri-implant clot, and are likely to be multipotent progenitor cells.[55,56] Mesenchymal stem cell (MSC) differentiation to an osteoblast phenotype is sensitive to implant surface microstructure.[57] MSCs cultured on Ti substrates exhibited osteoblast characteristics indicated by a reduction in cell number and increases in alkaline phosphatase-specific activity, osteocalcin, OPG, and TGF-β1. In addition, MSCs cultured on smooth Ti substrates displayed increased mRNA levels of RUNX2 and integrins α_2 and β_1 relative to tissue culture polystyrene controls.[57] These increases were further enhanced in MSC cultures on microrough Ti substrates. In the same study, a coculture model was developed in which conditioned media from MG63 cells cultured on both smooth and microrough Ti substrates resulted in the osteogenic differentiation of MSC cultures.[57] Taken together, these data demonstrate that surface microstructure is able to direct MSCs toward an osteoblast lineage without the use of osteogenic growth factors in the culture media, and that differentiated osteoblasts cultured on implant surfaces with microrough rugosities create a sufficient environment for osteogenic differentiation of surrounding MSCs.

6.622.3. Mechanisms Mediating the Microtopography Effect

Prostaglandin plays an important role in mediating the effects of surface microtopography on osteoblast physiology. As noted above, the amount of PGE_1 and PGE_2 released into the conditioned media by MG63 osteoblast-like cells increases as surface microroughness increases.[36] Blocking prostaglandin production with the general cyclooxygenase (Cox) inhibitor indomethacin also blocks the increase in markers typical of mature osteoblasts. Both constitutive Cox-1 and inducible Cox-2 are involved, as inhibitors specific to only one form of the enzyme fail to block all prostaglandin-dependent responses.[58]

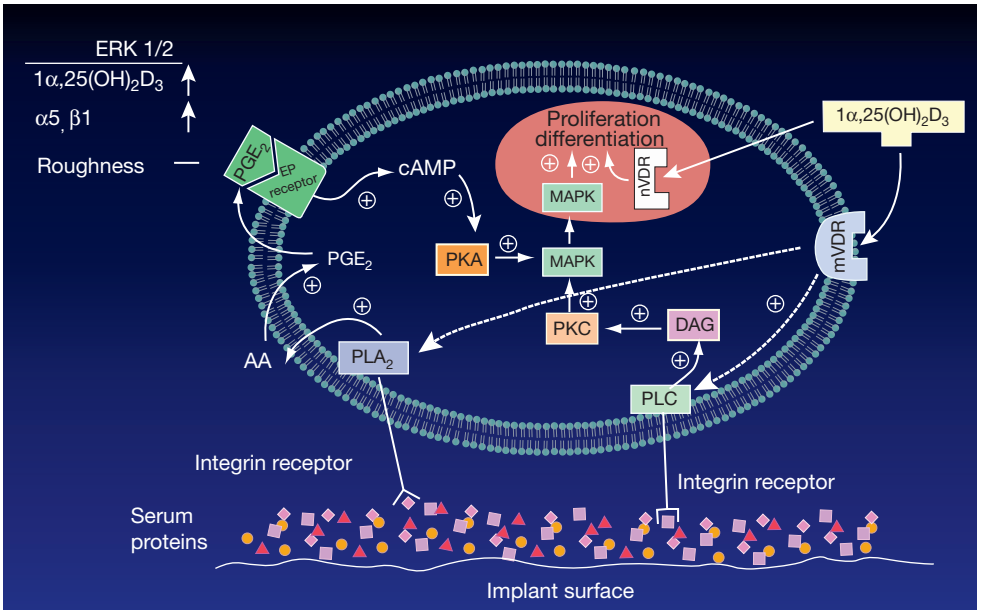

Figure 4 Integrin- and $1\alpha,25(OH)_2D_3$-mediated signaling and the interaction of the two pathways on osteoblasts grown on titanium surfaces.

Cells that are attachment dependent interact with their substrate through a number of mechanisms, including specific binding of integrins to components of the extracellular matrix, as well as to proteins adsorbed on the substrate surface (Figure 4). Part of the effect of surface microroughness on BMP-2 production by J774A.1 macrophages is mediated by the β_1 integrin and to a lesser extent by the β_3 integrin.[45] One of the integrins that mediates the binding of osteoblasts to proteins containing the arginine-glycine-aspartic acid (RGD) motif is $\alpha_5\beta_1$.[59] This binding initiates a signaling cascade resulting in new gene expression and protein synthesis. The signaling cascades initiated by integrin binding include protein kinase C (PKC)-dependent phosphorylation, culminating in mitogen-activated protein (MAP) kinase activation.[60] Part of the effect of $1\alpha,25(OH)_2D_3$ on osteoblasts is also mediated via this signaling pathway,[60] which may explain why MG63 cells respond in a synergistic manner to this vitamin D metabolite when they are cultured on microrough topographies.

To test this hypothesis, confluent cultures of MG63 cells were cultured for 24 h on smooth ($R_a < 0.6\,\mu m$) and rough (R_a 4–5 μm) titanium disk surfaces in the presence and absence of 10^{-8} M $1\alpha,25(OH)_2D_3$. One half of the cultures were treated with the MAP kinase inhibitor PD98059, which is specific for the ERK1/2 (extracellular regulated kinase) family of MAP kinases. The results of this study show that the decrease in cell number and increase in osteocalcin levels observed on rough surfaces are not regulated in this manner although the enhanced response to $1\alpha,25(OH)_2D_3$ is via ERK1/2. In contrast, the increase in alkaline phosphatase-specific activity on rough surfaces is due in part to ERK1/2, as is the stimulatory effect of $1\alpha,25(OH)_2D_3$ on this enzyme activity.[60] Thus, phenotypic expression due to surface microtopography may be modulated by multiple interacting pathways.

Recently, it was shown that MG63 cells exhibit increased phospholipase D (PLD) activity on sandblasted Ti surfaces and inhibition of PLD by 2,3-diphosphoglyceric acid reduced alkaline phosphatase-specific activity and osteocalcin production,[61] suggesting that PLD may also play a role in osteoblast differentiation on rough Ti substrates.

The main function of PLD is to hydrolyze membrane phosphatidylcholine (PC) to generate the precursor signaling molecules phosphatidic acid (PA) and choline.[62] PA can also be converted to lipid second messengers, such as lysophosphatidic acid (LPA) and diacylglycerol (DAG), which mediate the functional role of PLD. PA can be metabolized to DAG by PA phosphatase, which recruits PKC to the membrane to activate it.[63–65] This raises the possibility that changes in PLD activity might mediate the effects of surface microstructure on osteoblasts via PKC. To test this, PLD expression and activity in MG63 cells cultured on smooth and microstructured Ti substrates were examined.[66] PLD activity was inhibited using RNA interference for the PLD isoforms PLD1 and 2. The results of the study showed that inhibition of both PLD isoforms reduced surface roughness-dependent increases in osteoblast differentiation and reduced PKC activity, suggesting that PLD is upstream of PKC in mediating osteoblast response to surface microstructure. It was further shown that PLD2 is the primary isoform involved in this process.[66]

Osteoblasts assume distinct morphologies depending on the architectural features of their substrates. On microrough surfaces, as long as the peak-to-peak distance is less than the length of the cell body,[67] the cell bodies become more cuboidal, and anchor themselves to the surface through long dendritic filopodia.[1] In contrast, on the smoother surfaces, the cells flatten and spread, resulting in a fibroblastic appearance. The cell morphology correlates with the physiological behavior of the cells. On smooth surfaces, prostaglandin synthesis is low, TGF-β1 levels are low, alkaline phosphatase-specific activity is low, and osteocalcin levels are low, whereas proliferation rates are relatively high in comparison with cells cultured on rougher surfaces.[36] Moreover, these parameters are either not affected by $1\alpha,25(OH)_2D_3$ or the effect of the

hormone is minimal, supporting a fibroblastic phenotype. In contrast, on rougher surfaces, proliferation is reduced and the other parameters are increased, including responsiveness to $1\alpha,25(OH)_2D_3$, supporting a mature secretory osteoblast-like phenotype.[33,34]

It is not yet clear if the change in morphology precedes the expression of a more mature physiology or if the differentiation of the cell is activated by another yet-unidentified factor and the cell now responds differently to the surface microarchitecture. Observations suggest that the architecture of the surface forces the cells to adapt their morphology and this is translated to the cell through the integrin receptor system.[68] In subsequent experiments, cells were cultured on smooth and microrough Ti disks that were coated with polyethylene glycol (PEG) grafted to poly-L-lysine (PLL-*g*-PEG) to prevent nonspecific adhesion of serum proteins.[69] The experiment was conducted in three formats: cells were cultured on (a) PLL-*g*-PEG alone, and PLL-*g*-PEG on which a subset was modified to exhibit an RGD peptide; (b) PLL-*g*-PEG surfaces containing varying concentrations of the RGD peptide up to the concentration tested under format (a); and (c) PLL-*g*-PEG as defined in subset (a) in the presence of a soluble competing RGD peptide. The results of this study[69] indicate that MG63 cells will attach to PLL-*g*-PEG and those that do so exhibit the physiology of a mature osteoblast. Perhaps the most important observation is that inclusion of the RGD peptide on the surface restores the cells to the immature phenotype noted on smooth surfaces and tissue culture plastic, whereas inclusion of the inactive RDG peptide has no effect.[69]

The combination of osteoblast-specific peptide adhesive ligands with rough implant surface microtopographies could potentially enhance early osteoblast attachment and differentiation to better promote osseointegration and improve long-term implant fixation. It is unlikely that any one mimetic is responsible for all responses of osteoblasts on a functionalized surface. Integrin-mediated cell adhesion to extracellular matrix proteins initiates a cascade of intracellular signaling events that serve to direct cell differentiation and function.[68] Osteoblasts express several integrin subunits, including α_1, α_2, α_3, α_4, α_5, α_6, α_v, β_1, and β_3.[70–72] On tissue culture polystyrene, osteoblasts primarily express $\alpha_5\beta_1$ integrins.[73] However, when grown on Ti substrates, expression of α_2 and β_1 integrin subunits is increased,[74] indicating that the surface roughness-dependent differentiation of osteoblasts may be mediated specifically through $\alpha_2\beta_1$ signaling. Studies using antibodies to $\alpha_5\beta_1$, the integrin that binds RGD in fibronectin, and $\alpha_2\beta_1$, the integrin that binds type I collagen, indicate that the former is responsible for attachment and proliferation, but differentiation is mediated by the latter.[75,76] This suggests that combinations of peptide mimetics may be more effective than materials that are functionalized with a single motif.

To test this hypothesis, MG63 osteoblast-like cells were cultured on microrough Ti implant surfaces coated with a combination of peptide motifs: RGD to target $\alpha_5\beta_1$ integrin signaling, and a lysine-arginine-serine-arginine (KRSR) peptide sequence that is hypothesized to target transmembrane proteoglycans present on osteoblasts.[77] In addition, microrough Ti implant surfaces were coated with a lysine-serine-serine-arginine (KSSR) peptide sequence that is not known to target osteoblast binding. The results of the study demonstrated again that Ti surface coating with RGD increased osteoblast attachment but reduced osteoblast differentiation. In a similar manner, surfaces coated with either KRSR or a combination of RGD/KRSR inhibited overall osteoblast differentiation compared to uncoated, microrough Ti surfaces, as seen by reduced levels of alkaline phosphatase-specific activity, and levels of osteocalcin, PGE_2, and TGF-β_1. Conversely, surface coating with KSSR promoted a differentiated osteoblast phenotype with reduced cell number and increases in alkaline phosphatase activity and levels of osteocalcin and PGE_2 compared to uncoated surfaces. These data indicate that a combination of rough surface microarchitecture and surface functionalization with mimetic peptide sequences may further enhance osteoblast differentiation, although further study is needed to determine the mechanism by which KSSR mediates its effect.[78]

The $\alpha_2\beta_1$ integrin recognizes and binds the glycine-phenyalalanine-hydroxyproline-glycine-glutamate-arginine (GFOGER) motif present on residues 502–507 of the α_1(I) chain of type I collagen.[79,80] To examine whether the GFOGER peptide motif promoted osteoblast attachment and differentiation, biomolecular surface coating of GFOGER was done on glass and Ti substrates and the response of osteoblasts was examined both *in vitro* and *in vivo*.[81]

Tissue culture polystyrene dishes were coated with a 300 Å titanium layer via electron beam evaporation. The GFOGER peptide sequence was passively adsorbed onto the Ti surfaces. The results of the study showed that bone marrow stromal cell adhesion on GFOGER-coated Ti substrates was significantly higher compared to substrates coated with RGD peptide motif, and cells cultured on GFOGER-coated surfaces displayed higher mRNA transcript levels of Runx2, osteocalcin, and bone sialoprotein compared to cells cultured on uncoated Ti substrates.[81] Examination of osteoblastic differentiation showed that surface coating with the GFOGER peptide motif increased alkaline phosphatase-specific activity as well as calcium content *in vitro*, relative to uncoated controls.[81]

To evaluate the performance of the GFOGER peptide motif *in vivo*, osseointegration in a rat tibia cortical bone model was quantified on GFOGER-coated smooth Ti surfaces using histomorphometry and pull-out mechanical testing. After 4 weeks, greater bone mineral was observed along GFOGER-coated Ti implants versus type I collagen-coated and -uncoated controls and quantification of bone to implant contact (BIC) revealed a greater than twofold increase in BIC in GFOGER-coated Ti substrates versus -uncoated controls. Pull-out force of GFOGER-coated implants was also significantly higher compared to that of both uncoated and type I collagen-coated implants.[81] These results suggest that direct targeting of the $\alpha_2\beta_1$ integrin on osteoblasts promotes cell adhesion and osteoblast maturation *in vitro* and promotes osseointegration *in vivo*. It is important to note that in this study, only smooth Ti substrates were examined and the effect of implant microroughness and GFOGER surface coating is not known.[81]

Responses to the surface also depend on the state of maturation of the cell in the osteoblast lineage. Numerous cell lines and primary cell cultures have been examined in this model, from the multipotent fetal rat calvarial cells to the osteocyte cell line MLO-Y4.[31,82] These experiments indicate that as cells become more mature, the stimulatory effect of the microrough surface on differentiation becomes attenuated. However, it is

only on rough surfaces and only in the presence of BMP-2 that fetal rat calvarial cells are able to establish three-dimensional nodules that form minerals in a physiologically relevant manner.[31] Why this is the case is not yet clear. The results support *in vivo* observations that a material can affect cells directly on the surface as well as cells distal to the biomaterial,[83] indicating that the extracellular signaling factors released by the cells in direct contact with the material are sensed by other cells in the microenvironment, and potentially systemically as well.

6.622.4. *In Vivo* Studies

It has been difficult to definitely determine the relative clinical value of specific surface morphologies because of the confounding variables of surface chemistry, surface energy, and clinician expertise, and the inherent variability of the human patient population. Recently, Albrektsson and Wennerberg[84] reviewed the literature related to topographic and chemical properties of implants and concluded that moderately rough surfaces, defined as having S_a values between 1 and 2 μm, exhibited 'stronger bone responses' than either smoother or rougher surfaces. Some studies have reached similar conclusions, but other studies have reached quite different conclusions. A representative sample is described here.

In a meta-analysis published in 1999, evaluation of clinical data revealed that predictably high success rates can be achieved for implants with both rough and smooth titanium surfaces. When studies were clustered by specific indications or patient populations, rough-surfaced implants had significantly higher success rates compared to implants with smoother surfaces except in the cases of single tooth replacement where success rates were comparable. However, in the partially edentulous patient group, titanium implants with rough surfaces had significantly higher success rates in the maxilla than in the mandible.[85] A multicenter study compared 247 dual acid-etched (HCl/H_2SO_4) and 185 machined-surfaced implants implanted in various bone qualities in 97 patients. It was found that at 36 months, the cumulative success rates (CSRs) were 95% for the dual acid-etched and 86.7% for the machined-surfaced implants.[86]

Several studies have addressed various types of surface roughness (**Figure 5**) and their effects on human bone formation. A comparison of the BIC at 6 months was conducted for dual acid-etched and machined commercially pure titanium implant surfaces in 11 patients. Two-surfaced titanium microimplants were manufactured. One side received the rough surface modification and the opposite side maintained a machined surface. In each patient, one test implant was placed in the posterior maxilla during conventional dental implant surgery. Histologic analysis following 6 months of unloaded healing indicated that the mean BIC values for the rough surfaces were $72.96 \pm 25.13\%$ and BIC values for the smooth surfaces were $33.98 \pm 31.04\%$.[17] A similarly designed study examined the relationship between the actual BIC and the expected BIC after 6 months of nonloaded healing using both rough and machined implant surfaces. The investigators found that the actual BIC for rough surfaces was greater than expected, whereas the actual BIC for the machined surface was generally lower than expected.[87]

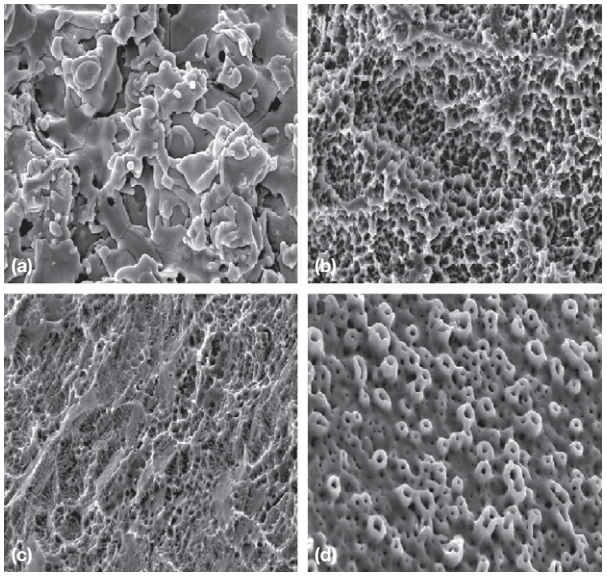

Figure 5 Scanning electron micrographs showing the different microrough morphologies on the surfaces of four commercially available dental implants: (a) titanium plasma-sprayed (TPS) surface; (b) sandblasted and acid-etched Ti surface (SLA®, Institut Straumann AG, Switzerland); (c) acid-etched Ti (Osseotite®, Biomet 3*i*, Palm Beach Gardens, FL); and (d) phosphate-enriched Ti oxide (TiUnite®, Nobel BioCare, Sweden).

The response of human bone tissue to oxidized and turned (machined) titanium surfaces has also been examined.[88] Twenty patients received one oxidized and one turned microimplant each during implant surgery. After a mean healing period of 6.6 months in the maxilla and 3.5 months in the mandible, the microimplants and surrounding tissue were removed. Histomorphometric evaluation demonstrated significantly higher BIC for the oxidized implants. Whether this was due to the fact that the oxidized implants have greater surface area because of the micron-scale TiO_2 cones produced during fabrication, or to the roughness itself, is not known. Moreover, significantly more bone was found inside the threaded area for the oxidized implants, whether placed in the maxilla or mandible, supporting a number of studies indicating that macroroughness is also a factor in osseointegration.

Placement of dental implants is often done under adverse conditions. Several articles have examined the influence of surface roughness on clinical outcomes when the implant is placed in poor quality bone, augmented ridge, or sinus. In a meta-analysis examining the cumulative success rate of 2614 machined-surfaced implants and 2288 dual etched-surfaced implants, the machined-surfaced implants had a 4-year CSR in all bone sites of 92.7%. For the implants placed in good bone, the 4-year CSR was 93.6% compared with the 4-year CSR in poor (soft) bone of 88.2% ($P < 0.05$). However, for rougher dual-etched implants in all sites, their overall 4-year CSR was 98.4% in good bone, and 98.1% in poor bone.[89] Another study compared the overall survival rate of 78 machined and 80 sandblasted, acid-etched implants that were inserted in an augmented bone of a reconstructed atrophied maxilla. The implants were followed between 20 and 67 months postimplantation. Fifteen machined implants, but only two

sandblasted, acid-etched implants, were lost. The overall survival rate for the machined implants was 81% and for the sandblasted, acid-etched implants 98%.[90]

A recent published systematic review analyzed the data from 43 human studies with a minimum of 20 interventions and a minimum follow-up period of 1-year loading of implants placed in sinuses augmented with the lateral window technique. The results pointed out that rough-surfaced implants have a significantly higher survival rate than machine-surfaced implants when placed in grafted sinuses. However, there was no statistical difference between different types of rough-surfaced implants.[91]

Custom-made microimplants with two different surface topographies were used to compare the effect of machined and microtextured surfaces on BIC in augmented human maxillary sinuses.[92] After 6 months of submerged healing, the microimplants were removed with the surrounding bone. Histologic analysis revealed that the mean BIC was significantly greater on the microtextured surfaces ($72 \pm 17\%$) compared to machined surfaces ($38 \pm 19\%$).

Other *in vivo* studies support the hypothesis that rough implant surfaces enhance osseointegration. Significant increases in pull-out strength between weeks 5 and 8 were noted with dual-etched Ti implants, and these increases were maintained.[93] Removal torque values (RTVs) of dual acid-etched and titanium plasma-sprayed (TPS) implants attained at 2 months postimplantation were comparable to those achieved only after 3 months of healing by the machined implants.[94] This may reflect higher BIC on the rougher surfaces. In order to compare the effectiveness of machined and acid-etched implants on BIC following short healing times in human posterior maxillas, custom-made microimplants were placed in 11 patients and allowed to integrate for 2 months. Histologic analysis of the surrounding bone showed that the BIC on the dual acid-etched side was 47.8%, significantly higher than the BIC on the machined side of 19%.[95] Moreover, the BIC on the dual acid-etched side was higher than that found in a previous study even after 6 months on the machined side (33.98%).[17]

It has been advocated that after implant placement, surgical sites should be undisturbed for at least 3–6 months to allow uneventful wound healing, thereby enhancing osseointegration between the implant and bone. The rationale behind this approach is that implant micromovement caused by functional force around the bone–implant interface during wound healing may induce fibrous tissue formation rather than bone leading to clinical failure.[96] Use of implants with microrough surfaces may permit clinicians to reduce or even eliminate the preplacement healing period. Histomorphometric analysis of bone surrounding two immediate loaded dual-etched implants implanted in the mandible and retrieved after 4 months of function showed high levels of BIC ranging from 78% to 85%.[97]

This case report led several groups of researchers and clinicians to redefine the minimum healing time needed before loading a rough surface dental implant. In a prospective multicenter study evaluating loading of 429 dual-etched implants 2 months after placement, only seven implants were lost at 2 years postloading. Six of these implants were identified prior to loading. The cumulative implant survival rate was 98.5% at 12.6 months. The cumulative postloading implant survival rate was 99.8% at 10.5 months.[98] Similar results were found when other groups examined the survival rates of sandblasted, acid-etched implants restored as early as 6 weeks after implant placement surgery. Out of 329 implants, three were lost prior to abutment connection. The success rate for these implants, 2 years after restoration, was 99.3%.[99]

In a paper published recently, sandblasted, acid-etched implants were placed in molar and premolar areas of the mandible according to a one-stage protocol and were loaded 2 or 6 weeks after implantation. After 1 year, the implant survival rate was 98.8%. Two test implants and one control implant rotated at time of abutment connection and were left unloaded for 12 additional weeks and then loaded. Loading the implants as early as 2 weeks did not appear to jeopardize osseointegration in the posterior mandible.[100]

Patient smoking is often attributed to the failure of dental implants to achieve osseointegration. An interesting meta-analysis examined the outcomes of clinical studies that monitored the performance of 2609 machined-surfaced and 2274 dual acid-etched implants and also isolated the effect of smoking. Among the machined implant surfaces, the 3-year CSR was 92.8% for nonsmokers and 93.5% for smokers while the 3-year CSR for dual acid-etched implants was found to be 98.4% for nonsmokers and 98.7% for smokers, resulting in no significant differences between smokers and nonsmokers. There was, however, a clinically relevant difference observed between the two implant types.[101]

6.622.5. Summary

Increased surface roughness of dental implants enhances the process of osseointegration. It increases bone formation and increases BIC in all types of bone, resulting in elevated RTVs. In preparing histologic sections of implants with their surrounding bone, the weak point when smooth surfaces are used is at the implant–bone interface. However, if rough surfaces are used, the weak point is inside the bone and not at the implant–bone interface (**Figure 6**). Surface roughness elevated the cumulative success rate of implants implanted in adverse conditions such as augmented ridges and sinuses and areas of poor bone such as posterior maxilla, and in some cases abolished the deleterious effect of smoking. A growing number of clinical studies suggest

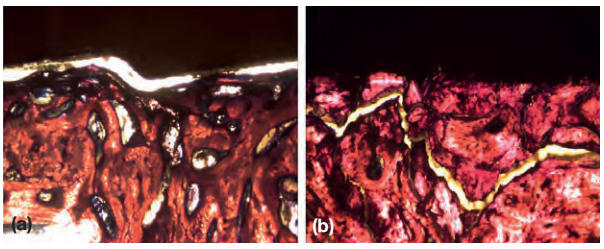

Figure 6 Histologic micrographs of the bone–titanium surface interface showing the fracture plane caused by sectioning: (a) smooth-surfaced implant; (b) rough-surfaced implant. Sections are stained with hematoxylin and eosin.

that early and immediate loading of rough-surfaced implants may lead to predictable osseointegration. However, it is important to note that these studies provide short-term results based only on radiographic observations and clinical mobility. Before we adopt new surgical and prosthetic guidelines, longer and broader studies are needed. Most recent research has examined the effect of surface roughness on bone healing around implants *in vivo* and the influence of surface roughness on osteoblasts *in vitro*. In a recent study, it was found that changing surface chemistry by submerging an implant in an isotonic NaCl solution following acid etching to avoid contamination with molecules from the atmosphere significantly increased osteoblast differentiation *in vitro* and BIC *in vivo*.[102]

Glossary

Bridge Restoration that replaces one or more missing teeth and that is supported by neighboring teeth or by implants. Also coined fixed (partial) dental prosthesis (F(P)DP).

Cantilever A cantilevered artificial tooth or pontic attached toward neighboring tooth abutments.

Direct restoration Mode of manufacturing chair side by the dentist in a moldable consistency (e.g., composite, amalgam).

Indirect restoration Mode of manufacturing by a dental lab or production unit (e.g., cast or milled from an alloy or ceramic blank).

Inlay Partial restoration not covering the tooth cusps.

Onlay Partial restoration covering the tooth cusps.

Post-and-core Root canal post, cast with the tooth core to build the basis of a devitalized tooth.

Precision attachment Patrix (male) and matrix (female) device that fits precisely the one into the other aiming at replacing, for example, cast claps in removable partial dentures to guarantee retention to the latter.

Pyroplastic flow A characteristic of a material by overheating, for example, the flow of the molten glass.

Resin-bounded Mode of connection (micromechanical) of a restoration during cementation by means of a composite luting cement after pretreatment of the tooth and restoration by acid-etching.

Veneer Restoration that covers, for example, tooth tissue, metal, or ceramic and is used to restore the shape and the esthetics of a tooth or its replacement.

6.623.1. General Introduction

Historically, the clinical disciplines involved to restore or to replace missing teeth are on the one hand named conservative or operative dentistry where moldable materials named fillings are put into tooth cavities (direct restorations), while on the other hand are named prosthodontics where cast/grinded crowns, bridges, and (removable) dentures (indirect restorations/prostheses) are made. Today there is a shift in the European dental schools to bring these activities under one and the same umbrella of restorative dentistry.

This chapter deals with the indirect (fixed) restorations used during clinical activities to restore damaged and/or missing teeth, in order to replace oral function in its broadest sense (chewing, speaking, swallowing, esthetics, social well-being). This means that to manufacture these devices, a third player, namely a dental laboratory/device, is involved. More and more of the latter are chair-side produced and the term semi-direct has been introduced as well. Contrary to prostheses that replace some (partial prostheses) or all teeth (full prostheses or dentures) and that must be taken out at least daily to be able to maintain the supporting oral structures, restorations are dental material devices that are permanently fixed onto teeth or implants and cannot be removed by the patients themselves (inlays, onlays, crowns, and bridges).

6.623.2. Indirect Restorations

As mentioned in the general introduction, indirect restorations need some laboratory handling or at least are not directly manufactured without any additional tool/machine, before the final restoration can be handed-over to the dentist.

6.623.2.1. Metallic Restorations

Four main techniques are used in dentistry to produce metal crowns as well as for frameworks for bridges; lost-wax casting, spark erosion, grinding, and more recently selective laser melting (SLM).

6.623.2.1.1. Lost-wax casting

6.623.2.1.1.1. Introduction

The production of cast metallic restorations, such as crowns, bridges, inlays, cast posts-and-cores in the dental laboratory is traditionally carried out by the *lost-wax casting* technique. The technique can be found back beyond 3000 BC, but it was not used in dentistry until Taggart in the early 1900s first developed the lost-wax casting technique by the use of gold alloys. Over the last century, for the manufacturing of removable partial dentures, the gold alloys were gradually replaced by cobalt–chromium (CoCr) alloys during the 1950s. At the end of the twentieth century, titanium made its entrée after its successful indication in implant dentistry. Owing to more esthetic demands of patients in the Western population, full metal crowns became the exception rather than the rule and are used only for indications were esthetics are of no concern (posterior area/cast post-and-cores) or when large occlusal forces are acting onto the teeth such as in patients suffering from bruxism, a disorder (during night) or bad habit (during daytime) characterized by grinding and clenching of the teeth leading to excessive wear or fracture of weakened teeth. Substructures/frameworks, that later on are porcelain veneered (see Section 6.623.2.3.1), are currently widely used, although also there ceramic-based substructures are rapidly gaining importance.

The basic principles of the lost-wax casting consists of a wax pattern that is molded of the desired shape, and this pattern is invested in a refractory investment. The wax is then removed by melting and burning, leaving behind a cavity of the desired tooth anatomy. This cavity can be filled with molten metal, so that the metal corresponds to the shape of the original wax pattern. The full clinical and technical events, used over decades in the production of cast dental restorations are as follows: tooth preparation, impression taking, model pouring, wax-up of the pattern, investing the wax pattern, wax burnout and heating, melting and casting the alloy, finishing and polishing, heat treatments, and eventually luting of the restoration onto the teeth. Thus it can be seen that many different materials are involved in the production of a metal casting. These include impression materials, model and die materials, waxes, investment materials, casting alloys, and luting cements. Attention will be focused on the materials that are used and the requirements that are placed upon them for the restorations themselves and not on a detailed description of the various clinical and practical stages involved.

6.623.2.1.1.2. Noble and precious metal alloys

These alloys are very resistant to corrosion (noble) and are expensive (precious). They consist of eight elements that have a number of features in common. The noble metals are considered to be made up of gold, platinum, rhodium, iridium, ruthenium, and osmium, whereas silver and palladium are generally referred to as the precious metals.[1]

6.623.2.1.1.2.1. High-gold alloys Their high precious metal content (gold, silver, platinum, and palladium) must not be <75% and the pure gold content in excess of 60%. These alloys can be classified into four distinct groups: type I (soft), type II (medium), type III (hard), and type IV (extra hard). Type I and II alloys are best suited for one-surface inlays (type I) in low-stress situations and for most multiple-surface inlays (type II). Their indications are fully taken over by direct composites/indirect ceramics today. Type III alloys can be used for all inlays, onlays, full-coverage crowns and short-span bridges, cast posts-and-cores because of their greater strength. Type IV alloys are used for cast posts-and-cores and long-span bridges.

6.623.2.1.1.2.2. Medium- and low-gold alloys In the 1970s, due to the rapid rise in the prices of noble metals manufacturers produced many new alloys with a reduced gold content. Some of these may be classified as *medium-gold alloys*, with the gold content varying from 40 to 60%. Compositions of a representative commercial example are presented in Table 1. The palladium and silver contents were increased to compensate for the reduced gold content, while the copper content is in the range of 10–15%. Palladium is added to counteract the tendency of silver to tarnish. The medium-gold alloys are recommended for the same indications as type III and IV high-gold alloys. Their ductility tends to be lower than that of the type IV high-gold alloys. They are very suitable for long-span prostheses and may be used for implant-supported prostheses and posts-and-cores as well.

Table 1 Composition, physical, and mechanical properties of a representative commercial example of a medium-gold alloy (Medior 3®, Cendres & Métaux SA, Biel, Switzerland)

Composition	*Au*	*Pd*	*Ag*	*Cu*	*Zn*	*Ru*
	55%	5.95%	26%	10.9%	2.1%	0.05%
Physical properties		*Melting range*		*Density*		*Young's modulus*
		875–920 °C		13.6 g cm^{-3}		106 kN mm^{-2}
Mechanical properties		*Vickers hardness*		*0.2% proof stress (N mm^{-2})*		*Elongation (%)*
As cast		295		865		4.0
Soft		170		435		35.0
Hardened		280		815		4.5

The *low-gold alloys* tend to have lower mechanical properties than the medium-gold alloys, and are recommended as an alternative to type III high-gold alloys. These alloys are extensively used for posts-and-cores, where the white color does not present a problem as the casting will be covered with another material.

Although, in general, the medium-gold alloys are a suitable alternative to the type IV high-gold alloys, and the low-gold alloys for type III high-gold alloys, one problem with these alloys is that their properties are more variable from one alloy to the other than for each of the four types of high-gold alloy series. The biocompatibility of these alloys appears to be good, and corrosion does not seem to be a problem, even with the two-phase low-gold copper-free alloys.

6.623.2.1.1.2.3. Silver–palladium alloys These alloys were introduced in the 1960s as an alternative to the high-gold alloys, and are also called 'white gold.' Ag–Pd alloys contain predominantly silver with significant amounts of palladium. The palladium improves the resistance to corrosion and helps to prevent tarnish, which is common with silver. Alloys with reduced silver content and increased palladium content have properties similar to those of the type IV high-gold alloys. Nevertheless, their use for long-span prostheses is generally contraindicated. This may be associated with the high casting temperatures for these alloys, which is the second most notable feature of this material. Although they are highly biocompatible, tarnishing does occur with these alloys.

6.623.2.1.1.3. Base metal alloys

Base metal alloys do not contain noble and precious alloys.

6.623.2.1.1.3.1. Cobalt–chromium alloys CoCr alloys were first introduced to the dental profession in the 1930s, and since then have effectively replaced the type IV high-gold alloys for the manufacturing of removable partial denture frameworks, and therefore will not be further dealt with. However, these materials gain anew popularity when milled out of blanks or laser melted from powder particles in the manufacturing of restoration on teeth and implants (see **Section 6.623.2.3.2.5**).

6.623.2.1.1.3.2. Titanium alloys The interest in titanium-based castings for (removable) and fixed prosthodontics came about at the same time as the development of titanium dental implants. Titanium has a number of attractive features such as high strength with low density and excellent biocompatibility. Clinically two forms of titanium have received the most interest. One is the commercially pure form of titanium (cpTi) and the other is an alloy of titanium–6% aluminum–4% vanadium.

6.623.2.1.1.3.3. Commercially pure titanium The term commercially pure titanium (cpTi) is applied to unalloyed titanium and designates several grades (1–4) containing minor amounts of impurity elements, such as carbon, iron, and oxygen. The amount of oxygen can be controlled at various levels to provide increased strength. Titanium is allotropic, with a hexagonal close-packed (HCP) structure (α) at low temperatures and a body-centered cubic (BCC) structure (β) above 882 °C. cpTi is in fact an alloy of titanium with up to 0.5% oxygen. The oxygen is in solution so that the metal is single phase. Oxygen, nitrogen, and carbon have a greater solubility in the HCP structure of the α-phase than in the cubic form of the β-phase. These elements form interstitial solid solutions with titanium and help to stabilize the α-phase. Transition elements such as niobium, molybdenum, and vanadium act as β-stabilizers. The elastic modulus of cpTi is 110 GPa, which is half that of stainless steel or CoCr alloy. The tensile properties of cpTi depend significantly on the oxygen content.

6.623.2.1.1.3.4. Titanium–6% Aluminum–4% Vanadium When aluminum and vanadium are added to titanium in only small quantities, the strength of the alloy is increased over that of cpTi. Aluminum is considered to be an α-stabilizer with vanadium acting as a β-stabilizer. When these are added to titanium the temperature at which the α–β transition occurs is depressed such that both the α- and β-forms can exist at room temperature. Thus, Ti–6% Al–4% V has a two-phase structure of α and β grains. While cpTi should not be used in situations where the tensile stress may exceed 175 MPa, for the Ti–6% Al–4% V, the fatigue limit is approximately 450 MPa. Castability does present a serious problem with these alloys. All castings need to be carried out in a vacuum or an inert atmosphere, which requires special casting equipment, because of its reactivity to oxygen. Hence, other forms of processing titanium for dental prostheses are also used such as grinding or laser melting (see **Section 6.623.2.5.4.1**).

6.623.2.1.2. Spark erosion

The spark erosion technique also know as electrical discharge machining (EDM) is utilizing base metal alloys and was first reported in dentistry in 1982. Mostly used for precision attachments, which are double structures in the fixed-removable (implant) prostheses, as well as for Ti single crowns in combination with, for example, outer grinding (Procera Ti crowns,

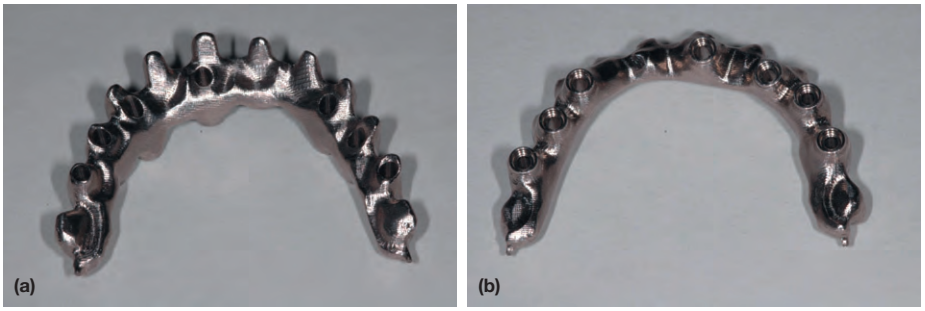

Figure 1 Milled Ti-substructure for an implant supported fixed full prosthesis top (a) and bottom (b) view. Courtesy by ES-Healtcare, Hasselt, Belgium.

Nobelpharma AB, Göteborg, Sweden.[2] In fact, it is a noncontact removal process using a series of electrical sparks per coping to erode material from a work piece in a liquid medium under carefully controlled conditions. The total time to erode, for example, one Ti coping is about 10 min. Because EDM is a thermal or melting process, conductivity and melting point of the metal or alloy are the key factors determining the amount of electrical energy required. EDM machines for dental applications have an output ranging between 10 and 30 A. Currently this technique is overruled by grinding.

6.623.2.1.3. Grinding

Construction data produced with the CAD software are converted into grinding strips for the Cam-processing and finally loaded into a grinding device. Processing devices are distinguished by means of the number of grinding axes: 3-, 4-, and 5-axis grinding devices.

6.623.2.1.3.1. Three-axis grinding devices

This type of grinding device has 3° of movement in the three spatial directions. Thus, the mill path points are uniquely defined by the *X*-, *Y*-, and *Z*- values. The calculation time is therefore minimal. Grinding of subsections, axis divergences, and convergences, however, is not possible.

6.623.2.1.3.2. Four-axis grinding devices

In addition to the three spatial axes, the tension bridge for the component can also be turned infinitely variably. As a result, it is possible to adjust bridge constructions with a large vertical height displacement into the usual mold dimensions and thus save material and grinding time.

6.623.2.1.3.3. Five-axis grinding devices

With a 5-axis grinding device there is also, in addition to the three spatial dimensions and the rotatable tension bridge (4th axis), the possibility of rotating the grinding spindle (5th axis). This enables the grinding of complex geometries with subsections, as for example, lower jaw bridge on converging abutment teeth, or also crown and bridges substructures that, as a result of anatomically reduced formation, demonstrate converging areas in the exterior of the frame.

It should be noted that the quality of the restoration does not necessarily increase with the number of processing axes. The quality results much more from the result of the digitalization, data processing, and production process (**Figure 1(a)** and **1(b)**).

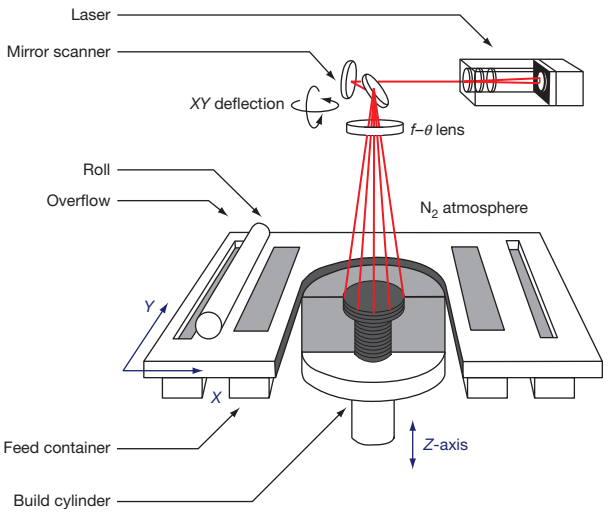

Figure 2 Overview of the basic principles of selective laser melting technology. Courtesy by Vandenbroucke, B. PhD. Thesis, K.U.Leuven, 2008.

6.623.2.1.4. Selective laser melting

The latest production technology use in dentistry is the generative production method which is a special CAD–CAM method, in contrast to grinding technology, that does not work by subtracting, but rather by adding material. **Figure 2** depicts a scheme of the basic features of SLM technology.[3] In the dental field, there are some areas of application for which this technology is already applied for single metal crown copings and in implant dentistry for substructure fabrication. In the production centers, the so-called laser sintering devices are used to produce crowns and bridge frames from CrCo, Ti, and its alloys. Since the productivity of such devices is very high, dental restorations can be produced very cost-effectively. Basically, geometries are conceivable with this technology that cannot be realized with grinding technology (**Figure 3(a)** and **3(b)**).

6.623.2.2. Dental Ceramics

6.623.2.2.1. Introduction

Dental porcelain dates back to 1774, when A. Duchateau considered the possibility of replacing his ivory teeth with porcelain ones. The most important indication of dental porcelain is in the construction of veneers, inlays, crowns, and for layering of metal or ceramic substructures where the esthetic qualities of

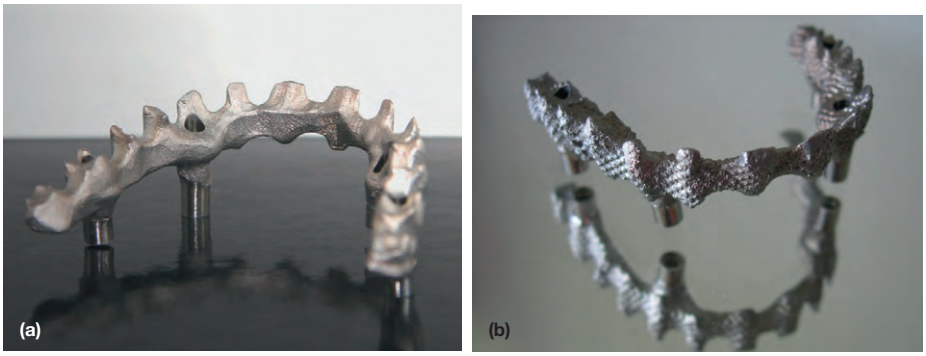

Figure 3 Selective laser melted substructure (Ti) for porcelain veneering (a) and for composite resin veneering (b). Basically, geometries (to mechanically retain the resin) are conceivable with this technology that cannot be realized with grinding technology. Courtesy by Layerwise, Leuven, Belgium.

the porcelain still are superior to that of any other substitute for enamel and dentine, such as dental composites.

Porcelains were the first materials used in the construction of the historical porcelain jacket crown. The latter is today replaced by the all-ceramic restorations because of its high fracture incidence and poor fit (see below). Many new materials did appear on the market over recent years that are described as porcelains, but are in fact very different forms of ceramic when compared with the early porcelains. It is now more appropriate to use the more general description of *dental ceramics*, within which the *dental porcelains* are but one group of materials.[4]

6.623.2.2.2. Dental porcelains

The earliest dental porcelains were mixtures of kaolin, feldspar, and quartz, and were quite different for earthenware, stoneware, and domestic porcelain. It was not until 1838 that E. Wildman produced dental porcelain with the translucency and shades that well matched those of natural teeth. The compositions for domestic porcelain are 50, 20–25, and 25–30% kaolin, quartz, and feldspar, respectively. For dental porcelains, these are 0, 25, and 65%, respectively, which are thus quite different from each other. For dental porcelains, the kaolin was omitted and could be considered to be a feldspathic glass with crystalline inclusions of silica. Kaolin is a hydrated aluminum silicate ($Al_2O\ 2SiO_2\ 2H_2O$) and acts as a binder in domestic porcelains. Quartz remains unchanged during the firing process and acts as a strengthening agent. It is present as a fine crystalline dispersion throughout the glassy phase that is produced by the melting of the feldspar. The feldspar fuses when it melts, forming a glass matrix. The feldspars are mixtures of potassium alumino-silicate ($K_2O\ Al_2O_3\ 6SiO_2$) and sodium alumino-silicate, also known as *albite* ($Na_2O\ Al_2O_3\ 6SiO_2$). Feldspars are naturally occurring substances, so the ratio between the potash (K_2O) and the soda (Na_2O) will vary somewhat. This affects the properties of the feldspar, in that the soda tends to lower the fusion temperature and the potash increases the viscosity of the molten glass. Typical oxide composition of a dental porcelain is; 63, 17, 7, 7, 4, and 2 wt% for silica, alumina, boric oxide, potash, soda, and other oxides, respectively.[5]

Dental porcelain powders are mixtures with additional metal oxides that are fused and then quench the molten mass in water. The resultant product is known as a *frit*, and the process as *fritting*. A consequence of the rapid cooling is that large internal stresses build up in the glass, resulting in extensive cracking. This material can be ground very easily to produce a fine powder for use by the dental technician. Besides, metal oxides, which provide the wide variety of colors of the porcelain, are added too. For example, oxides of iron, copper, titanium, and cobalt act as a brown, green, yellowish-brown, and blue colors, respectively.

6.623.2.2.3. Processing of dental porcelains

The production of the historically – no any longer used – porcelain crown (jacket crown), involves three technical stages namely: compaction, firing, and glazing. It will be used to explain the procedure because the principles remain the same when firing, for example, veneer porcelain onto a substructure (see below).

6.623.2.2.3.1. Compaction

To veneer the jacket crown, the porcelain mixture of powder and water is applied onto the die coated with a platinum foil to support the porcelain during firing in the oven. This follows in a number of ways such as: by spatulation, by brushing, by whipping, or vibrating, all of which are aimed at compacting the powder. The objective of these condensation techniques is to remove as much water as possible. Then the substrate is brought to the furnace. Conventionally, three basic types of porcelain powder are used. These are an opaque shade to mask the color of the underlying structure (e.g., tooth core). Then a dentine shade is applied and finally an enamel shade. A binder helps to hold the particles together as the material is very fragile in this so-called *green state*.

6.623.2.2.3.2. Firing

Initially, the porcelain is heated slowly in the open entrance to the furnace. This is carried out in order to evacuate excess water to avoid steam forming. Once the compact has been dried, it is placed in the furnace and the binders are burnt out. Some contraction occurs during this stage. A large contraction takes place during this phase (~20 vol%), and the resultant material is virtually nonporous. If the porcelain should remain in the furnace for too long, it will lose form due to *pyroplastic flow* (flow of the molten glass) and will become highly glazed.

Figure 4 An example of a finished jacket crown.

A very slow cooling rate is essential in order to avoid the possibility of cracking or crazing.

6.623.2.2.3.3. Glazing

There will always be some porosity in the porcelain, with small air voids being exposed at the surface. These will favor adhesion of bacteria and oral fluids and act as potential sites for the plaque build-up. To avoid this, the surface is glazed to produce a smooth, shiny, and closed outer layer. An example of a finished jacket crown is shown in Figure 4.

6.623.2.2.4. Properties of dental porcelain

Dental porcelain is chemically very stable, and does not deteriorate with time. The thermal conductivity and the coefficient of thermal expansion are similar to those of enamel and dentine. Thus in the presence of a good marginal seal, marginal percolation is less likely to be a problem. Although the compressive strength of dental porcelain is high (350–550 MPa), its tensile strength is very low (20–60 MPa). The material, being primarily a glass, and thus very esthetic, lacks any fracture toughness. The maximum strain that a glass can withstand is $<0.1\%$. Glasses are extremely sensitive to the presence of *surface microcracks*, and this represents one of the major drawbacks in the use of dental porcelain. The answer is to provide a high-strength support for the porcelain and nowadays a number of different systems became available (see Sections 6.623.2.2.5 and Sections 6.623.2.4).

6.623.2.2.5. Classification of modern dental ceramics

One of the most serious drawbacks with the early dental porcelains described above was their lack of strength and toughness, which seriously limited their use. To overcome the problem, there are two possible solutions. One solution is to provide the dental porcelain with support from a stronger substructure. The other option is to produce ceramics, which are stronger and tougher.[5] In this context, it is possible to consider dental ceramics to fall into three categories based on the nature of the *supporting* structure:

- Ceramo-metals
- Reinforced ceramic core systems
- Resin-bonded ceramics

In each case, the idea is to provide a high-strength supporting structure for the veneering ceramic providing the esthetic finish. Obviously, the ideal ceramic would have both the strength and the esthetics to perform both functions. In case of the ceramo-metal restoration, the esthetic veneering ceramic is supported by a strong and tough metal. This system is considered in detail in the next section dealing with metal-bounded ceramics. In the case of the reinforced ceramic core systems, the support for the esthetic veneering ceramic is provided by another ceramic material, which has the necessary high strength and toughness but may lack the desired esthetics. The various options using this approach are explored in the chapter dealing with all-ceramic restorations. In case of the resin-bonded ceramic, the support of the ceramic is provided by the tooth structure itself by bonding the esthetic ceramic directly to the enamel and dentine. In this instance, the ceramic provides the necessary esthetics and the strength is provided by the ability to bond to the tooth tissues. For resin-bonded ceramic restorations, success depends on the *quality of the bond*, since bond failure will lead to a loss of support of the ceramic restoration and eventually result in fracture of the ceramic restoration. This approach only became possible with the advent of enamel- and dentine-bonding procedures.

6.623.2.3. Ceramo-Metals

6.623.2.3.1. Introduction

A major limitation with the dental porcelains such as the feldspathic glasses was their lack of strength. For ceramic restorations the presence of microcracks on the fitting surface is a major source of weakness. A possibility to overcome the latter is bonding the ceramic to a metal substrate such that these microscopic cracks are effectively eliminated, with the consequence that the structure is considerably stronger. This is the basic premise behind the metal-bonded system also called ceramo-metal restorations. The significant breakthrough came by Weinstein *et al.*, in 1962, where they explained how it is possible to get a feldspathic glass to bond to an alloy surface by the inclusion of leucite crystals. The latter were added so as to ensure that the coefficient of thermal expansion of the ceramic closely matched that of the metal (see Section 6.623.2.3.2).

The crown/bridge consists of a cast metal coping/substructure onto which a veneering ceramic is fired (Figure 5(a) and 5(b)). If a proper bond is created, then the internal cracks are eliminated as the metal presents a barrier to the propagation of cracks by virtue of its high fracture toughness. One of the most likely modes of failure with this system is the separation of the ceramic from the metal due to an interfacial breakdown of the ceramo-metal bond. The success of the system depends upon the quality of this bond. An important contributory factor to the ability to bond the ceramic to the metal is the degree for a mismatch between the coefficients of expansion of the ceramic and the metal. If the mismatch is too great then stresses will build up during the cooling process after firing. These stresses can be sufficient to result in crazing or cracking of the ceramic.[5] The issues of the bond and the coefficients of expansion both require careful consideration. Three mechanisms are involved in the bond: mechanical retention, compression fit, and chemical bonding.

The composition of the ceramic for ceramo-metal restorations needs to be different from that of the ceramic used for all-ceramic restorations. The coefficient of thermal expansion (α) of the feldspathic glasses used in the construction of the porcelain jacket crowns is 7–8 ppm $^{\circ}C^{-1}$. This is far too low to be

compatible with the alloys, which are in the region of 14–16 ppm °C^{-1}. This mismatch would give rise to serious problems due to excessive differential shrinkage on cooling. The best combination of metal and ceramic is one where the coefficient of expansion of the ceramic is only slightly lower than that of the metal.[6] In fact the flexural strength of the ceramics used for ceramo-metal restorations is only of the order of 30–50 MPa. Hence the ceramic build-up on the metal framework should not be too thick as this can lead to ceramic fractures when loaded in the mouth. The general recommendation is that the ceramic thickness should not exceed 1–1.5 mm.

An increase in the number and size of the leucite crystals can occur when firing the ceramic onto the metal. In case of multiple firings, this will increase the coefficient of expansion of the ceramic. Such an increase can compromise the compatibility of the metal and the ceramic.

6.623.2.3.2. Choice of ceramo-metal alloys

The requirements for alloys used in the metal-bonded ceramic system are somewhat different from those for the all-metal constructions. As it is necessary to fire ceramic onto the surface of the metal, its high melting temperature must be higher than the sintering temperature for the ceramic. If the melting temperature of the metal is too close to the firing temperature of the ceramic, partial melting of thin sections of the coping may occur, or the coping may deform. Especially in the construction of long-span bridges, the metal must have a high elastic modulus and high yield stress. The resultant high stiffness of the bridge structure will prevent the occurrence of excessively high strains (that the ceramic cannot cope with) on occlusal loading. In addition, a low stiffness of the metal framework can result in distortion due to the differential contraction stresses that are generated on cooling after porcelain firing. Formerly, only high-gold alloys were available, but, with the rising cost of gold, a variety of alternative alloys have been developed, which may be classified as high-gold, gold–palladium, high-palladium, palladium–silver, nickel–chromium alloys, or cpTi.[7]

6.623.2.3.2.1. High-gold alloys

For the high-gold alloys, the melting temperature is raised by the addition of platinum and palladium, both of which have a high melting temperature. Compositions of a representative commercial example are presented in Table 2.

6.623.2.3.2.2. Gold–palladium alloys

The performance of Au–Pd alloys is comparable to that of the high-gold alloys in terms of castability, accuracy of fit, and corrosion resistance. Compositions of a representative commercial example are shown in Table 3.

6.623.2.3.2.3. High-palladium alloys

These alloys are primarily palladium, with small additions of other elements, such as copper, gallium, and tin and have become very popular in the last 30 years. The alloys are contraindicated for long-span bridges because the sag resistance can be poor due to excessive creep on ceramic firing.

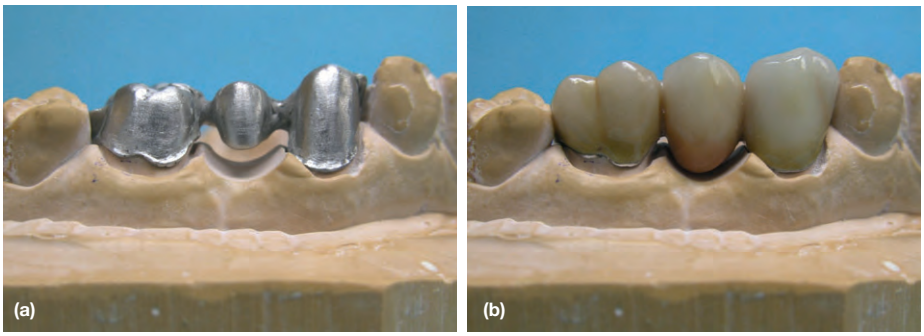

Figure 5 Metal substructure for porcelain veneering (a) and de porcelain veneered three-unit posterior bridge (b).

Table 2 Composition, physical, and mechanical properties of a representative commercial example of a high-gold alloy for porcelain veneering (BioEthic®, Cendres & Métaux SA, Biel, Switzerland)

Composition	*Au*	*Pt*	*Zn*	*Rh*	*Ta*	*In*	*Sn*	*Ag*	*Ir*

6.623.2.3.2.4. Palladium–silver alloys

The Pd–Ag alloys have the most favorable elastic modulus of all of the precious metal alloys, producing castings with low flexibility and a reduced tendency to sag on porcelain firing. Owing to the presence of high amounts of silver, there is concern that porcelain discoloration may occur. The composition and the properties of such a representative alloy are presented in Table 4.

6.623.2.3.2.5. Cobalt–chromium alloys

The CoCr alloys are very stiff as their elastic modulus can be some 2.5–3 times higher than that of the high-gold alloys. They are indicated for the construction of long-span bridges as they provide greater rigidity, and because of the high melting temperature, there is less potential for sag during firing. Those days CAD–CAM produced frameworks may overcome this shortcoming. Also clinical experience would indicate that the ceramic to metal bond is not as reliable as for the other alloys although this is improved by gaining more experience over the years. The biocompatibility of Ni–Cr alloys, formerly used, has long been a matter of concern because of allergy reactions. That is why Ni-free alloys came into the market. Four to six percent wolfram was additionally added. The compositions of such an alloy are shown in Table 5.

6.623.2.3.2.6. Commercially pure titanium

Titanium has become popular for ceramo-metal restorations because of its good corrosion resistance, excellent biocompatibility, low weight, and relatively low cost compared to the

precious metal alloys. When titanium is cast, a reaction layer with a thickness of 50–100 μm forms on the surface of the casting due to an interaction between the titanium and the refractory investment. Even if the casting problems can be avoided by producing the restorations using an alternative technique, such as spark erosion and copy-grinding, titanium has a high chemical reactivity and if taken above 800 °C during porcelain firing, this gives rise to a thick oxide coating, with the consequence of a weak bond to the ceramic. The bonding of the ceramic to cpTi is problematic and the bond strength is not as good as that obtained to the alloys. Unlike the alloys described above, titanium has a coefficient of expansion of 9.6 ppm $°C^{-1}$. Thus the leucite-containing ceramics developed for the ceramo-metal alloys are inappropriate and it is important that ceramics specially designed for use with cpTi are used.[8]

6.623.2.4. All-Ceramic Restorations: High-Strength Core Ceramics

6.623.2.4.1. Introduction

Land, in the early 1900s, and others since then had shown that one of the problems with the porcelain jacket crown was that the porcelain would fracture from the fit surface outward. Some improvements in the strength of porcelain were achieved by the introduction of vacuum-firing furnaces, but the search was on for a core material that would provide the necessary strength and toughness to prevent fractures arising from cracks propagating from the fit surface of the crown.

Since ceramics tend to fail at the same critical strain of 0.1%; one means of achieving an increase in fracture strength is to increase the elastic modulus of the material. If, at the same time, the propagation of cracks is made more difficult such that a greater strain can be supported, a higher strength ceramic will result. The flexural strengths of a number of ceramics are: 800–900, 400–750, 640, and 420–520 MPa for hot-pressed silicon and carbide, partially sintered zirconia, and alumina 98% pure, respectively. Alumina and zirconia are white and strong and therefore these ceramics are now used in a number of dental ceramic systems.

McLean and Hughes, in the mid-1960s developed a core material based on the reinforcement of a feldspathic glass with alumina, commonly referred to as the alumina-reinforced porcelain jacket crown. Since then, other systems have been developed. A major contributor to the development of glass ceramics was Dicor (Dentsply Int, York, PA). This was a glass-ceramic material composed of 70% tetrasilicic fluormica crystals precipitated in 30% glass matrix and is no longer available today. In the 1980s, the glass-infiltrated high-strength ceramic *cores* were developed (In-Ceram, Vita), and in the 1990s, the pure alumina core made its first appearance (e.g., Procera AllCeram, Nobel Biocare). Recently yttria-stabilized zirconia for the fabrication of cores for crown and bridge framework was introduced.

6.623.2.4.2. Core materials

6.623.2.4.2.1. Silica-based ceramics

The alumina-reinforced feldspathic core introduced in the early 1960s consists of a feldspathic glass containing 40–50% alumina. The alumina particles are far stronger than the glass, and are more effective at preventing crack propagation than quartz and act as crack stoppers. Whereas the flexural strength of feldspathic porcelain is, at best, some 60 MPa, this is raised to 120–150 MPa for the aluminous core porcelains. In the construction of a crown, the opaque shade is made with an aluminous core porcelain. It is still necessary to use the weaker dentine and enamel shades of the feldspathic veneering porcelains. The main indication of the alumina-reinforced porcelain jacket crown, but today hardly used anymore, was for the restoration of the anterior teeth.

Ivoclar Vivadent (Schaan, Liechtenstein) developed the lithium disilicate glass ceramic (SiO_2–Li_2O) (IPS Empress 2, Ivoclar Vivadent) in the 1990s. It is fabricated through a combination of the lost-wax and heat-pressed techniques. A glass-ceramic ingot of the desired shade is plasticized at 920 °C and pressed into an investment mold under vacuum and pressure. IPS Empress 2 has improved flexural strength by a factor of 3 over the original IPS Empress which is a leucite-reinforced glass ceramic (SiO_2–Al_2O_3–K_2O), and can be used for three-unit bridges in the anterior area as well. The framework is veneered with fluoroapatite-based veneering porcelain (IPS Eris; Ivoclar Vivadent), resulting in a semitranslucent restoration with enhanced light transmission. IPS e.max Press (Ivoclar Vivadent) was introduced in 2005 as an improved press-ceramic material compared to IPS Empress 2. It also consists of a lithium disilicate pressed glass ceramic, but its physical properties and translucency are improved through a different firing process.

6.623.2.4.2.2. Infiltration ceramics

The addition of alumina to the feldspathic glass during the prefritting process limits the amount of alumina that can be incorporated to about 40–50 vol%. An alternative approach has been adopted in a new system called In-Ceram (Vita Zahnfabrik, Bad Säckinge, Germany). This core material has an alumina content of ~85%. The procedure consists of a ceramic core that is formed onto a refractory die from a fine slurry of alumina powder by a process known as slip-casting. After the die has dried it is sintered for 10 h at 1120 °C. The melting temperature of alumina is too high to produce full densification of the powder by liquid-phase sintering and only solid-phase sintering occurs. Consequently, the coping thus created is only just held together at the contact points between the alumina particles and a porous structure is the result. The strength of this porous core is only about 6–10 MPa. The porous structure is then infiltrated with a *lanthanum* glass, which has a low viscosity when fired at 1100 °C for 4–6 h. The molten glass is able to penetrate into the pores, producing a dense ceramic, the reason why these are also called glass-infiltrated high-strength ceramics. The esthetics and functional form are then achieved by veneering the core with conventional feldspathic veneering porcelains. Very high flexural strength values (400–500 MPa) have been claimed for this core ceramic, which makes this system suitable for anterior and posterior crowns, with excellent results. Several attempts have also been made at producing anterior cantilever and posterior three-unit bridges, which is a highly ambitious use of ceramics, but show considerable promise.

A similar approach has been adopted with *spinel* ($MgAl_2O_4$) replacing the alumina. The InCeram–Spinel offers superior esthetics over the InCeram–Alumina at a slightly reduced flexural strength (~350 MPa) and is recommended for inlays and anterior crowns.

The InCeram–Zirconia is based on the InCeram–Alumina, but with the addition of 33 wt% *zirconia* and produces a ceramic core with a strength of some 700 MPa. Its drawback is that the combination of a glass, alumina, and zirconia means that this core material is very opaque and not popular those days.

6.623.2.4.2.3. Pure alumina cores (see Chapter 1.105, Alumina)

There are several systems on the market that offer pure alumina cores. The potential advantages are increased strength and superior translucency compared with the glass-infiltrated core materials. A production example, of for example, the Procera AllCeram core (Nobelbiocare, Gothenburg, Sweden), involves producing a die from the impression, digitizing the geometry of the desired coping using specially designed computer software, and transferring this information down a modem to a centralized plant. This is all done by a designated dental laboratory. The coping is produced by a special process, which involves sintering 99.5% pure alumina at 1600–1700 °C such that it is fully densified. The coping is then returned to the dental laboratory for building on the crown's esthetics using compatible feldspathic veneering porcelain. The flexural strength of the Al_2O_3 core materials is in the order of 700 MPa and thus similar to that achieved with the InCeram–Zirconia. One of the potential benefits of producing a pure alumina core is that the *translucency* is improved compared to that of the glass-infiltrated alumina composite structures.

6.623.2.4.2.4. Zirconia core systems (see Chapter 1.106, Zirconia as a Biomaterial)

The reason zirconia became popular those days is due to the high strength of this material, which is in excess of 1000 MPa. The actual material used is yttria-stabilized zirconia and the yttria plays a very important function, although it is only there in a small amount (~3.0 mol%). Under normal circumstances, zirconia forms a stable monoclinic crystal structure at room temperature, but the addition of a small amount of yttria results in the formation of a metastable tetragonal crystal structure at room temperature. When a small defect such as a crack is present, it progresses through the material due to the localized stress at the crack tip being relieved by crack growth. As mentioned earlier, the way to improve ceramics is to prevent cracks from growing and in the case of yttria-stabilized zirconia, when the stress at the crack tip reaches a certain level, the metastable tetragonal crystal structure of zirconia transforms to the more stable monoclinic form. This stress-induced change in structure is accompanied by an expansion of the material, which causes the crack tip to close up and thus prevent it from advancing. Hence, it is very difficult for a crack to advance through an yttria-stabilized zirconia ceramic. In fact, the material is not only very strong but also very tough by comparison with other ceramics. It is this particular feature of zirconia that makes it possible to contemplate using this material not only as a core for crowns but also for bridge frameworks.

Until CAD–CAM became available it was inconceivable to consider the use of zirconia (ZrO_2) as a material for the construction of crowns and bridges, largely because a zirconia powder would not densify until reaching a temperature in excess of 1600 °C, making it impractical as a dental laboratory material. Because zirconia is so strong and tough, the most common approach used to deal with this is a technique often referred to as 'soft' machining. In this method, the restoration is machined from a porous blank, which is easy to machine and once the desired shape has been achieved the coping is fired in a furnace to cause the material to densify. The shrinkage that occurs, typically some 20 vol%, is taken care of during the computer-aided design process. The result is a very close-fitting, white core or bridge framework (**Figure 6**).

On the short run, zirconia-ceramic bridges exhibited a similar 3-year survival rate to ceramo-metal.[9] Chipping of the veneering porcelain seems to be higher in zirconia- versus ceramo-metal-veneered restorations. Although zirconia-based restorations are widely used those days, their susceptibility to hydrothermal degradation remains elusive. CAD–CAM machined surfaces initially exhibited superior hydrothermal degradation resistance, but deteriorated at a faster rate upon prolonged autoclave treatment compared with ground and grit-blasted surfaces. The accelerated hydrothermal degradation of CAD–CAM surfaces is attributed to the machining damage and the absence of surface compressive stresses in the fully sintered material. Clinical relevance for surface treatments of zirconia frameworks in terms of hydrothermal and structural stabilities still has to be addressed.[10]

6.623.2.4.2.5. Drawback of high-strength core systems

One drawback with all the high-strength core systems described above is that none of them are amenable to acid etching to produce a micromechanically retentive surface, although some bonding with the cementing medium will arise due to the roughness of the surface from processing. Since the fit surface is made up largely of alumina and/or zirconia rather than silica, no coupling agents are currently available that can effectively bond the core to resins. Without

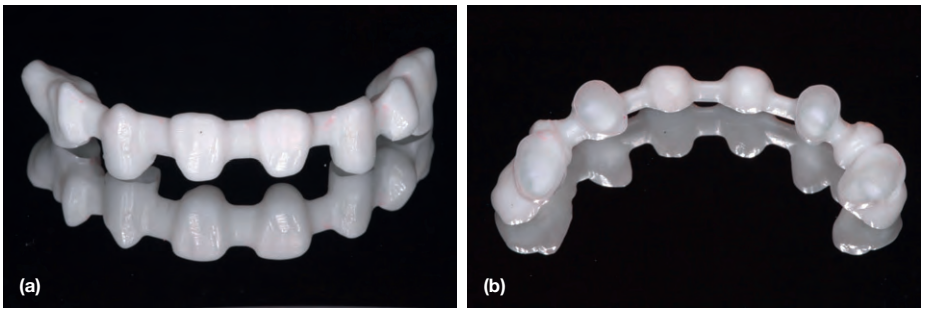

Figure 6 An example of a ZrO_2-milled substructure of a eight-unit bridge on teeth to be veneered with porcelain top (a) and bottom (b) view.

an effective coupling agent or an ideal micromechanically retentive surface, these systems cannot be resin-bonded to the tooth tissues and will not derive the added benefit associated with resin-bonded ceramic restorations. The reinforced core ceramic restoration must rely primarily on the strength and toughness of the core material and appropriate design in terms of retention and resistance of the tooth preparation to resist the forces of occlusion. However, recent work has shown that gridblasting the core with 50 µm grid at 1 bar combined with an adhesive luting cement (Panavia Ex and 21, Kuraray) do form a stable bond in time with the tooth enamel. This is why ZrO_2 is currently being explored to adhesively bond wings.[11]

The introduction of CAD–CAM technology to manufacture copings and bridge frames has been having a profound influence on the choice of the materials used. The next paragraph will deal with the principles of CAD–CAM generated restorations in dentistry.

6.623.2.5. CAD–CAM in Dentistry

6.623.2.5.1. Definition

The term CAD–CAM does not provide any information on the method of fabrication. All CAD–CAM systems consist of three components:

- A digitalization tool/scanner that transforms the geometry into digital data that can be processed by the computer.
- Software that processes data and, depending on the application, produces a data set for the product to be fabricated.
- A production technology that transforms the data set into the desired product.

6.623.2.5.2. CAD–CAM concepts in dentistry

Depending on the location of the CAD–CAM devices, three different production concepts are available: chair-side production, laboratory production, and centralized fabrication in a production center.[12]

6.623.2.5.2.1. Chair-side production

All components of the CAD–CAM system are located in the dental surgery. Fabrication of dental restorations can thus take place chair side without a laboratory procedure. The digitalization instrument is an intraoral camera, which replaces a conventional impression with elastomers in most situations. This saves time and offers the patient indirectly fabricated restorations at one appointment. An example is the Cerec® System (Sirona, Gemany). Since the Cerec® system functions with water cooling, a variety of materials can be processed, from glass-ceramics to high-performance oxide ceramics. Scientific literature reported success rates for CAD–CAM produced inlays of 90% after 10 years and 85% after 12 and 16 years.[13,14] Historically, this system was the first CAD–CAM system in dentistry and is currently available in its third generation.

6.623.2.5.2.2. Laboratory production

This variant of production is equivalent to the traditional working sequence between the dentist and the laboratory. The dentist sends the impression to the laboratory where a master cast is fabricated first. The remaining CAD–CAM production steps are carried out completely in the laboratory. With the assistance of a scanner, three-dimensional data are produced on the basis of the master die. These data are processed by means of dental design software. After the CAD-process, the data are transferred to a grinding device that produces the real geometry in the dental laboratory. Finally, the exact fit of the framework can be evaluated and, if necessary, corrected on the basis of the master cast. The ceramist carries out the veneering of the frameworks in a powder-layering technique.[15,16]

6.623.2.5.2.3. Centralized production

The third option of computer-assisted production of dental prostheses is centralized production in a grinding center. In this variation, it is possible for satellite scanners in the dental laboratory to be connected with a production center via the Internet. Data sets produced in the dental laboratory are sent to the production center for the restorations to be produced with a CAD–CAM device. Finally, the production center sends the restoration to the responsible laboratory. Thus, production components 1 and 2 take place in the dental laboratory, while the third one takes place in the production center.[17] As a result, the configuration of the restoration remains in the hands of the dental technician. The benefit of outsourcing CAM production is found in its small investment requirement, since only the digitalization tool and software have to be purchased, while still assuring a high-quality production process.

In addition, this procedure results in greater independence, since there is no relation to a particular production technology (e.g., grinding technology). It must, however, be noted that presently almost all CAD–CAM systems are only available as closed systems. In other words, if one acquires a scanner from one manufacturer, this implies, in the case of a closed system, that there is only access to that manufacturer's processes and line of products. Many production centers also offer, to smaller laboratories without a scanner, the possibility of sending the master cast to the production center for scanning, designing, and fabrication. The additional veneering of the frameworks for prosthetic restorations is still carried out in the dental laboratory.

6.623.2.5.3. CAD–CAM components

6.623.2.5.3.1. Scanner

In the area of dentistry, the term scanner implies data collection tools that measure the jaw and tooth structures three-dimensionally and transform them into digital data sets. Basically there are two different scanning possibilities, optical and mechanical. The latter is not much in use in the market today. The basis of the optical scanner is the collection of three-dimensional structures in, for example, a triangulation procedure or other. Here, the source of light (e.g., laser) and the receptor unit are in a definite angle in their relationship to one another. Through this angle the computer can calculate a three-dimensional data set from the image on the receptor unit.[18] Either white light projections or a laser beam can serve as a source of illumination. Until recently, dental scanners were aimed at scanning the plaster die or model. Recently, laboratories have been offered the possibility to scan the impression directly eliminating the plaster cast as an important potential source of error by means of the so-called conoscopic holographic principle (NobelProcera scanner, Nobel Biocare, Zürich, Switzerland). A further simplification in CAD–CAM production consists of intraoral data collection (intraoral

scanning) or the so-called 'digital impression taking.' This means a digitalization of what is now only an analog step through an elastomer impression technique transferred into a plaster cast or die. This could lead to an additional improvement in quality and cost reduction. Currently these systems have become available in the market (e.g., Lava Cos, 3MEspe).

6.623.2.5.3.2. Design software

Special software is provided by the manufacturers for the design of various kinds of dental restorations.[19] The software of CAD–CAM systems presently available in the market is continuously being improved. The data of the construction can be stored in various data formats, often standard transformation language (STL) data.[18] Many manufacturers, however, use their own data formats, specific to that particular manufacturer, with the result that data of the construction programs are not compatible with each other.

6.623.2.5.4. Materials to be processed on dental CAD–CAM devices

6.623.2.5.4.1. Metals

At present, titanium, titanium alloys, and chrome cobalt alloys are processed using dental grinding devices. The grinding of precious metal alloys has been shown to be of no economic interest, due to the high metal attrition and the high material costs.

6.623.2.5.4.2. Resin materials

On the one hand, resin materials can be used for the grinding of lost-wax frames for casting technology; on the other hand, it is possible to use resin materials directly as crown and bridge frameworks for long-term provisional or for full anatomical long-term temporary prostheses.

6.623.2.5.4.3. Silica-based ceramics

Grindable silica-based ceramic blocks are offered by several CAD–CAM systems for the production of inlays, onlays, veneers, partial crowns, and full crowns (fully anatomical, anatomically partially reduced). A machinable feldspathic porcelain Vita Mark II (VITA Zahnfabrik, Bad Sackingen, Germany), introduced in 1991 for the CAD–CAM CEREC 1 system (Siemens AG, Bensheim, Germany), has improved strength and finer grain size (4 μm) as compared to the Vita Mark I. It is primarily composed of SiO_2 (60–64%) and Al_2O_3 (20–23%) and can be etched with hydrofluoric acid to create micromechanical retention for adhesive cementation with composite resin cements. In addition to monochromatic blocks, various manufacturers now offer blanks with multicolored layers (Vitablocs TriLuxe (Vita), IPS Empress CAD Multi (IvoclarVivadent)), for the purpose of full anatomical crowns. Owing to their higher stability values, lithium disilicate ceramic blocks are particularly important in this group; they can be used for full anatomical anterior and posterior crowns, for copings in the anterior and posterior region, and for three-unit bridge frameworks in the anterior region due to their high mechanical stability of 360 MPa.[20] Glass ceramics are particularly well suited to chair-side application as a result of their translucent characteristics, similar to that of natural tooth structure; they provide esthetically pleasing results even without veneering. As a result of their relatively high portion of glass, these ceramics are, in contrast to oxide ceramics, etchable with hydrofluoric acid and thus can be inserted very well using adhesive systems.[21]

6.623.2.5.4.4. Infiltration ceramics

Grindable blocks of infiltration ceramics are processed in a porous, chalky condition and then infiltrated with lanthanum glass. All blanks for infiltration ceramics originate from the Vita In-Ceram system (Vita) and are offered in three variations. Vita In-Ceram Alumina (Al_2O_3), is suitable for crown copings in the anterior and posterior region, three-unit bridge frameworks in the anterior region.[22] Vita In-Ceram Zirconia (70% Al_2O_3, 30% ZrO_2), is suitable for crown copings and three-unit bridge frameworks in the posterior region. VITA In-Ceram Spinell ($MgAl_2O_4$), has the highest translucency of all oxide ceramics and is thus recommended for the production of highly esthetic anterior crown copings, in particular in vital abutment teeth and in the case of young patients.

6.623.2.5.4.5. Oxide high-performance ceramics

At present, aluminum and zirconium oxide are offered as blanks for CAD–CAM technology.

6.623.2.5.5. Processing

Processing can take place in different density stages.

Green stage processing: Is used on a blank without heat treatment, that is, an object pressed from ceramic powder and binding agents. Since there was no presintering, the object is as soft as chalk. This permits very easy processing, but results, due to the low degree of stability, in great problems in transport and application. Processing is by means of carbide metal grinders without liquid cooling. The green stage has an open porosity, and in firing a 25% linear shrinkage is to be expected. At present, zirconium oxide is not processed as a green stage in any of the CAD–CAM systems on the market.

White stage processing: As a result of the thermal pretreatment, the organic compressing additives have vanished and the blank has an adequate stability. As a result of presintering, the white body has already had shrinkage of approximately 5%. In the case of CAD–CAM production of objects from white bodies, the subsequent shrinkage of some 20% (linear) must be taken into consideration. Processing of white stage can be either with carbide metal grinders without water cooling or with diamond grinders with liquid cooling.[17,23]

Processing in hot isostatic pressing condition: Some systems also process zirconium oxide in HIP (hot isostatic pressed) condition with diamond tools and water cooling. The advantages are: no sinter shrinkage, as a result no sinter distortions, no sinter furnace necessary, and no additional time needed for sintering procedure. The disadvantages are: devices with high rigidity and stability necessary, longer grinding times, resulting in lower utilization of devices, high wear of the cutters.[24,25]

Figure 7 depicts an overview of the different steps in CAD–CAM and its technologies used in dentistry today.[3]

6.623.2.5.6. Reflections

The quality of dental prostheses has improved significantly by means of standardized production processes. This makes very efficient quality management possible. It changed dental laboratories from craftsmanship to modern computerized production centers. CAD–CAM technology has made it

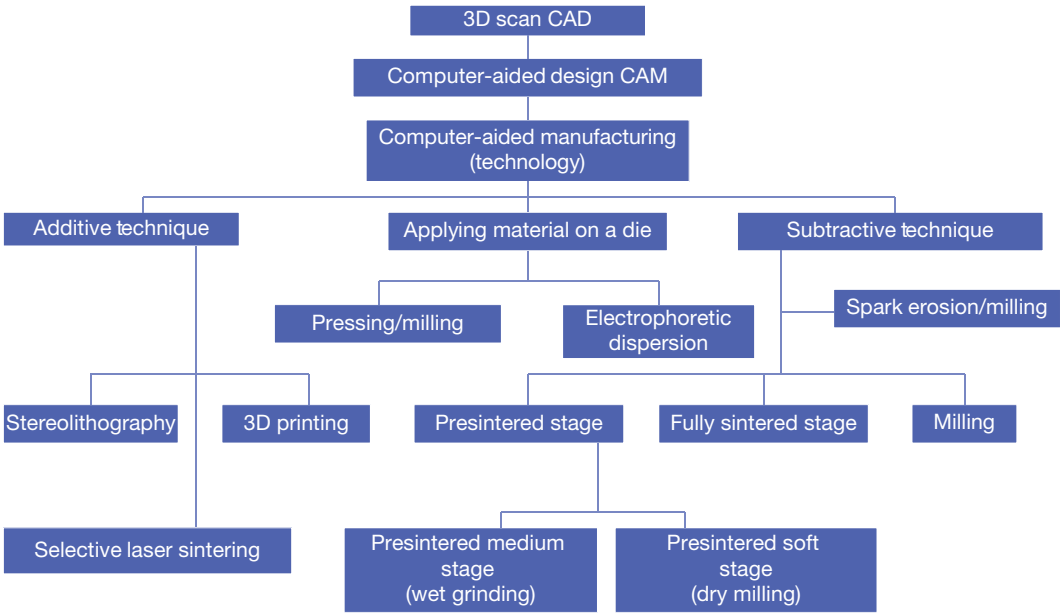

Figure 7 Overview of the different steps in CAD–CAM and its technologies used in dentistry today. Courtesy by Vandenbroucke, B. PhD. Thesis, K.U. Leuven, 2008.

possible to machine interesting new materials such as the high-performance ceramics and titanium with high accuracy. However, the high investment for machines might overextend the budget of smaller laboratories and some applications are limited due to software and production procedures. Overall, CAD–CAM technology has already changed dentistry and will replace more and more of the traditional techniques in fabricating dental restorations.

ESC	Embryonic stem cell
HOCM	Hypertrophic obstructive cardiomyopathy
iPS	Induced pluripotent stem cells
LAD	Left anterior descending artery
MI	Myocardial infarction
MMP	Matrix metalloprotease
PEG	Poly(ethylene glycol)
PEUU	Polyester urethane urea
PGA	Poly(glycolic acid)
PTFE	Polytetrafluoroethylene
RGD	Arginine-glycine-aspartic acid
RVOT	Right ventricular outflow tract
VSD	Ventricular septal defect

6.624.1. Native Myocardium: Unique Tissue Properties

6.624.1.1. Anatomical Considerations

The human heart consists of four chambers that are functionally organized in two different units. Each unit consists of an atrium, a ventricle, and two heart valves that ensure the unidirectional blood flow through the heart. In the human body, the blood flow passes through a circuit where a pulmonary circulation and a systemic circulation are arranged in a serial order. The venous blood that returns from the peripheral organs, such as musculature, gastrointestinal organs, and the brain, is directed via the venous system toward the right atrium. Blood that returns after capillary passage through the myocardium itself also arrives in the right atrium where the pooled blood volume enters the cardiac cavity. Further blood flow leads through the tricuspid valve into the right ventricle, from where blood is ejected through the pulmonary valve into the pulmonary artery and the branching vessels. After gas exchange in the pulmonary system, the oxygen-saturated blood returns into the left atrium, which fulfill the function of a blood pooling cavity, similar to the right atrium. Through the mitral valve, a further transport of the blood takes place, first into the left ventricle and from there through the aortic valve into the aorta and the main systemic arteries.

6.624.1.2. Anisotropic Architecture of the Heart

A specific anisotropic arrangement of the myocardial fibers accounts for a highly efficient contractile function of the heart. The contraction of cardiomyocytes as well as their multicellular aggregates is potentiated by the spatial distribution and orientation of the individual myocardial fibers, which display a twisted assembly. There has been an ongoing debate on the functional role of the specific anatomical design of the heart and the history of scientific disquisition on the helical structure of the myocardial muscle is long lasting with current pertinence.[1] The unique structural plan of the heart that already exists throughout the prenatal development and persists during the postnatal life is characterized by an anisotropy, a distinct feature of the myocardium that helps to generate a level of myocardial force that may not be explained by the power of the myocardial subunits (e.g., cardiomyocytes or myocardial fibers) and their collective wrap up on isolated examination. What certainly works as perfect as an ingenious natural solution to the need for a robust circulatory pump has proven inaccessible to most sophisticated human endeavor, aiming at the creation of a homologous copy of the heart. This fascinating organ derives its attraction from the well-tuned interplay between the different anatomical and functional units that each may become the focus of congenital malfunction or alternatively may also be prone to acquired degeneration in later life. Recently, a new perspective on the anatomical assembly of the heart was generated by an extensive preparation work on explanted hearts that revealed the striking finding of a single muscle band constituting the complex cardiac structure through helical windings and loops forming the different chambers and allowing their coordinated function.[2] It is astonishing how challenging the seemingly simple uncoding of the anatomy of an organ may be, in spite of the collaborative approach by modern medical specialties and in spite of the availability of most advanced technical recourses.[3]

Some aspects of cardiac anatomy and physiology that deserve particular consideration in the context of tissue engineering and regeneration are highlighted in the following sections of this chapter. These are not intended as a comprehensive and structured discussion of the macroscopic and histological anatomy of the heart *per se*. More importantly, those basic subjects that are related to the main topics of the later Sections 6.624.4–225.7 are briefly mentioned, along with matters that are substantial for the explanation of the highlighted experimental work and their results.

6.624.1.3. Coronary Blood Flow

The working heart muscle derives its own nutrition and oxygen supply through the coronary vessels that originate from two different main vessels, the right and the left coronary artery. In case of a healthy adult person, the blood volume that passes through the coronary vasculature (coronary blood flow) is about 250 ml min^{-1}. At the same time, the total blood volume that is transported through the heart (cardiac output) ranges between 4 and 6 l min^{-1} at rest. Hence, the coronary perfusion accounts for about 5% of total body circulation, although the relative myocardial mass in relation to the whole body weight accounts for about 0.5% only. The main effectors in the coronary system are the capillaries, which densely surround cardiomyocytes and thereby provide a sufficient support of oxygen and nutrition as well as prohibiting an accumulation of metabolic products in the same way. According to the constantly high metabolic state of cardiomyocytes, an extensive capillary network is necessary for the prevention of undersupply. Hence, the average distance between two neighboring capillaries lies beneath 20 μm.[4,5] The combination of a dense vascular network with a relatively large perfusion volume results in a highly efficient gas and substrate exchange. In view of this background, the perfusion status of the myocardium appears excessive in relation to the supply of other organs in the human body. However, the high energetic demand of the cardiac muscle is dependent on such a high level of organ perfusion for an optimal functional performance. These are only some spotlights shed on the broad landscape of physiological supply conditions in the native myocardial tissue; any engineered cardiac patch will have to match up with this natural gold standard in terms of perfusion.

6.624.1.4. Electrophysiological Integration

In the native heart, the concerted function of the different myocardial regions is facilitated by a specialized system that allows rapid and interference-resistant impulse propagating throughout the heart along a specific anatomical path, the conduction system. The establishment of such a functional network requires the presence of specific cells embedded in adopted extracellular structures, each with its own particular biochemical and biomechanical features. The His–Purkinje system fulfills a wide range of criteria that are necessary for successful accomplishment of the task of impulse propagation in an active organ, such as the heart. Purkinje cells represent a great

example of the unique properties of the involved cells. Unlike other cardiac cells, unique physical dimensions (e.g., a long axis of up to 200 mm), a specific orientation of cell communication channels with special molecular features concerning their cell–cell junctions, a spatial relation to the extracellular matrix (ECM), and many more detailed specifications characterize the conducting cells.[6,7] Furthermore, the installation of a hierarchic order with a superior pace setting unit (as represented by the sinus node) and downstream regulatory units (atrioventricular node, His bundles) not only requires a delicately graduated pattern of morphological cell development for each subunit, but also involves a comprehensive arrangement for a functional integration of this system within the working myocardium. Moreover, the conduction system governs the rate of the cardiac cycles in a manner that is physiologically integrated with the activity level of the whole organism. There are a large number of independent or interrelated pathways that link the cardiac electrophysiology to systemic regulatory pathways, and the complexity of these naturally well-balanced arrangements, a subject that is reflected by a recent scientific field termed system biology, may remain out of reach for current and near-future technical options that are available in the laboratory.[8] The ultimate goal of cardiac tissue engineering that is defined by the creation of a cardiac patch that can entirely incorporate into the recipient's heart will have to have ready the appropriate tools to address the question of a complete electrophysiological integration.

6.624.1.5. Physiologic Cellular and ECM Turnover

For a long time, the heart and the constituting contractile cell fractions have been regarded as incapable of an innate regeneration. However, the discovery of a distinct cardiac cell type that exhibits cell cycle activity and may give rise to mature cardiomyocytes has attracted much attention in the very recent years.[9,10] Subsequently, other progenitor and stem cell characteristics have been proposed for a number of other cell types in the adult human body, giving rise to the hope for the possibility of a cardiac regeneration that enables the recovery of impaired organ function.

It is estimated that under physiological circumstances, a constant – although quantitatively very low – rate of cardiomyocyte regeneration exists, by which a compensation for the simultaneously occurring cell death may be achieved. The herein involved regulatory mechanisms ensure a balanced order of cell turnover, maintaining the quantity and functional quality of the working cardiomyocytes as well as those levels for the noncardiomyocytes. The implications of this cellular turnover may hardly be overestimated and currently, more questions are generated than resolved with respect to the regulatory pathways and the options for a therapeutic intervention. One of the early and extensively evaluated topics in cardiovascular medicine covers the significant contributions of the cardiac fibroblasts to the cardiac ECM constitution and remodeling.[11–13] In this context, it is worthwhile to recognize the full role of the ECM of the native heart, which is not merely a space dividing scaffold but also a significant contributor to the biomechanical performance of the heart and a distinct actor and cooperator in the process of regulation of cardiomyocyte function.[14–16] A wide range of different components are embedded in the entire network of the ECM. There are structural proteins, most prominently fibrillar collagens and elastins, with a predominantly biomechanical role, whereas other proteins, such as the constituents of basal lamina, primarily have an impact on cell adhesion properties and thereby regulate the degree of cell–matrix interaction. In the latter group, collagen type IV, laminin, and fibronectin are well-recognized promoters of cell adhesion. Hence, the addition of the components of the basal lamina significantly enhances the functional outcome of three-dimensional (3D) cultures of cardiac cells *in vitro*.[17] In contrast, a number of functional counter players exist, such as tenascin C or thrombospondin, to allow a fine tuning of cell adhesion properties of the native ECM depending on the activation of different signaling pathways. Furthermore, ECM-associated proteins, such as osteopontin (OPN), are recently recognized as differentially expressed components that are critically involved in pathological changes leading to degeneration and calcification of cardiovascular structures.[18] The presence of OPN is associated with different pathological changes, such as viral myocarditis or postmyocardial infarction remodeling, and a cross talk with other ECM regulating systems is suspected. However, the full range of the different interactions of ECM-associated proteins, such as OPN,[19] remains to be elucidated in future studies. An important group of cardiac ECM components is represented by proteoglycans, which are structurally composed of one or more glycosaminoglycan (GAG) chains covalently bound to a (core) protein. Their physical properties are of paramount importance in biomechanically challenged tissues where a dynamic change of compressive forces occurs. As a general filling matrix, also called ground substance, proteoglycans are generally present in the connective tissue of different organs and are capable of building complexes with other ECM components, such as collagens. Furthermore, proteoglycans have a relatively large binding capacity for extracellular H_2O and cations, such as Ca^{2+}, which underlines their functional role in regulating extracellular water and electrolyte homeostasis.[20] The aforementioned tenascin-C is recently shown to play a role in myocardial remodeling after ischemic injury, and it is most likely that many (if not all) of the different components of the cardiac ECM have an impact on the physiologic cellular and extracellular turnover of the heart, as well as on the remodeling pattern after myocardial injury.[21]

Because of ECM-linked biomechanical cues, interactions between the ECM, ECM producing cardiac fibroblasts, and coronary endothelial cells are expected, which in turn may act on cardiomyocytes by a series of bioactive messengers.[22] Conclusively, cardiomyocytes are strongly dependent on their cellular and extracellular environment. Endothelial cells and cardiac fibroblasts are well-known teammates in maintaining and supporting cardiomyocyte morphology and function, both *in vivo* and *in vitro*.[23] A dysfunction of either of the former cell types has deleterious effects on the natural fate of cardiomyocytes and may lead to a global functional impairment of the heart, and ultimately to cardiac failure. Coronary microangiopathy and cardiac fibrosis are only two of many pathological developments, in which a misbalance in noncardiomyocyte regulation impairs cardiomyocyte function in a direct or indirect manner with significant downstream effects.

The challenge of the old paradigm that used to neglect any regenerative capacity in the adult mammalian heart depicts the importance of a deeper understanding of the mechanisms that

direct regeneration under physiological or pathological conditions. Furthermore, functional properties, such as the electrophysiological integration of the cardiac cells, are sensitive products of perfect structural arrangements.

The *in vitro* generation and *in vivo* guidance of a cardiac patch imperatively warrant a high level of control of the development and the integration of all, cardiomyocytes and non-cardiomyocytes as well as their functional interplay within a physiological extracellular environment.

6.624.2. Clinical Indications for Myocardial Patch Repair

6.624.2.1. Congenital Malformations

A series of anomalies with a wide range of severity demand a surgical repair and the use of external patch material is often mandatory. Along the relatively young history of pediatric cardiac surgery, different strategies for the correction of the most common cardiovascular malformations have been established. In parallel to the development and refinement of surgical techniques, a continuous evaluation of different materials for their use as a functional and long-lasting surgical patch has been taking place.

According to their anatomical implementation, patch implants designed for reconstruction of vascular structures may be distinguished from those that are used for replacing myocardial (intracardiac) structures. Among the vast number of isolated congenital cardiac defects and their combinations, the most common anomalies and the surgical approaches using patch materials will be briefly outlined in the following. The development and the clinical use of vascular patch materials are discussed in other chapters of this work.

6.624.2.1.1. Atrial septal defect

A structural defect in the muscular wall that separates the left from the right atrial cavity is called atrial septal defect (ASD). Simple forms of an ASD are described by an isolated defect in the central region of the septal wall. A small to mid size ASD may be closed by a direct suture during open heart surgery, representing an exceptionally safe procedure with excellent long-term results. In recent years, many centers have adopted transcatheter device implantation techniques as a routine intervention for most of ASD patients with high success rates, although complications necessitating operative correction may impact the overall outcome.[24] However, large ASDs, usually with a diameter larger than 20–25 mm, may be optimal candidates for primary operative patch repair, and modern surgical strategies involving a less invasive access, for example, via right anterolateral minithoracotomy lead to high satisfaction for both, the patient and the surgical team.[25] The interatrial and the interventricular septal wall are mostly muscular structures that nevertheless have little contractile contribution to the overall pump function of the heart, although this view has been challenged for the interventricular wall.[26] As a consequence, noncontractile patch material of synthetic (e.g., polytetrafluoroethylene (PTFE) or Dacron) or biological (fresh or glutaraldehyde-fixed autologous pericardium) origin may be used for ASD repair with an excellent short-term outcome and almost no limitations in the longer term. Hence, the outcome of pediatric patients with a successful ASD repair is not limited by the characteristics of the patch material and the overall long-term survival of these patients matches that of the general population. Even in cases when ASD is accompanied by other malformations needing surgical correction and even when xenogenic pericardial material is used, long-term durability turns out favorable. In a clinical series of 60 patients, the 15-year freedom from patch failure has been reported to range around 92%.[27]

More complex cases may present as a rather superior (cranial) or inferior (caudal) location of the ASD within the septal wall. These cases frequently include additional defects along the atrioventricular continuity (partial atrioventricular septal defect) or they may be associated with any other abnormal development affecting the superior vena cava or the pulmonary veins (superior sinus venosus). But even under these circumstances, the reconstruction of the atrial septal wall and the correction of the vascular blood flow may yet be well managed using the above-mentioned patch materials. However, considering the low blood flow velocity and the flow pattern in the atrial cavities and in venous vasculature, a cardiac patch at these implant sites are at a potential risk for thrombosis. This is of particular importance for the design of an optimal biomaterial for the reconstruction of such complex ASD malformations.

Moreover, associated defects of the atrioventricular valve(s) may need the use of valve reconstruction techniques or the implantation of valvular prosthesis, if a reconstruction cannot be achieved. Special considerations in designing and manufacturing of heart valves are discussed in other chapters.

6.624.2.1.2. Ventricular septal defects and tetralogy of Fallot

The most common congenital anomaly among all born alive babies is a ventricular septal defect (VSD), which can occur in the superior, membranous part (so-called perimembranous defect) or in the inferior, muscular region of the septal wall. As for an ASD, a combination of this anomaly with other malformations, such as the tetralogy of Fallot or common arterial trunk, is possible and common. Also an association with other systemic conditions, such as trisomy 21 (Down syndrome) is recognized. The combined incidence of a VSD, whether as an isolated defect or part of a syndrome, reaches roughly half of all congenital heart defects.[28] VSD of muscular type, particularly if of smaller size, may undergo spontaneous closure in the first years of life, but a multifocal presence or a large VSD with significant shunting volume may urge for an early intervention because of progressive heart failure. Moreover, a persisting VSD that permits a significant blood volume to shunt from the high pressure left ventricle to the low pressure right ventricle may represent an indication for patch repair even in the absence of any symptoms in order to prevent the late development of pulmonary vascular disease (pulmonary hypertension and right ventricular hypertrophy).

VSD repair involves the implantation of a patch via a right atrial, a right ventricular, or alternatively, a pulmonary artery incision, depending on the location of the defect. Because of the high pressure gradients across the ventricular septum, strong synthetic patch materials are preferred to autologous pericardium or conventional biological solutions that are

commercially available today. Using this approach, some theoretical limitations may arise from the fact that the surgical repair takes place at a very young age and somatic growth might overload the small patch in the long term. Also, thrombembolic events and the risk of infection may be listed as theoretical drawbacks. However, in the clinical setting, growth-associated problems as well as neurological complications due to left heart embolic events are very rare, and other prophylactic measures, for example, to prevent an infective endocarditis are only recommended during the initial 6 months after patch repair,[29] when the autologous endothelialization of the implant material is yet underway. In specialized centers, a low operative risk is expected for uncomplicated cases, usually in the range of very few percents. Additional risks derive from concomitant defects or other conditions, such as pulmonary hypertension in patients with a long-standing history of VSD.

A relatively frequent syndrome that consists of (1) a VSD, (2) a right ventricular outflow tract (RVOT) stenosis, (3) a so-called overriding aorta with an anatomic dislocation with respect to the ventricular septum plane, and (4) right ventricular hypertrophy was named after a French physician, Etienne-Louis Arthur Fallot, who was among the first to report on this anomaly.

Unlike the initial situation in isolated cases of ASD or VSD, the combination of RVOT stenosis and VSD leads to a right-to-left shunt in the Fallot babies. This way, the shunting blood volume with low oxygen saturation circumvents the pulmonary circulation and enters directly the systemic circulation. As a result, peripheral arterial oxygen saturation is diminished and these babies appear morphologically as cyanotic, which is generally referred to as blue baby syndrome. Varying extents of the involved defects are observed and correlate with the phenotypic presentation as well as the degree of symptoms and also the level of risk for the life of the diseased. Similarly, the management of the tetralogy of Fallot patients may vary significantly depending on the individual constellation. As a general rule, the corrections of the VSD and the RVOT obstruction are main therapy goals. In both steps, often a patch reconstruction is employed (**Figure 1**). Regarding the VSD, similar considerations as mentioned above will govern the strategy, although reconstruction in the setting of Fallot might become more challenging because of the abnormal anatomical constellation of the aorta with a shift toward the RVOT. The reconstruction of the latter is frequently performed by using a synthetic patch to augment the narrowed outflow tract. When the pulmonary valve and a considerable segment of the pulmonary artery are also stenotic, the use of further implants, such as an allogenic donor valve conduit (so-called homograft), optionally with an additional prosthetic extension may be considered.

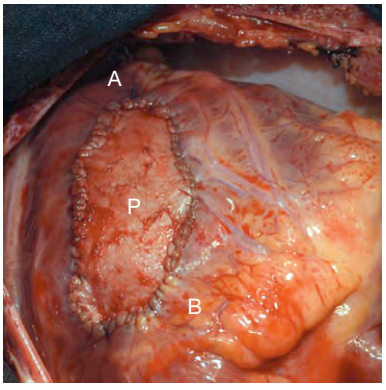

Figure 1 Intraoperative image demonstrates the anterior cardiac aspect after the implantation of a large pericardial patch (P) to reconstruct the obstructed right ventricular outflow tract. A indicates the apex of the heart and B indicates the base of the heart. Image provided by Dr. T. Loukanov.

Considering the complex nature of this syndrome and the large extent of the operative steps involved in the complete reconstruction, the initial outcome is remarkably satisfactory with a low operative risk of about 3% and a late survival rate of greater than 90% after 25 years.[30] However, the use of different implant materials (VSD patch, RVOT patch with or without homograft) and the accumulation of their individual risks (thrombosis, restenosis, degeneration and calcification, etc.) contributes to long-term morbidity and mortality.[31] Therefore, a further improvement of overall outcome for this patient cohort may be achieved by novel surgical strategies involving the use of superior biomaterials.

However, for the isolated patching of a VSD or an ASD, the currently achieved outcome with available synthetic materials leaves hardly any margin for a further improvement. Any future trend in the development of novel materials will have to consider both, the limited clinical need and tiny potential for a further clinical improvement by superior implant materials and the necessary financial and manpower investment in the engineering process and application-related resources for the use of novel cardiac patch materials.

6.624.2.1.3. Hypoplastic left heart syndrome and functional single ventricle

In some very complex malformations, one of the two ventricular chambers is severely underdeveloped (hypoplastic). Under these circumstances, the fetal and early postnatal circulation can be managed by the single functional ventricle only because of physiological fetal shunts, for example, the arterial duct connecting the pulmonary with the systemic circulation, or because of further concomitant defects, for example, a VSD. Either anatomical constellation resulting in a functional single ventricle represents a serious and life-threatening malformation that warrants best current therapy in order to provide considerable survival chances for the newborn. Different strategies have been developed to create a circulatory situation that permits the survival of the neonate period and the early infancy to reach an age and a body size that allows for more definite surgical therapy (staged procedures). However, despite the significant improvements in surgical techniques resulting in better outcome with regard to early survival, all currently applied strategies are mainly of palliative nature and no cure has become available for this group of severe malformations. A detailed description of the various anatomical pictures and a detailed surgical approach for their respective correction certainly goes beyond the scope of this chapter. However, it is important to understand that an early and comprehensive surgical intervention is necessary for the affected babies to survive. This involves the use of patch materials to reconstruct intracardiac and extracardiac structures, such as the ventricular septum, or the ascending aorta. In a very general way, the surgical goal is defined by an

optimal structural preservation and functional employment of the single developed ventricle for the maintenance of the systemic circulation, while a passive blood flow from the caval veins to the pulmonary vasculature (Fontana circulation) remains as the best available situation in the face of the severely hypoplastic morphology of the other ventricle. The challenging surgical plan may be abstracted in one single sentence, yet its completion takes up to a few repetitive operations over a time course of several years. Staged surgical interventions and frequent hospitalizations may amplify the general disadvantages of the currently available patch materials, thus contributing to a negative impact on the overall patient outcome. Hence, the risk of outgrowth of the installed patches or conduits, or the rate of thrombotic events and infections, is of particular concern in patients after an operative therapy for this kind of severe cardiac defects. Moreover, the late complications of an impaired cardiac output and the resulting high rate of congestive heart failure have a tremendous impact, both on freedom from reoperation and total survival.[32] Although the absolute number of babies born alive with a functional single ventricle is fairly low (a substantial proportion of severe cardiac malformations are prenatally lethal), the severity of the clinical impact imperatively calls for sustained efforts in developing a strategy for a cure. Notably, more than for any other patient group a cardiac transplantation is the only therapy that comes close to a cure.[33,34] An alternative approach that aims at the recreation of the dysfunctional ventricular parts will depend on the availability of a significant amount of additional contractile tissue, and may offer the perspective of not only an improved long-term prognosis including higher survival rates but also a normal level of quality of life.

6.624.2.2. Acquired Heart Disease

6.624.2.2.1. Coronary heart disease

Coronary heart disease (CHD) is a degenerative process that affects a large proportion of the population worldwide. A number of risk factors associated with the development of CHD have been identified and some of them have become accessible to medical therapy, for example, arterial hypertension, diabetes, and disorders of lipid metabolism, while others may be controlled by modifying patterns of daily behavior, which are collectively referred to as lifestyle issues. However, a number of further factors remain unknown or untreated, for example, genetic disposition. Hence, despite the growing amount of knowledge on the development and progression of CHD, the complications of this disease pose an unbowed burden on the individual patient and the whole community. The typical complications of CHD include the acute myocardial infarction (MI) with subsequent loss of contractile tissue and adverse myocardial remodeling, the development of ischemic cardiomyopathy on further progression, and also the occurrence of associated arrhythmia or thromboembolic events. Congestive heart failure represents the end stage of CHD, and also occurs as a consequence of other cardiac pathologies. To prevent the development of end-stage heart failure, a large armamentarium has been developed and proven effective for the treatment of CHD, including pharmacological, interventional, and surgical options. And yet, in a significant number of patients the development of end-stage heart failure cannot be prevented. Heart transplantation and mechanical assist device implantation remain as last therapeutic options for these very ill patients. Cell transplantation and other methods have been investigated as novel options to augment the myocardial contractile activity, but until today no success of a broad clinical relevance has been achieved. A myocardial patch has been suggested as an ideal solution for many currently untreatable chronic cardiac conditions and especially as a cure for localized ischemic injuries, for example, as a replacement part for post-MI dysfunctional regions of the heart. But unfortunately, until today the idea of a contractile myocardial tissue fragment has not been accessible to humankind bioengineering.

Another challenging situation currently without a perfect solution is the rupture of recently infarcted myocardial tissue. Following an acute MI, an inflammatory process is triggered by the factors released from the necrotic tissue. The loss of contractile cells and the acute injury diminish the active contractile performance of the heart. In parallel, a vicious circle of hypoxia and marked inflammatory infiltration of the myocardium leads to a dramatic reduction of the biomechanical strength of the myocardium, which reaches a maximum impact a few days after the initial infarction, typically within the first 2 weeks. A rupture of myocardial tissue, often in ventricular septal region, is one of the most critical complications of an acute MI. In contrast to a congenital type of VSD, post-MI VSDs are very difficult to manage and even in the modern era of cardiac surgery a high risk of mortality shadows the perspectives of the concerned patient. There are two different explanations for this unfavorable outcome. (1) An acute onset of a VSD is hemodynamically poorly tolerated because of the absence of any adaptation time for the circulatory system and the involved physiological mechanisms of compensation. (2) As mentioned before, following an MI, localized tissue necrosis and inflammation not only weaken the ischemic area of infarcted myocardium but also reduce the biomechanical strength of the adjacent areas, which translates into an extremely fragile tissue on surgical exposure and manipulation. Hence, endeavors for suturing a cardiac patch for direct repair are often frustrating and sometimes end up even abortive.

In the setting of a post-MI-VSD, some characteristics of an ideal cardiac patch are of paramount importance: (1) instant availability, (2) durability under a high range of dynamic mechanical loading, (3) resistance to the hostile biological milieu that is present in the acute ischemic setting, and (4) pronounced compatibility of the passive biomechanical features of the patch with those of the surrounding myocardium, for example, pliability and elasticity, for an optimal fit after implantation. However, because an ideal cardiac patch that fulfills all of these criteria does not exist, the same patch materials that are used for the reconstruction of chronic (e.g., congenital) VSD are also used for the repair of post-MI-VSD in the acute clinical setting.

6.624.2.2.2. Dilatative myocardial dysfunction

Idiopathic dilatative cardiomyopathy (DCM) is a term to describe a condition in which the cardiac function is significantly impaired because of a structural alternation of the heart with dilated chambers and no otherwise diagnosed reason for the observed functional impairment. Depending on the underlying cause, other forms of cardiomyopathy, such as toxic, inflammatory, or endocrine types, are distinguished.

If a specific cause is identified, a specific treatment, for example, anti-inflammatory and antiviral therapy, or correction of an endocrine dysregulation, may be initiated to support the symptomatic cardiocirculatory therapy. However, only limited therapeutic options may be offered on the diagnosis of an advanced cardiac impairment, and a prevention of further disease progression by conservative means of heart failure treatment represents the first line therapy. When end-stage heart failure develops, only heart transplantation or the implantation of a mechanical assist device remains as a further option. This progression affects up to half of all patients diagnosed with DCM and thus the underlying disease represents a significant medical problem.[35] Similar as for ischemic cardiomyopathy, also for this entity of cardiac disease a few novel strategies that are guided by the spirit of regenerative medicine have been investigated, including cell transplantation and scaffold-based cell and gene therapy.[36]

In the clinical arena, however, a surgical approach other than transplantation or ventricular assist device implantation could not be established so far.

6.624.2.2.3. Other forms of cardiomyopathy

A morphological development that is contrary to the situation in dilatative forms of cardiomyopathy may be observed in some hereditary syndromes, because of an unphysiologic hypertrophy of the myocardial tissue (hypertrophic obstructive cardiomyopathy, HOCM) or because of the deposition of excessive amounts of abnormal substrates (e.g., in amyloidosis). There is a large heterogenic group of cardiomyopathies that share common morphological features of nondilated but yet dysfunctional ventricles, but may be distinguished by a wide range of histopathological and molecular biological characteristics with different associated genetic disorders and systemic diseases.[37–40] In case of mainly cardiac localized tissue alterations, for example, subaortic septal hypertrophy and left ventricular apical hypertrophy, surgical or interventional options for the reduction of the pathologic myocardial mass have been applied with considerable success. In case of primary systemic conditions with secondary cardiac manifestation, a targeted treatment for the underlying disease may be the best option when available.[41,42] However, therapy strategies aiming at reversing morphological organ alterations and thereby restoring myocardial function often show little success when large parts of the organ are affected, particularly at later stages of the disease.[42] Thus, the prevention of disease progression and fatal complications (e.g., implantation of an internal cardioverter-defibrillator to prevent death from ventricular arrhythmia) represents the main principles of current therapy.

In some systemic conditions, such as amyloidosis, even cardiac transplantation can offer no cure, but remains palliative because the same pathological changes reoccur within the donor organ over time.[43,44] Further rare entities of nondilatative cardiomyopathies include infections pathologies and enzyme-deficiency-based storage disorders.[41,42]

The role of surgical or catheter-based interventions is largely depending on the specific type and the localization of the pathologic changes, for example, systemic versus local cardiac manifestation. A total replacement of dysfunctional parts of the myocardial tissue or even the whole organ can only lead to sustained cardiac improvement when a postoperative degeneration is effectively prevented. Unfortunately, many of the different syndromes associated with a progressive cardiac dysfunction appear only moderately accessible to current therapeutic options and thus even a total replacement of the heart by orthotopic transplantation cannot promise a substantial long-lasting benefit for the patient. Given the aforementioned diverse features of the numerous disease forms, a potential impact of a living cardiac patch, even if one day available, for the therapy of the majority of non-dilatative cardiomyopathies is largely unclear.

6.624.3. Patch Materials in Current Clinical Use

6.624.3.1. Autologous Pericardium

There are numerous situations where a congenital or acquired defect warrants coverage by an implant material that ideally displays the same characteristics as the surrounding native tissue. Autologous pericardium has been successfully employed in various cardiac surgical procedures for a long time. In general, the surgical access to the heart and proximal vascular structures is created by an incision to the pericardial sac after entry into the thoracic cavity and preparation through the extrapericardial structures (e.g., thymus or retrosternal adipose tissue). Irrespective of ventral (that is median sternotomy) or lateral (e.g., anterolateral thoracotomy) surgical access, a considerable area of the pericardial tissue may be exposed, which may be sacrificed for the achievement of crucial reconstructive goals, for example, enlargement of a vascular stricture or closure of a septal defect. The only delicate structures that must be preserved and deserve minituous caution during the preparation are the phrenic nerves that run laterally on both sides of the pericardial sac. As a consequence, the entire anterior part of the pericardial sac may be harvested as a valuable biological material.

There are many advantages that support the use of autologous pericardium in the setting of congenital as well as adult cardiac surgery: (1) the availability of the material without the need of additional surgical trauma for the harvesting of the tissue; (2) the instant availability in case of the use of native pericardium; the application of a fixation step by using glutaraldehyde (varying concentrations and corresponding incubation times) may cause minor delay, which may be without relevance, if proper planning of the order of the surgical steps has taken place prior to the procedure; (3) because of the autologous origin, no immunological reaction or clinically relevant inflammatory process is expected on implantation; (4) because of the biological origin and particularly because of the fact that native pericardium is a living tissue, a certain benefit regarding the risk of infection has been anticipated for this material and autologous pericardium is favored for the reconstruction of abscess cavities in the setting of surgery for infective endocarditis; (5) the easy access and preparation avoid additional time-consuming efforts for a tissue harvesting by the surgical team, and the involved instrumentation and media are ubiquitously available. Also, intraoperatively harvested tissue is sterile and needs no further treatment to avoid an infection. Hence, from the economic point of view, autologous pericardium represents the most favorable solution when a patch material is needed in cardiac surgical procedures;

(6) the passive biomechanical strength of pericardium integrated with the dense tissue structure results in suitability as a patch material in the pulmonary as well as in the systemic circulation; (7) the low incidence of bleeding from suture holes in a pericardial patch (in contrast to some synthetic counterparts); and (8) finally, the potential for remodeling and possible growth is an attractive advantage of autologous pericardium.

Because the heart is surrounded by pericardial tissue, an *in situ* use of pericardium may be feasible for specific reconstructive procedures, although a convincing amount of data supporting the superiority of an *in situ* or a pedicled pericardial patch to a free graft does not exist.[45] The question regarding the necessity of a fixation prior to implantation may be regarded in a controversial way by different institutions and surgeons. In general, a more or less advanced cross-linking of all protein structures, involving all cellular and extracellular components, is achieved by the incubation of native pericardium in a glutaraldehyde solution with varying concentrations of 0.5% up to several percentage over a time period of several minutes up to 15 or 30 min. This leads to a reduced elasticity of the material and also causes the later patch implant to be prone to calcification in the long term. Moreover, the toxicity of glutaraldehyde necessitates a thorough washout of the fixation solution before implantation. In turn, the risk of dilatation is reduced by a fixation, particularly, when the patch is exposed to high pressures *in vivo*, for example, in the systemic arterial circulation or in the left ventricular wall structures.[46]

As the native pericardium mainly consists of interstitial cells, no dynamic contractile activity may be expected for this tissue material. Experimental studies have demonstrated that a transformation of these interstitial cells from a quiescent fibroblast-like phenotype to a more activated myofibroblastoidal form may take place on stimulation by mechanical or biochemical cues. Hence, a certain remodeling process is expected for nonfixed pericardium when used as a cardiac or vascular patch. Glutaraldehyde fixation results in a widely inert material that will remain purely passive and also will not permit a relevant *de novo* repopulation for a later myogenic function.

As a consequence of the aforementioned issues, pericardial patches are widely used in congenital and adult cardiac surgery, where an enlargement of cardiac or vascular structures by a biocompatible material is necessary. Autologous pericardium is also used for repair of structures that are injured by an infective or inflammatory process. One classical indication for the use of autologous or xenogenic pericardium is the reconstruction of annular structures that are affected by an abscess formation in the context of infective endocarditis.[47] In other settings, when the ventricular outflow tract is replaced, a gain in the global ventricular contractile function may only be achieved by the support of existing native myocardium through the operative procedure, for example, by an enlargement of the RVOT, or by the correction of a regurgitation or shunt pathology, for example, as part of the correction of the tetralogy of Fallot. Under either circumstance, pericardial patch materials have proven long-lasting durability of several to many years, which is correlated by high rate of freedom from re-intervention.[48,49]

A disadvantage of the use of autologous pericardium is related to the postoperative adhesions that involve cardiac structures and the surrounding tissue. The pericardial surface that faces the heart usually is less susceptible to excessive adhesions, and a partial or near-complete closure of the pericardial sac at the end of the operation is an effective method that some surgeons rely on as a safety measure for a possible future reoperation. The partial resection of autologous pericardium always includes the compromise associated with increased adhesions in that particular area.

6.624.3.2. Xenogenic and Decellularized Xenogenic Pericardium

The need for an off-the-shelf material that is characterized by an unlimited and ubiquitous availability has inspired the exploration of an animal source for the manufacture of appropriate surgical materials. Bovine pericardial tissue (donor animal: cow) and equine pericardium (donor animal: horse) are commercially available materials that are subjected to a fixation process during their industrial processing. Unlike autologous pericardium, the fixation-mediated cross-linking of the donor cell antigens is of paramount importance for the immunological tolerance of these xenogenic implants in a human recipient. Unfortunately, the use of commercial xenogenic tissues is associated with a pronounced calcification, which may be explained by a chronic process due to the strong immunological cross-species barrier. When considering the use of xenogenic pericardial patches, degenerative events and calcification have to be weighed with respect to the advantage of a ready-to-use material with no donor-site-related concerns for the recipient.

Recently, the decellularization of different natural tissues has resulted in the production of several novel biomaterials, of which a few have entered commercial distribution as bioimplants in different surgical fields, although their role in the field of cardiac surgery has not been defined, yet. Today, bovine and equine pericardia are commercially available for human surgical application.[50,51] However, the use of decellularized xenogenic materials in the cardiovascular surgical field has suffered a tremendous loss of credibility after reports on limited durability and increased rates of failure in the setting of heart valve implants made of decellularized animal tissue.[52,53] The underlying problem of complete antigen removal without major destruction of the ECM is the major hurdle for the broad introduction of decellularized xenogenic biomaterials into clinical practice. While some studies with focus on the reconstruction of abdominal or musculoskeletal structures allow for diverse conclusions on the outcome of the currently commercially available decellularized materials,[50,51] caution is indicated when a cardiovascular structure has to be replaced, as a failure of these structures has potentially life threatening consequences for the recipient.[52]

6.624.3.3. Synthetic Polymers

For many years, chemically produced polymers have been used in surgical procedures. Suture material and patch materials are today widely used across all surgical specialties. For cardiovascular procedures, synthetic polymer materials made of Dacron

and PTFE are the most popular implants, either as vascular grafts or as cardiac patch implants.

A long-standing history of application found the ground for the safe and routine use of Dacron. On implantation, a stable persistence of highly pressure-resistant Dacron materials guarantees reliable long-term structural survival and maintained function. As a drawback of Dacron, a pronounced nonspecific inflammatory reaction to the implant (foreign body reaction) is observed, that causes excessive adhesions at the interface between the implant and the recipient (host) tissue. Furthermore, Dacron ranges among the most rigid synthetic materials, which impacts the overall compliance of cardiac chambers or vascular segments that are reconstructed with Dacron materials. In this sense, PTFE (also, Gore-Tex®) has some advantages over Dacron. On reoperation, technical difficulties arising from adhesions around graft material are less intense and at the same time, a microporous structure allows a higher level of interaction between the implant and the surrounding recipient tissue by the permissive character toward migrating interstitial cells. A favorable increase in elastic characteristics is paralleled with some tendency for bleeding of needle holes.

Although novel synthetic materials with markedly improved characteristics are under current experimental investigation (see Section 6.624.4), the current clinically available synthetic materials display major disadvantages when compared to their biological counterparts: (1) as a nonviable material, Dacron, PTFE, and other polymers do not support any growth tendency – a significant limitation in the pediatric cardiac surgery; (2) because of the long-term persistence *in vivo*, an elevated risk of infection with the need for challenging reoperative procedures threatens the recipient in the long term; (3) as with all current cardiac patch materials in clinical use, there is no active participation in the contractile function of the heart; (4) when implanted at intracardiac sites with direct contact with the blood circulation, an elevated risk of thrombosis and embolic events impacts the clinical outcome of pediatric and adult patients which may be managed by temporary anticoagulation or antiplatelet medication – each with its own associated risks for bleeding complications.

6.624.4. Experimental Synthetic Polymers

With the advent of technical advances in chemical engineering, the first generation polymers are most likely to be abandoned by novel materials that fulfill a number of essential criteria for a truly bioactive material. Biodegradability has already been realized with the introduction of poly-lactic and poly-glycolic acid materials. However, the exact control over the speed of polymer degradation has continuously been in the focus of experimental work. Beyond the speed of ECM degradation, a cell-responsive pattern of ECM turnover has been desired for novel synthetic ECM materials. One interesting approach lies in the use of enzymatically degradable poly (ethylene glycol) (PEG) hydrogels. By introducing specific amino acid sequences that are susceptible to cellular matrix metalloproteases (MMPs), a more physiologic cell migration pattern has been demonstrated for PEG.[54,55] In other circumstances, the introduction of bioactive peptides that specifically trigger integrin-dependent cellular responses has been proven as a promising tool to direct various basic cell characteristics, such as cell phenotype, cell migration, cell division, and differentiation.[56,57] In a study with a cardiac progenitor cell line, the use of an engineered ECM based on PEG, including MMP-sensitive domains, arginine-glycine-aspartic acid (RGD) containing domains, and integrin-responsive domains, has resulted in an enhanced cell differentiation toward cardiac cells, improving differentiation markers on the RNA and protein level.[58] Most interestingly, a cell driven release of matrix-bound molecules may also be successfully applied using PEG. By such an 'enzymatically accessible' addition of growth factors, the site-specific release of desired factors within the recipient organism, dependent on the site of cell invasion, becomes feasible.[59] Although the majority of the published studies so far have focused on wound healing or angiogenesis, myocardial engineering and regeneration is certainly an area that may benefit from the application of such smart bioactive ECM materials.[60] Using basically the same approach, the delivery of matrix-bound DNA with a controlled release pattern *in vivo* may become feasible in order to achieve a targeted local gene delivery without using viral vectors.[61,62] The use of an ECM-bound delivery of DNA not only offers the advantage of a greater spatial control of gene delivery, but may also enhance the degree of efficacy.[63] With a similar level of enthusiasm, the control over a wide range of physical characteristics of novel synthetic materials has become accessible. Using polymers and copolymers containing polyesters, polypeptides, poly (amino urethane), and chitosan, a number of synthetic materials may be produced with a thermoresponsive or a pH-sensitive physical state (for review refer to Nguyen and Lee[64]). The possibility of controlling the conditionally regulated solid to gel transition of a specific material *in vivo* paves new avenues for a variety of pharmaceutical and bioengineering applications. As an example, the injection of a liquid- or gel-based mixture of ECM and cells into a region of infarcted myocardium may result in higher cell retention, if the applied ECM material provides a temperature and/or pH transition to a solid phase under the *in vivo* conditions, thereby successfully immobilizing the injected cells at the site of delivery. This may further improve the results of previously applied, less controllable ECM components that have been used for cell delivery to injured or ischemic myocardial regions.[65] The advantage of tailored responsiveness to pH and temperature variations paired with bioactive molecular cues make these novel ECM materials attractive components for bioengineering purposes, particularly for soft tissue engineering using demanding cell types, such as skeletal myoblasts, cardiomyocytes, and their respective progenitors.

6.624.5. Strategies for Myocardial Tissue Engineering

The evident need for an alternative to some currently unsatisfactory therapy options in the cardiovascular field has inspired a growing scientific community to develop strategies for *in vitro* or *in vivo* organ engineering or regeneration, respectively. Over the past two decades, the scientific field of tissue engineering has experienced a dramatic progress in quantitative measures as well as with respect to the complexity of the involved

techniques. Studies with the focus on generation of a cardiac tissue surrogate with the ability for a later use as a patch started in the mid-1990s as rather simple 3D cell culture units and emerged as multifaceted and complex arrangements of multiple cellular and extracellular components in the recent years. In the following sections, different general strategies for the repair of malfunctioning myocardium or myocardial defects are highlighted. Representative models of a cardiac patch or a tissue analog that already have been demonstrated to be successful *in vivo* will be discussed along with further *in vitro* results that hold a lot of promise for a successful *in vivo* application in the future.

When a summary of the past achievements in cardiac tissue engineering is to be drawn, a categorization of different experimental series and models becomes necessary. Notably, a large number of published reports describe a 3D beating structure that has been achieved through the *in vitro* application of a cell suspension on a porous scaffold material, or alternatively by mixing cells with solidifying liquid ECM components *in vitro*.[17,66–71] A complete discussion of all related reports goes beyond the scope of this publication. Therefore, the focus in the following sections is directed toward some of the *in vitro* models that result in a structure with the potential use as a cardiac patch. A series of other investigations that follow the innovative idea of guided tissue regeneration, thereby strictly relying on the *in vivo* present local milieu, are discussed in the Section 6.624.6. Finally, a large number of further novel interventions for the treatment of irreversible myocardial injury have been recently introduced, with some remarkable preliminary success. However, in the majority of these approaches, a cardiac patch may not be generated *in vitro* or *in vivo* and the so far anticipated therapeutic effects may rather be derived from an indirect change of the natural fate of the cardiac disease. Hence, Section 6.624.7 only sheds a light on some of these alternative approaches, their current advances, and controversies.

6.624.5.1. *In Vitro* Construction of 3D Structures with Cardiomyogenic Characteristics

The laboratory manufacture of cardiac tissue has been one of mankind's dreams for many years. Early *in vitro* cell studies were restricted by primitive technical tools and the lack of a deeper cell and molecular biological understanding of the basic requirements of cultured cardiac cells.[72–75] The advent of biotechnological methods for the production of enzymes, complex culture media, and growth factors resembles an important prerequisite for the isolation and culture of demanding primary cell types, such as primary adult cardiomyocytes.[76] Additional advances in biochemical engineering allowing the production of increasingly biocompatible scaffold materials led to the first opportunity of *in vitro* construction of 3D cell cultures. With the dawn of the last decade of the past century, a growing body of knowledge about the crucial principles of *in vitro* development of 3D cell cultures formed the fundament for a novel discipline that was termed tissue engineering.[67,77,78] The principles of tissue engineering were applied to different organ systems and preliminary experimental results give rise to hope for a novel universal solution in therapy of various disorders.[79] Similarly, the engineering of a bioartificial cardiac patch was anticipated for the cure of both acquired and congenital heart disease.[66,71]

In parallel, 3D cardiac cell cultures were suggested as a substitute for animal models in the development and testing of novel pharmaceutical products.[17,70] Some of the involved pioneering experiments were conducted by surgical institutions, driven by the hope for a potential surgical utilization of the engineered tissue as a cardiac patch, which has been among the top goals of the investigators ever since.[79,80]

The first generation of cardiac tissue engineering models may be characterized by a few common features: a 3D physical structure was generated *in vitro* by the joint culture of isolated cells within a porous scaffold[66,71,80] or a consolidating solution of liquid scaffold components.[17,81] Collagen- and gelatin-based porous scaffolds have been commercially available for many years and a routine clinical application of these materials for the control of diffuse bleeding underlines their general biocompatibility and harmless use in humans. When mixed primary cardiac cells are cultured in an extracellular environment that is mainly constituted of collagen and gelatin, early beating activity and ultrastructural evidence of reconstituted contractile elements may be observed without any sophisticated auxiliary instruments, for example, bioreactors and mechanical simulators.[81] In parallel, synthetic polymer scaffolds were introduced as a controlled degradation pattern, and a definite composition supported their implementation in many laboratories.[82] In most experiments, a successful *in vitro* processing was defined by the ability to demonstrate basic morphological features of native cardiac tissue. When cardiomyocytes were employed, the retention of the contractile activity and some rudimentary electrophysiological features were further advocates of an advanced overall maturation of the novel tissue surrogate, suggesting the option of a future use of these constructs as cardiac patch implants.

6.624.5.2. Commonly Used Cell Sources

With the introduction of a robust cell source, such as fetal or neonatal hearts of rodent or chicken donors, a cell population that contains large numbers of cardiomyocytes became accessible. These cardiomyocytes have been preferred for cardiovascular research purposes for a long time.[83,84] They display a sustained high contractile activity *ex vivo* and a relatively low susceptibility to injury and death during the isolation process and the subsequent culture period under the artificial *in vitro* conditions. These cardiomyocyte populations become adherent to most simple materials (such as standard tissue culture dishes) even after a harsh enzymatic isolation (e.g., using trypsin), and they resume spontaneous contractile activity shortly after plating, typically resulting in beating activity in a significant proportion of the cultures soon after 24–72 h.[85] Taken together, these cardiomyocytes are strongly reliable actors *in vitro* and they may fulfill their mission and continue to demonstrate reliable function despite many constraints present under standard *in vitro* conditions. Consequently, when the choice of an appropriate ECM for the establishment of a 3D culture has to be made, a wide range of biomaterials may fulfill the basic criteria for the culture of these cardiomyocytes.

However, in most models the isolated primary cell population contains not only cardiomyocytes but also noncardiomyocytes, for example, cardiac fibroblasts, endothelial cells, and vascular smooth muscle cells. In various more recent experiments, a regulatory effect of the noncardiomyocytes on some important characteristics of the developing 3D construct and the embedded cardiomyocytes has been demonstrated.[23] Hence, cell culture techniques for specific modification of the cardiomyocyte fraction in the finally seeded cell population have been introduced early in the history of cardiac tissue engineering, all aiming at a targeted modification of specific characteristics of the developing cardiac patch.[86,87] Moreover, the effect of total cell density on the overall functional outcome of multicellular organizations of cardiomyocytes has been described decades ago[85] and more recently confirmed for *in vitro* seeded scaffolds.[71,80,88] The underlying mechanisms have been subject to studies on the cellular and molecular level, and among other issues, a critical role for spatial cell–cell communication, as well as interactions via paracrine pathways, have been suggested.[89–92] With improved protocols for the generation and selection of embryonic stem cell (ESC)-derived cardiomyocytes, the next level of cardiac tissue engineering has been entered. Although substantial ethical concerns have accompanied the scientific exploration of ESC-derived cells, their advent has – for the first time in the young history of cardiac tissue engineering – defined a specific investigative path with a potentially allogenic cardiac patch on the horizon. Although meanwhile a few technical hurdles, most prominently the tumorogenic risk on implantation, have cut down on the initial enthusiasm about ESC-derived cells, the proof of principle that has been delivered for a rodent and also for a human ESC-derived cardiac patch deserves particular attention. In an astonishing work that has somewhat revolutionized the field of regenerative medicine, a novel entity of autologous cells with an apparently unbound capacity for self-renewal and differentiation to various tissue-specific cell types has been produced by the *in vitro* manipulation of adult somatic cells. These man made cells were termed induced pluripotent stem cells (iPS) and have taken over as the anticipated protagonists in the cardiac tissue engineering scene. Their use is favored because of the circumvention of ESC and the associated ethical problems. However, with the first notice of a certain risk for the development of teratomas *in vivo*, a series of questions have been raised that are now common tasks for groups working on ESC and iPS.[93,94]

6.624.5.3. Solid or Gelling Scaffold Components: Some Considerations

Those models of tissue engineering that rely on a solid starter scaffold have been mostly limited by a heterogeneous spatial cell distribution. This warrants further manipulation and optimization in order to improve cell distribution.[80,95,96] The general principles that may govern the decision making process are comparable to those that direct the engineering approach of other organ systems or tissue fragments. The pore size of solid scaffolds is obviously a fundamental factor that may limit maximum medium convection and cell suspension penetration, although some other factors, such as the hydrophilic character of the material and the cell size, also have an impact on the initial cell seeding result. A pore size of 50–500 μm has been used successfully in previous reports.[23,86] However, some authors have noticed an optimization on cell seeding enhancing steps, such as the application of a mild centrifugal force of the seeding of the scaffolds under medium convective flow.[86,96,97] The herein described modification steps are simple and yet effective tools for improving the overall cell distribution, but on the other hand their effectiveness stems from the shortcomings of the basic setup prior to the modification. Moreover, the occurrence of scattered cell clusters within singular cavities of the scaffold and the need for the employment of further gelling scaffold materials (such as Matrigel™) for the entrapment of the cells in large scaffold pore structures[23,86] are typical phenomena associated with the use of solid scaffold materials and their predefined pore structures. In contrast, models consisting of a casting of initially liquid cell and matrix components that aggregate on mixing generally result in a more homogeneous cell distribution.[17] Beyond morphological changes, functional outcome is significantly influenced by the various characteristics of the scaffold, and most importantly, the biomechanical features and the electrophysiological performance of a cardiac patch are partially determined by the employed scaffold.[98] Early models of cardiac tissue engineering employed basic woven or knitted polymers or biological ECM materials of solid (gelatin, collagen) and liquid or gelling characteristics (collagen type I, fibrin, basement membrane extract). When biomechanical features are considered, solid polymers and biological ECM materials that are used for tissue engineering purposes outrange the cellular impact on the overall tissue performance in the initial culture phase. However, in the later culture period, for example, after 2–4 weeks, applying biomechanical testing reveals the impact of the cellular components within the cultures and the variation of parameters such as maximum tensile strength and elasticity.[95] On the microscopic level, this change in biomechanics correlates with (1) a degradation of the initial ECM material, (2) a *de novo* synthesis of natural ECM components by the embedded cells, and (3) a proliferation of oriented cells with an increasing level of cell–cell and cell–ECM adhesion. When liquid or gelling ECM materials are used, the initial overall physical strength is generally lower than in solid-scaffold-based cultures. Hence, the development of cell-derived biomechanical features becomes detectable at an earlier stage, and also active force measurements may become readily successful as early as 2 or 3 days after initiation of the cultures when the appropriate cell sources (e.g., neonatal rat cardiomyocytes) are used.[17,99]

Furthermore, the composition of the seeding cell suspension grossly correlates to the initially achieved cell composition in the condensated construct and cell size or cell shape is not a major determinant of the spatial positioning of the seeded individual cell types. This way, several different cell types with varying physical characteristics may be entrapped in a uniformly scattered order within a 3D scaffold.[23,87,100]

6.624.5.4. From Diffusion to Perfusion

However, diffusion capacity limits the maximum tissue depth in cardiac patches that are engineered according to either principle, and malnutrition and hypoxia may decrease viability of

the core regions of a growing cardiac patch.[71,96,101] For models that use higher initial cell densities resulting in a compact multicellular aggregate, a maximum tissue depth of ~100–200 μm has been proposed by multiple authors. At the most extreme, scaffold-free cardiomyocyte multilayer cultures that are produced by a method referred to as cell sheet engineering may experience diffusion limitations at a very low thickness of the assembly, resulting in a maximum thickness of even less than 100 μm.[101] However, a cardiac patch is unlikely to ever develop the desired active forces for an *in vivo* augmentation of cardiac function, neither will it withstand the forces that are periodically loaded on the various myocardial wall regions *in vivo*, unless the present dramatic limitations on the physical patch dimensions are overcome by novel modifications to the current manufacturing approaches, particularly the limitations regarding the tissue thickness. To this end, a larger thickness of the growing tissue may be achieved by several methods, including (1) targeting a lower cellular density in the final patch, (2) using a scaffold with larger average pores, (3) installing a medium convection system or even a true perfusion via a vascular network, and (4) addition of further cell types, such as endothelial cells and interstitial cells. Concepts of the category (1) and (2) may result in a thicker tissue, but functional results are expected to deteriorate because the scaffold characteristics are likely to overweigh the impact of the inoculated cells.

Following concept (3), a series of bioreactors have been tested by various groups in order to increase the quality of *in vitro* engineered cardiac patches. In early trials, a medium convection at the outer surfaces of the patch resulted already in an improved outcome.[71] Cell viability, total cellular content, and cardiac differentiation markers were improved and these effects may even be further enhanced by the installation of a true perfusion. However, a truly physiologic perfusion pattern depends on an enormous capillary capacity, and a capillary density as it is present *in vivo* may not be achievable *in vitro* because of assumable technical limitations. Notably, the average distance of capillary vessels in the native myocardial tissue ranges in the order of only 15–20 μm.[102] Yet far away from this ideal level of perfusion, a single central vessel in a 3D cardiomyocyte construct may provide the structural platform for a significant improvement in cell viability and function when culture medium is pumped through it.[103] Using disruptive imaging techniques, a spatial correlation of viability with perfusion level may become visible, which demonstrates the striking beneficial effect of relatively simple modifications to an *in vitro* model. Needless to say, along with and even beyond the pure survival of cardiomyocytes, a wide range of functional parameters are strongly dependent on tissue perfusion.[104] Hence, the extension of a central vessel to multiple vessels has been attempted in several studies.[105–107] A cardiac patch that is based on a porous synthetic material containing several scaffold-penetrating channels has been seeded with cardiomyocytes to result in improved spatial cell distribution and preservation of markers of mature cardiomyocytes. However, despite the apparent positive changes regarding the nutrition and oxygen supply in the core regions of the 2-mm-thick cardiac patches, a compact cellular mass of considerably larger depth than 100 μm is difficult to achieve, even in the instance of the use of channeled scaffolds.[105] As a next logical step, more delicate structures have been evaluated for their suitability as substitutes for a vascular network. Branching and collecting ensembles of interconnected tubular structures with smallest diameters created in the range of 60–120 μm have been proven accessible to *in vitro* reendothelialization techniques.[108] Apparently, the ongoing technological progress continuously pushes the limits for miniaturization of biocompatible structural components, such as vascular networks and ECM patterns.[109] Experiments of micropatterned scaffolds have not only extended our understanding of the interrelation of morphology and function but also have opened a new path to the *in vitro* manipulation and generation of multicellular living substrates.[108–112] Whether this trend in experimental downscaling will be guided by a continuous transfer of the involved technology into clinical practice remains speculative. From the clinical view, in the case of a channeled cardiac patch some limitations that may be experienced in replacing a blood barrier function bearing structure (e.g., septal wall between two ventricular chambers or the free ventricular wall) have to be addressed. More challenging, in the case of a miniaturized vascular tree, a connection of all channels to one single network and the linking of this network to the blood circulation warrant further novel strategies before these constructs may be evaluated *in vivo* in long-term studies. In spite of these concerns, the convincing principles that are highlighted by these experiments have set new standards for the generation of a bioartificial cardiac patch.

Another approach that aims at establishing functional tissue perfusion is based on the preservation and employment of an intact native vasculature network after the selective removal of the surrounding cellular components. This method has been developed over the past two decades and has spread among various disciplines as decellularization.[113] However, the field of myocardial tissue engineering has been granted little attention, when compared to similar scientific work with a focus on other tissue types or organ systems, e.g., urological tissue engineering or heart valve tissue engineering.[114–117] But recently, decellularization has experienced a revival as a magic tool to bypass the tremendous problems that currently limit soft tissue engineering concepts. By controlled application of a series of balanced detergent solutions, a disruption of cell–cell and cell–ECM junctions is possible with acceptable changes to the ECM. This principle has been applied to many tissues and organ fragments, including urinary bladder, small intestinal submucosa, skeletal muscle, arterial vessels, and heart valves.[118–121] In a recent study, the perfusion of a rodent heart with detergent solutions resulted in a decellularized whole heart that consequently served as a template for cardiac tissue engineering. By multifocal injection of neonatal rat cardiomyocytes, macroscopic contractile activity may be achieved that contributes to detectable force generation. This preliminary model of a tissue engineered whole heart has been characterized on the histological, the molecular biological, and the electrophysiological level and the *in vitro* results boost the enthusiasm about the future of cardiac tissue engineering. Most importantly, this model already comprises a vascular network of high quality in terms of vessel distribution throughout the scaffold (**Figure 2**). Moreover, a smooth and gradual reduction of the vessel diameter leading on the arterial side from the millimeter scaled aorta down to micrometer scaled capillaries and returning on the venous side from the capillaries to the right atrium are major advantages of the native developmental origin of decellularized scaffolds.[122]

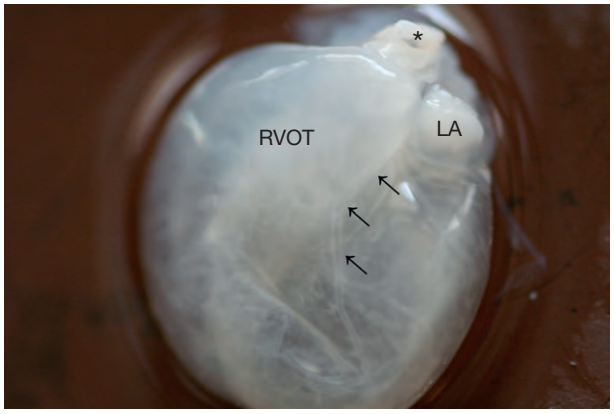

Figure 2 Macroscopic view of a detergent-decellularized rat heart with preserved macrovasculature. Ascending aorta is labeled with asterisks; arrows indicate the left anterior descending artery (LAD). LA, left atrial appendage; RVOT, right ventricular outflow tract.

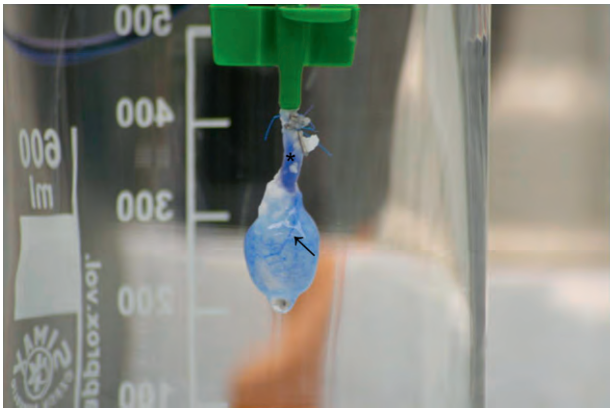

Figure 3 Gross evaluation of the patency of coronary macrovasculature. The ascending aorta (asterisk) is intubated with a canula and a dye solution is injected to perfuse the coronary vascular system in an antegrade fashion to demonstrate the preserved coronary macrovasculature. Arrow indicates the left anterior descending artery (LAD).

However, attention must be directed to maintain patency of the capillary structures, as they may be obstructed by cellular debris during the washing out process along the decellularization. A practical evaluation may be performed by perfusion of the coronary system by indicator dye injection into the aortic root of the decellularized heart (**Figure 3**). However, a quantitative assessment of the microvasculature patency is more challenging and warrants a considerable amount of investigative labor in order to establish valid and reproducible results. Also, a thrombotic occlusion during the subsequent transluminal repopulation (e.g., application of endothelial cells through the coronary vasculature) or during *in vivo* perfusion with whole blood has to be prevented, and more detailed studies have to prove the reproducibility and efficacy of maintained perfusion under *in vivo* conditions.[123–125] However, the proof of concept is there[122] and data from related studies on decellularized cardiovascular implants suggest the feasibility of innate anti-thrombotic measures through modification of decellularization protocols. To this end, a decellularized myocardial ECM ranges among the top candidate scaffolds for the creation of a cardiac patch, as it fulfills several general prerequisites: (i) biocompatibility, (ii) biomechanical stability, (iii) vascularization, and (iv) the potential of biological interaction and remodeling.[116] Ongoing studies will ultimately prove the *in vivo* value of this approach.

According to yet other strategies with the aim to overcome size limitations in cardiac patch engineering, the *in vitro* formation of capillary-like structures by endothelial cells and their progenitors is promoted. Using a liquid scaffold and a mixture of cardiac and endothelial cells, a spontaneous *in vitro* reorganization of both major cell types has been observed by different groups.[23,126] Endothelial cell-derived tubular structures that may resemble primitive capillary-like structures have been observed in synthetic as well as in biological scaffolds during *in vitro* culture. Although the respective structures represent single entities in loose and scattered localization without a uniform continuity, they have been regarded as surrogates of a vascular prearrangement with the option of finalizing maturation on *in vivo* application.[126] The latter issue is demonstrated by trials involving a cardiac implantation model in rodents,[100] which are further discussed in **Section 6.624.5.2**. But irrespective of the possibility of an eventual connection of these primitive capillaries to the systemic circulation, there is a growing body of evidence supporting the hypothesis that a wide range of biological effects on cardiomyocytes and interstitial cells may be triggered by the endothelial cell fraction in a growing cardiac patch. The addition of EC supports the maintenance of a differentiated status, represents a prosurvival factor, and increases functional performance of cardiac patches.[23,127] Surprisingly, although different biological and synthetic scaffold materials with varying microstructure have been employed, the effect of this strategy on the outcome in terms of optimized cell viability and contractile activity was comparably high, suggesting an independent protective role for cocultures of EC in a cardiac patch.

6.624.5.5. Controlled Stimulation by a Cellular Workout Program

'Form follows function.' This often cited basic principle proves valid for a wide range of remodeling processes on the cellular, tissue, and organ level *in vivo*. The most acknowledged examples concerning muscular tissue are hypertrophy on an increased level and the adverse process, hypotrophic degeneration, which occurs after withdrawal of a minimal level of physiological stimulation. Adopting this principle for cardiac tissue engineering purposes, an increasing number of different stimulation modes have been applied in order to control the morphology and function of an *in vitro* engineered cardiac patch construct. Highly effective stimulation of a cardiac patch may be achieved by passive mechanical loading.[87,95,100] In most experimental settings, a periodical loading and unloading of the cardiac patch has been maintained over a period of 7–14 days. In analogy to the physiologically occurring range, most of the past experiments involved a frequency and strain rate that varied between 1 and 2 Hz and 5 and 20%, respectively, depending on the cell donor species.[95,128]

The induced multifaceted effects of mechanical stimulation that are collectively referred to as hypertrophy include a higher content for contractile elements, an increased capacity for aerobic metabolism as determined by increased mitochondrial density, intensified cell–cell and cell–ECM junctions, a reorganization of the cytoskeleton elements, an altered pattern of ECM turnover, and many more.[87,100] In a cardiac patch, an increased level of passive mechanical strength and higher levels of active force generation encourage the use of mechanical stimulation. Furthermore, a structural maturation may be proposed because of the fact that *de novo* ECM production is increased in a stimulated cardiac patch in addition to a spatial cell orientation that is coordinated by the applied mechanical stress. Furthermore, the simple physical agitation of the patch causes a periodical spatial shift of soluble components in the culture medium, which may increase substrate exchange in core parts of a cardiac patch. On the molecular level, markers of mature cell phenotype may be preserved by mechanical stimulation, thus supporting the suitability of a hereby conditioned patch for a successful *in vivo* use.[129,130] Adding to the complexity, when a cardiac patch is stimulated, the primary effects on the cardiomyocytes may be further modulated by paracrine factors that are released from the adjacent noncardiomyocytes.[131,132] Thus, the ultimately achieved optimization covers structural, biomechanical, and electrophysiological maturation, along with further characteristics, such as increased functional response to physiological stimulations, for example, β-adrenergic agents. Under the appropriate level of stimulation, these tremendous effects join in concert to elevate the performance of engineered cardiac patches with macroscopic dimensions. Taking advantage of mechanical stimulation, a series of successful and standard defining experiments have been performed, where *in vitro* cardiac patches from neonatal rat cardiomyocytes were generated. Because of technical issues, a transformation of the physical shape of the same constructs from a rectangular patch to a circular or oval ring was achieved and further modifications by introducing rodent or human ESC-derived cardiomyocytes were performed, each with a high level of success.[133,134] Particularly, the introduction of ESC-derived cells demands a highly instructive environment for a maintained and even improved level of differentiation *in vitro* as well as *in vivo*.[133–135] Mechanical stimulation and other means of guidance of cellular growth and differentiation are tremendously helpful, if not being mandatory components of a successful *in vitro* generation of a cardiac patch.[136,137] The application of cyclic mechanical strain improves the spatial distribution of cells within the ECM, leads to cellular hypertrophy, and also enhances the synthesis of ECM components.[95] These three components of tissue remodeling have been in the center of previous studies on myocardial tissue engineering using mechanical stimulation. The hereof-resulting alternations of tissue characteristics are numerous. Obviously, the overall active (i.e., contractile) force is increased because of enhanced expression of contractile elements by the embedded cardiomyocytes and also by a qualitative shift of the contractile proteins.[138] But passive tissue characteristics are also changed because of the enhanced ECM production under mechanical stimulation.[95] Furthermore, both spatial cell distribution and alignment as well as the presence and distribution of ECM have an impact on the development of cell–cell adhesion complexes, which in turn may influence the contractile tissue activity via mechanical and electrophysiological cues. The complex setting of different tissue characteristics that are altered through mechanical stimulation is yet not fully understood. On the basis of current knowledge, it appears reasonable to assume that the benefits of mechanical stimulation during *in vitro* culture of bioartificial myocardial patch structures, for example, via application of cyclical bidirectional tensile stress to the tissue, are limited by a maximum efficacy range at a certain setting of stimulation (e.g., frequency of cycles per time, proportional displacement of tissue, or maximum force applied at each cycle, configuration of stimulation vs. resting phases, etc.). One of the challenges in myocardial tissue engineering lies in the determination of the optimal parameters of stimulation for every specific combination of cellular and extracellular components. Unfortunately, because of the wide range of the different cell sources and ECM materials in current use, only limited data transfer between different published models of myocardial tissue engineering is possible. The use of different bioreactor systems allowing multiple qualities of stimulation further adds to the complexity of this field.[138]

However, a growing body of evidence suggests the feasibility of further potentiating of *in vitro* generated cardiac patches by the addition of further stimulation modalities.[139] From the current perspective, the ultimate goal is the creation of a fully controlled culture environment that is capable of mimicking various aspects of the organ-specific local milieu that exists *in vivo*. This paradigm has been referred to as the biomimetic approach to tissue engineering.[140,141] The magic tool that may allow investigators to install the anticipated high standards is represented by bioreactor systems that allow simultaneous multimodal stimulation of the growing cardiac patch. Among the top candidates for potent modalities, mechanical stimulation and electrical stimulation are the most explored in cardiac tissue engineering.

6.624.5.6. Pacing for a Better Cardiac Patch

The second modus of stimulation that has resulted in an improved outcome of cardiac patches consists of periodical application of electrical stimulation. In several studies using electrical stimulation, a cardiac patch containing spontaneously contractile cardiomyocytes has served as a solid platform for investigation. Whether field stimulation or direct current application is used, in either case distinct morphological changes and an altered functional performance may be observed *in vitro*. As for the case of mechanical stimulation, the overall response covers a wide range of biological responses that lead to a profound modification of the cardiac patch, including changes in cell morphology, functional integration, and supracellular organization.[70] Electrical stimulation has proven effective in improving the coordinated conduction of action potentials throughout a 3D cardiac patch.[130] An almost doubled impulse propagation velocity was achieved in parallel with an enhanced expression pattern for key proteins of gap junctions, for example, connexin-43.[142] Further structural elements, such as desmosomes and adherens junctions or specific features of mature sarcomeres, such as of *Z*-bands, have been subject to several studies and their presence has been more pronounced in cardiac patches that were produced under electrically or mechanically

stimulated conditions.[88,100] However, the identification of molecular cues for the *de novo* formation of cell–cell junctions in stimulated cardiac patches, most importantly the formation of functional gap junctions, also speaks in favor of the electrical stimulation.[143] Moreover, an improvement of the electrophysiological capacity on the subcellular level has been observed, which has been linked to preservation of a mature and functional sarcoplasmatic reticulum and thereby to maintenance of physiological intracellular calcium handling during excitation as well as relaxation.[144] All of the above-mentioned aspects of cardiac patch maturation by electrophysiological stimulation will gain further importance on a shift of the employed cell source from robust neonatal cardiomyocytes to more delicate cell types or cell entities with a predetermined differentiation fate but not with a fully accomplished terminal differentiation process yet, for example, cardiomyocytes derived from ESC or induced pluripotent stem cells (iPS).

6.624.6. *In Vivo* Maturation of a Cardiac Patch

A tissue engineered cardiac construct that is designed for an *in vivo* utilization as a cardiac patch has to be capable of robust *in vitro* development and also has to survive the *in vivo* milieu after implantation. Hence, in a conceptual way amphibian adoptive capacities are warranted. However, none of the currently presented models convincingly fulfills all of the involved criteria for a distortion-free transition from *in vitro* culture to *in vivo* integration. Ischemic injury, immunologically triggered damage, inappropriate speed of structural remodeling, instable cellular composition, and functional incompatibilities significantly diminish the *in vivo* benefit of a cardiac patch. The following sections are intended as a recollection of the current experience with the observed events *in vivo* after implantation of a cardiac patch and its consequences. In this context, a distinction between two different groups of cardiac tissue engineering models is made. In contrast to a total replacement of cardiac tissue by a patch (**Section 6.624.5.1.**), other models of a structurally supported implantation, for example, by surface superpositioning to the ventricular free wall (**Section 6.624.5.2**), involve a distinct functional setting, and therefore, the discussion of these two families of *in vivo* models is separated.

6.624.6.1. Experimental Transmural Ventricular Replacement

A partial replacement of the myocardial tissue over the full thickness represents a challenging intervention with respect to both surgical technique and perioperative management of the patient. On the long term, the restoration of cardiac function by the implanted material and the associated changes in biomechanics, global geometry, and local milieu are expected to be of major relevance. Tissue engineered cardiac patches hold the promise of an ideal implant that may overcome several limitations of the currently available materials for the use in the clinical arena.

In one of the pioneering *in vivo* studies, a transmural defect in the RVOT of rats was patched with gelatin scaffolds that were implanted as plain biomaterial or after seeding with fetal or neonatal cardiomyocytes. The results on this study documented the feasibility of a small animal model for the study of a partial myocardial replacement. Although the use of gelatin was associated with a considerable inflammatory response, a persistence of the initially seeded cells was suggested. With the degradation of the patch over 12 weeks, a gradual thinning of the implant was noted, which was somewhat prevented by a preimplantation cell seeding. Also an endocardial endothelialization and a neovascularization of the patch were observed after 4 weeks.[145] Using the same model, a comparative study of three scaffold materials for generation of an autologous cardiac patch seeded with smooth muscle cells was conducted with specific focus on the morphological *in vivo* development of the patches.[146] A composite polymer, consisting of poly(caprolactone) and L-lactic acid, was proven superior to porous gelatin or polyglycolic acid (PGA) scaffolds as determined by maintained macroscopic integrity, apparently greater cell accommodation, and a favorable ECM *de novo* synthesis. However, the level of the *in vivo* occurring angiogenesis was comparable.

Since the spread of these and similar reports, different groups have introduced an increasing number of studies that use a full thickness myocardial replacement. Rats have represented the lower end of the size scale of the employed species, whereas large animal models also appear feasible and may offer distinct advantages over small animal models. Because of the wide range of combinatory possibilities between various cell types, different scaffold models, and preparation strategies, a direct comparison may not be appropriate. However, some data have been confirmed by independent studies. In most of the so far published experiments, a gradual formation of vascular networks that penetrate the cardiac patch has been documented. The scaffold properties have an impact on the *in vivo* vascularization, and although an overall benefit of the vascularization is anticipated, such development may be on the basis of adverse events, such as inflammation, and probably related to the utilized scaffold.[145] However, the inoculated cell population also impacts on the *in vivo* vascularization of a cardiac patch and thus may indirectly contribute to structural and functional outcome.[147] In parallel with *in vivo* angiogenesis, a cellular repopulation is observed with ingrowth of activated interstitial cells (i.e., myofibroblasts), smooth muscle cells, endothelial cells, and cell entities that display a partially differentiated phenotype. These findings lead to a topic that has ever since been guided by the question of the underlying mechanisms of angiongenesis and a search for the source of the cells that migrate into a cardiac patch. Using cell-labeling techniques, the survival of the initially seeded cells (i.e., donor cells) in a cardiac patch has been demonstrated for cardiomyocytes and noncardiomyocytes in small and large animal models.[145–147] However, there is no such agreement regarding the recipient cells, which appear in a cardiac patch after a certain time, usually 2–4 weeks *in vivo*. A delay in the repopulation and angiogenesis of central patch regions has led some authors to favor the theory of continuously ingrowing cells from the adjacent native myocardium across the patch margins toward the patch center.[148,149] However, in studies involving the implantation of a noncardiac patch, the scattered pattern of new cardiomyogenic cells on explantation and their predominant localization in the vicinity of scaffold-embedded vessels have been advocates for the hypothesis of a circulating

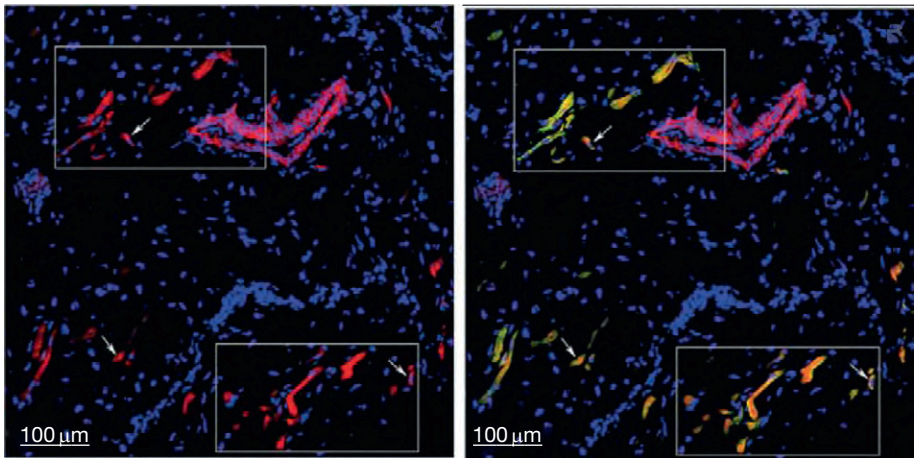

Figure 4 Autologous, noncardiac patches after cardiac implantation for one month. Immunohistochemistry shows premature cardiomyocytes (green, myosin heavy chain; and smooth muscle-α-actin indicated by arrows) of varying size around a mesenteric artery (red, smooth muscle-α-actin). (a) shows staining for muscle-α-actin (red) with nuclear counterstaining by DAPI (blue). Colocalization of yellow color (in b) results from overlapping green and red signals. Adapted from Tudorache, I.; Kostin, S.; Meyer, T.; *et al. Eur. J. Cardiothorac. Surg.* **2009**, *36*, 306–311; discussion 311.

cell source[150] (Figure 4). Irrespective of their original source, *in vivo* repopulating cells contribute to the development of a cardiac patch and their frequency appears to vary with different initially present scaffolds and cell components. The history of *in vivo* studies on cardiac patches comprises a shift from more primitive but robust cell sources (e.g., neonatal rat cardiomyocytes) to more delicate cell sources with the perspective of a future clinical application. Hence, mesenchymal stem cells have been studied on several occasions for their potential as progenitors of mature cardiomyocytes. Unfortunately, the available amount of data is yet too small, with a varying experimental framework and heterogeneous levels of cell characterization in each report further complicating a clear conclusion. Hence, controversial results are available regarding the potential of mesenchymal stem cells to give rise to cardiomyocytes.[147,148,151] More interestingly, in several studies the analysis of ingrowing cell types has indicated that cells with phenotype characteristics of cardiomyocytes may be observed over time within the implanted cardiac patch, even in the instance of an initially acellular implant.[149,150,152,153] The contribution to the overall outcome after a cardiac patch implantation harboring cardiomyocytes as opposed to non-cardiomyocytes has been studied on different morphological levels, including (i) the extent of patch vascularization, (ii) alternations in the physical dimensions of the patch, (iii) the source of the overall ventricular dimensions, (iv) functional ventricular performance, and many more. In general, a superior effect of cell-seeded patches over plain scaffolds is expected with respect to morphology on the macroscopic and microscopic level. The hallmarks of the better outcome are defined by an attenuation of the ventricular dilatation, prevention of patch thinning, and aneurysm formation and by the *de novo* synthesis of ECM components and microvascular structures along with a balanced repopulation throughout the patch vicinity.[147,151,154,155] These elements of a favorable outcome have been observed in synthetic biomaterials as well as biological scaffolds[153,155] and may be enhanced by the addition of cells to the patch. The ultimate goal of a functional improvement is determined by further parameters, such as the global (ventricular) and regional (patch areal) contractility and relaxation patterns, as well as the resulting force and pressure indices. Few recent studies have included sophisticated diagnostic algorithms to address a number of these questions.[148,149,156] In the limited number of studies that have been performed to date, the superiority of novel biomaterials over conventional patch materials (e.g., Dacron) has been proved with respect to several core parameters[146] including regional systolic function in the area of the implanted cardiac patch and a partial recovery of electrophysiological activation levels at the implant site.[149,156] Using even more biocompatible implants, such as an autologous patch of noncardiac origin but with preserved native vasculature, an elegant setup for the study of cardiomyocyte regeneration along with a tool for the successful surgical management of regional myocardial defects has been introduced.[150] This effect is probably related because of a spontaneous *in vivo* repopulation of cardiac patches by different cell types, including myogenic cells, although specific markers of differentiated cardiomyocytes (α-sarcomeric actinin, α-myosin heavy chain, specific Troponin isomers, presence and distribution pattern of specific cell adhesion proteins, developmentally altered nuclear expression, etc.) are infrequently analyzed (Figure 4).[148,150,153] In some studies and under different experimental settings, even opposing evidence has been gathered regarding the *de novo* generation of cardiomyocytes in MSC-seeded cardiac patches.[147] Hence, the quantitative range of the *in vivo* cardiac regeneration in an implanted full thickness patch varies considerably, even within reported series on the same scaffold material.[149,153,157,158] However, some fundamental benefits in terms of qualitative changes in patch morphology are commonly observed that speak in favor of the concept of guided tissue regeneration, that is, achievement

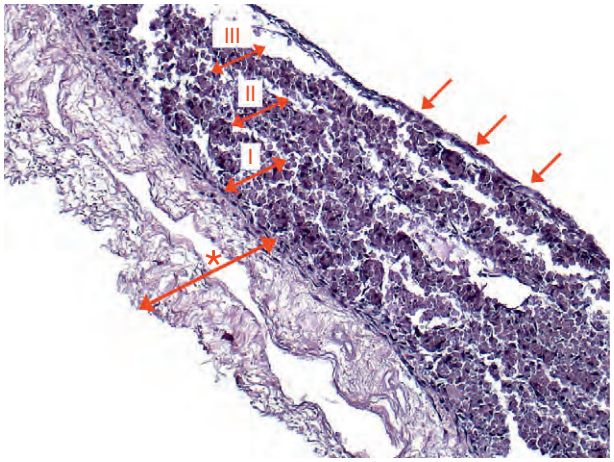

Figure 5 Cell sheet engineering and vascularized biological matrix. Neonatal rat cardiomyocyte cell sheets were cultured on a three-dimensional, vascularized biological matrix (decellularized porcine intestinal submucosa) to result in a single vital and vascularized myocardial patch. I–III indicate three cell sheets stocked over the vascularized (asterisk) ECM. Single headed arrows indicate an outer lining of *de novo* grown cells with myofibroblastoid phenotype. H&E staining, magnification: 50×. Image provided by Dr. Hilfiker.

of a functional benefit with an implant that experiences significant remodeling and final maturation after the implantation. In order to support this process, the scaffold alone may not be the most potent solution. Further improvement may be achieved through the *in vitro* addition of autologous cellular cues with the inherent potential of cardiomyogenic regeneration.

Unfortunately, on review of the reported effects of cell seeding and the choice of a specific cell type or cell differentiation level, the available functional data are even more diverse and difficult to interpret, a situation that may be compared to the obstacle in the meta-analysis of cell transplantation studies. So far, the effect of seeding of uncommitted mesenchymal stem cells may be questioned, whereas the initiation of a cardiac lineage commitment may result in an improvement of global ventricular function and measurable pressure indices.[147,151,159] Advanced cell seeding techniques and *in vitro* conditioning are major fields of future optimization (**Figure 5**).[101,147] Future strategies are likely to employ current *in vitro* techniques for controlled cardiomyocyte differentiation and angiogenesis in the setting of stem or progenitor cell seeded cardiac patches for a transmural myocardial reconstruction. Of particular interest is that an evaluation of the model *per se* has to be performed, as the currently available data are based on surgery in different animal species (i.e., rat, dog, or pig) on healthy or experimentally injured (i.e., with prior ischemic infarction) hearts. The bottleneck for *in vivo* applications will most likely be the establishment of a functional vascular network that is connected with the systemic circulation in order to supply the patch with sufficient metabolic substrates for increased biomechanical strength, high cellular density, and differentiation level. All of the latter parameters are hallmarks of functional performance and have to be coordinated in a single multifaceted biological system.

6.624.6.2. Experimental Ventricular Support by Patch Material

In contrast to the applications that are outlined in the previous section, the herein described models involve a cardiac patch that is primarily intended as a transport vehicle for cell transfer purposes. In other words, the following models described here are in a way an extension of cell transplantation studies. Obviously, all of these experiments involve a preserved continuity of all cardiac structures. In this sense, we are dealing with cardiac patch models that serve as supporting structures (as opposed to patches for a reconstruction by tissue replacement). The indication for a supporting patch is the treatment of an ischemic myocardial area (acute setting)[160] or a postischemic myocardial scar area[126,161,162] and application is performed by superpositioning of the patch onto the target myocardial region and fixation by suturing or gluing (e.g., with fibrin glue).

The idea of using a cardiac patch as transport vehicle is on the basis of the observation that the majority of cells are lost during other implantation procedures and a very low fraction, generally less than 10%, experience an acute engraftment. Further diminishing of the cell number is attributed to the hostile environment, which affects the isolated and unprotected cells in a direct manner. Thus, the concept of patch-mediated cell transfer was introduced. Initial studies using porous scaffolds confirmed the efficacy of patch implantation for sustained delivery of cardiac cells and prevention of adverse remodeling of ischemic hearts,[66,80] along with the demonstration of interstitial cell repopulation and vascular sprouting phenomena from the surrounding myocardial tissue. Interestingly, similar effects were described for cardiac patches where skeletal myoblasts were used instead of cardiac cells.[162] In a series of continuously optimized experiments, the engraftment, survival, *in vivo* vascularization, and continued functional performance of cardiac patches made of collagen-based scaffolds and cardiac cells were successfully demonstrated in small animal models of MI by LAD ligation.[100,126,163]

On the morphological level, embedded primary cardiomyocytes were organized in a compact and oriented pattern and maintained a high level of differentiation. This has been interpreted as an indicator of advanced culture maturation. As outlined in **Section 6.624.7**, such *in vitro* casted patches provide a highly homogeneous and compact microarchitecture, which turns them to be a particularly suitable tool for a supporting application where the ultimate biomechanical strength is somewhat less limiting.

In most studies, the epicardial implantation of a cardiac patch led to a significantly improved cardiac function as opposed to untreated hearts, and this had an impact on the overall animal survival. By using elaborate techniques in extensive series of experiments, the evidence for a functional integration of a cardiac patch with the host myocardium was demonstrated on the electrophysiological level.[100] Also, a maintained contractile activity has been demonstrated, which supports the hypothesis of partial contribution of active biomechanical performance to the overall benefit of a cardiac patch. When significant numbers of endothelial cells are mixed with the cardiac cells, the resulting patch will experience an accelerated *in vivo* vascularization, which is regarded as a key

component of favorable long-term development for the patch and the overall organ function. Recently, further modifications to the preparation protocols of a cardiac patch have been introduced to promote an intensified and accelerated *in vivo* angiogenesis.[164] Some modifications are based on the intrinsic capacity of the recipient organism; that is, in the clinical setting the patient's body is to act as an ideal bioreactor. In such a staged concept of tissue engineering, parts of the final tissue are implanted and preincubated at a remote location in the recipient organism in order to initiate a prevascularization or partial interstitial repopulation of the tissue, before explantation and further *in vitro* processing of the tissue can take place. After the final preparation is completed, the mature implant tissue is transferred to the target body site, for example, the posterior ventricular wall of the heart. Further scientific interest and considerable clinical attention has been attracted by another concept that is on the basis of the engineering of cell monolayers that can be detached from the culture dish and stacked on each other to form a multilayered, 3D cell culture. This concept that is referred to as cell sheet engineering has become available through chemical engineering advances and the advent of thermoresponsive polymers that can change their surface characteristics from hydrophilic to hydrophobic, depending on the temperature that they are exposed to. The fascinating advantage of this technology lies in the elimination of the need for enzymatic solutions for detachment of cell assemblies from the culture substrate. This is particularly of interest in the culture of cell entities with high degree of cell–cell adhesions, for example, cardiomyocytes that functionally depend on intact gap junctional connections. Using neonatal rat cardiomyocytes as a spontaneously beating cell source, this technology has been shown to result in beating 3D constructs with remarkably reproducible results and stable performance over time.[165,166] Even more interesting, some experimental reports demonstrate signs of electrophysiological integration of cell sheets within the implant site after the application to a recipient's heart.[167] Following this report, the involved technology has been applied to many cell types to enable regenerative therapy in the context of various organ systems. In the context of heart disease, the quest for the ideal cell source still goes on. A potential solution may be the acceptance of noncardiomyogenic cells as the therapeutic cell type, which has led some groups to apply interstitial cells or endothelial cells for ischemic or dilatative cardiomyopathies.[168] After the partially satisfying results of clinical trials performing myoblast cell transplantation for ischemic heart disease, the use of these cells in the form of multilayered cell sheet constructs has gained experimental attention recently,[36,169] and consecutive clinical attention may lead to a multicenter clinical trial that may in near future resume to evaluate the clinical relevance of cell sheet engineering in combination with skeletal myoblasts. However, beyond skeletal myoblasts further adult cells, such as mesenchymal stem cells, and also other progenitor or stem cells are regarded as candidate sources for the generation of a living cardiac patch.[170] Scientific debate is currently concentrated around the functional integration of cell sheets after their cardiac implantation, that is, (1) electrophysiological integration without the initiation of ectopic potentials; (2) biomechanical integration; and (3) rapid access of the sheet-enclosed cells to the tissue supplying vascular network *in vivo*.[171,172]

Other exciting developments include the use of stem or progenitor cells with the potential to generate autologous cardiomyocytes.[173] The latter option is a crucial one, because the optimal use of this technology remains unclear despite the numerous advantages of cell sheet engineering (e.g., better functional state of the cell components due to the omission of aggressive enzymes, physiological orientation and polarization of cells within the initial assembly, omission of artificial ECM materials, and more physiological ratio of cellular to extracellular components). As a matter of fact, it remains yet unclear whether an available adult cell source, that is, skeletal muscle, will clinically prove as sufficiently appropriate to initiate a true turn in the fatal cascade of heart failure which is observed in the setting of an ischemic or dilatative cardiomyopathy. Clinical trials certainly will be needed to shed some light on the clinical value of cell sheets as cardiac patch implants.

Whereas cell sheets are initially based on cellular components only, the exact opposite concept to achieve a cardiac patch is described by a cell free ECM material that becomes repopulated *in vivo* after implantation, for example, onto the region of a MI. In this setting, the implant material may fulfill mechanical function by preventing a progressive dilatation of postinfarction scar tissue. By choosing appropriate biomaterials with certain biodegradation kinetics and favorable bioinstructive characteristics, an ideal patch material may induce a local regenerative remodeling of the host tissue. Different groups using various ECM materials have evaluated such a concept. In a recent report, polyester urethane urea has been used as a cell free cardiac patch material after a subacute MI.[174] The application of this elastomeric and biodegradable material resulted in functional and histological improvement over time, leading to a diminished deterioration of left ventricular function as well as increased myogenic protein mass in the infarct region (**Figure 6**), which may be related to an increase in smooth muscle cell proliferation in response to the patch implantation. Also, a new vascularization at the vicinity of the biomaterial was observed (**Figure 7**). As indicated in **Section 6.624.4**, the bioactive action of modern biomaterials may be further enhanced by addition of functional bioactive molecules, such as gene encoding DNA, ECM degrading enzymes, and specific growth factors.[59] In another recent report, clinically relevant degradation patterns have been demonstrated for composite synthetic materials, with gradually released products being soluble and nontoxic. Future chemical engineering advances may provide further degrees of freedom, integrated in one single synthetic ECM material.

However, despite the apparently unbound options for some of the aforementioned models to promote comprehensive *in vivo* integration of a cardiac patch, competing experimental setups have resulted in partially divergent results, particularly with respect to stem cell homing, survival, and differentiation.[160,175] Therefore, the elucidation of the crucial factors that lead to a wide diversification of the individual outcome of similar experiments deserves a high priority setting in the upcoming investigative engagements. Finally, the general suitability of a supportive, patch-based cell therapy for the treatment of conditions other than ischemic cardiac disease may be defined in a more precise way,[36] once the underlying mechanisms are better understood.

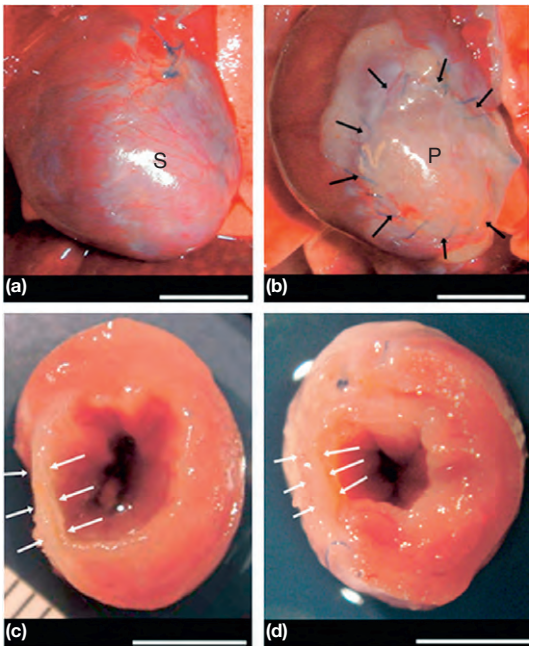

Figure 6 Implantation of a biodegradable polyester urethane urea (PEUU) material to prevent adverse postmyocardial infarction (MI) remodeling of the left ventricle. Control animals experienced scar formation and subsequent thinning of the respective LV wall region (a, c). The PEUU biomaterial (P in image b) was implanted onto the MI area to result in an enforced LV wall after 8 weeks, as demonstrated by cross-sectional view images (d). Black arrows point to the implanted PEUU patch (b), and white arrows indicate the infarcted anterior wall (c, d). Scale bar: 55 mm. P, the patch implanted area; S, the infarcted scar. Figure 7 Histological evaluation of post-infarction myocardial tissue (a, b) and polyester urethane urea (PEUU) patched (c, d) myocardial wall 8 weeks after implantation shows a dense repopulation of the biomaterial resulting in a *de novo* tissue generation (c), where increased smooth muscle actin is apparent (green, α-smooth muscle actin) (d). Also, new microvascular structures that stain positive for endothelial markers (such as CD31, red) are observed within the formerly acellular patch. Nuclear staining appears blue. Scale bars are 200 μm. Adapted from Fujimoto, K. L., Tobita, K., Merryman, W. D., *et al. J. Am. Coll. Cardiol.* **2007**, *49*, 2292–2300.

6.624.7. Scientific Frontiers

The *in vitro* creation of a cardiac patch, the ultimate goal of the scientific field of cardiac tissue engineering, has experienced considerable progress over the past two decades. Above the so far achieved bioengineered tissue products, the extent of knowledge and insight into the cell biological events that govern the *in vitro* maturation and *in vivo* integration of cell seeded biomaterials are of great value for the ongoing and future experimental work.

Our understanding of the complexity of cell–cell and cell–ECM interactions even in the most simple 3D culture models has led us to reevaluate our knowledge about the natural developmental process of tissue formation. In fact, a number of biological events that occur during early native development are of crucial importance for the *in vitro* culture of 3D multicellular cultures.[176] Hence, the development of increasingly complex bioreactor systems that allow for the controlled *in vitro* mimicking of *in vivo* conditions with respect to a variety of parameters has become a scientific field of its own. One of the future challenges in cardiac tissue engineering will be the designing and engineering of bioreactor systems that provide maximum control over numerous culture conditions and also allow for the online and noninvasive monitoring of vital parameters in the developing culture.

In the field of cardiac patch engineering, the importance of cell type diversity has become evident. Hence, the role of multifunctional bioreactor systems has gained further importance. The need for cell types other than the cardiomyocyte fraction or the progenitors is even more urgent in studies that involve clinically more relevant progenitor or stem cell populations. It appears necessary to apply more than one single cell population in order to create a functional cardiac patch;[23] more interestingly, an increase in the complexity of the employed cell population may result in an advanced differentiation status and a higher functional outcome.[177] Thus, a successful approach for bioengineering of a cardiac patch includes the careful choice of a number of cell types and also will have to consider a well-planned sequence of introduction of theses cells into the developing tissue construct.[177]

One of the most relevant limitations to current bioengineering approaches to create a clinically useful cardiac patch concerns the cell source for the creation of a sufficient amount of autologous cardiomyocytes or their functional substitutes. Beyond the aforementioned ESC and iPS, other cell sources for obtaining pluripotent stem cells have been suggested in recent studies.[178,179] However, despite the discovery of different adult stem cell entities, some of them available in the adult human body, no method has provided the necessary quantity and quality of cells that are needed for the creation of a cardiac patch of significant size and function. Hence, novel concepts of cell harvesting, amplification, and preimplant conditioning

are most warranted for future successful application of a cardiac patch.

As outlined in Section 6.624.8, perfusion remains a problem in most of the current experimental models of myocardial tissue engineering and until today, no clinically relevant solution has been suggested to overcome the boundaries that are defined by diffusion limits. While some of current approaches involve cutting-edge biomedical and engineering sciences,[108,110] others rediscover principles that have already been applied decades ago.[180–182] It appears unpredictable whether a completely *in vitro* engineered or *in vitro* modified vascular network will prove successful in the long-term perfusion of a cardiac patch in a potentially pathological environment, such as an ischemic heart.[101,108,110,122] However, it remains unchallenged that a functional perfusion system is necessary, and thus, further improvements of available concepts or the development of novel strategies will be subjects of future investigation.

A series of *in vivo* studies have demonstrated the impact of a postimplantation remodeling on the morphological and functional development of a cardiac patch. A clinically relevant concept of cardiac patch engineering has to recognize the possible mechanisms of both beneficial and adverse graft remodeling *in vivo*. The preservation of the morphological and functional features of a cardiac patch translates into patient safety and overall success of the concept. Moreover, further gains in function and a physiological maturation on the morphological level characterize a superb outcome in the long term. Evidence from previous studies suggests the involvement of a large number of factors that affect the *in vivo* maturation of a cardiac patch. The complexity of the *in vivo* regulation and the numerous cross talk possibilities of these biological mediators question the feasibility of a successful therapeutic manipulation at a single factor level. Instead, a large group of single events and their mediators may be influenced, hoping for a desired overall outcome. One of the most relevant biological complexes is referred to as the postimplantation inflammatory response and many studies have focused on a therapeutic modulation.[16] Some preliminary studies that aimed at the *in vitro* modulation of the fate of a tissue engineered patch have employed single cytokines or a defined mixture to enhance the functional outcome, and it appears likely that more complex protocols involving a sequence of multiple factors with varying concentrations over time will lead to higher success rates in terms of morphological and functional maturation.[164]

6.624.8. Clinical Relevance and Perspectives

The field of tissue engineering has fascinated basic science investigators to the same degree as clinicians and a therapeutic implementation of laboratory grown tissues and organs has been predicted years ago. However, as with many other scientific fields, the optimism of the first few years has been challenged by a series of limitations and problems that were encountered in the following era of detailed *in vivo* studies. Notably, other previous concepts of end-stage heart failure have been developed and clinically introduced with a tremendous amount of effort and guided by a major wave of scientific and public enthusiasm.[183,184] The frustration on the investigator's side and the public disappointment about the long-term limitations of the concept of dynamic cardiomyoplasty are only two of the many recent examples for the demanding process of a successful bench-to-bedside transfer of a therapeutic approach to end-stage heart failure.[185–187] A bioengineered cardiac patch that is designed to change the fate of heart failure is yet far away from mankind's access.

Moreover, the clinician's point of view regarding the real demand for a bioengineered cardiac patch has not always been consistent with the predicted problems that have been driving the laboratory engagements. For instance, a contractile bioengineered cardiac patch may in theory represent the optimal solution for the repair of an ASD or a VSD, but considering the excellent clinical long-term outcome of synthetic patch materials, it is questionable whether a similar reproducibility and long-term durability will be achieved by a bioengineered patch. In addition, the laboratory manufacturing of such a cardiac patch will certainly need a vast amount of investment in terms of personal and material resources, which will have to be rewarded by a superior clinical outcome and thus also by a long-term benefit on the economic level.

The currently most exciting frontier is defined by experimental work to increase the maximum tissue thickness and to enhance the level of the actively generated contractile force by 3D bioengineered cardiac structures. These strategies, when paired with a clinically relevant cell source and effective *in vivo* maturation guiding mechanisms, ultimately may result in a concept with a realistic clinical perspective that can stand the competition from relatively cheap and ubiquitously available synthetic biomaterials already available on market.

6.624.9. Summary

In the young history of cardiac tissue engineering, significant improvements have been introduced, and the turnover rate in the applied models and concepts has been remarkably high. Early models of a bioengineered cardiac patch consisted of porous materials made of simple polymers or biological materials such as collagen and alginate, which were seeded with suspensions of primary cardiac cells to result in a contractile 3D structure. With growing experience, a diversification of the employed cells with a trend toward more immature progenitor or stem cells was paralleled with the introduction of decellularized biological scaffolds as well as novel synthetic scaffolds that were produced according to sophisticated biochemical engineering methods. Further input to this field was granted by the application of advanced bioreactor systems that provide an increasing level of control over major culture conditions *in vitro*. The induction and maturation of a vascular network, the introduction of a clinically relevant cell source, and the validation of the entire elements of a cardiac patch in an appropriate preclinical model are further challenges that the current cardiac tissue engineering field is confronted with.

TAH	Total artificial heart
TET	Transcutaneous energy transmission
VAD	Ventricular assist device

6.625.1. Introduction

6.625.1.1. Evolution of VADs and TAHs

Long-term implantable ventricular assist devices (VADs) and total artificial hearts (TAHs) have been under development since the late '60s as therapies for late-stage heart failure (HF), a debilitating and deadly malaise that affects millions worldwide. HF accounts for ~7% of death (mortality rate of 1 in 5) from cardiovascular diseases, affects 4.8 million Americans with 500 000 new Americans diagnosed every year and is the leading cause of death in the United States and the rest of the world.[1,2] These staggering figures give us an estimate of the magnitude and impact of HF on the society and the motivation for proliferating research and development initiatives from both academia and industry, to address this challenge.[3]

HF may be caused by coronary atherosclerosis, hypertension, viral or idiopathic cardiomyopathy, or congenital defects. The pathogenesis of chronic HF is a complex process that involves a series of morphological and molecular alterations of the myocardium ('remodeling'). Causes such as myocardial infarction, myocarditis, or genetic defects, can initiate cardiac insufficiency. This is followed by several pathophysiological compensatory mechanisms that cause additional stress on the weakening heart, leading to HF, a positive feedback mechanism. A primary component of such a mechanism is the volumetric expansion of the heart in order to provide adequate blood flow, a deficiency that weakens the heart muscle and leads to further volumetric expansion, resulting in a significantly enlarged heart. This is termed congestive HF – as the heart grows to 'congest' the chest.

Although traditional medical therapy (defibrillator implantation, biventricular pacing) provides a temporary solution to manage and control the seemingly unstoppable progression of HF to end-stage, until now, transplantation has been the only effective treatment for most end-stage HF patients. But a severely limited supply of donor hearts has meant that only about 3000 persons receive transplants each year worldwide while about 15% die waiting for a donor heart.[4,5]

This gap and the increasing need for a longer-term solution (an alternate to a heart transplant) was recognized in the 1960s by the US government thanks to early efforts by pioneering clinical researchers that showed the promise for mechanical circulatory support (MCS). The Artificial Heart Program was set up and run by the National Heart, Lung, and Blood Institute (NHLBI) with a goal to fund and foster the development of two types of MCS for long-term implantable use: ventricular assist devices (VADs) and total artificial hearts (TAHs). A Ventricular Assist Device or VAD in short, circulates blood through the host's circulatory system to compensate for the otherwise poor circulation provided by the recipient's failing heart which is left intact, while a TAH replaces the natural heart.

Since its inception in 1962, by Dr. Domingo Liotta of the Baylor College of Medicine in Houston, the VAD has been used to complement the function of a human heart, either as a 'bridge-to-transplant' (BTT) for patients with ailing heart waiting for a natural donor heart or sometimes as a 'permanent' implant (the so-called DT indication).[6,7] There is a fledgling new indication for VADs called bridge-to-recovery (BTR) in which, after VAD implant and support, native cardiac function of the recipient recovers ('reverse remodeling') and removal of the device is possible without subsequent support due to stable restoration of the natural heart pumping function.[8]

The NHLBI program has spawned the development and growth of a global industry comprised of many VAD/TAH academic institutions and companies not only in the US, but in Europe, Japan, and other locations. There are now several VADs and TAHs that have been approved by regulatory agencies for commercial sale and distribution in these locations, and ~10 000 implants with these devices have been performed worldwide to date, with the number increasing significantly every year. Use of LVADs has predominated, with the TAH being used to date in less than a thousand patients. Randomized and controlled clinical trials have shown that VADs provide significant improvement in the quality of life and survival of patients with HF.[2,9]

Further development continues – several companies are now developing MCS devices to provide short- or long-term support to reduce their size, improve safety and reduce adverse events, and optimize performance and ease-of-use. The use of computer-aided design (CAD) and its application complemented by computational fluid dynamics (CFD) has resulted in the development of some ingenious and novel 'smart' devices with potentially superior performance. These next-generation devices are presently being clinically evaluated.

This chapter outlines the need for MCS devices and focuses on long-term (multimonth to multiyear) implantable MCS devices, since challenges with these are most relevant from a biomaterials perspective. We provide an overview of generations of VADs that have seen some clinical use, emphasizing so-called left VADs (LVADs). LVADs support the failing left ventricle, which supplies oxygenated blood to the body and does the most work and typically fails more often than the right ventricle. Key devices representative of each generation are described, including a summary of their design configuration, technological innovations, especially biomaterials related, development status, clinical results, and future plans. The intent is to provide a representative overview to promote an understanding of the field and the various technologies, rather than provide an exhaustive and detailed summary description of every MCS device ever developed. Given their predominant clinical use, long-term implantable LVADs are the primary focus, while TAHs are also described.

6.625.1.2. Anatomical and Physiological Considerations

The anatomy of a human heart reveals two sides (left and right), each side having two chambers: an atrium and a ventricle. Each atrium collects incoming blood and helps provide it to the corresponding ventricle which actively pumps it for circulation through the pumping circuit: the right ventricle pumps deoxygenated blood into the lungs, and the left ventricle pumps oxygenated blood into the body, as illustrated in **Figure 1**. The basic mechanics underlying the functioning of a human heart is such that the ventricles act as unidirectional positive displacement pumps with a pulsatile motion alternating between filling (diastole) and ejection (systole) phases. The blood flow for each phase is regulated by inflow (mitral and tricuspid) and outflow (pulmonary and aorta) valves for the right and left sides, respectively. A normal functional adult heart ejects about 60 cm^3 of blood in each stroke and controls cardiac output by primarily varying the heart rate which can range from 40 beats per minute (bpm) at rest to 180 bpm during exercise.

Although VADs were designed to assist the right ventricle (RVAD), the left ventricle (LVAD), or both ventricles (BiVAD), this chapter focuses on the LVAD, which is shown schematically implanted in a human in **Figure 2(a)**. **Figure 2(b)** depicts an implanted TAH. About 15–30% of LVAD implants are reported to need right ventricular support.[10] However, this is usually clinically alleviated with short-term measures like nitric oxide or a temporary (multiday) RVAD such as the external Thoratec VAD or the Levitronix CentriMag VAD.[11,12] The authors have estimated that the clinical need for mechanical circulatory support can be provided by devices in the proportions of: 80% LVADs, 15% BiVADs, and 5% TAHs.

LVADs are designed to support blood circulation when the LV is no longer able to meet the body's systemic perfusion needs, presuming that the RV normally supports an adequate load, owing to its adaptability to elevated preload and after load changes. An LVAD may be implanted in the upper abdomen, chest, or inside the pericardium either extraventricular or transventricular. The inflow for long-term LVADs is typically from the apex of the left atrium via a cannula to the pump, and the outflow of the pump is connected to the ascending aorta via a graft.

Based on various mechanical and physiological performances, an ideal VAD would be expected (1) to provide sufficient cardiac output and complement an ailing heart so as to allow patients to return to their daily activities; (2) to have a low risk of thromboembolism, damage to and activation of blood components, driveline and pump infection, (3) to have a low incidence of malfunction; (4) to be easily implantable and also removable; and lastly (5) to fit well in the human anatomy which usually translates to a small size.

6.625.2. Configuration

The basic configuration of a pulsatile VAD has three components; (1) an electrically driven electromechanical pump,

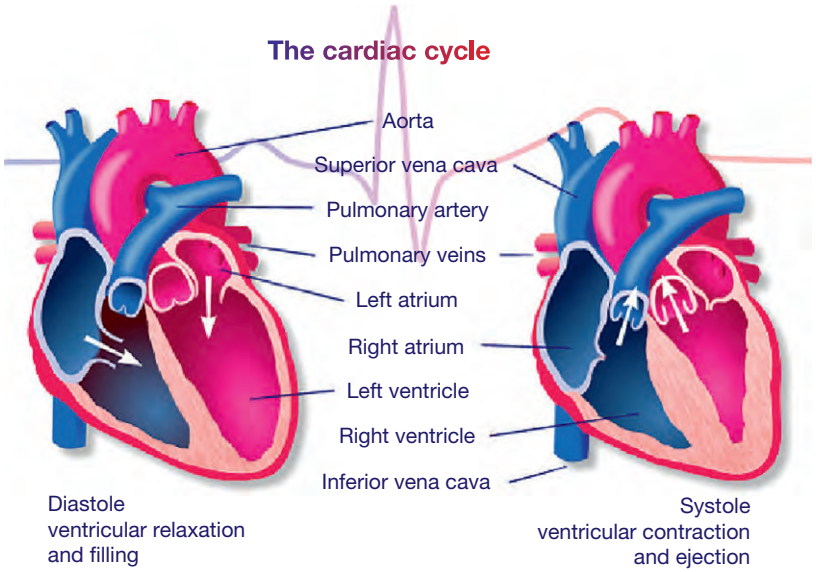

Figure 1 The normal Cardiac Cycle. *Source:* http://www.xaraxone.com/FeaturedArt/mar04/html/05.htm

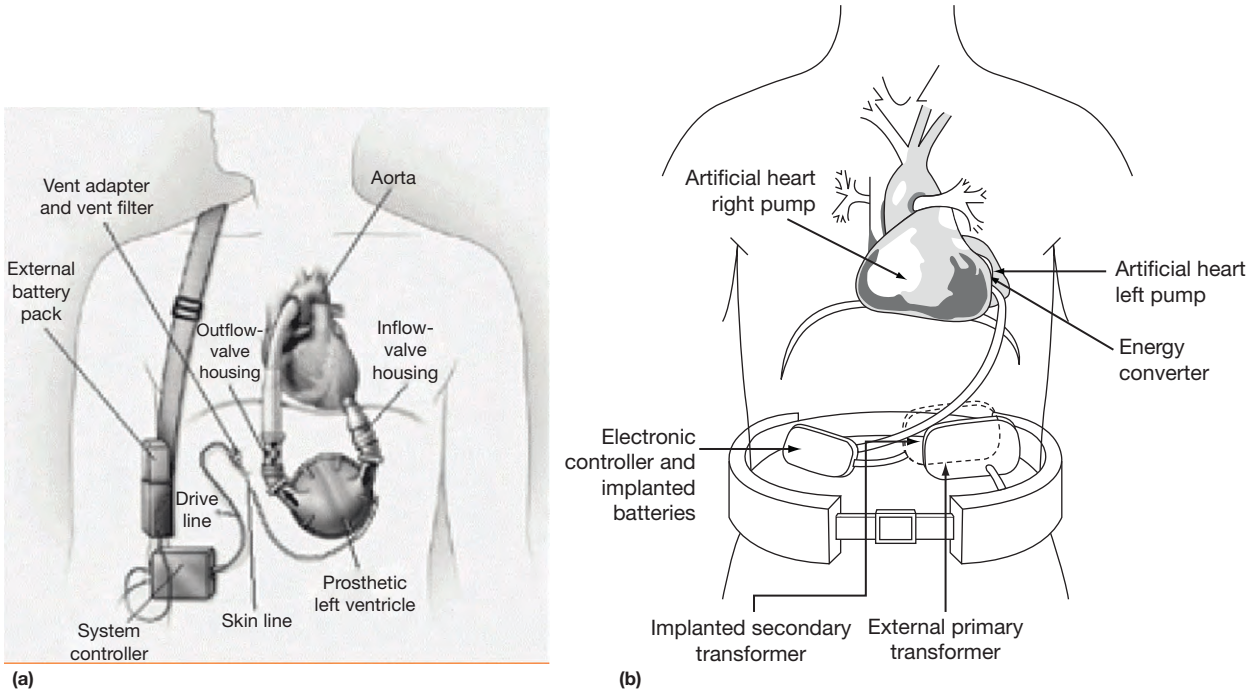

Figure 2 (a) Left ventricular assist device. (b) Total artificial heart.

(2) an electronic controller, and (3) a power supply. The pump weighs ~1.5 pounds typically made of biocompatible titanium with the flexing components made of biocompatible polyurethane. The circumferential acceleration of blood is achieved by controlled electric currents passing through coils contained in the pump housing that apply forces to an electromagnetic actuator that rotates and/or translates. This mechanism in turn squeezes a plastic blood sac to provide systole with the lack of a squeezing action being the diastolic phase of the LVAD's beat; the direction of blood flow is controlled by a pair of unidirectional valves embedded in the LVAD, the same types used when a natural heart valve is replaced (e.g., valves from pigs' hearts or ones made of metal and plastic).

A VAD could be classified in numerous ways based on (a) the mechanics of its pump: (1) volume or positive displacement or pulsatile, (2) rotary or continuous flow encompassing axial flow, or centrifugal pumps, (b) pump location (para corporeal, implantable, or extracorporeal): (c) intended clinical use (temporary, bridge-to-decision, recovery, transplant, or destination): (d) support provided (left – LVAD, right – RVAD,

or both ventricles – BiVAD): and (e) surgical approaches (percutaneous, subcostal, laparaotomy, sternotomy, thoracotomy). The first classification pulsatile and rotary pumps is how they are described going forward.

Table 1 shows the different types of LVADs (pulsatile, and so-called 'continuous flow') as well as TAHs and highlights a few representative pulsatile VADs that have played a pioneering role in developing the field.

The electronic controller is typically a microprocessor chip-based set of digital and analog electronics component that adjusts functions of the pump, such as pumping speed and provides diagnostic, alarms, alerts, and communications to an external monitor.

The power supply for the pump is by two external batteries, via a cable through the abdomen, carried in underarm holsters or a waist pack. A few efforts have been made to transmit electric power across the skin in a transformer-like arrangement; typically, one pair of coils is permanently implanted below the skin and the other is strapped over the skin with the electromagnetic coupling between the two coils allowing power transfer. This transcutaneous energy transmission (TET) technology has seen very limited clinical use and still needs additional improvements prior to further use in the clinical setting.

6.625.3. LVAD Evolution

The developmental evolution of LVADs dates back to early cardiopulmonary bypass (CPB) machines and experiments in the late 1950s, during which artificial hearts were implanted in dogs. Both TAHs and heart assist devices have achieved significant development and clinical milestones since then. Starting in the 1980s, these advancements in technology and refinements in implantation paved the way for the development of innovative and novel devices, gradually overcoming the shortcomings of earlier versions. LVAD design has made tremendous advances over the last decade, reducing size, increasing durability, and eliminating noise and vibration.

The first-generation pulsatile pumps were designed to emulate the natural heart. As a result, they were bulky, large, needed heart valves, consumed much power, and suffered from high noise and vibration. As Table 1 shows, they either suffered from limited life or high complication rates.

A new paradigm for long-term blood pumping with MCS was provided by the high-speed rotary Hemopump developed and clinically used in the mid-1980s. This device, despite being commercially unsuccessful, demonstrated that there were no discernible worse outcomes associated with the direct pumping of blood with a rotary pump as compared to a pulsatile pump. This provided the incentive for the development of next-generation rotary pumps to pump blood directly while being immersed in blood.

These long-term implantable rotary pumps have also evolved over three generations beyond the first-generation pulsatile pumps. From second-generation pumps (axial flow pumps supported by mechanical bearings) that proved that long-term circulatory support provided by rotary pumps was viable and accepted well by the human body, to third-generation pumps (centrifugal pumps supported by hydrodynamic bearings) to fourth-generation pumps (centrifugal pumps whose rotor is

Table 1 A summary of available cardiac devices highlighting their advantages and disadvantages

Thoratec	
Indications	Right, left, or biventricular support
Advantages	Fits in a wide range of patient sizes (body surface area 0.73–2.5 m^2)
	Pump can be changed without invasive surgery
	Can replace the entire function of the supported ventricle
Disadvantages	Need for strict anticoagulation with risk of bleeding or thromboembolism
	Large lines crossing the skin with a high risk of infection
	Limited patient mobility
	Not approved for home use
HeartMate	
Indications	Left ventricular support
Advantages	No need for anticoagulation
	Portability of controller and batteries permits good patient mobility and hospital discharge
	Can replace the entire function of the supported ventricle
Disadvantages	Driveline crossing the skin poses a risk of infection
	Left ventricle support only
	Does not fit in patients with body surface area $\leq$1.5 m^2
Novacor	
Indications	Left ventricular support
Advantages	Portability of controller and batteries permits good patient mobility and hospital discharge
	Can replace the entire function of the supported ventricle
Disadvantages	Need for strict anticoagulation with higher risk of bleeding or thromboembolism
	Driveline crossing the skin poses a high risk of infection
	Left ventricle support only
	Does not fit in patients with body surface area $\leq$1.5 m^2
Continuous-flow pumps	
Indications	Left ventricular support
Advantages	Small size permits greater patient mobility
	Quiet
	Fit in a wide range of patient body habitus
Disadvantages	Need anticoagulation; risk of bleeding and thromboembolism unknown
	May not replace the entire function of the supported ventricle
	Nonpulsatile flow
	Still in early clinical trials
Total artificial hearts	
Indications	Advanced biventricular dysfunction
	Pulmonary hypertension?
	Cardiac tumors?
Advantages	Complete replacement of the heart function
Disadvantages	Need anticoagulation; risk of bleeding or thromboembolism
	Due to the size of equipment, they only fit in patients with larger body habitus
	Still in early clinical trials

Source: DeBakey, M. E. *Ann. Thorac. Surg.* **2005**, *79*, S2228–S2231.

suspended completely using magnetic levitation), VAD technology has developed by leaps and bounds. Because the clinical development cycle time is extensive, today there are second, third, and fourth-generation VADs undergoing clinical trials concurrently.

The earliest LVAD was reported in 1961 by Dennis *et al.* and the strategy was to employ a roller pump to off-load LV by receiving blood from RA and in turn return it to femoral artery.[13] Although the device was supposed to have supported 12 patients for 4–17 h, no significant support to recovery was observed. Since then, several researchers and developers had made progress toward VAD and TAH that are fully implantable. In 1963, DeBakey developed the first implantable pulsatile VAD using unidirectional ball valves that bypassed the heart between the left atrium and the descending thoracic aorta.[14] The implanted VAD consisted of two coaxial tubes: the blood flowed through an inner biocompatible Dacron tube surrounded by a rigid outer tube. Blood was then pumped by pneumatically increasing the transluminal pressure causing the flexible inner tube to narrow. A second patient, supported for 10 days with an extracorporeal version of this device, became the first patient to be supported to recovery with a VAD.

Later in 1969, Cooley *et al.* performed the first successful BTT using a TAH demonstrating the possibility to support the patient's circulation until a donor heart became available (Figure 3).

Worldwide attention was focused on the University of Utah in 1982 when Barney Clark, received a Jarvik-7 TAH intended for long-term use. Despite an in-hospital stay with numerous complications, this implant was followed by William Schroeder, Murray Haydon, and Jack Burcham who fared a little better. In 1998, two LVAD systems were approved by the FDA and used for bridge-to-transplantation. The HeartMate™ VE pump (Thoratec Laboratories Corp., Pleasanton, CA) and Novacor™ (WorldHeart, Ottawa, Canada) were evaluated in the United States for permanent mechanical circulatory support in the REMATCH (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure) and INTREPID trial (Investigation of nontransplant eligible patients who are inotrope dependent) (Figure 4).[7]

These early pioneering clinical successes fueled the development of second-generation devices, such as the HeartMate II shown below. The HeartMate II was the first second-generation pump to be approved in 2008 for a BTT indication, a milestone followed by its 2010 approval for DT (Figure 5).

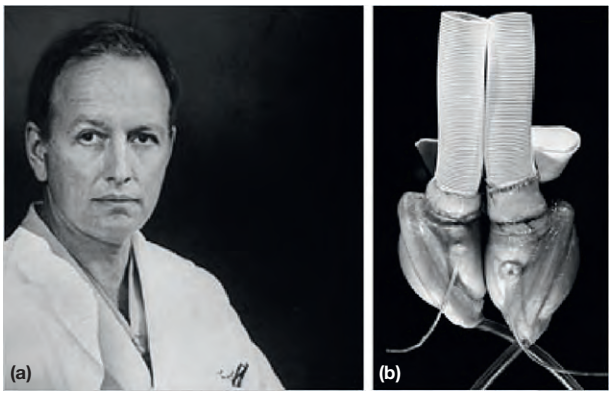

Figure 3 (a) Dr. Denton A. Cooley and (b) the total artificial heart used for the first successful bridge-to-transplant.

6.625.3.1. First-Generation LVADs

Positive/volume displacement pumps mimic the action of the human ventricles to pump blood. These could further be classified based on the mechanism by which they eject blood as pneumatic or electric. The valves incorporated into these VADs may either be bioprosthetic that offers superior biocompatibility, while suffering from poor longevity or of durable, mechanical valve with thrombogenic potential.

The most widely used and studied first-generation VADs include HeartMate® I[15] (originally developed by Thermo Cardiosystems, Inc., Waltham, MA and acquired by Thoratec Corporation of Pleasanton, CA) and the Novacor® LVAS (originally developed by Novacor Medical of Oakland, CA and later acquired by WorldHeart Corporation of Salt Lake City, Utah by way of Baxter HealthCare and Edwards LifeSciences).

The HeartMate I LVAD is available either as implantable pneumatic (IP-portable power unit on a console) that is used as bridge-to-heart transplant or, a more refined vented electric model (XVE), developed after REMATCH trial success that is currently approved for both BTT and DT use in the United States.[16,17] Both HeartMate pumps use titanium alloys and Cardioflex® polyurethane with advanced fabrication technology. The device has textured blood-contacting surfaces (textured titanium, textured blood sac) that reduces stroke and thrombus formation and does not require anticoagulant therapy benefiting patients that poorly tolerate these drugs.[18,19] A comparative study versus home inotropic infusion therapy reveals that this device certainly improves the quality of life and survival rate of patients (Figure 6).[20]

The Novacor and the HeartMate™ LVASs are both intracorporeal LVADs. Both incorporate porcine valves and have portable controllers that permit the patient to be discharged from the hospital and to be more ambulatory.[15,21] The HeartMate I is estimated to have been implanted in 5000 patients and the Novacor in 1800 patients worldwide.

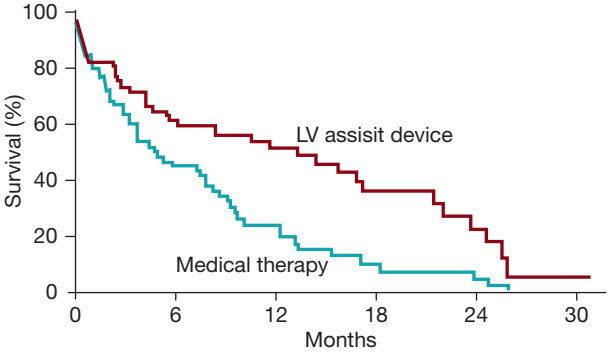

Figure 4 An outcome of survival of patients in the randomized evaluation of mechanical assistance for the treatment of congestive heart failure trial. The results reveal an obvious increase in survival of patients with end-stage heart failure. Reproduced with permission from Rose, E.A. *et al.* Long-term mechanical left ventricular assistance for end-stage heart failure. *N. Engl. J. Med.*, **2001**, *345*(20), 1435–1443.

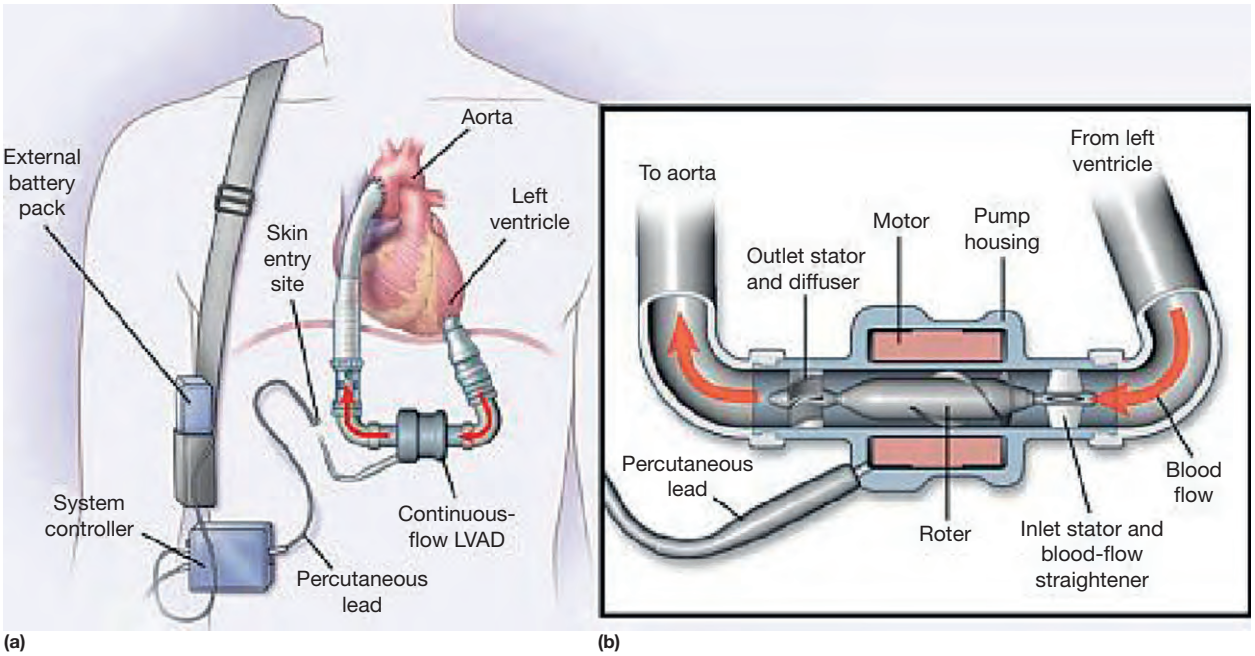

Figure 5 (a) Schematic of patient implanted with the HMII and (b) a close-up cross-section of HeartMate II.

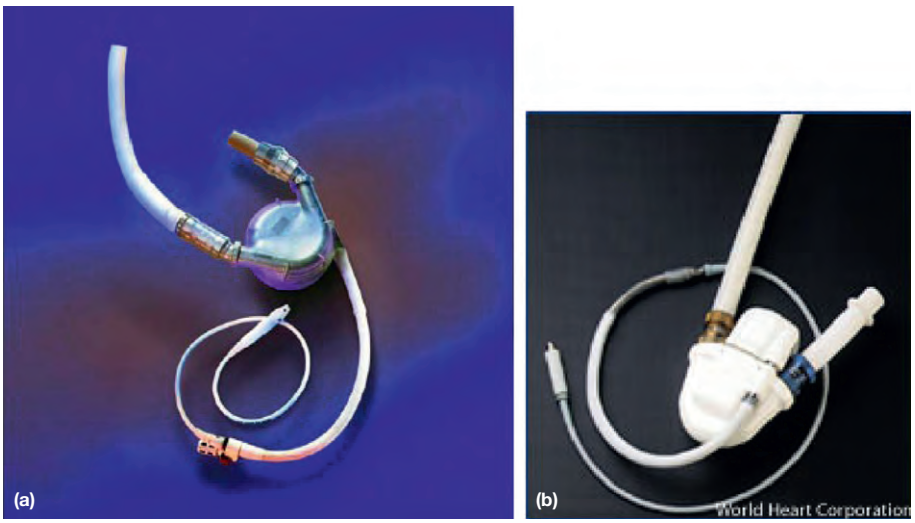

Figure 6 (a) Thoratec HeartMate I XVE pump. (b) Novacor LVAD blood pump.

The Novacor LVAS had the distinction of supporting a patient for more than 6 years with a single device, and was approved for BTT in the United States, and is CE Marked in Europe as well as approved in Japan.

As a historical footnote, it is worthwhile to mention the Arrow LionHeart™ (LionHeart Ventricular Assist System; Arrow International, Reading, PA) whose manufacture and distribution has been discontinued. The LionHeart was a pulsatile LVAD and was notable for its use of transcutaneous wireless power transmitter (TET – transcutaneous energy transfer). In Europe, the CUBS trial (Clinical Utility Baseline Study) evaluated its use as a permanent implant and it obtained the CE Mark. The LionHeart™ received an Investigational Device Exemption from the US FDA in 2001 and was undergoing Phase I human clinical trials in the United States until it was discontinued in 2006. Since it did not employ a vent tube for exchange of air, unlike its predecessors, and achieved it via an implanted compliance chamber, coupled with its use of a TET for power and data transmission across the skin, it eliminated the need for a percutaneous cable. While this certainly helped address the driveline infection issue, the trade-off was increased volume and number of separate implantable components, and the need to periodically (once every 2 weeks) prime the supple compliance chamber with working gas through an access port (shown in Figure 7), due to its gradual dissipation through the synthetic membrane.

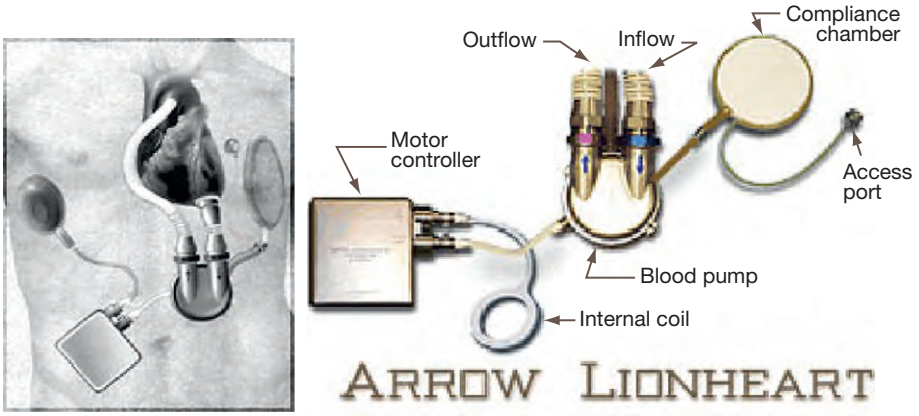

Figure 7 Arrow LionHeart™ (LionHeart Ventricular Assist System; Arrow International, Reading, PA).

The Berlin Heart Group (Berlin Heart AG, Berlin, Germany) produces and sells the EXCOR pulsatile VAD. This external device comes in a variety of sizes selected depending on patient needs, and has been used primarily in adults as a short-term support and more predominantly in newborns and infants with cardiac failure. The EXCOR VAD has received an HDE from the US FDA for this latter niche application.

While offering several advantages, the first-generation VAD suffered from serious drawbacks such as bulkiness (pump, driving console), noise, limited life due to mechanical wear and breakdown, high incidence of adverse events, and non-physiologically high systolic pressure that could result in elevated calcification and hence eventually to valve failure.

6.625.3.2. Rotary Axial Pumps

The pitfalls of first-generation volume displacement pumps were overcome to some extent with the 'second-generation' axial pumps.[17,22] Axial pumps were anticipated to be less obtrusive, of low noise and less prone to driveline infections due to reduced driveline diameter, increased flexibility, and less stiffness of the percutaneous cable. Furthermore, these pumps are driven by impellers that operate on a continuous basis using rotary pump technology. With speeds typically up to 12 000–15 000 rpm, these could generate higher flow rates at lower pressure (up to 10 l min^{-1}), without the need for a valve.[22,23] Initially, concerns were raised about the possibility that such speeds might lead to hemolysis of blood, but soon was discarded when the Hemopump was successfully used in a clinical setting.[24] The Hemopump thus set the stage for further evaluation of other types of axial flow pumps.[16,17,25–29]

Key second-generation pumps include the HeartMate II LVAD[23] (Thoratec), the DeBakey- MicroMed VAD® (MicroMed Cardiovascular, Houston, TX), and the Jarvik 2000 (Jarvik Heart, Inc., New York, NY). MicroMed's device uses an impeller/inducer with six blades and eight magnets, enclosed in a titanium tube and is capable of pumping up to 10 l min^{-1}, and is identical to the HeartMate II in many respects. Based on NASA-developed technology, the DeBakey's compelling features are its size, which is anatomically designed for fit even in the pediatric populace for which it has obtained FDA approval as a BTT, and an implantable ultrasonic flowmeter

Figure 8 HeartMate II left ventricular assist device.

to allow better patient monitoring and device speed adjustment.[25,27] The DeBakey VAD has been redesigned several times due to thrombotic issues leading to several changes in blood-contacting coatings. and the latest version is being evaluated under a CE Mark trial in Europe (Figure 8).

The Jarvik 2000, also known as the Flowmaker®, has the advantage of requiring no cannulation and potentially decreased thromboembolic events due to its design that is presently being qualified. It is 2.5 cm wide, 5.5 cm long, and weighs 85 g. The pump speed can be tuned by an analog controller on the basis of symptoms and individual requirements offering a unique biofeedback mechanism for the patients. The entire casing is of titanium with the pump suspended on ceramic bearings.[26] This device has the distinction of having supported a patient for more than 7 years and is presently in a US BTT clinical trial having received a CE Mark in Europe. The Jarvik 2000 is being adapted and miniaturized for use in the pediatric population (Figure 9).

Overall the second-generation VADs offers effective circulatory support and durability, less extensive and invasive surgical procedures hence postoperative complications, and reduction in pocket infections. Based on the above facts demonstrated through controlled clinical trials, HeartMate® II has been approved by FDA as BTT therapy and more recently for DT as well.[16] The main disadvantages of these devices are the intense anticoagulation regimens to treat embolic complications,

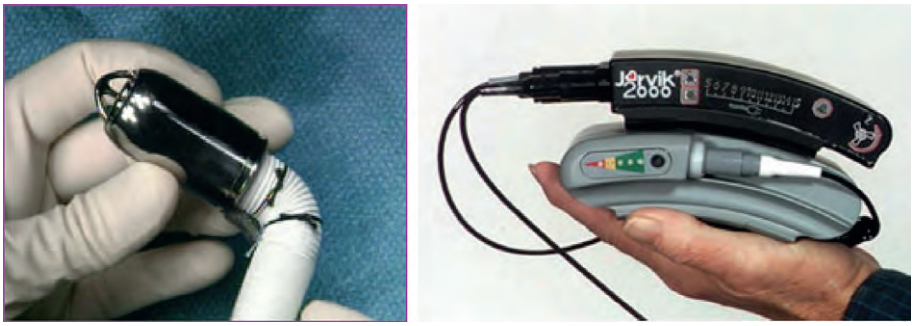

Figure 9 Jarvik 2000 also known as Flowmaker.

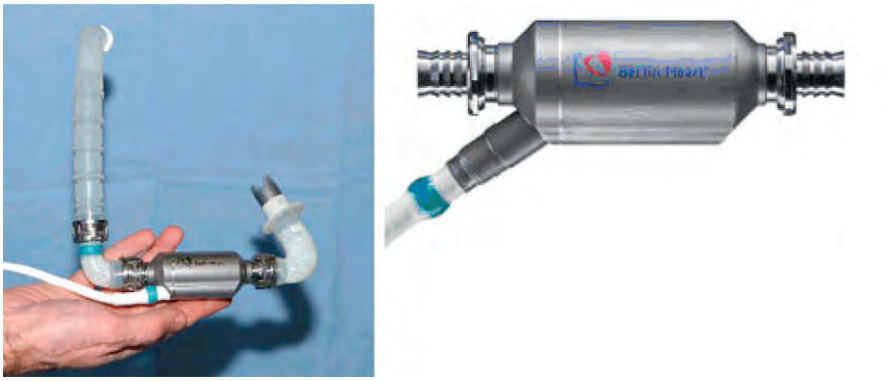

Figure 10 BerlinHeart Incor ventricular assist device.

bleeding, and the activation of undesirable blood constituents such as von Willebrand's factor.[30]

Since these pumps traditionally rely on mechanical bearings to suspend the rotor spinning at high speeds, the BerlinHeart Incor VAD incorporates an axial flow pump with a fully magnetically levitated suspension. The Incor® LVAD is an impeller device developed by the Berlin Heart Group (Berlin Heart AG, Berlin, Germany).[31] The pump is 30 mm in diameter, 12 cm in length, and weighs 200 gms. Blood enters the device through a cannula and passes the inducer and the flow is driven by an impeller that is held in suspension by magnets (both permanent and active electromagnets) and can develop a flow of up to 7 l min^{-1} with motor speeds of 5000–10 000 rpm. The clinical investigation of this device began in 2002 and the results showed a dramatic reduction in infection rate, with a significant increase in thromboembolism.[32] A retrospective study revealed that the long inflow cannula in the design yielded better clinical outcomes than a short one (138 patients – short length of inflow cannula and 78 with long inflow cannula) and a lower incidence of embolism.[31–33] A 2004–2005 study to evaluate BTT potential of the device revealed its feasibility for long-term use using a combination of LMWH (Heparin) and antiplatelet therapy as an alternative to oral anticoagulants. The study also revealed that, out of 10 patients, 6 patients successfully received transplants and 4 patients died – the last death occurred after 405 days of INCOR implantation. The autopsy indicated the causes of death to be sepsis, intestinal hemorrhage, acute right ventricular failure, and one major stroke.[34] A total of 500 patients worldwide have been implanted with the INCOR VAD (Figure 10).

6.625.3.3. Rotary Centrifugal Pumps

Centrifugal pumps are regarded as the next stage of evolution of VADs.[35] Although similar to axial pumps, in that they are rotary pumps, the rotor of a centrifugal pump is shaped so as to cause the blood to move circumferentially along the outer rim of the pump housing and be ejected. Centrifugal VADs have been found to improve myocardial function and be beneficial to end-organ functioning through pulsatile perfusion.[16,31,36] Due to its different pressure-flow characteristics compared to an axial flow pump, a centrifugul pump may be physiologically better suited for adults than an axial flow pump: it provides greater pulsatility in flow, and a more physiologic response to changing preload. The key area of distinction for the centrifugal pumps is how their single moving part, the impeller, is supported. Earlier designs such as the EVAHeart (Pittsburgh, PA) employ solid mechanical bearings, while next-generation centrifugal blood pumps either employ the blood itself to suspend the spinning impeller in a hydrodynamic suspension (HeartWare HVAD, VentrAssist's VentraCor, and the Arrow CorAide). The culmination of centrifugal blood pump technology has resulted in fourth-generation pumps (Terumo DuraHeart, Thoratec HeartMate III, WorldHeart Levacor) whose impellers are completely magnetically levitated inside the pump cavity.

These pumps stay suspended with magnetic levitation, providing a smooth, uniform, and unrestricted flow path to blood, and eliminate contact of the spinning rotor with the housing, thereby theoretically eliminating any wear on the impeller blades and mechanical friction resistance.

6.625.3.3.1. Rotary centrifugal pumps using hydrodynamic suspension

The VentrAssist™ LVAD (Ventracore, Chatswood, NSW, Australia) was a recently developed third-generation centrifugal blood pump with hydrodynamic suspension.[35] Its only moving part, an impeller, consists of four small blades that are embedded with permanent magnets. The combined dynamic interplay of fluid, bearing, and gravitational forces prevents the impeller from contacting the housing. The VentrAssist™ weighs 298 g and is made of titanium. It is ~60 mm in diameter and is suitable for use both in children and adults (Figure 11).

Recent studies have shown the device's ability to perform in BTT therapy.[24,37,38] The initial pilot study was conducted on four DT and five BTT patients in 2003. Having acquired considerable patient-years of experience (7 years), the safety and efficacy profile displayed no embolic events, minimal sepsis/infections and reportedly remarkable performance even in complex cases.[37,39] This pilot study instigated a phase II trial that led to its CE mark approval in the European Union. The overall performance was exceptional with over 70% of patients who achieved early hospital discharge, with better functional status and compliance. To corroborate the survival to transplant or the continued support while the patient was still on transplant wait list, a US multicenter, pilot study to BTT was conducted and the results showed a statistically and clinically significant improvement in the quality of life and functional status, with adverse effects similar to the current LVADs, while certainly being better than pulsatile LVADs.[40] The study was terminated early by Data Safety Monitoring Board because its interim analysis criteria for study discontinuation requirement had been fulfilled.[40] Further investigation of the device was not feasible owing to the company's lack of funds and subsequent dissolution.

The Arrow CorAide VAD (centrifugal pump, hydrodynamic suspension) was also CE Marked in Europe, but its owner exited the VAD space, and there are no further reports of any future development as both the CorAide and the LionHeart have been mothballed. This attrition leaves the Heartware HVAD as the only clinically used pump in this category.

The HVAD™ (Heartware Inc.,) consists of a small continuous flow rotary centrifugal pump with a hydrodynamic bearing design with a unique feature of its size that could be accommodated within the pericardial space near the left ventricle. This design obviates the need for an abdominal dissection. The impeller is suspended via a combination of passive magnetic and active hydrodynamic bearings. This reduces the mechanical strain on the pump and therefore its wear. The integrated design contains two motor stators for single-motor fault protection to increase reliability. A thin blood film generated by the bearings eliminates physical contact between the housing and the impeller during normal operation.[41,42] Since its implantation in March 2006, HVAD™ has undergone clinical evaluations in Europe and Australia and a US BTT trial consisting of 150 patients completed its enrollment in February 2010. After a 6-month follow-up for the last patient enrolled in August 2010, it is anticipated that a BTT PMA submission will occur by year-end 2010, with approval following earliest in mid-late 2011. A DT trial for HVAD with 450 patients randomized 2:1 to the HMI or II has been recently conditionally approved by the FDA (Figure 12).

6.625.3.3.2. Rotary centrifugal pumps using full magnetic levitation

The two devices in this category in clinical development are the Duraheart VAD (Terumo Cardiovascular), and the Levacor VAD (WorldHeart Corporation). Both these devices have a similar configuration, including a 'flat' inlet to the centrifugal pump that allows the pump to be implanted in the upper abdomen of even small patients. In comparison, the third-generation pumps described above have a traditional inlet to their centrifugal pump, one that is at right angles to the pump body. While this somewhat simplifies the blood flow path design, it is possible it may compromise anatomic fit and position of the third-generation pumps, including that of the inlet cannula. The flat inlet of the fourth-generation pumps described here may avoid this potential problem.

The DuraHeart™ VAD comprises an implantable pump with several components to augment its function.[43] The ingenuity of the device is attributed to the magnetically levitating centrifugal rotary pump (impeller with 3 positional sensors)

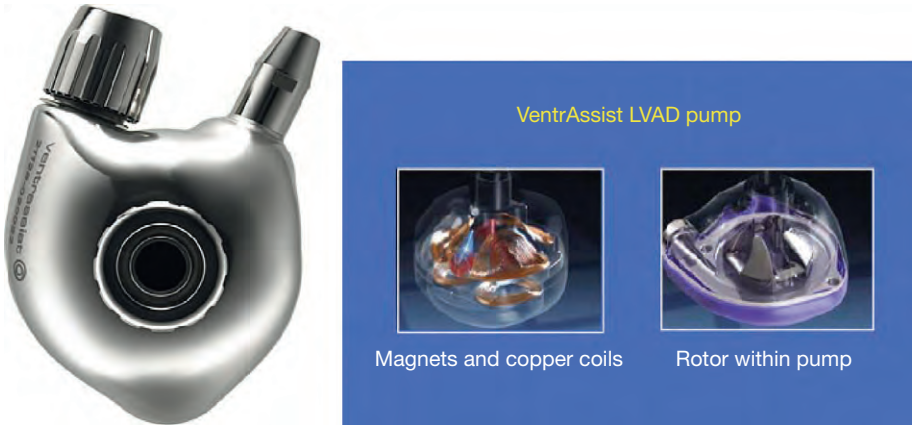

Figure 11 The VentrAssist™ left ventricular assist device (Ventracore, Chatswood, NSW, Australia).

Figure 12 HVAD Heartware, Inc.

Figure 13 DuraHeart™.

with a thin outflow conduit (Vascutek Gelweave™) that exits the skin and connects to the controller that controls and monitors the system status. The pump comprises an upper housing with the levitation system and the impeller, and bottom housing with an external-drive motor. The device has been fabricated with an active magnetic levitation of the impeller coupled with hydrodynamic bearings to support impeller levitation in case of failure of the magnetic levitation system. This design provides flow rate of 2–8 l min^{-1}, with rotor speeds of 1200–2400 rpm. The flow rate can be programmed to vary with physiological changes. DuraHeart™ with its combination of centrifugal pump and magnetic levitation technology was the first such device to reach clinical trial.[43] The pump is implanted in an abdominal pocket. The magnetic levitation of the impeller is designed so as to eliminate friction by allowing a wide gap between blood-contacting surface areas, and to enable blood to flow unimpeded, through the pump in a smooth nonturbulent fashion.

The DuraHeart™ pump has the dimensions of diameter 72 mm, thickness 45 mm, and weighs ~540 g. The displacement volume is 196 ml, that is, 30–50% smaller than the pulsatile pumps. The total horizontal length is ~50–60% shorter than that of axial flow LVADs.[44]

The DuraHeart™ LVAS (Figure 13) is currently being studied in a Pivotal US trial for BTT, a multicenter, nonrandomized study that involves 140 patients. The study is meant to evaluate the safety and efficacy in sustaining patients awaiting transplant and who are more prone to end-stage HF. The DuraHeart™ LVAS carries a CE Mark and is currently available for sale in European countries.[45] Furthermore, the company has completed enrollment for clinical trial in Japan.

The Levacor™ VAD was initially developed by MedQuest Products, Inc., a spin-off of the University of Utah's decades-long contributions to the MCS field, and is now being commercialized by WorldHeart Corporation (Salt Lake City, UT). The device incorporates an ultracompact, bearingless rotary centrifugal pump that is implanted in the peritoneal space. The rotor which acts as an impeller is completely magnetically levitated, ensuring the lack of contact with the housing under any normally encountered operating condition and thereby virtually minimizing thrombosis, damage to blood components, lack of heat, wear and mechanical damage. The inflow cannula is titanium while the outflow graft consists of 12 mm woven collagen sealed polyester anastomosed to the ascending aorta.[46] Its initial clinical evaluation was in Europe in 2006, with anticipated BTT/BTR outcomes in a shorter-term in-hospital setting: after 3 months of support, both patients' natural hearts recovered. To promote recovery of the natural heart, blood flow provided by the Levacor VAD was slowly reduced while the load on the natural heart was gradually increased. The unique maglev technology allowed the Levacor VAD to provide flow rates as low as 1.3 l min^{-1} for weeks at a time to each patient to promote recovery. Both of these devices were explanted after recovery was deemed to be stable. Now 4 years later, both patients are leading a normal device-free life at home.

Subsequently, the system underwent further development to enhance its suitability for longer-term applications and out-of-hospital use. Pump refinements included: a biocompatible coating on the blood-contacting surfaces to further enhance device performance, hermetic sealing of the motor/electronics cavity, a modular pump lead with implanted connector to permit replacement of the percutaneous lead without pump replacement, and an external connector that allows the distal extension cable to be quickly replaced, without surgery, either prophylactically or in case of damage.

Compact, lightweight, and ergonomic controller and battery packs were developed. The controller incorporates a rechargeable reserve battery to support pump operation during exchange of the primary power source. This reduces the number of separate modules to be carried by the recipient, and mitigates the possibility of pump stoppage due to accidental power source disconnection. The controller also provides the ability for the physician to set three different pump speeds, and the patient to then select any of these speeds depending on their condition and activity level.

A pivotal US trial evaluating this device for a BTT in 160 patients was initiated in January 2010, with 8 patients implanted in 4 centers through June 2010. the Levacor™ VAD is expected to be evaluated as an alternative to heart transplant and in future probably as a BTR. Potentially, due to its use of the simplest magnetic levitation allowed by physical laws combined with other innovations, the Levacor™ VAD could last and provide MCS for many years longer than other blood pumps (Figure 14, Table 2).[47]

6.625.4. Partial Circulatory Support VADs

While most devices have focused on providing full and complete support to the circulation, a hypothesis has emerged that, in order to support less-sick HF patients, a much smaller, less-invasive, more user-friendly device that only has to provide partial circulatory support (from 0 to 2.5–4 l min^{-1}) would be needed.

Several such devices are in early development (HeartWare MVAD, WorldHeart MiVAD, Orqis Medical Exceleras) and only one (Circulite Synergy) has been clinically evaluated to date.

The Synergy® micro-pump (Circulite, Inc., Hackensack, NJ, USA) measures roughly the size of an 'AA' battery. The device incorporates a combination of axial, centrifugal, and orthogonal flow paths with a single-stage impeller powered by an integrated brushless micro-electric motor. With the following dimensions: diameter 14 mm, length 49 mm, and weight of only 25 g, Synergy® can pump up to 3 l min^{-1}. The pump design features both a combination of magnetically and hydrodynamically levitated and stabilized rotor, that is sealed and a self-washing flow path that is designed to minimize the risk of thrombus formation in or around the rotor. The

Figure 14 Levacor™ ventricular assist device.

power console weighs ~3.3 pounds and the dual battery pack powers the device for ~16–18 h. The controller provides the patient with information on the battery status and also alerts the patient to any change that requires attention. With continued research and innovation, the company also intends to expand the Synergy platform with a fully implantable system with physiological feedback, in the near future. The device also comes with a built-in 'fail-safe' mechanism in case of accidental power disconnects, augmented by the patient's native cardiac flow.

CircuLite's development of *Synergy* is backed by established proof-of-concept in ongoing clinical studies and 8 years of engineering at the Helmholtz Institute in Aachen, Germany, one of the world's pioneering centers for blood pump technology development, in collaboration with Katholieke Universiteit in Leuven, Belgium and is specifically designed for long-term use in NYHA Class IIIb/early IV patients (INTERMACS 4–6) (**Figure 15**).

6.625.5. Total Artificial Heart

It has been man's immense quest to find a synthetic replacement for the human heart that could virtually eliminate the need for heart transplant. With the accrued advancements in science and technology over five decades, a TAH in clinical use is now a reality.

A TAH is, in design and operation, similar to VADs, but replaces the heart and presents many more challenges than simply to complement the failing ventricle. The challenge lies in positioning both the ventricular pumps in the abdomen. While developing earlier models, the top portions of the natural heart's atria were left in place when the heart's components were removed, to facilitate suturing the TAH into position. These portions of the atria provided the natural electric stimuli so that the TAH's speed could increase during exercise and slow during rest.

Despite its earlier start, TAH evolution has not progressed as rapidly as LVADs. The only FDA approved TAHs today are the C7–70 pneumatically driven TAH made by SynCardia Systems Inc. (Tucson, AZ, USA) and the electro-hydraulically driven AbioCor TAH commercialized by Abiomed Corp (Danvers, MA).

Some of the earliest pioneering work was done by Cardiowest™ (which was itself a successor to first Kolff Associates and then Symbion, both of Salt Lake City, UT). Nonprofit CardioWest was acquired by for-profit SynCardia Systems Inc., and its device, the C7–70 TAH was approved by the FDA in 2009 following a decade of clinical study, for use in BTT for patients with irreversible end-stage biventricular failure. The recent innovation is its conditional approval of the Freedom ™ driver for investigational device exemption (IDE) clinical study and it is the first-ever US portable driver designed to power the SynCardia temporary TAH inside and outside the hospital by the FDA in March 2010. The device driver weighs 13.5 lbs including two onboard batteries, designed to be charged via a standard electrical outlet and a power adaptor. The entire console could be carried in a shoulder bag or backpack. The driver is designed with a 'dark cockpit,' meaning the driver only sends an alarm when something requires the user's attention. The Freedom ™ driver is intended for use as a BTT in clinically stable cardiac transplant-eligible candidates who are implanted with the TAH (**Figure 16**). The Syncardia TAH costs about $125 000 and about $18 000 a year to maintain.[48]

Like the thoratec implantable VAD, and SynCardia Temporary Heart System, the Jarvik-7 TAH (named after Dr. Robert Jarvik and developed by the University of Utah and Symbion under the leadership of Dr. Willem Kolff, and later named the Symbion TAH) was also pneumatically driven. This device in its refined form is the present-day Syncardia System; so it is useful to describe it here.

It consists of two ventricular pumps joined together and requires a portable console (Big Blue) for power. The ventricle is ellipsoid shaped and is made of polyurethane that has a sac that pushes the blood from the inlet to the outlet valve as it is deflated and inflated by air on the nonblood side of the sac. Air is pulsed through the ventricular air chambers at rates of 40–120 bpm. The artificial heart is fastened to the heart's natural atrium by cuffs (Dacron™ felt). The drive-lines are made of reinforced polyurethane tubing. The outlet lines exiting the skin are covered with velour-covered Silastic™ to ensure stability, durability and also encourage tissue growth (minimal scarring). The power console is pretty large and heavy as that of a household refrigerator. In case of emergency or power failure, the system is also backed up by a rechargeable battery and includes on-board compressed air tanks (modified scuba type) for use during transport. Controls in the console regulate pump rate, pumping pressure, and other essential functions.[49]

Unlike the pneumatically powered devices described above, Abiomed devised an electrohydraulically driven, fully implantable device, the AbioCor® TAH, with transcutaneous energy delivery system (TET). This device is still in investigational use under a humanitarian device exemption (HDE) approved by the FDA. In a limited set of patients, who

Figure 15 The Synergy® micropump (Circulite, Inc., Hackensack, NJ, USA).

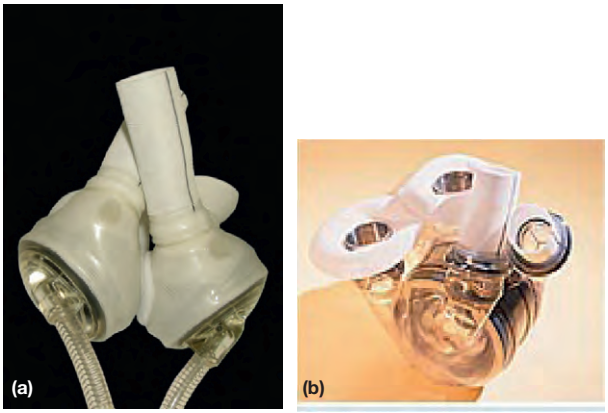

Figure 17 (a): Total artificial heart – Jarvik-7. (b): The AbioCor total artificial heart.

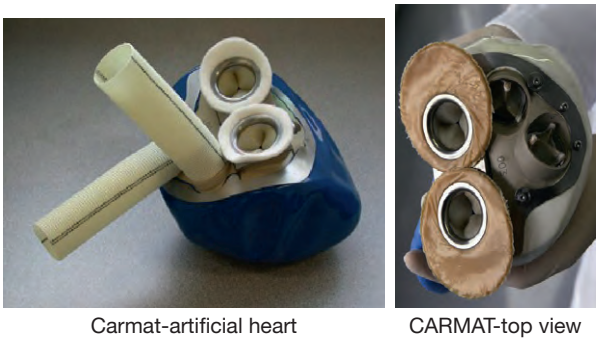

Figure 18 Total artificial heart developed by Carmat SAS.

have no other treatment options, the device is reported to have been found safe and beneficial with end-stage HF. Its uniqueness lies in the design of a mechanism that enables both systoles to occur sequentially. The AbioCor® system comprises a TAH, implanted TET, controller, battery, and cables. An energy converter in the replacement heart helps both the pumps keep blood flowing normally. The Energy Converter contains silicone hydraulic fluid in a sealed compartment that is separated from the right and left chambers by flexible membranes. A pump in the energy converter pushes the fluid against the membranes, causing the pumps to empty and fill (Figure 17).[50,51]

However, both the available TAHs have drawbacks; the former is bulky and obtrusive, while the latter could lead to stroke.

A recent TAH under early development by Carmat SAS, the company founded by professor Carpentier and EADS, Europe's aerospace and defense giant, promises to overcome these hurdles by utilizing 'pseudo-skin' of biosynthetic, microporous materials, and the power source, by implanting a titanium receiver in the skull that would channel energy sent through the skin (noninvasively) from a battery to the heart. The second would work by generating electricity through the skin between two transformers, one inside and one outside the body. The battery is likely to last for between 5 and 16 h, after which it would have to be recharged to prevent the artificial heart stopping. Equipped with 'smart' motors and unlike previous artificial hearts, this one detects the body's activity level (and therefore how much oxygen it requires) and changes its pace accordingly. This new design is likely to be available for clinical use by 2013 (Figure 18).[52]

While traditional TAH designs in clinical use and under development have focused on positive displacement pumps that inherently provide pulsatility, early work is being done by other researchers to install two rotary pumps back-to-back as ventricular replacements in a TAH configuration. These results are too early but it is a possibility that such a configuration might find greater use than the traditional 'pulsatile' devices.

6.625.6. Conclusions

The LVAD has been a remarkable technology that has bridged the void between conventional medical therapy and cardiac transplantation. With increasing number of people diagnosed with heart diseases, and ratio of aging population increasing every year, constraints in donor heart availability, VAD options that aim to support patients with late-stage HF as an alternative to a heart transplant are on the rise. The LVADs have certainly had a positive impact in its role of reducing hospitalization as well as improving the functional status and quality of life of patients. With ongoing research in improving design and performance, the newer LVADs promises to be patient-friendly, durable and minimally invasive to implant or explant, and potentially offer a safety and efficacy profile much superior to earlier-generation devices.

The future of LVADs, when complemented with gene therapy could culminate in a permanent 'dream' cure, wherein the device takes over the heart's functions providing the cardiac stem cells with a conducive environment to regenerate [REF].

With emerging technological advances, there certainly is likelihood for a slew of devices that will provide safe and effective therapy to less-severe HF patients. These devices will need to be significantly refined, smaller, and easier-to-use than the marketed ones.

In the long-term, it is clear to the authors that the answer to the biological question of HF will need to be answered by biological solutions that involve disciplines such as tissue engineering and genetic engineering.

Acknowledgments

The authors would like to acknowledge the contributions of Vivek Srinivasan and Priya Nayar for their diligent work toward the extensive research, sourcing and compilation, and editing of the information needed for this chapter.

Abbreviations

α-SMA	Alpha smooth muscle actin
ECM	Extracellular matrix
EDTA	Ethylenediaminetetraacetic acid
eNOS	Endothelial nitric oxide synthases
FDA	The United States Food and Drug Administration
GAGs	Glycosaminoglycans
MMPs	Matrix metalloproteinases
MSCs	Mesenchymal stem cells
P4HB	Poly-4-hydroxybutyrate
PERV	Porcine endogenous retrovirus
PGA	Polyglycolic acid
PGs	Proteoglycans
PHA	Polyhydroxyalkanoate
PLA	Polylactic acid
PLGA	Poly(lactic-*co*-glycolic acid)
PLLA	Poly-L-lactide
PTFE	Polytetrafluoroethylene
PVA	Polyvinyl alcohol
SDS	Sodium dodecyl sulfate
VECs	Valvular endothelial cells
VICs	Valvular interstitial cells

6.626.1. Introduction

Heart valve disease is a significant cause of mortality worldwide. It occurs when one or more of the valves in the heart are stenosed, restricting the flow of blood, or when one or more of the valves become insufficient, failing to make a tight enough seal during diastole, allowing backflow. While the aortic valve is the most commonly affected valve; valvular disease may occur in any of the valves of the heart likely because of the high pressures to which it is exposed. The major complication of valvular heart disease is cardiac failure resulting from a change in the myocardium induced by pressure or volume overload of the chambers upstream or downstream of the diseased valve. In 2006, the American Heart Association reported that in the United States alone, heart valve disease accounted for 21 386 deaths, and of these deaths, 13 752 deaths were attributed to aortic valve disease, and it was listed as a contributory factor in an additional 27 380 deaths.[1]

Although surgical valve repair is available, in most advanced cases implantation of a prosthetic heart valve, which may be either mechanical or biological in nature, is the preferable option. These prosthetic valves, although extensively used, have a number of problems associated with them, including requiring the patients to undergo anticoagulation treatment for the remainder of their lives. Thus far, a nonthrombogenic, noncalcific prosthetic valve that is capable of maintaining sufficient mechanical properties and hemodynamic flow, and exhibits appropriate fatigue properties, has yet to be fabricated. Current prosthetic designs do not have the necessary potential for growth and healing and are therefore unsuitable for implantation into young patients. The fact that heart valve design has remained virtually unchanged for the last 30 years suggests that the current valves are probably as advanced as they can become, and a new approach must be considered. Researchers have in recent times focused on the use of tissue engineering to achieve this goal. It has been suggested that an optimal heart valve replacement would contain regenerating interstitial cells to provide sufficient turnover of extracellular matrix (ECM), endothelial cells to provide an antithrombogenic element, and a suitable scaffold biomaterial with both appropriate mechanical properties to mimic the native valves and an optimized degradation rate to provide a medium in which the interstitial cells and endothelial cells can repopulate and replace it.[2]

The aortic heart valve facilitates the flow of blood from the left ventricle to the aorta, where it supplies the peripheral blood vessels, through a complex mechanism of opening and closing in an unrelenting, extremely demanding environment over a wide range of hemodynamic conditions.[3] The valve opens and closes 100 000 times every day which amounts to approximately 3 billion cycles over the life time of the average adult.[4,5] With over 8000 l of blood passing through the aortic valve and being pumped out of the heart each day, the physiological demands on the aortic valve are particularly harsh.

Biaxial mechanical analysis of the aortic valve cusp by Christie *et al*. has quantified the strain in the radial and circumferential directions. At a tension of 60 N m^{-1}, strains in the radial and circumferential directions are 75% and 12%, respectively.[6] Billiar *et al*. presented similar results following the application of physiologically relevant strain ratios to both the circumferential and radial axes of valve cusps.[7]

The primary cell types found in the aortic valve are valvular endothelial cells (VEC) and valvular interstitial cells (VIC). VECs form a confluent layer on the fibrosal and ventricular surfaces of the valve cusp. They function primarily in maintaining a nonthrombogenic surface, while it is thought that they play a role in regulating the activity of the VICs,[8] which are present in the underlying spongiosa layer. VICs function mainly in maintaining valve structure and producing ECM.[9] Both cell types have previously been seeded on scaffolds; however, concerns do exist as to the number of available cells. To this end, a number of alternative cell types have also been considered. These include human saphenous vein endothelial cells,[10,11] ovine circulating endothelial progenitor cells,[12] and ovine carotid artery endothelial cells,[13] which have all been assessed for their potential in fulfilling the role of VICs. Meanwhile, human neonatal fibroblasts,[14] human myofibroblasts,[15] ovine myofibroblasts,[13] human aortic myofibroblasts,[16] and neonatal rat smooth muscle cells[17] have all had their ability to fulfill the ECM-producing role of VICs characterized. In addition to functionally replacing VICs and VECs, cells seeded onto a scaffold must be available in clinically relevant quantities, while being free of contamination and pathogens of any type.

Two approaches have historically been taken in the design of scaffolds: the traditional approach and the tissue guided regeneration approach.[18] The traditional approach, which shows the most promise, involves *in vitro* seeding of cells on a scaffold often in the presence of the appropriate signals. These signals may include forces such as shear stresses, growth factors, cytokines, and topography, or a combination of two or more of these. Of these, the application of physiologically representative shear forces seems particularly critical during *in vitro* cell culture.[19,20] In a somewhat related field, studies have shown that preseeding vascular grafts with endothelial cells improves their long-term patency[21] and reduces thrombogenicity.[22] This finding is also relevant in the field of valvular tissue engineering. The development of a fully confluent endothelial cell layer and the regeneration of native ECM are the two critical attributes of a scaffold for valve replacement.[23] With the appropriate signals present, cells will ideally adhere to, proliferate on, and infiltrate the heart valve scaffold. This will result in the deposition of native ECM prior to implantation. The alternative method, guided tissue regeneration, has a similar concept but a different approach. It involves the implantation of a scaffold which will be autologously reseeded by the adjacent host tissue through cell migration or circulating stem or progenitor cells.[24] The benefits associated with this approach include the lack of preseeding and conditioning usually associated with the traditional approach, and the lower risk of an immunogenic reaction which has been associated with allogenic or xenogenic cells used to repopulate scaffolds *in vitro* in the traditional approach.

Synergraft™ (Cryolife, USA) conducted the most widely reported study which utilized the guided tissue engineering approach. The scaffolds were implanted into four male children in 2001. Two of the valves were prepared from noncoronary segments of aortic root while the other two were prepared from pulmonary roots. All valves were cryopreserved and then thawed out, under strict company protocol, prior to implantation. The xenogenic collagen matrix of the scaffold valve provoked a strong inflammatory response in humans that was nonspecific early on and followed by a lymphocyte reaction at 1 year. This trial resulted in death of all but one of the patients.[25] So while the guided tissue approach may seem advantageous when compared with the traditional approach, and has shown some success in animals,[26] human trials have failed. In fact, there is currently no scientific evidence to suggest that following human implantation heart valve scaffolds will be recellularized.[27] Many researchers are very skeptical of this approach, doubting its relevance and efficacy. It has been described as 'highly speculative and highly unlikely' by Stock and Schenke-Layland.[24] While the growth of endothelial monolayers on vascular grafts implanted in animals has been demonstrated,[28] it has thus far proved very different with grafts implanted in humans. Even in the case of Synergraft™, where implants survived for up to 1 year, *in vivo* scaffolds remained acellular.[25] The growth of an endothelial cells layer, and hence the maintenance of a nonthrombogenic layer on implanted scaffolds in the vascular system, is vital in heart valve replacement therapies. In addition, the repopulation of the scaffolds with native cells is vital for ECM deposition and remodeling. Mounting evidence suggests that the most clinically relevant approach to heart valve replacement therapy is utilization of the traditional tissue engineering approach, that is, the *in vitro* seeding of cells onto a scaffold, followed by *in vitro* conditioning, and finally implantation *in vivo*.

6.626.2. Native Heart Valve Structure

In a process known as valvuloseptal morphogenesis, the valves of the heart are derived from embryonic mesenchymal outgrowths, referred to as endocardial cushions.[29] Two valves are formed in the atrioventricular canal and two are formed in the ventricular outflow tract. The two valves in the atrioventricular canal are trileaflet and bileaflet, while the valves in the ventricular outflow tract are both trileaflet (the pulmonary and aortic arterial valves). It had been thought that valves were simple, passive structures whose role in maintaining unidirectional flow was controlled by changes in pressure across the valves.[30] This belief in passive valve function led to the design of passive valve replacement prosthesis, namely, mechanical valves and decellularized xenografts and homografts. However, it has since been established that valves are not merely passive structures, and that in fact they have a far more complex structure, which positions them ideally for their specialized role in the microenvironment in which they are present.[31] It is this realization that has led researchers to consider current treatment outdated, and to pursue an alternate route in which they attempt to replace diseased valves with valves that have both a similar structure and composition.

6.626.3. Current Treatments

The field of heart valve replacement began in the 1950s, with the first successful human implantation taking place as early as 1952.[32] Since then, over 100 models of prosthetic heart valves have been developed and used with varying degrees of success. The two main classifications of valves are mechanical valves composed entirely of synthetic materials and biological valves, fabricated from biological tissue (bioprosthetic). The split between the types of valves used is quite even, with 55% of implanted valves being mechanical and 45% being biological.

Major advances in both biomedical engineering and biomaterials science have facilitated the design and manufacture of very efficient mechanical heart valves with a life span of approximately 25 years. Early designs of mechanical valves were mainly ball and cage valves, progressing then onto tilting and bileaflet tilting disk valves. The opening and closing of these valves is purely a passive phenomenon, with the occluding apparatus (ball or disks) moving in response to the changes in pressure and blood flow within the heart and associated vessels. However, they are associated with thrombolytic therapy and thrombosis, and require the patient to undergo lifelong anticoagulation treatment, which has a number of associated complications. Other limitations include the risk of infective endocarditis, and the risk of failure or separation of valvular components, which may become embolised.[33]

Bioprosthetic valves may be composed from either animal-derived tissue (xenograft) or human-derived tissue (homograft). Xenografts are typically composed of bovine or porcine tissue, and mounted on a synthetic supporting frame (usually PTFE (polytetrafluoroethylene)) allowing it to be sewn into place. Valves are typically treated with glutaraldehyde to increase durability and to ensure decellularization, reducing the risk of immune rejection. The advantages of xenografts include the widespread availability of valves and the superior flow through them as they exactly mimic the architecture of native valves, as well as obviate the need for anticoagulation therapy. However, progressive tissue deterioration has been associated with xenografts resulting in a short life span of 10–15 years,[34] meaning that they are not suitable for use in younger patients. Also, they are susceptible to calcification in young patients and are therefore only implanted in elderly patients. Homografts may be either cryopreserved cadaveric valves or healthy valves from heart transplant patients. As with xenografts, the architecture matches that of the native valves with natural blood flow preserved and hence the valves perform well compared with mechanical valves with a low rate of thromboemoblic complications.[35] The valve contains living, viable cells, which is of course not the case with either mechanical valves or xenografts, and this leads to increased biocompatibility. However, it is still inadequate as a replacement for diseased valves.[36] There exists the risk of damage to the valves because of chronic rejection of the implant, with the foreign tissue and cells provoking an immune response. Although little evidence exists of acute rejection, there have been reports of rapid failure of homograft valves implanted into infants.[37] A further drawback of homograft valves is the lack of donor valves available.

It is clear that although major advances have been made in the field of heart valve replacement, each prosthetic valve designed has major flaws associated with it. A major underlying flaw is that nonliving prostheses lack the ability to grow and repair themselves. An ideal valve would be biocompatible with the capacity for both growth and regeneration.[38] In order to achieve this, researchers have moved toward the fabrication of a living, functional valve as a replacement for diseased valves. Current strategies in the field of tissue engineered heart valves involve the seeding of the appropriate cell types onto a scaffold, preconditioning in the presence of the correct signals, and implantation. The task of current researchers is to identify the appropriate cells and scaffold biomaterials to use, as well as the ideal preconditioning environment, or signals, necessary to fabricate the ideal heart valve replacement scaffold (Figure 1).

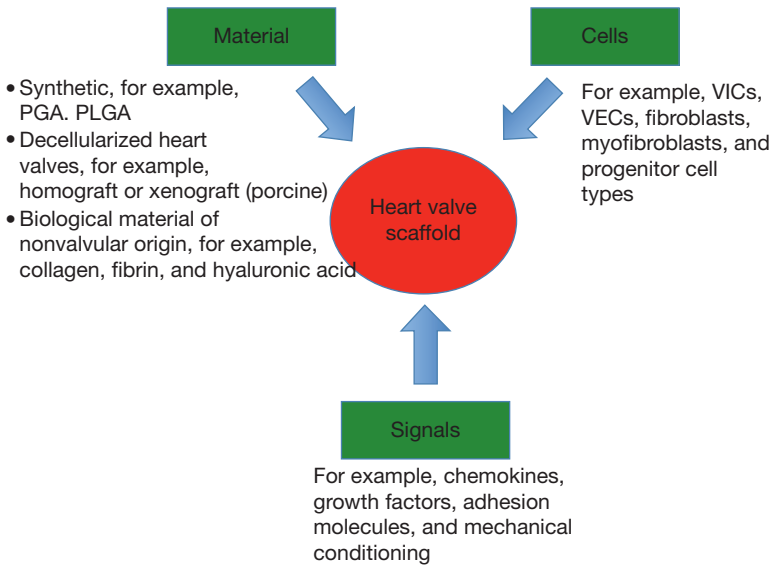

Figure 1 Components necessary for the fabrication of the ideal heart valve replacement scaffold.

6.626.4. Ideal Scaffold

There are many properties which a tissue engineering scaffold must possess to succeed following implantation. There are some which are common to all scaffolds, such as providing guidance for new tissue growth and organization, regulation of cellular behavior such as adhesion, proliferation, migration, and differentiation, all while maintaining the correct phenotype. As cells infiltrate the scaffold, ECM will be deposited, and the scaffold must degrade at a similar rate to facilitate replacement by native tissue. In particular, an ideal scaffold for heart valve replacement would be capable of the following:

- Withstanding the dynamic conditions in which it is implanted over the life span of the patient, in particular, be sufficiently elastic to maintain a tight seal during the diastole phase of the cycle; that is, it should have the appropriate mechanical properties.
- Mimicking the micro- and macroarchitecture of the native heart valve; mechanical properties of the heart valve are related to collagen fiber and elastin fiber microarchitecture, and the structural orientation of collagen fibers influences cellular orientation and mechanical properties.
- Incorporating nanotopography similar to that of the native aortic heart valve basement membrane to ensure the development of a confluent layer of endothelial cells. This will be critical to maintain a nonthrombogenic surface, with cellular growth and orientation significantly influenced by nanotopography.
- Supporting the adhesion, proliferation, and phenotypic expression of VICs and VECs or whichever cell type that has been identified and chosen to replicate the previously stated functions.
- Degrading (without releasing cytotoxic breakdown products) at a rate similar to that at which the ECM is being deposited, allowing for its replacement by a composition similar to that of native valves, while maintaining the ability of the construct to withstand the high pressure environment and maintain a tight seal during diastole, preventing backflow.

6.626.5. Synthetic Scaffolds

As with all biomaterial applications, synthetic scaffold materials offer a wide range of benefits not possible with biologically based materials, such as greater control over numerous scaffold parameters such as mechanical properties, degradation rates, fabrication, reproducibility, and geometrical design specifications. Similarly, sourcing of the raw material for synthetic scaffolds is usually a much simpler process than acquiring material for biological scaffolds. Synthetic scaffold biomaterials also have a much longer shelf life than biological biomaterials, which is an important factor for valve prosthesis, and they are known to initiate less of an immune response, with no possibility of the remaining cellular materials causing graft rejection (**Figure 2**). Unlike biological scaffold biomaterials, synthetic biomaterials contain no epitopes bound to cellular adhesion receptors. This limits any possible immunogenic reactions *in vivo*. There are a large number of processes used in polymer scaffold fabrication, including weaving, meshing, porogen leaching, emulsion freeze-drying, expansion in high pressure gas, 3D-printing, phase separation, and stereolithography.[39] By exploiting these techniques, synthetic scaffolds may be specifically designed to have specific, biologically relevant, porosities, mechanical properties, and surface topographies (**Table 1**).[61]

Shinoka *et al.* pioneered initial synthetic scaffold designs in the mid-to late-1990s.[41–43] Composites of poly(lactic-*co*-glycolic acid) (PLGA) layered with nonwoven PGA were studied. In most cases, scaffolds were seeded with autologous arterial cells and implanted *in vivo*, in an ovine pulmonary model. Although the cusps were thicker and less flexible than native cusps, overall results were quite favorable.[41] Seeded cells were shown to persist in the scaffold structure 6 weeks after implantation. Histological examination of the scaffold postmortem revealed a cellular architecture and tissue structure similar to that *in vivo*, although there was an inflammatory response and some complications due to infection in the animal.[42] As PGA is a biodegradable, relatively biocompatible, well-characterized biomaterial which has been approved for human implantation by the FDA (The United States Food and Drug Administration), its use as an independent scaffold for heart valve replacement design would have been favorable. However, when its mechanical properties were compared to those of the native heart valve it was deemed excessively stiff.[39,40,42,62] As a result, alternative biomaterials had to be investigated. Materials, which have been investigated thus far, include P4HB, PLA, PLLA, PHA, PVA, and PGA copolymers.

A method to improve the mechanical performance of PGA was investigated by dip coating the PGA scaffold in P4HB.[12,13,47–50] Contradictory evidence exists with regard to the success of this method, with Hoerstrup *et al.*[13,48] and Perry *et al.*[49] reporting synchronous opening and closing, pliable and mobile cusps, and mechanical properties comparable to those of the native valve, while Kadner *et al.* found that although

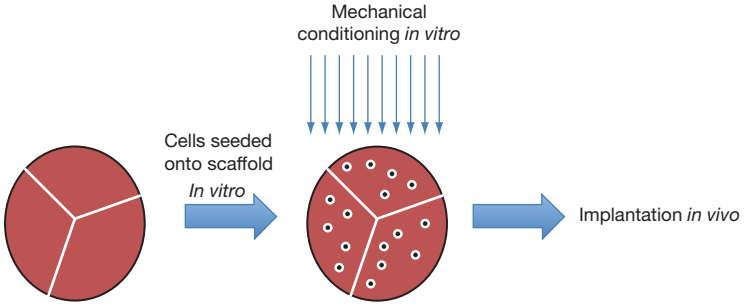

Figure 2 Typical approach taken to prepare heart valve prosthesis for implantation.

Table 1 Synthetic biomaterials tested for heart valve scaffold applications

Scaffold composition	*Cell population(s)*	*Mechanical forces/signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM deposition*	*Study limitations*	*Reference*
Nonwoven PGA or PHA or P4HB	Ovine carotid artery smooth muscle cells, endothelial cells, and fibroblasts	Continuous laminar flow	*In vitro*, 8 days in static culture, subsequently tested for 1 h in continuous flow	Trileaflet vavles formed from PHA and P4HB Surface morphology of all scaffolds after 1 h of continuous flow was similar	Cells formed confluent layers on the PHA and P4HB scaffold Initially cell numbers on the PGA scaffold were higher Collagen production was highest on the PGA scaffold	Nonwoven PGA cannot maintain a predefined structure	39
Nonwoven PGA mesh	Ovine femoral artery endothelial cells and fibroblasts	–	*In vivo*, allogenic ovine pulmonary valve model for up to 8 weeks	No evidence of stenosis, trivial regurgitation Increase in tensile strength	Increased ECM deposition (collagen and elastin)	High stiffness if implanted prematurely, but prolonged incubation causes degradation	40
PLGA woven mesh surrounded by nonwoven PGA	Ovine femoral artery endothelial cells and fibroblasts	–	*In vivo*, three autologous and four allogenic ovine pulmonary valve models for up to 21 days	Valve cusps were thicker and less flexible than native cusps, but had similar tensile strength prior to implantation Autologous cusps maintained size and shape; showed no stenosis; trivial regurgitation Allogenic cusps showed significant shrinkage	Constructs had 30% of the collagen content of the native valve at 7 days Constructs resembled native tissue histoligically 1 day postimplantation	Not fully investigated	41
PLGA woven mesh and nonwoven PGA	Ovine femoral artery endothelial cells and ovine femoral artery fibroblasts and smooth muscle cells	–	*In vivo*, autologous pulmonary model for up to 11 weeks	At 6 weeks cusps were thicker than native cusps Tensile strength was similar to that of the native cusp By 11 weeks, stenosis and regurgitation had not developed; 6 weeks postimplantation, PGA had almost fully degraded	Elastin and collagen fibers were expressed At 11 weeks collagen content was similar to that of the native valves Von Willebrand factor was expressed by the endothelial cells	Long-term cusp thickening may lead to functional problems	42
PLGA woven mesh sandwiched between nonwoven PGA mesh sheets	Ovine femoral artery endothelial cells and fibroblasts Ovine subdermal fibroblasts	–	*In vivo*, autologous pulmonary model for up to 10 weeks	At 10 weeks dermal cell-seeded cusps were thicker than native cusps Dermal cell-seeded cusps had lower mechanical tensile strength than arterial-seeded cusps and native pulmonary cusps Complete degradation of PGA at 10 weeks	Elastin and collagen fibers were expressed in all constructs Variation in elastin fiber organization was observed Endothelial cells expressed von Willebrand factor	Polygalactin degradation and cellular phenotypic expression, other than von Willebrand factor expression, were not investigated	43

(*Continued*)

Table 1 (Continued)

Scaffold composition	*Cell population(s)*	*Mechanical forces/signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM deposition*	*Study limitations*	*Reference*
PGA layered with a copolymer of PGA and PLA	Human dermal fibroblasts and bovine aortic endothelial cells Ovine aortic valve VICs and VECs	–	*In vitro* up to 14 days	Initially, scaffold was easily torn and stretched when gently handled Later scaffolds were stronger and stiffer	Initially fibroblasts or VICs covered the surface of the scaffold and these were then covered with a layer of endothelial cells In both cases endothelial cells did not infiltrate and capillaries were not formed	Functionality testing not complete	44
Inner layer of PGA and PLA fibers surrounded by an outer layer of PGA fibers	Ovine carotid artery endothelial cells and myofibroblasts	–	*In vivo*, ovine pulmonary valve model for up to 9 weeks (preseeded *in vitro* for 20 days)	Cusps were thicker and stiffer than the native valve cusps Polymer mesh fibers remained visible at 9 weeks	Endothelial cells formed a confluent layer on the surface and reduced thrombogenicity compared to unseeded cusps	Three of the seven animals experienced post operative valve insufficiency Inflammatory cells were identified at the implantation site at 9 weeks	45
Copolymer of PGA and PLA	Endothelial cells, smooth muscle cells and fibroblasts from ovine femoral arteries	–	*In vivo*, nine autologous and four allogenic ovine pulmonary valve models for up to 11 weeks	Thickness greater than that of the native cusp Tensile strength increased over time	Confluent layer of endothelial cells developed Development of ECM including collagen	Inflammatory response and mild regurgitation in allogenic valves PGA exhibits high stiffness	46
Nonwoven PGA coated with P4HB	Human umbilical cord cells	Continuous laminar flow	*In vitro*, up to 21 days	Constructs had similar uniaxial stress response to native pulmonary valves, but constructs were less pliable and less distensible Multiple breakages and fragmentation of scaffold	Collagen types I and III were deposited At 3 weeks cell/DNA content was higher than that of the native cusp	Stiffness of construct may limit *in vivo* functionality	47
PGA nonwoven mesh dip coated in P4HB, fabricated by welding techniques	Human marrow stromal cells	Pulsatile flow	*In vitro*, 7 days in static culture followed by 14 days in a pulsatile flow bioreactor	Synchronous opening and closing Cusps were intact, mobile and pliable Mechanical properties were comparable to native valves multiple hydrolytic breakage and fragmentation of polymer fibers	Cells grew to confluence, expression of α-SMA and vimentin and deposition of GAGs and collagen types I and III	Fragmentation may cause distal blockages	48
PGA nonwoven mesh dip coated in P4HB	Ovine aortic VECs and circulating endothelial progenitor cells	VEGF TGF-β1 basic fibroblast growth factor (bFGF)	*In vitro*, 1–8 days in static culture	Not reported	Cell proliferation increased in response to bFGF and VEGF TGF-β1 induced endothelial-to-mesenchymal transdifferentiation	Expression of VIC markers other than α-SMA not investigated	12

PGA coated with P4HB	Ovine MSCs	Pulsatile flow	*In vitro*, up to 3 weeks	Cusps coated uniformly Effective stiffness of the construct was similar to that of the native cusp At 3 weeks, residual polymer fibers remained	Cells were found throughout the full thickness of the cusps	Cellular phenotype and expression postseeding were not characterized	49
PGA nonwoven mesh dip coated in P4HB Fabricated by welding techniques	Autologous ovine carotid artery myofibroblasts and endothelial cells	Pulsatile flow for 14 days preconditioning	*In vivo*, Ovine pulmonary valve model for up to 20 weeks	Tensile strength was 130% that of native tissue at 20 weeks Complete polymer drgradation at 8 weeks	180% native valve collagen content at 8 weeks 150% of native valve DNA content, 140% of GAG content after 20 weeks Elastin detected at 6 weeks	Increase in inner diameter of constructs Moderate regurgitation at 16–20 weeks	13
PGA coated with P4HB	Ovine carotid artery medial cells and endothelial cells	Pulsatile flow *in vitro* for 14 days prior to implantation	*In vivo*, Autologous ovine pulmonary position for up to 20 weeks	Not reported	Expression of collagen types I and III was detected Myofibroblasts retained phenotypic expression Elastin was detected at the ventricular side	Valve function and mechanical properties not reported	50
Layers of PHO and PGA films	Ovine carotid artery endothelial cells and myofibroblasts	–	*In vivo*, autologous ovine pulmonary valve models for up to 24 weeks	No thrombus formation and mild nonprogressive valvular regurgitation Molecular loss of the PHA was observed but degradation time exceeds 6 months	Cellular and ECM contents increased over 24 weeks	The long degradation time is deemed an obstacle	46
Nonwoven PGA and PLLA (50:50)	Ovine carotid artery smooth muscle cells	Uniaxial cyclical three-point flexure at physiological frequency	*In vitro*, Up to 3 weeks	At 3 weeks, cyclic flexure had increased scaffold stiffness by 429% to 978±228 MPa	Flexure increased cellular infiltration, decreased cellular necrosis, and increased collagen expression	Elastin was not produced	51
Flat nonwoven sheets of PGA and PLLA fibers	Ovine bone marrow MSCs	–	*In vivo*, seeded *in vitro* in a rotating culture vessel for 4 weeks and autologous pulmonary valve model for up to 4 months	Prior to implantation scaffold stiffness was 50% that of the native valve At 24 weeks, scaffold tensile strength was 30% of the initial value Burst strength at the same stage exceeded the target strength for pulmonary valve substitute	Similar ECM organization to that of the native valve cusp Collagen fibers were found on the fibrosal surface and elastin was found on the ventricular surface GAGs were found in the remainder of the cusp	Explanted cusps were thicker than native cusps Incomplete coaptation of the valve cusps and mild regurgitation	52
Porous PHA	Ovine carotid artery vascular cells	–	*In vitro*, 4 days in static culture	Cusps opened and closed synchronously under pulsatile flow prior to seeding	Cells attached to the scaffold forming a confluent layer Cells also grew into pores	Short culture time Cellular behavior not fully characterized Pulsatile flow only applied prior to seeding No elastin formation	53

(*Continued*)

Table 1 (Continued)

Scaffold composition	*Cell population(s)*	*Mechanical forces/signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM deposition*	*Study limitations*	*Reference*
Porous PHA	Ovine carotid artery cells	Pulsatile flow	*In vitro*, 1, 4, and 8 days in a bioreactor under pulsatile flow	Not reported	Cells initially grew into the pores Confluent layers of cells formed on the surface orientated in the direction of flow Collagen and GAGs were expressed	No elastin expression	54
Porous PHA	Ovine jugular vein endothelial cells and a mixed population of ovine carotid artery cells	–	*In vivo*, allogenic ovine pulmonary valve model up to 17 weeks	Synchronous opening and closing Similar stress–strain response and morphology to that of the native valve at 17 weeks	ECM surrounding the implant was rich in collagen and GAGs but not elastin	Confluent intact endothelial lining not achieved	55
PVA with grafted PLA side chains	Porcine aortic VICs	–	*In vitro*, 1 day in static culture	Degradation, mass erosion profile, and hydrophobicity can be controlled	Ability of VICs to attach was demonstrated	Cellular behavior not fully characterized	56
Polyethylene glycol (PEG)-containing RGD and/or PHSRN (a fibronectin-derived peptide sequence)	Porcine aortic VICs	–	*In vitro*, up to 7 h in static culture	Not reported	RGD and PHSRN only slightly improved VIC proliferation	VIC adhesion not deemed adequate	57
Porous PCL coated with varying concentrations of chitosan (0.5–2%)	Human fetal lung fibroblasts	–	*In vitro*, up to 1 week	PCL scaffold morphology is minimally affected by the chitosan coating Chitosan adsorption remained stable for the duration of the experiment	Chitosan coating significantly improved cellular adhesion and proliferation	Cellular expression and phenotype not investigated	58
Multilayer PLA fibers using a cast and thermal fixation	Adult bone marrow-derived stem cells	Pulsatile flow	*In vivo*, ovine pulmonary valve model up to 8 weeks	Mobile but thickened leaflets	Layered neotissues with endothelialized surfaces ECM analysis at 8 weeks showed higher values for DNA, collagen, and GAGs compared to native valves	Small sample numbers No elastin expression	59
POSS–PCU	(Platelets)	Pulsatile flow	*In vitro*, up to 31 days	Minimal calcification The tensile strength remained unchanged following exposure to the pulsatile flow	Low platelet adherence to surface	VIC, VEC adhesion not assessed	60

the scaffolds did show a similar uniaxial response to that of the native pulmonary valve cusp, they did not match the mechanical properties of native valves as they were less pliable and less distensible.[47] Both Kadner *et al*. and Hoerstrup *et al*. noted multiple mechanical failures such as breakages and fragmentation *in vitro* which raise major concerns regarding suitability of this scaffold *in vivo*. Dvorin *et al*. examined the use of growth factor signaling to induce transdifferentiation of endothelial cells seeded onto the same scaffold. Ovine aortic VECs and circulating endothelial progenitor cells were seeded onto the scaffold, and through vascular endothelial cell growth factor (VEGF) and transforming growth factor beta (TGF-β) signaling, endothelial-to-mesenchymal transdifferentiation was induced.[12]

Recently, Englemayr *et al*.[51] and Sutherland *et al*.[52] have investigated the use of a number of copolymers of nonwoven PGA and poly-L-lactide acid (PLLA) for heart valve applications. Following 3 weeks of cyclic flexure *in vitro*, scaffold integrity remained intact, stiffness increased fourfold, infiltration of ovine carotid smooth muscle cells increased, and collagen was expressed.[51] The scaffold was seeded with ovine bone marrow mesenchymal stem cells (MSCs) and implanted in an autologous model. The construct functioned for 4 months, although incomplete coaptation and mild regurgitation were reported, possibly because of the thickness of the valve cusps observed following retrieval.[52] A major finding from this study was, in addition to the formation of a confluent endothelial layer on the scaffold, the site-appropriate phenotype assumed by the MSCs and the structural appearance of the scaffold. Structural remodeling created three distinct layers in the construct which were equivalent to the fibrosa, spongiosa, and ventricular layers of the native heart valve.[52,63]

Porous polyhydroxyalkanoate (PHA) has been characterized by Sodian *et al*. as a scaffold biomaterial using both *in vivo* and *in vitro* studies.[39,54,55] Scaffolds have been seeded with mixed populations of ovine carotid artery cells for both *in vitro* and *in vivo* studies. Confluent layers of cells were formed *in vitro* on the surface of the biomaterial and grew into the scaffold pores. However, when this scaffold was transferred *in vivo*, it failed to form a confluent endothelial cell lining. ECM expressed *in vivo* was rich in collagen and glycosaminoglycans (GAGs), although it lacked elastin. PGA demonstrated favorable properties when it was compared with PHA and P4HB. It was found that when compared to PHA and P4HB, the PGA scaffold induced the greatest initial cellular proliferation and the greatest overall collagen expression.[39]

The integration of cells within a synthetic biomaterial is a major challenge considering the delicate and specific environment that cells are accustomed to *in vivo*. Furthermore, promoting ECM production from these integrated cells to replace the synthetic biomaterial as it degrades is required to ensure the maintenance of scaffold integrity. Qzawa *et al*. fabricated and investigated the use of a copolymer sponge fabricated from PCLA (ε-caprolactone-*co*-L-lactide reinforced with poly-L-lactide fabric). It showed promising integration with only the fibrous polylactic acid (PLA) component of the PCLA remaining 8 weeks postimplantation. The scaffold had been successfully endothelialized, in the presence of the preseeded smooth muscle cells ensuring the presence of elastin in the deposited ECM.[64] Nuttelman *et al*. seeded VICs on a synthetic polyvinyl alcohol (PVA)–PLA scaffold. The tissue-like elasticity and high water content of the hydrogel seemed to suggest that it would be a suitable biomaterial to fabricate a heart valve scaffold. It was thought that its combined degradation profile, hydrophobicity, and ability to photo-cross-link would optimize cellular behavior. While VIC attachment was achieved, the cell proliferation rate and, as a result, the level of ECM deposition were considered insufficient.[56]

A recent study by Schmidt *et al*. investigated the combination of sandwich structured PLA scaffolds seeded with adult stem cells and minimally invasive surgery.[59] The valve was delivered using a crimping and delivery system. The implanted valves showed good performance *in vivo* following minimally invasive implantation, with leaflet movement and sufficient opening and closing. The presence of collagen in the outer layers was confirmed, while cells of the leaflet surface layer expressed endothelial nitric oxide synthases (eNOS) and α-smooth muscle actin (α-SMA), resembling the pattern of native valve endothelial cells. The relative success of this study could prove to be an important step in the movement toward a minimally invasive surgical technique for valve replacement.

A major issue with replacement valves has been calcification, a complex phenomenon induced by a large number of both mechanical and biochemical factors. Recent work has focused on the fabrication of novel polymers with anticalcification properties as biomaterials. Ghanbari *et al*. tested the calcification-resistance efficacy and other mechanical and surface properties of a new nanocomposite polymeric material (polyhedral oligomeric silsesquioxane–poly(carbonate-urea) urethane; POSS–PCU).[60] They found that after incubation in a calcium solution in a specifically designed *in vitro* physiological pulsatile system for 31 days, this new polymer had considerably less calcification when compared with polyurethane and bovine pericardium sample, and also that the mechanical properties showed no deterioration. This work shows that specifically designed novel polymers with tailored surface and mechanical properties hold promise for use as cardiac valve replacement biomaterials.

Long-term mechanical properties of synthetic scaffold biomaterials can change as the polymer degrades and the biomaterial is, ideally, replaced by native ECM. For example, it has been shown that when elastomeric polymers are placed under long-term cyclic strain *in vivo* they undergo irreversible deformation.[65] PHA had been suggested as an optimal scaffold owing to its flexibility and some promising *in vitro* results.[54] However, the work of Sodian *et al*. has shown that the rate of degradation and replacement by native tissue *in vivo* is not sufficient to retain its mechanical properties.[55] This is a common theme, with many materials offering a wide range of properties, but as yet none has been identified with the ideal set of properties. Synthetic materials, while offering many advantages such as great control over scaffold parameters, also have disadvantages. Their potential to induce a toxic response when releasing degradation products is a considerable and major limitation. Although a great many *in vitro* and *in vivo* studies are carried out to assess the toxicity of synthetic biomaterials and the associated degradation products, little can be predicted until the biomaterial is implanted in a human patient. These limitations and other uncertainties associated with the use of synthetic materials are fuelling the drive toward a solution using a biological alternative.

6.626.6. Decellularized Heart Valve Scaffolds

The use of decellularized heart valves as replacement for diseased valves is quite intuitive, with the first human clinical use of aortic valve allografts being reported in 1956 by Murray.[66] Allografts implanted into the descending aorta demonstrated durability, retained the ability to open and close correctly, and, furthermore, did not calcify. Indeed, it was thought originally that decellularized valves were viable and integrated with the host tissue. However, work by Gall *et al*. showed the absence of an endothelial layer and only very few fibroblasts present on the biomaterial years after implantation.[67] Because of issues regarding the supply of cadaveric allografts, research focused on xenografts, mainly of porcine origin. Xenografts are much more widely available. However, they are also associated with many more complications than homografts, such as cross-species contamination. Therefore, even more care must be taken to ensure complete removal of all cells or cell remnants from the scaffold. Ideally techniques to decellularize the scaffold should remove all cells and cellular debris from the tissue without causing damage to the surrounding ECM architecture, inhibiting the growth of seeded cells, or causing immunogenic reactions or calcification (**Table 2**; see **Chapter 2.221, Decellularized Scaffolds**).[24]

There is a great need to completely decellularize xenografts to ensure no cross-species contamination. In the presence of porcine cells or cell remnants, interaction occurs between the naturally occurring Gal α-1-3 Gal β-1-4 GlcNAc-R (α-Gal) antibodies in humans and α-Gal epitopes on porcine cells. This leads to an inflammatory response and the rejection of the implanted valve construct. Indeed, this failure to completely remove cell remnants was linked with the failure of Synergraft™ *in vivo*. Studies have revealed traces of the α-Gal epitope in the cusps of the valve, which may be a factor in its failure.[78] The porcine endogenous retrovirus (PERV) must also be considered when working with porcine-derived tissue, as a number of previous studies have shown human cell line and primary endothelial cell infection with PERV.[71,85–87] To ensure no cross-species contamination and ultimate rejection of the scaffold, it is essential that all cells or cell fragments are completely removed from the scaffold prior to implantation. Currently implanted valves are not susceptible to this type of rejection as glutaraldehyde treatment ensures complete cellular removal.[88]

Initially, studies focused on the use of freeze-drying as a technique to remove cellular remnants on heart valve and also to provide a porous matrix for cellular growth. It was hypothesized that freeze-drying would remove cell remnants and provide a porous surface, while at the same time preserving the ECM microarchitecture and thus the native valvular mechanical properties. However, because of the high water content of the native valve cusps, ice build-up during the freeze-drying procedure caused the native ECM of the scaffold to collapse. Freeze-drying failed to preserve the native ECM structure, thus negating the reason for using decellularized valves. The technique also failed to create a porous surface, which would restrict the infiltration of seeded cells into the scaffold. Further, preparation of the surface by wiping it with cotton wool was necessary to improve endothelial cell adhesion. Also, the danger of cross-species contamination was not removed as the removal of cells or cellular debris could not be confirmed.[89]

In vitro studies utilizing human fibroblasts and vascular endothelial cells were performed on the scaffold to assess any potential in *in vivo* use. It was found that while the fibroblasts did not reach physiologic densities during the experiments, endothelial cells did form confluent layers.[68]

Numerous alternative methods to decellularize native heart valves have also been investigated. These methods are usually detergent or enzyme based. Various combinations and concentrations of the following reagents have been utilized: ethylenediaminetetraacetic acid (EDTA), trypsin, RNase, DNase, (enzymatic), and Triton® X-100 and sodium dodecyl sulfate (SDS, detergent).[71,90,91]

Reider *et al*. compared three very standard methods of decellularization. They attempted to decellularize porcine, aortic, and pulmonary heart valve roots using three separate protocols followed by DNase and RNase treatment: trypsin–EDTA, SDS, and detergent-based Triton X-100. Treatment with EDTA-trypsin and SDS failed to completely decellularize the heart valves, while cell growth on the SDS-treated tissue was inhibited. This is due to the failure to wash away residual ionic-detergents. Triton X-100 treatment was deemed the best as following this treatment, the most favorable results for human cell attachment were observed in *in vitro* cell seeding studies. Although not as big a concern as complete cell removal, decellularization by trypsin and EDTA does not eliminate all active matrix metalloproteinases (MMPs).[91] Exposure to active MMPs for too long affects the microarchitecture and integrity of the ECM structure of the valve. However, the MMP activity decreases and eventually stops on a decellularized scaffold. A combination of enzymatic and detergent-based treatment successfully removed PERV and cellular components from aortic heart valves. This technique involved successive washes in 0.1% trypsin solution, hypotonic and hypertonic Triton X-100, DNase solution, and RNase solution, and rinses in Hank's solution in succession.[92]

Ideally, any decellularization technique would have minimal effects on the native valvular architecture and mechanical properties of the valve. However, this is very rarely the case. For example, longer incubations in trypsin can lead to improved decellularization of heart valves; however, adverse disruption to the ECM bundles is often caused.[93] Furthermore, the collagen triple helix can be disrupted and the elastin network can become swollen by SDS treatment.[93] An important area in which few studies have been carried out is the effect of the various decellularization techniques on the mechanical properties of valve scaffolds. However, a study by Dohmen *et al*. investigated ovine myofibroblasts and carotid artery endothelial cells seeded *in vitro* onto porcine decellularized heart valves and implanted into an ovine model. Following postimplantation at 6 months, the scaffold demonstrated both favorable mechanical properties and functional characteristics. Mechanical integrity was maintained while the seeded cells were still proliferating with no PERV sequences detected in the heart valve tissue or blood.[71]

Bertipaglia *et al*. took an approach that, although seemingly obvious in nature, has not been fully exploited. Usually, cells of a nonvalvular origin are seeded onto a decellularized scaffold, with the idea that they replace the functions of the VECs and VICs, which have been removed. However, in this case Bertipaglia *et al*. seeded cells from the heart valve onto

Table 2 Decellularized heart valves tested for heart valve scaffold applications

Scaffold composition	*Cell population(s)*	*Mechanical forces/ signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM production*	*Study limitations*	*Reference*
Freeze-dried porcine pulmonary valves	Human dermal fibroblasts and human umbilical vein endothelial cells	–	*In vitro*, up to 20 days in static culture	Freeze-drying created cavities	Fibroblast cell density was low and no cells were found on unperforated scaffolds Fibroblasts were metabolically active and adhered to the scaffold Endothelial cells formed a confluent layer	Freeze-drying created an impervious crust on the scaffold surface	68
Porcine aortic heart valves treated with 1% TX, RNase, and DNase	Human saphenous vein endothelial cells	–	*In vitro*, up to 3 days in static culture	Loose ECM structure	Confluent layer of endothelial cells on surface	Presence of immunostimulating cell remnants could not be excluded	10
Porcine aortic heart valves treated with Tris-buffer, PMSF protease inhibitor, DNase, RNase, trypsin, and phospholipases	Human dermal fibroblasts	Pulsatile flow	*In vitro*, up to 8 weeks, half in static and half in dynamic conditions	Good preservation of region specific achitecture	48% of average nuclear cell density after 8 weeks Detectable collagen expression reported	Cytoplasmic elements only partially extracted	14
Porcine aortic heart valves treated with either TX, cholate, and nucleases or *N*-cetylpyridinium and nucleases	Human dermal fibroblasts	–	*In vivo*, subdermal rat implantation of unseeded scaffold *In vivo*, seeded scaffold in static culture	Both treatments removed most cells while preserving endothelium basal membranes, ECM texture (collagen fibril bands), and mechanical properties Calcification was significantly reduced by TX-cholate treatment	Cells grew in patchy aggregates on the scaffold surface and infiltrated the scaffold Intercellular and cell–matrix contact was observed	Cellular behaviors only assessed by SEM and TEM Mechanical properties based only on uniaxial tests	69
Porcine pulmonary vaves treated with 0.1% deoxycholic acid	Ovine saphenous and jugular vein endothelial cells	–	*In vivo*, cell seeding in static culture for 7 days and then implanted in an autologous ovine pulmonary model for up to 6 months	No cusp tearing, perforation, fibrous tissue, or deformation observed at 6 months	Confluent cells at the commissures but only islands in the middle of the cusp Fibroblast migration observed at 3 and 6 months	Only islands of endothelial cells developed and no cells were seen at the free edges Calcification found at suture lines	70
Porcine pulmonary heart valves treated with 0.5% trypsin/0.2% EDTA	Ovine right carotid artery myofibroblasts and endothelial cells	–	*In vivo*, static cultured for 18 days and implanted in an autologous model for up to 6 months	Not reported	Collagen, GAG, and elastin contents similar to those of native valves No PERV detectable at 6 months in the construct or the blood	Decellularization procedure did not remove all PERV from the scaffold	71

(*Continued*)

Table 2 (Continued)

Scaffold composition	*Cell population(s)*	*Mechanical forces/ signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM production*	*Study limitations*	*Reference*
Porcine aortic valves treated with TX, Sodium deoxycholate (NaDC), and benzonase, and pretreated with fibronectin	Porcine aortic valve VICs	–	*In vitro*, static culture for up to 15 days	Good ultrastructural preservation	Cellular infiltration of scaffold Trace levels of smooth muscle myosin expressed Evidence of collagen and elastin generation	Nucleic acid detected post-decellularization	72
Porcine aortic valves treated with 0.5% trypsin and coated in a copolymer of 82% P3HB and 18% P4HB	Mouse fibroblasts	–	*In vivo*, allogenic porcine aortic and pulmonary model for up to 3 months	Valves in aortic position were functional and clinical signs of valve dysfunction were not demonstrated	Complete endothelial cell lining was formed and collagen was deposited	Inflammation was evident in both locations and in the pulmonary location valve was 'severely obliterated'	73
Porcine aortic and pulmonary valves treated with TX, NaDC, DNase, and RNase	Human saphenous vein endothelial cells Human saphenous vein myofibroblasts	–	*In vitro*, static culture endothelial cells up to 5 days Myofibroblasts up to 10 days	Not reported	Confluent layer of endothelial cells formed Confluent layer of endothelial cells formed	Effects of this decellularization technique on mechanical properties and structure not investigated	15
Porcine pulmonary valves treated with trypsin/EDTA	Ovine carotid artery endothelial cells and myofibroblasts	–	*In vitro*, static culture for up to 9 days	Structure comparable to that of the native porcine and ovine valves; well defined layers, collagen on the fibrosal layer, and elastin in the ventricular layer	Confluent endothelial lining developed Expression of α-SMA, myosin, calponin, and h-caldesmon detected	Complete valvular cell phenotypic expression not replicated by seeded cells	74
Porcine aortic valves treated with EDTA, gentamisin, DNase, RNase, and either 1% TX or 0.5% trypsin	Porcine descending thoracic aorta endothelial cells	–	*In vitro*, static culture for up to 10 days	Both treatments caused a loss of collagen density and GAGs and an increase in intercellular space Trypsin caused further loss of chondroitin sulfate (CS), laminin, and fibronectin	Endothelial cells covered 80% of the surface of the TX treated cusp Cells expressed vWf, fibronectin, laminin, and CS	Neither treatment completely removed cells from the aortic wall	75
Porcine aortic valves decellularized by TX, NaDC, and endonuclease	Porcine aortic valve VICs	Serum deprivation	*In vitro*, static culturte for up to 4 weeks	Not reported	Serum deprivation increased VIC numbers and infiltration rates At 4 weeks, cellular density was similar to that of the native valve	Preliminary study, endothelial response, and effects on mechanical properties also need to be considered	76

Porcine heart valves decellularized by 0.5% TX, 0.5% SDS, 0.5% Igepal CA-630®, and RNase	Human umbilical vein endothelial cells	–	*In vitro*, static culture for up to 24 h	Decellularization removed cells without affecting collagen and elastin contents	Endothelial cells grew to confluence on the scaffold The seeded scaffold did not cause platelet activation	Platelet adhesion experiments carried out in static culture	77
Porcine pulmonary vavles decellularized by 0.5% TX, 0.5% NaDC, 0.5% Igepal CA-630® and nucleases	Human umbilical vein endothelial cells	–	*In vitro*, static culture for up to 24 h	Decellularized cusps were totally cell free	A confluent monolayer was achieved on the surface of the decellularized scaffold and in the presence of platelet rich plasma, no platelet activation occured	Decellularization inhibits, but does not elininate, migration of monocytes into the scaffold	78
Ovine pulmonary valves treated with 0.5% trypsin and 0.2% EDTA	Ovine carotid artery endothelial cells and myofibroblasts	–	*In vivo*, autologous pulmonary model for up to 12 weeks	Moderate cusp thickening was observed Valve insufficiency was not observed	*In vitro* cell seeding was patchy and incomplete *In vivo* scaffolds developed a confluent endothelial cell lining at 4 weeks Positive procollagen staining demonstrated ECM synthesis	Subvalvular calcifications found on all tissue engineered constructs	79
Ovine pulmonary valves decellularized by 0.5% NaDC and 0.5% SDS	Ovine jugular vein endothelial cells	Pulsatile flow	*In vitro*, pulsatile flow bioreactor for up to 36 h	Basement membrane remained intact following decellularization	Confluent endothelial cell monolayers formed at moderate flow rates ($0.5\,l\,min^{-1}$) At higher and lower flow rates cellular proliferation and metabolic activity decreased Cells retained expression of vWf and eNOS	Valvular functionality within the bioreactor not reported	80
Ovine pulmonary valves decellularized by 0.5% NaDC and 0.5% SDS	Ovine jugular vein endothelial cells	Pulsatile flow	*In vitro*, pulsatile flow bioreactor for up to 36 h	Basement membrane was retained following decellularization Ultimate force, stiffness, ultimate strain, and ultimate stress decreased	Endothelial cells reached confluence forming a monolayer and maintaining expression of vWf High endothelial cell metabolic activity was maintained	ECM production was not addressed	81
Human aortic and pulmonary heart valves treated by agitation in 0.5% Trypsin/0.2% EDTA	Human saphenous vein endothelial cells	–	*In vitro*, preseeded, and cultured in a bioreactor for up to 10 days	Tissue integrity post-decellularization was superior in aortic valves than in pulmonary valves	Positively stained endothelial cells present on both sides	Cellular behavior, including expression, not fully analyzed	82

(*Continued*)

Table 2 (Continued)

Scaffold composition	*Cell population(s)*	*Mechanical forces/ signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM production*	*Study limitations*	*Reference*
Porcine aortic heart valves fixed with GTA alone or EDC–NHS and a hyaluronidase inhibitor followed by GTA cross-linking	–	–	*In vitro*, cyclic fatigue and buckling	EDC–NHS scaffolds with a preserved GAG content had a reduced rate of buckling when compared with GTA-fixed valves which do not retain GAGs The buckling patterns mimicked that of fresh, untreated cusps subjected to similar bending curvatures	GAGs were preserved within the scaffold using EDC–NHS cross-linking but not with the GTA alone	Cellular viability/ proliferation not assessed	83
Porcine pulmonary valves decellularized using NaDC, sodium dodecyl sulfate, Trypsin–EDTA, or Trypsin–detergent–nuclease	–	–	*In vitro*	Histological examination revealed no remaining cells and no significant differences in the ECM histoarchitecture in any group LSM detected significant ECM alterations in all groups except NaDC group with an almost completely preserved ECM	–	Compared to GTA-fixed tissue significantly increased immune responses, and thrombo-genicity were observed in all protocols No cellular testing	84

a decellularized scaffold. This explores the potential ability to take patients own cells, expand them *in vitro*, then seed them onto a decellularized scaffold, and implant them back into the patient. Results were quite promising with cells retaining their phenotype and penetrating the scaffold after an incubation period of 15 days. However, further analysis revealed an unequal, unrepresentative cellular distribution within the scaffold.[72]

The use of different cell types to repopulate decellularized valves is widespread, as a number of cells have demonstrated a potential to replace the functions of VECs and VICs. Human saphenous vein endothelial cells have been reported to completely recellularize decellularized valvular scaffolds,[10] thus replacing the VECs. They have been seeded successfully in conjunction with myofibroblasts on decellularized porcine aortic and pulmonary roots.[15] A confluent monolayer of endothelial cells was formed on the scaffold surface with active collagen synthesis by the myofibroblasts.[15] In addition, the behavior of neonatal fibroblasts on decellularized scaffolds has also been characterized. Following 8 weeks of culture in a dynamic pulsatile fluid flow bioreactor, cells were deemed to have attached, migrated into the scaffold, and remained viable. Studies at 1, 2, and 4 weeks of leaflets cultured statically demonstrated that the human fibroblasts were mitotic and synthesized human ECM proteins.[14]

Another approach which has been examined is that of decellularizing native heart valves and then coating them to improve mechanical properties and cellular infiltration. This has been investigated by Grabow *et al.*[94] and Stamm *et al.*[73] who have coated decellularized porcine aortic valves with forms of PHB in order to improve the mechanical properties. The hybrid valves demonstrated superior tensile strength and suture retention strength, and showed good fluid dynamic performance. At 12 weeks postimplantation, confluent endothelial cell layers were formed on the scaffolds and collagen was deposited; however, there was evidence of inflammation.[73] *In vitro* mechanical testing of decellularized scaffolds has found that the decellularization technique alone stiffens the valve cusp by 74–128 MPa and increases tensile strength by 11–17 MPa. These values are further increased by coating with PHB.[94] Fibronectin was also considered as a coating for decellularized heart valves. However, although the fibronectin enhanced cellular infiltration, it did not improve scaffold mechanical integrity.[72]

Development of effective decellularization protocols requires the establishment of a perfect balance between both the adequate removal of cellular elements and the preservation of the native ECM architecture. It is difficult to find a protocol that is harsh enough to completely decellularize the valve, but not too harsh as to damage the structure. For example, Zeltinger *et al.*[14] and Bertipaglia *et al.*[72] developed decellularization techniques which maintained cusp integrity, but failed to remove all cellular remnants. Treatments investigated by Grauss *et al.*[75] included EDTA, gentamicin, DNase, RNase, and either 1% Triton X-100 or 0.5% trypsin. These resulted in a complete loss of cellular structures from the valve cusp (but not the root), but caused damage to the ECM with a loss of collagen density, GAGs, chondroitin sulfate (CS), fibrin, and laminin from the tissue and increased intercellular space.

An area which has not yet been thoroughly investigated is the effect of GAGs on heart valve performance. Current glutaraldehyde-treated valves do not retain GAGs as they do not contain the amine functionality necessary for cross-linking by aldehydes.[95] Shah *et al.* investigated the role of GAGs in buckling of *in vitro* cross-linked heart valves by comparing carbodiimide cross-linked valves (which retain GAGs) and glutaraldehyde cross-linked valves, which do not.[83] They attached a hyaluronidase inhibitor (neomycin trisulfate) to the carbodiimide cross-linked valves to ensure that GAGs were not digested. They found that the carbodiimide cross-linked valves with the hyaluronidase inhibitor underwent reduced buckling compared with glutaraldehyde-treated valves. Hence, they concluded that the stabilization of GAGs may improve the durability of bioprosthetic valves.

Zhou *et al.* compared a number of decellularization protocols and their effects on 3D ultrastructure, immunogenicity, and thrombogenicity.[84] They compared four different protocols: sodium deoxycholate (NaDC), sodium dodecyl sulfate, trypsin/EDTA, and trypsin–detergent–nuclease. Using histology and two-photon laser scanning microscopy (LSM), they found that the NaDC group had an almost completely preserved ECM architecture. However, when compared with glutaraldehyde fixed valves, significantly increased immune responses and thrombogenicity were observed. This highlights the difficulty that while there are protocols which will perform some functions very well (i.e., cell removal, maintenance of ECM architecture), it has thus far proved impossible to establish a protocol which will deliver the perfect scaffold.

The decellularization of native heart valves for use as scaffolds seems like an ideal scenario: a preformed, natural scaffold ideally designed to direct tissue ingrowth. However, there are a number of issues associated with their use. The complete removal of cellular remnants from xenografts is of vital importance to ensure that no possibility of cross-species contamination exists. However, this has not yet been achieved.[14] In addition, in general, studies will focus on the valve cusp and neglect the valve root which contains different cell types such as smooth muscle cells.[15] The continued presence of cellular remnants leads to immune reactions, calcification, and, as a result, graft rejection. Indeed, calcification has been detected on decellularized heart valves following retrieval postimplantation.[69,70,79] As stated, the benefits of decellularized heart valves as scaffolds are plentiful. However, given that thus far researchers have failed to identify an appropriate technique to completely decellularize valves without damaging their structure or mechanical properties, it seems that alernative roots need to be explored. Hence, the use of natural biomaterials of a nonvalvular origin has in recent years gained prominence among researchers.

6.626.7. Naturally Derived Biomaterials of Nonvalvular Origin

Many natural biomaterials derived from various species and organs have been considered as potential scaffolds for the creation of the ideal heart valve implant. The list of natural biomaterials which have been investigated for heart valve scaffold design includes, but is not limited to, collagen, chitosan, small intestinal submucosa (SIS), hyaluronic acid (HA), fibrin, and CS (**Table 3**; see **Chapter 2.211, Polymers of Biological Origin**).

Table 3 Natural biomaterials tested for heart valve scaffold applications

Scaffold composition	*Cell population(s)*	*Mechanical forces/signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM deposition*	*Study limitations*	*Reference*
Fibrin gel with various concentrations of aprontonin	Human aortic myofibroblasts	–	*In vitro*, 1 month in static culture	20, 15, and 5 $\mu g\,ml^{-1}$ aprontonin caused no degradation, degradation at 3 weeks and degradation at 1 week	Multilayers of cells surrounded by ECM Collagen production increased with aprontonin concentration	Poor mechanical properties are associated with fibrin gel	16
Fibrin gel cross-linked either with poly-L-lysine or by mechanical fixation	Human aortic myofibroblasts	–	*In vitro*, 50 days in static culture	Construct was sutureable but stiffness was too low for implantation Shrinkage was lowest on the poly-L-lysine boarder fixed tissue	Well-developed ECM with organized collagen bundles Cell proliferation was optimal on the poly-L-lysine border fixed group	High degree of shrinkage and poor mechanical stiffness	96
SIS or SIS coated with fibronectin	Human dermal neonatal fibroblasts	–	*In vitro*, up to 4 weeks	SIS thickness (not including the cell layer) did not change	Minimal cellular infiltration Collagen type I production was highest in fibronectin-coated SIS	Lack of cellular infiltration and insufficient thickness of scaffold may reduce mechanical properties	97
Photopolymerized methacrylated hyaluronic acid (HA)	Porcine aortic VICs	–	*In vitro*, up to 5 days in static culture	Cross-linking did not affect the ability of fibronectin to bind with HA	VICs readily proliferated and formed confluent monolayers within 4 days	Mechanical properties and VIC infiltration not investigated	57
Methacrylated (HA) or methacrylated (HA)–PEG gels	Porcine aortic VICs	–	*In vitro*, up to 6 weeks in static culture	Addition of PEG to the gels reduced swelling PEG increased degradation time of the methacrylated HA from 2 days to more than 1 week	HA degradation products increased VIC proliferation VICs expressed ECM including elastin	Mechanical response and ability to support VECs not yet addressed	98
HA gel cross-linked with divinyl sulfone and surface treated with UV light	Neonatal rat aortic smooth muscle cells	–	*In vitro*, up to 6 weeks in static culture	Not reported	Significant expression of elastin was found Collagen expression plateau reached at 4 weeks ECM formed a homogenous layer at the cell–HA interface	Collagen synthesis was deemed insufficient and mechanical properties were not investigated	17
Collagen type I derived from bovine skin	Porcine thoracic aorta smooth muscle cells or human ascending aorta smooth muscle cells	–	*In vitro*, up to 28 days in static culture	Scaffold contraction prevented by a specially designed seeding ring	Porcine cells developed in layers which were separated by newly formed ECM including collagen, proteoglycans and ECM proteins thrombospondin 1 and fibronectin	Sufficient numbers of human cells were not isolated to complete experiments; results are therefore limited to porcine cellular behavior	99

Collagen sponge (Actifoam, Coetica, France)	Human VICs	–	*In vitro*, up to 51 days	Not reported	Phenotypic VIC expression of vimentin, α-SMA, and myosin was retained VICs demonstrated long interconnecting extensions indicating cell communication	VIC expression of prolyl-4-hydroxylase and desmin was reduced on the scaffold Poor cellular attachment to the scaffold during initial 24 h	100
Collagen type I	Porcine aortic VICs or porcine aortic smooth muscle cells	–	*In vitro*, up to 10 days in static culture	Both cell types caused gel compaction Protein degradation was seen in smooth muscle cell cultures, but protein synthesis was observed in VIC cultures	Both cell types had 70% viability GAG content in VIC cultures was initially lower, by day 6 similar GAG contents were seen in both cultures	Effects of mechanical forces on cellular behavior not considered	101
Collagen type I – 1%, 2%, and 5% w/v fabricated by rapid prototyping	Human aortic VICs	–	*In vitro*, up to 28 days in static culture	Not reported	Highest cell proliferation was on 1% collagen, and 2% and 5% demonstrated similar proliferation rates Good cellular infiltration	VIC expression on the scaffold was not investigated	102
Collagen type I	Neonatal human dermal fibroblasts	–	*In vitro*, up to 6 weeks in static culture	Similar collagen fiber alignment and geometry to that of the native valve cusp and root	Cell viability and infiltration were high and cellular orientation was similar to that of the collagen fibers Elastin and other structural proteins were not produced by the cells	Although gross collagen fiber alignment is similar to that of native valves, failure mechanisms differ suggesting differing microstructures	103
Collagen type I hydrogels	Porcine aortic VICs and VECs	Steady flow	*In vitro*, up to 96 h	High degree of collagen alignment of collagen fibers on the scaffold surface exposed to flow	Incomplete endothelial layer formed Endothelial cells orientated perpendicular to flow Cell numbers decreased upon exposure to flow but protein expression increased	Mechanical properties of the scaffold were not considered and a confluent endothelial cell layer was not formed	20
Collagen type I coated with Matrigel™ (Collaborative Research, USA)	Porcine thoracic aorta endothelial cells and porcine heart valve myofibroblasts	–	*In vitro*, up to 6 weeks in static culture	Not reported	15% of myofibroblasts infiltrated the scaffold Types of proteoglycans produced and their distribution resembled that of the native heart valve	Behavior of endothelial cells not fully characterized Inherent scaffold proteoglycan content was not investigated	104
Collagen type 1 coated with Matrigel	Porcine thoracic aorta endothelial cells and porcine heart valve myofibroblasts	–	*In vitro*, up to 6 weeks in static culture	Not reported	Myofibroblasts and endothelial cells lined both surfaces Collagen type I was expressed; fibers had smaller diamters, but a similar architecture to that of the native heart valve Proteoglycans and chondroitin/dermatan sulfate were expressed	Minor myofibroblast infiltration (5%); confluent endothelial layer was not formed	104

Table 3 (Continued)

Scaffold composition	*Cell population(s)*	*Mechanical forces/signals utilized*	*Model, time period*	*Structure, function, and degradation*	*Cell response, ECM deposition*	*Study limitations*	*Reference*
Collagen fiber – collagen gel composite or hyaluronic gels coated with collagen and fibronectin	Neonatal rat aortic smooth muscle cells		*In vitro*, up to 8 weeks on collagen composites and up to 3 weeks on HA gels	On collagen composites, the gel contracted and collagen fibers became aligned; stiffness, extensibility, and failure strength were 5 MPa, 14%, and 1.1 MPa Branched collagen fiber bundles were also formed on the collagen composites	On collagen composites, an elastin sheath had formed around the fiber bundles at 5 weeks On HA gel, elastin was produced at 1 week and collagen at 2 weeks and a 12-μm thick basement membrane formed between the cell and HA gel layers	Preliminary study prior to fabrication of a composite valve	
Chitosan or chitosan–collagen IV films	Bovine aortic VECs	–	*In vitro*, 7 days in static culture	Not reported	VEC adhesion to uncoated chitosan was superior to PHA, similar to PLGA, and inferior to gelatin coatings Chitosan–collagen IV films further enhanced cell growth	Chitosan has been considered only as a material for coating heart valve prosthesis	106
Collagen type I or collagen type I – chondroitin sulfate (CS) composite	Porcine mitral VICs and porcine mitral VECs	–	*In vitro*., up to 28 days	Both scaffolds contracted during culture ≈24% of the CS was eluted from the collagen–CS scaffold CS increases porosity of the collagen scaffold	VICs infiltrated both scaffolds Confluent layers of VECs grew on the collagen–CS scaffolds and VECs on the collagen scaffolds were not confluent Phenotypic cellular expression and ECM production were evident on both scaffolds	Mechanical properties of the collagen gel scaffold not considered	107
Fibrin gel	Ovine-carotid-artery-derived cells	Mechanical conditioning	*In vitro*, 12 days in a bioreactor	Construct demonstrated intact and flexible tissue consisting of three leaflets attached to and continuous with a conduit wall The valve leaflets demonstrated synchronous opening and closing during the entire *in vitro* culture period	Dynamic conditioning increased cell attachment/alignment and expression of α-SMA enhanced deposition of ECM proteins, including types I and III collagen, fibronectin, laminin, and CS	Mehcanical testing not performed	108
Collagen gel	VICs	Cyclic mechanical strains	*In vitro*, 48 h	Not reported	The effect of cyclic strain magnitude on cellularity was negligible GAG and PG synthesis by VICs is regulated by cyclic stretching conditions	No mechanical testing performed	

The advantages that these natural biomaterials offer over synthetic biomaterials, and in some cases over decellularized heart valves, are numerous. They include inherent cell compatibility, and a topography and microarchitecture with which cells are familiar.[109] In addition to the usual scaffold characterization studies, such as those of cell–scaffold interactions and construct mechanical testing, research on natural scaffolds also often includes the optimization of scaffold isolation techniques, sterilization, preservation, and degradation studies.[109]

Collagen comprises 50% of the dry weight of the aortic valve cusp.[110] With it being the principal structural component of the cusp and a nonimmunogenic material compared with other structural proteins,[111] its choice as a biomaterial for scaffold fabrication is not surprising. Indeed, collagen has previously demonstrated its suitability as a biomaterial for scaffold design. Scaffolds have been fabricated from type I collagen derived from bovine skin and seeded with porcine heart valve myofibroblasts, and porcine aortic endothelial cells, mimicking the functions of the VICs and VECs, respectively. The cells infiltrated into the scaffold, with the seeded myofibroblasts expressing ECM and the development of an endothelial cell layer.[112] Taylor *et al*. assessed VIC behavior following seeding on collagen sponge scaffolds.[100] VICs seeded on the scaffolds expressed phenotypic markers, remained viable, and proliferated for up to 4 weeks. One of the primary limitations associated with the use of collagen foams and gels as biomaterials is poor mechanical properties. As a result, *in vivo* analysis of collagen foams and gels as scaffolds for heart valve replacement has not yet been assessed. In an attempt to overcome this limitation, Shi *et al*. formed composite heart valve scaffolds composed of collagen fibers and collagen gel. Following 8 weeks in static culture, elastin had been deposited on the scaffold by neonatal rat aortic smooth muscle cells and formed sheaths around the collagen bundles.[105] Improved mechanical properties were also observed, with stiffness and strain having reached 5 MPa and 14%, respectively (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**).

Gupta *et al*. assessed the effect of cyclic mechanical strain on GAG and proteoglycan (PG) formation by VICs and chordate interstitial cells.[113] These cells were seeded separately within collagen gels and subjected to various strain rates at a fixed frequency of 1.16 Hz. They found that there were numerous differences in the cells subjected to different strain rates, and hence they concluded that GAG and PG synthesis is regulated by the cyclic strain conditions. They concluded that cyclic strain conditions (which these cells would experience *in vivo*) cause an upregulation of specific GAGs and PGs that are usually present in abundance in the native tissue where these particular cell types are present. This suggests an important role for GAGs and PGs in conditioning heart valves for the demanding *in vivo* environment.

Chitosan, formed from the structural polysaccharide chitin found in crustaceans, has previously been investigated as a potential scaffold in many applications including cartilage, liver, and heart valve tissue engineering.[106,114,115] Advantages of chitosan as a scaffold include minimal foreign body reaction, mild processing conditions, controllable degradation, structural similarity to GAGs, and the presence of many hydroxyl and amino functional groups, which allow the functionalization of the scaffold, allowing the fabrication of bioactive scaffolds.[114] Specifically related to valve scaffold fabrication, it has been shown that chitosan can support the growth of VECs. Indeed, in comparative studies with standard tissue culture conditions, gelatin, poly-L-lactide-*co*-glycolide, and PHA, chitosan was considered as good as, or better than, all substrates other than tissue culture plastic in terms of optimizing the attachment of VECs, as well as proliferation and morphology. Although coating chitosan with proteins failed to improve VEC adhesion, chitosan–collagen type IV films improved VEC proliferation and morphology better than chitosan alone. These initial studies have demonstrated the usefulness of chitosan, which can therefore be considered as a suitable candidate for the fabrication of heart valve scaffold (see **Chapter 2.213, Chitosan**).[106]

Fibrin, a fibrous protein involved in clot formation of blood, promotes cellular migration, proliferation, and matrix synthesis through the release of platelet-derived growth factor and TGF-β;[116] it can also serve as a reservoir for cell mediators, such as bioactive peptides, gene vectors for gene therapy, alternative growth factors, and proteins.[117–119] Fibrin gels seeded with human aortic myofibroblasts dissolve within 2 days, which is too short a period to allow for cellular infiltration and tissue formation. However, it has been suggested that degradation rates could be regulated by cross-linking, or the addition of aprotinin.[16] Fabrication techniques for fibrin scaffolds have also been investigated;[96,120] injection molding was used to create heart valve constructs from fibrin gel, which was supplemented with aprotinin, to improve degradation rate, and chemically fixed with poly-L-lysine. The constructs were seeded with human aortic myofibroblasts and cultured *in vitro*. Following 4 weeks, a uniform cell distribution was found and a well-developed ECM with well-organized collagen bundles was formed. However, fibrin gel has two main limitations associated with it that limit its potential for heart valve scaffold design: shrinkage of the gel and, as with many natural biomaterials, a low initial mechanical stiffness (see **Chapter 2.217, Fibrin**).

Flanagan *et al*. investigated the effect dynamic culture conditions had on the phenotype, attachment, proliferation, and ECM expression of cells seeded on a fibrin scaffold.[108] Scaffolds were placed in a bioreactor chamber where the pulse-rate was increased from 5 b.p.m. to 10 b.p.m after 6 days, and a pressure gradient of 20 mm H_2O was maintained across the valve leaflets. They found that when compared to stirred controls, dynamically conditioned scaffolds exhibited enhanced attachment/alignment and the presence of α-SMA, as well as increased expression of ECM proteins such as collagen type I and III, fibronectin, laminin, and CS. Although no elastin was detected, this study demonstrates that identification of the ideal dynamic conditions may lead to the production of autologous fibrin-based heart valve replacements.

HA has been considered for heart valve scaffold fabrication because of its role in embryonic heart valve formation. As a component of the cardiac jelly present during heart morphogenesis, it may have a substantial influence on valvular cellular behavior when used as a scaffold biomaterial.[98] It is nonimmunogenic, nonthrombogenic, and may be cross-linked through various mechanisms to create hydrogel structures.[121–124] Its relevance for cardiac valve applications was demonstrated by seeding VICs on HA scaffolds. The VICs exhibited an increased production of the structural protein elastin, remained viable for up to 6 weeks, infiltrated the HA hydrogel, and demonstrated

an increased proliferation in the presence of the HA degradation products.[98] Techniques have also been developed to cross-link HA scaffolds with ultraviolet light to improve cellular attachment.[125] However, as is a common theme, the primary limitation of HA in the design of heart valve scaffolds is its poor mechanical properties. As a result, it has been utilized more often as a biomaterial in composite scaffolds. HA was cross-linked using divinyl sulfone to fabricate a nondegradable spongiosa-like biomaterial, which was embedded within an elastin gel to fabricate an aortic valve scaffold. The nondegradable biomaterial was thought to be more capable of withstanding the physically demanding *in vivo* conditions. Neonatal rat smooth muscle cells were seeded onto the composite constructs and onto tissue culture plastic, with the components of the deposited ECM being examined. The composite biomaterial induced the cells to proliferate more rapidly and over longer time periods (4 weeks) than those on tissue culture plastic (2–3 weeks). Cells grown on the composite scaffold deposited an unusual matrix rich in elastin at the scaffold–cell interface. This deposited elastin was found to be organized into fenestrated sheets and loose elastin fibers, structures that were also isolated from the elastin matrix of the ventricularis layer of porcine aortic valve cusps.[17] This could lead to the fabrication of mechanically relevant scaffolds (see **Chapter 2.214, Hyaluronic Acid**).

Shi *et al*. took a different approach to that of many researchers in that they attempted to form a biomimetic, composite scaffold. Collagen bundles, elastin sheets, and GAG gel matrix, formed by cross-linking hylauronan with divinyl sulfone, were stacked together in an attempt to mimic the structure of the native valve. Collagen bundles were embedded into the gel which was constrained in the longitudinal direction, thus aligning the collagen bundles and optimizing mechanical properties which are often the main limitations with biological scaffolds of nonvalvular origin. Elastin sheets were formed adjacent to the collagen bundles and on top of the GAG gel, by neonatal aortic fibroblasts which were in culture for more than 4 weeks.[105]

When compared with synthetic and decellularized valves, natural scaffolds offer many advantages. Unlike synthetic biomaterials, natural scaffold biomaterials are derived from nature and contain natural cellular adhesion sites and inherent cell stimuli such as growth factors. In addition, their degradation products are nontoxic. In fact, some biomaterials such as elastin and hyaluronan have degradation properties with beneficial stimulatory effects on cells. They are less likely to initiate toxic immune responses. Unlike decellularized heart valve scaffolds, natural materials investigated for heart valve scaffold design are acellular; so the application of harsh decellularization techniques, which may affect the structural integrity and cellular adhesion properties, is not necessary. Also, the inflammatory reaction and other consequences associated with incomplete decellularization are of no concern. Although natural scaffolds would appear to be the optimal choice in heart valve scaffold design and many biomaterials have been investigated to date, none has fulfilled all of the requirements of an optimal heart valve scaffold, and none has been trialed *in vivo*. The main criterion in which these natural biomaterials often fall short is that of mechanical properties, which often falls far short of what is necessary *in vivo*. Current researchers should focus on attempting to alter the mechanical properties of biological scaffolds through novel cross-linking, compositional changes, or the use of combinatorial scaffolds, as, if this hurdle can be overcome, natural biomaterials offer many more advantages than synthetic or decellularized scaffolds.

Another approach that could yield dividends for researchers is to take a sequential approach to scaffold fabrication (**Figure 3**). By drawing inspiration from natural developmental

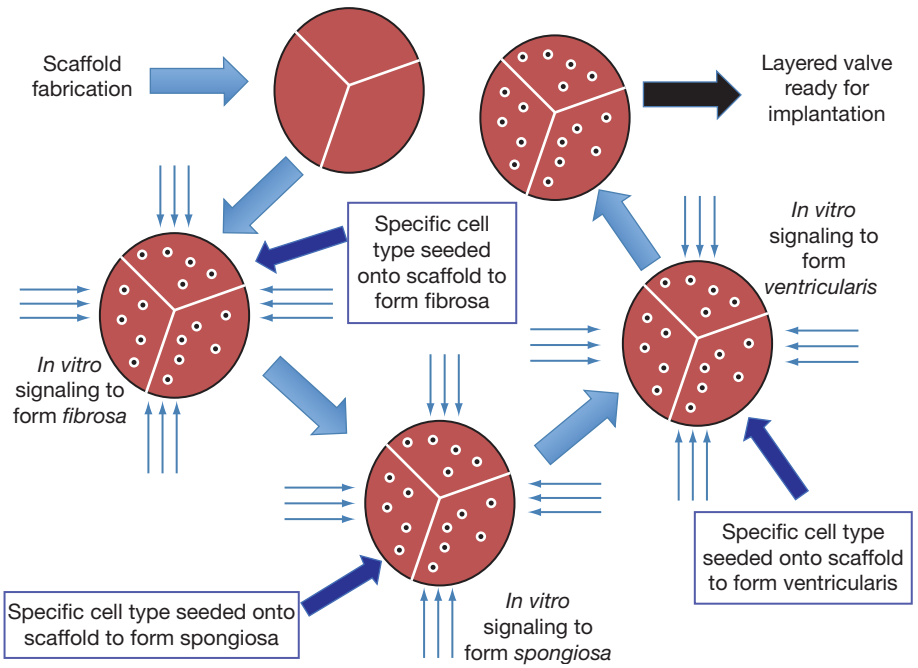

Figure 3 Schematic of fabrication of sequentially layered heart valve scaffold. At each stage an appropriate cell signal must be present to guide the correct formation of the desired layer.

processes, where a distinct sequence is followed, a biologically relevant scaffold could be fabricated. It is up to current researchers to identify the optimal cell types, and signals required to recreate the three distinct layers present in valves: the fibrosa, the spongiosa, and the ventricularis. By sequentially ordering the seeding of these cells and the application of specific signals, a layered scaffold similar to that of native valves could be fabricated.

6.626.8. Conclusion

The field on heart valve replacement is one which started off very promisingly with the great success of utilizing mechanical and bioprosthetic valves. However, the stagnation in the field is evident from the fact that valve design has changed very little since this early success story. As stated, although currently used clinically, mechanical and bioprosthetic valves are far from ideal. Although clinically available prostheses do greatly improve quality of life and life expectancy, they are associated with a number of problems such as thrombosis, hemolysis, and calcification, requiring patients to undergo lifelong antithrombosis therapy, with the mechanical and bioprosthetic valves having an expected lifetime of about 25 and 15 years, respectively. The major flaw associated with these valves is their lack of integration with the native tissue and capacity to repair and grow to match the needs of the patient. Hence, a large number of researchers have attempted to fabricate scaffolds which can be seeded with the appropriate cell type(s) *in vitro*, conditioned, and then implanted *in vivo*, where the idea is that they will degrade and be replaced by functional native tissue. Three main biomaterial approaches have been taken in the fabrication of these scaffolds: synthetic materials, decellularized valves, and natural materials of a nonvalvular origin. Each of these approaches has its associated advantages and disadvantages, and as yet, none has reached the clinic.

Synthetic biomaterials have the potential to be tailored to match the mechanical properties of native valves. However, this can quickly change when the biomaterial degrades *in vivo* and the effect of the degradation products *in vivo* on human patients cannot always be accurately predicted from *in vivo* animal models. Other problems which have been reported following implantation include scaffold shrinkage,[41] fragmentation,[48] thickening,[42] failure to coapt,[13,45,52] poor extensibility,[40,47] and failure to achieve a confluent endothelial cell lining.[55]

Decellularized valves provide a native scaffold architecture for cells to repopulate. Again however, there are a number of problems associated with decellularization procedures. Some methods fail to completely remove cellular remnants, while others are too severe and can affect the architecture and structural integrity of the ECM. A failure to completely decellularize these scaffolds prior to implantation leads to inflammation, while calcification is also associated with these scaffolds.

Natural scaffolds have none of the problems associated with synthetic or decellularized scaffold. There is no issue with toxic breakdown products or the effects of incomplete decellularization. In fact, these scaffolds demonstrate many of the requirements of the ideal scaffold biomaterial, such as mimicking the macro- and microarchitecture of the native valves, incorporating nanotopography similar to that of the native aortic heart valve basement membrane, supporting the adhesion of many appropriate cell types (VICs and VECs), and degrading without the release of toxic breakdown products. However, where they fail is in the mechanical properties of the biomaterial, as the scaffolds usually possess mechanical properties of orders of magnitude less than those of native valves, and in consequence would fail in the demanding *in vivo* environment. This is the reason that no natural scaffold of a nonvalvular origin has been assessed *in vivo* as yet. However, if this, admittedly crucial, limitation can be overcome, then natural scaffolds seem like the ideal replacements to promote regeneration of cardiac valves.

6.627.1. Introduction

The prevalence of ischemic heart disease is rising in line with increasing longevity of population, and the increased frequency of obesity, diabetes, and other coronary risk factors. Coupled with this is a lower threshold to investigate patients with symptoms suggestive of coronary artery disease (CAD), thereby increasing the importance of establishing an optimal form of treatment for patients with obstructive coronary lesions. Historically, owing to the problems associated with plain old balloon angioplasty (POBA) and the initial coronary stents, coronary artery bypass surgery was the preferred treatment in all but the simplest patient. In the past decade, new coronary stents have been developed which have revolutionized the ability to treat complex coronary lesions by percutaneous means. This chapter, after reviewing the problems associated with POBA and bare-metal stents (BMS), describes the first and second generation of drug-eluting stents (DESs), before finally reviewing some of the newer permanent stents which are currently being evaluated in on-going clinical trials.

6.627.2. The Need for Coronary Stents: Problems with Baloon Angioplasty and Bare-Metal Stents

The concept of wiring a diseased coronary artery and restoring luminal patency by means of a percutaneous approach has gone through extensive developments and advances since its first application in man by Andreas Grüntzig in 1977.[1] It has revolutionized the way we treat CAD and brought about a major shift from surgical to percutaneous intervention in all but the most severe and diffuse forms of the disease.[2]

POBA, the first form of percutaneous coronary intervention (PCI) relied on compression of atherosclerotic plaque through mechanical dilatation by balloon inflation. This process often caused vessel injury with tearing of the media. While chronic sequele in the form of vascular shrinkage (mediated by myofibroblasts, smooth muscle cells, and their proteoglycan and collagen secretions as well as elastic recoil) was a major concern, more sinister complications including abrupt vessel closure instigated the need for further development or alternatives of this technology.[3–5]

The use of a prosthetic device to improve vessel patency after POBA had already been proposed by Charles Dotter in 1964.[6] Two decades later, Puel implanted the first coronary stent – the Wallstent, a self-expanding metallic mesh.[7] The ability of such a device to cause and maintain a larger acute gain in luminal diameter proved to be key for its success, and the reason stents are implanted in the majority of PCIs performed today. The first stents to be implanted however were associated with a significant thombogenic risk which resulted in an 18% subacute stent thrombosis (ST) rate.[8] Measures to counteract this phenomenon, which included the introduction of complex anticoagulation regimens, resulted in an excess of vascular bleeding complications, and subsequent prolongation of hospitalization which altogether marred the initial successful results of the stenting concept when compared to POBA.[9]

Refinements in the stent system as seen in the landmark BENESTENT (BElgian NEtherlands STENT) (Figure 1)[10] and STRESS (STent REStenosis Study)[11] trials, as well as proof of the importance of adequate stent deployment,[12] redirected favorable light on the coronary stenting concept. Additionally, evidence that stenting was safe without need for anticoagulation through improvement in stent expansion and apposition, and with the use of dual antiplatelet therapy (DAPT), led to the exponential and widespread use of these early devices (Figure 2).[13–15]

The initial strengths and enthusiasm with the safer acute outcomes of stainless steel, cobalt–chromium alloy, and nitinol based stent implantation however met with what was described as the Achilles heel of BMS – in-stent restenosis (Figure 3). Neointimal growth mediated by smooth muscle hyperplasia and extracellular matrix produced significant luminal narrowing that peaked between 1 and 6 months after stent deployment.[16–18] As much as 20–40% of patients in whom

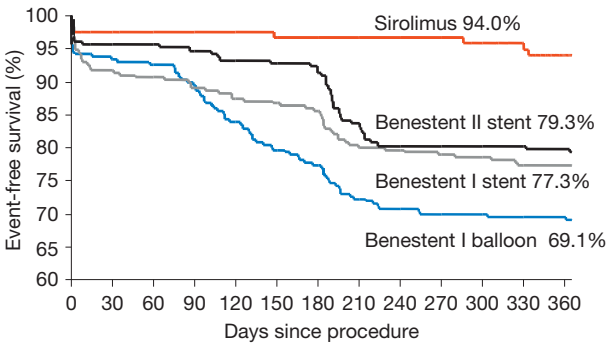

Figure 1 The improved event-free survival in the Benestent I and II trials with the use of a bare-metal stent (Benestent I stent) or a heparin coated stent (Benestent II) compared to only balloon angioplasty (Benestent balloon).[10] Event-free survival however is considerably greater with a sirolimus-eluting stent.

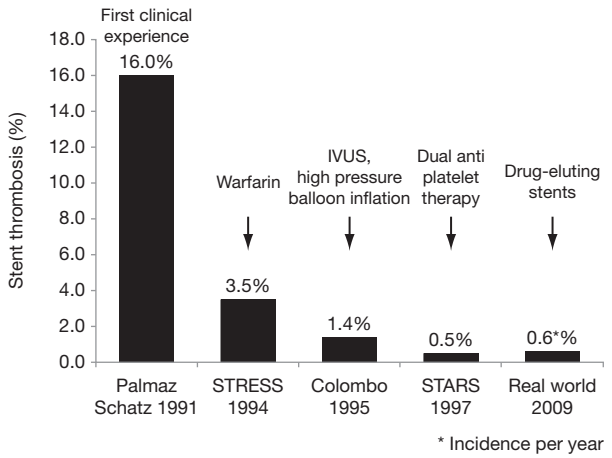

Figure 2 Temporal changes in the incidence of stent thrombosis following introduction of adjunct phamacotherapy, increased awareness of the importance of technique when implanting coronary stents, and the change from the use of bare-metal to drug-eluting stents. Adapted from Colombo, A.; Hall, P.; Nakamura, S.; *et al*. *Circulation* **1995**, *91*, 1676–1688; Leon, M. B.; Baim, D. S.; Popma, J. J.; *et al*. *N. Engl. J. Med*. **1998**, *339*, 1665–1671; Schatz, R. A.; Baim, D. S.; Leon, M.; *et al*. *Circulation* **1991**, *83*, 148–161; Fischman, D. L.; Leon, M. B.; Baim, D. S.; *et al*. *N. Engl. J. Med*. **1994**, *331*, 496–501; Wenaweser, P.; Daemen, J.; Zwahlen, M.; *et al*. *J. Am. Coll. Cardiol*. **2008**, *52*, 1134–1140.

these BMS were implanted, especially diabetic patients, those with small vessels and long lesions, presented with recurrence of anginal symptoms and angiographic restenosis (>50% diamenter stenosis). Restenosis rates, especially those confined to the stented part of the vessel (not including the 5 mm peristent segment) decreased dramatically after 6–12 months and this is attributable to replacement of the smooth muscle cells by a fibrotic matrix that halted further thickening of the neointimal layer.

Research efforts focusing on the neointimal proliferation phenomenon led to development of vascular brachytherapy, which employed beta or gamma sources to reduce in-stent restenosis.[19–22] Despite being shown to be effective in reducing recurrent stenosis by 30–70%, logistic problems associated with implementation of the treatment, recurrence of restenosis after 4 years[23] and the evolving concepts of using safer pharmacological agents instead of radiation, led to the downfall of this reparative technique.

Intravenous or oral antiproliferative, anti-inflammatory, or immunomodulatory agents failed to effectively reduce the neointimal hyperplasia in humans.[24] Attempts to increase local drug delivery by administration through porous angioplasty balloons also failed.[25,26] The possibility to link these bioactive substances to the stent surface itself and its release from the stent to the endothelium was then explored – DESs were born.

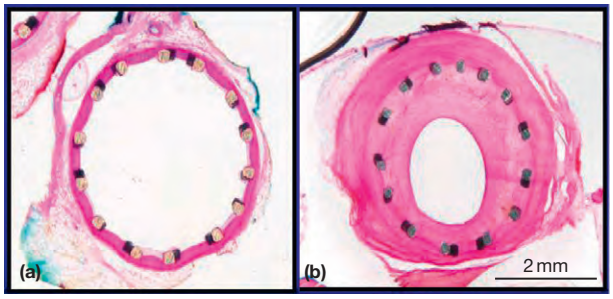

Figure 3 (a) Stent implantation in the porcine model demonstrating development of significant neointimal hyperplasia at follow-up (b).

6.627.3. Development of DESs

The first drug to be applied to coronary stents was in fact heparin, which was intuitively chosen to counter the thrombogenicity of BMS. Heparin-coated stents such as BX-Velocity Carmeda-coated stent (Johnson & Johnson, Warren, NJ), the Wiktor Hepamed-coated stent (Medtronic, Inc, Minneapolis, MN), and the Jostent Corline-coated stent (Jomed International AB, Helsingborg, Sweden) had their drug covalently bonded to the device, thereby significantly prolonging its presence on the stent.

Multiple drugs classes and types which inhibit restenosis by interference in pathways of inflammation and neointimal proliferation have been explored. These drugs can be classified as anti-inflammatory and/or immunomodulatory agents, antiproliferative agents, inhibitors of smooth muscle cell migration or extracellular matrix production, or promoters of healing and endothelialisation (**Table 1**).

The macrocylic lactone or 'limus' family of drugs which includes sirolimus, everolimus, biolimus A9, zotarolimus, tacrolimus, and pimecrolimus has been studied (**Figures 4** and **5**). The first four bind to the FKBP 12 binding protein which subsequently binds to the mammalian target of rapamycin (mTOR) and in doing so blocks the cell cycle mainly of the smooth muscle cell from the G1 to the S phase. Tacrolimus and pimecrolimus, on the other hand, bind to FKBP506 and form a complex which subsequently inhibits the calcineurin receptor, leading to decreased cytokine expression on the cell surface membrane. This results in inhibition of T cell activation and lower smooth muscle cell selectivity. Paclitaxel (**Figure 6**) is a nonlimus drug that stabilizes microtubules and thereby inhibits cell division in the G0/G1 and G2/M phases. It has also been applied to stents and thoroughly studied.

Table 1 A list of the various agents that were tested for potential application to drug-eluting stents

Anti-inflammatory, immunomodulators	*Antiproliferative*	*Smooth muscle cell migration inhibitors, extracellular matrix modulators*	*Promoters of healing and reendothelialization*
Limus family (sirolimus, everolimus, zotarolimus, biolimus A9, pimecrolimus)	Limus family (sirolimus, everolimus, zotarolimus, biolimus A9, pimecrolimus)	Batimastat	BCP671
Paclitaxel	Paclitaxel	Prolyl hydroxylase inhibitors	Vascular endothelial growth factor
Tacrolimus	Actinomycin D	Halofuginone	Estradiols
Cyclosporine	Methotrexate	C-proteinase inhibitors	Nitric oxide donors
Dexamethasone	Angiopeptin	Probucol	Endothelial progenitor cell antibodies
M-prednisolone	Vincristine		Biorest
Biorest	Mitomycine		Advanced coatings
Interferon gamma-1b	Statins		
Mycophenolic acid	CMYC antisense		
Mizorbine	RestenASE		
Tranilast	2-Chlorodeoxyadenosine		
	Proliferating cell nuclear antigen ribozyme		

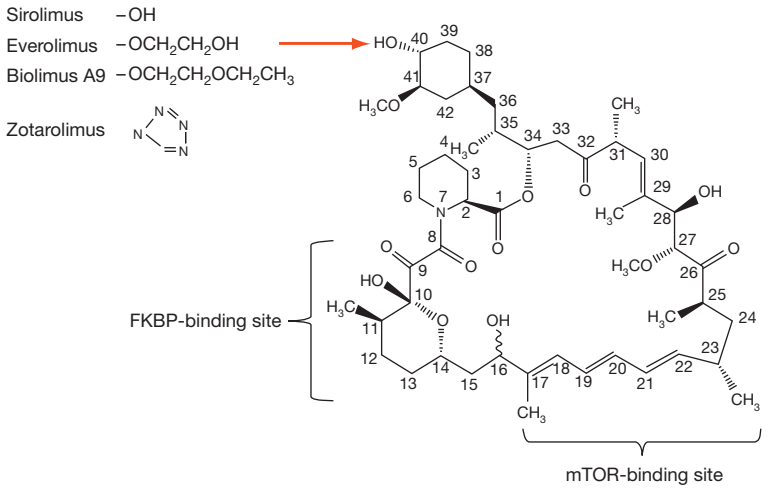

Figure 4 The macrocylic lactone or 'limus' family of antiproliferative agents. The different agents are derived following modifications to the macrocylic ring as shown. Their common mode of action includes binding to the FK-binding protein 12 (FKBP12), which in turn inhibits the mammalian target of rapamycin (mTOR) pathway. This subsequently prevents the down regulation of the cell division kinase inhibitor $p27^{kip1}$, thereby inhibiting cell division between phases G1 and S1 of the cell cycle.

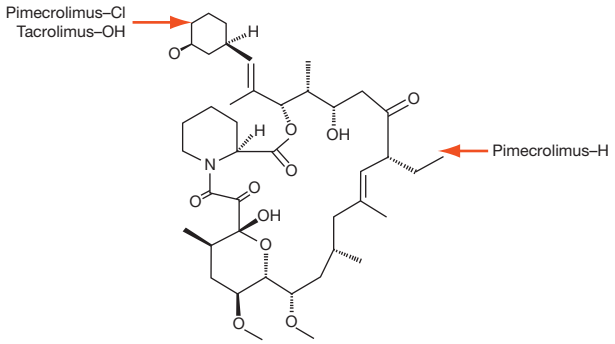

Figure 5 The chemical structure of tacrolimus and pimecrolimus.

Presently, only four DESs have been approved for use by the Food and Drug Administration (FDA). The first two DESs that were developed, the sirolimus-eluting and paclitaxel-eluting stent, are collectively known as first generation DESs, while the newer zotarolimus-eluting and everolimus-eluting stents are known as second generation DESs.

6.627.4. First Generation DESs

6.627.4.1. Sirolimus-Eluting Stent

Sirolimus was the first 'limus' agent to be used on a coronary stent (Figure 4). This macrolide antibiotic, produced by *Streptomyces hygroscopicus* has potent antifungal and antimitotic properties. It was discovered in Easter Island (Rapa Mui) in the South Pacific during an expedition in 1975 and was originally named rapamune to reflect its place of discovery. This highly lipophilic macrolytic lactone inhibits mTOR and exhibits potent antiproliferative and immunosuppressive effects. The first clinical application was as an immunosuppressive in renal transplant patients following FDA approval in 1999. The first sirolimus-eluting stent (SES) was the Cypher stent, developed by Cordis Corporation, Warren, NJ. It consisted of sirolimus in a concentration of 140 $\mu g\,cm^{-2}$, incorporated in an amalgam of two biostable polymers, with the polymer/drug matrix then applied onto the tubular 316L stainless steel BX-Velocity stent (Tables 2–4).

Both fast release stents with drug release in <15 days and slow-release stents with ≥ 28 days drug release were developed and tested in the 'First in Man' (FIM) study in 1999 in Sao Paulo, Brazil and Rotterdam, the Netherlands. Angiographic and intravascular ultrasound (IVUS) results from the 45 patients who were studied showed remarkable suppression of in-stent neointimal hyperplasia, which continued out to 4 years of follow-up (Figure 7).[27–29]

The pivotal RAVEL study (RAndomised study with the sirolimus-eluting VElocity balloon-expandable stent in the treatment of patients with de novo native coronary artery Lesions) evaluated the Cypher SES by randomizing 238 patients with relatively low-risk lesions to treatment with SES or BMS. At 1-year follow-up the rate of binary stenosis was 0.0 and 26.6% for patients treated with Cypher SES and BMS, respectively.[30] These results were subsequently confirmed in the much larger SIRIUS trial (SIRolImUS-coated BX-Velocity balloon-expandable stent in the treatment of patients with de novo coronary artery lesions) that enrolled 1058 patients with more complex lesions than were seen in RAVEL. Significantly lower rates of target lesion revascularization (TLR) and major adverse cardiovascular events (MACE) following treatment with the Cypher SES were demonstrated when compared to BMS controls at 9-month, 2-year, and 5-year follow-up.[31–33] The Cypher stent was thus the first DES to receive Conformité Européenne (CE)-mark in April 2002 and was subsequently approved by the FDA in 2003.

Performance of the Cypher stent has been also assessed in 'off-label' situations and specific subgroups of patients such as diabetic patients,[34,35] and those presenting with ST-elevation myocardial infarction.[36,37] In addition, it has been assessed in patients with different lesion types including chronic total occlusions,[38,39] saphenous vein grafts,[40,41] lesions in small coronary vessels,[42,43] and complex lesions.[44,45]

Titanium				1.0[a]

[a]Maximum.

Irrespective of clinical situation, when compared with BMS, the use of SES results in significant reductions in angiographic in-stent late loss; in-stent angiographic stenosis; and repeat revascularization at both short- and long-term 5-year follow-up, with results consistent across numerous different patient and lesion types. Furthermore, meta-analyses of patient data from the initial approval trials reaffirm the sustained advantage of SES over BMS in terms of reduced repeat revascularization, together with comparable rates of death and MI at long-term follow-up.[46–50]

Table 4 Comparison of the radio-opacity, strut thickness, radial strength, acute recoil, and conformability of different stent platforms

Stent	*Endeavor*	*Xience V*	*Cypher*	*TAXUS Liberté*	*TAXUS Element*
Stent platform	Cobalt–chromium	Cobalt–chromium	Stainless steel	Stainless steel	Platinum–chromium
Strut thickness (μm)	91	81	140	96	81
Radio-opacity ($g\,cm^{-3}$)		9.1		8.0	9.9
Radial strength[a] ($N\,mm^{-1}$)	0.14	0.11	0.17	0.24	0.26
Recoil[b] (% recoil)	5.1	4.6	3.4	2.8	3.0
Conformability[c] ($N\,mm^{-1}$)	0.06	0.30	1.00	0.09	0.04

[a]Amount of radial force required to reduce the diameter of a deployed stent (higher values preferred).
[b]Percentage of the stent diameter which decreases after balloon deflation (lower values preferred).
[c]Measure of the ability of the stent to naturally conform to the vessel (lower values preferred).

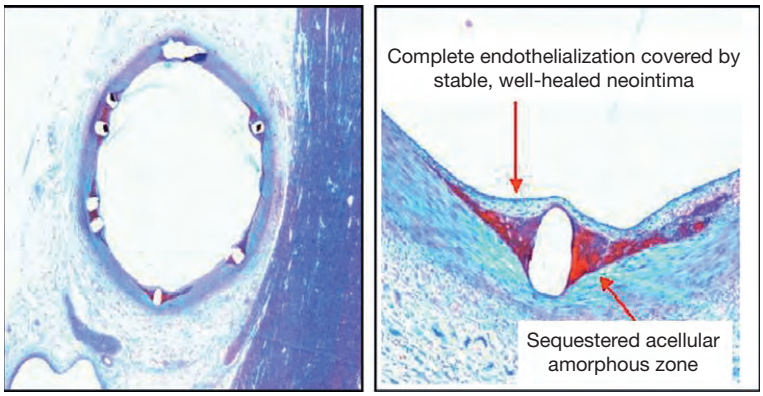

Figure 7 Sirolimus-eluting stent implantation in a porcine model demonstrating complete endothelialization of the stent struts without the development of significant neointimal hyperplasia.

Registries have also evaluated the performance of the Cypher stent in a 'real-world' setting. The first of these registries was the single-center RESEARCH (Rapamycin Eluting Stent Evaluated at Rotterdam Cardiology Hospital) registry, which enrolled 508 consecutive patients, who were treated with the Cypher SES irrespective of lesion complexity. Running concurrently with the RESEARCH registry was the multicenter ARTS-II (Arterial Revascularization Therapies Study) registry, which assessed the Cypher stent in 607 patients with two and three vessel CAD. Results from both registries at short and long-term follow-up, which now extends to 4 and 5 years for the respective RESEARCH and ARTS-II registries, mirror those from other registries, and the aforementioned randomized studies and meta-analyses, by continuing to demonstrate significantly lower rates of MACE and TLR following the use of the Cypher SES compared to historical BMS controls.[51–55]

6.627.4.2. Paclitaxel-Eluting Stent

Paclitaxel is a highly lipophilic diterpenoid compound that was first discovered in the pacific yew tree *Taxus brevifolia* in 1963 (Figure 6). This agent shifts the cytoskeletal equilibrium toward assembly, thereby inhibiting cell division in the G0/G1 and G2/M phases, which leads to reduced vascular cell proliferation, cell migration, cytokine and growth factor release and activity, interference with secretory processes, antiangiogenic effects, and impaired signal transduction.[56] At high doses, paclitaxel produces mitotic arrest in the G2/M phases of the cell cycle and promotes apoptosis. Conversely, at the low doses that are used on the paclitaxel-eluting stent (PES), paclitaxel affects the G0-G1 and G1-S phases, resulting in cytostasis without cell death. The first TAXUS PES (Boston Scientific, Natick, MA) consisted of paclitaxel contained within a polyolefin derivative biostable polymer coated on the stainless steel NIR platform. A slow-release (SR) formulation with an 18-μm thick coat, a moderate release (MR) with a 7-μm coat, and a fast release with 4-μm coat shed 8, 22, and 50% of the paclitaxel within 30 days, respectively. The difference in release was achieved by changing the polymer to drug ratio while maintaining the same paclitaxel concentration ($1\,\mu g\,mm^{-2}$).[57] The TAXUS PES has been evaluated in the TAXUS series of trials which have enrolled different patient and lesion types:

- The TAXUS I trial, a FIM phase I feasibility study with 61 randomized patients, reported a 3% MACE rate versus 10% in BMS at 1 year. Patients in the PES group had no TLR or binary stenosis, proving that paclitaxel effectively inhibited neointinal proliferation.[58]
- The TAXUS II study randomized 536 patients to treatment with BMS or SR PES, and BMS or MR PES. The reduction in percentage neointimal hyperplasia as measured by IVUS at 6 months was 7.8% for SR and 7.8% for MR versus 23.2% and 20.5% for control BMS.[59] These results provided the foundation for the sustained reduction in TLR of 4.5 and 10.3% for the MR PES and SR PES, respectively, (BMS 18.4%, BMS vs. PES $p < 0.001$) out to 5 years.[60] Of note, the MR formulation which was not subsequently used for

commercialization showed a better antirestenotic effect than the SR formulation at 5 years.

- TAXUS III tested the fast release PES in 28 patients with in-stent restenosis. At 6 months, the in-stent late loss was 0.54 mm with a neointimal hyperplasia volume of 20.3 mm^3, and a subsequent MACE rate was 29%. Overall results suggested that PES was a potentially efficacious treatment in those with in-stent restenosis.[61]
- The platform of the PES was changed from the NIR platform to less rigid Express platform (Table 2) and this combination was studied in the TAXUS IV study, which randomized 1326 patients with noncomplex CAD to treatment with the TAXUS Express stent or Express BMS. TVR at 9 months was significantly lower in the PES group (12.1% vs. 4.7%; $p < 0.0001$) and this advantage was maintained through to 5 years (27.4% vs. 16.9%; $p < 0.0001$), despite comparable annual TVR rates for BMS and PES between years 1 and 5 (4.1% per year vs. 3.3% per year, respectively, $p = 0.16$).[62,63]
- TAXUS V randomized 1156 patients, over half of whom had complex coronary lesions not studied in earlier PES trials, to treatment with PES ($n = 557$) and BMS ($n = 579$). Consistent with earlier studies, use of PES lead to significantly lower rates of angiographic stenosis, TLR, and TVR at 9 months, with comparable rates of death, MI, and ST. The benefit in favor of PES was maintained out to 5-year follow-up; however, PES was also associated with higher rates of MI (9.3% vs. 5.6%, $p < 0.05$) and definite/probable ST (2.4% vs. 1.5%, $p < 0.05$).[64,65]
- TAXUS VI also randomized 446 patients with long complex lesions to treatment with either PES or the Express BMS. At 9-month follow-up, use of PES led to significantly lower rates of binary stenosis, TLR, and TVR, while the overall MACE rate was similar. Subsequent 5-year follow-up demonstrated the sustained antirestenotic effect of PES on TLR (14.6% vs. 21.4%, $p = 0.03$); however, a significantly higher rate of non-TLR was also seen in the PES group (10.9% vs. 5.1%, $p = 0.03$). Rates of ST and MACE were similar.[66,67]

In a fashion similar to the SES, the TAXUS PES has been assessed in an unrestricted single-center registry, which used the PES as the default stent for all PCI in 576 consecutive 'real-world' patients. Two-year results from the T-SEARCH registry (Taxus Stent Evaluated at Rotterdam Cardiology Hospital) demonstrate similar efficacy in terms of suppression of neointimal growth and reduction of restenosis when compared to historical controls treated with SES.[68,69] In addition, patient level meta-analysis of the initial PES approval trials has confirmed the comparable safety and superior efficacy of PES, in relation to BMS, up to 4-year follow-up.[49,50]

6.627.4.2.1. TAXUS express versus TAXUS liberté

The TAXUS PES Express stent was the first PES approved by the FDA; however, it was subsequently replaced by the TAXUS PES Liberté stent, which was designed to be more deliverable and conformable, and to provide a more homogenous drug distribution.[70] Both stents utilized an identical polymer, dose of paclitaxel and release kinetics; however, the Liberté stent had a more uniform cell geometry allowing more enhanced and uniform drug delivery; thinner struts (97 vs. 132 μm); a smaller profile; and different stents designs depending on stent diameter (two cell stent for diameters 2.25–2.5 mm and three cell stent for diameter >2.75 mm) (Tables 2–4).

The superiority of the newer Liberté stent was confirmed by the multicenter noninferiority TAXUS ATLAS clinical trial. The study enrolled 871 patients treated with the TAXUS Liberté stent, who were compared to historical controls treated with the TAXUS Express-SR stent from the TAXUS IV and V trials.[70] In spite of similar inclusion criteria, patients with the Liberté stent received treatment for significantly more complex baseline lesions, however,the primary endpoint of 9-month TVR achieved the prespecified criteria for noninferiority (Express 7.0% vs. Liberté 8.0%, $p = 0.049$). There were no significant differences in other clinical outcomes.

Two subsequent studies, the TAXUS ATLAS Small Vessels study and the TAXUS ATLAS Long Lesions study, have also confirmed improved outcomes up to 3-year follow-up with the newer Liberté stent, specifically in patients with lesions treated with a single 2.25 mm TAXUS Express stent, and in patients with lesions 26–34 mm in length treated with a single 38 mm TAXUS Express stent.[71,72]

6.627.5. Benefits of DES

The previous discussion highlights the clear benefit DESs have over BMS in terms of reducing the risk of restenosis, which has been demonstrated in multiple randomized trials, and reaffirmed by meta-analyses. Results from the largest meta-analysis thus far, which included over 18 000 patients from 38 DES trials, indicated a reduction in TLR of 70% ($p < 0.0001$) with the use of SES, and 58% ($p < 0.001$) with the use of PES, when compared to BMS, which is up to 4-year follow-up.[49] This corresponded to a number needed to treat to prevent a single revascularization of only seven and eight patients for SES and PES, respectively. Encouragingly, consistent results have also been demonstrated in numerous other meta-analyses.[46–48,50] Importantly, these impressive results are not only confined to randomized studies which enrolled patients treated for 'on-label' indications, but have also been seen in registries, and randomized controlled trials which have included patients receiving DES for complex or 'off-label' indications.[52,73,74]

6.627.6. Risks of DES

- Restenosis

Despite the marked reduction in restenosis rates with the use of DES as compared to the use of POBA and BMS, clinically driven TLR remains common. These events which hinder the efficacy profile of the stents are even more common in real-world practice as has been consistently shown by registry data. Stenting in patients with diabetes, in those lesions at ostial locations, in small vessels, in lesions requiring long stented segments or stent overlap, and in the treatment of in-stent restenosis has been associated with a higher risk of repeat TVR. Restenosis in these high risk situations cannot be attributed to excessive neointimal proliferation alone, and in fact, failure of stenting in these situations is more likely to

be due to a combination of factors such as operator chosen stenting strategy, patient and lesion characteristics, as well as physical characteristics of the stent, including scaffolding/recoil. Inadequate stent expansion, incomplete apposition, strut fracture, geographical miss, and lesion calcification may all contribute to vessel recoil and inadequate drug elution to the vessel wall.[75,76]

- Stent thrombosis

ST is not unique to DES and in fact, as mentioned earlier, it has been a major problem since the first BMS were implanted. Although rare, it is a devastating, unpredictable event which carries significant morbidity and mortality.[77,78] The partial or complete clogging of the artery with thrombus results in the commonest mode of presentation, being symptoms typical of an acute coronary syndrome including ST-elevation MI.

In the DES era, concerns over the possible increased risk of ST compared to the earlier rates experienced with BMS led to collaborative efforts to investigate this issue. To assist in this assessment, large-scale registries and meta-analysis were performed, the majority of which employed the standardized definitions proposed by the Academic Research Consortium,[79] and reported no overall difference in rates of ST between DES and BMS. Of note, division of ST according to its timing indicated comparable rates of early (<30 days), and late (30 days to 1 year) ST; however, DESs were associated with significantly higher rates of very late (>1 year) ST (Table 5).[47–50,80]

The annual risk of ST seen in post marketing surveillance registries was ~0.2%, rising to 0.5% in trials of multivessel PCI.[81–84] Of importance, rates of ST at the different time points post DES implantation vary significantly as exemplified by the Dutch Stent registry (437/21009 patients with documented ST) where 32.0%, 41.2%, 13.3%, and 13.5% (146) of ST events occurred acutely, subacutely, early, and late.[85] Furthermore, registry data from the Rotterdam–Bern group (8146 patients), the SCAAR registry (21 717 patients), and from Pinto Slottow's *et al.* registry (8000 patients) have all indicated that the risk of very late ST persists at an annual rate of between 0.36% and 0.6% per year out to at least 5 years after DES implantation.[86–91] In addition, the results at 2-year follow-up from both the ARRIVE and STENT registry also suggest that the risk of ST is higher in those patients treated with DES for 'off-label' compared to 'on-label' indications.[92,93]

Numerous potential causes have been implicated as a risk factor for a ST event.[85,86,91,94] The possible increased thrombogenicity of DES as compared to BMS was attributed to lack of vessel endothelialization, vascular toxicity, and hypersensitivity reactions. A recent small scale study suggested stent malapposition as a more frequent finding in DES, whereas disease progression with neointimal rupture was more common in BMS.[95] Procedure related factors, such as stent under sizing, lesion length >28 mm, dissection, multiple stent implantation, stenting at bifurcations, calcification, and small vessel diameter, and most notably early cessation of DAPT, have been associated with development of early/late, but not very late, ST.[85,94] Renal failure and previous brachytherapy seem to be more important in very late ST.

Currently, efforts are underway to reduce the risk of ST, utilizing the vast acquired knowledge of factors which have been implicated in its occurrence. As discussed in the rest of this chapter, the development of newer stents with new stent platforms, new stent designs, and safer drug release mechanisms aims to decrease the inherent thrombogenicity of the stent itself. Coupled with these changes, are developments in imaging techniques that help better identify features implicated in precipitating ST, such as malapposition and dissections in the acute phase, thereby allowing immediate correction, which could potentially help in reducing ST events. Finally with respect to DAPT, investigations are underway to establish the optimal duration of DAPT, the full potential of new antiplatelet agents such as prasugrel and ticagrelor, and the optimal treatment of patients with antiplatelet resistance.

6.627.7. Second Generation DES

The previously discussed safety concerns that emerged with the first generation DES prompted the development of newer coronary stents, which utilized more biocompatible polymers, aimed more specifically at mimicking the endothelial lining in order to prevent thrombotic complications. In addition, these newer stents moved away from stent platforms using 316L stainless steel, and instead used cobalt–chromium, an alloy with improved radio-opacity and superior radial strength, thereby allowing thinner stent struts (Tables 2–4). Notably, previous studies of bare-metal and drug-eluting stainless steel

Table 5 Rates of overall, early, late, and very late stent thrombosis from recent meta-analyses comparing drug-eluting stents to bare-metal stents

stents have indicated that stent strut thickness has a significant adverse impact on long-term rates of restenosis and clinical outcomes (Figure 8).[70–72,96,97] Therefore, reducing strut thickness not only has distinct potential advantages with respect to outcomes, but also allows devices to be of lower profile, improving overall stent deliverability. The second generation DES comprise the Endeavor (Medtronic, Santa Rosa, CA) zotarolimus-eluting stent (E-ZES), the Resolute (Medtronic) zotarolimus-eluting stent (R-ZES) and the XIENCE V everolimus-eluting stent as described below.

6.627.7.1. Zotarolimus-Eluting Stents

- Endeavor stent (Medtronic, Santa Rosa, CA)

This cobalt–chromium stent has a strut thickness of 91 μm, and is loaded with 100 μg cm^2 of the macrocylic lactone zotarolimus. The drug is released in a rapid fashion such that 95% is eluted within 14-days of implantation, release of which is facilitated by a 4.1-μm thick permanent 'biomimetic' phosphorylcholine polymer which is biostatic and biocompatible, being a natural component of the cell membrane (Tables 2–4). The superior biocompatibility of the polymer is suggested by studies which demonstrate less inflammation with this polymer compared to the methacrylate polymer found on the Cypher SES; in addition, animal and *in vivo* studies using angioscopy and optical coherence tomography (OCT) both demonstrate a greater endothelial coverage of struts, potentially as a result of less inflammation, with E-ZES compared to SES, and PES (Figure 9).[98–101]

The first clinical evaluation of the stent took place in the 100 patient single-arm ENDEAVOR I study. At 12 months, in-stent late loss and binary restenosis were 0.61 mm and 5.4%, respectively. Clinic event rates were low, with two TLRs, one MI, and one definite/probable ST at 1 year, and only one further TLR and no additional MIs or ST events were reported up to 5-year follow-up.[102,103] More extensive assessment of E-ZES has taken place in randomized comparisons with BMS, and first generation DES as described in Sections 6.627.7.3 and 232.7.4, respectively.

- Resolute ZES (Medtronic, Santa Rosa, CA)

The Resolute ZES (R-ZES) uses the same stent platform and dose of antiproliferative agent as that found on the Endeavor stent; however, zotarolimus release is controlled by the BioLinx polymer – a blend of three different polymers: the hydrophobic C10 polymer to control drug release; the biocompatible and hydrophilic C19 polymer; and polyvinyl pyrrolidone to allow an early burst of drug release (Table 2 and Figure 10).[104] The polymer prolongs drug release, such that at least 85% of the zotarolimus is released within 60 days, with the remainder being released within 180 days. The prolonged drug elution is aimed at matching the delayed healing times seen in complex lesions.

The first assessment of the R-ZES took place in the 139 patient, single-arm RESOLUTE study. At 9-month follow-up, angiographic in-stent late loss was 0.22 mm, which was notably less than the ≈0.6 mm consistently seen with the E-ZES. Rates of MACE, TLR, and any definite/probable ST were 8.6%, 0.7%, and 0.0%, respectively at 12-month follow-up, and 11.6%, 1.6%, and 0.0%, respectively at 3-year follow-up.[105–107] The R-ZES has also been assessed in a large randomized study as described in Section 6.627.7.5.

6.627.7.2. Everolimus-Eluting Stent

- XIENCE V

The cobalt–chromium EES stent has a strut thickness of 81 μm, and is coated with a 7.6-μm thick, nonerodable, copolymer of poly vinylidene fluoride *co*-hexafluoropropylene (PVDF-HFP), and poly *n*-butyl methacrylate (PBMA) (Tables 2–4, and Figure 11). The polymer facilitates the elution of the sirolimus analog, everolimus over 120 days. Of note,

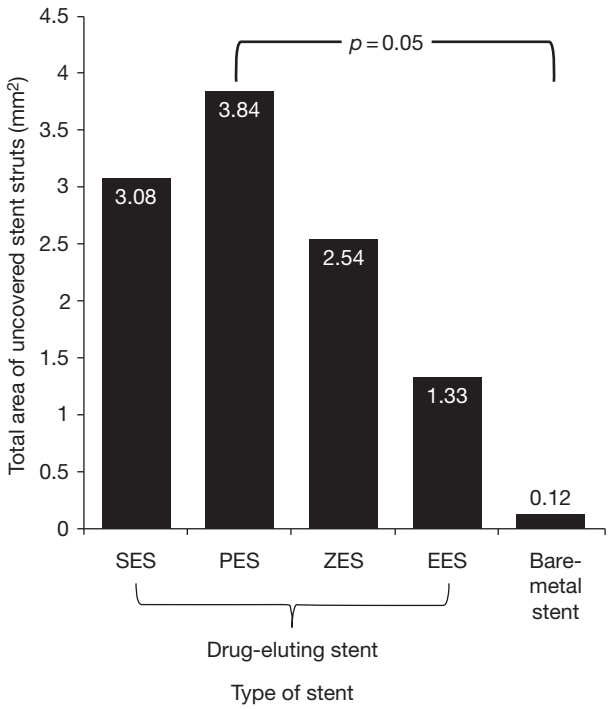

Figure 9 The difference in total area of stent struts that have not been endothelialized according to stent type at 1 month in a rabbit model. SES, sirolimus-eluting stent; PES, paclitaxel-eluting stent; ZES, Endeavor zotarolimus-eluting stent; EES, everolimus-eluting stent. Adapted from Joner, M.; Nakazawa, G.; Finn, A. V.; *et al. J. Am. Coll. Cardiol.* **2008**, *52*, 333–342.

preclinical studies have demonstrated more rapid endothelialization in rabbit iliac arteries implanted with an EES when compared to that with SES, PES, and E-ZES (Figure 9).[99]

The FUTURE I[108,109] and FUTURE II[110] studies were the first to demonstrate the feasibility of using everolimus on a DES, and subsequent trials, as indicated below, include randomized studies comparing EES with BMS, PES, and R-ZES.

- Xience PRIME™ (Abbott Vascular, Santa Clara, CA)

The Xience PRIME EES, which represents the newest development of the Xience® V stent, has recently gained regulatory approval in Europe. This modified EES has a CoCr platform; however, this is mounted on a new enhanced stent delivery system that enables the stent to be more flexible and deliverable. Furthermore, the stent balloon has higher rate burst pressures, and shorter balloon tapers to minimize the risk of edge dissections. The stent is being evaluated in the prospective, multicenter, nonrandomized SPIRIT PRIME study in 500 patients at 75 hospital centers, with the aim of gaining US FDA approval.

6.627.7.3. Second Generation DES Versus BMS

The ENDEAVOR II and SPIRIT FIRST trials were the first respective randomized evaluations of E-ZES and EES, with BMS as the comparator. The ENDEAVOR II trial enrolled 1197 patients (E-ZES = 598, BMS = 599) and demonstrated significantly lower rates of in-stent late loss (0.61 vs. 1.03 mm, $p < 0.001$),

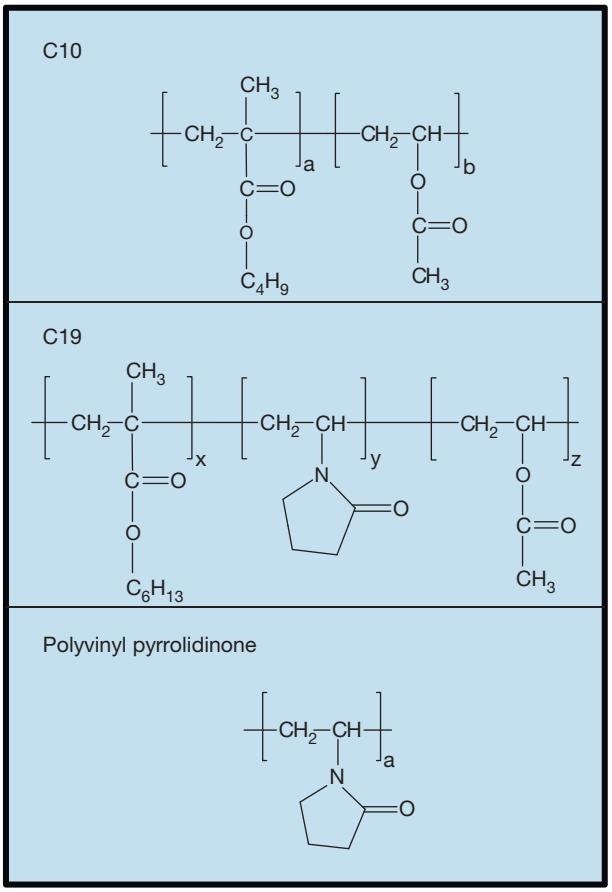

Figure 10 The chemical structure of the three components of the BioLinx polymer on the Endeavor Resolute stent. The hydrophobic C10 polymer is based on hydrophobic butyl methacrylate to provide adequate hydrophobicity for zotarolimus. The hydrophilic C19 polymer is manufactured from a mixture of hydrophobic hexyl methacrylate, and hydrophilic vinyl pyrrolidinone and vinyl acetate monomers, to provide enhanced biocompatibility. The hydrophilic polyvinyl pyrrolidinone increases the initial drug burst and enhances biocompatibility.

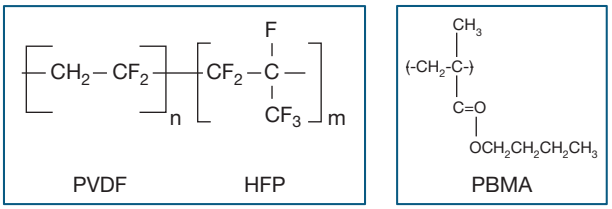

Figure 11 The structure of the Xience V everolimus-eluting stent polymer which is a copolymer of poly vinylidene fluoride *co*-hexafluoropropylene (PVDF-HFP), and poly *n*-butyl methacrylate (PBMA).

binary in-stent restenosis (9.4% vs. 33.5%, $p < 0.001$), TLR (4.6% vs. 11.8%, $p < 0.001$), and target vessel failure (TVF; a composite of cardiac death, MI attributable to the target vessel, and clinically driven TLR) (7.9% vs. 15.1%, $p < 0.001$) at 9-month follow-up, with additional clinical follow-up at 5 years indicating a sustained benefit in favor of E-ZES with respect to TLR and TVF.[111,112] Mortality and rates of MI and ST were comparable at all time points. Of note, unlike long-term

follow-up of the SIRIUS and TAXUS II study,[33,60] there was no reduction with time in the absolute difference in TLR between E-ZES and BMS (Δ7.2% at 1 year, Δ8.8% at 5 years).

The smaller SPIRIT FIRST study enrolled 56 patients (EES = 27, BMS = 29) and demonstrated superior performance of EES at 6-month and 5-year follow-up with respect to similar angiographic, and clinical endpoints as assessed in the ENDEAVOR II study.[113,114]

6.627.7.4. Second Generation DES Versus First Generation DES

After establishing their superiority over BMS, both second generation DESs have been compared to the first generation DES. While E-ZES has been compared in different randomized trials to both PES and SES, EES has only been compared to PES. Overall results with E-ZES have been inconsistent, while a clear benefit in favor of EES has been shown in its comparison with PES.

- E-ZES versus SES

The comparison of E-ZES and SES has taken place in the randomized ENDEAVOR III study which enrolled 436 patients (E-ZES = 323 and SES = 113) and the SORT-OUT III study which randomized 2332 patients (E-ZES ($n = 1162$) and SES ($n = 1170$)).[115–117] At short-term follow-up, results of both studies suggested superiority of SES. Notably, the ENDEAVOR III study failed to reach its noninferiority primary endpoint of in-stent late loss at 8-month follow-up (E-ZES 0.34 mm vs. SES 0.13 mm, $p < 0.001$); however, despite this, rates of TLR, mortality and TVF were similar in the stent groups. In contrast, in the SORT-OUT III study at both 9- and 18-month follow-up, significant differences in favor of SES were observed with respect to MI, TLR, and ST. Results at long-term follow-up of the ENDEAVOR III study suggest a more sustained antiproliferative effect with E-ZES compared with SES. Specifically at 5 years, the absolute difference in TLR between E-ZES and SES was 1.6% (E-ZES 8.1% vs. SES 6.5%) compared to an absolute difference at 9 months of 2.8%. Rates of ST remained similar in both groups throughout follow-up, although neither study was powered for this endpoint.

- E-ZES versus PES

The ENDEAVOR IV study randomized 1548 patients to E-ZES ($n = 773$) and PES ($n = 775$).[118] The study demonstrated noninferiority of E-ZES compared to PES with respect to the primary endpoint of TVF (E-ZES 6.6% vs. PES 7.2%); no significant differences were noted in other clinical endpoints at 1-year, with results maintained through to 3-year follow-up.[119] Similar to the ENDEAVOR III study, there was a reduction with time in the absolute difference in TLR between E-ZES and PES from 1.3% at 1 year to 0.5% at 3 years. Angiographic follow-up at 8 months demonstrated an in-stent late loss of 0.67 and 0.42 mm for E-ZES and PES, respectively ($p < 0.001$).

In summary, the comparison of E-ZES with first generation DES have shown similar results, with significantly inferior values for late loss observed on angiographic follow-up at between 6 and 8 months; however, this has not translated into any significant differences in clinical endpoints. Moreover, at long-term follow-up a reduction in the absolute difference between E-ZES and the comparator stent has been seen, which may suggest absence of the 'late catch-up' phenomena with E-ZES.

With respect to ST, no study has been adequately powered to detect differences, and consequently the results of the PROTECT study, anticipated in 2011, are eagerly awaited. This study has randomized 8800 'all-comers' patients to treatment with either the E-ZES or SES, and will report a primary endpoint of definite/probable ST at 3-year follow-up.[120]

- EES versus PES

EES has been compared to PES in several randomized studies which have enrolled increasingly complex patients ranging from those with up to two *de novo* lesions in the SPIRIT II study,[121–125] to the unrestricted all-comers population in the COMPARE study.[126] Irrespective of patient complexity or follow-up period, angiographic and clinical outcomes have been superior in those treated with EES. Specifically, in the SPIRIT II and SPIRIT III study in-stent late loss at 6 and 8 months, respectively, was significantly lower with EES.[125,127] Longer angiographic follow-up has only been performed in the SPIRIT II study, and this demonstrated evidence of delayed late loss with EES such that there was no longer a significant difference in in-stent late loss at 2 years.[121] Nevertheless, despite this observation, clinical outcomes at 3- and 4-year follow-up in the SPIRIT II study remained consistent with those seen at 6-month and 1-year follow-up, with numerically lower rates of cardiac death, MI, TLR, and overall MACE with EES. Similarly, at 3-year follow-up in the SPIRIT III study, treatment with EES led to significantly lower rates of TVF, target lesion failure, and MACE.[128] More extensive assessment of EES has taken place in the SPIRIT IV, which randomized 3690 patients (EES = 2458, PES = 1229), and represents the largest randomized trial comparing two DESs, and the COMPARE study, which recruited 1800 patients (EES = 897, PES = 903) and was the first randomized all-comers trial of the EES.[126,129] Both studies demonstrated significantly superior efficacy and safety with EES compared to PES. In addition, while nonsignificantly lower rates of ST have been observed in the SPIRIT II and III studies, the SPIRIT IV and COMPARE studies were the first to demonstrate a significant reduction in ST between two DES. At 12-month follow-up, rates of definite/probable ST for EES and PES were 0.29% versus 1.06% ($p = 0.003$), and 0.7% versus 2.6% ($p = 0.002$) in the SPIRIT IV and COMPARE studies, respectively.

6.627.7.5. Second Generation DES Versus Second Generation DES

The only data comparing two second generation DES come from the RESOLUTE All-Comers Trial. This study, which randomized 2300 patients to treatment with the R-ZES or EES, had an all-comers design, such that one-third of the population enrolled presented with ST-elevation MI, and two-thirds had at least one off-label indication.[130] The study achieved its prespecified criterion for noninferiority of the primary endpoint of target lesion failure (a composite of cardiac death, MI attributable to the target vessel, and clinically driven TLR) at 12-month follow-up (R-ZES 8.2% vs. EES 8.3%, $p_{\text{noninferiorty}} < 0.001$). In addition, the study also achieved its powered angiographic

endpoint of percent diameter stenosis at 13-month follow-up (R-ZES 21.7% vs. EES 19.8%, $p_{\text{noninferiorty}} = 0.04$). All other clinical endpoints were similar in both groups, including rates of ST, which were reassuringly low despite the complexity of the patient population.

6.627.8. New Drug-Eluting Stents

There is no doubt that the introduction of the DES revolutionized the practice of interventional cardiology. The first generation DESs undeniably offered distinct advantages over their BMS predecessors; however, safety concerns emerged with their use in the more diverse patient populations encountered in routine clinical practice. These concerns subsequently prompted development of second generation DES which had more biocompatible polymers, and results have so far been impressive, albeit at only medium-term follow-up.[122,131] The problem of ST persists however, and focus has now turned to developing newer DESs which utilize newer types of polymer. Of note, current first and second generation DESs use nonerodable polymers, which remain exposed to the coronary artery environment long after their useful function has been served, and consequently have been implicated in causing persistent arterial wall inflammation, and delayed vascular healing, both of which may play a role in precipitating ST and delayed restenosis.[99,132–135]

Advances in polymer technology have led to the development of DESs which have polymers that biodegrade into inert monomers over 6–9 months, or DESs which are completely polymer free. A final extension to these new developments is the concept of completely biodegradable stents which are discussed in.

A robust method of classifying this heterogeneous group of new stents, many of which are still undergoing preclinical and/or early FIM studies, has not yet been determined, but for simplicity, in the following discussion they are grouped according to the type of polymer. Of note, those stents utilizing new stent platforms such as platinum–chromium and nitinol are covered separately.

6.627.8.1. DES with Biodegradable Polymers

This represents the largest group of new DESs, with numerous devices undergoing current clinical evaluation, and some already commercially available in Europe. In theory, immediately after implantation these devices function similar to conventional DES; however, after polymer breakdown, they speculatively may offer the safety benefits of BMS. Short-term results from these stents have been encouraging; however, in the absence of long-term data it is not possible to definitively state that this technology will lead to improved clinical outcomes, most notably with respect to improved safety.

There are many challenges remaining for this new polymer technology, which include among others, establishing the optimal biocompatibility, composition, formulation, and degradation time of the polymer. In addition, attention must be paid to the pharmacokinetics of the antiproliferative agent released by the degradation of the polymer, and the variation in polymer degradation time which can be affected by production factors such as the use of long polymer chains, decreased polymer hydrophobicity, and greater polymer crystalinity, together with physical and biological environmental factors.[136] Evidence indicates that polymer breakdown can be associated with a significant inflammatory reaction which at times can create an acidic environment; moreover, complications may also occur as a result of a persistent immune response to monomer breakdown products.[137] These uncertainties reiterate the need for continued research, with clinical outcomes assessed at long-term follow-up.

The most prominent DESs with biodegradable polymers include those eluting biolimus A9, sirolimus, and paclitaxel, as described below.

6.627.8.1.1. Biolimus A9-eluting DES with biodegradable polymers

The most widely studied DESs with biodegradable polymers elute the highly lipophillic macrocyclic lactone biolimus A9, which is an analog of sirolimus that inhibits T cell and smooth muscle cell proliferation. The main difference between biolimus A9 and rapamycin is replacement of hydrogen by alkoxy-alkyl group at 40-O position, increasing its lipophilicity (Figure 4). The drug has been combined on several different stent platforms with an abluminal poly-lactide polymer, which biodegrades completely within 6–9 months of stent implantation (Figure 12). The abluminal location of the drug/polymer matrix is aimed at further improving overall safety, by allowing more targeted tissue release, and reducing systemic exposure.

- Biomatrix™ stent (Biosensors, Morges, Switzerland)

The stainless steel BioMatrix Flex™ stent (Figure 12) was initially evaluated in the 120 patient FIM STEALTH I trial which randomized patients to the biolimus-eluting stent (BES) or a BMS. At 6 months, angiographic follow-up rates of in-stent late lumen loss and angiographic stenosis were significantly lower with BES.[138] Results at 5-year follow-up from a subgroup of 32 patients demonstrate low rates of overall MACE, and importantly no episodes of ST.[139]

More recent evaluation took place in the all-comers noninferiority LEADERS study, which randomized 1707 patients to treatment with BioMatrix BES or the Cypher SES. At 9-month follow-up, BES was shown to be noninferior with respect to the primary endpoint of MACE, a composite of cardiac death, MI, and ischemia driven TVR (9% vs. 11%, $p_{\text{noninferiority}} = 0.003$, $p_{\text{superiority}} = 0.39$),[140] with results subsequently maintained at 12- and 24-month follow-up.[141,142] The stent's PLA polymer is expected to have completely biodegraded by 9 months (Figure 12), and therefore, even though the study is not adequately powered to detect differences in ST events, it is promising to observe the occurrence of less very late ST events (>1 year) with BES (0.2% vs. 0.5%).[142] Further data in support of the biodegradable polymer concept were obtained in an OCT substudy, which demonstrated a higher rate of near complete (>95%) strut coverage with BES when compared to the Cypher SES at 9-month follow-up (89.3% vs. 63.3%, $p = 0.03$).[143]

- Nobori™ stent (Terumo, Japan)

The Nobori™ stent is very similar to the BioMatrix Flex stent, utilizing the same polymer, antiproliferative agent, and stent platform; however, the delivery system, delivery balloon,

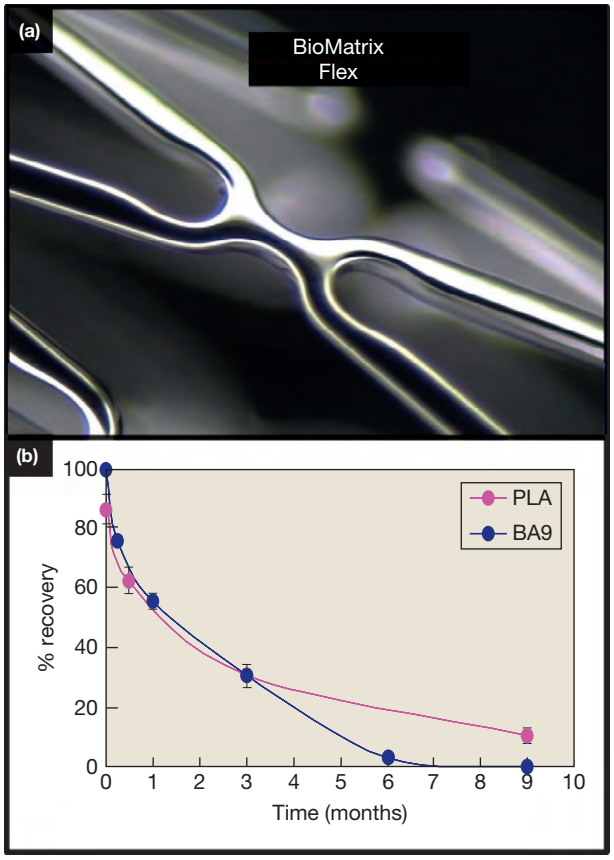

Figure 12 The BioMatrix Flex stent. (a) The stainless steel BioMatrix Flex stent. (b) The elution pattern of Biolimus A9 (BA9) and the corresponding biodegradation pattern of the poly-lactic acid (PLA) polymer.

and the stent coating process are different. In the NOBORI CORE study, which randomized 99 patients to treatment with the Nobori BES or the Cypher SES, there was no significant difference in 9-month angiographic in-stent late lumen loss (0.10 vs. 0.12 mm, $p = 0.66$).[144]

In the larger Nobori I study, 243 patients were randomized to treatment with either the Nobori™ stent ($n = 153$) or the TAXUS PES stent ($n = 90$). At 9 months, the Nobori stent was shown to be noninferior, and subsequently superior to the PES with respect to late loss (0.11 vs. 0.32 mm, $p_{\text{noninferiority}} < 0.001$, $p_{\text{superiority}} = 0.001$). In addition, the rate of ARC defined ST at 9-month follow-up was also lower with the Nobori stent (0.0% vs. 2.2%).[145] Encouragingly no episodes of very late ST have been reported in any study assessing the Nobori stent, which in total have enrolled over 3000 patients. Clinical evaluation continues in large-scale randomized trials comparing the stent to the EES in the COMPARE 2 ($n = 2700$ patients) and BASKET PROVE 2 ($n = 2400$ patients) studies, and to the Cypher Select SES in SORT-OUT IV study ($n = 2400$ patients).[146]

- Axxess™ stent (Devax Inc., Lake Forest, CA, USA)

The Axxess stent is a BES which is made of nitinol and designed specifically for bifurcation lesions. It is described in Section 6.627.8.4.2.

6.627.8.1.2. Sirolimus-eluting DES with biodegradable polymers

- NEVO™ Stent (Cordis, Warren, NJ, USA)

The NEVO™ stent is an open-cell, cobalt–chromium stent, with a PLGA biodegradable polymer which facilitates elution of sirolimus. The stent is unique in its design as the polymer and sirolimus are contained within reservoirs, which eliminate the need for a surface polymer coating, and subsequently reduce tissue-polymer contact, by over 75%. This stent design was previously used on the durable polymer, paclitaxel-eluting CoStar stent (Conor MedSystems, Palo Alto, CA). Unfortunately, despite promising initial results,[147–149] the CoStar stent failed to develop following disappointing results from the CoStar II study,[150] where it was shown not to be noninferior to the TAXUS PES with respect to clinical outcomes in terms of MACE (CoStar 11.0% vs. PES 6.9%, $p = 0.005$), and angiographic outcomes such as in-stent late loss (CoStar 0.49 mm vs. PES 0.18 mm, $p < 0.0001$). The failure of the stent was attributed to several factors including changes in the manufacturing process during the trial that may have affected the paclitaxel release kinetics and the small number of patients in the earlier studies. Perhaps of greatest relevance was that the dose of paclitaxel, which was reduced in an attempt to maximize long-term safety, may have been too low to inhibit neointimal hyperplasia. Learning from this, the NEVO stent has the same sirolimus dose and release kinetics as found on the Cypher SES, thus ensuring that drug elution is complete within 90 days.

The stent has so far only been evaluated in the NEVO-RES I study, which was a randomized, multicenter, noninferiority study comparing the NEVO™ stent to the TAXUS™ Liberté PES stent in 394 patients with single *de novo* coronary artery lesions. At 6-month angiographic follow-up, the primary endpoint of in-stent late lumen loss was significantly lower in patients treated with the NEVO stent (0.13 vs. 0.36 mm, $p < 0.0001$); a superiority which was preserved irrespective of diabetic status, lesion length, or vessel diameter.[151] Clinical endpoints at both 6 and 12 months were numerically lower in the NEVO treated group, although these differences did not reach significance. The rate of ST was 0.0% and 1.1% ($p = 0.24$) in patients treated with the NEVO and PES stent, respectively.

A more extensive evaluation of the NEVO stent is in the currently enrolling NEVO-II study, which will randomize 2500 'all-comers' in a 2:1 ratio to treatment with either the NEVO™ stent (1667) or the Xience V EES (883) stent, with a primary endpoint of target vessel failure at 12 months, and angiographic follow-up in a subset of patients planned at 13 months. Similarly, the NEVO-III will enroll 1300 US patients in a nonrandomized registry.

6.627.8.1.3. Paclitaxel-eluting DES with biodegradable polymers

- JACTAX™ stent (Boston Scientific, Natick, MA, USA)

The JACTAX™ Liberté PES stent is a stainless steel PES stent, which utilizes a novel abluminal PLA biodegradable polymer, known as the Juxtaposed Abluminal Coating technology (JAC™). This polymer, which is fully resorbed within 6–9 months and controls the release of paclitaxel over 90 days,

has a microdrop structure such that the 16 mm JACTAX™ stent has 2700 microdots, each containing 3.4 ng of polymer (total 9.2 μg, Figure 13). The thickness of the polymer (≤1 μm) is ~18 times less than that found on the TAXUS Liberté stent, while the corresponding polymer mass is 100 times less.

The JACTAX™ stent is currently being evaluated with a coating of either low (LD) or high dose (HD) paclitaxel. The JACTAX HD FIM study[152] has recently reported 9-month clinical and angiographic results among a cohort of 103 patients treated with the JACTAX HD stent, who were compared to 217 historical matched controls treated with the TAXUS Liberté stent from the ATLAS study.[70] The primary endpoint of MACE achieved the prespecified criterion for noninferiority; moreover there were no deaths, Q-wave MIs, or ST during follow-up. Finally, there were also no significant differences in the angiographic endpoints of in-stent late loss (0.33 vs. 0.39 mm, $p = 0.36$) and binary restenosis (5.2% vs. 9.2%, $p = 0.22$).

Clinical evaluation of the JACTAX™ LD stent is currently on-going in the JACTAX LD DES Trial, which is randomizing 130 patients to treatment with either the JACTAX™ LD stent or the TAXUS Liberté stent; the primary endpoint is MACE at 9-month follow-up. Additional studies are planned to evaluate this new polymer technology on different stent platforms including a platinum–chromium alloy (Element™ stent platform, Boston Scientific, Natick, USA) and in combination with everolimus on the JacPro™ stent (Boston Scientific, Natick, USA).[153]

6.627.8.2. Polymer-Free DES

Nonpolymeric stents offer the potential advantages of avoiding the long-term adverse effects of a polymer, improved healing, and an improvement in the integrity of the stent's surface because no polymer is present that can be peeled off the struts. Several different techniques are available to enable drug elution from stents in the absence of a polymer:

(1) The bioactive substance can be directly attached to the stent surface using covalent bonding, or crystallization–chemical precipitation on the stent surface.
(2) The bioactive agent can be dissolved in a nonpolymeric biodegradable carrier on the stent surface.
(3) The bioactive agent in its pure form can be impregnated into the porous surface of the stent, or the stent's body.

A brief over view of the available polymer-free stents is given below.

6.627.8.2.1. BioFreedom biolimus A9-eluting stent

This BioFreedom (Biosensors, Morges, Switerzland) 316L stainless steel stent elutes biolimus A9 without the presence of a polymer. Preclinical studies in the porcine model have reported lower injury scores; fewer struts with fibrin, granulomas, and giant cells; significantly lower percentage diameter stenosis; and greater endothelialization with the BioFreedom stent when compared to SES at 180-day follow-up.[154]

The only clinical trial performed so far enrolled 75 low-risk patients with *de novo* lesions, who were randomized to treatment with either a standard dose BioFreedom stent (15.6 μg mm^{-1}), a low dose BioFreedom stent (7.8 μg mm^{-1}), or a TAXUS PES. At 4-month angiographic follow-up, the in-stent late loss was 0.08, 0.12, and 0.37 mm for the standard dose BioFreedom stent, low dose BioFreedom stent, and TAXUS PES, respectively (Standard dose vs. TAXUS $p < 0.001$; low dose vs. TAXUS $p = 0.002$). At 4-month follow-up, there were no MACE or ST events with either the standard dose BioFreedom stent or the TAXUS PES. Clinical evaluation in larger patient populations is on-going.[155]

6.627.8.2.2. VESTAsyn sirolimus-eluting stent

The VESTAsyn SES (MIV Therapeutics, Atlanta, GA) is a polymer-free stainless stent which has a nanothin, microporous, hydroxyapatite surface coating impregnated with 55-μg dose of sirolimus (Figure 14(a) and 14(b)). Sirolimus is eluted over 90 days, while the hydroxyapatite remains stable over the first 4 months, before completely dissolving around 9–12 months after stent implantation. Preclinical studies indicate that the low dose of sirolimus, which is made possible by the hydroxyapatite platform, results in reduced signs of delayed vascular healing, suggesting less local toxicity, and a faster healing response.[156]

Primary evaluation of the stent took place in the 15 patients of the VESTAsync I FIM study.[157] At 4- and 9-month angiographic follow-up, effective reductions in late loss and intimal hyperplasia were observed, with no evidence of 'late-catch' seen on quantitative coronary angiography (QCA) or IVUS. Up to 3-year follow-up, the only clinic event was a single TLR.[158] Needless to say, randomized trials in more complex patient populations are planned, including the VESTAsyncII study which will enroll 75 patients randomized 3:1 to either

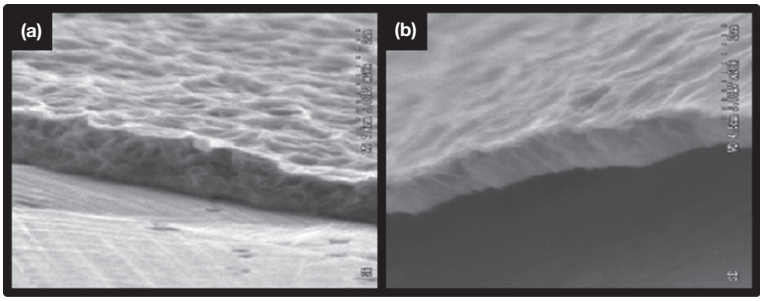

Figure 14 The polymer-free VESTAsyn stents have a (a) rough surface because of their hydroxyapatite coating; however this is (b) smoothed over following the addition of 0.6-μm coating of sirolimus.

the VESTAsyn SES or a control BMS, with a primary endpoint of late loss at 8-month follow-up.[158]

6.627.8.2.3. YUKON: sirolimus-eluting stent

The stainless steel YUKON SES (Translumina, Germany) was the first and consequently now the most extensively studied polymer-free DES. The stent has a microporous surface, with pores that are 2-μm deep and effectively function as a drug reservoir removing the need for a polymer.[159] Uniquely, the dose of sirolimus is customized in the cath lab, just prior to stent implantation, in a coating process taking ~8 min. Initial studies have established that the optimal concentration of rapamycin to prevent restenosis and TLR is 2%.[160]

After complete drug release, the remaining microporous surface appears to favor the adhesion of endothelial cells, a hypothesis initially suggested by angiographic follow-up data,[161] and now confirmed by OCT, which has demonstrated significantly greater neointimal thickening and stent strut coverage with the YUKON stent compared to SES at 3-month follow-up.[162] Clinical studies including both registry and randomized data demonstrate noninferiority of a YUKON stent eluting 2% rapamycin when compared with PES out to 1-year follow-up.[163,164]

Observation data extending out to 2-year follow-up have indicated that the YUKON stent is less susceptible to delayed restenosis than the conventional DES. Of note, Byrne *et al.* reported a significantly lower change in late loss between 6 and 8 months and 2 years for the YUKON stent, when compared with SES and PES (YUKON 0.01 ± 0.42 mm, SES 0.17 ± 0.50 mm, and PES 0.13 ± 0.50 mm, $p < 0.001$).[165] This important finding has also been observed during similar 2-year follow-up of the ISAR-TEST 2 and ISAR-TEST-3 studies, both of which randomized patients to treatment with polymer-free stents, or either conventional polymer or biodegradable polymer DES.[166–169] Collectively these results suggest that polymer-free stents may not be subject to the 'late-catch' phenomenon which has been reported with permanent polymer DES, and appears to be worse in those stents eluting macrocylic lactone derived antiproliferative coatings.[121,170,171]

6.627.8.3. DES Made from New Metal Alloys

Two new DESs, the PROMUS Element and the TAXUS Element (Boston Scientific, Natick, MA), both utilizing a platinum–chromium alloy have recently gained C.E mark approval. This new stent alloy, whose composition is compared to other stent platforms in Table 3, offers several distinct advantages over conventional stent materials. Platinum is two times more dense than iron or cobalt, malleable, corrosion resistant, and fully incorporated into the platinum–chromium alloy. Consequently the platinum–chromium stent offers the advantages of increased radio-opacity and thinner stent struts, which as previously discussed confer distinct advantages in terms of potential reductions in restenosis and improved clinical outcomes (Figure 8);[70–72,96,97] however, these must be balanced with the potential reduction in radial force and increase in acute recoil. However, encouraging initial bench mark studies have indicated that despite thinner struts, the platinum–chromium alloy stent has better radial strength, lower acute recoil, and better vessel conformability compared to conventional stent platforms; Table 4. In addition, rates of uncovered stent struts have been shown to be lower with the Element stent when compared with the stainless steel Liberté and Express stents at 14 days.

6.627.8.3.1. TAXUS element

The TAXUS Element stent (Figure 15) has a poly(styrene-*b*-isobutylene-*b*-styrene) polymer, which facilitates controlled elution of paclitaxel (concentration 1 $\mu g\,mm^{-2}$) in an identical pattern to that seen on the stainless steel TAXUS Liberté and Express stent. The TAXUS Element is currently being assessed in the PERSEUS (A Prospective Evaluation in a Randomized Trial of the Safety and Efficacy of the use of the TAXUS Element Paclitaxel Eluting Coronary Stent System for the Treatment of De Novo Coronary Artery Lesions) clinical trial program, which includes the following features:[172,173]

- The PERSEUS Workhorse trial randomized 1262 patients, with lesions <28-mm long, in vessels between 2.75–4.00 mm in diameter, to treatment with the TAXUS Element ($n = 942$) or the TAXUS Express PES ($n = 320$).[172] At 12-month clinical follow-up, the rate of TVF, the primary endpoint, was Element 5.6% and Express 6.1%, which met the prespecified criterion for noninferiority. The secondary endpoint, percent diameter stenosis at 9-month angiographic follow-up also met the prespecified criterion for noninferiority. In addition, no significant differences were seen between stents with respect to late loss (Element 0.34 ± 0.55 mm vs. Express 0.26 ± 0.52 mm, $p = 0.33$), or other the clinical points such as MACE, mortality, MI, and ST.
- The PERSEUS Small vessel trial compared the TAXUS Element stent to historical BMS controls in patients with

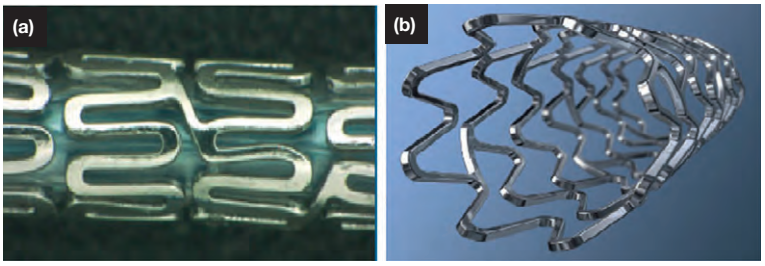

Figure 15 The platinum–chromium Element stent crimped (a) and expanded (b). Courtesy of Boston Scientific, Natick, USA.

lesions which were <20 mm long, in vessels between 2.25–2.75 mm in diameter.[173] Overall, the study enrolled 224 patients treated with the Element stent, who were compared to 125 lesion-matched historical controls treated with a BMS from the TAXUS IV study. Results at 9-month follow-up demonstrated a significantly lower in-stent late loss (the primary endpoint) with the Element stent compared to the BMS stent (0.38 ± 0.51 vs. 0.80 ± 0.53 mm, $p < 0.001$). At 12-month follow-up, the rates of target lesion failure and MACE were both significantly lower with the Element stent, while safety endpoints and ST were comparable between both stents.

6.627.8.3.2. PROMUS element

The PROMUS Element stent has a PBMA primer coating, a PVDF-HFP polymer, and is loaded with 1 μg mm^{-2} of everolimus, 87% of which is eluted within 90 days of stent implantation. No clinical data are available at present; however, the stent is undergoing evaluation in the PLATINUM clinical trial program comprising the following studies:[153]

- The fully enrolled multicenter PLATINUM Workhorse noninferiority study which randomized 1532 patients to treatment with the PROMUS Element or PROMUS Xience V EES stent (Boston Scientific, Natick, M). Results are expected in late 2010.
- The single-arm PLATINUM Small vessel study which will enrol 94 patients with lesions in vessels between 2.25 and 2.5 mm.
- The single-arm PLATINUM Long lesion study which will enrol 102 patients with lesions between 24 and 34 mm in length.
- The single-arm PLATINUM QCA study which will assess QCA in 100 patients at 9-month follow-up.

6.627.8.4. Nitinol Stents

In recent times, there has been increasing interest in the use of nitinol as a platform for coronary stents. Nitinol, which is an alloy of nickel and titanium, has shape memory property, which has resulted in its use in self-expanded coronary stents that have been specifically designed for dedicated coronary lesions such as those in small vessels, those at bifurcations, and those due to vulnerable plaque. In addition, the alloy also has other notable properties which make it favorable for use as a coronary stent platform, namely it is biocompatible, fatigue resistant, and has superelastic properties, which allow it to withstand large amounts of recoverable strain.

Historically, the early stents to be implanted in coronary arteries were self-expanding stents;[7] however, they were eventually replaced by balloon-expandable stents which are currently the preferred type of stents. Of note, self-expanding stents offer important advantages over conventional balloon-expandable stents which include a lower incidence of edge dissections; reduced rates of side-branch occlusion and no-reflow; positive remodeling; and reduced immediate vessel wall injury which may lead to a reduction in neointimal hyperplasia and a larger vessel lumen.[174–176]

Despite these potential advantages, there are some drawbacks of self-expanding stents which are related to their delivery systems and properties:

- *Delivery systems*: Self-expanding stents are housed within a delivery catheter that ensures stent security; however, these catheters can be cumbersome to use, and have an associated learning curve. The delivery profile of these stents is dictated by strut dimensions, as opposed to the balloon profile as in balloon-expandable stents.
- *Mechanical properties*: The continued outward radial force that self-expanding stents exert even after deployment leads to negative chronic recoil, and results in a larger vessel at follow-up. This phenomenon can make matching stent size to vessel size difficult. Secondly, self-expanding stents foreshorten on expansion and/or can move forward because of spring movements when the stent is released from the delivery system; these properties can make accurate placement difficult.

Recently reductions in strut thickness, improvements in delivery systems, and the addition of a drug coating have lead to increased interest in self-expanding stents for the treatment of the following types of lesion.

6.627.8.4.1. Lesions in small vessels

The use of balloon-expandable stents to treat lesions in small diameter coronary arteries is associated with a risk of edge dissection, owing to the high pressures required for optimal stents implantation. Ample evidence exists relating inadequate stent strut apposition, and stent expansion to a subsequent increased risk of restenosis and ST.[134] As stated previously, self-expandable stents offer the advantage of minimizing baro-trauma and the risk of edge dissections, and therefore have a potential role in the treatment of small vessel lesions.

The Cardiomind Sparrow™ (Cardiomind Inc, Sunnyvale, CA) is a small profile nitinol self-expanding stent that is designed specifically for treating lesions in coronary vessels with a diameter of between 2.00 and 2.75 mm (**Figure 16(a)**).

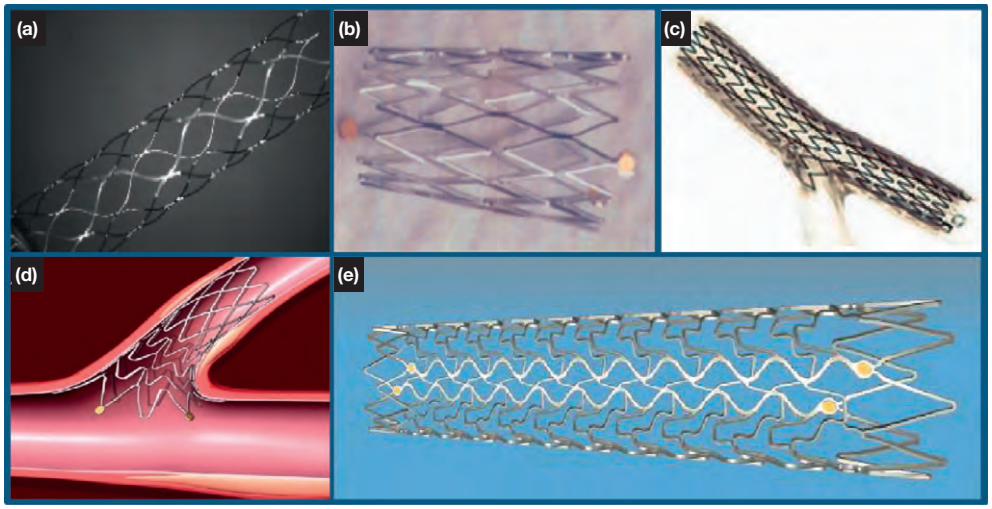

Figure 16 Self-expanding nitinol stents (a) The CardioMind Sparrow stent, (b) Axxess bifurcation stent, (c) Stentys bifurcation stent, (d) Capella side-branch stent, and (e) the vProtect® Luminal Shield stent.

The stent, which has a strut thickness of 61 μm, is preloaded on a 0.014″ guidewire, with 2–3 cm of radio-opaque guidewire at the distal end enabling positioning within the vessel. A dedicated delivery system is used to deploy the stent. The uncoated stent has been assessed in the CARE I feasibility study, which recruited 21 patients with *de novo* lesions in vessels 2.0–2.5 mm in diameter. A 13% rise in the in-stent volume index was observed at 6 months, together with a binary restenosis rate of 20%. There was no ST at 30 days, and two MACE events occurred through to 24-month follow-up. These patients have subsequently been compared to a group of historical controls, treated under the same inclusion and exclusion criteria, but with implantation of a balloon-expandable stent. Results demonstrate a significantly lower in-stent late lumen loss (0.73 vs. 1.11 mm, $p = 0.04$), and intimal hyperplasia volume obstruction (31.9% vs. 39.9%, $p < 0.001$) with the Cardiomind stent.[177,178]

The next-generation Sparrow stent has a strut thickness of 67 μm and is coated with a 4-μm thick layer of sirolimus at a dose of 6 $\mu g\,mm^{-1}$, and an 8-μm thick layer of biodegradable PLA/PGLA polymer. It is currently being assessed in the CARE-II study that will randomize 220 patients with lesions ≤20 mm in length, in vessels between 2.00 and 2.75 mm in diameter to treatment with the bare-metal Cardiomind Sparrow™, the drug coated Cardiomind Sparrow™, or a BMS. Interim results at 8-month follow-up are expected in 2010.[179]

6.627.8.4.2. Lesions in bifurcation

Bifurcation lesions remain a challenging lesion subset for today's interventional cardiologist. Discussion continues over the optimal number of stents to implant and the stenting technique to use; however, the wide anatomical variation in bifurcation lesions suggests that no optimal strategy suitable for all will be established. In view of these ongoing issues, some dedicated bifurcation stents have been developed, some of which utilize nitinol in view of its ability to conform more optimally to angulated coronary anatomy, compared to conventional balloon-expandable stents.[180,181]

The following are three such stents:

- Axxess™ (Devax, Irvine, CA)

This conical nitinol stent has a strut thickness of 152 μm, and is coated with a biodegradable PLA polymer, which degrades over 6–9 months, and release the macrocylic lactone biolimus A9 (Figure 16(b)). The stent is released by withdrawing a covering sheath, and is ideally placed at the level of bifurcation carina, allowing easy access to both distal branches, which can be stented if required. The stent has been assessed in the DIVERGE (Drug-Eluting Stent Intervention for Treating Side Branches Effectively) registry which recruited 302 patients who were followed-up for 9 months. Of note, additional stent implantation was required in 64.7% of patients. At 9-month angiographic follow-up, in-stent late loss was 0.29 mm in both branches, while the rates of binary in-stent restenosis were 2.3% and 4.8% in the main-branch and side-branch, respectively. Clinical event rates at follow-up were low with a rate of MACE of 7.7%, TLR 6.4%, and ST 1%.[182]

- StenTys™ (Stentys, SAS, France)

This paclitaxel-eluting self-expanding stent is made of a z-shaped mesh linked by small interconnections (Figure 16(c)). It consists of a preformed main-branch stent with side ports to facilitate access to the side-branch. Uniquely, the stent struts can be disconnected with the use of an angioplasty balloon; therefore, an opening for the side-branch can be created anywhere in the stent after it is implanted; the disconnected struts can subsequently scaffold the ostium of the side-branch. Evaluation of the stent has been performed in the OPEN (Stentys coronary bifurcation stent system for the percutaneous treatment of *de novo* lesions in native bifurcated coronary arteries) study which enrolled 40 patients and reported a low rate of additional stent implantation (main-branch 9%, side-branch 13%). Angiographic follow-up at 6 months demonstrated a late loss of 0.83 mm and a binary in-stent restenosis rate of 25% and 14% in the main- and side-branch, respectively. The rates of MACE, death, MI, and TLR were 5.1%, 0.0%, 2.5%, and 2.5%, respectively.[183,184]

- Cappella Sideguard™ (Cappella Inc, Auburndale, MA)

This nitinol stent is shaped like a trumpet (Figure 16(d)), to allow excellent conformability to vessel anatomy and is designed for bifurcation lesions with significant side-branch disease. It is implanted in the ostium of the side-branch, and facilitates conventional stent implantation in the main-branch without restriction. The stent has been evaluated in the 93 patient Sideguard I and II FIM studies. Encouraging at 12-month follow-up, angiographic in-stent late loss in this bare-metal stent was 0.21 and 0.58 mm in the main- and side-branch, respectively. With respect to clinical outcomes, the rates of cardiac death were 1.2%, MI 3.6%, and TLR 7.2%.[185,186]

6.627.8.4.3. Lesions due to vulnerable plaque

Data indicate that unstable presentations such as MIs are commonly the result of a disruption of thin-cap fibroatheromas (TCFAs).[187] It follows that preemptive treatment of these lesions involves preventing cap rupture, and promoting endothelialization. The very nature of these thin-cap lesions indicates that the high deployment pressures required for implantation of a balloon-expandable stent are undesired. Advantageously, self-expanding stents do not induce vessel injury during implantation, thereby minimizing the risk of embolizing necrotic material and thrombus distally. In the long-term, the lack of strut penetration into necrotic core may reduce the risk of ST, which may occur through the substantially delayed arterial healing that occurs when struts penetrate necrotic core.[188,189] The vProtect® Luminal Shield (Prescient Medical, Inc., Doylestown, PA) is a self-expanding nitinol stent (Figure 16(e)) which has been shown in animal studies to promote vascular healing, and importantly, achieve complete endothelialization of the stented segment within 7 days.[190] Encouragingly, data from the FIM study has demonstrated that the 'shield' can induce plaque remodeling, and has a positive vascular healing profile as demonstrated on IVUS. The randomized SECRITT I (Santorini Criteria for Investigating and Treating Thin Capped Fibroatheroma Trial) is currently evaluating the safety and feasibility of stenting a vulnerable plaque with the vProtect® Luminal Shield compared with a medically treated, nonstented (control) group.[191]

6.627.9. Less Successful Medications on DES

Apart from the drugs that have made it on to mainstream workhorse DES in catheterization labs around the world and those which are currently being tested, many have been tried with less than satisfactory results. The following are three such examples:

- Tacrolimus

Tacroliumus (FK506) (Figure 5) is a water-insoluble macrolide immunosuppressant produced by *Streptomyces tsukubaensism*, whose drug formulation (Prograf) is commonly used to prevent allograft rejection after organ transplantation. Its inhibitory effect, which is greatest on smooth muscle cells rather than endothelial cells, is mediated by means of its cytostatic effect, holding cells in their G_0 or resting phase.

In the Janus tacrolimus-eluting stent (Sorin Biomedica Cardio, Saluggia, Italy), the drug is embedded in reservoirs on the outer stent surface that allow release of the drug toward the vessel wall only. The stent also has an integrated thromboresistant carbofilm coating the whole stent surface. The largest assessment of the stent took place in the JUPITER-II trial, which randomized 332 patients to treatment with either the Janus tacrolimus-eluting stent or a carbofilm coated BMS. Despite a low frequency of clinical outcomes, which were nevertheless comparable between groups, angiographic results were disappointing, with no significant differences seen in the mean in-stent late lumen loss (tacrolimus-eluting stent 0.65 ± 0.47 vs. BMS 0.66 ± 0.53 mm).[192]

Further studies of DES-eluting tacrolimus include the evaluation of the MAHOROBA stent (Kaneka, Osaka, Japan), which had a cobalt–chromium stent platform and eluted tacrolimus from a bioabsorbable polymer (poly-DL-lactide-coglycolide). In the 47 patient FIM study, a 4-month in-stent late loss of 0.99 ± 0.46 mm and an IVUS determined in-stent % volume obstruction of $34.8 \pm 15.8\%$ reconfirmed the absence of any clinical advantage with use of this drug.[88,89]

- Pimecrolimus

Although pimecrolimus (Figure 5) is part of the 'Limus' family, it does not block mTOR, and therefore it has limited effects that are mediated through an anti-inflammatory action on endothelial proliferation. The FIM study with 15 patients showed a high rate of angiographic restenosis (61%), mean late loss (1.44 mm), and TLR (53%) at 6 months.[193] Further assessment of this drug took place in the ProLimus trial, which evaluated a cobalt–chromium pimecrolimus-eluting stent with a biodegradable polymer. The study enrolled 61 patients with relatively simple coronary lesions and had a MACE rate of 18% at 6 months, which actually achieved the study's primary endpoint of a 6-month MACE rate below 20%. Nevertheless, the late loss was 1.11 ± 0.65 mm, the rate of binary restenosis was 32.7% and the rate of TLR was 32.8%, thereby demonstrating an overall inferior antirestenotic effect of the pimecrolimus stent, compared to results from other established DESs.[194]

Pimecrolimus has also been combined with other antiproliferative agents with the hope that a synergistic effect would ultimately improve its overall neointimal inhibitory effect. The GENESIS trial randomized 246 patients to treatment with the PES CoStar stent ($n = 49$, Conor Medsystems, Menlo Park, CA); the SymBio stent, which eluted a combination of pimecrolimus and paclitaxel ($n = 97$); and the pimecrolimus-eluting Corio stent ($n = 100$).[195] The trial was prematurely suspended with the in-stent late lumen loss being significantly lower with the CoStar compared to either the SymBio or Corio stent (PES 0.58 ± 0.58 mm vs. PES/pimecrolimus 0.96 ± 0.73 mm and PES 0.58 ± 0.58 mm vs. pimecrolimus 1.40 ± 0.67 mm, $p < 0.001$ for both comparisons).

These results were consistent with other studies of the pimecrolimus-eluting stent, and thus are more reflective of the lack of efficacy of pimecrolimus rather than a lack of benefit in the use of dual DESs. Of note, the benefit of dual drug elution has been suggested by results of the ISAR-TEST 3 study, which demonstrated comparable clinical outcomes and a durable antirestenotic efficacy out to 2 years with a polymer-free stent eluting a combination of sirolimus and the antioxidant probucol, when compared to SES and E-ZES.[166,168]

- Estradiols

Experimental studies have suggested that estradiols can improve vascular healing, reduce smooth muscle cell migration and proliferation, and promote local angiogenesis.[196–198] In addition, animal data have indicated that local delivery of estradiol can inhibit neointimal hyperplasia, and also promote endothelial repair and recovery.[199–202]

The feasibility of using 17-β-estradiol to inhibit restenosis in humans was first assessed in the EASTER study, which enrolled 30 patients who received a 17-β-estradiol BiodivYsio (Biocompatibles Ltd., London, UK) stent in a *de novo* coronary lesion. Similar to the preclinical data, results were encouraging with a 6-month in-stent and in-segment late loss of 0.57 and 0.32 mm, respectively, and only one repeat revascularization.[203]

These promising results were further assessed in the ETHOS I study, which randomized 95 patients to treatment with a BMS ($n = 32$), a moderate-release estradiol-eluting stent ($n = 31$), or a slow-release estradiol-eluting stent ($n = 32$).[204] Despite good tolerability of the stent, the study disappointingly demonstrated no advantage from the use of the oestradiol stent over the BMS at 6-month follow-up. In particular, there were no significant differences between the three groups in the intravascular endpoints of neointimal hyperplasia volume, volumetric plaque burden, and in-stent volume obstruction; the angiographic endpoints of in-stent binary restenosis and in-stent late loss; and the clinical endpoints of TLR and MACE.

This lack of benefit from using a 17-β-estradiol-coated stent has been subsequently confirmed in two additional randomized trials.[205,206] Airoldi *et al.* randomized 108 patients to treatment with an estrodiol-eluting stent ($n = 54$) or a phosphorylcholine-coated stent ($n = 54$) and observed no between stent differences with respect to angiographic or clinical outcomes at 1-year follow-up.[206] In the ISAR-PEACE study, which is the largest evaluation of 17-β-estradiol-eluting stents, 508 patients with *de novo* lesions were randomized to treatment with a polymer-free estradiol plus rapamycin stent or a polymer-free rapamycin stent alone.[205] Angiographic follow-up at 6–8 months and clinical follow-up at 12 months failed to demonstrate any advantage with the addition of estradiol to a rapamycin-eluting stent.

6.627.10. Conclusions

Coronary stents have undisputedly revolutionized the treatment of patients with CAD; however, an element of concern remains regarding their long-term safety. In an effort to address some of these concerns, second generation DESs were developed and they have already demonstrated an overall improvement in the outcomes seen with the first generation DESs. Currently, a vast number of new stent designs are being evaluated and only time will tell if these newer stents will lead to further meaningful improvements in clinical outcomes and safety. A step further from stent implantation is the concept of restoring normal vascular function through the use of devices which completely biodegrade. This exciting new concept of completely biodegradable implants is explored in the next chapter.

Glossary

Biocompatibility The biologic compatibility of an implanted material to the host, affected by host responses such as protein adsorption, inflammation, biomechanics, endothelialization, and mesenchymal cell infiltration.

Bioresorbable Pertaining to the incorporation of a material into the native host tissue, mediated by host inflammatory, hydrolytic, and phagocytic mechanisms.

Graft endothelialization The process by which an endothelial monolayer covers a prosthetic surface, secondary to anastomotic ingrowth, transmural angiogenesis, and endothelial progenitor cell deposition.

Heparin-bonded grafts Grafts covalently linked to heparin for the purposes of promoting antithrombotic and antiproliferative effects.

Polyurethane Polymer consisting of a chain of organic units joined by urethane (carbamate) links.

Saphenous vein A major vein of the lower extremity which is commonly used as a conduit for peripheral and coronary bypasses.

Tissue-engineered blood vessel An broad conceptual title for any nonautologous vessel created *ex vivo* or induced *in vivo* using a variety of bioengineering and cell biologic techniques.

Abbreviations

ADP	Adenosine diphosphate
ASA	Acetylsalicylic acid
bFGF	Basic fibroblast growth factor
CABG	Coronary artery bypass graft
DLC	Diamond-like carbon
ePTFE	Expanded polytetrafluoroethylene
EC	Endothelial cell
ECM	Extracellular matrix
EPC	Endothelial progenitor cell
GA	Gluteraldehyde
GP	Glycoprotein
HMG-CoA reductase	3-Hydroxy-3-methylglutaryl-coenzyme A reductase
HUV	Human umbilical vein
ICAM	Intercellular adhesion molecule
IL	Interleukin
LIMA	Left internal mammary artery
LTB4	Leukotriene B4
MB-lectin	Mannose-binding lectin
MMP	Matrix metalloprotease
PAF	Platelet-activating factor
PDGF	Platelet-derived growth factor
PDS	Polydiaxonone
PEG	Polyethylene glycol
PEO	Polyethylene oxide
PET	Polyethylene terepthalate
PG910	Polyglactin 910
PGA	Polyglycolide
PGS	Poly(glycerol sebacate)
PLA	Polylactic acid
PLCA	Polycaprolactone
PLGA	Poly(lactic-*co*-glycolic acid)
PU	Polyurethane
SMC	Smooth muscle cell
TEBV	Tissue-engineered blood vessel
TGF-β	Transforming growth factor-β
TNF	Tumor necrosis factor
uPA	Urokinase-type plasminogen activator
VEGF	Vascular endothelial growth factor
vWF	von Willebrand factor

6.628.1. Introduction

Since their first use in 1906 by Goyanes to repair a popliteal arterial aneurysm, native autogenous vessels have served as the gold standard material in the treatment of many vascular diseases. They function as bypass conduits for aneurysmal defects and stenoses in the peripheral or coronary vascular system, as patches for the closure of arteriotomies or as conduits for the creation of arteriovenous fistulae for patients receiving hemodialysis. However, a significant percentage of patients lack suitable autogenous vessels for use in vascular interventions due to intrinsic vascular disease or because they have been used in previous vascular procedures. For these patients, alternative grafts most commonly comprising synthetic polymers are used. While these have generally been suitable for the bypass of larger vessels, their long-term success in bypasses of arteries of smaller caliber (<4 mm) has been limited. For this reason, strategies that utilize the knowledge of vascular cell biology and injury response, protein and molecular biology, and biomaterials and bioengineering sciences have focused on improving the long-term patency of alternatives to autogenous vessels. This chapter begins with a discussion of the clinical efficacy of autogenous vessels in comparison to the most commonly utilized synthetic materials used in vascular procedures, expanded polytetrafluoroethylene (ePTFE), and polyethylene terepthalate (PET). It then discusses the interactions between the host and the material at circulatory, perivascular, and anastomotic interfaces, which generally account for the inferior performance of currently available synthetic grafts. It concludes with a discussion of some of the strategies employed to improve the long-term efficacy of synthetic grafts by modulating host–biomaterial interactions, including a description of methodologies utilized for the construction of tissue-engineered blood vessels (TEBVs).

6.628.2. Materials Used for Vascular Grafts: Current Clinical Experience

6.628.2.1. Autogenous Vein and Artery: The Gold Standard Material

6.628.2.1.1. Veins

Under most circumstances, native vessels provide for the highest rates of long-term primary patency (continuous patency without any interventions such as angioplasty or rebypass of the graft to maintain patency), secondary patency (patency maintained by a thrombectomy of the graft), and limb salvage. Among the options for harvested autogenous vessels, the greater saphenous vein is the most commonly utilized for both peripheral and coronary vascular applications and provides the standard by which the efficacy of all other materials utilized for peripheral vascular procedures are compared (discussed in Section 6.628.2.2.1).[1,2] In addition to the greater saphenous vein, veins of the upper extremity such as the cephalic and basilic veins have also demonstrated superior

results compared with prosthetics when ipsilateral saphenous veins are not present or suitable. In a study of 740 patients receiving distal bypasses with arm vein versus prosthetic graft, the 3-year primary patency rates for arm vein in femoral to below knee popliteal artery bypasses and femoral to tibial bypasses were 73% and 68%, respectively, while patency rates for prosthetic grafts were 55% and 41%, respectively. Similar benefits were seen in overall limb salvage.[3,4]

Cryogenically preserved allogenic human umbilical veins (HUV) supported by an external polyester mesh were introduced by Dardik as a biological alternative for small caliber vascular bypasses. Interestingly, while being associated with increased graft thrombosis and amputation rates compared to ePTFE and saphenous vein within the first 30 postoperative days, HUV conduits have demonstrated superior patency compared with ePTFE at 5 years.[5,6] Notably, superior patency rates with HUV were dependent on the creation of a distal arteriovenous fistula. Because of concerns related to technical difficulties in handling and suturing HUV and fistula creation, and of potential late degeneration and aneurysm formation, HUV has not presented itself as a viable alternative for vascular reconstructions to most vascular surgeons. As a result of FDA guidelines regarding tissue donor eligibility in response to fears of communicable disease transmission, the manufacture of HUV has all but ceased.[7]

6.628.2.1.2. Arteries

Autogenous arterial grafts such as the left internal mammary artery (LIMA), radial artery, and gastroepiploic artery, most commonly used in coronary revascularization, have also demonstrated success compared to prosthetic grafts, with some evidence of superiority even to saphenous vein in coronary bypasses.[8] Early and recent studies have demonstrated the superiority of the internal mammary artery conduit in comparison with saphenous vein for coronary artery bypass, with 10-year patency rates of 85% versus 61%, respectively, and an increased 20-year survival compared to saphenous vein.[9,10] Excellent patency rates similar to those in the early studies have been demonstrated in radial artery conduits in coronary revascularization of roughly 89%, 93%, and 93% at 4, 7, and 10 years.[11] While, speculative, potential explanations for the superior patency rates of arterial grafts in comparison to vein grafts may be attributable to improved platelet resistance and differential vasoactive responses of the endothelium and arterial media to circulatory mechanical stresses, which may contribute toward limiting the intimal hyperplastic response (discussed below).[12,13]

While the patency of arterial conduits in the coronary vasculature is generally superior or noninferior to the saphenous vein, it is important to note that patency rates are dependent on not only the conduit, but also the target vessel, the side of the vasculature, the timeline of follow-up, the vessel hemodynamic and biomechanical characteristics, and patient comorbidities. Improvements in statin therapy, antiplatelet therapy, and medical management over the last two decades may have improved short-term outcomes of saphenous vein grafts, although randomized trials of long-term efficacy of these drug regimens on coronary graft patency are, surprisingly still lacking.[8,14–16] In addition, the use of the radial and gastroepiploic arteries remains somewhat controversial due to the morbidities associated with radial artery harvest and the technical challenges of gastroepiploic artery harvest, unknown long-term complications and cardiac event-free survival rates, and histologic characteristics, which affect their vasoactivity and competition for blood flow. Thus, radial and gastroepiploic arteries remain secondary choices after the availability of LIMA and saphenous vein conduits has been exhausted.[17–19]

6.628.2.2. Synthetic Grafts

Primarily used in bypasses of the arterial vasculature outside of the coronary vascular system, products comprising ePTFE and PET are most commonly used when suitable autogenous vessels are lacking. Their hydrophobic and crystalline structures prevent hydrolytic degradation, making these products relatively durable for use in bypassing vessels of medium to large caliber such as the aorta. However, due to the lack of an endothelium, the absence of histologic and molecular properties, which minimize platelet adherence and regulate cellular phenotypic characterization, as well as their mismatched compliance profiles in comparison to the native vasculature, these materials are prone to thrombosis and intimal hyperplasia. This section discusses the clinical experience associated with these common materials used for vascular grafts.

6.628.2.2.1. Expanded polytetrafluoroethylene

As indicated by its name, ePTFE is a polymer of carbon and fluorine, which comprise nodes of material connected by fibrils. The extruded material undergoes a forcible expansion, which results in a final structure that is microporous in nature, with most clinically used ePTFE grafts having an average internodal distance of 30 μm. ePTFE is relatively resistant to dilatation and can be implanted without preclotting with blood, its electronegative surface providing some benefits as it acts to minimize its interaction with surrounding tissues *in vivo*.[20]

However, ePTFE is far from inert and induces numerous host responses, and its relative stiffness is likely to exacerbate the intimal hyperplastic response. These characteristics are key contributors to its poor longer term results. The inferiority of ePTFE in comparison to native vessel conduits such as the saphenous vein is most pronounced in the bypass of more distal targets. However, while bypass of the femoral artery to the popliteal artery above the knee with ePTFE has demonstrated comparable rates of patency in comparison to saphenous vein within the first year or two, it is apparent that the intermediate to longer term results of these more proximal bypasses are also less successful. In a study of patients receiving bypass grafts predominantly for claudication, the primary 5-year patency of bypasses from the femoral artery to the popliteal artery above the knee utilizing the saphenous vein was 77.2% versus 57.4% for bypasses utilizing ePTFE.[21] Differences in patency rates for the saphenous vein compared with ePTFE in above knee bypasses were significant as early as 3 years post bypass. The patency for vein bypasses to the popliteal artery below the knee was 64.8% at 5 years, demonstrating the diminishing patency rates even for native vessel conduits for bypasses of greater distances, which cross the

knee articulation. In addition to their greater length and the flexion induced by the knee, these longer bypasses are commonly needed in patients with more advanced disease and are anastomosed to smaller diameter and less healthy recipient arteries. Similar trends were seen in patients in this study who received bypasses for critical ischemia of the lower extremity. These results are consistent with data from other meta-analyses, which demonstrate 5-year patency rates for ePTFE bypasses to the popliteal artery above the knee to be as low as 39% versus 73% for saphenous vein.[5] Long-term results of infrapopliteal bypasses (bypasses to the tibial or peroneal artery) with ePTFE are even less successful. In a meta-analysis of 43 studies, pooled estimates for the 5-year primary patency, secondary patency, and limb salvage rates of infrapopliteal bypasses with ePTFE were 30.5%, 39.7%, and 55.7%, respectively.[22]

Alterations in the geometric structure of ePTFE grafts with an interpositioned vein cuff at the site of the anastomosis has been reported to improve graft patency and the intimal hyperplastic response.[23] These results are theoretically attributable to the presence of a venous endothelium at the anastomosis, improved vein compliance, and the creation of a larger anastomosis. The literature provides little clarification on the mechanisms of this effect. Interestingly, animal studies have suggested that alterations of anastomosis hemodynamics may not account for these improved results.[24] While previous evidence in animals had suggested that cuffing grafts with ePTFE did not improve graft patency, early results of clinical trials of precuffed ePTFE vascular grafts have demonstrated 1-year primary patency, secondary patency, and limb salvage rates for below knee popliteal bypasses of 83.5%, 94.7%, and 94.4%, respectively.[25–27] This may suggest that hemodynamic modifications secondary to the increased size of the anastomosis may indeed account for improvements in graft patency. Longer-term results are required to further elucidate the efficacy and mechanisms of venous and synthetic graft cuffs on bypass patency.

6.628.2.2.2. Polyethylene terepthalate

First introduced in the 1930s and patented by Dupont as Dacron in 1950, PET has become a staple in peripheral vascular reconstructions most commonly involving the aorta. It is a polyester fiber that is available in both woven and knitted conformations. While the multifilament over and under weave of the woven PET limits its porosity, the knitted conformation introduced by Debakey allows for a more porous structure, which is thought to augment tissue incorporation and vascular healing.[28] In order to minimize extravasation of blood through the pores, the increased porosity of knitted PET has required the use of extracellular matrix (ECM) coatings such as gelatin, albumin, or collagen, or a preclotting period with blood prior to implantation in order to fill the interstices with fibrin clot.[20] Additionally, the velour finish of knitted grafts, which add loops of yarn at right angles to the surface of the graft, is thought to promote tissue integration by increasing the surface area for the binding of cells and the surrounding tissue and fibrin coagulum. Whether these theoretical advantages have made any significant impact on the clinical patency of PET grafts is unclear.

While knitted PET has been suggested to be prone to dilatation, the clinical implications have not been commonly observed in practice. With this exception, few clinically significant differences among the different formulations of PET and ePTFE have been demonstrated. One randomized control trial comparing the patency of knitted gelatin-coated PET, knitted collagen-coated PET, and ePTFE demonstrated patency rates of 77%, 78%, and 79%, respectively at 8 years for aortoiliac bypasses.[29] Similarly, PET and ePTFE demonstrate comparable patency rates to one another when used for femoro-femoral, axillo-femoral, or femoro-popliteal bypasses.[30–32] This said, due to cost considerations, easier handling, and surgeon habit, the standard use of PET has been reserved for aortic reconstructions, while ePTFE remains the material of choice for infrainguinal bypasses.

6.628.2.2.3. Endovascular surgery

Increasingly, endovascular treatments such as balloon angioplasty of stenotic lesions have been utilized as therapeutic strategies for peripheral vascular disease. The recent BASIL trial compared amputation-free survival in patients receiving balloon angioplasty versus surgery for infrainguinal stenoses with a mean follow-up of 5.5 years.[33] Among other conclusions, the study suggested that balloon angioplasty may be superior to prosthetic grafts in relation to amputation-free survival, especially in patients not expected to live beyond 2 years. More recently, self-expanding stent-grafts, primarily comprising a nitinol (a Ni–Ti alloy) stent supported by ePTFE, are being placed in conjunction with balloon angioplasty. The utilization of metal alloys with polymeric substances is likely to complicate the host response to these endovascular procedures. Studies comparing the results of such strategies to the long-term patency rates of standard synthetic grafts implanted by the open approach are ongoing and have become an area of intense study. A recent randomized control trial of 100 limbs in 86 patients was performed to compare the performance of stent-grafts to above knee surgical bypass with synthetic grafts for superficial femoral artery occlusive disease.[34] The stent-graft group demonstrated a primary patency of 81%, 72%, and 63% while the surgical group demonstrated a primary patency of 84%, 77%, and 64% at 6, 12, and 24 months, respectively ($p = 0.716$). The secondary patency rates were also not significantly different. Importantly, while patency rates between less severe versus more severe occlusive lesions at 24 months did not significantly differ in either of the two treatment groups, there was a trend toward improved outcomes in higher severity lesions when treated with fem-pop bypass with synthetic graft versus angioplasty and stent-graft (67% vs. 47%, respectively, for primary patency rates). Longer term and larger trials are required to determine if this is a true difference and how the long-term patency of stent-grafts compare with both synthetic and autogenous conduits.

In addition to infrainguinal bypasses, endovascular approaches to aortic reconstructions with aortic stent-grafts are becoming increasingly common and preferred in anatomically appropriate cases. A detailed review of these important methods is beyond the scope of this chapter; however, excellent reviews can be found in the literature.[35]

To summarize, while proponents of endovascular approaches point to potential benefits such as minimization of time in the operating room, less invasive wounds, reductions in procedural morbidity and mortality, and reduced costs and lengths

of stay, further data on long-term patency rates, limb salvage, mortality, morbidity, and health-care costs are necessary to determine the optimal treatment choice.

6.628.3. Host Responses to Implanted Biomaterials

After implantation into the host, vascular devices initiate blood–material and tissue–material interfacial processes, which are a constellation of normal adaptive responses to vascular injury and foreign devices. These processes begin almost immediately upon establishment of circulatory flow and continue over time based on the specific nanostructural and chemical properties of the biomaterials that comprise the device.

The histology of the native vessel comprises a quiescent endothelial monolayer, a basement membrane, internal elastic lamina, a vasoactive arterial media comprised primarily of smooth muscle cells (SMCs), collagen and elastin, the external elastic lamina, and the adventitia. (**Figure 1**) Synthetic grafts used to bypass vessels of smaller diameters are prone to failure in large part due to the absence of these native histologic features, which are critical to the long-term durability of autogenous native vessel conduits. Specifically, a quiescent endothelium provides for antithrombogenic properties, proper mechanotransduction of shear stresses and cyclic strain from pulsatile bloodflow in part by nitric oxide synthase signaling, and limited SMC proliferation rates. Quiescent SMCs, in turn, allow for proper cell–ECM interactions, which respond to mechanical and chemical stimuli to remodel the matrix and provide proper vessel compliance and elasticity. In the absence of such dynamic histologic functionality in most commonly utilized synthetic vascular grafts, host responses such as protein adsorption, platelet deposition and fibrin coagulum formation, inflammation, and mesenchymal cell infiltration are left unchecked and, consequently, often lead to graft thrombosis and intimal hyperplasia.

Strategies such as the systemic delivery of pharmacotherapeutic agents, the development of new or surface modified biomaterials, and the engineering of biological alternatives that possess the components of the native vasculature are all aimed at minimizing the injurious host responses at the material–circulation and material–tissue interfaces. This section discusses in detail the host responses to implanted biomaterials in the context of common vascular graft biomaterials. This is followed by a discussion of current and potential future advances aimed at improving the outcomes of vascular reconstructions in patients lacking autogenous conduits by modulating these host responses.

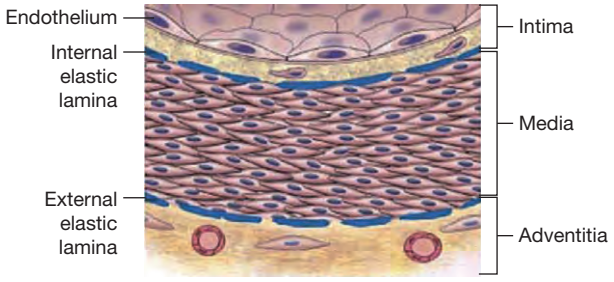

Figure 1 Representation of the vessel. Reproduced from Brewster, L. P.; Brey, E. M.; Greisler, H. P. *Adv. Drug Deliv. Rev.* **2006**, *58*, 604–629, with permission from Elsevier.

6.628.3.1. Host–Material Interfacial Processes

6.628.3.1.1. Protein adsorption

Almost immediately after the establishment of circulatory flow, protein adsorption to the biomaterial surfaces occurs in a manner dependent on both the intrinsic properties of the material itself and the concentration and diffusion coefficients of blood proteins. Thus, the most abundant and mobile proteins such as albumin, IgG, LDL, HDL, fibrinogen, and others are among the earliest adsorbed to the graft surfaces. Over the next 30–60 min after establishment of flow, however, protein adsorption continues on the biomaterial surface as determined by the Vroman effect.[36] This is characterized by the dynamic interchange between proteins initially adsorbed on the biomaterial surface with higher affinity proteins whose binding properties are dependent on their intrinsic 3D conformational and electrochemical properties, as well as the nanostructural irregularity and electrochemical activity of the biomaterial itself.[37]

Protein–surface interactions after adsorption can further alter the surface properties of the biomaterials, actively modulate the deposition of platelets, inflammatory cells, and coagulation cascade proteins, or alter the structure of the adsorbed proteins themselves. Atomic force microscopic analysis of fibrinogen bound to titanium (Ti), for example, has demonstrated alterations in the conformation of bound fibrinogen in comparison to unbound fibrinogen.[38] Such altered structural conformations of bound proteins demonstrate the specificity of protein interactions with the composition of the biomaterial, and may suggest a proximate mechanism for the way in which specific biomaterials can differentially activate downstream host responses.

6.628.3.1.2. Platelet deposition

The tendency of biomaterials to adhere platelets and promote their aggregation and activation prior to fibrin coagulum formation is a critical component with respect to the biocompatibility of vascular grafts. Clearly, thrombus formation not only leads to acute graft failures as seen in conduit thromboses, but also serves as a scaffold for mesenchymal and inflammatory cell infiltration prior to the formation of atherosclerotic plaques and intimal hyperplastic lesions.

After intimal injury, platelet adherence *in vivo* occurs via binding of the platelet surface glycoprotein (GP) receptor complexes to exposed subendothelial ECM proteins such as collagen or von Willebrand factor (vWF) bound to collagen.[39] The interaction between these glycoproteins with vWF bound to the exposed subendothelium or to endothelial cell (EC) surfaces activates platelets and causes the release of α-granule products such as fibrinogen, β-thromboglobulin, thrombospondin, vWF and fibronectin, and increases the local concentrations of serotonin, epinephrine, and adenosine diphosphate (ADP), among others. This degranulation serves to propagate platelet aggregation and activation. The formation of the prothrombinase complex on activated platelets mediated by the extrinsic coagulation pathway facilitates thrombin formation and subsequent fibrin generation.[39] Other factors released,

including platelet-derived growth factor (PDGF), platelet factor 4, and thromboxane A2, act to further modulate the subsequent inflammatory response, as well the mesenchymal cell infiltrative response.

The impact of these glycoproteins on the direct adherence of platelets to specific biomaterial surfaces remains unclear. However, the interaction of GPIIb/IIIa with the adsorbed RGD peptide sequences of fibrinogen and fibronectin appears to be an important mediator of platelet deposition onto artificial surfaces, and there is evidence of a direct correlation of fibrinogen adsorption to platelet adherence.[37,40–42] In addition, fiberoptic analyses have demonstrated wide variability in platelet adherence to several synthetic and metallic biomaterials, with woven polymeric PET demonstrating the greatest amount after 5 min in an *ex vivo* perfusion system.[43] Genetic expression patterns of platelets circulating in *ex vivo* flow systems containing tantalum stents demonstrate increased expression of CD62p (P-selectin) and CD63 expression within a few minutes of perfusion compared to platelets circulating in systems without stents, pointing to the universality of this problem as regards many biomaterials.[44]

Platelet deposition contributes to graft failure not only by the formation of an occlusive or lumen narrowing thrombus, but also by the induction of potential alterations in drug release kinetics from drug carrying polymer coatings as utilized in drug-eluting stents in both peripheral and coronary endovascular procedures. Drug deposition within developed thrombi have been shown to alter local drug concentrations, which may have the effect of limiting or increasing their bioavailability and efficacy.[45]

6.628.3.1.3. Inflammation and immunology

The inflammatory and immunologic responses to implanted vascular grafts can lead to direct tissue damage mediated by leukocytes and their released products, and may contribute to the initiation, remodeling, and progression of intimal hyperplasia.

The activation of complement is a key component of the innate immune response, which occurs via the classical pathway mediated by antigen or C1q binding to antigen, the alternative pathway mediated by activated complement components binding directly to the foreign body surface, or the mannose binding (MB)-lectin pathway. Biomaterials activate complement primarily via the classical and alternative pathway, and the degree of complement activation appears to be dependent on the type of biomaterial used. Complement activation assayed by C5a generation has been shown to be significantly greater in patients with implanted PET compared to ePTFE via the classical pathway as well as the alternative pathway.[46] All complement pathways converge on the formation of C3 convertase, which catalyzes downstream cleavages and generation of C5a, C3b, C3a, and other products, which have effector functions that include peptide mediation of inflammation, phagocyte and other leukocyte recruitment, and opsonization.[47–49] Thus the activation of complement can have significant downstream effects by propagating inflammation, inducing anaphylactoid reactions, and potentially promoting graft thromboses.[50,51]

In response to complement activation and generated C5a, leukotriene B4 (LTB4), platelet activating factor (PAF) and other chemokines, and deposited fibrin coagulum, neutrophils are recruited early in inflammation and produce products of oxygen metabolism and proteases that contribute to tissue and biomaterial injury. If an endothelium is present, neutrophil integrin receptors and sulfated sialyl-Lewis receptors bind to EC intercellular adhesion molecules (ICAM) and P- and E-selectins. The demonstration that pyrolytic carbon does not induce expression of these adhesion proteins on ECs has suggested its potential utility as a coating for PET synthetic prostheses.[52] It is important to note, however, that factors present *in vivo* modulate EC and neutrophil interactions on the biomaterial surface. These include products of platelet degranulation, complement activation, and macrophage activation, such as interleukin-1 (IL-1), tumor necrosis factor (TNF), LTB4, PAF, and C5a, which have been demonstrated to increase adhesiveness between neutrophils and ECs, and these are likely to serve to promote leukocyte adherence to the endothelium either surrounding the graft or growing on the graft.[53–55]

Macrophages, which are either resident in the tissues or derived from circulating monocytes, also comprise part of the early response to vascular grafts. Monocytes are recruited to implanted grafts by numerous chemokines and macrophage recruiting mediators from various sources including the regenerating endothelium, and platelets and other macrophages, as well by the fibrin coagulum and complement products.[53,56–63] These activated macrophages produce inflammatory mediators such as IL-1, TNF, and others, which propagate the host response to wound healing, the reaction to foreign materials, and the remodeling of pseudointimal and atherosclerotic plaques on the surface of grafts. The materials themselves may also induce inflammatory reactions as evidenced by the PET-mediated induction of TGF-β release by macrophages, an effect that may alter EC proliferation rates and modulate the healing and injury response after bypass.[64]

Dendritic cells and other antigen presenting cells link the innate immunologic response to the antigen specific and T cell-mediated adaptive response. The role of specific T cell responses to implanted biomaterials is still unclear.[65] Emerging literature, however, has explored the role of biomaterial surfaces as enhancers of adaptive immunity and investigated the role of biomaterials on dendritic cell maturation and phenotype.[66] Similarly, the role of regulatory T cells in the response to vascular graft implantation remains largely unknown.

6.628.3.1.4. Endothelialization

A quiescent endothelial monolayer provides a nonthrombogenic and mechanotransductive surface, which is thought to be critical to the prevention of synthetic SMC activity that leads to the intimal hyperplastic response after vascular injury (**Figure 2**).[67] However, this effect is partially dependent on the phenotypic characterization of the endothelium, as an endothelium activated by injury may function to promote thrombosis or intimal hyperplasia by the upregulation and release of adhesion receptors, vWF, tissue factor, endothelin-1, PDGF, and other EC products.[68,69]

It is likely that the inability of humans to promptly generate a functional endothelium and establish normal histological archeology in the coronary and peripheral vascular system after graft implantation or intravascular intervention impacts the long-term patency of synthetic vascular grafts.[70]

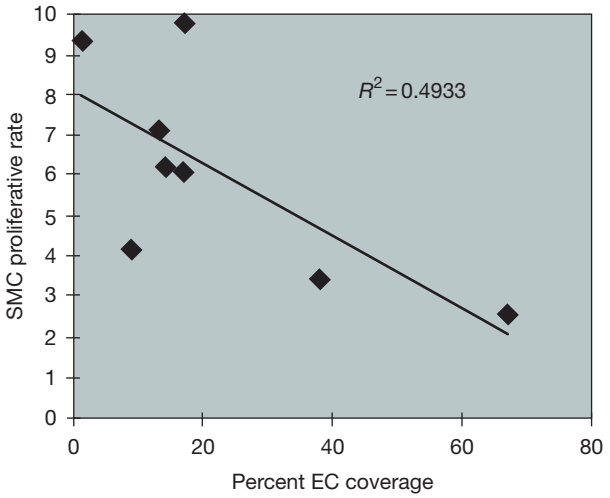

Figure 2 Smooth muscle cell proliferation, showing decreases with increased percent of reendothelialization *in vivo* using a canine carotid artery balloon angioplasty model. Reproduced from Zarge, J. I.; Huang, P.; Husak, V.; *et al*. *J. Vasc. Surg.* **1997**, 25, 840–848; discussion 848–849, with permission from Elsevier.

This phenomenon is not simply a function of insufficient EC proliferation, as the cessation of EC ingrowth ~1–3 cm from the edges of vascular anastomoses is seen even in the presence of elevated EC mitotic activity at these points on standard ePTFE grafts (30 μm internodal distance).[71–73] Interestingly, the utilization of more porous ePTFE (60 μm internodal distance) has been associated with increased EC coverage of the grafts in some animal models, probably as a result of transmural angiogenic mechanisms.[72,74–77] Thus, the endothelialization of vascular grafts is a function of spontaneous transanastomotic endothelial pannus ingrowth, angiogenic mechanisms, and, probably, the deposition and differentiation of endothelial progenitor cells (EPCs) onto the deendothelialized surface within the circulation.

While the specific effects of particular biomaterials on EC proliferation, turnover, and functionality, remain confusing, with the existence of a variety of contradictory studies, sufficient literature does suggest that EC–biomaterial interactions in general contribute to the biocompatibility of vascular grafts.[69] For example, one study compared the production of prostacylin, an inhibitor of platelet aggregation, by the endothelium generated *in vivo* on polyglactin 910 (PG910), PET, and polydiaxonone (PDS) grafts that had been interposed into rabbit aortas and later explanted and perfused under *ex vivo* flow conditions. After 1 month, the endothelium generated on PDS and PG 910 demonstrated significantly less prostacyclin production in response to arachidonic acid compared to normal aorta, while prostacyclin production by the endothelium of PET did not differ from normal aorta. By 3 months, all groups demonstrated prostacylin production equal to normal aorta.[78] How the apparent delay in normal endothelial function affects the long-term patency of the implanted material is a critical question as patency exceeded 90% in all groups up to 6 months. However, the increased incidence of atherosclerosis, thrombosis, and intima/media ratios in prostacyclin receptor knockout mice suggests that it is probably an important factor in synthetic graft longevity.[79]

Additionally, biomaterials may induce the release of growth factors from ECs, which can modulate mesenchymal cell mitogenesis and the subsequent intimal hyperplastic response. For example, *in vitro* data has demonstrated that PET induces release of the SMC mitogen basic fibroblast growth factor (bFGF) by ECs.[80] In addition, inflammatory and other cells in contact with specific biomaterials may modulate EC growth on vascular grafts. For example, macrophages cultured in the presence of PET have been shown to release greater amounts of TGF-β compared to macrophages cultured in the absence of biomaterial,[64] a significant observation as TGF-β may inhibit angiogenesis *in vitro*,[81] and stimulate the recruitment of inflammatory cells *in vivo*.

6.628.3.1.5. Mesenchymal cell infiltration

The infiltration of SMCs, fibroblasts, and cardiomyocytes onto the luminal surface of implanted grafts in the peripheral and coronary vasculature is an early event in the development of intimal hyperplasia, which is the primary cause of intermediate-term failures of vascular interventions utilizing both stents and bypass conduits.[1,82–85] The intimal hyperplastic response and formation of plaques are the pathologic consequences of the body's healing response either to iatrogenic injuries to the established endothelium and vascular tissue acquired during interventions or to implanted tissues, which lack the normal architecture of vascular tissue.[86–90] The injury response to angioplasty exemplifies the pathogenesis of intimal hyperplasia, which is common to the process in all vascular implants. The response to injury starts early, with a conversion of a subpopulation of SMCs from a 'contractile' to a 'synthetic' phenotype during the first 24 h after injury. These synthetically active SMCs demonstrate an increased responsiveness to mitogenic and chemotactic factors such as PDGF and FGF secreted in part by activated platelets and ECs, and have an increased ability to secrete their own growth factors when in the active cell cycle.[91,92] Observations that SMCs and fibroblasts from thrombosed vein grafts demonstrate higher proliferation rates in response to PDGF-BB and are more resistant to heparin-mediated attenuation of proliferation suggest the importance of these specific subpopulations of mesenchymal cells.[93] Indeed, a prospective study of SMCs harvested from vein segments used as conduits for revascularization in patients found that SMCs taken from veins that went on to develop graft failure were relatively less responsive *in vitro* to the antiproliferative effects of heparin.[94]

Thus, SMCs migrate and proliferate, and invade from the arterial media to the disrupted intraluminal area of injury, resulting in the formation of a 'pseudointima' within the first couple of weeks after injury. Over the next several weeks to months, continued synthetic behavior by SMCs contributes to the deposition of ECM proteins and further propagation and remodeling of the intraluminal pseudointimal lesion. After 2–3 months, in contrast to the earlier synthetic behavior, 'contractile' SMCs may contribute to the restenotic process by inducing contractile properties on the arterial wall, inducing further vessel narrowing by inward remodeling, which leads ultimately to an occlusive lesion.[95] Thus, while the initial synthetic response leads to the development and remodeling

of the pseudointimal lesion, both 'synthetic' and 'contractile' SMCs are likely to contribute to the eventual failure of angioplasty. While the utilization of stents and synthetic grafts in endovascular or open surgical approaches can serve to minimize the inward remodeling process due to their relative rigidity, stents and grafts are still prone to the formation of the initial restenotic pseudointimal hyperplastic lesions as a result of the injury response. Thus a significant factor in the long-term patency of any implanted vascular device is its ability to minimize this injury response.

6.628.3.1.6. Biomechanics

Circulatory shear stresses and cyclic strains impact the biocompatibility of vascular grafts almost immediately after the establishment of flow. These external mechanical factors interact with material surfaces and significantly impact cell signaling responses, SMC and EC phenotypic changes, and alterations in mitotic indices and cytoskeletal reorganizations. For example, direct comparisons of platelet activation by coated or uncoated stainless steel stents have demonstrated that the thrombogenicity profiles of these materials were significantly dependent on the flow patterns to which they were exposed.[96] Similarly, rates of shear stress can affect platelet content on vascular grafts. Higher rates of shear may increase platelet deposition on bypass conduits, but they may also cause dislodgment of adherent platelets depending on the amount of time that the high shear rates are maintained.[97] Similar results have been demonstrated on various metallic alloys such as titanium (Ti) and diamond-like carbon (DLC).[43]

Local hemodynamic conditions also significantly affect EC phenotypic behavior including cellular alignment and mitotic index.[98–101] Increased EC pinocytosis and prostacyclin production under both pulsatile and steady shear conditions, and increased endothelin production under low shear[102–104] can have significant effects on the healing, thrombotic, and endothelial regenerative processes, which are thought to modulate graft patency. In addition, flow related shear stresses impact the efficacy of cell seeding strategies utilized in the development of tissue-engineered or biohybrid grafts (discussed below). Rotational shear stresses (both high and low rates) have been shown to induce significant EC desquamation from fibronectin-coated ePTFE grafts in an *ex vivo* flow system.[105] Hydrogel coatings containing ECs in cell seeding experiments have demonstrated improved EC retention rates in response to pulsatile *ex vivo* flow compared to fibronectin-coated grafts.[106]

The biomechanical effects of circulatory flow are translated to the cellular level according to the intrinsic biomechanical and viscoelastic properties of the vascular implants themselves. Thus, the compliance and elasticity of various biomaterials can significantly impact the phenotypic and proliferative properties of vascular cells adherent to the surface or involved in the healing response. In one study, two composite partially bioresorbable PG910/polypropylene aortic grafts differing only in their nonresorbable polypropylene elasticity properties were implanted in rabbits. By 1–2 months, the PG910 component was bioresorbed, and the differential mechanical properties of the explanted prostheses/tissue complexes in each of the groups were determined by the elastic property of the remaining nonresorbed polypropylene. Cell proliferation rates within the inner capsule of the aortic graft was significantly higher at later time points in the higher compliance grafts, and this correlated with increased inner capsule thickness. These results demonstrate the apparent relationship between cellular activity and the intrinsic deformative properties of biomaterials implanted in circulatory flow conditions.[107]

6.628.4. Improving Clinical Outcomes and Future Concepts

The phenomena of protein adsorption, platelet deposition and thrombogenesis, graft endothelialization, and inflammatory and mesenchymal cell injury responses described above affect the long-term patency and efficacy of grafts and stent-grafts. Several systemic and locally applied strategies to modulate these processes have been investigated more recently in conjunction with tissue engineering strategies, in order to improve the long-term efficacy of current and investigational biomaterials. The following is a discussion of these strategies.

6.628.4.1. Systemic Pharmacotherapy

With the exception of anatomic limitations to the adequacy of inflow or outflow of revascularization targets, the thrombotic and restenotic failures of vascular grafts are local manifestations of the systemic processes, described above, that have long been targeted by systemic pharmacologic therapy. These include the use of warfarin, antiplatelet medications such as aspirin, clopidogrel, and dipyridamole, ACE inhibitors, statins and others.[108,109]

6.628.4.1.1. Acetylsalicylic acid

One of the oldest and most ubiquitous medications, acetylsalicylic acid, or aspirin (ASA), is a staple of therapy in patients with peripheral and coronary vascular disease. Its efficacy, as well as the currently less commonly used dipyridamole, in improving the outcomes of coronary and peripheral open and endovascular revascularizations is also well established. Early studies after coronary artery bypass grafting (CABG) demonstrated that ASA administration started prior to CABG significantly improved the early patency rates of saphenous vein grafts.[110] A large overview of 60 randomized trials including ~8000 patients demonstrated that ASA or ASA with dipyridamole significantly improved graft patency in all vascular interventions including coronary artery grafts, coronary angioplasty, peripheral arterial bypasses, and hemodialysis shunts or fistulae.[111] In addition, there was a significant reduction of ~25% in the risk of having a 'vascular event,' defined as nonfatal myocardial infarction, nonfatal stroke, or vascular death. In this and other studies, there appears to be no significant difference in the effects of ASA on vascular occlusion if the regimen is started before operation or soon after.[112] Of note, benefits of ASA or dipyridamole on coronary graft patency have not been demonstrated in studies where treatment was initiated 3 or more days after operation,[113,114] while some studies have suggested increased intraoperative bleeding and perioperative blood transfusion requirements in patients receiving ASA preoperatively.[115]

Interestingly, more recent systematic reviews of the literature and randomized control trials have brought into question some of the conclusions of these earlier studies. These studies have suggested that the efficacy of ASA in infrainguinal bypass patency is more pronounced in patients receiving synthetic bypass grafts, with less clear benefits in patients receiving vein grafts.[116–118] However, most consensus statements still recommend antiplatelet therapy with ASA soon after operation for its likely benefits on the patency of at least some bypasses, improvements in patient morbidity and mortality, and generally low complication and side effect profile.[119] Similar benefits are seen in peripheral arterial endovascular procedures utilizing percutaneous angioplasty with one meta-analysis demonstrating ~60% reductions in all endovascular restenoses up to 12 months postprocedure in patients who started an antiplatelet regimen including ASA prior to the procedure.[120] The use of stents in these cases was limited and further studies evaluating these effects with newer generation stents are warranted.

6.628.4.1.2. Clopidogrel

Recently, newer antiplatelet medications such as clopidogrel which target GPIIb/IIIA receptor activation and platelet aggregation by interfering with cell surface ADP receptors have been investigated in various outcome studies comparing ASA alone with ASA with clopidogrel. The benefits of this therapy in improving graft patency is unclear. A recent trial comparing clopidogrel alone to combination therapy with clopidogrel and ASA did not demonstrate any significant differences in patency rates for LIMA or saphenous vein grafts at 1 or 12 months after coronary artery bypass.[14] The role of combination therapy or monotherapy in the prevention of prosthetic graft thrombosis or restenosis in open and in endovascular peripheral interventions is even less clear. A study that demonstrated that ASA alone does not sufficiently attenuate arachidonic acid-induced platelet aggregation longer than 5 postoperative days after CABG suggests that alternate medications may be beneficial, at least in some cases.[121] For example, one study demonstrated that in patients who have postoperative thrombocytosis, combination therapy with ASA and clopidogrel may have increased benefits compared with ASA alone in maintaining CABG patency.[122] The potential for increased hemorrhagic complications should be seriously considered when evaluating the literature on clopidogrel and similar medications. The utilization of targeted approaches with systemic therapy such as the fusion of platelet integrin receptor (GPIIb/IIIa) ligands to antiplatelet drugs may have some benefit in minimizing systemic complications.[123]

6.628.4.1.3. Statins

Statins, which are a broad family of drugs that lower cholesterol by inhibiting HMG-CoA reductase, have a clear role in reducing hypercholesterolemia and cardiac mortality. In addition to this important benefit, their utility in preventing vascular graft failure has been suggested by some studies.[124] One such study, which analyzed 338 infrainguinal bypasses demonstrated that statin drug use was an independent factor associated with increased graft patency up to 17 months.[125] Further analyses on the effects of statin therapy on autogenous and synthetic graft primary and secondary patency, and limb salvage are needed.

6.628.4.1.4. Warfarin

Data on the efficacy of anticoagulation with vitamin K antagonists are less conclusive for most arterial bypasses. However, a recent meta-analysis demonstrated that the use of anticoagulation with vitamin K antagonists may provide more benefit in venous bypass graft patency compared with ASA therapy.[126] Benefits of vitamin K antagonists in comparison to ASA in prosthetic graft patency, however, were not demonstrated in this study. Separate studies with similar endpoints have found conflicting results, suggesting that, overall, those with prosthetic bypasses benefited from therapeutic levels of warfarin therapy.[127] The conflicting results exemplified by these studies, and the risks of fatal intracranial hemorrhages, higher transfusion requirements, as well as other minor bleeding events associated with the combinatorial use of warfarin with ASA, has led to the general practice of consideration of use of warfarin only in patients with high risk infrainguinal bypasses.[108,128]

6.628.4.2. Coating and Surface Modification

The coating of synthetic grafts with various synthetic and natural polymers, hydrogels, and ECM proteins, is a strategy that allows for the local delivery of drug, cell, and gene therapy. The utilization of bioresorbable polymer coatings as seen in newer generation drug-eluting stents further allows for the release or delivery of the therapeutic agent of interest while minimizing the long-term consequences of foreign material reactions. The following section discusses several past, current, and investigational graft coating and surface modification strategies that have been studied.

6.628.4.2.1. Surface passivation

The coating of grafts with several natural and synthetic materials alters the active binding sites on graft surfaces, and modifies the electrochemical and hydrophobic properties that contribute to protein and cell adhesion to biomaterial surfaces. For example, carbon coating of ePTFE vascular grafts has been shown to decrease surface thrombogenicity due to its negative charge and hydrophobic nature, and demonstrated reduced platelet deposition on graft surfaces.[129] Histologic assessment of several graft materials in a carotid artery patch model in sheep has suggested that the intimal hyperplastic response in fluoropassivated PET and carbon-lined ePTFE was reduced in comparison to gelatin-coated PET.[130] Specific semiconductive properties of amorphous silicon carbide and magnesium alloy, novel biomaterials utilized to coat metallic stent surfaces, have been shown to be associated with lower rates of platelet adhesion, platelet activation, and fibrin formation compared to uncoated stainless steel stents.[131] The use of albumin as a graft coating material, while demonstrating some encouraging results preliminarily, did not translate to clear benefits in improved graft patencies when applied clinically.[132]

More recent attempts to coat graft surfaces with synthetic hydrogels and polymers that are relatively resistant to cell and protein attachment offer a new potential direction for this strategy. Polyethylene glycol (PEG), otherwise known as polyethylene oxide (PEO), has been used for surface modification because of its relative hydrophilicity, flexibility, nontoxicity,

and nonimmunogenicity,[133] and has been demonstrated to reduce both protein and platelet adhesion when coated onto hydrophobic surfaces.[134] These effects may be dose-dependent, however, as higher concentrations of PEG coatings on ePTFE have demonstrated increases in surface platelet adhesion, in addition to increased albumin adsorption and decreased fibrinogen adsorption.[135] Sulfonated PEO-grafted polyurethane (PU) (PU-PEO-SO(3)) was used to coat PU vascular grafts and was found to have beneficial effects on surface platelet adhesion and thrombosis in a canine model.[136] To date, however, the benefits of many of these passivation strategies in the absence of other therapeutic interventions remain unclear after translation into the clinical realm.[133] Interactions among inflammatory, immunologic, and protein and cell adhesion effects of PEG and other such materials may be critical to their potential benefits as nonthrombogenic coating surfaces.[50]

6.628.4.2.2. Heparin-bonding

The modification of graft surfaces with the antithrombotic agent heparin has been an attractive strategy in improving graft patency. Early studies in animals demonstrated its utility in decreasing thrombogenesis and thromboembolic events and improving graft patency.[137138] In addition to its antithrombotic effects, which can mitigate immediate thrombus formation after graft implantation and alter the ECM of the early pseudointima, observations that heparin modulates SMC protease expression, proliferation, and migration rates after arterial injury may also suggest that it inhibits the intimal hyperplastic response.[139] In one study using a baboon aortoiliac bypass model, heparin-coated ePTFE grafts demonstrated decreased acute platelet deposition, as well as decreased perianastomotic pseudointimal proliferation and reduced pseudointimal area 4 weeks after implantation compared to controls.[140]

In our lab, silyl-heparin adsorbed onto a carbon-coated ePTFE graft in a canine aortoiliac bypass demonstrated significantly less platelet adherence, acutely with a trend toward longer term (7 days) reductions in platelet adherence and improved graft patency in the heparin-coated grafts.[141] Of note, 8% of preimplantation heparin activity was found to be active after 2 h, and only 2% of preimplantation activity remained at 7 days. Interestingly, the utilization of PEG hydrogels as a cross-linking agent for silyl-heparin bonding of ePTFE grafts led to significant differences in aggregated long-term graft patencies versus uncoated controls (7 days and 30 days), as well as a significant reduction in platelet deposition and intraluminal thrombus formation as far as 30 days after implantation versus controls.[142] Heparin activity in this group at 7 days was ~5% of preimplant heparin activity, and was present as late as 30 days postimplantation. The quantitative roles of increased heparin activity versus the potential passivation of the surface by PEG in the improved long-term patency results are not clear. More recent studies have investigated modalities of altering heparin release kinetics from PEG-DA (diacrylate) hydrogels in order to affect SMC synthetic activity.[143] By modifying both PEG-DA molecular weights and concentrations, optimal release kinetics led to a reduction in SMC proliferation rates and the upregulation of contractile markers associated with lower levels of synthetic activity. Controlled release strategies such as this can improve future formulations of heparin-bonded or releasing grafts.

Recent clinical investigations have begun to evaluate the patency rates of heparin-bonded ePTFE grafts. One year results of the PEPE II trial demonstrated patency rates of 83% in femoro-above knee popliteal bypasses for heparin-bonded ePTFE grafts, and the 1 year primary patency rates of 74% and 79% in femoro-below knee popliteal and femoro-infrapopliteal bypasses, respectively, were encouraging.[144] Another study of 350 patients demonstrated 92% primary patency rates for both above and below knee femoro-popliteal bypass and 79% for femoro-infrapopliteal bypasses at 1 year with heparin-bonded ePTFE.[145] Similarly encouraging results were found at 2 years with 83% primary patency rates for both femoro-above and below knee popliteal bypasses and 69% for femoro-infrapopliteal bypasses. Patency rates of heparin-bonded grafts at each time point were not significantly different from those of bypasses with autogenous saphenous vein. Other studies have demonstrated comparable results after 2 years follow-up.[146–148] Longer-term results have suggested that heparin-bonding may provide its most significant benefits for use in infragenicular bypass procedures compared to uncoated ePTFE 2–3 years after implantation. A recent study demonstrated ~71% primary patency rates at 3 and 4 years for femoro-below knee popliteal bypasses and ~50% patency at 5 years for femoro-infrapopliteal bypasses.[149] Clinical investigations, which have shown that implantation of heparin-bonded ePTFE grafts for lower extremity bypass is not associated with any markers of systemic alterations in hemostasis or antiheparin antibodies up to 6 weeks after implantation, suggest that these grafts have a good systemic biocompatibility.[150] Further randomized head-to-head trials comparing graft patency and limb salvage to uncoated grafts and autogenous saphenous vein in infrainguinal bypasses may be warranted. In addition, while ePTFE is the predominant graft of choice for infrainguinal bypasses, studies that have shown significantly improved primary patency rates in heparin-bonded PET compared to uncoated ePTFE at 3 years and near significant improvements at 5 years (46% vs. 35% for heparin-bonded PET vs. ePTFE, respectively; $p < 0.055$) suggest that direct comparisons between heparin-bonded PET and heparin-bonded ePTFE may be warranted.[151]

6.628.4.2.3. Graft endothelialization

For reasons discussed earlier, the induction of endothelialization on biomaterial blood-contacting surfaces is thought to be critical to establishing the long-term biocompatibility of vascular grafts. Early observations in animal models suggested that ePTFE grafts with larger pore sizes (60 μm internodal distance) compared with standard ePTFE (30 μm internodal distance) demonstrated increased EC coverage on the luminal surface. This has led to the general belief that a significant component of vascular endothelialization results from transmural angiogenic mechanisms, which consequently seed the luminal surface of the graft.[72,74–77] Increased porosity, while likely beneficial in promoting endothelialization, has also been shown to decrease the compliance of implanted grafts by promoting fibrovascular infiltration into the wall of both PET and ePTFE.[72,77] Thus, the dual effects of graft pore size on both mechanical biocompatibility and vascular healing capacity may or may not work in concert to improve graft performance.

Alternative strategies that can augment more rapid graft endothelialization in available and investigational prostheses

may prove useful.[20,152] These strategies can be broadly separated into two categories: (1) the *in vivo* augmentation of transmural angiogenesis, spontaneous anastomotic endothelialization, and EPC incorporation utilizing locally or systemically delivered drugs such as angiogenic growth factors[153–156]; and (2) the seeding of ECs or EPCs onto the graft surface via natural and synthetic polymeric coatings with or without adjunctive angiogenic growth factors prior to implantation.[157–160]

A fairly large body of investigational literature has focused on the utilization of hydrogels and polymers as drug delivery vehicles for the purpose of promoting angiogenic ingrowth and endothelialization. One group demonstrated that bFGF delivered from a gelatin coating on porous polyurethane grafts implanted in rats provided for improved endothelialization when compared with controls.[161] In our lab, ePTFE grafts (60 μm intermodal distances) coated with fibrin glue containing FGF-1 and heparin were placed in infrarenal aortas of rabbits. At 28 days, grafts treated with fibrin containing FGF-1 demonstrated extensive transmural capillary infiltration, seen neither in untreated controls, nor in controls treated with fibrin devoid of FGF-1.[162] This strategy, however, can be tempered by the nonspecific effects of growth factors or polymers in inducing SMC or fibroblastic infiltration and an intimal hyperplastic response. In other studies, the delivery of angiogenic growth factors has resulted in poor rates of endothelialization. For example, one group found that while fibrin delivery of vascular endothelial growth factor (VEGF) after carotid artery injury in a porcine model did not affect patency or endothelialization, treatment with fibrin, in the presence or absence of VEGF, resulted unexpectedly in an increased narrowing at the proximal anastomosis, an increased SMC infiltration, and intimal hyperplasia compared to controls.[163] These deleterious effects may be a consequence of the prothrombotic or prointimal hyperplastic effects of fibrin and/or a direct or indirect activation of SMC activity by VEGF.[164,165] Strategies that can improve graft endothelialization while minimizing these unwanted side effects are under investigation. *In vitro* observations that FGF-1 and 500 U ml of heparin released from fibrin hydrogels increase EC proliferation while decreasing SMC proliferation may provide one avenue for improvement.[166] Our lab has investigated the use of designer FGF-1-derived growth factors, created by site-directed mutagenesis, which possess some characteristics that are more clinically advantageous compared to wild-type FGF-1. These include relative thrombin resistance for improving bioavailability, heparin independence, and relative EC specificity.[167–172]

It is important to note that while *in vitro* data may initially prove promising, interactions between cell, drug, biomaterial, and host responses may affect the activity or the release kinetics of the therapeutic agent once implanted. bFGF has been found to bind specifically to fibrinogen and fibrin, impacting its release kinetics from fibrin-based drug delivery coatings and subsequent drug activity.[173] Indeed, it has been shown that the binding of bFGF to fibrinogen can affect the expression of EC urokinase-type plasminogen activator (u-PA), an important mediator of angiogenesis.[174,175] Strategies that try to control for drug release kinetics and cell–drug–polymer interactions may provide for more predictable host responses *in vivo*. The covalent binding of VEGF to fibrin or PEG hydrogels modified to contain tethering sites for the growth factor allows for cell-demanded matrix degradation and drug release, which have appeared to lead to more normal appearing microvasculatures *in vivo*.[176,177] The fusion of collagen binding domains to growth factors or designer growth factors can similarly improve bioavailability and cell-demanded drug release for utilization in collagen hydrogel delivery systems.[153] Thus, proper control of drug release kinetics is likely to be a critical element in hydrogel or polymer-based graft coating systems that aim to induce graft endothelialization by inducing transmural angiogenesis.

In contrast to the *in vivo* induction of graft endothelialization, the seeding of synthetic vascular grafts with ECs prior to implantation can be advantageous as it does not rely on the capacity of the host tissue to endothelialize the surface. Animal studies have provided hope for the efficacy of this strategy. Autologous ECs embedded within fibrin glue containing both FGF-1 and heparin were locally delivered to canine carotid arteries after balloon angioplasty. Carotid arteries treated with ECs in the fibrin glue demonstrated decreased pseudointimal formation at 30 days following procedure, in comparison to controls (**Figure 3**).[67]

A primary challenge of cell seeding strategies is preventing the loss of seeded ECs after exposure to physiologic shear

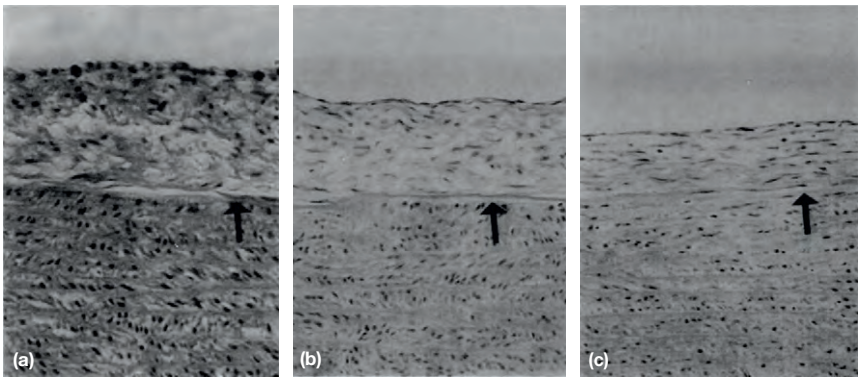

Figure 3 H&E photomicrographs of longitudinal sections of balloon-injured canine carotid arteries (Mag., 25×). Note the decreased pseudointimal formation in balloon-injured carotid artery treated with FG/FGF-1/heparin plus endothelial cell. Arrows indicate internal elastic lamina. Reproduced from Zarge, J. I.; Huang, P.; Husak, V.; *et al*. *J. Vasc. Surg*. **1997**, 25, 840–848; discussion 848–849.

stresses within the circulation. Numerous strategies have been employed to address this limitation. The coating of graft surfaces with various adhesion peptides, ECM proteins, and hydrogels is one such strategy. Coating of endovascular stents and vascular grafts with fibronectin and poly-L-lysine, or linking integrin ligand peptide sequences such as RGDV and YIGSR to polymeric coatings can significantly increase EC adhesiveness under both static and dynamic flow conditions.[154,178–181] The utility of RGD and heparin coatings, both alone and in combination, has been demonstrated on poly(carbonate-urea) urethane grafts, with significantly improved EC retention after stringent washings.[182] ePTFE covalently linked to fibronectin either via gluteraldehyde (GA) or sulfosuccinimidyl-4-(*p*-maleimidophenyl) butyrate (SMPB) has been shown to be significantly more effective in promoting cellular adhesion compared to uncoated ePTFE.[183] Increases in cell adhesion seen in fibronectin–GA-linked grafts compared to fibronectin–SPMB-linked graft groups were attributable to increased availability of RGD binding sites in the fibronectin–GA group.

Many other strategies for improving EC adhesion and growth on biomaterial surfaces have also been studied. These include the alteration of electrochemical surface properties by the implantation of negative silver ions,[184] coating of surfaces with a polyamino-acid urethane copolymer,[185] and cross linking of bFGF to collagen matrices.[186] The utilization of fibrin-based composite matrices as a coating with growth factors has also been shown to support the differentiation of seeded EPCs to nitric oxide-producing ECs on coated ePTFE and PET.[187]

As in methodologies used for *in vivo* tissue induction, strategies that augment *ex vivo* EC seeding and growth may be limited by nonspecific effects on other circulatory or vascular cells, which limit graft biocompatibility. Thus, cell specificity in cell adhesion strategies is desirable in promoting endothelialization while limiting the deposition of platelets or the adhesion of migrated SMCs onto the graft surface after implantation of the graft *in vivo*. REDV, another fibronectin peptide sequence, has been demonstrated *in vitro* to be relatively specific for EC adhesion, perhaps attributable to $\alpha 4\beta 1$ integrin receptors, which have been shown to be present on ECs, but not on platelets.[188–190] In addition, while increasing EC adhesiveness by surface modification may be beneficial in improving graft endothelialization, it has also been found that increasing adhesiveness to material surfaces can attenuate endogenous ECM production by SMCs, ECs, and fibroblasts, which may be required for proper tissue formation in tissue engineering strategies.[191]

Recently, long-term results of endothelialized ePTFE grafts used clinically as infrainguinal bypass conduits were reported. ECs were harvested from autologous subcutaneous veins and seeded onto grafts with a fibrin glue. 153 above knee femoro-popliteal, 155 below knee femoro-popliteal, and 33 femoro-infrapopliteal bypasses were performed with EC-coated ePTFE grafts.[192] Five-year patency rates were found to be 68% and 71% for femoro-above knee popliteal and femoro-below knee popliteal bypasses, respectively, and 61%, overall, at 10 years (59% and 64% for above knee and below knee, respectively). Fifty-two and thirty-six percent patency rates were seen in femoro-infrapopliteal bypasses at 5 and 10 years, respectively. While it was not possible to know the source of ECs because of the study design, explanted grafts after graft failure did demonstrate the presence of an endothelium on the lumens of the grafts. These results are encouraging, as they demonstrate the availability of autogenous ECs for graft seeding, and the feasibility of the strategy, as well as the apparent efficacy in comparison to historic controls. Further investigations into the functionality of autogenous ECs harvested from diabetic and vasculopathic patient populations, as well as improvements in cell harvest, culture, and seeding techniques are likely to promote the widespread use of this strategy in peripheral and coronary vascular procedures. Randomized control trials directly comparing endothelialized synthetic grafts versus uncoated grafts would provide further evidence as to the efficacy of this strategy.

6.628.4.2.4. Drug-eluting stents and graft

New generations of drug-eluting stents and grafts are being commonly used in the coronary vasculature; and they are also being investigated for use in the peripheral circulation. Although a thorough review of drug-eluting stents and grafts is beyond the scope of this chapter, it is to be noted that the delivery of numerous drug families, which aim at minimizing graft thrombogenicity, intimal hyperplasia, and inflammation from polymer coatings have been tested. In the peripheral vasculature, sirolimus-eluting polyurethane-based grafts used for arteriovenous fistulae in hemodialysis, patients have demonstrated encouraging, albeit nonsignificant, early benefits in improving stenosis secondary to intimal hyperplasia.[193] Polyurethane grafts with a polymer coating containing nitric oxide have demonstrated improved thromboresistance and patency compared to controls in limited animal studies,[194] and the delivery of nitric oxide from polyurethane-based polymers has been demonstrated in some studies to decrease platelet adhesion and SMC proliferation, and increase endothelialization.[195] Recent studies that evaluated the release of monoclonal antibodies targeted at GPIIb/IIIa platelet receptors from L-polylactic acid (L-PLA)-coated stents demonstrated a decreased platelet uptake compared to bare nitinol stent controls, highlighting a potential for the future utilization of monoclonal antibody therapy in the next generation intravascular prostheses.[196] New generations of investigational stents and grafts that utilize bioresorbable polymers to deliver therapeutic agents are becoming increasingly attractive for the minimization of the longer term responses to the foreign body (discussed below).

6.628.4.3. Optimization of Biomechanical Biocompatibility

The relative noncompliance of available synthetic grafts is thought to be one of the key factors in their propensity for inducing the intimal hyperplastic response.[152] For this reason, the development of synthetic polymers with more elastomeric properties has generated interest in order to improve compliance mismatches between native vessels and anastomosed grafts.[197] This is exemplified by synthetic polyurethanes. Comprising three monomeric components including a hard domain diisocyanate, a chain extender, and a soft domain (commonly polyol), polyurethanes provide flexibility and strength profiles dependent on the relative percentage of the polymer in each of its monomeric units.

While early attempts at utilizing polyurethane as a vascular graft demonstrated a good biocompatibility for infragenicular bypasses, unacceptable occlusion rates and reports of hydrolytic instability of poly(ester) and poly(ether) urethanes has limited its clinical use.[198–200] Newer generation grafts made of poly(carbonate)-based PUs have demonstrated improved hydrolytic and oxidative stability due to the elimination of ether linkages.[201] In addition to their more compliant characteristics, observations in rats that poly(carbonate)-based PUs appear to demonstrate earlier endothelialization and reduced intimal hyperplasia compared to ePTFE may offer another potential advantage to PU as a graft material.[202]

Polyetherurethaneurea-based PUs have been tested clinically as vascular access grafts for patients receiving hemodialysis. A comparison between PU grafts and ePTFE grafts used for hemodialysis access demonstrated that patency rates for polyurethane grafts did not differ significantly from patency rates of ePTFE grafts (44% vs. 36% primary patency rates at 12 months for PU vs. ePTFE grafts, respectively).[203,204] Similarly, 2-year patency rates of PU grafts are comparable to ePTFE.[205,206] However, due to the manufacture of PU grafts with pore sizes of 15 μm, these 'self-sealing' grafts have offered the advantage of earlier access because of the increased rates of hemostasis early after cannulation compared with ePTFE. Notably, a more recent study has demonstrated that while primary patency rates were equivalent between the PU-based grafts and brachial artery–basilic vein fistulae, achieving equivalent secondary patency rates necessitated an increased graft surveillance and endovascular procedures in PU-based grafts.[207] The authors of this study have cautioned that the need for a more vigilant surveillance and the increased risk of graft infections should be balanced with the benefits of earlier access when choosing PU-based hemodialysis grafts.

6.628.5. Gene Therapy

While progress in the field of gene therapy in medicine and cardiovascular disease has been slow in general, the strategic genetic modification of host cells that respond to vascular grafts or of cells seeded in or on tissue-engineered constructs provides theoretical opportunities for improving the biocompatibility of vascular grafts.[208] Adenoviral delivery of β-interferon has been demonstrated to decrease SMC proliferation *in vitro* and to reduce the intima/media ratio *in vivo* in a porcine balloon injury artery model.[209] The overexpression of endothelial nitric oxide synthase (eNOS) by intraluminal viral delivery in vein grafts has limited the intimal hyperplastic response in an animal model, though the mechanism of this effect was not clear.[210] Interesting results in a carotid artery injury model in rabbits demonstrated that EPC transplantation onto the luminal surface of injured arteries improved endothelialization rates and the neointimal hyperplastic response.[211] Further, the transplantation of EPCs transduced *ex vivo* with eNOS further reduced the intimal hyperplastic response after injury. The utility of polymers as gene delivery vehicles offers an exciting path for future investigations.[212,213] One study demonstrated that the coating of metallic stents with hydrogels carrying naked plasmid DNA encoding VEGF accelerated endothelialization of the stents in a rabbit balloon angioplasty model.[214]

Clinical applications have to this point been limited. However, the finding that the inhibition of the transcription factor E2F with transfected decoy oligodeoxynucleotides using therapeutic ultrasound minimized neointimal formation in a rat carotid artery injury model has offered hope.[215] However, clinical results in humans in both peripheral and coronary revascularizations have appeared to be less promising than predicted from the preclinical animal studies.[216,217]

6.628.6. Tissue-Engineered Blood Vessels

Vascular tissue engineering is a somewhat amorphous field that utilizes knowledge of vascular biology to engineer tissues resembling native vascular structures. The investigational concepts in the creation of a TEBV are founded on molecular and cellular biology, biomaterials science, bioengineering, and clinical sciences. The following section presents a focused discussion on the basic concepts and strategies involved in the creation of a TEBV.

6.628.6.1. General Concepts

While the methodologies described in the literature for the development of a TEBV can seem infinitely variable, they are founded on one ultimate goal: the organization of a structure comprising cells and ECM that mimics the biological functionalities of a native blood vessel, including mechanotransduction and vasoactivity and the maintenance of vessel wall and hemodynamic homeostasis. The way these structures are cellularized, the methodologies and materials used to construct or direct the deposition of ECM, and the strategies used to allow for the proper cell–matrix interactions requisite to the aforementioned biological functionalities are theoretically endless. However, as introduced in the section discussing graft endothelialization, the broad strategic categories include (1) the implantation of cells, materials, and drugs *in vivo*, utilizing the host body as a living bioreactor, which formulates the final structure after implantation; (2) the complete creation of a biological blood vessel *ex vivo* prior to implantation; or (3) a combination of both strategies. The sourcing of the cellular component, the materials utilized as scaffolds or drug delivery vehicles, and the nature of the genetic and protein level manipulations are fundamental and exciting territories in the field of tissue engineering. In addition, due to the advent of bioresorbable materials, the engineering of blood vessels from bioresorbable polymers, which incorporate entirely into the host tissue as a result of normal vascular healing, has become a possibility. The following discussion focuses on hydrogel-based TEBVs, self-assembled TEBVs, bioresorbable TEBVs, and TEBVs constructed from decellularized vessels.

6.628.6.2. Hydrogel-Based TEBVs

Natural hydrogel polymers such as fibrin, collagen, alginate, hyaluronan, as well as synthetic hydrogels such as PEG and polyvinyl alcohol are commonly used in tissue engineering as scaffolds or components of scaffolds for TEBVs.[218] The first credited attempt at the creation of a TEBV by Weinberg and Bell in 1986 utilized a collagen hydrogel scaffold constructed

as a tubular structure with layers of ECs, SMCs, and fibroblasts.[219] While poor burst strengths, a common limitation to hydrogel-based TEBVs, necessitated the use of sleeves comprising PET for mechanical support, these investigators demonstrated the feasibility of TEBV creation utilizing hydrogels as scaffolds.

Fibrin has also been utilized as a scaffold for TEBVs and has demonstrated its own advantages and disadvantages. In comparison to collagen hydrogels, fibrin has been found to promote an increased native collagen production by entrapped fibroblasts and SMCs, suggesting its ability to support the matrix remodeling processes involved in host tissue incorporation after implantation.[220] The presence of deposited elastin in fibrin hydrogels as compared to collagen hydrogels also suggests beneficial effects on cell-mediated matrix remodeling processes, which affect construct biomechanics.[221,222] Implantation of fibrin-based TEBVs into lamb external jugular veins demonstrated endogenous collagen and elastin deposition by SMCs in the arterial media, which orientated circumferentially in a direction perpendicular to the circulatory blood flow.[223] Interestingly, these TEBVs gained mechanical strength and vasoactivity comparable to that of native blood vessels after 15 weeks *in vivo*. Fibrin-coated vascular prostheses have been evaluated in animal models for coronary artery bypass.[224] While early results were encouraging, with patency up to 12–22 days, thrombus formation and platelet deposition as well as degradation of the hydrogel after the first 2 weeks limited the efficacy of these prostheses. As in collagen-based constructs, the mechanical strength of fibrin-based TEBVs in general remains a significant limitation and often requires the use of synthetic polymers, such as a polyvinylidene fluoride mesh, to improve their mechanical stability.[225]

Several modifications to hydrogel-based TEBVs have been developed in order to improve the mechanical strength of the constructs. These include chemical modifications that regulate the degradation of the hydrogel matrix, induce the cellular deposition of endogenous matrix proteins such as collagens and elastins, and promote covalent cross-linking among ECM fibers. For example, mechanical properties of fibrin-based TEBVs can be modified by the addition of plasmin inhibitors such as aprotinin, cross-linking agents such as Factor VIII, and media supplements such as insulin and TGF-β, which induce endogenous matrix deposition by embedded cells.[226,227] The use of media supplements such as retinoic acid and ascorbic acid has been shown to promote SMC elastin and collagen mRNA and protein expression within type I collagen tubular constructs.[228] This was associated with an increased TEBV tensile strength and a decreased stiffness compared to untreated TEBVs. Finally, TEBVs can be constructed in layers varied by the composition of the ECM and cellular component, with each layer performing separate functions. For example, fibrin-based TEBVs with an inner layer containing a lower concentration of fibrinogen to support SMC vasoactivity, and an outer cell-free layer comprising a higher concentration of fibrinogen for mechanical stability demonstrated significantly improved burst strengths compared to single layer constructs while maintaining vasoreactivity.[229]

Mechanical preconditioning with cyclic strain bioreactors has also been efficacious in improving the structural integrity of hydrogel-based TEBVs. In collagen-based constructs, this has been shown to be attributable in part to the modulation of cell and matrix organization, as well to the alteration of the expression of matrix metalloproteases (MMPs).[230,231] Recent studies have also demonstrated that the application of incremental cyclic distention from 5 to 15% significantly improved tensile strength, tensile modulus, and collagen deposition per cell in fibrin-based TEBVs.[232] In addition, a direct comparison of the mechanics of fibrin, collagen, and fibrin–collagen TEBVs showed that the mechanical properties of the TEBV were dependent not only on the application of mechanical strain, but also on the composition of the hydrogel scaffold.[233] Linear modulus was directly associated with collagen content, and gel compaction, which was associated with improved tensile strength, was augmented by the addition of fibrin. This study also found that cyclic mechanical strain not only augmented the tensile strength and gel compaction of collagen–fibrin TEBVs, but also decreased cellular proliferation. The effects of mechanical strain on cellular phenotype are further exemplified by increased levels of vWF, nitric oxide, SMC α-actin, and SMC myosin heavy chain in mechanically conditioned collagen/PLGA TEBVs containing ECs and SMCs compared with statically cultured TEBVs.[234] In addition, this study demonstrated that mechanical strain affected cellular orientation, with embedded cells aligning radially in mechanically conditioned TEBVs in contrast to the random alignment of statically cultured TEBVs.

6.628.6.3. Bioresorbable TEBVs

Bioresorbable materials can serve as temporary scaffolds for vascular prostheses, which incorporate into the native tissue, or as polymeric vehicles from which drugs can be eluted with controlled kinetics. Implanted devices comprising these materials, such as drug-eluting stents, can serve their functional purpose for the time it is required and then histologically 'disappear,' theoretically minimizing the long-term inflammatory and injury responses, and the potential for graft infection. As a scaffold for a TEBV, bioresorbable materials can serve as 'smart' materials that are modified to promote native tissue infiltration after implantation. Knowledge of the resorption kinetics of specific bioresorbable materials based on the intrinsic properties of the materials being used is critical to controlling host–material interactions, which lead to tissue incorporation.[235–238] The study of the histologic, immunologic, inflammatory, and other biologic mediators, which modulate the resorption kinetics of these biomaterials, is a field of intense study and should serve to provide optimal polymer constructs both for TEBV creation and for the delivery of drugs to interventional sites.

The conceptual utility of these biomaterials has been acknowledged for some time. Early studies with polyglycolic acid (PGA) demonstrated its regenerative capacity in comparison to PET. PGA prostheses implanted into rabbit aortas were found to have significantly more intramural and luminal surface myofibroblastic and endothelial cellular infiltration in comparison to PET.[239,240] Similarly, grafts of PDS and polyglactin 910 (PG910) demonstrated mesenchymal and EC infiltration, and even small amounts of PET woven into or around the absorbable polymer inhibited this process.[241] In addition, the rates of collagen deposition in both PG910 and PDS grafts were greater than that of PET, and appeared to parallel the

kinetics of cellular proliferation, tissue thickening, and the resorption of PG910 and PDS grafts.[242,243] Coincident mesenchymal cell infiltration with macrophage-mediated degradation of the bioresorbable material suggested the association of the two processes, and implied that the differential cellularization capacity of bioresorbable materials is, at least in part, attributable to their susceptibility to macrophage-mediated degradation.[76] This is consistent with *in vitro* data, which demonstrated that media conditioned by macrophages cultured in the presence of PG910 were significantly more mitogenic for ECs compared with negative controls or media conditioned by macrophages cultured in the presence of PET. In fact, media conditioned by macrophages cultured in the presence of PET did not demonstrate any significant EC mitogenicity compared with negative controls.[61,244] Thus, while inflammatory and mesenchymal cell infiltrative processes may be detrimental to the long-term biocompatibility of vascular grafts, they are also likely to be beneficial in the incorporation of bioresorbable vascular grafts. This highlights the importance of developing proper methodologies for the regulation of the kinetics and magnitude of these processes in order to fully realize the advantages and benefits of these materials.

While these early studies were encouraging, the increased prosthetic compliance coincident with endogenous cell repopulation potentially compromised the biomechanical biocompatibility of these TEBVs.[245] At 6–36 weeks postimplantation, the compliance of distal and proximal sections of PG910 grafts was found to be greater than that of midportions of the grafts, with compliance increasing significantly over time in the proximal portion of the grafts, and nonsignificantly in other portions. These changes were preceded by myofibroblastic changes and macrophage-mediated phagocytosis, suggesting that the histologic changes preceded the changes in graft biomechanics. Thus the cellular response to the materials probably affects significant consequences, which may lead to the undesirable sequelae of aneurysm formation and longer-term compliance mismatches.[245]

Several strategies have been employed in order to impart more strength to bioresorbable TEBVs. Altering the components of grafts by adding nonresorbable or more slowly resorbable materials is one such strategy.[246] At explantation, compounded resorbable PG910 and nonresorbable polypropylene grafts implanted in rabbits were found to withstand burst pressures exceeding those of perianastomotic native aorta, and no aneurysms were found up to the latest explant time point of 2 months.[247] Of note, only the nonresorbable polypropylene was present after 2 months. Biochemical and histologic data were suggestive of a functioning endothelium at the time of explant. Partially bioresorbable grafts comprising PG910/polypropylene or PDS/polypropylene were implanted into a canine model for up to 1 year and compared to PET or ePTFE controls.[248] Over the 1 year period, combined patency rates of partially bioresorbable grafts were significantly greater than those of nonresorbable grafts. Additionally, no aneurysms were found in any of the explanted grafts. Increased inner capsule EC and myofibroblastic infiltration and collagen deposition paralleled the kinetics of material resorption. The observation that varying the elasticity of the polyprolene component of PG910/polyprolene bicomponent grafts impacts the extent of cell infiltration and matrix deposition highlights the importance of the biomechanical contribution of the nonresorbable material to cellular activity.[107] Interestingly, it was shown that increased inner capsule mitotic index and thickness correlated with graft formulations with greater compliance.

Other bicomponent bioresorbable and partially bioresorbable grafts have also been investigated. PGA/polyhydroxyalkanoate copolymeric scaffolds with and without seeded carotid artery ovine cells were implanted into the aortas of lambs.[249] While all acellular polymeric graft controls were occluded by 5 months, TEBVs demonstrated 100% patency, no aneurysm formation, collagen levels and elastin content similar to those of native aorta, and vWF positive ECs along the luminal surface. More recently, investigators utilized a tubular scaffold comprising an inner and outer porous polylacticglycolic acid (PLGA) layer with a polyurethane layer in between.[250] They were seeded with bone marrow stromal cells (BMSCs) and, after a 7-day culture period, they were implanted into canine abdominal aortas. The results of the study did not demonstrate any dilatation up to 3 months after implantation. Additionally, α-SMA and VWF staining cells and collagen were seen in the grafts at explants, and the burst strengths of the explants were approximately the equivalent of 1200 mmHg.

The addition of mechanical conditioning may further augment the mechanical biocompatibility of bioresorbable grafts. The implantation of a TEBV comprising a PGA scaffold and endogenous collagen deposited by seeded SMCs into swine demonstrated the feasibility of the creation of a suturable construct that can withstand physiologic pressures *in vivo* after a period of mechanical preconditioning in bioreactors *in vitro*.[251] More recently, a TEBV was constructed by the incorporation of a bioresorbable macroporous poly(L/D)lactide 96/4 mesh into the wall of a fibrin-based graft containing SMCs and fibroblasts. The constructs were seeded with ECs and then made to undergo a 21-day mechanical conditioning period in a dynamic strain bioreactor.[252] In this model, while cell proliferation and endogenous collagen deposition increased within the wall during the conditioning period, the graft demonstrated burst strengths capable of withstanding supraphysiologic pressures.

One caveat to the selection of materials that increase construct burst strength, however, is that the differential compliance characteristics of various materials may lead to stiffer constructs without adequate compliance. This can affect the intimal hyperplastic response and the long-term durability of the TEBVs. Additionally, the components of the scaffold matrix can affect the deposition of elastin, the critical ECM component affecting elasticity, within the TEBV from seeded cells. One study compared the viscoelastic properties of bioresorbable TEBVs composed of either rigid PLGA or elastomeric poly (glycerol sebacate) (PGS).[253] It was shown that while the addition of SMCs within the scaffold increased the burst strengths of all constructs, the elastic modulus of PLGA-based constructs was significantly greater than that of native arteries or of PGS-based constructs and demonstrated no elastic deformation compared to PGS. Additionally, PGS-based constructs were found to contain less collagen and increased elastin in comparison to PLGA-based constructs. Therefore, a balance between compliance, elasticity, and burst strength must be achieved utilizing proper copolymeric formulations in order to optimize mechanical biocompatibility.

Some clinical experiences with bioresorbable grafts have provided encouraging results. Because current prosthetic materials cannot grow proportional to the growth of the native tissue during child development, bioresorbable TEBVs are especially useful in the pediatric population. TEBVs comprising a composite PGA/poly-4-hydroxybutyrate (P4HB) scaffold were seeded with vascular cells and implanted in the pulmonary arteries of a growing lamb model in which body size doubled over a 2-year period.[254] The TEBVs demonstrated a 30% increase in diameter and a 45% increase in length over time, with concomitant increases in collagen, proteoglycan, and cellular content. In addition, there was no evidence of thrombus formation, calcification, stenosis, suture dehiscence, or aneurysm in any of the grafts. However, a decreased elasticity and an absence of elastin in the TEBVs in comparison to native pulmonary arteries was noted.

In 2001, a TEBV comprising a bioresorbable polycaprolactone (PCLA)/PLA tubular scaffold seeded with autogenous cells were implanted into the pulmonary artery of a 4-year old child with pulmonary artery atresia.[255] At 7-month follow up, the patient was doing well, with no evidence of aneurysm formation or graft occlusion. Subsequent efforts utilized autologous bone marrow cells as a cell source to seed hybrid scaffolds of a copolymer of PLA and PCLA with a PGA reinforcement. These were implanted as vascular conduits in a clinical study of 23 patients with a 6-year follow-up.[256,257] Computed tomography studies did not demonstrate evidence of aneurysmal dilation and there was only one case of graft stenosis, which was successfully treated with angioplasty. With evidence of growth of the vessel conduit over the time period, these results provided encouraging initial clinical experiences. The investigators have received IRB approval and are hoping to begin clinical trials in the Unites States in the near future.

In the coronary vasculature, a fully bioresorbable stent comprising a poly-L-lactic acid backbone and a coating of poly-D-L-lactic acid containing the antiproliferative agent everolimus has recently been implanted in the first-in-human trials, with promising tolerance and clinical results up to 24 months.[258–260] At 2 years, there were no cardiac deaths, no revascularizations of the target lesion due to ischemia, and no stent thromboses. Additionally, there was evidence of tissue incorporation and vasomotion at the stented site and the adjacent coronary artery in response to vasoactive agents. This trial is ongoing, and continued encouraging results may provide the source for a potential revolution in the endovascular treatment of coronary and peripheral vascular stenoses.

6.628.6.4. Self-Assembled TEBVs

A promising strategy for TEBV construction, which has been tested in human subjects, is the self-assembly strategy described by L'Heureux *et al*.[261] Human SMCs are cultured with ascorbic acid and serve as a cellular sheet, which is wrapped around a tubular support to produce the media of the vessel. A second sheet generated by cultured human fibroblasts is then wrapped around the media to provide the vessel adventitia. After a period of culture, the tubular support is removed and ECs are seeded onto the lumen of the TEBV. This methodology is advantageous as it avoids the use of any foreign materials, and relies on the cellular components to provide the ECM scaffold. Implantation of these cell-assembled TEBVs in a canine model demonstrated tissue incorporation with intact endothelium, vasa vasorum, and an arterial media containing α-SMA positive SMCs as well as elastin and collagen.[262] Mechanical stability was demonstrated up to 8 months after implantation. Implantation in a limited number of human subjects for hemodialysis access has demonstrated encouraging early results, although long-term aneurysmal dilatation may appear to be a potential limitation for this strategy.[263,264]

6.628.6.5. Decellularized Vessel Scaffolds

Decellularized veins and arteries are a potential scaffold for TEBVs, and have the obvious advantage of possessing intact native vascular ECM structures.[265,266] Animal experiments have demonstrated some success with this methodology. Explanted decellularized grafts seeded with ECs and implanted in animal models have demonstrated EC lined lumens at the time of explant with repopulating SMCs after 4 weeks.[267,268] Of note, 89% of grafts seeded with ECs prior to implantation remained patent at 4 weeks, with only 29% of unseeded grafts remaining patent over the same time period. A decellularized cryopreserved human vein allograft, which was seeded with autologous ECs in a bioreactor, was implanted in a human patient for iliac vein reconstruction. This demonstrated the feasibility of this approach, although the tissue-engineered graft failed after 4 months.[269]

6.628.6.6. Final Remarks

While various alternatives to available synthetic grafts have been developed and investigated, a single commercially mass-produced product has yet to be introduced to the market. However, advances in the field of vascular tissue engineering have brought this endeavor closer than ever to patient care. As most of the current methodologies described in this chapter require several weeks to months, optimization of TEBV construction and synthetic graft modification will be required in order to produce a viable, cost-effective product for broad clinical use.

Glossary

Antibiotics Drugs that are used to inhibit or kill bacteria in the treatment or prevention of infection.

Biofilm A functional community of microorganisms attached to a surface or interface and integrated in a self-produced polysaccharide matrix. Biofilm infections are characterized by their failure to respond fully to antibiotic treatment.

Cerebral ventricles Spaces within the brain, one on each side, and two centrally, that are filled with cerebrospinal fluid that circulates from one to the other.

Cerebrospinal fluid A clear watery fluid produced inside the ventricles of the brain.

External ventricular drainage A temporary means of draining excess cerebrospinal fluid from the cerebral ventricles into a sterile collecting bag at the bedside.

Hydrocephalus A pathological accumulation of cerebrospinal fluid in the ventricles of the brain, usually caused by obstruction.

Shunts Devices usually made from silicone and consisting of tubes and a valve mechanism to control rate and direction of flow. They are inserted to drain excess cerebrospinal fluid from the cerebral ventricles to another body site, commonly the abdomen.

Staphylococcus A group of common bacteria found on human skin and elsewhere. *Staphylococcus aureus* is often pathogenic, causing would infections, septicaemia, etc. The others, termed coagulase negative, are usually harmless except when an implanted biomaterial or device is present.

Abbreviations

CFU	Colony–forming units
CNS	Central nervous system
CoNS	Coagulase negative staphylococci
CSF	Cerebrospinal fluid
CT	Computerised tomography
DNA	Deoxyribonucleic acid
EVD	External ventricular drainage
LP	Lumbar-peritoneal
NPH	Normal pressure hydrocephalus
ScCO2	Supercritical carbon dioxide
TDMAC	Tridodecylammonium chloride
VA	Ventriculo-atrial
VP	Ventriculo-peritoneal

6.629.1. Introduction

Cerebrospinal fluid shunts are used to treat hydrocephalus, caused by raised pressure in the brain. They are intended to remain in place for life. A more temporary measure is external ventricular drainage (EVD), used for acute rises in pressure such as those due to trauma or hemorrhage. Before the 1950s, no reliable treatment was available for hydrocephalus and many people either died or lived with very serious mental and physical disabilities, but then shunts became widely used and their complications soon appeared. Infection remains the most serious of these despite advances in antibiotic prophylaxis and surgical techniques, and this has led to the development of antimicrobial biomaterials for use in both shunts and EVDs. Laboratory evaluation of such devices requires insight into the microbiological, surgical, and biomaterials aspects of the problems.

6.629.2. Hydrocephalus

This condition is due to the accumulation of cerebrospinal fluid (CSF) in the ventricles of the brain, leading to increased pressure, with damage to the nervous tissue and reduction of essential blood supply. The accumulation arises due to blockage of the flow pathways, as CSF continues to be produced at an undiminished rate. The pathways can become blocked as a result of congenital anomaly such as spina bifida, meningitis, brain tumor, hemorrhage, or trauma, and hydrocephalus can appear at any age. A relatively newly recognized form, normal pressure hydrocephalus (NPH), affects the elderly.

6.629.3. Treatment of Hydrocephalus

6.629.3.1. Shunting

Though attempts to treat hydrocephalus with drugs have been made, the mainstay is surgical insertion of a device to divert CSF from the cerebral ventricles to another body site, where it can be reabsorbed. These devices, or shunts, consist of a catheter inserted into the cerebral ventricles, leading out through a burr-hole in the skull, under the scalp, and then subcutaneously to either the heart or the abdomen (Figure 1). Somewhere in the system there is usually a valve to regulate pressure or flow rate or both, and this can be placed either at the distal end of the catheter or about 15 cm from the proximal end, so that it lies behind the ear.

6.629.3.2. Early Shunts: Biomaterials and Biocompatibility

Before the 1950s, there was no satisfactory treatment for hydrocephalus and those with it either died within weeks or months, or lived with severe mental and physical disability, usually in institutions. The need to allow accumulated CSF to escape was realized centuries ago, and attempts to release it by trepanning or drilling holes in the skull were made. In 1898, a silver wire with a U-shaped cross-section was used in two patients to drain the CSF from the lumbar spinal part of the central nervous system (CNS) (which is usually in continuity with the cerebral ventricles) to the peritoneal cavity.[1] Both patients treated in this way died soon afterwards. Later, tubes were inserted into the ventricles in the same manner as modern shunts. These were originally made of either natural rubber or silver. The latter was chosen because of its presumed antiseptic properties. Hartwell in 1910 (cited by Haynes[2]) used silver wire to form a conduit from the cerebral ventricle to the abdomen in a child who lived for 2 years before dying due to fracture of the wire in the neck. At autopsy, a fibrin sheath had formed around the wire, producing a tubular fibrin conduit along which CSF had presumably flowed. Natural rubber tubing was used by Kauch in 1905[3] and this was also used by Heile in 1914.[4] Polyethylene tubing was used by Ingraham *et al.* in 1948.[5] The history of shunting is reviewed extensively by Aschoff *et al.*[6] Almost all attempts ended in failure, largely due to obstruction at the distal end

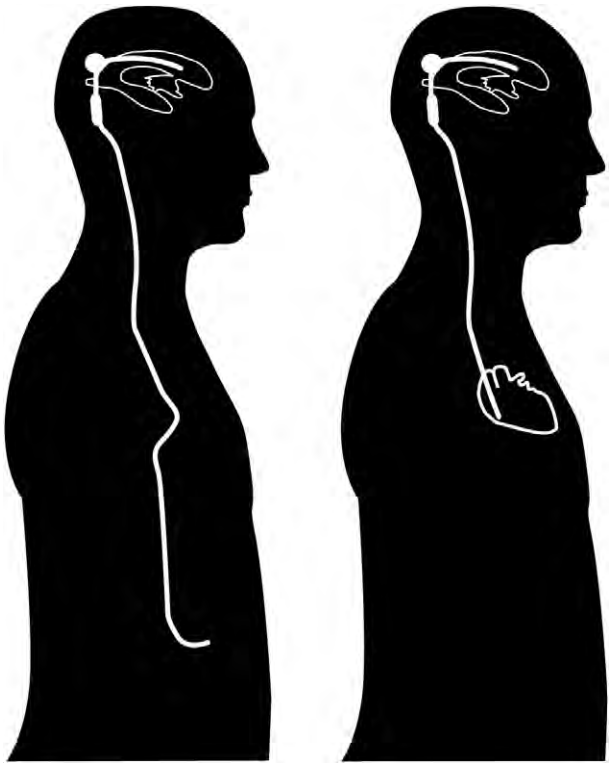

Figure 1 Routes of shunting for hydrocephalus. The shunts collect cerebrospinal fluid (CSF) from the ventricles in the brain. The fluid then flows through the circular reservoir and then through a valve that controls rate of drainage and prevents backflow. From there, the two routes differ. In (a), the ventriculoperitoneal (VP) shunt, the catheter lies subcutaneously over the ribs and enters the abdominal cavity, where the CSF is discharged and is reabsorbed into the bloodstream. In (b), the ventriculoatrial (VA) shunt, the catheter enters a neck vein and then, via the superior vena cava, discharges CSF into the right atrium of the heart, directly into the blood stream.

in the peritoneal cavity. The abdominal cavity is occupied by the small and large intestines, the latter of which contains enormous numbers of bacteria. If perforation of the colon occurs, perhaps due to ingestion of a sharp object, then the perforation is usually sealed very effectively by the large omentum, a membranous organ in the peritoneal cavity that has been referred to as 'the policeman of the abdominal cavity.' If any infective or inflammatory agent appears in the peritoneal cavity, the greater omentum moves to isolate and engulf it. The presence of a tube of natural rubber, polyethylene, or other poorly biocompatible materials in the peritoneal cavity attracts the attention of the omentum and the end of the tube is sealed, thus occluding it and stopping CSF drainage.[7] The peritoneal cavity is thus a critical site in terms of biocompatibility.

Valved shunts were being used on an experimental basis in the 1940s, but they were still made from natural rubber and while they functioned satisfactorily in a mechanical sense, they were not clinically successful. In addition, they could not be sterilized, a problem that unfortunately often still becomes apparent late in implant or biomaterial development.

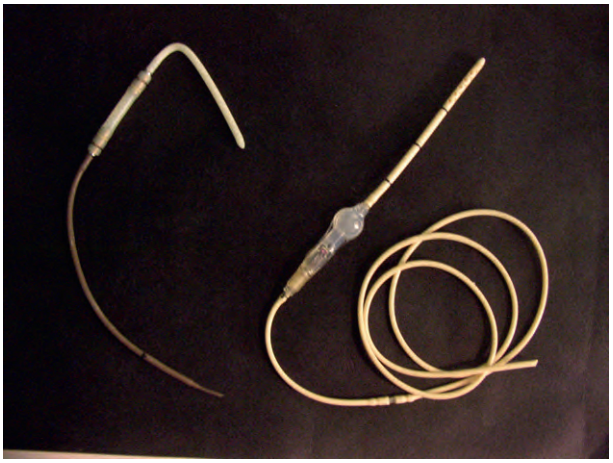

Figure 2 Shunts for hydrocephalus management. The original Holter shunt, with an angled ventricular catheter, two valves in series inside a silicone housing, and a tapered distal catheter for ventriculoatrial shunting. A modern shunt with a straight, graduated ventricular catheter that can be bent, leading to a magnetic step mechanism controlling the valve setting, which can be readjusted externally by a magnetic device without further surgery. The lower catheter is long, for insertion into the peritoneal cavity.

6.629.3.3. The Next Stage

The two problems to be overcome were biocompatibility and sterilization, and these were solved by John Holter in the 1950s. Holter was an American engineering technician whose son was born with spina bifida, a congenital anomaly that is usually accompanied by hydrocephalus. No treatment was available, but after discussing the problem with the surgeons, Holter constructed a valved shunt from silicone, then a new electrical insulating material (Figure 2). This could be sterilized, and silicone was soon found to be biocompatible. Unfortunately, Holter's son did not benefit from this development, but it paved the way for development of modern hydrocephalus shunts, all of which are made from silicone. An early development was to add barium sulfate to the silicone before extrusion so that the shunt catheters would be radio-opaque, allowing their location and inspection by radiography. Though early attempts were made to shunt into various body sites such as the fallopian tube, ureter, gall bladder, sagittal sinus and mastoid cavity,[8–11] and not just the abdomen or heart, it is the attempts to shunt into the abdomen and the heart that eventually proved most successful. With the adoption of silicone for shunt construction, the biocompatibility problems associated with the peritoneal cavity were largely, though not completely, overcome. However, the widespread use of these shunts in the heart ventriculoatrial (VA) was soon curtailed by the emergence of thrombus formation around the catheter in the right cardiac atrium.[12,13] This often caused shunt occlusion, but fragments of clot also broke away and were deposited in the vascular system of the lungs, often causing serious, potentially life-threatening pulmonary embolism.[14,15] This led to a decline in the use of VA shunts, and ventriculoperitoneal (VP) shunts are now predominant. Occasionally, for specific reasons, shunting by other routes is adopted, such as into the pleural space around the lungs, or from the spinal CSF space into the peritoneal cavity

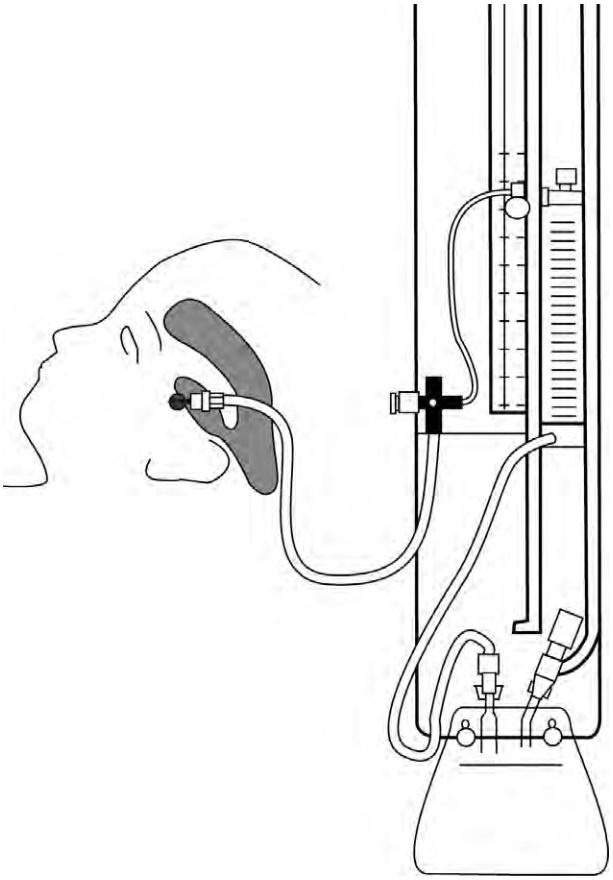

Figure 3 External ventricular drainage. The ventricular catheter is similar to that in a shunt, and drains cerebrospinal fluid from the ventricles in the brain. The catheter is connected to a drainage set with a manometer to adjust the height relative to the ventricles, and hence the rate of drainage. The fluid is collected into a sterile plastic bag at the bedside.

(lumbar–peritoneal, LP shunts). Temporary shunts for management of raised intracranial pressure are also often used in acute settings. These drain CSF from the cerebral ventricles using a catheter identical to permanent shunts, but the CSF is then collected in a bag at the bedside (Figure 3). Such EVD is used for a few days or for 2–3 weeks and is replaced by permanent shunting if the need for CSF drainage persists.

6.629.3.4. State-of-the-Art Shunts

The design of shunts has changed many times since Holter, though his design was used till 1990. The existence of a number of different designs perhaps suggests that the optimal one has not yet been achieved. In functional terms, the current clinical problems are overdrainage and the fact that it is impossible to predict the 'setting' of the valve for each individual. Most valves are supplied in low, medium, or high pressures, loosely equating to the CSF pressure that will result from their use. However, 'normal' CSF pressure ranges from 80 mm to about 150 mm water depending on age and other factors. If it is drained too rapidly, the cerebral ventricles will 'deflate,' and the surface of the brain will be pulled away from the overlying membranes, causing bleeding.[16,17] This collection of blood, a subdural hematoma, presses on the brain and causes malfunctions such as severe headache, convulsions, vomiting, and loss of consciousness. It usually requires surgical drainage. If the valve overdrains later and more slowly, the ventricles can collapse to the point where they are virtually invisible on CT scanning (Figure 4), a condition known as slit ventricles.[18] This paradoxically leads to increased intracranial pressure as the shunt catheter is no longer in the correct position in the ventricles.[19] Overdrainage is often referred to as siphoning, but the fluid mechanics of the phenomenon are ill-understood, and whether it is siphoning is debated. However, there does seem to be some connection between overdrainage and the length of the distal catheter from the valve to the peritoneal

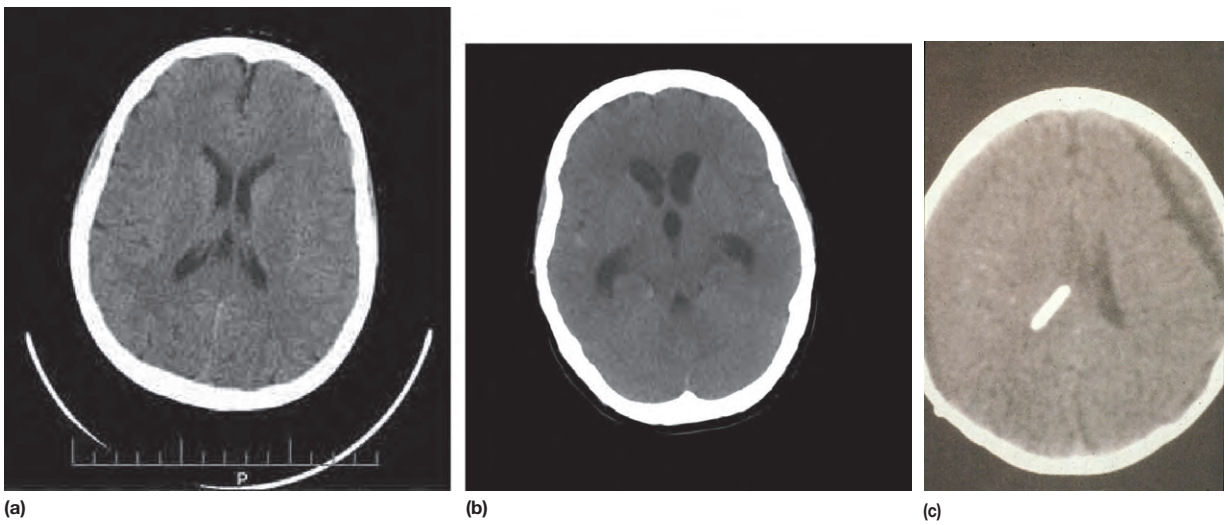

Figure 4 Computerized tomogram (CT) scans showing normal ventricles (a), enlarged ventricles in hydrocephalus (b), and reduced (slit) ventricles due to overdrainage (c).

cavity. One way in which overdrainage might be prevented is to place an 'antisiphon device' in the shunt system distal to the valve mechanism. Various types of devices are in use, but the one in which the CSF is diverted, if flow rate increases suddenly, into a much narrower pathway can slow the rate of flow and possibly arrest siphoning. Such devices appear to be successful in some patients but not in others and the mechanisms of overdrainage are still unclear. Certainly, changing the valve to one with a higher 'pressure' does not necessarily have any effect on overdrainage. The problem of predicting the CSF flow rate suitable for an individual patient, that is, the choice of a low, medium or high 'pressure' valve setting, has been solved by the introduction of the so-called programmable, or adjustable, valves (**Figure 2**). These contain a magnetic device that can be manipulated noninvasively at any time after surgical insertion of the shunt by means of another magnetic device placed on the scalp over the valve. The setting of the valve can then be changed according to the demands of the situation; if a patient shows signs of underdrainage after shunt insertion, the setting can be lowered to allow more CSF flow, and vice versa. In addition, the requirements of many patients change after shunt insertion, and these can also be accommodated without further surgery.[20,21] Currently, the factor limiting the more extensive use of such devices is their cost, but this has to be set against the cost of further admissions to hospital and more operations. Future developments in valve design will include biofeedback so that the valve will automatically respond to changes in CSF pressure, and telemonitoring and control of an individual patient's valve function.

6.629.4. Biocompatibility of Silicone Shunts

Medical grade heat-vulcanized silicone is highly biocompatible compared to natural rubber or polyethylene. However, after insertion, a fibrin sheath usually appears around the extracranial parts of the shunt tubing. This sheath is not usually attached to the silicone and does not interfere with its function. In some patients, usually after a few years, the fibrin sheath calcifies and this calcific layer attaches to the silicone and erodes the material, causing distortion and friability.[22] It is therefore responsible for local pain, and shunt failure due to catheter fracture, and it makes removal of defective catheters extremely difficult. Calcification has been blamed on the barium sulfate filler used in most shunt catheters; yet, the evidence for this is weak and it is also seen in shunts that do not contain barium sulfate (**Figure 5**). Nevertheless, in response to physician pressure, shunt tubing without barium sulfate is now being supplied. The reason for calcification is obscure, but it could be due to collection of blood around the catheter after surgical insertion. Calcification has also been shown to occur experimentally around longfixed catheter segments but not around small unfixed segments, suggesting that repeated tissue damage over time due to body movements over a fixed catheter might have a role.[23] Silicone allergy is very rare, but it does seem to occur occasionally.[24] Whether this is mainly due to patient predisposition or to some allergic property of silicone is unclear, but some cases reported are convincing. In particular, reports of persistent failure of shunts in the absence of infection or mechanical obstruction where replacement with an 'extracted' silicone shunt has solved the problem indicate that some extractable agent might be responsible.[25,26] It has been suggested that the small amount of residual uncross-linked silicone might in some individuals be allergenic, and this is presumably the agent that is extracted to make the shunts nonallergenic in the case reports. Fully cross-linked silicone is unlikely to be allergenic, though degradation due to lipid adsorption or mechanical damage might make reactive microparticles available. Another possible cause of allergic reaction to silicone shunts is adsorbance of contaminants such as latex proteins during insertion.[27]

Figure 5 A removed Holter shunt valve showing extensive surface calcification. The valve was made from plain silicone without barium sulfate filler.

6.629.5. Infective Complications

6.629.5.1. Causative Bacteria

As with any implantable device, infection is a possible complication. Soon after shunts began to be used for treatment of hydrocephalus, infection was reported.[28] At first the nature of the infection was unclear, but it soon became apparent that the hitherto harmless skin commensal *Staphylococcus epidermidis* was responsible for most cases. The genus *Staphylococcus* is divided for medical purposes into two groups. The first, consisting of one species, *S. aureus*, produces an enzyme, coagulase, and is therefore 'coagulase positive.' Members of this species were known to cause infection, and could easily be distinguished from the remainder (coagulase-negative staphylococci, CoNS) by the coagulase test. The CoNS were considered to be nonpathogenic and were generally disregarded, which is why it took so long to determine the cause of shunt infections. We now know that CoNS, of which *S. epidermidis* is by far the commonest, cause the majority of shunt infections. Shunt isolates of CoNS have been characterized[29] though the nomenclature has now changed.

6.629.5.2. Source of the Infecting Bacteria

In a modern operating theater with ordinary plenum ventilation, the theater air and environment are not a significant source of bacteria that infect shunts, and virtually all are caused by bacteria that inhabit the patient's skin.[30–32] Before any operation, the patient's skin at the surgical site is disinfected using antiseptics. The most effective is a solution of povidone iodine (a compound of polyvinylpyrrolidone and iodine) in alcohol. However, even when skin is prepared twice with this, viable skin bacteria survive in the sweat glands and hair follicles.[33] When the incision is made through the skin, they contaminate the surgical field and then gain access to the shunt tubing. Those that remain on the outside are usually phagocytosed and killed by the cellular immune system after closure, but those on the inside of the tubing are safe from host defenses. They attach to the silicone tubing and begin to change their phenotype and develop biofilms.[34–36] A few shunt infections are the result of skin abrasion over the shunt at a later date and another cause is perforation of an abdominal organ such as the colon or bladder by the distal catheter.[37] Sometimes this protrudes from the anus or urethra. However, though the catheter tubing obviously becomes contaminated and has to be removed, serious infection rarely results.

In EVD, the infecting bacteria might arise from the patient, the medical or nursing staff, or the environment and can gain access to the ventricular catheter at any time but especially during CSF sampling or collection bag change. While the infecting bacteria are similar to those in shunts, the proportion of Gram-negative bacteria such as *Escherichia coli* and *Klebsiella pneumoniae* is higher. Also, *Acinetobacter baumannii* is a bacterium that is particularly prevalent in intensive care units, where many EVDs are used. It is multiresistant and persists in the environment.[38]

6.629.5.3. Incidence of Shunt Infection

The infection rate in shunts varies considerably from one institution to another, and this might be due to different types of institutions, different patient populations, and different diagnostic criteria. There are also differences within institutions over time, and 'spikes' of infection arise and fade inexplicably in most. One factor is thought to be the routine change of junior medical or nursing staff at certain times of the year, and this does seem to influence infection rates.[39] However, the main difference is that between adults and older children and infants <6 months of age when shunted. In the former group, rates of 2–5% are not unusual, whereas in the infant group, rates of over 15% have been reported.[31,40] The 'average' rate often cited in the literature is 10%.[41]

6.629.6. Treatment of Shunt Infections

6.629.6.1. Biofilms and Other Reasons for Treatment Failure

The reasons for the great difficulty in treating shunt infections with antibiotics, to which the CoNS were usually very susceptible, were not understood earlier. In 1961, Cohen and Callaghan found that the intravenous antibiotics, which they usually used to treat staphylococcal infections, were failing to treat shunt infections, and this seemed to be because the drugs were not penetrating into the CSF in sufficient quantities.[42] The CNS is a privileged, protected area and we now know that most antibiotics when given intravenously do not penetrate into the CSF in healthy people. *S. epidermidis* does not cause sufficient inflammatory response in the CNS to open up the blood–CSF barrier, as would happen in the more acute forms of meningitis. While this was the explanation for the failure of intravenous antibiotic treatment, the infections were not eradicated even when antibiotics were introduced directly into the cerebral ventricles. The reason became apparent when shunts that had been removed for intractable infection were examined.[34] The offending bacteria were found to be confined to the inner surfaces of the shunt tubing. Moreover, they were adherent to the silicone, and they grew as microcolonies that produced a substance that appeared to hold them together and possibly to protect them from antibiotics. This 'mucoid substance' was found to stain with alcian blue, suggesting that it was a polysaccharide, and it reacted with fluorescent-labeled antiserum, showing that it was antigenic. This was in fact the first published demonstration of a biofilm in a medical device setting. At least 140 000 papers have now been published on biofilms in medical devices, and the significantly decreased susceptibility of bacteria when growing in a biofilm is now appreciated. While there may be more than one reason for this, in staphylococcal biofilms, the assumption that the 'mucoid substance,' now known as polysaccharide intercellular adhesin or exopolymer, is able to significantly impede access of antibiotics to the bacteria in the biofilm is known to be incorrect.[43,44] The penetration of antibiotics into bacterial biofilms has also been modeled mathematically.[45] Bacteria are able to adhere by means of specific adhesins to host proteins coating the biomaterial surface. Examples of these are the binding proteins for fibronectin and fibrinogen. Once adhesion has taken place, the bacteria begin to modify their metabolism, under genetic control, and to produce exopolymer. By the time the biofilm is fully developed in 1 or 2 weeks, the bacterial phenotype has undergone such modification that they are 500–1000 times less susceptible to antibiotics.[46–48] During this time, genes responsible for rapid multiplication and production of cell wall material, enzymes, toxins, etc. are downregulated, and those responsible for exopolymer production and stress response, a bacterial survival mechanism, are upregulated. The bacteria enter a dormant phase (**Figure 6**), with energy generation and transport drastically reduced.[49] Antibiotics act on bacteria by inhibiting cellular processes, and the three main groups of antibiotics inhibit cell wall synthesis (penicillins, cephalosporins, and vancomycin), protein synthesis (gentamicin, clindamycin, tetracyclines), and DNA replication (quinolones). As the biofilm bacteria do not synthesize much cell wall material, proteins, or enzymes, nor replicate their DNA, the antibiotics have no target sites and become therapeutically irrelevant. This is probably the most important mechanism explaining treatment failure in biofilm infections. Therefore, in view of the pharmacological problem of getting the antibiotics to the bacteria in the shunt, and their insusceptibility to all but concentrations toxic to the patient, the treatment of shunt infections must include total surgical removal of the infected device.

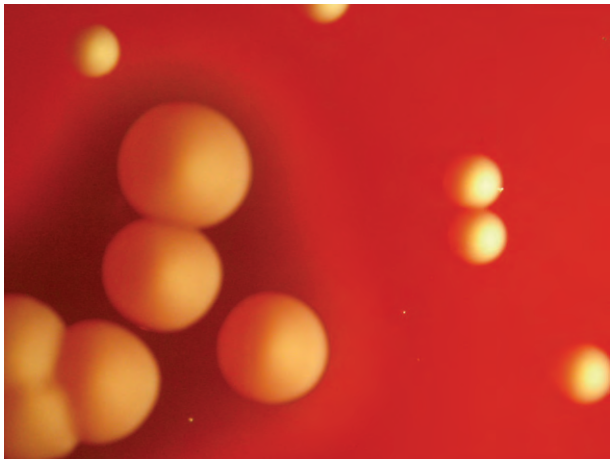

Figure 6 Small colony variants of *Staphylococcus aureus* on blood agar medium. The large bacterial colonies are the parent strain, and the small colonies are the resistant variants. Note the absence of enzyme activity around the small colonies. The image is not color-enhanced. Magnification ×200.

6.629.6.2. Treatment Regimens

As soon as possible after the diagnosis of shunt infection, the shunt system should be removed. The hydrocephalus is then managed by an EVD, with excess CSF draining through a collecting system into a bag. Antibiotics are also given, and many doctors prefer to include direct administration into the CSF.[50] The EVD is itself a source of infection as it represents a direct access to the CNS for bacteria from the scalp or the environment, and careful management is required. After the infection in the cerebral ventricles has been eradicated, typically after 10–14 days, the EVD can be removed and a new shunt inserted. Guidelines for treatment of shunt infections have been published,[51] and if these are followed, relapse of the infection is unlikely. However, relapse or a second infection are serious problems where guidelines are not followed, and the repeated surgery and infection cycle leads to diminished mental and physical ability with a poor overall outcome and possibly to death.[52]

6.629.7. Prevention of Shunt Infections

6.629.7.1. Surgical Technique

In any modern operating theater, a ritual involving scrupulous cleaning of surgeon's hands, gloving, gowning, and the use of caps and masks and sterile instruments is routine. Any break in this ritual often leads to a higher risk of infection. Some surgeons have applied the ritual more rigidly and have claimed that measures such as limiting the number of people in the theater, inserting shunts first thing in the morning, and introduction of ultraclean air systems are responsible for their reduction in infection rate.[53] However, so long as the usual ritual is maintained, the extra measures themselves are unlikely to be responsible, in view of the source of the infecting bacteria. Advocates of such enhanced systems often apply them rigorously, and it is probably this that is responsible. The Hawthorne effect, where the fact that changes are being made or a study or an audit is being carried out leads to improvement in infection rates irrespective of the nature of the changes,[54] is a powerful influence, but it must be regularly reinforced or the effect will diminish with time as personnel become accustomed. The effect can be exploited by constructing a protocol of procedures, none of which might be evidence-based but all of which appear sensible, and applying it rigorously with frequent personalized feedback of results. This is often called 'bundling' to describe the grouping together of such procedures. Bundling alone has been reported to reduce the incidence of shunt and EVD infections.[55,56] However, the effect is volatile, often disappearing when personnel change or lose interest.

6.629.7.2. Prophylactic Antibiotics

It is common practice in most types of surgery to administer an intravenous antibiotic, usually a cephalosporin, about 30 min before the first incision is made. This is to ensure adequate tissue concentrations of the antibiotic so that any bacteria reaching the operation site are killed or inhibited, and prevented from causing an infection. However, as the blood–CSF barrier is not patent in the absence of inflammation (and it is hoped that those to be shunted do not have ventriculitis), the intravenous antibiotics do not penetrate into the CSF in significant quantities to be effective.[50,57] Many trials and studies have been carried out to determine whether the use of prophylactic antibiotics reduces shunt infection, but a meta-analysis[58] has shown that there is no significant benefit unless the infection rate is >15%. In addition, published infection rates with an average of 10% are all from centers where antibiotics are used. The benefit from prophylactic antibiotics in shunt surgery is therefore doubtful. In EVD, prophylactic antibiotics are used in two ways. Firstly, they are given as in shunt surgery to prevent infection at the time of the insertion of the device. Secondly, some centers prefer to continue prophylaxis throughout the period of EVD. Studies have shown that the latter does not reduce infection but risks encouraging infection with resistant Gram-negative bacteria such as *Pseudomonas aeruginosa* and *E. coli*.[59,60]

6.629.8. Antimicrobial Shunt Catheters

6.629.8.1. Principles of Antimicrobial Biomaterials for Shunting

There have been many attempts to produce experimental antimicrobial biomaterials, mainly for use in catheters. Most have shown some antimicrobial activity in laboratory tests but few have been commercialized, and of those that have, few have been clinically successful. The two main types of antimicrobial catheters are coated and impregnated catheters, which are coated or impregnated with one or more antimicrobial agents. The differences between the two are clinically very important. Coating is, as the term suggests, the application of the agent to the catheter surface, either passively or by some bonding process, while impregnation consists of dispersing the agent throughout the biomaterial.

The required duration of antimicrobial activity and its activity against a range of microorganisms is determined by the

intended use of the catheter, and the known period of risk of infection. In the case of CSF shunts, the period of risk is during and immediately after the surgical procedure,[30] though once bacteria have attached to the shunt surface they take longer to kill.[61] Therefore, at least 2 weeks of sustained activity are desirable, and this must be directed against the main bacterial causes, that is the staphylococci and propionibacteria. In the case of EVDs, the activity is required for the duration of EVD use, which can be 3 weeks or more. The antimicrobial activity must cover not only the staphylococci but preferably also the Gram-negative pathogens such as *E. coli*, *K. pneumoniae*, and *A. baumannii*. In addition, EVDs are often used in cases of hemorrhage or trauma, when the CSF contains blood and clot breakdown products that coat the inside of the catheter. This can increase the chances of bacterial attachment, and it can also obliterate a bioactive surface.

6.629.8.2. Coated Catheters

These can be manufactured by various means including dipping, spraying, or coextrusion. Any process that is confined to the line of sight cannot access the inner surface of the catheter, and some catheters have shown disappointing results in clinical trials because of this.[62–64] However, the main reason for the failure of coated catheters is the lack of any depot effect, coupled with the usually rapid wash-off of the agent in flow conditions. The deposition of a host-derived conditioning film can also reduce the activity.[65] Preclinical testing must include these factors to approach clinical predictiveness. The antimicrobials used to coat catheters experimentally have ranged from antibiotics and antiseptics to silver. Some of the antiseptics and bonding agents, such as chlorhexidine[66] and tridodecylmethylammonium chloride (TDMAC),[67] are too neurotoxic for use in shunts and EVDs although their use has been suggested.[68] Silver coatings for catheters used in the urinary tract or for vascular access have included silver salts and metallic silver, deposited by ion beam. They have not been used in the CNS. Another approach consists of coating the catheter in a hydrogel such as polyvinylpyrrolidone, which swells on soaking in water to become a very hydrophilic layer. This is said to reduce bacterial attachment, and if antibiotics are dissolved in the water used for soaking, they are said to be released after implantation to reduce infection risk even further.[69]

6.629.8.3. Impregnated Catheters

Impregnation is far more difficult to achieve than coating, unless one includes admixing of powders prior to extrusion. Ideally, impregnation should disperse the antimicrobial as molecules, or at least nanoparticles, rather than granules. Impregnation is a postmanufacture process, and the antimicrobial agents must be introduced into the polymer matrix by some means. The exception is one form of silver impregnation in which metallic silver particles compounded with the polymer are then admixed into the main bulk of the polymer before extrusion.[70] This has been used for silicone and polyurethane EVD catheters.[71] Antimicrobials such as antibiotics have been impregnated into silicone using a solvent-swelling process.[72] This depends on the antimicrobial being soluble in the solvent, and the solvent being able to swell the matrix of the cross-linked silicone. The antimicrobial is dissolved in the solvent, and the silicone catheter is immersed in the solution. Within a few minutes, the silicone swells to approximately twice its volume, imbibing the solution. After complete swelling, the solvent is removed by evaporation, leaving the molecules of antimicrobial evenly dispersed throughout the silicone, which returns to its original volume and shape. In order to be clinically effective, the antimicrobial must be capable of migrating through the silicone. Most antimicrobials such as penicillins, cephalosporins, gentamicin, and vancomycin will not migrate, and even if they are introduced by some means, they will remain in the polymer without exerting any antimicrobial effect. These agents are also insoluble in the usual swelling solvents, of which chloroform is the most used, and a clear relationship can be developed between the solubility of the proposed antimicrobial in chloroform and the rate of its migration through the silicone.[73,74]

Metallic silver, being insoluble in swelling agents such as chloroform, cannot be impregnated in this way. However, a method by which metallic silver nanoparticles can be impregnated into silicone using a swelling agent has been developed.[75] In this method, silver is complexed with organic compounds such as glymes in anaerobic conditions. The organosilver complex is then solubilized in supercritical carbon dioxide ($scCO_2$), which also swells the silicone matrix under these conditions. As with the chloroform-based method, the organometallic complexes are left behind when the $scCO_2$ is removed and the silicone matrix returns to its original volume. The organic material then has to be removed as it is toxic, and this is done by reducing the complex with hydrogen and flushing out the organic residues with $scCO_2$. The effect is to leave nanoparticles (20–200 nm) of metallic silver dispersed throughout the silicone.[76] Nanoparticles are known to have much greater chemical and biological activity than the corresponding larger particles, and they can be expected to generate silver ions, on which antimicrobial activity depends, at a far greater rate. There is currently no clear information on whether the nanoparticles or their ions can migrate through silicone in the same way as organic antimicrobials.

6.629.8.4. Biological Importance of the Boundary Layer

The interface between the catheter and the CSF passing through it is critical, as it is here that any bacteria accessing the catheter lumen will attach. In order for an antimicrobial catheter to be clinically effective, the boundary layer must maintain a concentration of antimicrobial sufficient to kill the bacteria for long enough in flow conditions. As we established earlier, this must be for at least 2 weeks in shunts and over 3 weeks in EVDs. As the CSF flow removes antimicrobial ions or molecules constantly from the catheter surface, this concentration must be replenished by migration from the matrix to maintain activity (**Figure 7**).

6.629.9. Evaluation of Antimicrobial Catheters

It would appear from the above that any evaluation must include an assessment of bacterial attachment and time to kill, and include the effect, if any, of a protein conditioning film.

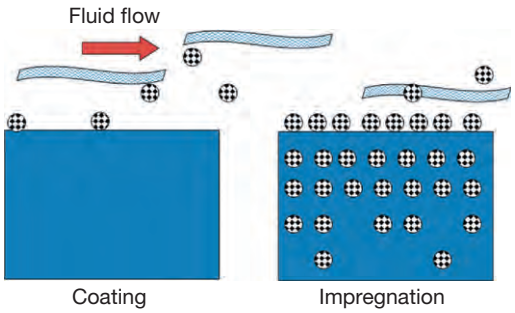

Figure 7 Comparison of the behavior of antimicrobial coatings and impregnation. As the cerebrospinal fluid flows over the antimicrobial surface, molecules of the antimicrobial are washed out of the boundary layer and removed. Eventually, no antimicrobial activity remains on the coated surface, but the boundary layer of the impregnated biomaterial remains full of antimicrobial molecules due to replenishment by diffusion from the matrix.

Demonstration of prevention of colonization after repeated bacterial challenge in flow conditions at 37 °C is also required. However, a variety of other tests have been applied.

6.629.9.1. Broth Culture Test

Here a segment of test catheter is added to a fluid ('broth') culture of test bacteria and incubated overnight. The numbers of surviving bacteria are compared to those before incubation. Any antimicrobial activity shown is against planktonic, that is unattached, bacteria and this is of questionable clinical relevance. Also, the activity depends on the antimicrobial agents being released from the catheter into the culture medium in sufficient quantity to kill or inhibit the test bacteria. If they do this, there is very little likelihood that useful activity would extend much beyond the 24-h test period in the absence of extremely high loading. The method is easy, inexpensive, and uninformative.

6.629.9.2. Roll Plate Test

A segment of a catheter is immersed in a suspension of test bacteria to allow them to attach to its surface. After removal, it is incubated in nutrient medium and then removed, rinsed, and rolled over the surface of a plate of solid culture medium. After incubation of this medium, colonies are counted and compared to those from a plain control catheter. While this assesses the ability of the catheter to kill attached bacteria, it gives no information about the duration of the effect. Also, only the outer surface is sampled, and where this method has been used in clinical trials the results have been flawed as most catheter-related infections begin on the luminal surface.[77]

6.629.9.3. Zone Plate Test

This consists of placing a segment of catheter on the surface of an agar plate that has been seeded with test bacteria. After incubation, the diameter of any zone of inhibition surrounding the catheter is measured. A zone of more than 18 mm has been taken as an indication that the catheter is likely to show clinical efficacy.[78] This test tells us whether a catheter has any activity at all, and can be used as a screen. However, it tells us nothing about duration of activity, nor does it test the effect of flow conditions. Also, some catheters that do not rely on release of water-soluble agents, such as silver-processed catheters, will not show any effect in this test.

Figure 8 Serial Plate Transfer Test, showing three segments of an antimicrobial shunt catheter after incubation on an agar plate seeded with staphylococci. The catheters had been transferred from plate to plate for 7 days.

6.629.9.4. Serial Plate Transfer Test

This initially appears to be very similar to the zone plate test, but it introduces an assessment of duration of activity. After demonstrating a zone of inhibition as in the zone plate test, the test segments are marked so that the same arc of the circumferential surface is presented to the agar surface on each occasion (Figure 8). The segments are then transferred to a fresh seeded agar plate and incubated overnight. Again, any zone of inhibition is measured and the segments are transferred until no more zone of inhibition is seen. Whereas the Zone Plate test can give a zone of inhibition from a small amount of antimicrobial on the catheter surface that would be removed in minutes in a flow system, a Serial Plate Transfer test that shows inhibition for several days or longer relies on a maintained antimicrobial boundary layer.[72] The longest durations of activity in the Serial Plate Transfer test are seen in impregnated biomaterials, where inhibition zones can persist for more than 250 days.[79] Even so, the test is no more than a screen for duration; it tells us nothing about actual protection against bacterial colonization in flow conditions.

6.629.9.5. Time to Kill Assay

This assay is known as the tK100, as it determines the time taken by an antimicrobial biomaterial to kill 100% of bacteria attached to its surface.[80] Test catheter and plain control catheter segments are immersed separately in a bacterial suspension for 1 h to allow attachment. They are then removed and rinsed to remove unattached bacteria, and immersed in a nutrient

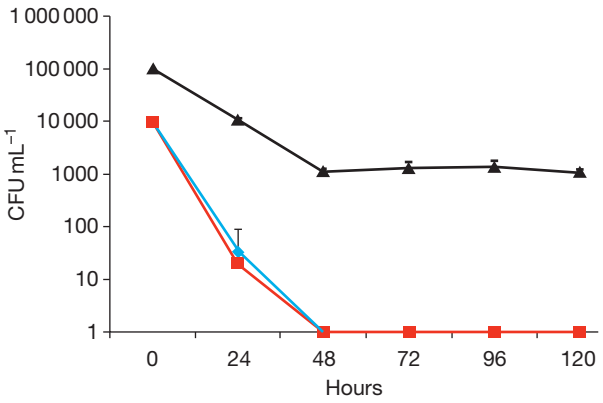

Figure 9 tK100 results to show persistence of bacteria in the plain control (▲) compared to the antimicrobial material (■). The activity is shown in colony-forming units per milliliter (CFU per milliliter) of surviving bacteria that are attached to the material surface. All bacteria attached to the antimicrobial material are nonviable by 48 h.

medium and incubated at 37 °C. The concentration of the medium is titrated for each test bacterium to allow bacterial survival on the plain catheter surface but not significant growth in the surrounding fluid; otherwise, constant reseeding of the segments will invalidate the test. Three segments are removed at intervals, rinsed, and sonicated to remove attached bacteria, and the viable bacteria in the sonicate are counted. Typically, the counts from the plain control segments remain constantly high while for a successful antimicrobial catheter, they will reach zero in 2–4 days. It is important to include sufficient catheter segments to allow for further testing after this period to rule out recovery and regrowth. The results of this assay (Figure 9) show that the time taken to kill attached bacteria is much longer than that taken to kill their planktonic counterparts, which can be killed in a few hours.

6.629.9.6. *In Vitro* Challenge

Here the catheters are tested in flow conditions at 37 °C by repeated challenge with bacteria.[72,80] Typically, plain control and antimicrobial catheters are perfused with nutrient medium at 20 ml h^{-1} (the normal CSF production rate) for 42 days. A suspension of test bacteria is injected into each catheter on the first day, and viable bacteria are counted in the effluent daily for the next 13 days. Control catheter counts increase and remain high, but if the counts have by then fallen to zero in the antimicrobial catheters, a new set of plain control catheters is set up and both are rechallenged. The process is repeated until the antimicrobial catheters become colonized. Counting the bacteria in the effluent can be criticized as not giving information about biofilm formation on the luminal surface of the catheters, but in practice it proves to be a reliable indicator.

6.629.9.7. *In Vivo* Testing

The insertion of a segment of antimicrobial catheter subcutaneously or into the muscle of an animal, and injecting bacteria around it, is a commonly used *in vivo* model,[81] but it is so uninformative and clinically irrelevant as to be unethical. *In vivo* testing that gives clinically useful results is very difficult for shunts and EVDs. Several hydrocephalic animal models are available, but the only one that gives the opportunity to use a full-size shunt to treat hydrocephalus is the dog. In this model, the dog is made hydrocephalic by obstructing the CSF pathways in the brain.[82] The test shunt can then be inserted in the same way as for human hydrocephalus. The model has been validated for shunting but so far has not been used to evaluate antimicrobial shunts or EVDs, almost certainly because of the high cost of the initial surgery, the shunting, and animal maintenance.

6.629.10. Application of *In Vitro* Tests to Existing Shunt and EVD catheters

6.629.10.1. Hydrogel: Coated Catheters

A catheter with a hydrogel coating is commercially available (Bioglide, Medtronic, Minneapolis, USA). According to the manufacturer's instructions, catheters were soaked in solutions of various antibiotics. They were then removed, blotted dry, and tested by the Serial Plate Transfer test.[83] Despite high concentrations of antibiotic, all except one showed no zones after day 2. The exception, rifampicin, failed by day 9, but this antibiotic cannot be used alone as resistance readily appears. Using the *in vitro* challenge test, all catheters colonized immediately. Further testing showed that, contrary to company assurances, the internal surfaces were not coated with hydrogel, explaining why the catheters could not have shown protective activity in the *in vitro* challenge.

6.629.10.2. Admixed/Impregnated Catheters

The method of manufacture of the rifampicin- and minocycline-processed EVD catheter (Ventriclear, Cook, Bloomington, USA) is unclear, but it appears to be a hybrid of admixture and impregnation. The minocycline appears to be released very rapidly,[84] leaving the rifampicin to act alone after a few days. The catheter behaves well in the Serial Plate Transfer test against staphylococci and *E. coli*, but the activity against the latter is lost if the catheter is first soaked for 5 days, probably due to the early loss of minocycline.

6.629.10.3. Impregnated Catheters

A shunt catheter impregnated with rifampicin and clindamycin is commercially available (Bactiseal, Codman, Raynham, USA), and an EVD version is also available. The antimicrobials are introduced by the solvent-swelling method and are distributed throughout the polymer. On testing by the Serial Plate Transfer method, the catheters show inhibition for ~50 days.[80] The tK100 assay shows that the catheters kill all attached bacteria by 48–52 h with no regrowth,[61] and these results are not affected by prior soaking of the catheters. No colonization appears after three consecutive challenges in the *in vitro* challenge test, with failure on the fourth challenge at 42 days. The catheter is active against Gram-positive shunt and EVD pathogens such as staphylococci, but not against Gram-negative bacteria.

6.629.10.4. Silver: Processed Catheters

An EVD catheter impregnated with nanoparticulate silver is commercially available (Silverline, Spiegelberg, Hamburg, Germany). The catheter is available in either silicone or polyurethane. The silver nanoparticles are apparently admixed prior to extrusion. In view of the wide antimicrobial spectrum of silver ions, the catheter is claimed to protect against infection by both Gram-positive and Gram-negative bacteria and fungi. Not surprisingly in view of its mode of action, the catheter gives no zones of inhibition in the Serial Plate Transfer test,[85] but in this case, this does not necessarily mean that it has not antimicrobial activity. On testing the silicone catheter using the tK100 assay,[86] *S. epidermidis* was killed within 72 h but *S. aureus* was not eradicated. On testing against *E. coli*, the bacteria appeared to be eradicated within 48 h but then regrew at 72 h. While the mechanism of antimicrobial action of silver is debated, it has been suggested that, at low concentrations, silver ions cause nonfatal damage to bacteria from which they can recover. There was no activity in the tK100 assay against *P. acnes*. No antimicrobial activity was shown by these catheters in the *in vitro* challenge. Scanning backscattered electron microscopy showed that the silver particles were ~500 nm in diameter, and it is possible that more activity could be achieved if they were <200 nm, that is, true nanoparticles.

6.629.11. Clinical Studies on Antimicrobial Shunt and EVD catheters

6.629.11.1. Hydrogel: Coated Catheters

One clinical trial has been published on the use of these catheters for EVD.[63] The catheters were soaked in bacitracin, an antibiotic with activity against most Gram-positive bacteria. No significant difference was seen in infection rates between plain and hydrogel-coated catheter groups, as suggested by the Serial Plate Transfer test and *in vitro* challenge results.

6.629.11.2. Admixed/Impregnated Catheters

One trial on Ventriclear catheters for use in EVD has been published.[87] The infection rate in the Ventriclear group was 1.3% compared to 9.4% in those receiving plain catheters ($p = 0.002$). This was mainly due to there being no infections due to staphylococci in the Ventriclear group, but there were two due to Gram-negative bacteria, confirming the validity of the results of the tK100 assay on these catheters.

6.629.11.3. Impregnated Catheters

Ten clinical trials of Bactiseal shunt catheters have been carried out in various parts of the world.[88–97] The trials are of varying design and quality, most not being the standard randomized controlled double-blind model. This might be for several reasons: the Bactiseal catheters are orange in color and cannot be 'blinded' against a white plain catheter; and the catheters have become widely used, so that ethical issues arise regarding possible randomization to the plain catheter, which could be considered inferior. Nevertheless, with one exception, use of the impregnated catheters was associated with a reduction in shunt infection rate, and in four cases this reached statistical significance and in two failed to do so because of small numbers. The average reduction in infection rate in the statistically significant trials was 80%. A study carried out by the UK Cambridge Shunt Registry[98] showed a 36% reduction in infection rate compared to controls ($p = 0.048$), but the study involved almost 2000 patients from most neurosurgery units in United Kingdom, and there were no diagnostic criteria for shunt infection other than the surgeon's opinion. Infection could therefore have been overdiagnosed. A recent German study[89] examined the cost-effectiveness of the antimicrobial shunt catheters, taking into account the increased cost of the catheters and the costs of treating an infection, and found that their use in 197 children and adults resulted in a saving of $50 000. Another study from United States[99] showed that factors leading to higher medical costs were reduced when antimicrobial catheters were used.

The Bactiseal EVD catheter has been available for a shorter period, and while trials are under way, only one has been published.[100] There was a reduction in positive CSF cultures from 31.8% in the plain catheter group to 2.1% in the Bactiseal group ($p = 0.003$). The results of more extensive trials are awaited.

6.629.11.4. Silver: Processed Catheters

Silver coatings in various forms have been used in catheters for vascular access and urinary use for some time, but the clinical results are very variable and seem to be influenced by the length of time that the catheters are in place. Silver nanoparticle impregnation offers theoretical advantages based on significantly greater ionization, and a catheter containing these has been tested as a central venous access catheter.[101] The catheters were in place for relatively short periods, and the reasons for catheterization were different in control and test groups, but the authors reported a significant reduction in infection rate with the use of the silver catheters. In a prospective study using retrospective selected controls, Lackner *et al.*[71] showed a significant reduction in infection rate, from 25% to 0%, though there was no difference in numbers of EVD catheters colonized by bacteria. The clinical significance of catheter colonization, that is bacteria growing inside the catheter in the absence of symptoms of infection, is unknown.

6.629.12. Conclusions

Infections associated with shunting and EVD are serious and potentially life threatening, and conventional measures such as prophylactic antibiotics are not very effective in reducing the risk while introducing the additional risks of side effects and resistance.

Various antimicrobial catheters have been proposed with the aim of killing any bacteria that reach the device on insertion or during use, but testing methods vary. While some take into account the biological and clinical factors, some others give clinically misleading data. Most proposed devices have not shown clinical benefit. Those that have are impregnated with antimicrobial(s) rather than being coated. Antimicrobial-impregnated shunt catheters have proved to be very successful,

and while there has been less clinical experience with similar EVD catheters, results suggest that they may also be useful. Silver nanoparticle-impregnated EVD catheters have recently been introduced, and early data suggest that these may be useful but more studies are needed.

6.630.1. An Introduction to Spinal Cord Injury

Spinal cord injury (SCI) is devastating, resulting in lifelong disability. The physical, emotional, and economic costs are real and burdensome for the individual, their families, and society. Current treatment options for SCI are limited to delivery of methylprednisolone, decompressive surgery, and rehabilitation, each of which results in only modest functional recovery. Biomaterials will play a prominent role in future treatments for SCI because they enable localized drug delivery, provide physical support to regenerating tissue, and enhance survival of transplanted cells. These strategies are part of the treatment paradigm known as tissue engineering or regenerative medicine. In Sections 6.630.1.1–6.630.1.3, the complex anatomy of the spinal cord is introduced and animal models of SCI are reviewed. Current treatment methods and clinical trials are discussed in Section 6.630.1.4. Localized spinal drug delivery from hydrogels and polymeric particles is described in Section 6.630.2 and nerve guidance channels and scaffolds for cell delivery are elucidated in Section 6.630.3. These innovative strategies are enabled by the development of materials with desirable physical, chemical, and biological properties.

6.630.1.1. Anatomy of the Spinal Cord

The brain and spinal cord together make up the central nervous system (CNS) and are two of the most complex organs in the human body. The spinal cord serves as the communication pathway between the brain and the peripheral nervous system (PNS) and also coordinates reflex responses without the involvement of the brain. A cross-section of the spinal cord in the thoracic region is shown in **Figure 1**. Moving outward from the center of the spinal cord is the butterfly shaped gray matter, which contains motor and sensory neuron cell soma. The surrounding white matter contains myelinated axons which carry messages to and from the brain. The spinal cord is tightly wrapped by the pia mater, a highly vascularized connective tissue. The intrathecal space separates the pia mater from the arachnoid membrane and is filled with cerebrospinal fluid (CSF). The CSF cushions the spinal cord and brain against sudden motion and provides nutrition to the CNS while simultaneously removing metabolic byproducts. CSF is acellular, with an osmolarity and a salt composition similar to serum but with far lower protein content. The arachnoid and dura mater are the second and third of the three meninges and together contain the CSF and spinal cord. Lastly, the epidural space between the dura and inner surface of the vertebra is filled with fatty tissue, which supports and cushions the CNS.

An important feature of the spinal cord is the blood–spinal cord barrier (BSCB), which lines blood vessels within the cord and consists of endothelial cells and astrocytes. The BSCB protects the spinal cord from changes in the biological and chemical environment of the periphery, including fluctuations in the concentration of ions, small molecules, and growth factors. The filtering action of the BSCB restricts systemic drug delivery to the CNS to low molecular weight compounds, excluding therapeutic antibodies and proteins. Localized delivery methods, including the use of biomaterials to localize drug release, have been studied.

6.630.1.2. The Tissue Response to SCI

Traumatic SCI is described as resulting from compression or laceration (transection) of the cord. In both cases, damage results in necrotic cell death and severing of axons from the cell soma. The permanence of SCI is the result of differences in the wound healing response in the spinal cord relative to other soft tissue, including the PNS as described in **Chapter 5.531, Peripheral Nerve Regeneration**. While it was long believed that axons in the CNS were fundamentally incapable of regenerating, this was disproved in the early 1980s by Aguayo and colleagues who showed that CNS retinal neurons can regenerate within peripheral nerve grafts, but not beyond the graft into the CNS tissue.[1] This significant finding suggested that manipulation of the chemical and biological environment around the injury could serve as a powerful strategy to treat CNS damage.

Axonal regeneration is prevented in the CNS by the inhibitory environment. Specifically, glial cells at the CNS injury site produce a large number of inhibitory factors that limit axonal regeneration, including myelin-associated glycoprotein,[2,3] chondroitin sulfate proteoglycans,[4] and NogoA.[5] The potency of the inhibitory chemical environment present after CNS injury is evident in the hours following axotomy, during which severed CNS axons develop new growth cones that extend into very short distances before stabilizing and then receding in a process known as abortive sprouting.[6] Axonal regeneration in compression injury has been enhanced through the delivery of neuroregenerative factors (see **Section 6.630.2**). In transection injury, regeneration has been encouraged through the use of hydrogels or nerve guidance tubes which act as physical guides for regenerating tissue (see **Sections 6.630.2.1 and 6.630.3.1**, respectively).

After SCI, the primary mechanical insult is followed by a biochemical secondary injury which results in further loss of function. The cascade is initiated by the inflammatory response which results in increased production of growth factors, cytotoxic proteins, free radicals, and nitric oxides.[7] First ischemia

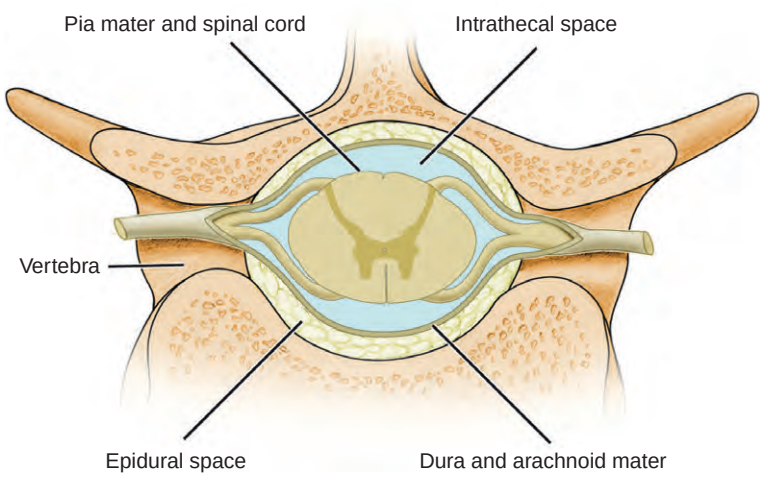

Figure 1 Gross anatomy of the spinal cord. Neural tissue is protected by the vertebrae, dura, arachnoid, and pia mater. Cerebrospinal fluid flows through the intrathecal space. The dorsal and ventral roots carry sensory and motor information, respectively, from and to the periphery. Image copyright (2005) by Michael Corrin.

and then hypoxia appear in the gray matter[8] with accompanying production of free radicals and lipid peroxidation which damage the fatty acids of cell membranes. These processes drive neurons and oligodendrocytes to apoptosis for weeks after injury and increase the volume of injured tissue, resulting in a spindle-shaped cystic cavity. This lesion is eventually isolated from healthy tissue by reactive astrocytes which migrate to the lesion and form a glial scar.[7] The duration and complexity of secondary processes in SCI suggest that there is no magic bullet for repair. Biomaterials can be used either to achieve simultaneous and sustained delivery of multiple pharmaceutics or to promote tissue regeneration using cell scaffolds.

6.630.1.3. Animal Models of SCI

6.630.1.3.1. Small animal models

Treatment strategies are tested in different injury models to determine safety and efficacy according to the therapeutic target. For example, a cellular transplant may initially be tested in a hemisection model to prove efficacy and later in a compression model which closely mimics human SCI. The safety and performance of the corresponding cell delivery scaffold will likewise be evaluated in both injury models. Rats are a common, low-cost mammalian model that offers better working size for spinal surgery and device implantation than mice. Rat models of SCI fall into three categories: *transection* models involve cutting all or part of the spinal cord, *contusion* models quickly crush the cord with measured force,[9] and *compression* models compress the cord for a defined time.[10] These models are illustrated in Figure 2. Each model may be *acute*, where treatment is initiated immediately after injury, or *chronic*, where the treatment is delivered during a second surgery 4–6 weeks after injury. Acute models are used to assess neuroprotection and/or neuroregeneration, while chronic models can test only the latter.

Compression models produce astrogliosis and also mimic the residual displacement of the spinal column similar to that seen in human SCI.[9] In the model developed by Rivlin and Tator,[11] the cord is exposed by laminectomy and a modified aneurysm clip creates the injury as a function of both closing force and duration of compression. Force is simultaneously applied to both the dorsal and ventral aspects of the cord, as in human SCI.[12] The model has previously been used to study the pathology of secondary injury[13] and the importance of surgical decompression following injury, the latter of which is now a clinical practice option.[14] More recently, clip compression has been used to evaluate neuroprotective agents[15,16] and a novel biomaterial-based drug delivery strategy.[17] Variants on balloon compression, a technique in which injury severity is related to both the pressure of an inflated angioplasty balloon and its period of application, are also in current use. The balloon is inflated intrathecally or epidurally, being introduced into the intervertebral canal via laminectomy[18] or an intervertebral foramen.[19] The least invasive balloon compression models reach the spinal cord by lumbar puncture, causing minimal extraneous tissue damage and facilitating medical imaging by eliminating surgical artifacts.[19]

Contusion models produce a cystic cavity, axotomy, and demyelination through a defined force or displacement of the cord. Reviews by Park[20] and Kwon[21] describe how secondary injury increases the severity of SCI in the days postinjury and is the target of neuroprotective strategies. Multiple contusive models are in current use, most notably the New York University (NYU) Impactor[22] and Ohio State University (OSU) Impactor.[23] The NYU device impacts the cord with a defined force whereas the OSU Impactor produces a defined cord displacement. In both cases, the contusion is accomplished quickly, with the force applied and removed within 1 s. Two criticisms of contusive injury models are the asymmetric application of force (dorsal only) and short duration of compression.[11] These features are not present in human SCI and may be problematic for clinical trials based on data collected in a contusion model.

Transection models are used extensively to evaluate the efficacy of a regenerative therapeutic approach. This model

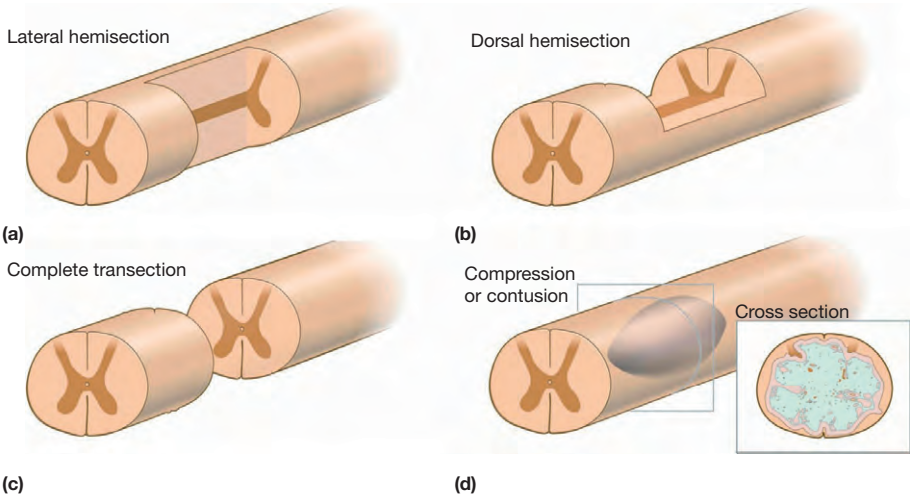

Figure 2 Animal models of spinal cord injury: (a, b) hemisection models cut sections of the spinal cord to produce specific functional deficits; (c) transection models create a gap between the rostral and caudal portions of the spinal cord; and (d) compression/contusion models mimic human spinal cord injury by creating a fluid-filled cyst. Image copyright (2006) by Michael Corrin.

can provide unambiguous proof of regeneration if a therapy leads to functional recovery and then the observed recovery is lost after resection. Hemisection leads to defined neurological deficits; thus, hemisection models are used when specific neuronal tracts are of interest. Dorsal hemisection cuts the sensory tracts in the dorsal horns while lateral hemisection disrupts both motor and sensory function. The main limitation of the hemisection model is the difficulty in accurately reproducing the injury and the consequent interanimal variability. Although transection does not accurately reflect the injury most often sustained by the individual (unless by stabbing or gunshot wound) or the pathophysiology of secondary injury, these injuries are useful for understanding the regenerative effect of experimental interventions.

6.630.1.3.2. Large animal models

The same models of SCI – compression, contusion, and transection – are also used in larger animals. Cats, dogs, and nonhuman primates, especially, are valued for functional neuroanatomy which more closely matches human structure and thus presents a more realistic scale of the injury. Promising therapies often progress from a rat model to a larger animal once the additional complexity and cost of the study can be justified. For example, data collected in an acute contusion model in the cat prompted the evaluation of methylprednisolone in multiple clinical trials, and the eventual use for treatment of human SCI. The preclinical data showed that so-called mega doses of methylprednisolone delivered within a short time of injury preserved the conduction velocity and amplitude of evoked potentials relative to controls.[24–26] Electrophysiology is an accepted predictor of injury severity (or recovery of function) and correlated well with locomotor assessment in the cat.[27]

More recently, acute application of the polymers poly (ethylene glycol) (PEG) and Poloxamer 488 was evaluated in naturally occurring, neurologically complete canine SCI. Outcome measures included pain perception, proprioceptive limb placement, locomotor testing, and electrophysiology.[28,29] In many ways, this model comes closest to what a surgeon might encounter in the clinic: unscheduled presentation; varied etiology, severity, and location; and a potentially demanding surgical timeframe. Though these factors understandably introduce variability into the study, positive outcomes may be more easily translated to the clinic because efficacy must be greater than the (large) interanimal variability. The disconnect between the controlled environment of a laboratory induced injury and often unknown character of real world SCI has been cited as a contributing factor to the high number of failed clinical trials in the field.[30]

Perhaps because of this fact, the use of nonhuman primate models is increasing, although there is not yet proof that a positive outcome in a 'clean' laboratory SCI in a nonhuman primate is a better predictor of efficacy for human SCI than the aforementioned feline, canine, or even rodent models. Much of this work is in Macaque monkeys, focused on the anti-NogoA family of antibodies first developed by Martin Schwab and coworkers. A recently completed a Phase I trial sponsored by Novartis examined anti-NogoA delivery over different periods between 1 and 28 days at participating European and Canadian hospitals. A Phase II trial is now being planned. The Macaque model used was an acute cervical hemisection which allowed testing of the forelimbs in tasks such as grasping and reaching.[31,32] Cervical injuries are the most common location of human SCI.[33]

6.630.1.4. Current Treatment Strategies and Clinical Trials

No device, drug, or cell therapy has shown significant functional recovery in a comprehensive clinical trial after SCI despite several trials.[30] Methylprednisolone sodium succinate (MPSS) was investigated in five clinical trials and adopted as a standard of care on the basis of modest functional recovery, but its continued use is debated because of an array of serious side effects.[34] These side effects are severe enough that the high dose arm of the most recent clinical trial was discontinued, a study in which MPSS was delivered intravenously for 48 h.[35] The modest functional benefit observed at lower intravenous doses and incidence of side effects at higher dosing suggest that localized delivery of MPSS, bypassing the BSCB, may achieve greater MPSS concentration at the injury site and increase function with fewer side effects. GM-1 ganglioside is a neuroprotective agent that was evaluated in over 700 patients with results similar to MPSS, showing a statistically insignificant trend toward improved function.[36] Modest functional benefit was observed at the lower dose and significant side effects were found at the higher dose, resulting in termination of this arm of the study. In this study, GM-1 was delivered intravenously over up to 8 weeks.[36] Current clinical studies are summarized in **Table 1**.

Cethrin is a Rho agonist which completed a Phase I/IIa safety trial in 2009 and entered Phase IIb, although this trial was terminated in early 2010. Cethrin is notable as the first use of a bioengineered delivery strategy. Cethrin is a bacterially derived kinase inhibitor coupled to a transport sequence which allows the molecule to pass from the epidural space, through the dura mater and arachnoid, to the intrathecal space and spinal cord. This route uses extra-dural administration where a fibrin matrix is used to deliver Cethrin on the dura mater; however, the concentration of Cethrin in the spinal cord has not been published.

Anti-NogoA, an anti-inhibitory neuroregenerative molecule, entered a Phase 1 clinical trial in 2006. Anti-NogoA was delivered clinically by continuous intrathecal infusion via an external pump; however, complications, likely due to infection, required multiple bolus injections over the course of the study. Anti-NogoA will enter a Phase II clinical trial.

Cell therapy holds great promise for treatment of SCI and will be the focus of more clinical trials as the technology matures. Two cellular treatments have been rigorously evaluated to date: the Procord trial for autologous macrophages[37] and a pilot study for bone marrow stromal cell (BMSC) injection.[38] The Procord trial did not progress and efficacy was not an endpoint of the BMSC trial. Geron currently has an embryonic stem-cell-derived oligodendrocyte precursor cell trial planned, with the view that the oligodendrocytes will save axons from degeneration. Cell therapy strategies face several key challenges for success: (1) defined starting cell population, (2) survival of transplanted cells, and (3) defined differentiation profile.

Biomaterials for the treatment of SCI are poised to grow as the advantages of drug delivery systems which reduce systemic

Table 1 Summary of select current clinical studies for spinal cord injury

Approach	*Description*	*Current stage of clinical trial*
Delivery of therapeutics		
Anti-NogoA	A monoclonal antibody that overcomes neurite outgrowth inhibition caused by NogoA. Delivered by osmotic pump or repeated bolus delivery by lumbar puncture	Phase I
Cethrin®	A Rho antagonist that promotes neuroprotection and neuroregeneration. Administered to the dura of the injured spinal cord with a fibrin sealant	Phase IIb – suspended
Minocycline	A broad spectrum antibiotic that has demonstrated neuroprotection in animal models. Injected intravenously	Phase I/II
Fampridine®	A voltage-dependent potassium channel blocker that improves sensory and motor function. Delivered intravenously or orally	Phase III
Cell-based therapies		
Procord®	Autologous macrophages that elevate the release of protective molecules. Delivered by injection onto the spinal cord	Phase II – suspended
Bone marrow stromal cells	Contains pluripotent cells that release growth factors to improve regeneration. Delivered by transplantation onto the spinal cord	Phase II

side effects and bypass the BSCB are recognized. The shift from repurposed small molecules with limited BSCB permeability (e.g., MPSS, minocycline) to larger and impermeable molecules (e.g., anti-NogoA) will accelerate this trend. The clinical use of cell-seeded scaffolds in other tissues[39,40] will drive clinical investigation of this strategy after SCI. Biomaterials which enhance cell survival or direct differentiation in the CNS are currently being developed.

6.630.2. Biomaterials for Drug Delivery

Strategies for delivering drugs to the injured spinal cord are categorized as either systemic or local. The primary obstacle to systemic drug delivery is the BSCB. A compounding problem for spinal drug delivery is that with the exceptions of methylprednisolone,[41] GM-1 ganglioside,[42] minocycline,[43] and cAMP moderators,[44] a majority of molecules proposed to treat SCI are high-molecular-weight proteins. These biomacromolecules generally possess short serum half-lives and can act nonspecifically (e.g., as mitogens), which further complicates systemic delivery. Local delivery of therapeutic molecules using biomaterials circumvents the BSCB and denaturation in serum by delivering the drug payload directly to the spinal cord, most often as a drug-loaded hydrogel injected into the epidural or intrathecal space. The possibility of systemic side effects and toxicity are likewise reduced by local delivery.[45]

The utility of a biomaterials strategy for localized release stems from the ability to deliver a sustained release formulation from a single injection. Sustained release is common for both neuroprotective and neuroregenerative molecules: in the latter case, efficacy is often improved when drug delivery is continued up to 28 days. This is currently only clinically possible from indwelling catheter and pump systems, although the method is not approved for use after SCI. These systems are initially appealing because they afford excellent control of the drug concentration delivered to the epidural fat or intrathecal space via a catheter over a period of weeks as shown in **Figure 3**. Both implanted and external pumps are available; however, external pumps are more susceptible to infection.[46,47] Significant drawbacks include the risk of scarring and compression of the spinal cord by an intrathecal catheter, chronic inflammatory response to the implanted pump, and the risk of infection when using an external infusion pump.[48]

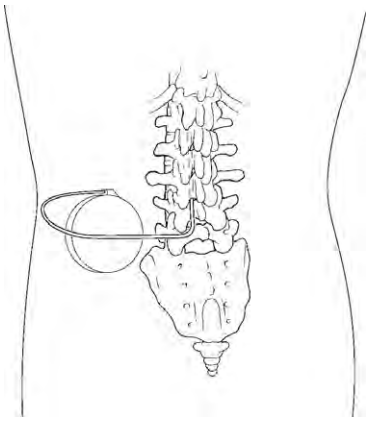

Figure 3 Infusions pumps may be implanted under the skin in a patient's abdomen and a catheter tunneled subcutaneously into the epidural or intrathecal space. Models used in animal studies are often powered by osmotic pressure whereas those in clinical use are powered by batteries or pressurized propellant. Image copyright (2006) by Michael Corrin.

The bolus injection of an appropriately formulated sustained release device is an attractive alternative to both the minipump/catheter and single bolus injection because it removes the risk of chronic catheter scarring, can be minimally invasive, and attenuates the host inflammatory response and risk of infection.

Among biomaterials strategies tested in compression/contusion models, the large majority are classified as epidural bolus delivery, such as injection of polymer hydrogels, liposomes, and combinations thereof.[49–51] In instances where a laminectomy is performed (i.e., in all injury models save balloon compression and as part of surgical decompression), gels may be applied directly to the exposed dura. Fibrin sealant has been used in this manner,[52,53] as have been foamed gelatin (e.g., Gelfoam)[54–56] and collagen.[57,58] Drugs released into the epidural space must cross the dura and arachnoid mater and

the fluid-filled intrathecal space before reaching the spinal cord. Various investigators also exploit intrathecal injection of a drug delivery system. This route affords greater localization than epidural delivery but requires puncturing the dura and arachnoid mater. One strategy is the injection of drug-loaded microparticles which are distributed throughout the intrathecal space by CSF flow. So long as the particles are too large to pass through the arachnoid granulations, the valves through which CSF drains to the venous blood, they can sustain release to the brain and spinal cord. This approach has been demonstrated using the analgesic Baclofen, where therapeutic concentrations were maintained for up to 30 days from 30-μm PLGA particles.[59–61] Another option is dispersing drug-loaded particles in a hydrogel, such as hyaluronan/methyl cellulose blend (HAMC) and injecting the resulting composite into the intrathecal space at the site of injury.[62] The drug can also be delivered from the HAMC hydrogel alone.[15,62,63] Localizing the drug payload on a specific area of the cord should avoid systemic side effects and other nonspecific effects elsewhere in the CNS and reduce the overall required dose.

Other biomaterials based drug delivery strategies have been developed on the basis of transection models of SCI, which may be modified to work with compression injuries in the future. Treating compression injury is important because 70% of clinical SCI is by compression.[64] Examples include photo-cross-linkable PEG,[65,66] fibrin gels,[67,68] and liposome or microparticle loaded agarose.[69,70]

6.630.2.1. Hydrogels

Many treatment strategies use hydrogels as a drug delivery device or scaffold for cell growth. Hydrogels are polymer matrices swollen by osmotic pressure and held together by intermolecular entanglement, reversible physical binding, or chemical cross-linking.[71] Forces of physical binding include hydrogen bonding, hydrophobic junction formation, and electrostatic attraction. Water content varies widely, from 40% in poly (2-hydroxyethyl methacrylate) gels to over 99% in the weakest agarose gels. Hydrogels, such as the one described in **Figure 4**, are the method of choice to achieve localization and spatial control of drug release within the intrathecal space because many are easily formulated to be injectable, can be gelled by various stimuli, and their high water content favors biocompatibility.[72] The extent of cross-linking of biodegradable polymers controls swelling.[72,73] Cell adhesion to the hydrogel can be intrinsic, such as with collagen (cell adhesive)[74] or agarose (noncell adhesive),[75] or modified through addition of cell-adhesive peptides.[76] In hydrogels with very high water content, drugs can be delivered at concentrations comparable to those used in infusion pumps, or a controlled release technology such as drug-loaded particles[62,70,77] or liposomes[69,78,79] can be incorporated.

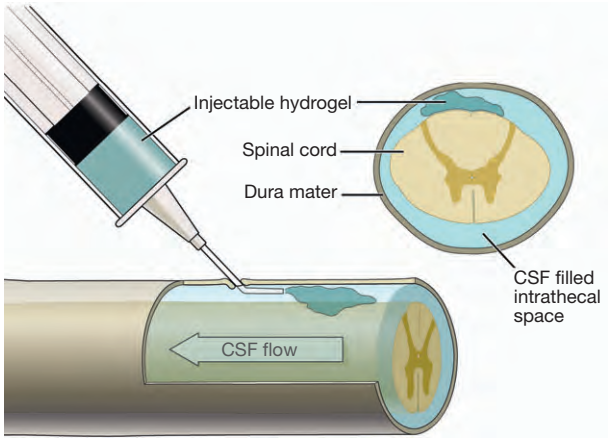

Figure 4 A hydrogel of hyaluronan and methylcellulose used for local and sustained drug delivery to the injured spinal cord. This fast-gelling, injectable hydrogel allows for a minimally invasive mode of treatment. Image copyright (2005) by Michael Corrin.

Both physical and covalently cross-linked hydrogels can be applied to the treatment of SCI. Physical gels generally offer milder cross-linking conditions and simplicity of use, and lack the possible toxicity associated with covalent coupling agents used *in situ*. Among physical gels which form by thermal means, inverse thermal-gelling polymers are most flexible because the subzero temperature needed for fast gelation of traditional materials is avoided. For example, agarose has been used as an *in situ* gelling epidural drug delivery system where gelation was triggered by flooding the injection site with air cooled by dry ice.[69,70] This type of system is less applicable intrathecally, where the gel is separated from the environment by the dura and arachnoid and subzero temperatures are likely to damage these tissues. Other polymers which gel on cooling include carrageenan and gelatin, among other polysaccharides.[80,81] Prominent inverse thermal-gelling polymers are methylcellulose, hydroxypropyl methylcellulose (HPMC), and chitosan–glycerol phosphate systems (CSGP). The cellulosic materials gel on heating as the water of hydration is lost, exposing hydrophobic portions of the backbone which then associate to form hydrophobic junctions. Gelation of MC in water occurs between 40 and 50 °C and HPMC between 75 and 90 °C.[82] Increasing the ionic strength of MC/HPMC solutions lowers the gelation temperature by reducing the number of free solvent molecules in the system through the salting out effect. This effect has been exploited for intrathecal drug delivery where methylcellulose formulated with anionic hyaluronan quickly forms a physical gel on exposure to body temperature.[15] CSGP solutions also gel as temperature is increased and the water of hydration is lost. In this case, gelation is a function of facilitated hydrophobic interactions and hydrogen bonding between chitosan chains.[83,84] Physical gels can also be formed through ionic interactions, most commonly between an anionic polymer such as alginate, gellan, or carrageenan, and divalent cations.[85] These gels can be stable *in vivo* and have been used for drug delivery.[86,87] Ionic gelation can be very fast, potentially making these materials difficult to use *in vivo*. A double barreled syringe or temporary loading of ions in liposomes may improve ease of use.[88]

Chemically cross-linked hydrogels are of interest because they allow greater flexibility to manipulate physical and biological properties than typically possible in physical cross-linking. For drug delivery, a polymer is modified with synthetic functional groups with the goal of enabling (or enhancing) gelation, improving *in vivo* stability, or imbuing specific enzymatic susceptibility. For example, the biocompatible, biodegradable, angiogenic, and anti-inflammatory nature of

hyaluronan drives synthetic efforts.[89–91] PEG and PEG–poly (lactic acid) block copolymers are also of interest. In these cases, the PEG backbone is nondegradable and cross-linking produces stable hydrogels.[92] Degradability is conferred by inclusion of PLA.[93] Some methods of chemical cross-linking, such as ionizing radiation and those requiring toxic organic solvents, are obviously incompatible with *in situ* gelation.[94] Photoinitiated radical cross-linking is most promising because the reactions are (a) fast, (b) proceed in water, (c) do not require a small molecule cross-linker, which can be toxic, and (d) can take place at physiological temperatures. Glycidyl methacrylate[90,95–97] and other acrylates[98,99] are most often used. Primary concerns are the choice and quantity of initiator with regard to toxicity, cross reactivity between the cross-linking chemistry and drugs in the hydrogel, and the potential for local heating during cross-linking. In addition, if the gel is rendered opaque by addition of drug-loaded particles or liposomes, it may not be possible to reliably photopolymerize the sample. A second cross-linking chemistry which has received significant interest is the grafting of thiol functional groups to create reversible disulfide bonds.[100,101] This chemistry is applicable to epidural use but the relatively slow rate of cross-linking, ~10 min, makes it unsuitable for intrathecal injection where CSF flow can dilute the pregel.

Overall, both physical and covalently cross-linked gel can be designed for spatial control of drug release in the intrathecal space. Physical gels are valued for the selection of biocompatible polymers, ease of fabrication, and absence of cross-linkers, initiators, or risk of gel–drug reactivity during cross-linking. The stability of chemically cross-linked gels, however, can be greater than that of physical gels.

6.630.2.1.1. Control of drug release

Bulk release is the simplest form of drug delivery from hydrogels and is a diffusive process often well described by Fick's law, wherein the fraction of drug released is linear with root time for the first 75% of drug released.[73,102] In this instance, the gel is formed in the presence of, or soaked in, a concentrated solution of the target drug so that the hydrogel bound solvent contains the molecule of interest. Drug release is completed quickly because the polymer chains present a minimal physical barrier, and drug diffusivity is similar to the rate observed in water. Exceptions are found when the hydrogel is highly cross-linked or the drug interacts with the hydrogel, either by electrostatic or hydrophobic interactions.[103,104] The period of drug release depends on molecular weight, diffusive path length, and sample geometry,[102] but is often reported to be 6–72 h *in vitro*.[16,62,77,105] This compares favorably to drug clearance from the intrathecal space after bolus injection of a drug solution, where the entire volume of CSF is turned over every 4–6 h.[106] A subset of bulk release is the suspension of poorly soluble drug particles in the hydrogel. In this case, release is limited by the rate of drug dissolution at the particle surface, and is prolonged relative to Fickian diffusion.[103,107,108] Bulk release is useful for the delivery of neuroprotective molecules which are required in the first weeks after injury.

Therapeutic molecules can also be incorporated into the hydrogel structure as part of the polymer backbone or as a pendant graft.[100,105,109] Incorporation into the backbone results in drug release only upon hydrogel degradation and is not suitable for use in the intrathecal space, where the partly degraded hydrogel with remaining drug load is likely to be removed from the injection site by CSF flow. Binding a drug to the polymer backbone *via* a hydrolytically cleavable linkage is useful when very specific release kinetics are required or it is not practical to delay release using particles/liposomes.[105,110,111]

6.630.2.2. Polymeric Particles

The ability of solid polymers to segregate drugs from the environment and control their *in vivo* release has led to their use in the delivery of peptides,[112] proteins, including neurotrophins;[113] DNA,[114] and many small molecules.[115–117] Solid polymer controlled drug release devices take many forms, with micro- and nanoparticles thoroughly studied because of their versatility in application.[118] Drug release from particles can be controlled by matrix degradation, passive diffusion, or a combination of the two. Degradative mechanisms are further subdivided into bulk degradation and surface erosion. In addition, the role of device fabrication technology, surface area to volume ratio, polymer structure, presence of excipients, and drug loading all play a part in governing drug release. In **Figure 5**, increasing the drug load is seen to increase surface porosity, accelerating drug release (and particle degradation). The size of particles used in epidural formulations is not restricted, but those of 40 μm and smaller are desirable for intrathecal delivery because they are likely to be injectable[92] and therefore minimally invasive.

Both synthetic and natural polymers find application as particulate delivery systems: in many cases the desired release profile informs polymer choice. Among synthetic polymers, poly(ortho esters), poly(hydroxyesters), poly(phosphazenes), and poly(ε-caprolactone) (PCL) are the most frequently cited.[22,23] Poly(anhydride) degradation by surface erosion and enzymatic degradation of polypeptides are also well known. Polymers of natural origin used to fabricate particles include chitin, poly(L-lysine), and alginate.[119,120] Fabrication of natural polymer-based particles often exploits the polyelectrolyte nature of these materials for drug encapsulation and particle formation. Particles of poly(lactic-*co*-glycolic acid) (PLGA) are especially important because the family of PLGA copolymers has been widely investigated for drug delivery, hydrophilic and hydrophobic drugs can be encapsulated using similar techniques,[117,121] and release of many molecules can be sustained for 30 days.[121,122] Additionally, PLGA is degraded by hydrolysis with well-characterized degradation products.[123] This degradation mechanism is expected to predominate when particles are injected intrathecally. When particles are prepared by double emulsion, the release kinetics, encapsulation efficiency, and particle size can be tailored by adjusting polymer concentration, molecular weight, copolymer ratio, solvent removal rate, drug loading, and surfactant concentration.[124,125]

With regard to the biocompatibility of PLGA in the CNS, the tissue response after epidural application is likely to parallel that in adipose tissue, where a thin fibrotic capsule can form around the polymer.[126] There are few reports of polymeric particle injection into the intrathecal space, and these indicated that PLGA was well tolerated.[59–61] This result is in accordance with the general literature, where PLGA and poly(alkyl cyanoacrylate) (PACA) particles are most thoroughly studied. PACA

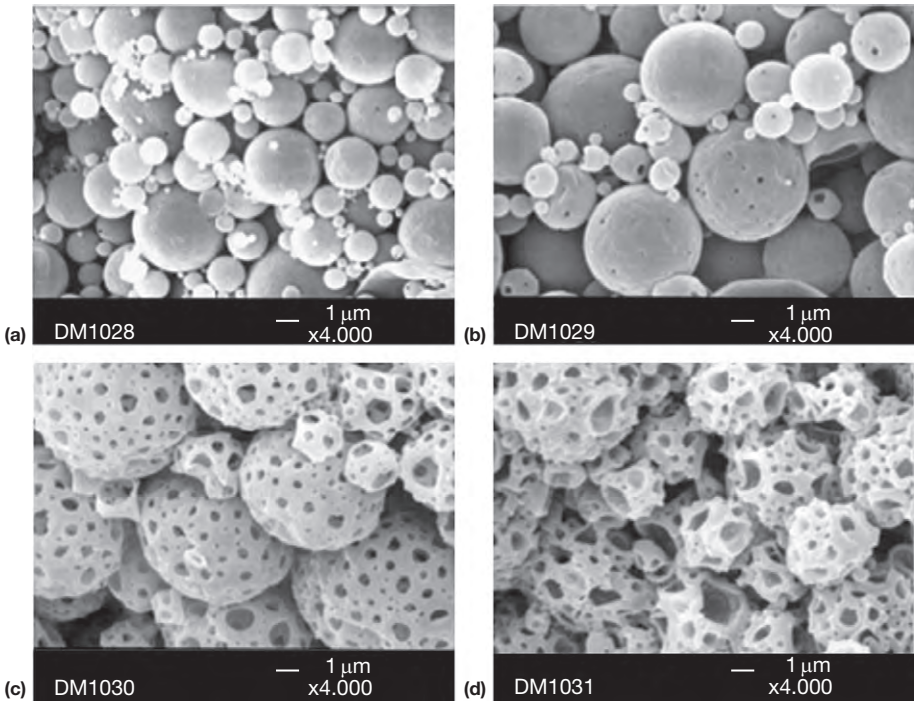

Figure 5 Electron microscope photographs of poly(lactic-*co*-glycolic acid) (50:50) microparticles prepared by the w/o/w solvent evaporation with increasing nominal drug loadings of (a) 0, (b) 1, (c) 5, and (d) 10% (w/w). Reproduced from Witschi, C.; Doelker, E. *J. Control. Release* **1998**, *51*(2–3), 327–341, with permission from Elsevier.

is clinically approved for *intra venous* use, but these particles degrade within hours[127] and are unlikely to sustain release sufficiently after SCI. Detailed studies of how injected particles are distributed in the intrathecal space, the local tissue response, and clearance mechanisms are needed to support the use of particulate biomaterials for spinal drug delivery.

6.630.3. Biomaterials for Cell Delivery

Biomaterials play a key role in strategies to encourage regeneration of native tissue by providing physical support and a controlled environment for repair. Nerve guidance channels, which aim to bridge nerve gaps after transection injury, have been developed on the basis of successes in the PNS.[128] The importance of polymeric scaffolds as fillers of tissue defects and as a transplantation matrix for cell delivery is increasing, encouraged by advances in other areas of tissue engineering.[129–131]

6.630.3.1. Nerve Guidance Channels

Nerve guidance channels, or conduits, are designed to assist in SCI repair by protecting and guiding nerve regeneration through the bridging of nerve gaps.[128] As such, key design criteria for nerve guidance channels are sufficient porosity for neurite ingrowth, cell adhesion, and mechanical strength. Nerve guidance channels may also be biodegradable, electrically active, enclose an internal matrix, or incorporate longitudinally parallel microchannels or fibers.[132–135]

Nerve guidance channels may be implanted for physical support alone after SCI, or seeded with cells in a combination therapy. The purpose of cell transplantation is to promote axonal regeneration and remyelination. Cell types that are transplanted include neural stem/progenitor cells (NSPCs), Schwann cells, and olfactory ensheathing glial cells.[136–138] Olfactory ensheathing glial cells have been delivered alone and with Schwann cells to promote axonal regeneration and functional improvement.[139,140] Schwann cells alone have been shown to provide a conducive environment for axonal regeneration when used in nerve guidance channels in the transected spinal cord.[141] However, in order to prove lasting functional recovery, the long-term survival of these cell types must be better understood.[142]

The appropriate polymeric biomaterial for nerve guidance channels must be biocompatible, nontoxic, and elicit only a minimal inflammatory response.[143] An example of a nondegradable material is poly(acrylonitrile)/poly(vinyl chloride) (PAN/PVC), which has been used in the delivery of Schwann cells and olfactory ensheathing glia.[128] As PAN/PVC is not cell adhesive, PAN/PVC channels were filled with Schwann cells suspended in Matrigel, resulting in partial regeneration but limited recovery.[137] Matrigel is derived from a mouse sarcoma and includes extracellular matrix (ECM) proteins and growth factors.[144] The inclusion of cyclic AMP (cAMP) to the Schwann cell/Matrigel PAN/PVC guidance channel promoted greater tissue regeneration and functional recovery.[44]

A second nondegradable polymer is poly(2-hydroxyethyl methacrylate) (PHEMA).[128] This is an attractive material for SCI therapy, as it is biocompatible and nontoxic.[142] It has tunable mechanical properties, and is the only polymer to date that has been fabricated as a nerve guidance channel with an elastic modulus corresponding to that of native spinal

cord tissue.[145] With the addition of an internal matrix such as collagen, fibrin, Matrigel, or methylcellulose, PHEMA has been shown to support axonal regeneration in injured rat spinal cords.[134] The surface charge of this polymer can be modified by the addition of quaternary amine groups or a second methacrylate subtype to promote cell adhesion.[141] In addition, it can incorporate bioactive compounds or functional concentration gradients to direct neurite outgrowth.[128,141]

The formation of nerve guidance channels from biodegradable polymers is of current interest because they do not require surgical removal. The majority of this class of biomaterials are natural polymers.[128] One such natural polymer, collagen, has been fabricated into guidance channels using chemical cross-linkers. Collagen has been approved by the FDA for use in the PNS as a nerve guide.[128] Collagen nerve conduits have also been modified with ECM proteins and peptide sequences to provide directional guidance.[146] Agarose scaffolds, with and without the addition of brain-derived neurotrophic factor, were found to guide axonal regeneration in a hemisection spinal cord model.[147] The natural polymers alginate and chitosan have also been used with seeded cells in transected spinal cord models.[141] Chitosan, introduced in **Chapter 2.213, Chitosan**, exhibits tunable properties through varying its acetyl group content and has been used to transplant peripheral nerve grafts and NSPCs into the injured rat spinal cord, showing increased axonal regeneration.[136,148,149] Tissue bridges formed in chitosan tubes seeded with brain-derived NSPCs were thicker than those formed in identical tubes seeded with spinal-cord-derived NSPCs. Both cell types formed tissue bridges that were thicker than those in animals which received chitosan tubes alone.[136] The tissue bridge can be easily observed through the transparent chitosan tube in **Figure 6**. Poly(α-hydroxy butyrate) (PHB) enhanced axonal regeneration in rat cervical spinal cord hemisection.[142] Partial regeneration and limited recovery were shown in rat models after the delivery of Schwann cells wrapped in PHB.[128]

Desirable synthetic polymers include poly(α-hydroxyacids), of which poly(glycolic acid) (PGA) and PCL have been approved by the FDA for PNS nerve regeneration.[128] Unlike poly(D,L-lactic acid), poly(L-lactic acid) (PLLA) has been used in nerve guidance channels without tube collapse, but has more rapid degradation.[141,142] PLGA has been shown to support neurite outgrowth to a greater extent than PCL and PLA.[141] A multichannel PLGA scaffold seeded with Schwann cells supported robust axonal growth but resulted in the formation of a rim of fibrous tissue surrounding the regenerated neurons. Subsequent investigations showed that a smaller channel diameter reduced the amount of fibrous tissue, yet it has not been pursued further.[141] Electrically active polymers such as poly(tetrafluorethylene) (PTFE), polypyrrole (PP), and polyvinylidene fluoride (PVDF) may be used to deliver electrical stimuli.[133,150,151] This approach is interesting as it has been shown that electrical stimulation results in increased neurite outgrowth.[152]

Many nerve guidance channels are designed to promote cell adhesion through either nonspecific or specific cell-surface receptors.[128] Nonspecific physical adhesion can be improved by changing the surface charge or increasing surface roughness. Specific cell–polymer adhesion can be achieved by functionalizing the conduit with ECM proteins such as laminin or fibronectin, or derived protein sequences such as RGD, YIGSR, or IKVAV.[153,154] The inclusion of an internal matrix can prevent tube collapse and improve bioactivity.[128] Multiple channels, longitudinally oriented fibers, or hydrogels have been used in this capacity.[128] An open path design using the internal matrix as minimal structural support was shown to improve regenerative capacity.[155] This demonstrates not only the importance of good cell–polymer adhesion, but also sufficient porosity for cell penetration.

An improvement in axon alignment can be achieved through the fabrication of microgrooves or the addition of cell-adhesive proteins or nanofibers.[141] Micro- and nanofibers synthesized by electrospinning, self-assembly, or phase-separation provide a large surface area for cell contact as well as spatial cues to promote nerve alignment.[152] Precise microtopographical features to control axon growth can be created using soft lithography, and most commonly using the nondegradable material poly(dimethyl siloxane).[152] These features influence axonal growth and direction by mimicking the microenvironment of the ECM; however, PDMS tubes are limited by poor permeability of nutrients across the wall structure.

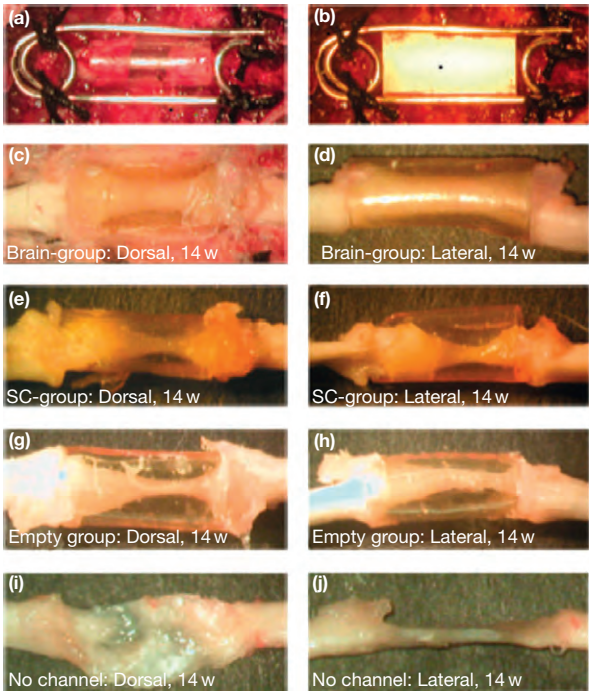

Figure 6 Surgical procedure for extramedullary chitosan channel implantation after spinal cord transection (a and b). At 14 weeks, gross appearance of the implanted channel (c–h) or spinal cord transection alone (i and j), from the dorsal and lateral aspects. In each panel, rostral is on the left. (a) Dorsal view of the transected spinal cord stumps placed within the transparent chitosan channel. The gap between the stumps is ~3.5 mm. (b) The spinal fusion with wire for spinal stabilization and the expanded polytetrafluoroethylene membrane placed on the dorsal aspect of the channel for prevention of scar invasion. (c–h) There is a tissue bridge inside the channels in the brain (c and d), spinal cord (e and f), and empty-channel groups (g and h). The brain group has the thickest bridge (c and d). In the no channel group, there is a pale connective tissue between the stumps (i and j). Reproduced with permission from Nomura, H., *et al*. *Tissue Eng. A* **2008**, *14*(5), 649–665.

6.630.3.2. Scaffolds

Polymer biomaterials are also used as scaffolds for cell transplantation to the injury site where they can fill defects and promote tissue repair, distributing cells throughout the injury. Because scaffolds are commonly used as cell carriers or to encourage host cell ingrowth, it is critical to consider cell–material interactions. High porosity is essential for cell attachment, allows for tissue vascularization, and will improve implant stability through the integration of scaffold and surrounding tissue.[141] However, high porosity materials may also exhibit weaker mechanical properties and faster degradation rates if the material is biodegradable. Successfully engineered scaffolds to be used in cell delivery have mimicked the cell microenvironment, or 'niche.'[156] The primary cells of interest are Schwann cells, neural stem/progenitor cells (NSPCs), and olfactory ensheathing glia.[128] Genetically modified cells that overexpress neurotrophic factors have also been pursued in a variety of combinatorial strategies.[157] An early example is the transplant of fibroblasts genetically modified to secrete NGF in collagen matrices applied to a hemisection model of SCI, resulting in neurite outgrowth from multiple neurite populations.[158] Scaffolds seeded with NSPCs provide platforms for cell differentiation, and potential for repair of large defects.[142] Coculture of NSPCs and endothelial cells (ECs) is being explored to enhance tissue survival by promoting development of vasculature.[156] For example, a scaffold seeded with brain ECs and neural progenitor cells implanted in a hemisection model of SCI promoted angiogenesis and BSCB formation.[159]

The most commonly used materials for SCI repair scaffolds are hydrogels.[128] Hydrogels, described in detail in **Section 6.630.2.1**, permit cell migration and nutrient exchange with the surroundings. Hydrogel structure mimics the native ECM and can be fabricated with varying elasticity and degradation rates to balance proliferation and differentiation of transplanted cells and/or in growth of host cells.[128,141]

ECM-derived hydrogels include collagen and hyaluronan (HA).[141] Collagen is thermoresponsive and gels at physiological temperatures. Therefore, it can be used for injectable polymer delivery and can incorporate cells. HA has been used as a matrix for embryonic spinal cord tissue in the transected spinal cord, but has also been used as a drug delivery scaffold when delivered as a physical blend with MC (see **Section 6.630.2**).[141] HA combined with cultured embryonic spinal tissue transplanted into the gap after spinal cord transection resulted in slight functional recovery.[142] HA and MC have also been shown to decrease the host inflammatory response relative to saline controls when injected into the intrathecal space.[143] Large-scale purification and sterilization of natural materials such as collagen are challenging however, and synthetic materials have been modified to include bioactive compounds similar to natural polymers.[156]

A wide range of synthetic polymers have been used as scaffolds for SCI because of the ease of purification and processing, and because their mechanical properties are more easily controlled. PEG has demonstrated neuroprotective properties *in vitro* and has been thoroughly examined as a polymer to control cell function.[142,143] PEG is attractive because, although it is not intrinsically cell adhesive, it can be modified with proteins and peptides to promote specific cell adhesion and differentiation.[143] PLA, PGA, and PLGA have also been investigated.[141] It has been shown that PLGA supports NSPC viability and proliferation. PLGA scaffolds seeded with NSPCs in a hemisection model showed persistent functional improvement for up to 1 year.[141] PLGA scaffolds seeded with murine neural stem cells were reported to significantly improve functional recovery. PLGA is undesirable for use in the spinal cord because it is more brittle than the spinal cord and degrades to acidic end products.[142] Scaffolds have also been fabricated to more closely mimic ECM through three-dimensional biochemical patterning and the inclusion of directionally guiding fibers.[128] Three-dimensional fibrin scaffolds are promising for neural stem cell differentiation and transplantation.[141]

Nondegradable polymers have also been used as membranes in encapsulated cell therapy.[143] In this approach, cells are protected from the host immune response by a polymeric membrane, facilitating use of nonautologous sources. Cells have been encapsulated in hollow fiber and microspherical membranes using polymers such as PAN/PVC, PHEMA–MMA, and alginate/poly(lysine), which were selected for their biocompatibility and processability. The challenge in encapsulated cell therapy is achieving a balance between effective nutrient, waste, and cell product exchange, while also shielding the cells from the host immune response. It has also been difficult to encapsulate therapeutically relevant numbers of cells.[143]

Through biochemical and structural modifications, it may be possible to control the behavior of exogenous or endogenous stem cells within scaffolds.[156] The microscale scaffold architecture of the ECM can be replicated and used to bias the fate of transplanted NSPCs. The mechanical properties, such as the elastic modulus, can also be manipulated to influence cell fate.[156,160] The biomimetic ECM can be chemically modified with bioactive molecules, such as proteins or derived peptide sequences, to promote cell adhesion or growth factors to induce proliferation and differentiation.[156] Both the scaffold material itself and the incorporation of bioactive factors can be used to direct cell differentiation.[142]

In on-going studies, biomaterials that promote cell survival, cell differentiation, and cell integration with the host tissue are being developed. Here, the biomaterials provide both the structural and chemical environment for survival and delivering factors, such as chondroitinase *abc*, to promote cell integration with the existing tissue.[161]

6.630.4. Future Outlook

Almost 30 years have passed since David and Aguayo demonstrated the regenerative potential of CNS axons and still no effective cure has been developed to overcome SCI. Translating positive results in animal models into the clinical setting has proven to be a significant challenge. There is clearly no 'magic bullet' that will overcome SCI. Instead combination strategies are now being pursued.

Biomaterials provide an opportunity to achieve greater efficacy for both therapeutic and cell delivery. For delivery of therapeutic molecules, biomaterials have been designed to achieve local and sustained release at the injured spinal cord, thereby overcoming the limitations of current delivery strategies. These new methods promise to achieve greater efficacy of

current molecules while also facilitating the release of multiple factors at different rates.

For the delivery of cells, biomaterials allow the codelivery of factors that promote survival and host tissue integration – two areas that have limited the efficacy of cell delivery. By providing an environment conducive to cell survival, biomaterials have already shown a significant benefit.[162] Moreover, biomaterials allow codelivery of therapeutic molecules and cells, thereby providing multiple strategies to promote repair in the complex spinal cord.

Biomaterials allow the combination of previously independent treatment strategies. For instance, an appropriately designed biomaterial could deliver a cocktail of neuroprotective/neuroregenerative molecules and stem cells, while providing a chemical and mechanical environment conducive to nerve guidance and regeneration. Through the development of clinically relevant biomaterials, it may be possible to achieve improved efficacy in the treatment of SCI.

TGF-β	Transforming growth factor beta
YIGSR	Tyrosine-isoleucine-glycine-serine-arginine

6.631.1. The Cornea and the Need for Corneal Replacement

The cornea is the transparent window at the front of the eye which acts as both the main refractive component of the eye and as a physical barrier, protecting the interior ocular components.[1] It consists of three cellular layers, the epithelium, the stroma, and the endothelium separated by Bowman's and Descemet's membranes, respectively. The epithelium consists of five to seven layers of corneal epithelial cells and is primarily responsible for providing the barrier function of the cornea. The stroma, the thickest corneal layer and its main structural element, consists of a highly hydrated (~80%) collagen network and relatively few keratocytes. The endothelial layer consists of a single layer of cells, organized hexagonally. It is mainly responsible for the regulation of corneal hydration.

As the cornea refracts light onto the retina, any damage or opacification of the organ will result in vision impairment or blindness.[2] According to the World Health Organization, vision loss due to corneal disease, trauma, scarring, or ulceration constitutes the second leading cause of blindness,[3] affecting more than 10 million people worldwide, primarily in the third world.[4] Estimates suggest that 1.5–2 million new cases of corneal blindness occur annually as a result of cornea trauma or ulceration.[4]

In the developed world, the most successful treatment for cornea blindness is corneal allograft surgery, or penetrating keratoplasty, involving the replacement of the diseased or damaged corneal tissue with donor tissue. An 80% success rate has been reported in the 2 years following the surgery;[4] however, this rate falls to 65% 5 years post surgery[5] with additional complications and lower success rates associated with specific disease states.[1] Furthermore, there is a risk of disease transmission with corneal allograft surgery, particularly HIV and hepatitis.[6] With a shortage of donor tissue, surgical wait times average 2 years in North America. These times are expected to increase mainly due to an aging population[4] and the increased popularity of laser *in situ* keratomileusis (LASIK) surgery, which renders the cornea unsuitable for donation.[6] An artificial corneal replacement therefore represents an attractive alternative to donor tissue in the developed world and may be the only option in developing countries.[2]

An artificial corneal replacement must be transparent, with a refractive index similar to that of the native tissue, nontoxic and able to interact and preferably integrate with the surrounding corneal cells and tissue. Furthermore, it must be sufficiently strong to withstand intraocular pressure, and for maintaining cellular viability, it has been suggested that oxygen and nutrient diffusion are desired.[1,2,6,7] Current artificial cornea devices are either considered as keratoprostheses (KPros), which are made from synthetic polymers with or without biological components, or as tissue-engineered corneal equivalents, typically made from natural polymers and an appropriate biological component.[7] The focus of this chapter will be KPro, including those that are currently used clinically and those that are under development.

6.631.1.1. Keratoprosthesis

Synthetic KPro devices have the advantage of being available off the shelf as well as reducing the risk of disease transmission associated with allograft surgery.[2] Current clinically available KPro are designed either as collar button devices, also referred to as the optical stem with skirt implant, or as core and skirt devices in order to promote device integration.[8] The former design consists of two plates joined by a transparent optical core, while the latter design has a transparent optical core surrounded by a porous skirt used to anchor the device into the stroma. In addition to transparency, it is desirable for the optical core to be sufficiently short to avoid anterior chamber penetration.[9] Anchorage segments must be flexible, matching the properties of the native tissue where possible and sufficiently strong to permit suturing.[8] In many designs, the porosity and pore size of the skirt is sufficient to permit cellular infiltration, cell interactions, and extracellular matrix deposition.[6] It has also been suggested that the anterior surface of a KPro should encourage epithelialization to promote tear interactions and minimize the risk of bacterial infection. However, epithelial downgrowth should be avoided as this can lead to device extrusion.[7]

Early KPros were fabricated from gold, quartz, and glass and were associated with a high incidence of device extrusion.[9,10] The observation during World War II that certain polymers were relatively benign in the eye, led to the introduction of a second generation of KPros fabricated from synthetic polymers. While poly(methyl methacrylate) (PMMA)[10] was the first to be used, polymers, including polytetrafluoroethylene (PTFE), polybutylenes:polypropylene, polyurethane, Dacron, poly(2-hydroxyethyl methacylate) (PHEMA), and poly(dimethyl siloxane) (PDMS), have also been examined in artificial cornea applications.[2,10] Failure of these devices is often the result of their inability to interact sufficiently with the host tissue, resulting in stromal melting and epithelial thinning and ultimately extrusion of the device from the eye as well as such complications as aqueous humor leakage, infection, retroprosthetic membrane formation, retinal detachment, and glaucoma.[6,7,11]

6.631.1.2. Dohlman–Doane KPro

The Dohlman–Doane KPro (D-KPro) is a US Food and Drug Administration-approved PMMA collar button device that sandwiches the corneal tissue between two plates which has been implanted in over 190 eyes since the 1990s.[12,13] There are two prototypes: type I is utilized for patients with good ocular surface hydration, while type II is intended for use in patients with such ocular surface diseases as dry eye, ocular mucous membrane pemphigoid, or Stevens–Johnson syndrome.[12,13]

Clinical results with this device have been quite promising and it is currently one of the most used artificial cornea devices. Following implantation in 63 eyes between 1990 and 1997, six devices required replacement, while ten devices were permanently removed.[14] Complications associated with the D-KPro were glaucoma (46%), retroprosthetic membrane formation (37%), tissue melting (29%), retinal detachment (19%), and endophthalmitis (8%). Although visual acuities between 20/20 and 20/200 were achieved immediately following the surgical procedure, in 42% of patients, this improvement in vision was subsequently lost due to device complications.

Ongoing work has led to improved design as well as better surgical and postoperative care regimens including treatment with anti-inflammatory agents, contact lens bandages, or antibiotics. This resulted in a lower incidence of device extrusion and improved visual acuity.[15,16] Furthermore, there have been no reports of occurrences of endophthalmitis, reoperations, dislocations, or extrusions of implanted 25 D-KPros as of 2005.[17]

6.631.1.3. Osteoodonto KPro

The Osteoodonto KPro (OOKP) was developed based on the observation of tissue interactions with tooth components; it is composed of a PMMA optic, secured to a haptic made from a tooth root belonging to the patient or a compatible donor.[18] Synthetic OOKP devices have also been fabricated using aluminum oxide, hydroxyapatite (HA) ceramic, and glass ceramic.[19] However, degradation of corals, HA-based materials, tooth, and bone was rapid and may not be suitable for the ocular environment; hence more chemically stable materials are necessary.[19] Long-term studies in 224 eyes between 1973 and 1999 demonstrated 85% retention over 18 years with few complications[18]; however, there are concerns of increased intraocular pressure and resorption of the bone, due to chronic inflammation, which loosens and leads to the eventual failure of the device.[19,20]

6.631.1.4. Seoul-Type KPro

The Seoul-type KPro (S-KPro) is of the collar button design and consists of a PMMA optic, surrounded by a polyurethane or polypropylene skirt. It is secured to the cornea using monofilament polypropylene haptics; these are secured to the sclera.[21] Although *in vivo* studies in animals showed better performance of the polypropylene device, fibroblast integration, collagen deposition, and corneal neovascularization, with mild tissue necrosis and inflammation, were observed with both versions of the device.[22] However, in short-term human trials with the polypropylene prototype, tissue melting around the skirt was noted.[21] Other complications included retroprosthetic membrane formation, retinal detachment, glaucoma, and endophthalmitis.[21] In long-term implantations, visual rehabilitation for about 32 months could be achieved. However,

instances of tissue melting and exposure of the skirt after ~13 months were noted. Furthermore, retinal detachment occurred following S-KPro exchange, attributed to poor vitrectomy techniques.[23] However, given that preliminary *in vivo* tests showed promising results, it may be that improvement in surgical techniques may enhance the long-term success of this prototype.[24]

6.631.1.5. AlphaCor KPro

The AlphaCor KPro is a core and porous skirt design, all composed of poly (hydroxyethyl methacrylate) (PHEMA).[9] As of February 2006, 322 AlphaCor KPro devices have been implanted in the United States, Europe, and Australia resulting in 416 patient years of experience.[25] The high retention of this device after 1 year at 80% is attributable to the integration of stromal fibroblasts into the porous skirt. Observed complications include tissue melting, retroprosthetic membrane formation, optic damage, and in some cases, opacification due to calcification.[25,26] Extracted devices show evidence of stromal cell integration, although chronic inflammation was also observed.[27–29] Omission of the second-stage surgical procedure whereby the implant is exposed to the external surface of the eye, resulted in improved KPro outcomes, including longer device (14–38 months) tolerance, despite the lack of a functional endothelium. The effect of this surgical alteration on corneal hydration is as yet unknown.[30]

6.631.1.6. BIOKPro

There are three prototypes to the BIOKPro device with type I consisting of a PMMA optic core and types II and III comprising silicone with a polyvinylpyrrolidone coating. In all cases, the devices have porous PTFE haptics.[31] However, generally, this device has shown disappointing results when implanted. While BIOKPro I demonstrated tissue integration through keratocyte migration and collagen production,[32] glaucoma, tissue necrosis, device extrusion, endophthalmitis, lens dislocation, and retroprosthetic membrane formation were noted in 11 devices implanted over 5 years.[33] Only 36% of the devices were retained. BIOKPro II showed better short-term clinical success with increased keratocyte integration and few corneal complications.[34] Although this version was also more successful in long-term studies, with only a 38% failure rate, instances of skirt exposure, retroprosthetic membrane formation, endophthalmitis, and device extrusion remained.[31] Further design changes including a smaller optic and larger skirt resulted in the BIOKPro III.[35] However, human implantation results were disappointing, with only one of the seven devices remaining intact.

6.631.1.7. SupraDescemetic KPro

The SupraDescemetic KPro (SDKP) can be fabricated from PMMA, or copolymers of PHEMA with MMA (PHEMA–MMA) or *N*-vinylpyrrolidinone (PHEMA–NVP).[36] While not yet tested in humans, animal trials to date have shown promising results. Implantation in seven rabbit corneas demonstrated that these KPros were well tolerated after 8 weeks; there was no evidence of inflammation in five eyes and only mild inflammation in the remaining two eyes, and no cases of retinal detachment.[36] Subsequent implantation, also in rabbits, was also promising with 100% of the PHEMA–MMA, 80% of the PMMA, and 60% of the PHEMA-NVP devices remaining transparent.[37] Furthermore, deposited collagen was observed in the device skirt.[37] Implantation was also performed in feline corneas. In this model, device extrusion was observed in all cases between 15 and 150 days. However, these results may not be representative of those that would be achieved in humans as felines demonstrate complete cornea regeneration, which is not possible in humans.[38]

6.631.1.8. Aachen KPro

The Aachen KPro is made of silicone rubber, whose design boasts of easy surgical handling and flexibility.[39] Although not widely tested *in vivo*, this model has shown positive results in limited testing. Following short-term implantation in ten patients, there were no occurrences of retinal detachment and clear visual acuity in four eyes, although edema was observed in three eyes.[39] The type II Aachen KPro, with immobilized fibronectin for increased cellular attachment, was implanted as a temporary implant prior to retinal surgery or corneal grafting.[40,41] It also allows for intraocular pressure measurements in porcine eyes.[42]

6.631.1.9. Other KPro Materials Developments

Improvements in materials and better understanding of the factors that influence biocompatibility have been the subject of ongoing research projects to improve on KPro success. An interpenetrating polymer network of PDMS and poly(*N*-isopropylacrylamide) (PNIPAAM) has been fabricated to combine the mechanical strength, transparency, wettability, and glucose permeability of these two materials for ophthalmic applications.[43] While preliminary cell testing was positive, further evaluation in a KPro model is necessary to demonstrate the impact of these factors on *in vivo* success. Other porous materials, specifically polybutylene, polypropylene (80:20), poly(ethylene terephthalate), and PTFE, intended for application as a KPro, were evaluated in rabbit cornea stroma over 12 weeks.[44] PTFE demonstrated decreased inflammation and stromal cell migration; the incidence of edema and neovascularization were similar among the different materials.[44] A poly(ethylene glycol)/poly(acrylic acid) (PEG/PAA) interpenetrating polymer network hydrogel, with glucose permeability comparable to the human cornea, was evaluated over 2 weeks in rabbit stromas and was well tolerated in nine out of ten eyes.[45,46] Further development in fabrication led to the usage of photolithography to form a patterned skirt of poly(2-hydroxyethyl acrylate) (PHEA) around the PEG/PAA core.[47]

6.631.1.10. Biological Enhancement of KPros

The incorporation of biological components including collagen, fibronectin and laminin, and oligopeptides into KPro devices, has been suggested as a method to render the devices more compatible and to enhance the interactions of the devices with host cells and tissue.[6,7]

To aid with epithelialization and tissue integration, collagen type I was tethered to a PEG/PAA hydrogel. Somewhat

surprisingly, corneal epithelial migration and wound healing rates were decreased.[46] The authors attributed this to the leaching of antimicrobial compound from the hydrogel as well as improper surgical technique and the choice of collagen that did not properly mimic the corneal basement membrane.[46] Elsewhere, a poly(vinyl alcohol) (PVA) hydrogel with tethered collagen demonstrated enhanced epithelialization *in vitro*,[48] but required modification with an amniotic membrane (PVA-AM) for epithelialization, reduced inflammation, and opacification *in vivo*.[49]

Among the more successful models in helping to understand the biological effects of materials implanted into the cornea is a corneal onlay model developed by the CSIRO group in Australia. These corneal onlays were fabricated from porous perfluoropolyether (PFPE) and were coated with collagen type I and demonstrated enhanced epithelialization in four feline corneas for 39 days.[50] Similarly, porous polycarbonate membranes coated with collagen type I, collagen type IV, or laminin showed enhanced corneal epithelial cell migration and adhesion *in vivo*, although coating with fibronectin, endothelial extracellular matrix, hyaluronic acid, or chondroitin sulfate resulted in materials that did not support epithelialization.[51]

PHEMA-MAA-PEG hydrogels were fabricated with extracellular matrix components: fibronectin, laminin, substance P, and insulin-like growth factor; or peptide sequences such as Arginine-Glycine-Aspartic acid (RGD) or fibronectin adhesion-promoting peptide (FAP), in particular, enhanced epithelialization significantly.[52] Previous work showed that tethered FAP and laminin had better epithelial adhesion compared to fibronectin.[53] Corneal epithelial cell adhesion was also demonstrated to increase in *in vitro* testing on PHEMA hydrogels through tethering of Arginine-Glycine-Aspartic acid-Serine (RGDS) and Tyrosine-Isoleucine-Glycine-Serine-Arginine (YIGSR) cell adhesion peptides.[54] Incorporation of growth factors, including epidermal growth factor (EGF) and transforming growth factor beta (TGF-β), have also been used to manipulate epithelialization.[7] Specifically, EGF was tethered to PDMS through a PEG spacer to improve epithelialization of the surface, which was found to rely heavily on the underlying surface chemistry.[55–57] Tethered TGF-β2 was also demonstrated to enhance epithelialization and to hinder stromal cell adhesion.[58]

6.631.2. Conclusion

The past decade has seen significant advances in the development of corneal substitutes. Extremely promising results have been obtained with the synthetic artificial corneas, with the availability of a number of different prototypes. As a result, replacement of corneal tissue with artificial substitutes, while not commonplace, is certainly possible. The development of new tissue-engineered prototypes will only serve to enhance the potential of these systems for restoring the sight of visually compromised patients.

6.632.1. The Retina

The retina is a critical component of the vertebrate visual system, which comprises the ocular globe and the subsequent subcortical and cortical targets in the brain. In the following sections, we describe the three main components of the retinal structure: the neuronal cells, the retinal pigment epithelium (RPE)–Bruch's membrane (BrM) complex, and the vascular networks that are intricately organized to ensure vision.

6.632.1.1. Basic Structure and Function of the Neurosensory Retina

After entering through the cornea, light is focused by the lens and is sensed by a thin laminated neural tissue on the back of the eye called the retina (Figure 1). The light stimulus is initially processed by the photoreceptors (PRs) in the outer nuclear layer (ONL), which are interestingly placed at the end of the light path, thus requiring the photons to travel through the entire thickness of the retina before being sensed. It is for this reason that some primates and birds of prey have developed a specialized region known as the macula.

PRs are highly specialized neurons able to detect light and transform it into an electrochemical impulse. They possess a unique compartmentalized, modified cilia, called outer segment (OS), that contains the light-sensitive machinery and enzymes necessary for phototransduction. PRs are divided into two cell types: rods and cones. Rods are highly light sensitive, with a slow response time course, and are therefore responsible for achromatic night vision. In contrast, cones are less light sensitive, but they are fast and color sensitive, and therefore mediate daylight vision. Once the PRs are activated, they signal to the inner nuclear layer (INL), which contains intermediary neurons (bipolar, horizontal, and amacrine cells) and glia cells (the Müller cells), through the release of the neurotransmitter, glutamate. Finally, the sensory stimulus is collected by the ganglion cells (GCs) in the ganglion cell layer (GCL), whose long axons bundle together to form the optic nerve, which extends to the brain. In some vertebrates, including humans, the retina contains a unique region with specialized topography and organization called the macula, which is responsible for

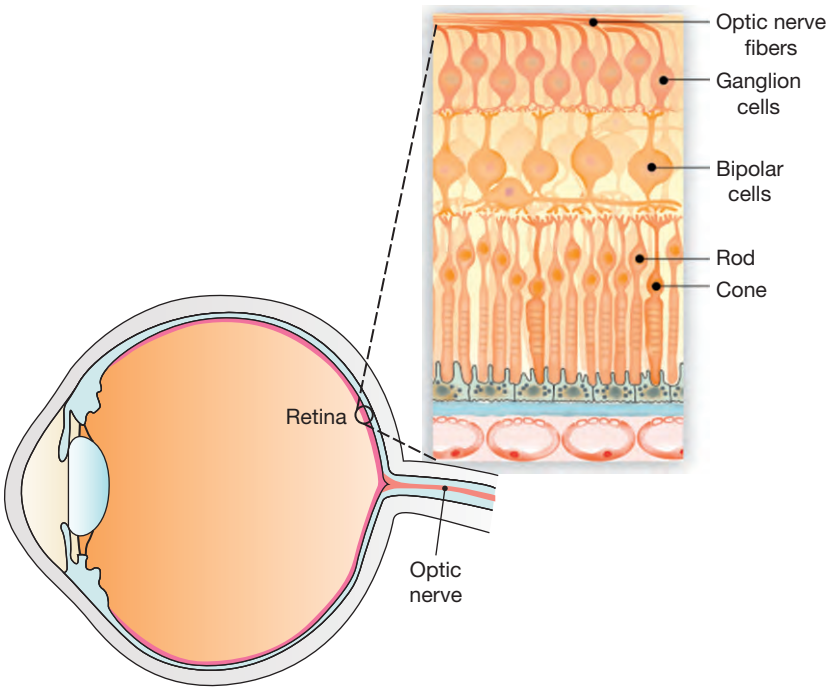

Figure 1 Schematic representation of the human eye. Illustration of a sagittal section of the eye, showing the cornea, the lens, and the retina, and of the retina structure. The human retina is a laminated neuronal tissue composed of distinct layers. From the innermost to the outermost layers, they include the ganglion cell layer (GCL) containing the GCs that give rise to the optic nerve fibers, the inner nuclear layer (INL) containing the intermediary neurons, the outer nuclear layer (ONL) comprising the photoreceptor cell bodies, and the retinal pigment epithelium (RPE). ONL, INL, and GCL are separated by synapses-rich layers called the plexiform layers (inner and outer).

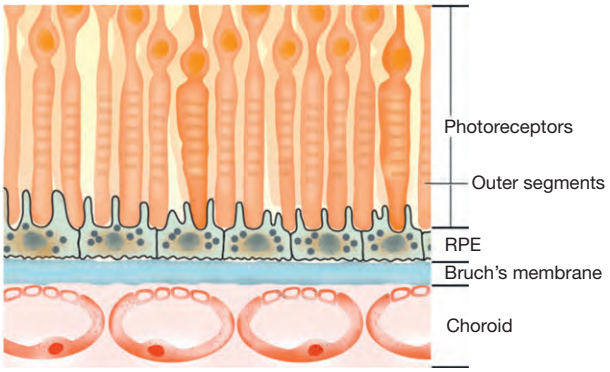

Figure 2 Organization of the outer retina. Schematic representation of the outer retina consisting of the photoreceptor's cell bodies and outer segments, of the retinal pigment epithelium (RPE) layer, and of Bruch's membrane. The outer segment is avascular, but its nutrients and oxygen supply are ensured by the choroidal vasculature located underneath the RPE layer.

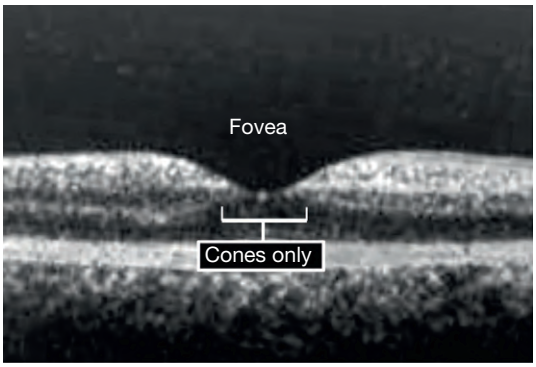

Figure 3 Optical coherence tomography image of a human fovea. The fovea corresponds to the pit at the center of the macula region. This highly specialized region contains mostly cone photoreceptors and is responsible for high-acuity vision. Courtesy of Dr. Ahad Fazelat, Massachusetts General Hospital, Boston, MA.

high-acuity vision. This specialized function is due to the high density of cone PRs, particularly in the fovea, a small pit 1 mm in diameter at the center of the macula (Figure 2).

6.632.1.2. The RPE–BrM Complex

The RPE constitutes the outermost cell layer of the retina. The apical membrane of this highly specialized and polarized pigmented epithelium faces the PRs' OS, while the basal side lies against a thick connective tissue, called the BrM, adjacent to the choroidal vasculature (Figure 3). The RPE has crucial functions in the normal eye as well as in pathological conditions. In the normal healthy eye, the RPE serves as the site of the outer retinal barrier. As the interface between the PRs and choroidal circulation, they are vital for the maintenance of the flow of water and ions, for protection against oxidative damage, for retinoid metabolism, and for the phagocytosis of the OS discs shed during the visual process.[1–4] RPE cells have been shown to secrete a variety of growth factors, including pigment epithelium-derived growth factor (PEDF) and vascular endothelial growth factor (VEGF), matrix metalloproteinases (MMP-9, MMP-2) and their inhibitors (TIMP-1, TIMP-3), and a wide

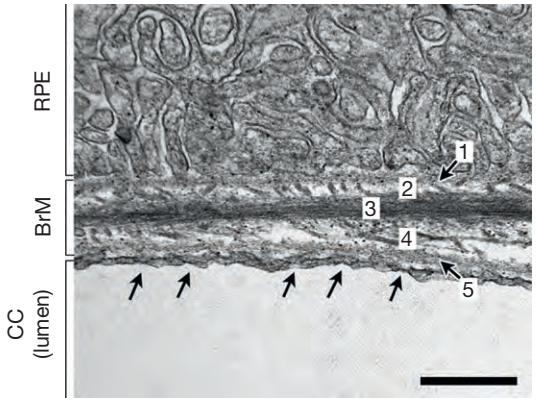

Figure 4 Ultrastructure of Bruch's membrane (BrM). Electron micrograph of the back of the eye of an adult mouse revealing the pentalaminar structure of the BrM: (1) retinal pigment epithelium basement membrane, (2) inner collagenous zone, (3) middle elastic layer, (4) outer collagenous layer, and (5) basement membrane of the choriocapillaris (CC). Endothelial fenestrations are indicated by arrows. Scale bar = 0.5 μm.

repertoire of cytokines.[1] These secreted molecules play an important role in RPE differentiation, maintenance of the endothelial cells (ECs) of the choriocapillaris (CC), and survival of PRs.[5]

Like most epithelium, RPE phenotype and function are intimately regulated by its interaction with the extracellular matrix (ECM) environment, in particular with BrM. BrM is a collagen-rich elastic lamina, with a thickness of 1–4 μm, depending on the retinal region, interposed between the basal surface of the RPE and the CC. BrM is classically described as a pentalaminar structure composed of the basal membranes of the RPE on the one side and CC on the other side, two collagenous layers, and one semicontinuous elastin layer (Figure 4). BrM serves as a critical physical and biological barrier, controlling the water and metabolic exchange between circulation and the outer retina. It regulates not only the diffusion of biomolecules and oxygen from the choroidal vasculature to the RPE and PR, but also the critical removal of waste products and membranous components of PR OSs produced during the visual cycle.

6.632.1.3. Blood Supply of the Retina

The retina is one of the most metabolically demanding tissues in the body. Therefore, maintenance of proper metabolic function and oxygen supply is crucial for retinal homeostasis and function. The retina is supplied by two independent vascular beds, the retinal vasculature proper and the choroidal circulation perfusing the inner and outer portions of the retina. These vascular beds exhibit extremely distinct morphologic and functional properties. The inner retinal vasculature is lined with ECs with tight junctions, making the vessels impermeable and constituting the inner blood–retinal barrier. In contrast, the walls of the CC endothelium are highly fenestrated, particularly on the side facing the RPE (fenestrations of the CC are shown in Figure 4). The anatomical organization of these two circulations is also highly dissimilar. The retinal vasculature has a classic anatomical organization, with the main veins and arteries extending radially from the optic nerve toward the periphery and dividing into smaller vessels extending into

the INL. The choroidal vasculature forms a mesh characterized by high blood flow, necessary to support the PR oxygen consumption.[6] In addition to its vascular functions as blood provider, the choroidal vasculature serves other critical roles: it is involved in the thermoregulation of the retina and in the lymphatic-like drainage of the debris and waste products produced by the PR and RPE.[7]

6.632.2. Ocular Diseases Associated with Retinal Degeneration

6.632.2.1. Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is a complex disease and the leading cause of blindness in the elderly population of industrialized countries.[8] AMD currently affects more than 1.75 million individuals in the United States and, with the aging of the population, this number is predicted to reach 3 million by 2020.[9] AMD affects the macular region of the retina, which is responsible for fine vision.

Early AMD is characterized by a spectrum of ocular anomalies often indistinguishable from the normal aging process of the eye. These changes in the outer retina include the presence of drusen (yellowish deposits) localized under the RPE or within the BrM and pigmentation changes (hyper- and hypopigmentation, Figure 5(a)). From this asymptomatic stage, the disease can progress to advanced or late AMD that is diagnosed in its dry (geographic atrophy (GA)) and wet forms. GA, which can be associated with progressive and severe visual loss, presents with localized degeneration of the RPE, atrophy of the overlying PRs and the underlying CC (Figure 5(b)).[10] GA often develops in the macular area just outside the fovea and gradually progresses into the foveal center in its late stage. A patient's visual problems are directly related to the development of visual blind spots (scotomas) within his or her central visual field. The prevalence of GA is about 3.5% in people over 75, with the rate increasing to 22% at age 90.[11] Histopathological studies of eyes with GA show isolated areas of RPE loss, and it is speculated that the loss of CC is secondary to the absence of RPE.[12–14] Wet AMD, which appears to arise from dry AMD in 10–35% of patients according to the study,[15] is characterized by the growth of highly permeable vessels from the choroidal vasculature into the subretinal space. Fundus imaging of advanced cases of wet AMD shows subretinal blood and fluid in the macular region (Figure 5(c)).

The etiology of AMD appears to be highly multifactorial, with definitive genetic and environmental components such as primary RPE aging, oxidative stress, and complement pathway alterations.[16] Despite recent significant research discoveries, particularly related to the contribution of the complement pathway,[17,18] the disease pathogenesis is relatively poorly understood. Over the last 20 years, various strategies have been developed to reduce choroidal neovascularization and subretinal edema. Available treatments for wet AMD include photodynamic therapy, antiangiogenic therapy using anti-VEGF reagents (Lucentis® and Avastin® from Genentech), vitreoretinal surgery, and steroid administration. Unfortunately, current treatments are limited to the vascular pathologies associated with AMD, and no pharmacological or surgical therapeutic option exists for the treatment of retinal cell loss.

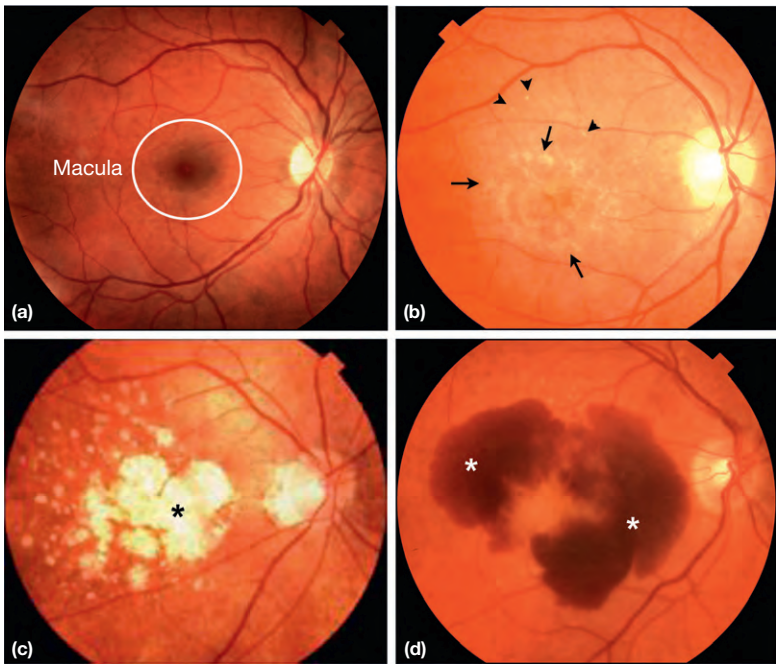

Figure 5 Color fundus photographs representing the different stages and types of age-related macular degeneration (AMD). (a) Normal fundus. The macular region is indicated by a circle. (b) Fundus of a patient with early AMD. Multiple small, medium-sized, hard drusen are seen here (arrowheads). Some confluent drusen with poorly defined edges are present temporally (arrows). (c) Case of advanced geographic atrophy. The loss of retinal pigment epithelium and choroidal atrophy can be clearly observed over the macula (black asterisk). (d) Fundus of advanced wet AMD showing a large polymorphic area of subretinal hemorrhage (white asterisks). Courtesy of Dr. Ahad Fazelat and Dr. Kam Lashkari, Massachusetts General Hospital, Boston, MA.

6.632.2.2. Retinal Degeneration

Heritable retinal degenerations such as retinitis pigmentosa (RP), Stargardt disease, and Usher syndrome are most often caused by one out of nearly 200-single-point mutations. These typically affect the rod PR, although cone and RPE mutations have also been described. Regardless of the primary genetic defect, the end result is PR cell death, with vision loss being an inevitable consequence. The tight coupling of PR and RPE cells, both metabolically and morphologically, makes repair through transplantation particularly challenging.

6.632.3. Retinal Reconstruction

6.632.3.1. Transplantation Success and Failure

While the prospect of using progenitor cells to repair the diseased central nervous system (CNS) has generated unprecedented interest in the field of neuroscience, the idea of using transplants of living tissues to replace organs that are no longer functional is a very old one. Historically, however, transplants exchanged between two members of a species routinely failed, and the reasons for the failure were unknown until the 1940s. At that time, Sir Peter Medawar, working on the problem of providing skin grafts for soldiers wounded in World War II, discovered that the destruction of transplanted tissues was dependent upon an immune response generated by the recipient against the so-called transplantation antigens expressed on the graft. These seminal observations laid the groundwork for the field of transplantation biology. It is no accident that within 20 years of Medawar's discoveries, the first successful solid organ transplants (kidneys) were conducted in human beings. By the 1980s, kidney, heart, liver, and bone marrow transplants were being performed routinely in humans, with a high rate of success.

Yet, despite the clinical successes, transplantation is not currently an option for many organs and tissues. CNS tissue, in particular, presents formidable technical and biological challenges with regard to successful transplantation. The demonstration that retinal grafts placed in the brain of neonatal hosts survive, develop, and make functional connections with the host brain[19] prompted investigators to attempt orthotopic retinal transplantation.[20] Because ectopic retinal transplants made functional connections, it was anticipated that achieving local connectivity in the retina would be relatively straightforward. Unfortunately, this has not been the case. The past 15 years of research on intraocular transplantation has yielded only scant evidence of integration between grafted neural tissue and the host retina. However, the recent demonstration by our group[21,22] and others[23,24] that progenitor cells can be isolated from the retina and ciliary margin suggests that the goal of functional PR replacement may finally be within reach.

6.632.3.2. Retinal Transplantation

We have recently demonstrated that neural progenitor cells (NPCs) derived from the hippocampus of mature rats can integrate with the mature, diseased retina.[25] While this is an essential requirement for functional neural reconstitution, morphological integration alone is not sufficient. An appropriate differentiation into retinal cells is also required. Despite showing very interesting morphological evidence of differentiation, hippocampal progenitor cells did not achieve full retinal-specific differentiation, as evidenced by the expression of retinal markers. Therefore, our next step was to obtain progenitor cells from the neuroretina,[22,26] with the rationale that retinal progenitor cells (RPCs) would be predisposed to differentiate into retinal neurons, particularly PRs. This supposition has been borne out by experimental studies in which we have shown that multipotent, self-renewing progenitor cells can indeed be isolated from the postnatal mammalian neuroretina. Importantly, these cells can be expanded greatly in culture prior to transplantation. When grafted back into mature, diseased hosts, they differentiate into cells of the PR lineage, as evidenced by the expression of the retinal- and PR-specific markers recoverin and rhodopsin.[22,26]

Previous experimental work in the field of intraocular retinal transplantation has relied on subretinal or intravitreal injection of either dissociated cells or tissue microaggregates, and it is now clear that these methods typically give rise to disorganized or incorrectly localized grafts. Studies of RPE cells have highlighted the importance of cellular continuity and polarity with respect to graft outcome.[27] In response to these concerns, investigators have begun isolating and transplanting organized sheets of RPE.[28–31] In addition, biodegradable polymers have been used as a substrate to obtain organized sheets of RPE for transplantation.[32] The ability of biodegradable polymer–progenitor cell composites to generate healthy, normal tissue has been shown in a number of settings, including bone,[33] cartilage,[34] and other tissue types.[35–37]

6.632.4. Challenges in Retina Reconstruction

6.632.4.1. Rationale

Ocular diseases such as AMD and RP lead ultimately to the degeneration of the PR cell layer and irreversible visual loss. At present, PR and/or RPE loss is untreatable and vision cannot be rescued. One of the most promising therapies for late-stage retinal degenerations involves the delivery of stem or progenitor cells to the outer retina, where limited cellular replacement has been shown to be possible in animal models.[38–40] Although bolus injection of stem cells has been sufficient to provide proof of principle for stem cell integration, it can also result in disorganized and incorrectly localized grafts. Therefore, in clinical situations where cell population has been severely depleted and the local laminar retinal architecture disrupted, a mechanism will be needed to confer organization to the grafted cells. Tissue engineering is founded on the basic principle that environmental cues can condition cell behaviors such as differentiation and functions. The clinical use of tissue engineering in the retina will depend on the ability to achieve the desired cell phenotype (PR and RPE) in a predictable and reproducible manner. Although the mere presence of certain stem cells may have beneficial effects, such as neuroprotection of PRs, on the retina, it remains highly improbable that formation of functional retinal tissue will be achieved simply by the delivery of cells. Harnessing the full regenerative potential of stem cells will most likely require additional attention to many detailed aspects of the complex and dynamic relationship

between the graft and the recipient microenvironment. Although no recipe for retinal reconstruction is currently established, recent advances in retinal development and materials science have shown that improved cellular assembly and organization are foreseeable with the precise coordination of physical, spatial, biochemical, and physiological cues.

6.632.4.2. Retinal Pigment Epithelium

As described earlier, AMD is characterized by the initial degeneration of the outer retina, including cellular changes in the RPE and the CC.[41] As the RPE layer is the primary support for both CC and PR,[1] the idea of replacing dysfunctional RPE using cell-based therapy is particularly attractive.[42] Successful RPE transplantation approaches need to address two major challenges: cell source selection and mode of delivery. Numerous cellular sources (fetal or adult autologous RPE) have been tested in various animal models and prospective clinical trials with very variable outcomes in terms of cell survival, organization, and vision rescue (reviewed in Binder *et al.*[43,44]). One of the main challenges in the use of stem cell-derived or native RPE for transplantation lies in the importance of delivering a monolayer instead of cell suspension. *In vitro* studies have clearly demonstrated that full maturation and proper polarization of RPE cells is a long process requiring weeks of culture after the cells have achieved full confluency.[45–47] While it is possible that a healthy ocular environment could accelerate RPE polarization compared to *in vitro* conditions, previous attempts at subretinal injections of RPE suspensions have shown to form abnormal epithelial layers and large clumps.[48] It is also important to note that although the intact retina constitutes an immune-privileged site,[49,50] alteration of the RPE monolayer in AMD can lead to allogenic transplantation failure,[51] particularly in wet AMD.[52,53] This observation supports the use of syngeneic cells to avoid the need of long-term immunosuppressive treatments.[54] Over the past decade, stem/progenitor cell transplantation as a means of inducing tissue reconstruction and functional regeneration has garnered extensive interest in the field of regenerative medicine. Significant advances have been made in the development of protocols for differentiation of RPE-like cells from embryonic stem cells (ESCs),[46] which have demonstrated the ability to halt PR loss in animal models of retinal degeneration.[55] However, clinical use of hESC is limited by ethical and immunological concerns. One significant achievement came in 2007, when the first stem cells were produced from adult tissue.[56] Unlike embryonic cells or tissue-specific progenitors, these induced pluripotent stem cells (iPSCs) offer the promise of creating patient-specific stem cells that obviate the need for chronic immunosuppression and eliminate the risk of immunorejection of the grafted cells. Recently, RPE cells have been successfully derived from mouse and human iPSCs.[57,58] Transplantation of iPS-derived RPE cell suspensions in an Royal College Surgeons (RCS) rat model of retinal dystrophy (similar to RPE-dependent RP) efficiently prevented PR death and improved visual function. However, some of the effects observed may not be directly attributable to the grafted cells but rather to macrophage infiltration secondary to graft rejection.[59] In addition, histological analysis demonstrated that the transplanted cells failed to form a proper monolayer,[59] again supporting the concept of cellular sheet transplantation.

6.632.4.3. Bruch's Membrane

The failure of most clinical trials using RPE cell therapy could be explained in part by the fact that AMD changes are not limited to the cellular components of the outer retina, but also affect the structure of BrM. Despite the fact that the more prominent anomalies associated with AMD are localized at the site of BrM, the critical role of this membrane in the success of cell-based therapy has been highly underestimated.[60] Although increased thickness and alteration of the BrM permeability have been reported as part of the normal aging process,[61,62] the accumulation of lipids and extracellular material beneath the RPE and in the BrM (also called drusen) is particularly predominant in AMD patients. As an acellular membrane, BrM functions are regulated by both its structure and molecular composition, and it has been proposed that by limiting the diffusion of water-soluble protein,[63,64] drusen formation and deposit accumulation contribute to RPE dysfunction. Studies have shown that changes in BrM precede the degeneration of the cellular component of the outer retina,[65,66] suggesting that an accelerated or exaggerated alteration of BrM may be responsible for the subsequent macular degeneration and disease onset. *In vitro* analyses have revealed that the culture of human RPE on BrM collected from aged or AMD patients drastically changes their behavior, gene expression profile,[67–69] and phagocytic activity.[70] BrM reconstruction is particularly difficult due to the lack of knowledge on BrM deposition[71,72] and turnover.[73] Some studies are exploring the option of BrM rejuvenation or, more precisely, resurfacing using enzymatic and chemical methods to remove the detrimental deposit on the matrix and improve RPE graft survival.[74] However, the clinical applicability of such an approach appears strongly limited. In addition, it appears to be clear that the transplantation of RPE as a cell suspension is unlikely to be as efficient as a preformed monolayer. Therefore, efforts are currently focused on the use of natural or bioengineered scaffolds for the transplantation of the RPE monolayer and BrM replacement. The majority of endogenous supports tested for the culture and transplantation of RPE have been isolated from ocular tissue such as lens capsule, Descemet's membrane (basement membrane of the corneal ECs), and the inner limiting membrane of the retina, with the exception of the amniotic membrane. While the results have been encouraging, problems associated with mechanical integrity have limited the success of this approach.

6.632.4.4. Choriocapillaris

The development of the adult choroidal and retinal microcirculatory systems represents a tightly regulated, highly coordinated process, where primordial microvascular networks are emergent from vasculogenic and angiogenesis-dependent processes. Indeed, the neural retina has a remarkable complexity and a significant metabolic demand, including a stringent requirement for heat dissipation. The choroidal microcirculation, an innovative plexus and 'heat exchanger,' achieves its fully functional status by the recruitment and local differentiation of vascular and cooperating nonvascular cells. Highly dependent upon local concentrations of metabolites and diffusible survival or growth factors, cell–cell and cell–matrix

interactions, the remodeling of the choroidal microvasculature contributes to the pathologic remodeling observable during aging.

Postnatally, and throughout adult life, nascent vessels are born, pruned, and stabilized, each event being driven and sustained via cell- and ECM-dependent signaling cascades that are not well understood. It has been suggested that once the preliminary endothelial tube is formed, vessel stabilization and maturation are initiated as ECs recruit mural cell precursors, which differentiate locally into pericytes (PCs).[75] Furthermore, the ECM produced and remodeled by proliferating and migrating ECs has also been postulated to provide a permissive or instructive role in signaling microvascular morphogenesis. Additionally, there is also recent evidence that suggests that there is partnering between nonvascular (glial) and vascular cells within the retina.[76] Astrocytes have been demonstrated to transiently express VEGF as they migrate across the GCL, preceding the formation of the superficial layer of retinal microvessels. Müller cells also express VEGF and may also participate in the microvascular morphogenetic events required to form the deeper retinal microcirculatory components. And, just as these complex cell- and matrix-dependent remodeling events are presumed to initiate and sustain the physiologic vasculature, metabolic demands and/or pathologic neuronal or vascular activity can comparably cause 'physiologic hypoxia,' which is detected by astrocytes and Müller cells.[76,77] It has been proposed that a lack of oxygen transfer to an area initially stimulates hypoxia-inducible factor 1 (HIF-1), which then induces the transcription of other angiogenic molecules, such as VEGF, insulin-like growth factor 1 (IGF-1), platelet-derived growth factor (PDGF), and hepatocyte growth factor (HGF), as mitogens, vasopermeability agents, and chemoattractants for EC.[78] Targeted disruption of a single allele of VEGF causes embryonic lethality in mice, with diminished angiogenesis and blood island formation.[79] VEGF binding to its specific receptor tyrosine kinase, VEGFR-2, induces receptor dimerization and phosphorylation. Subsequent tyrosine phosphorylation signaling activates several effector proteins, including protein kinase C (PKC), phospholipase-Cγ, and Ras GTPase-activating protein.[80] These factors and signaling cascades act to initiate the angiogenic cascade. In turn, these events have sparked anti-VEGF therapeutic strategies.

Blinding diseases such as AMD or neovascular glaucoma are believed to be consequences of this aberrant signaling among microvascular cells, plasma components, immune surveillance cells, and components of the nervous system, all of which contribute to the inception and etiology of aberrant angiogenic responses or pathologic angiogenesis. There are considerable gaps in our understanding of the 'angiogenic switch' that is responsible for inducing pathologic angiogenesis during AMD. Remarkably, of the nearly 2 million new cases that are reported every year in the United States, roughly 200 000 will develop wet AMD (http://nih.gov). These data are significantly compounded by the realization that there are likely to be nearly 3 million citizens who have AMD, but remain undiagnosed. Pathological changes in the choroidal microvasculature yield an invasive and proliferative endothelium, and recurrent rounds of endothelial migration and growth yield the pathologic angiogenesis observed during wet AMD.

6.632.4.5. Neuronal Regeneration of the Adult Nervous System: Regeneration in the Central Nervous System Versus Peripheral Nervous System

Following axotomy, the distal segment of the severed axon undergoes Wallerian degeneration. This is the process by which the distal part of the severed axon, which no longer has contact with its cell body, undergoes degeneration and subsequent removal.[81] During this process, there is an immune response that stimulates the infiltration of leukocytes and macrophages, which act to remove the degenerating myelin sheet via phagocytosis.[81]

Although the presence and rate of Wallerian degeneration are roughly the same in both the CNS and the peripheral nervous system (PNS), differences that are very important to axonal regeneration exist in these processes. In the CNS, myelin removal is slow and inefficient, and myelin debris, which contains a variety of inhibitory proteins, remains in the injury site for extended periods of time.[82] The injury site in the CNS is also plagued by the formation of a glial scar, which has also been shown to contain growth inhibitory molecules.[83,84] In contrast, axotomy of PNS neurons stimulates the complete removal of the myelin sheet, and Schwann cells change from their normal state of myelination, begin to proliferate, and form bands of Büngner, which act as basal lamina tubes providing guidance tracts for regenerating axons.[85] The Schwann cells of the distal nerve stump begin to release a variety of cell adhesion, ECM, and neurotrophic molecules in an attempt to provide a permissive environment for axonal regeneration.[81,85] During Wallerian degeneration in the CNS, oligodendrocytes do not change from a myelinating to a proliferating state, and the formation of structures such as the bands of Büngner does not occur. Unlike the PNS, there is a lack of permissive molecules such as nerve growth factor (NGF) and laminin that are secreted after CNS injury in the adult.[81,86]

It has long been known that CNS neurons, unlike PNS neurons, CNS neurons lack the ability to achieve significant amounts of axonal regeneration following injury.[87–90] However, when provided with the appropriate environmental conditions, CNS neurons have been shown to regenerate.[88,91–94] These findings suggest that the marked difference in regenerative capacity between CNS and PNS neurons is largely due to different environmental factors. Specifically, the adult CNS is faced with an inhibitory environment, which is created by the presence of inhibitory molecules associated with the myelin sheath and glial scar, and a lack of permissive molecules such as laminin and NGF associated with the Schwann cells of the PNS.[91,93,95]

6.632.4.6. Interdependence

As mentioned in the first paragraph, the survival of the neuronal cell in the retina is highly dependent on both the support cell such as RPE and the vascular system. Therefore, survival of transplanted retinal neurons (from stem cells or progenitor cells) would be particularly difficult if the main cellular and vascular support systems (i.e., the RPE and CC) were lost or become dysfunctional. This interdependence appears particularly critical in a complex disease such as ADM where anomalies and cellular loss are not confined to one retinal layer.

A widely investigated approach to tissue engineering in the retina is the design of novel scaffolds on which stem or progenitor cells can be cultured. Scaffolds provide structural support and direct cell behavior, and subsequently promote survival and integration when transplanted to the subretinal space. For transplantation into the eye, scaffolds must at least be biocompatible and mechanically stable. Recent advances in materials processing technology have enabled the design of materials to be tuned so as to mimic the normal developmental microenvironment. The incorporation of these properties provides the framework for efforts to regulate the behavior of the transplanted cell population and to orchestrate the host response.

6.632.5. Scaffold Biocompatibility

6.632.5.1. Material

For retinal reconstruction, the scaffold must be biocompatible in terms of both donor cells during culture and the host tissue following transplantation. Therefore, the materials of choice must not be appreciably immunogenic or cytotoxic, and they must neither elicit a chronic inflammatory response nor degrade into toxic by-products (see Volume 4: Biocompatibility). A variety of both natural and synthetic materials have been implanted and examined for compatibility in the subretinal space in conjunction with applications ranging from cell transplantation to drug delivery and retinal prostheses.

Natural polymers, or biopolymers, are a result of a polymerization process that takes place in nature in living organisms. These polymers are isolated from raw materials, such as donor tissue, and can also be postchemically modified. The use of natural polymers allows the creation of a scaffold that closely mimics the ECM of the targeted tissue. A variety of natural polymers constitute the matrix environment of the retina. For example, hyaluronan (HA) and several HA-binding proteins are key to the complex organization of the interphotoreceptor matrix located between the outer limiting membrane of the retina and the apical border of the RPE,[96] whereas in the RPE basement membrane and BrM, polymers such as collagen, elastin, laminin, and fibronectin are dominant.[73] Natural polymer matrices can be decellularized and left intact for direct use as scaffolds in cell support, or individual components of the ECM may be extracted for use in scaffold fabrication. Examples of intact biological matrices used as scaffolds in retinal tissue engineering include Descemet's membrane, amniotic membrane, BrM, and anterior lens capsule.[67,74,97–100] Examples of extracted ECM components used as scaffolds include collagen, gelatin, and fibrinogen.[101,102] Although natural materials have drawbacks, including lot-to-lot variability and immunogenicity associated with animal-derived products, these materials, in general, have been well tolerated *in vivo* in the subretinal space in the short term.

Synthetic polymers offer advantages over natural polymers in terms of synthetic flexibility and consistent reproducibility. Traditionally, scaffold biodegradability has been a necessary property to achieve full integration of an engineered construct, with the supportive role of the scaffold diminishing and transferring back to the host as the scaffold is resorbed (see **Chapter 4.401, The Concept of Biocompatibility**). The most widely used, and therefore widely studied, biodegradable polymers for implantation are based on poly(glycolide) (PGA), poly(L-lactide) (PLLA), poly(D,L-lactide) (PDLLA), poly(ε-caprolactone) (PCL), or their combinations (see **Chapter 1.123, Degradable Polymers**).

Although polymer properties are highly dependent on composition, form factor, and fabrication process, PGA-based polymers, including poly(lactide-*co*-glycolide) (PLGA), are known, in general, to possess relatively short degradation times (2–12 months). PLGA degrades by hydrolysis of its ester linkages in the presence of water to produce lactic acid and glycolic acid monomers. These monomers are normal byproducts of the body, and easily metabolized with minimal systemic toxicity. The degradation mechanism of PCL follows the same principles as those of PLGA. However, its hydrophobic nature and α-hydroxy acid structure make PCL a very slow-degrading polymer (two years or greater), especially at high molecular weights.

Synthetic polymers that have been implanted in the mammalian subretinal space have included both nondegradable polymers (poly(methyl methacrylate) (PMMA),[103] polyimide, parylene, poly(vinyl pyrrolidone) (PVP), polyethylene glycol (PEG),[104] poly(butyl methacrylate), and poly(ethylene-*co*-vinyl acetate) (EVAC)[105]) and biodegradable polymers (PLGA,[106,107] PCL,[108] and poly(glycerol sebacate) (PGS)[109,110]), depending on the particular application. Due to the differences in experimental design, animal model, and time course, there are varied reports of material compatibility in the subretinal space with regard to maintenance of the normal anatomy of the retina or the degree to which reactions were incited around the implant itself. However, the clinical application of fast-degrading polymers to retinal engineering may be limited. In the volume-limited subretinal space, the production and buildup of acidic degradation species by fast-resorbing PLGA have shown neural–retinal toxicity, thereby compromising retinal tissue repair.[106,111] Although a number of novel fast-degrading polymers are currently in development and under investigation, slow or nondegrading polymers may ultimately result in fewer physiological disturbances after transplantation.

6.632.5.2. Physical Constraint of the Subretinal Space

The physical constraint of the retinal space presents a formidable challenge to functional transplantation strategies. The neural retina averages ~250 μm in thickness, yet has a thickness of 100 μm in the central fovea, while the BrM has a thickness of only 5 μm.[111] The PRs derive their oxygen supply and nutrients from the choroidal circulation, which therefore necessitates transport of these molecules across the BrM and the RPE layer. The subretinal extracellular space between the PRs and the apical RPE is extremely thin; the thickness of any material substrate implanted within this space is therefore an important consideration. Scaffolds should be thin enough to allow a relevant diffusion pathway for the exchange of metabolites and nutrients between the retina and the CC, and at the same time sufficiently so to avoid physical distortion of the overlying PR layer after transplantation.

It has been demonstrated that the use of thin scaffolds increases the ease of delivery and reduces the risk of trauma, while allowing the scaffold to rest flat against the retina. This serves to enhance integration with the host. However, the

decreased volume of material also effectively limits the number of cells that can be delivered by the scaffold. A thickness of 5 μm was found to be the overall compromise between thinness and ease of physical handling and manipulation capabilities.

6.632.5.3. Mechanical Properties

The mechanical behavior of the native retina is characterized by a short elastic phase (Young's elastic modulus = 0.1 MPa) followed by a wide plastic phase range of 73.5% where irreversible deformation, but no tearing, can occur.[112] It is necessary for the retina to maintain a low level of elasticity in order to prevent retinal retraction, detachment, or visual distortion in conditions such as hypotony or myopic elongation. The retina's high degree of plasticity acts as a compensatory mechanism, providing a protective factor against tear formation. While a potential retinal transplant composite must be similar enough to natural tissue to handle potentially damaging stress and strain perturbations, it must also demonstrate a level of strength and stiffness amenable to surgical manipulation and implantation.

Natural polymers, such as gelatin and collagen, and hydrogels demonstrate poor mechanical properties, which can make them difficult to handle during transplantation and unpredictable in the presence of cells due to contractile-mediated gel shrinkage. Attempts to improve the mechanical properties of polymer gels for transplantation have been made with methods such as controlled cross-linking, where the level of cross-linking and substrate stiffness is tunable. However, when cross-linked collagen was used for transplantation, it was found to damage the retina. It is unclear, though, whether this may have been due to its mechanical properties, scaffold thickness, overall poor permeability, or inability to degrade.[102]

Biodegradable synthetic polymers may better provide the necessary mechanical properties to withstand the transplantation procedure. PLLA/PLGA membranes (Young's modulus = 9 MPa, strain at failure of 15%), though theoretically capable of delivering healthy cells,[107] have in some instances had the problem of stiffness and been damaging to the retina when implanted in the subretinal space of pigs.[111] Other polymers such as PCL and PGS have been successfully implanted in the subretinal space of mice with relative ease. Although the elastic moduli of these transplanted materials remained high, 280 and 2 MPa, respectively, in comparison to native retina, it is possible that the thin form factor of these constructs decreases the apparent stiffness to which tissue responds. Both materials maintained a strain at failure >110%, but with PGS acting as a completely elastic material, and PCL having a plastic phase of 92%, similar to the plasticity found in native retinal tissue (Figure 6).

In addition to the gross mechanical properties required for host transplantation, the apparent local stiffness may also play a substantial role in donor cell behavior (see Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation). Matrix elasticity is increasingly recognized as a key factor in cellular processes. Focal adhesions, the bridge between a material substrate and the cell cytoskeleton, are considered mechanosensory, and they change size and shape in response to the mechanical environment.[113,114] In response to local stiffness, cells rearrange their cytoskeletal filaments and

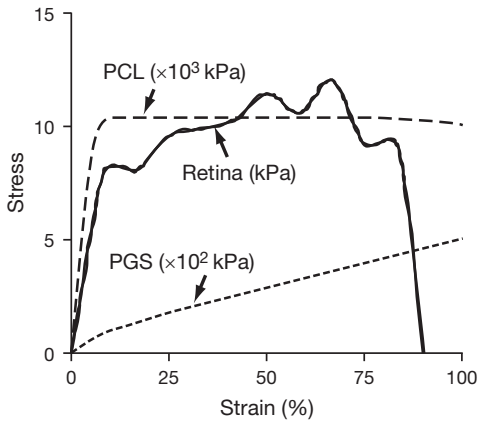

Figure 6 Example of a stress–strain curve for polycaprolactone (PCL), polyglycerol sebacate, and porcine retina. Porcine retina tested at a strain rate of 2 mm min^{-1} with data kindly provided by Dr. Gregor Wollensak[112]; 10 mm × 5 mm PCL (80 000 MW) scaffold 6 μm thick tested at a strain rate of 10 mm min^{-1} (adapted from Sodha, S.; Wall, K.; Redenti, S.; Klassen, H.; Young, M. J.; Tao, S. L. *J. Biomater. Sci. Polym. Ed.* **2011**, *22*, 443–456); 12 mm × 6 mm poly(glycerol sebacate) scaffold 45 mm thick tested at a strain rate of 2 mm min^{-1} (adapted from Neeley, W. L.; Redenti, S.; Klassen, H.; *et al. Biomaterials* **2008**, *29*, 418–426).

reorient their molecular machinery. Substrate stiffness influences the amount of traction force a cell exerts, and subsequently, the degree to which the cell adheres, spreads, and proliferates.[115,116] Furthermore, substrate stiffness has a fundamental effect on cellular differentiation. It has been proposed that matrix elasticity directs cell fate via nonmuscle myosin II. Myosin II, in conjunction with focal adhesions and the cytoskeleton, is thought to act as a cellular mechanosensor to detect substrate elasticity and, in turn, influence cellular lineage specification.[117] Undifferentiated stem cells grown on polymer gels mimicking the elasticity of a given tissue were found to express proteins for the cell type present in that particular tissue. As one of the softest tissues in the body, endogenous neural tissue has an elastic modulus of ~500 Pa. Recent studies have identified a range of 100–1000 Pa as being the optimal stiffness for neurogenic cell differentiation.[117,118] Mesenchymal stem cells, as well as neural stem/progenitor cells cultured on these 'soft' matrices (<1000 Pa), have been shown to develop neural morphology and express various neural markers.[117–119]

However, the mode by which cells mechanically respond to their environment will likely be substantially different between planar substrates and a three-dimensional (3D) material. In order to alter cell behavior and response with respect to mechanosensory response to a material scaffold, the scaffold may be altered not only by changing the biomaterial of choice, but also by modifying its thickness, structure, porosity, and topography.

6.632.6. Scaffold Fabrication

A biomaterial scaffold could promote the organization of grafted cells into defined layers, such as is seen in the normal retina. As long as there is adequate adhesion, culturing cells on a polymer scaffold results in a composite implant that, unlike

bolus injections, possesses an inherent structural organization. The most common methods of polymer scaffold fabrication include solvent casting and melt molding. During solvent casting, a polymer is dissolved in a solvent and cast into the desired mold. When the solvent evaporates, the polymer is left behind, taking on the shape of the mold. In melt molding, on the other hand, the polymer is brought to temperatures above its melt temperature (crystalline polymers) or its glass transition (amorphous polymers) to form a liquid for casting. Standard solvent casting of polymers (e.g., PCL) gives typical thicknesses of ~70 to upwards of 700 μm.[120–122] Melt molding under compression thicknesses can provide a thickness >50 μm while combined compression and biaxially stretching membranes are 5–30 μm in thickness; when combined with spin casting, they are <10 μm in thickness.[123–125] Implantation of polymer scaffolds of thickness greater than that of the retina have been found to significantly increase the incidence of retinal trauma and detachment during the transplantation procedure.

6.632.6.1. Micro- and Nanotopography

If surface topography and architecture are changed, a material may better mimic native guidance cues, thereby influencing cell response.[107] In a physiological environment, cells respond to micro- and nanometric topologies such as fibrous and porous materials formed by components of the ECM (see **Chapter 4.413, Patterned Biointerfaces**). Response to nanotopographic features (such as grooves, pores, pits, and pillars), though variable from cell type to cell type, has been reported in almost all mammalian cells and expertly reviewed in the literature (see **Chapter 4.409, Surfaces and Cell Behavior**).[126–129]

A highly utilized method to introduce topography is scaffold porosity. Pores can easily be incorporated into a scaffold during the solvent-casting or melt-molding process through introduction of a porogen, and subsequent leaching. Depending on the concentration and porogen used, this method can create a randomly open network within the scaffold, with the size of the porogen dictating the size of the pores. Other techniques of forming randomly open networks of pores include phase separation and foaming. The use of pores to introduce topography was first demonstrated in the context of the retina by Lavik and coworkers.[107,130] PLGA scaffolds, ~0.3 mm thick, were fabricated by phase-inversion casting and solid–liquid phase separation to contain pores ranging from 50 to 200 μm in diameter (**Figure 7(a)**). The use of the microporous composite graft not only increased the rate of retinal progenitor cell survival, but also promoted differentiation of RPCs, as evidenced by the induction of changes in morphology and gene expression.

Another approach to creating porosity is by electrospinning, a process that forms nanofibers through an electrically charged jet of polymer solution. Electrospinning can be used to create nanofibers ranging from <3 nm to >1 μm; however, this process remains dependent on jet stability (due to solvent viscosity, surface tension, and vapor pressure). Also, electrospinning essentially produces one infinitely long fiber, which is collected in an unordered mesh and is difficult to manipulate into higher order architectures other than uniaxial alignment (**Figure 7(b)**). It has been shown that electrospun nanofibers composed of laminin and PCL, as well as PLGA, promoted sufficient cell adhesion transplantation of isolated PR layers and retinal progenitor populations. Both of these composites developed large populations of recoverin- and rhodopsin-labeled PRs after transplantation.[131,132]

Nanotemplating is a simple method that can be used to nanostructure biodegradable materials without the use of organic solvents, pressure assistance, or custom instrumentation.[133] Templating entails synthesis of a desired material within the pores of a membrane.[134] Using a template of aligned and ordered pores produces ordered nanowire arrays perpendicular to the attached substrate (**Figure 7(c)**). Tao and Desai[133] demonstrated that template synthesis can be used as a fast and inexpensive method to form perpendicularly oriented high aspect ratio (>1:10) nanowire and nanofiber arrays from biodegradable and biocompatible polymers, including PLGA, PCL, and PLCL, without the use of organic solvents, pressure assistance, or custom instrumentation. Immunohistochemical analysis revealed that scaffold topology influenced protein expression levels. Only RPCs cultured on nanowire PCL demonstrated evidence of differentiation by expression of the bipolar cell marker PKC, the PR marker recoverin, and the rod PR marker rhodopsin. When transplanted subretinally in $Rho^{-/-}$ mice, RPCs cultured on nanowire PCL migrated into the retina ONL and INL, and developed an apparent cell polarity with early PR-like morphology and expression of recoverin.[108]

6.632.6.2. Microfabricated Scaffolds

However, in order to create an appropriate framework for the complex cellular organization of the retina, more sophisticated

fabrication approaches are needed. Microelectronic process engineering developed due to the rapid growth of the integrated circuit industry. Traditionally, microelectromechanical systems (MEMS) research has been used to produce functional devices on the micron scale, such as sensors, switches, filters, and gears, from silicon, the dominant material used throughout the integrated circuit industry. These devices are fabricated by the repeated application of unit process steps such as thin-film deposition, photolithography, and etching. The adaptation of microfabrication is an alternative method of fabricating scaffolds developed recently for retinal reconstruction to tailor spatial control over porosity and topography. Microfabrication techniques and the independent control of feature size and shape may provide a more uniform and precise method for creating retinal scaffolds. These micropatterned substrates can theoretically be designed to influence initial cell attachment and spreading, and allow the maintenance of differentiated cell phenotype throughout culture. The ability to culture tissue with proper anatomical organization and function could potentially result in a greater chance for reestablishing PR connections with the host.

In the microfabrication of scaffolds, a 2D feature layout is created utilizing computer-aided design software and printed into a photomask. The pattern is transferred to a substrate (typically silicon) via photolithography. During photolithography, a substrate is spin-coated with a photosensitive polymer (positive or negative) resist layer and exposed to UV light from a mask aligner through the photomask. If a negative photoresist is used, the photoresist is cross-linked when exposed to light. On the other hand, a positive photoresist is cleaved when exposed to light. During development, photoresist cross-linked to the substrate surface remains, while un-cross-linked or cleaved photoresist areas are washed away. While standard photolithography has a resolution of ~0.5–1 μm, it is possible to achieve sub-100-nm resolution using methods such as e-beam, ion beam, and dip-pen lithography. The pattern can then be transferred into the substrate material using a wet or dry etch process (Figure 8).

The hard patterned substrate can be used as a master mold in the process known as soft lithography to create a robust inverse replica in a soft elastomer poly(dimethyl siloxane) (PDMS). And, if maintained in a controlled environment, both the master mold and PDMS mold can potentially be used for limitless rounds of replication (Figure 8).

Utilizing microfabrication processes and soft lithography in combination with modified polymer processing techniques, such as spin-assisted solvent casting and nanotemplating techniques, polymer thin-film scaffolds can be structured precisely, simply, rapidly, and at low cost without the further use of specialized microfabrication equipment. A number of strategies utilizing MEMS base and nanotechnology have been developed to create micro- and nanostructured scaffolds for directing retinal cell behavior.[103,109,124,125,135,136]

One approach to the use of microfabrication is to form a transplantable thin-film scaffold containing regularly spaced through pores. Micropatterned scaffolds 6 μm thin were fabricated to contain through pores 11 μm in diameter with an interpore distance of 63 μm using a dual process of photolithography and reactive ion etching on a PMMA substrate.[103] Both nonporous and porous PMMA demonstrated full

Ed.* **2011**, *22*, 443–456; Steedman, M. R.; Tao, S. L.; Klassen, H.; Desai, T. A. *Biomed. Microdevices* **2010**, *12*, 363–369. SU-8 negative photoresist is spin-cast onto a silicon wafer and exposed to UV light through a negative mask. Unexposed areas are not cross-linked and developed away, and poly(dimethyl siloxane) (PDMS) is cured on the wafer. After peeling the PDMS mold from the wafer, a polymer, such as polycaprolactone, is spin-cast on the mold and peeled from the surface.

biocompatibility with RPCs in culture *in vitro*. Although RPC adherence and survival were nearly identical on both types of scaffolds in culture, transplantation with nonporous scaffolds showed limited RPC retention. The porous topography, however, allowed for RPC adherence through transplantation to the posterior eye for up to 4 weeks. The enhanced RPC attachment to porous scaffolds also provided a cytoarchitectural microenvironment permissive of eventual cell migration into the host retinal layers.[103] It seems probable that a mechanism of cell anchorage involved the insertion of individual cells or their processes into pores. RPCs embedded into pores remained attached to the scaffold during transplantation while also serving as an anchorage point for the surrounding RPCs through cell to cell contacts.

The concept of a tailored pore structure was further demonstrated in the use of PGS scaffolds. Using micromolding of a PDMS master, a PGS scaffold 50 μm thick, with an average pore size of 50 μm and an interpore distance of 200 μm, was fabricated. Though these pores were much larger than the size of a cell, this scaffold yielded a similar increase in terms of RPC survival,[109] and the mRPCs adherent to PGS differentiated toward mature phenotypes as evidenced by changes in mRNA, protein levels, and enhanced sensitivity to glutamate. Transplanted composites demonstrated long-term mRPC survival and cells that had migrated exhibited mature marker expression in host retina. Adhesion of RPCs to polymer scaffolds during the process of subretinal transplantation demonstrated the utility of a regular porous surface topography.

Another approach has been the use of guidance cues, particularly groove–ridge substrates, to direct differentiation and alignment of progenitor and PR cells. Tezcaner and Hicks[135] created both thin (10 μm) and thick (100 μm) groove–ridge substrates by solvent casting a blend of PLGA/poly (3-hydroxybutyrate-*co*-hydroxyvalerate) onto micropatterned silica templates. The scaffolds contained a final pattern dimension of 20 × (21 or 42) × 20 μm (groove width, ridge width, ridge height). When seeded with primary pig PRs, the cells displayed a preference for attachment to the groove structures as compared to ridges. The degree of alignment was found to be more than 90%. Similarly, polystyrene has also been cast onto micropatterned silicon wafers to create nondegradable scaffolds with a pattern dimension of 16 × 13 × 4 μm (groove width, ridge width, ridge height), which were subsequently seeded with human NPCs (hNPCs) isolated from 16- to 18-week fetal cortex.[136] No differences in proliferation or differentiation were found between micropatterned and nonpatterned substrates. However, hNPCs cultured on the micropatterned substrates were aligned in the direction of the micropattern (~90% within 10° of perfect alignment) compared with the cells cultured on the nonpatterned substrates. Furthermore, hNPC migration was directed in alignment with the micropatterned substrates. With the integration of high-resolution microfabrication processes, scaffolds for retinal transplantation can be fabricated with groove–ridge patterns in the submicron range, well below the size of an individual cell.[125] Rather than utilizing microfabricated topography to simply direct cell–cell and cell–substrate organization, it may be possible to direct the organization of individual cell machinery and function (Figure 9).

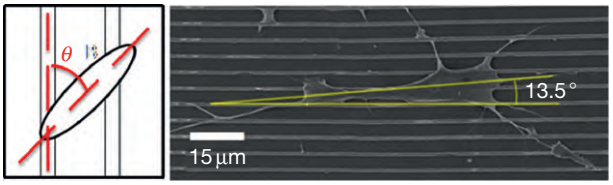

Figure 9 θ is the angle between the center axis of a cell and the vector along the direction of a ridge−groove. A cell preferentially aligns along a groove–ridge pattern. Courtesy of Chi Wan Ko, MIT University, Boston, MA.

6.632.6.3. 3D Scaffolds

Although it is possible to laminarly organize cells and direct alignment utilizing microfabricated planar substrates, the 3D structure and organization of the retina must be taken into account when considering its reconstruction. The retina is a highly ordered tissue consisting of stacked cell layers, and within the layers, there is the arrangement of neurons of the same type in orderly arrays, or mosaics. Mosaics are the earliest detectable patterned units during retinal development. Modeling and statistical analysis have shown that the spacing of like cells within the layer is nonrandom, and this spacing is a minimal distance by which the cells avoid being closer to one another than a given distance, usually comparable to several cell body diameters.[137,138] The spacing in the PR layer determines the ability of the retina to resolve fine spatial detail. In the PR layer, the inner segments of both rods and cones exhibit a hexagonal form and are regularly arranged in a honeycomb fashion – each cone or rod surrounded by six other cones or rods, respectively. The rod density is maximal at 150 000 rods per mm^2 and decreases to 30 000–40 000 cells per mm^2 toward the retinal periphery. The rod to cone ratio in the retina is 20:1 at the location with the highest rod density.[139] The rod diameter increases from 3 μm in the area with the highest rod density to 5.5 μm in the periphery and it is ~40 μm in length,[140] In a simplified two-compartment model, the retina is seen to be composed of two monostratified epithelial-like layers facing each other by their apical surfaces, and forming separate homeostatic compartments. The outer layer is formed of RPE cells, while the inner layer is composed of Müller cells. PR inner and outer segments alone reside within the outer compartment while the remaining neural elements (three sheets of neurons and their interconnections) are embedded in the inner compartment.[141] In a clinical situation, an engineered retina should maintain the transplanted cells within the ONL, and at the same time allow for the formation of OSs across the scaffold and interphotoreceptor space for invagination by RPE without being limited by the duration of scaffold degradation.

Utilizing the same microfabrication processes as described above, a 3D scaffold with an appropriate orientation can be built by aligning and bonding individually designed planar scaffolds. The encapsulation scaffolds were designed to be <30 μm in thickness with a centralized chamber for cell retention, and two porous membranes allowing for bidirectional molecule diffusion and graft–host cell communication. One example is described by Sodha *et al.*[125] (Figure 10). The assembled scaffold, with 200 μm diameter circular cell

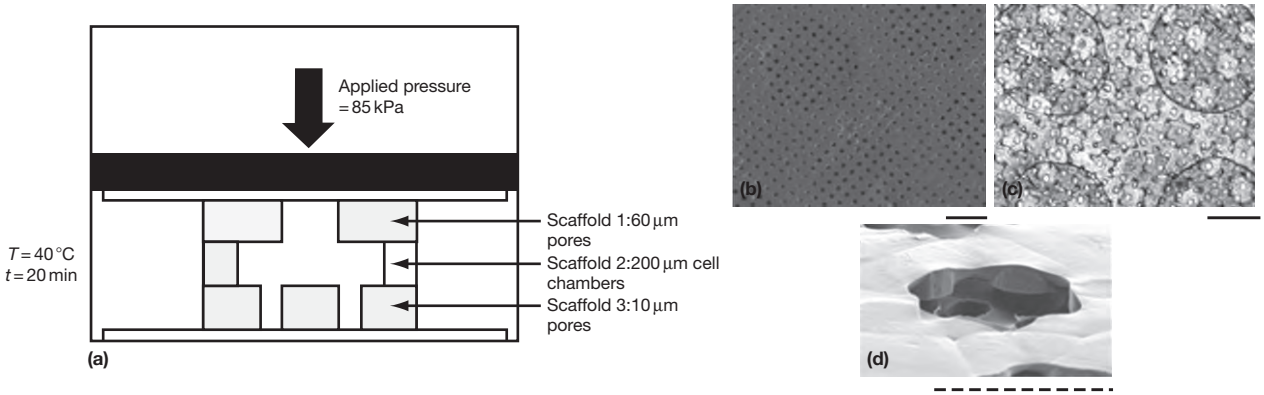

Figure 10 Thermal bonding to produce a three-dimensional (3D) polycaprolactone structure. (a) Scaffolds were aligned and stacked, and placed in a custom pressure vessel under constant pressure and temperature. (b) Scanning electron microscopy (SEM) image of a 3D scaffold from a 10-μm-diameter pore side. (c) Bright-field image of a 3D scaffold from a 60-μm pore side. (d) SEM image of a 3D scaffold from a 60-μm pore side. Black scale bar = 100 μm. Dashed scale bar = 50 μm. Reprinted from Sodha, S.; Wall, K.; Redenti, S.; Klassen, H.; Young, M. J.; Tao, S. L. *J. Biomater. Sci. Polym. Ed.* **2011**, *22*, 443–456.

holding chambers acts as a protective cell environment (Figure 10(a)). Each chamber was capable of holding ~600 cells by volume, assuming the cells were spherical, with a radius of 10 μm (Figure 10(b) and 10(c)). The 10-μm-diameter circular pores were designed as a potential interface between the transplanted cells and the host RPE. This pore architecture was based on previous studies, where individual cells could extend processes across a 10-μm pore, without migration of the cell body.[103] The 60-μm hexagonal star-shaped pores were designed as the neural retinal interface (Figure 10(c)). This pore architecture was designed to allow a possible migratory pathway, as demonstrated in previous studies,[109] while providing appropriate spacing of cells into a patterned unit, and adequate contact guidance for alignment in the *z*-direction. In this manner, the 3D scaffold combines the multiple requirements previously outlined. It is able to hold a number of cells in close proximity within a centralized chamber to lessen the effects of cell shearing, while retaining an appropriately thin form factor. It is highly porous and allows for diffusion as well as potential cell interactions from both sides (toward the neural retina and toward the RPE). The device can additionally serve as an organized framework to support cell adhesion, organization, and migration, and also as a barrier to prevent infiltration of surrounding cells.

6.632.6.4. Surface Modification of Scaffolds

The surface chemistry of a scaffold material may be patterned to change the surface energy of the material or to attach bioactive molecules (e.g., ECM proteins) in controlled orientation. The ability to chemically functionalize the scaffold surface provides a means for tuning interactions between cells and the artificial environment. The use of unmodified biocompatible polymers, which do not contain cell-binding domains, suffices for most cell-based studies. However, many materials are easily chemically modified to achieve cell-binding or activation characteristics for more directed material–cell interaction.

As many polymers are hydrophobic, a simple method of enhancing cell adhesion can be an alteration in the surface energy of the material, such as oxygen plasma or acid treatment to increase hydroxyl groups at the surface.[142] Surface chemistry can further include the simple adsorption or covalent attachment of ECM proteins (e.g., laminin, fibronectin, collagen IV, and heparin sulfate, singly or in combination) to the surface of the material. These simple methods of modifying the surface of a substrate can significantly influence cell adherence and differentiation.[74,143]

Similar to topography, scaffold chemistry can be modulated to form micro- and nanopatterns that can be used to control individual cell shape and adhesion patterns. Methods for precise chemical patterning of scaffolds include microfluidic printing and, more commonly, microcontact. Briefly, microfabrication processing is utilized to produce a PDMS mold with the desired pattern features. The 'inking' solution, comprising the desired proteins or molecules, is allowed to adsorb to the surface of the PDMS microstamp in the case of microcontact printing. The microstamp is then pressed against the substrate or scaffold with force. When the microstamp is removed, the molecules remain printed on the substrate. In the case of microfluidic printing, the PDMS stamp is brought into complete contact with the substrate, and the inking solution is allowed to flow through the open network created between the PDMS and substrate. By activating both the substrate and molecule prior to microcontact printing, permanent patterns of covalent linkages may also be formed. The shape and dimension of the transferred pattern, and the promotion of adhesion or repulsion by the molecules, will determine cellular shape and organization.

Lu *et al.*[144–146] patterned PLGA scaffolds with 50-μm circular islands of PEG/poly(lactic acid) (PLA) spaced 10 μm apart, as well as the inverse, PEG/PLA scaffolds with 50-μm circular islands of PLGA. In both instances, the repulsive PEG/PLA circles suppressed adhesion of D407 RPE cells, while the cells preferentially attached to the PLGA domains. However, while individual cells adherent to circles of PLGA were able to spread, they remained isolated in position in number. In contrast, cells adherent to contiguous PLGA increased in cell number over time and were seen to extend a number of cell processes for cell–cell interaction. Lee *et al.*[98,147] were able to utilize

microcontact and microfluidic printing, in addition to synthetic polymers, to prepare chemical micropatterns on human lens capsule tissue. The pattern was designed for a 2–10-μm-wide ring of cell repulsive poly(vinyl alcohol) (PVA) to enclose a 15–50-μm hexagonal space of unmodified lens capsule. RPE cells were able to selectively adhere to the cytoadhesive lens capsule region within the PVA ring. However, it was found that a 20-μm hexagon retained the highest cell density without clumping. Furthermore, these cells were able to spread across the PVA barriers with time and form the appropriate morphology of an RPE monolayer. This method of chemical modification may be an alternative method to enhance initial cell attachment and spreading, and to allow the maintenance of differentiated cell phenotype throughout culture and transplantation.

6.632.6.5. Controlled Release

The development and differentiation of cells during retinal reconstruction will also likely depend on a number of soluble growth factors. For example, retinoic acid, taurine, S-laminin, sonic hedgehog, activin, ciliary neurotrophic factor (CNTF), and a variety of additional neurotrophins have all been implicated in the differentiation of rod PR cells. In addition to directing donor cell response, methods to modulate the host environment may also be necessary to promote the integration of the transplanted construct. For example, in a diseased eye where immune privilege is disrupted, restoration of immune privilege through delivery of immunosuppressive or anti-inflammatory factors may be an important strategy for promoting the immunologic success of tissue-engineered constructs in the future (see **Chapter 4.419, Vaccine and Immunotherapy Delivery**).

Currently, delivery of therapeutics to the back of the eye is often performed by intraocular injection to the vitreous chamber, which requires frequent and large doses to account for clearance. Intravitreal implants and microparticle injections have been developed to provide sustained release; however, posterior to anterior convection still prevents adequate concentrations to the back of the eye. Many of the polymers utilized in scaffold fabrication are also well suited for use as long-term drug delivery systems. The rate of release is dependent on a number of factors including load concentration and distribution, surface area to volume ratio of the implant, diffusion, and polymer degradation rate. In particular, PCL has been demonstrated in an implantable system to the subretinal space for controlled delivery up to at least 1 month.[105] Therefore, therapeutic molecules could possibly be integrated into the scaffold during fabrication and processing to provide sustained, controlled, and localized delivery to the posterior segment after transplantation of the construct.

Tucker and coworkers[131] developed an effective PLGA scaffold to deliver stem cells as well as the enzyme MMP-2. The inability of the adult mammalian retina to regenerate can be partly attributed to the expression of injury-induced inhibitory ECM and cell adhesion molecules. In particular, PR degeneration stimulates deposition of neurocan and CD44 at the outer limits of the dystrophic retina, where they act as a barrier against cellular migration and axonal extension. Local delivery of MMP-2 has the potential to promote controlled degradation of CD44 and neurocan to reduce the inhibitory glial barrier and allow for the integration of donor cells. The PLGA scaffold was fabricated by two-phase electrospinning to produce a highly porous interwoven mat of PLGA fibers ranging from 100 to 5000 nm in diameter interlaced with picoliter domains of active MMP-2. As compared to control polymers, the controlled release of MMP-2 from the polymer scaffold was able to enhance stem cell integration and repopulation of the retina ONL while preserving retinal architecture and stem cell function.[131]

In the body, tissues are formed to maintain order, organization, and optimization of function. This is particularly demonstrated in the retina where the prevalent arrangement of cells into layers and arrays is a key element for efficient visual processing. The collective mechanisms controlling the building process and maintenance of this intricate architecture *in vivo* are still relatively unknown. Yet, recent *in vitro* experiments have demonstrated that numerous biochemical and physical cues can individually direct organization to a degree. To gain an understanding of how these mechanisms collectively confer organization, fundamental studies in which these components are varied systematically must be examined. With the capability of specifically directing stem cell behavior in a predictable manner, engineered tissues may prove a novel approach to retinal repair.

6.632.6.6. The CNS Environment

As noted earlier, it is postulated that the extracellular environment of the CNS is unfavorable for cellular integration and axonal regeneration, making functional recovery after CNS injury limited. The major inhibitory components of the CNS environment are derived from either the myelin sheath or the glial scar. Apart from the retinal GC axons housed within the optic nerve, myelin is absent within the retina proper, and as such the inhibitory molecules nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte myelin glycoprotein (OMgp) that are found within the myelin sheath are also absent. However, atrophy-associated glial scarring, as in the case of retinal degenerative diseases such as RP and AMD, produces both a chemical and physical barrier to cellular migration and neurite extension.

The glial scar is formed in a process known as reactive gliosis, whereby the infiltration of reactive astrocytes and or glial cells into the injury site causes the formation of a physical barrier along with the accumulation of inhibitory molecules such as the chondroitin sulfate proteoglycans and other glycoproteins.[148,149] These molecules, which include neurocan, brevican, phosphocan, NG2, tenascin, chondroitin sulfate, and CD44, are known to inhibit axonal regeneration. For instance, NG2 has been shown to be responsible for inhibiting sensory neuron regeneration into the dorsal root entry zone,[150] neurocan and phosphocan inhibit the regeneration of adult cortical and retinal ganglion neurons,[149,151] and CD44 and neurocan block donor–host cell integration following subretinal transplantation.[131,152,153] Like many other inhibitory ECM molecules, chondroitin sulfates exert their inhibitory effects via activation of RhoA and its downstream effector Rho kinase ROCK.[151] Inhibition of this signaling pathway via the C3 exoenzyme or the use of the chemical inhibitor specific to ROCK,

Y-27632, allows the cell to overcome glial scar-induced inhibitory effects.[151,154] Many other methods to overcome inhibition by chondroitin sulfates have also been explored. For instance, the use of chondroitinase ABC, an enzyme that removes the glycosaminoglycan side chains of chondroitin sulfates rendering them inactive, has seen some success in stimulating cellular integration following transplantation of Müller cell-derived progenitors.[155] Similarly, degradation of both neurocan and CD44 via induction and/or delivery of active MMP-2 has been shown to enhance cellular integration and retinal ONL repopulation following RPC transplantation.[131,152,153] Conversely, chemical and/or genetic inhibition/removal of MMP-2 was shown to completely eliminate cellular migration and axonal extension in this model.[131,152,153] To date, specific receptors for this class of molecules have been elusive, and thus, experimental attempts to stimulate regeneration via receptor inhibition have not been possible.

As a result of this work, there now is a strategy for removing inhibitory barriers in the degenerated CNS, including the retina, and permitting the establishment of new connections following transplantation, be they of stem cell origin, solid tissue, or other yet to be developed techniques.

6.632.7. Conclusions

It should now be apparent that retinal reconstruction is a complicated prospect. Multiple tissue types, from multiple embryological origins, are impacted in retinal injury or degeneration. This makes tissue engineering a requisite approach for repair of the diseased retina. Important concerns relate to the biocompatibility of scaffold material, BrM integrity, CNS connectivity, and the formidable challenge of replicating the blood supply from the CC. Diseases affecting the macula (such as AMD) present further design and biological challenges. The aging of the population will likely lead to an even higher prevalence of AMD and other retinal diseases associated with increased age. Therefore, while many challenges remain and a huge unmet need for retinal repair exists, tissue engineering offers hope for millions afflicted by these diseases.

Glossary

Conjunctiva Clear transparent vascularized protective tissue layer that covers the white sclera of the eye. The conjunctiva also lines the inside of the eyelids.

Conjunctival flap formation Deep folds in the conjunctiva caused by pressure from the edge of a soft contact lens, resulting in a flap of tissue.

Conjunctival staining Disruption of the superficial epithelial layer of the conjunctiva, as revealed by an orange dye (fluorescein) that is inserted into the eye. Fluorescein fills spaces created by tissue damage, and the pooled dye displays a bright green fluorescence when illuminated with blue light, revealing the location of tissue damage.

Contact lens A clear, transparent shell-like optical appliance that is placed on the front of the eye to correct errors of refraction of the eye.
Cornea The clear transparent tissue at the front of the eye through which light passes to form an image at the back of the eye.
Corneal staining Disruption of the superficial epithelial layer of the cornea, as revealed by an orange dye (fluorescein) that is inserted into the eye. Fluorescein fills spaces created by tissue damage, and the pooled dye displays a bright green fluorescence when illuminated with blue light, revealing the location of tissue damage.
Endothelial cell density The number of endothelial cells per unit area of the endothelial surface.
Endothelial polymegethism Change in appearance of the endothelium, whereby the cells in this layer display a large variation in cell size.
Endothelium Single layer of highly metabolically active cells at the back of the cornea. The cells all appear to be of uniform size and display, and characteristic hexagonal shape.
Epithelium Superficial layer of cellular tissue of an organ, such as the cornea.
Epithelial microcysts Small cystic spheres that form within the corneal epithelium, when subjected to hypoxic stress.
Epithelial oxygen uptake The movement of oxygen into the cornea, from either the atmosphere in front of the eye, or the aqueous humor (the fluid inside the eye).
Fluorescein staining A term describing the use of fluorescein to reveal the presence of tissue damage in the cornea or conjunctiva (see 'corneal staining' and 'conjunctival staining').
Microbial keratitis Inflammation of the cornea caused by infection with microorganisms. This inflammatory process can result in opaque scar formation on the cornea, thus impeding the passage of light into the eye, resulting in partial or complete vision loss.
Mucin balls Small spherical balls of mucin, derived from mucin in the tear layer, that form between the back of the lens and front of the cornea, during lens wear.
Myopia Nearsightedness, whereby the image of a distant object in space is focused in front of the light-sensing retina at the back of the eye. This is corrected using minus powered ophthalmic lenses.
Papillary conjunctivitis An inflammation of the vascular mucous tissue on the inside of the eyelid, caused by irritation of the front surface of the contact lens, especially of the lens surface if contaminated with deposits.
Prelens tear film The thin layer of tears that covers the cornea and conjunctiva of the eye.
Presbyopia The reducing ability of the eye to focus on close objects, caused by a thickening and loss of flexibility of the lens inside the eye.
Stroma Forms the bulk of the middle of the cornea, consisting of collagen fibrils and mucopolysaccharide ground substance.
Superficial epithelial arcuate lesions (SEALs) Arc-shaped lesion of the superficial tissue of the cornea, occurring at the surface of the cornea. This is a transient form of tissue damage that is self-limiting; that is, it heals by itself within 24 h if the lenses are removed.
Trial fitting The process of sequentially applying contact lenses with different characteristics (curvature, diameter, thickness, material, etc.) to the eye and assessing lens behavior on the eye (stabilized position, movement with blink, etc.) until a lens fitting of satisfactory performance is achieved.
Xerogel The anhydrous polymer from which soft lenses may be made; water needs to be added to turn the xerogel into a functional hydrogel.

6.633.1. Introduction

Soft contact lenses have had a massive impact on the global contact lens market since their introduction into the market in the early 1970s. Over the past 50 years, the number of soft contact lenses being prescribed around the world has steadily increased, and it is mainly the sale of soft contact lenses which is responsible for an industry which is estimated to be worth around US$8 billion annually (this figure does not include the sale of contact lens solutions). A recent survey has indicated that soft lenses currently make up over 92% of all new contact lens fittings worldwide.[1]

The saturation of the contact lens market with soft lenses has occurred primarily for two reasons. First, soft lenses provide wearers with what they see as the two most important requirements for successful contact lens wear – good vision and good comfort. Rigid lenses, which were originally made from glass (between 1888 and 1940) and later from polymethyl methacrylate (PMMA) or silicone acrylate materials, are uncomfortable to wear. They are now seldom fitted to new patients and are rapidly becoming obsolete.[2] The major obstacle as far as rigid lenses are concerned is generally accepted as being their lack of comfort and, in particular, their initial discomfort.[3] Figure 1 illustrates the demise in rigid lens fitting over the past 40 years in Australia – a country in which fitting trends have been well documented over this period.

Second, advances in manufacturing technology have directed the industry toward soft lenses and, still further, toward the concept of disposability. In view of the above, rigid contact lenses will not be discussed in this chapter.

Contact lens materials are good examples of biomaterials; indeed, they are classed as a medical device in most countries. Biomaterials manufactured for use as contact lenses must not only satisfy the requirements of not having toxic or injurious effects for safe use within the eye, but additionally they must also have very specific characteristics, such as being transparent (and remain so on-eye), comfortable, and relatively cheap to manufacture.

This chapter will review the properties and characteristics of the materials which are used to manufacture soft contact lenses, provide some of the history of development of these materials, introduce the nomenclature used to categorize contact lens materials, describe current approaches to contact lens

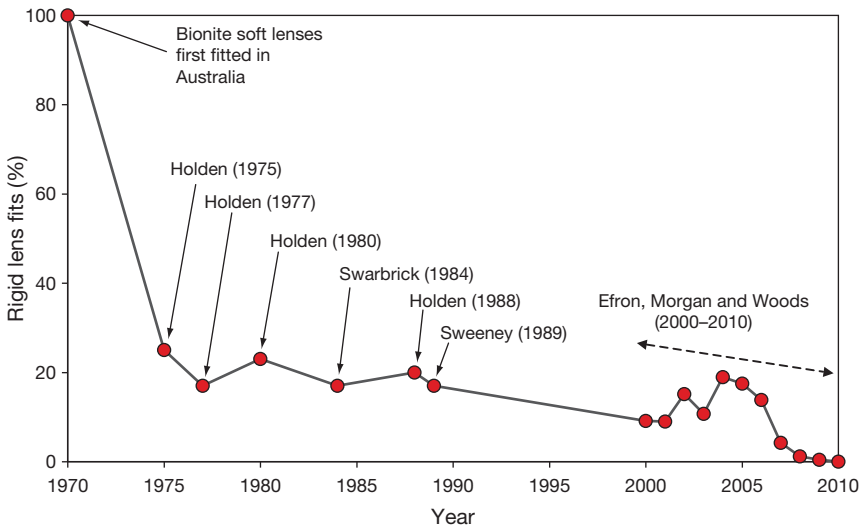

Figure 1 Decline in rigid contact lens new fits, as a proportion of all contact lenses fitted, between 1970 and 2010.

manufacture, and highlight the clinical implications of these developments.

6.633.2. General Properties of Hydrogel Materials of Relevance to Contact Lenses

The ocular environment places significant demands on the performance of hydrogels as biomaterials. These materials must have the following properties:

- maintain a stable, continuous tear film;
- be permeable to oxygen in order to maintain normal corneal metabolism;
- be permeable to ions in order to maintain on-eye movement;
- be comfortable;
- provide clear, stable vision.

These essential properties are expanded upon below.

6.633.2.1. Optical Transparency

A hydrogel to be used as a contact lens material needs to be transparent in order to achieve maximal visual performance. The light transmittance properties of polymers can be categorized as being transparent, translucent, or opaque. Transparent polymers are those that you can see through, translucent polymers are those that you cannot see through but allow light to pass through, and opaque polymers are those that neither permit you to see through nor allow light to pass through. Usually, the optical clarity of contact lens materials is expressed as the percentage of transmission of the visible electromagnetic spectrum. Hydrogels which are useful as contact lens materials transmit over 90% of light in the visible part of the spectrum.

When a hydrogel loses its transparency, it is likely to be due to microphase separation of water. This is due to regions of differing refractive index being formed within the gel. Hydrogels that show this type of behavior – typically synthesized by making copolymers with large blocks or segments of hydrophobic and hydrophilic monomers rather than randomly dispersing them – do have advantages in terms of enhanced strength and permeability performance.

If the phase separation is limited (e.g., the phase size is shorter than the wavelength of light), transparent materials can still be obtained. Some hydrogels are known to lose their transparency when heated, and this is an important consideration as there is an increase in temperature from lens packaging to eye. Additionally, some lens wearers still thermally disinfect their lenses although this approach is seldom used at the present time.

6.633.2.2. Mechanical Properties

The mechanical properties of hydrogel contact lenses are fundamentally important because they are directly related to factors such as comfort, visual performance, fitting characteristics, physiologic impact, durability, and handleability of the lenses.

In the hydrated state, most hydrogels are soft and flexible. When they are allowed to dehydrate, they become hard and brittle. Lower water content polymers tend to become more hard and brittle than higher water content materials. Because they are hydrophilic, hydrogels take up water, which causes them to become soft with elastic properties (the water acts as a plasticizer).

Unlike perfectly elastic materials which deform under stress but return to their original size and shape when the stress is released, hydrogels are viscoelastic. This means that they deform time dependently when a stress is applied to them and recover time dependently when the stress is removed. Theoretically, this can result in permanent deformation of the material.

One of the main difficulties in characterizing the mechanical properties of a contact lens is that there is no single property measurement which will accurately reflect its 'in use' situation. Contact lens hydrogels typically do not demonstrate a yield point. The strength of a hydrogel gives some indication of the behavior of the material during handling, while the modulus indicates the extent to which the eyelid will deform it and has an impact on the fitting characteristics of the lens. Rigid lens materials have a relatively high modulus (in the region of 10^3 MPa) whereas soft lens materials have a much lower value when in the hydrated state. The advantage of a lower value associated with greater comfort can be offset by poor visual performance.

New generation silicone hydrogel lenses have a higher tensile modulus (1.1–1.4 MPa) compared with conventional hydrogels (0.2–0.6 MPa). The higher moduli of silicone hydrogel materials have certain clinical implications which are discussed in more detail in Section 6.633.4.

The generally poor mechanical strength (including tear strength) of soft lenses is arguably the main reason why they have relatively short lifetimes. This problem has been somewhat overcome by the introduction of disposable lenses, which essentially means that the majority of soft lenses no longer need to last more than a day, 2 weeks, or a month depending on their intended replacement schedule.

Several factors can affect the mechanical properties of a hydrogel material and these can be broadly divided into (a) material composition factors and (b) polymer processing factors. Examples of material composition factors include changing the comonomers used in the hydrogel preparation. If the hydrogel is not a homopolymer, then increasing the relative amount(s) of physically stronger component(s) will lead to an increase in the final mechanical strength of the material. This may have the effect of altering the mechanical strength by increasing the stiffness of the backbone polymer by, for example, replacing acrylates with methacrylates, or it may alter the hydrophilicity of the polymer by, for example, replacing hydroxyethyl methacrylate (HEMA) with methacrylic acid (MAA). In general, as the equilibrium water content (EWC) of a hydrogel increases, its modulus decreases.

The mechanical properties of a hydrogel are dependent on the cross-link density in the system. In general, the strength of a hydrogel increases with increasing cross-link density, particularly when in the swollen state where physical entanglements are low. Cross-link density can be increased by the addition of larger amounts of cross-linking agent. Although increasing the cross-link density within a hydrogel network is beneficial in relation to its mechanical properties, it must also be considered that changes to other properties of the polymer will occur. The swelling capacity of the hydrogel is likely to be reduced with increasing cross-link density, and hence, its oxygen

permeability will also be reduced which is undesirable in a contact lens material. A balance of all the properties of a polymer is critical to its end application.

Polymer processing factors which can affect the mechanical properties of a hydrogel essentially refer to the fact that hydrogel materials are highly sensitive to the processing and fabrication conditions to which they are subjected. Lenses made by different methods of manufacture will undergo very different material processing – particularly polymerization. These different material processing steps may have an effect on the mechanical properties of the resultant lens. For example, lathed lenses are formed from solid buttons of dehydrated material. The buttons are usually bulk polymerized over relatively long periods.

Thermal initiators that have low activation energies are often used, thereby allowing water baths or ovens to be set to relatively low temperatures. This type of polymerization is likely to lead to a polymer structure consisting of longer chains (higher molecular weights) and, therefore, more chain entanglements.

In the cast-molding process, a small amount of monomer is placed between two casts to directly form the lens. The polymerization process is typically very fast which is one of the reasons why this is the method of choice for bulk (disposable) lens manufacture (see Section 6.633.6.3). Rapid polymerization times are likely to produce shorter chains, more chain ends, and less efficient cross-links.

6.633.2.3. Surface Properties

The surface characteristics of a hydrogel lens will directly affect its interactions with the tear film and consequently its biocompatibility in the ocular environment. 'Wettability' is used to describe the tendency for a liquid to spread on to a solid surface, and *in vivo* wettability in a contact lens context implies the ability of the tear film to spread and maintain itself over a contact lens surface. *In vivo* wettability is a key measure of clinical performance because the success of any contact lens is considered to be related to its ability to support a stable tear layer in the eye. General clinical consensus is that failure to meet this requirement is likely to result in a lens which is uncomfortable, has reduced visual performance, and deposits rapidly. The quality of the prelens tear film (PLTF) will also have an effect on the friction between the eyelid and the lens surface. This in turn is thought to be important in the etiology of physiologic responses such as contact lens-related papillary conjunctivitis. The issue of wettability has received considerable attention since the introduction of silicone hydrogel materials at the turn of the century, in view of the potentially poor wettability of untreated lenses manufactured from this material.

In vivo wettability is generally assessed using a range of relatively crude clinical tests which have been used for several decades. These include tear film break-up time (with or without the presence of fluorescein stain), interferometric techniques, and various techniques based around specular reflection. Unfortunately, these methods frequently fail to adequately differentiate between lens surface types, even when relatively different lens surfaces are evaluated.

On the other hand, laboratory measures of wettability are well established and are better at differentiating lens surfaces. Wettability in relation to contact lenses has traditionally been assessed *in vitro* using the sessile drop technique and measuring the contact angle of the drop with the surface to which it is applied (Figure 2). Figure 3 shows the contact angles of a conventional hydrogel and a silicone hydrogel. Note that the contact angle of the silicone hydrogel is considerably larger than that of the conventional contact lens. However, it is important to bear in mind that the wettability of a given surface depends on a number of factors including the surface tension of the test liquid and as such, it is a property of a liquid–solid combination rather than of the solid surface alone.

The contact angles obtained for a lens–liquid combination are highly methodologically dependent[4,5] and any reporting of contact angles should include experimental details such as the method itself, the probe liquid, and prior treatment of the material under test.

The sessile drop and the captive bubble techniques give discrepant results for a single sample because a different type of contact angle is measured in each technique: an advancing-type contact angle is measured in the sessile drop technique and a receding-type contact angle is measured in the captive bubble technique.

The receding contact angle obtained *in vitro* is especially relevant when considering the performance of a contact lens *in vivo*. The advancing angle corresponds more to the establishment of the tear film which is assisted mechanically by the eyelid. Conversely, the receding angle is thought to be important in the stability of the tear film between blinks.

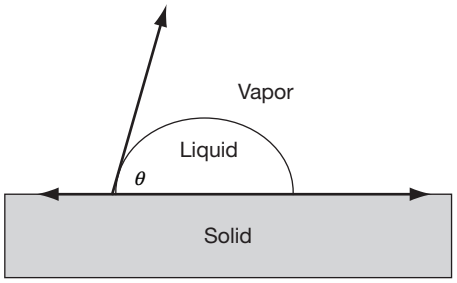

Figure 2 Schematic representation of the sessile drop technique showing the contact angle (θ) measured when a drop is placed on a solid surface. Adapted from Maldonado-Codina, M.; Efron, N. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 72.

6.633.2.4. Water Content

The EWC of a hydrogel lens is defined as follows:

$$\text{EWC} = \frac{\text{Weight of water in polymer}}{\text{Total weight of hydrated polymer}} \times 100$$

The EWC of a hydrogel may vary depending on the environmental conditions. For example, pH, tonicity, and temperature may alter the EWC of a hydrogel. Increased temperature is an important consideration because there is a significant increase in temperature when a contact lens is taken from its packaging solution (normally at room temperature) and placed on the eye. Most contact lens hydrogels will undergo a small change in EWC when placed in solutions of different pH and osmolality, but these changes will be most pronounced in ionic lens materials.

The surface EWC of a contact lens can be measured using a soft contact lens refractometer.[6] This is a simple hand-held optical instrument which can be readily used in the clinical setting. More sophisticated electronic versions of this instrument are also available.[7] The principle underlying the capacity of a refractometer to determine contact lens water content is the inverse relationship between refractive index and EWC of hydrogel materials. The measured refractive index of a contact lens is converted to percent water which is read directly from the internal scale. This approach does assume that dehydrated hydrogels have the same refractive index, which is not strictly true. However, errors due to small differences between hydrogel polymers in respect of refractive indices are clinically inconsequential.

Difficulties are also encountered with this instrument when attempting to measure the EWC of silicone hydrogel lenses. These lenses have a lower refractive index compared to conventional hydrogels and their EWC is overestimated with the soft contact lens refractometer. Additionally, as it is *surface* EWC which is being measured with this instrument, it is unknown what effect the surface coatings on some of these lenses have on the final result.

British and ISO (the International Organization for Standardization) Standards specify both thermogravimetric and refractive index methods as valid techniques for measuring the EWC of a hydrogel lens.[8,9] The thermogravimetric method involves measuring the weight of a lens in the hydrated state and then remeasuring the lens in the completely dehydrated state. The disadvantages of this method are that it is time consuming and essentially destroys the lens.

6.633.2.5. Oxygen Permeability

As the cornea receives most of its oxygen from the atmosphere, the oxygen transmissibility profile of a contact lens is one of its most important properties. Oxygen permeability is a property of the material itself and is described as the *Dk*, where *D* is the diffusivity of the material and *k* is the solubility of the material. Oxygen permeability of a hydrogel will vary with temperature.

Oxygen permeability is essentially governed by EWC in conventional hydrogels. This relationship is on the basis of the ability of oxygen to pass through the water rather than through the material itself. The relationship between EWC and oxygen permeability has been found to be[10]:

$$Dk = 1.67e^{0.0397\text{EWC}}$$

where e is the natural logarithm (**Figure 4**).

In order to calculate the amount of oxygen which will move from the anterior to the posterior surface of a lens, the oxygen permeability (*Dk*) is divided by the thickness of the lens (*t*). The units of *Dk* and *Dk/t* are as follows[8,9]:

$$(Dk) \text{ in } Dk \text{ units} = 10^{-11}(\text{cm}^2 \times \text{ml O}_2)/(\text{s} \times \text{ml} \times \text{hPa})$$

$$(Dk/t) \text{ in } Dk/t \text{ units} = 10^{-9}(\text{cm} \times \text{ml O}_2)/(\text{s} \times \text{ml} \times \text{hPa})$$

6.633.2.6. Fluid and Ion Permeability

The development of silicone hydrogel materials has highlighted the importance of the so-called 'hydraulic permeability' or water transport of a contact lens material. Essentially, a

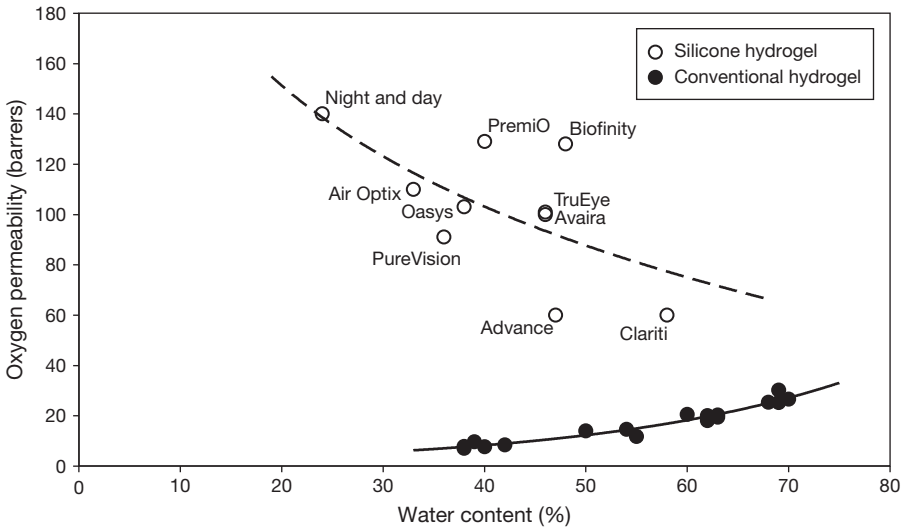

Figure 4 Relationship between oxygen permeability and equilibrium water content for conventional hydrogel lenses (solid curve) and silicone hydrogels (dashed curve).

minimum level of hydraulic (as well as ionic) permeability is necessary to maintain adequate lens movement. This is important in allowing the postlens tear film to reform between blinks, thus reducing the likelihood of these quite elastic lenses from binding to the cornea. Water is able to move through a hydrogel in a way quite different from the movement of sodium ions, that is, it is more difficult for sodium ions to travel through the gel, as in order to do so they must be accompanied by a shell of water.[11] In the eye, the sodium ion permeability of contact lens materials is particularly important as it is a major constituent of the tear film. Sodium ion transport is impeded in gels with a water content below 20%.

6.633.2.7. Refractive Index

Ideally, a hydrogel fabricated for contact lens materials should have a refractive index similar to that of the cornea, that is, near to 1.37. The variation of refractive index with EWC in conventional hydrogels is almost linear, with most hydrogel refractive indices falling within 1.46–1.48 at 20% water content and 1.37–1.38 at 75% water content, that is, the refractive index decreases with increasing water content. Because of this relationship, it is possible to calculate the refractive index of a hydrogel if its EWC is known (and vice versa), which is the basis for the use of the soft contact lens refractometer, as discussed in Section 6.633.2.4.

It is unlikely that a relationship between refractive index and water content will hold for all silicone hydrogel lenses on the market as many are fabricated on the basis of completely different material chemistries. British and ISO Standards recommend the use of an Abbe refractometer to measure the refractive index of a hydrogel contact lens.[8,9] However, other more automated instruments have been used for the assessment of hydrogel lens refractive index.[7,12,13]

6.633.2.8. Swell Factor and Dimensional Stability

The dimensional stability of a hydrogel lens refers to its ability to maintain its original dimensions under various conditions. It is dependent on any factor that will change the water content of the hydrogel or the *swelling* behavior of the hydrogel. Factors that influence the swell factor of a hydrogel include temperature, pH, and tonicity. The swelling behavior of a hydrogel is particularly important during the manufacture of contact lenses in the dry state, for example, when a soft contact lens is lathed. During the lathing process, a smaller, steeper lens of greater power is made so that when it is hydrated, it swells to the required dimensions and power required. It is vital, therefore, that the swell factors of the material are accurately known. The swell factor is described by the following relationship:

$$\text{Swell factor (SF)} = \text{Wet dimension/dry dimension}$$

Initially, it was thought that a hydrogel material swelled isotropically. Over time, it was found that the consistently anomalous swelling behavior of hydrogels could only be explained by specifying two swell factors. These swell factors are those in the diameter and axial (thickness) directions. From these, the value of the radial swell factor of a contact lens can be calculated using the following equation:

$$SF_{rad} = (SF_{dia})^2/SF_{ax}$$

where SF_{rad} is the radial swell factor, SF_{dia} is the diametral swell factor, and SF_{ax} is the axial swell factor.

6.633.3. Conventional Hydrogel Contact Lens Materials

Hydrogel materials can be conveniently divided into two groups: (1) conventional hydrogel materials (now sometimes referred to as low *Dk* materials) and (2) silicone hydrogels (high *Dk* materials). This section will discuss conventional hydrogel materials.

6.633.3.1. Historical Development

Hydrogel lenses were developed as a result of the extraordinary pioneering efforts of Professor Otto Wichterle (Figure 5) and colleagues in the Institute of Macromolecular Chemistry of the Czechoslovak Academy of Sciences in Prague in the mid-1950s. Essentially, Wichterle was working on the synthesis of a new material that he hoped could be used for implantation into the human body. That material was poly(hydroxyethyl methacrylate) or pHEMA.[14] Wichterle soon realized that the material had potential applications in the manufacture of contact lenses, but he was prevented from researching such a project by the directors of the Institute, who perceived this work as being a petty distraction from fundamental studies in chemistry. He was forced to carry out his experiments at home. Despite such difficult circumstances, he successfully managed to produce the first spun-cast lens (made from his son's toy construction set) in 1961.[15] The enormity of his breakthrough for the contact lens industry cannot be overstated.

6.633.3.2. Polymeric Formulations

HEMA (Figure 6) is made by polymerizing 2-hydroxyethyl methacrylate monomer with a cross-linker such as ethylene glycol dimethacrylate (EGDMA) (Figure 6). Most of the hydrophilic behavior of HEMA is due to the presence of the hydroxyl

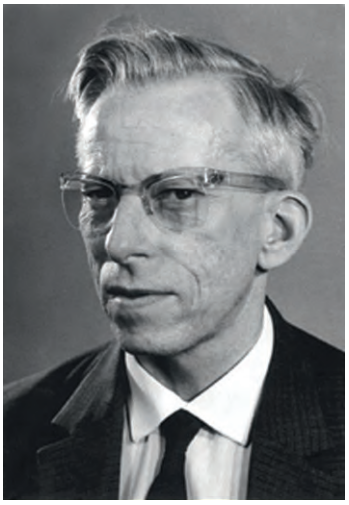

Figure 5 Otto Wichterle.

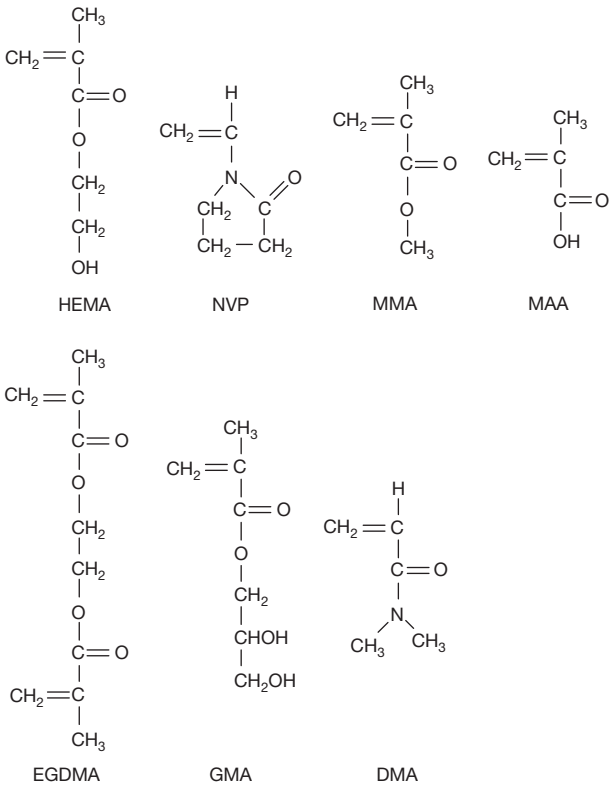

Figure 6 Some of the monomers used in conventional hydrogel lens materials. HEMA, hydroxyethyl methacrylate; NVP, *N*-vinyl pyrrolidone; MMA, methyl methacrylate; MAA, methacrylic acid; EGDMA, ethylene glycol dimethacrylate; GMA, glyceryl methacrylate; DMA, *N*,*N*-dimethyl acrylamide. group (OH) at the end of the monomer. At this location in the resultant polymer, hydrogen bonding with water molecules occurs, causing them to be drawn into the polymer matrix. The result is that contact lenses made from pHEMA contain approximately 40% water in the fully hydrated state.

Lenses fabricated from pHEMA were first distributed in Western Europe in 1962 but sales were disappointing. In 1965, the National Patent Development Corporation (NPDC) bought the licence for the American rights to the technology from the Czechs. This was subsequently sold on to Bausch & Lomb who at that time manufactured ophthalmic equipment and spectacle lenses. Bausch & Lomb significantly refined Wichterle's spin-casting process and finally obtained approval from the Food and Drug Administration (FDA) for their pHEMA lenses in 1971. This time, the lenses quickly became very popular – both practitioners and patients enjoyed the benefits of increased comfort, reduced adaptation time, and easier fitting procedures. With time, more and more companies developed their own pHEMA lenses; however, it soon became clear that these lenses were not problem-free. Most of these problems stemmed from the fact that the lenses caused hypoxia but other problems relating to solution toxicity and lens spoliation were also common.

Contact lens manufacturers, therefore, had two possible avenues to follow to increase the oxygen transmissibility of lenses: develop 'hyper-thin' lenses or develop materials with higher water contents. Producing lenses which were thinner was a relatively straight forward matter for lens designers and several such lenses were launched, for example, the Hydrocurve thin lens (Soft Lenses, Inc.) in 1977 and subsequently the O3 Series (Bausch & Lomb). These lenses were in the region of 0.035–0.06 mm in thickness which was less than half the thickness of the original Bausch & Lomb pHEMA lenses.

Developing materials with higher EWC led to the successful development of HEMA copolymers. One of the first successful copolymerizations was with *N*-vinyl pyrrolidone (NVP) (Figure 6). The amide (N–C=O) moiety is very polar and two molecules of water can become hydrogen bonded to it. NVP-based copolymers lose the slippery 'feel' of pHEMA and consequently can feel quite rubbery. These copolymers also tend to have relatively high evaporation rates of water which may be seen as a problem for lens stability and comfort. This occurs because the amide group does not bind water as strongly as a hydroxyl group. In addition, these polymers are significantly more temperature-sensitive than pHEMA-based materials; that is, their parameters tend to change with increasing or decreasing temperature. This is important when removing a lens from its packaging (at room temperature of, say, 20 °C) and inserting it into the eye (~33 °C); that is, lens parameters may change on-eye.

NVP-based lenses have also been associated with increased toxic reactions to the corneal epithelium – observed as patches of 'staining' on the corneal surface, which are observed clinically with the aid of fluorescein dye[16] – and decreased comfort when used in conjunction with solutions containing higher levels of polyhexanide.[17,18] This does not mean that polyhexanide-based solutions cannot be used with NVP-containing lenses, rather the interaction should be born in mind if any significant corneal staining or discomfort symptoms arise – these can usually be treated simply by changing the solution to one containing a lower level of polyhexanide or one free from polyhexanide.

Methyl methacrylate (MMA) is the material from which rigid contact lenses are originally made, that is, PMMA (Figure 6). When MMA and NVP are copolymerized, a completely new material is obtained with very different characteristics to the HEMA/NVP (also known as HEMA/VP) copolymers. Depending on their composition, contact lenses made from MMA/VP copolymers can contain 60–85% water. MMA is very hydrophobic but is useful in soft lens hydrogels as it gives the resultant polymers increased mechanical strength.

Another hydrophilic monomer that has been very successfully used in contact lens hydrogels is MAA (Figure 6). When added to a soft lens polymer formulation, it results in a soft lens with ionized groups (negatively charged) within the polymer matrix, allowing the lens to absorb more water. The higher the amount of MAA, the higher the EWC of the resulting polymer. Amounts of MAA in the region of 1.5–2.5% will increase the water content of a HEMA material into the mid-water content range of 50–60%, thereby allowing oxygen permeability to increase significantly.

Once HEMA/MAA lenses have been manufactured, they need to be ionized (i.e., the hydrogen atom in the carboxyl group is removed). The conversion of the carboxyl group (CO_2H) to the more hydrophilic ionized form (the carboxylate anion, CO_2^-) produces an increase in water content. This is commonly achieved by washing the lenses in sodium

bicarbonate solution or buffered saline and is referred to as 'expanding the matrix.' Unfortunately, using MAA to increase the water content of a polymer also has its disadvantages. These include the following:

1. A lens which is extremely sensitive to changes in tonicity.[19] The Na^+ ions present in saline solution have the effect of 'shielding' the carboxylate anions. In hypotonic solutions (e.g., pure water), as these shielding ions are present to a far lesser degree, more chain repulsion will occur, which increases the swelling of the network and consequently the EWC of the material. In hypertonic solutions, the reverse situation occurs and the material network shrinks, causing its EWC to decrease.
2. A pH-sensitive lens.[20] If the pH of the solution in which the lens is immersed is decreased (i.e., the hydrogen ion concentration is increased), the carboxylate anions are more shielded and the network becomes less expanded. This will cause a decrease in the lens EWC.
3. A very significant level of protein buildup both on the lens surface and within the lens matrix.[21,22] However, it is the biological activity of deposited proteins such as lysozyme which is thought to be most relevant in biocompatibility issues such as contact lens-related papillary conjunctivitis and comfort; that is, protein which remains active (as opposed to becoming denatured) is thought to be biocompatible. The protein deposited on HEMA/MAA lenses has been found to denature to a significantly lower degree compared to other lens materials.[23]
4. Dimensional instability when the lens is heat disinfected.

Glyceryl methacrylate (GMA) is more hydrophilic than HEMA because of the fact that the monomer contains two hydroxyl groups (**Figure 6**). This monomer has been used in contact lens materials in two main ways. The first method has used GMA in combination with MMA to produce materials which have water contents in the range of 30–42%. These materials are thought to be stiffer and stronger than pHEMA hydrogels but their oxygen permeabilities are not ideal for in-eye use.

The second method has been to use GMA in combination with HEMA to produce a high water, nonionic contact lens material (up to ~70% has been possible). These contact lenses are said to be 'biomimetic,' that is, they are claimed to improve biocompatibility by imitating the hydrophilic properties of mucin. Manufacturers also suggest that these lenses show a low rate of dehydration and a rapid rate of rehydration, that is, they have good 'water balance ratios.' In addition, the materials are thought to be relatively deposit resistant and seem to be relatively insensitive to pH changes in the range of pH 6–10. An example of such a lens is the hioxifilcon A material used in the Clear 1 Day lenses manufactured by Clearlab. Another example of a so-called 'biomimetic' lens is the Proclear lens (Coopervision) which contains phosphoryl choline (PC) and HEMA. PC is said to mimic the natural chemistry of cell membranes.

6.633.3.3. High Water Content Hydrogel Lenses

In the early days of soft lens development, de Carle[24] proposed that if the EWC of hydrogel lenses could be sufficiently increased, then these lenses could be worn successfully on an overnight or continuous basis. He developed the first extended wear lens to be distributed in the United Kingdom known as Permalens.[24] The lens material had an EWC of 71% and was made from a HEMA/VP/MAA copolymer. In 1981, the lens was given FDA approval for 'extended wear' of up to 30 days along with another lens, the Hydrocurve II (Wesley Jessen).

Slowly, other lenses were given approval for extended wear during the 1980s but along with the increase in demand for these lenses, so too came an increase in complications. In 1989, studies were published which showed that the risk of microbial keratitis was 5–15 times greater for extended wear than daily wear.[25,26] As a result, the FDA recommended that extended wear be limited to six consecutive nights and with that, the enthusiasm for extended wear died down – that is, until the emergence of silicone hydrogel lenses in the late 1990s.

Table 1 lists some of the most common hydrogel lenses on the market and groups them into their appropriate FDA classification. See Appendix A for details on the classification of hydrogels.

6.633.3.4. Strategies for Enhancing Lens Comfort

In recent years, so-called 'enhanced' hydrogel daily disposable lenses have been developed, such as 1 Day Acuvue Moist (Johnson & Johnson), Focus Dailes with AquaComfort (CIBA Vision), and SofLens daily disposable (Bausch & Lomb). These lenses utilize techniques of macromolecular entrapment and/or release of hydrophilic surface-active polymers at the lens surface in order to improve end-of-day comfort by stabilizing the PLTF.

The Focus Dailes with AquaComfort lens is manufactured from nelfilcon A which essentially consists of a cross-linked functionalized polyvinyl alcohol (PVA) macromer with the addition of nonfunctionalized PVA.[27]

PVA and polyvinyl pyrrolidone (PVP) are common soluble polymeric components in comfort drops and artificial tears and have a viscous consistency at elevated concentrations and molecular weights giving them good surface spreading characteristics. The 1 Day Acuvue Moist lens is manufactured from the etafilcon A polymer (HEMA/MAA) together with the incorporation of small concentrations of low-molecular-weight PVP into the ionic material network.

The Focus Dailies 'enhanced' lenses contain more unfunctionalized PVA than the original lenses. Unfunctionalized PVA is a non-cross-linked PVA macromer of a carefully selected molecular size which does not take part in the polymerization process and which is added to the monomer mix before polymerization. No imbibing step after the lens is polymerized is required. This unfunctionalized PVA macromer is thus free to elute from the lens into the tear film throughout the day with each blink. This PVA is thought to emerge from the lens matrix as 'strands' at the lens surface and it is this effect together with the effect of soluble PVA in the tear film which is what is referred to as the 'surface modification' of these lenses. The released PVA may improve lens comfort by decreasing the surface tension of the tears, or by mimicking mucin, found naturally in the tear film.[28]

In the 1 Day Acuvue Moist lens, the PVP is 'locked' into the lens matrix and is not released from the lens during wear. The PVP is adsorbed on to the preformed lens surface after manufacture from solution. The lens packaging states that the lenses

are packaged in 'buffered saline with povidone.' Povidone is another name for PVP. PVP is quite polar and it is likely to be relatively strongly attracted to the etafilcon material, potentially providing a mechanism for its retention on the lens surface. The persistence of the PVP at the lens surface during wear has been verified by Ross *et al.*[29] who have also described the PVP as being in a predominantly 'looped structure' across the lens surface.

PVP decreases the coefficient of friction of the lens surface compared to its original counterpart. These changes are thought to improve comfort by reducing lens–lid interaction on blinking or, in much the same way as the Focus Dailies lens, by mimicking mucin found naturally in the tear film.

The new SofLens daily disposable lens is modified by the adsorption of Tetronic 1107 – a hydrophilic surface-active polymer composed of ethylene oxide/propylene oxide block copolymer – on to the lens surface. The Tetronic at the surface lowers the coefficient of friction of the lens but it has been shown to be progressively lost from the surface during wear.[29] It is likely, therefore, that the Tetronic is held by weak forces at the lens surface, which would explain the least in-eye persistence of the three 'enhanced' lenses.[29]

6.633.4. Silicone Hydrogel Contact Lens Materials

6.633.4.1. The Drive for Increased Corneal Oxygenation

When Holden and Mertz[30] defined the critical oxygen levels in order to avoid corneal edema for daily and extended wear, they concluded that 24 Barrer per centimeter was the oxygen transmissibility required for daily wear and 87 Barrer per centimeter was that required for overnight wear. These values were reevaluated by Harvitt and Bonanno[31] who found that the minimum oxygen transmissibility required to avoid anoxia throughout the entire cornea was 35 Barrer per centimeter for the open eye and 125 Barrer per centimeter for the closed eye.

From inspection of the relationship between the EWC and the *Dk* of conventional hydrogels (Figure 4), it is obvious that there is an upper limit to how much oxygen permeability can be attained simply by increasing the EWC of conventional hydrogel materials. A hydrogel with a theoretical EWC of 90% and a central thickness of 0.1 mm would have an oxygen transmissibility in the region of 60 Barrer per centimeter which still falls far short of that required to avoid additional overnight corneal edema. Such a lens would need to be in the region of 0.06 mm thickness which is unrealistic both from a manufacturing and a clinical point of view.[32]

6.633.4.2. The Challenge of Incorporating Silicone into Hydrogel Materials

As reducing the thickness of lenses made from conventional hydrogels was not an option for achieving success in extended wear, polymer scientists had to come up with an altogether new kind of material. That material was silicone. Incorporating silicone into contact lens materials was not a new concept when scientists began trying to produce silicone hydrogels. Indeed, the first material to be used in contact lenses was silicone dioxide (glass). Additionally, silicone rubber (polydimethyl siloxane, PDMS) (Figure 7) has been used with limited success as a contact lens material in the form of silicone elastomer lenses. These lenses have not become popular mainly because of lens tightening and surface wettability problems (PDMS is extremely hydrophobic).[33] PDMS has an oxygen permeability in the region of 600 Barrer but is unwettable by tears, deposits high degrees of lipid, and needs to be surface treated. Surface treatments of silicone elastomer lenses have not been particularly successful in the past because Si–O chains have a tendency to rotate very easily and any hydrophilic parts of a newly treated surface tend to disappear inside the polymer.

Silicon, however, has been very successfully incorporated into rigid lens materials, and it was this development which has proven to be a key milestone in the subsequent development of silicone hydrogel materials. The first siloxane-based rigid lens material merged the properties of MMA with the increased oxygen performance of silicone rubber.[34,35]

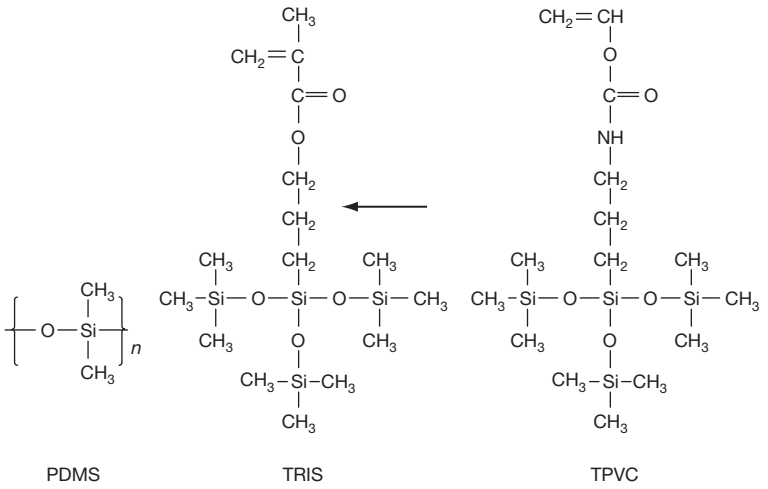

Figure 7 Silicone-based materials. PDMS, polydimethyl siloxane; TRIS, tris(trimethylsiloxy)-methacryloxy-propylsilane; TPVC, carbamate-substituted TRIS. Adapted from Maldonado-Codina, M.; Efron, N. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 79.

The resultant siloxymethacrylate monomer was tris(trimethylsiloxy)-methacryloxy-propylsilane (Figure 7) and is more commonly referred to as TRIS.

The patent literature shows that combining silicone with conventional hydrogel monomers has been a goal for polymer scientists since the late 1970s. The biggest obstacle to this approach, however, is that silicone is hydrophobic and poorly miscible with hydrophilic monomers resulting in opaque, phase-separated materials. In order to solve this problem, two main approaches have been utilized.[11] The first approach involves the insertion of polar groups into the TRIS molecule in order to aid its miscibility with hydrophilic monomers.[36,37]

The second approach is that of utilizing macromers. These are large monomers formed by preassembly of structural units that are designed to bestow particular properties on the final polymer.[11] Figure 4 demonstrates the relationship between *Dk* and EWC for silicone-containing hydrogels based on TRIS, highlighting the benefits of increased oxygen performance.

6.633.4.3. The Launch of Silicone Hydrogel Lenses

The first two silicone hydrogels were launched in the late 1990s – the PureVision lens (Bausch & Lomb) and the Focus Night & Day lens (CIBA Vision). Both were licensed for 30 days of continuous wear. The PureVision lens (balafilcon A) has an EWC of 36% and an oxygen transmissibility of 110 Barrer per centimeter (at −3.00D). The exact compositions of these materials are proprietary but the USAN-registered components of the balfilcon A material show that it is based on a carbamate-substituted TRIS-based material known as TPVC (Figure 7). The TPVC is then copolymerized with NVP to form the balafilcon material.

The Focus Night & Day lens (lotrafilcon A) has an EWC of 24% and an oxygen transmissibility of 175 Barrer per centimeter (at −3.00D) and is said to be 'biphasic.' Tighe[11] describes the lens as being a fluoroether macromer copolymerized with TRIS and DMA (*N*,*N*-dimethyl acrylamide) in the presence of a diluent. Its biphasic structure means that oxygen and water permeability channels are not reliant on each other. The silicone-containing phase allows passage of oxygen while the water phase primarily allows the lens to move.

6.633.4.4. Surface Treatments

Without further treatment both of these lenses would be unsuitable for wear because of the fact that the resultant material surfaces are very hydrophobic. In order to overcome this problem, both lenses are surface treated using gas plasma techniques. High-energy gases or gas mixtures (the plasma) are used to modify the lens surface properties without changing the bulk properties. The result for the balafilcon lens is that surface wettability is gained via plasma oxidation which produces glassy silicate islands on the lens surface.

The lotrafilcon lens is coated with a dense 25-nm-thick coating. Both resultant surfaces have low molecular mobility which minimizes the migration of hydrophobic silicone groups to the surface. However, despite these surface modifications, wettability problems with these lenses have been reported. It is generally accepted that these lenses have inferior wettability compared to conventional hydrogels which occurs as a result of the hydrophobic interaction of silicone with the tear film.

6.633.4.5. Material Modulus of Elasticity

Another important difference between these materials and conventional hydrogels is that they have significantly greater elastic moduli. Such mechanical characteristics mean that the lenses are easy to handle but have also been implicated in the etiology of a number of clinical complications.[38] These include higher incidences of superficial epithelial arcuate lesions (SEALs), mucin balls, and contact lens papillary conjunctivitis, especially with continuous wear of these lenses.[39] The stiffness of the material may contribute to the mechanical irritation of the lens rubbing against the conjunctiva of the upper eyelid producing a localized response.

6.633.4.6. Lens Edge Design

The design of the lens, and in particular the edges, may also impact ocular compatibility. It has also been suggested that the design of the lens edge in conjunction with the mechanical properties of silicone hydrogel lenses may be responsible for increased conjunctival staining and conjunctival epithelial flaps observed with these lenses.[40] A knife-point edge or chisel-shaped edge may cause more conjunctival staining and flap formation than a round edge by 'carving' into the conjunctival tissue.[41] It has been proposed that certain edge designs incorporating localized increases in posterior edge lift, reduced peripheral thickness, or peripheral channels may reduce the pressure on the conjunctiva.[41]

6.633.4.7. 'Second Generation' Silicone Hydrogel Lenses

In an attempt to improve on the problems encountered with the early silicone hydrogels, manufacturers have engaged in a program of research aimed at manufacturing silicone hydrogel lenses with improved mechanical and surface characteristics. This has resulted in the gradual emergence of 'second generation' silicone hydrogel lenses such as Acuvue Advance, Acuvue Oasys, TruEye, Avaira, Biofinity, and Clariti. Table 2 compares the properties of all the silicone hydrogel lenses currently on the market.

The main advantage of these 'second generation' silicone hydrogels compared to the early silicone hydrogels is that they have increased water contents and reduced moduli, and they do not need to be surface treated. The mechanical and surface properties can be thought of as being 'in between' those of conventional hydrogels and the early silicone hydrogels. Results of clinical studies indicate that there may be a lower incidence of contact lens-induced papillary conjunctivitis (CLPC) with these lenses.[42]

6.633.4.8. Optimizing Surface Characteristics

Some of the lenses in Table 2 are based on materials containing TRIS-like components. Acuvue Advance and Acuvue Oasys are on the basis of Tanaka's original patent (following it's expiration after 25 years) using a modified TRIS molecule, a silicone macromer, and hydrophilic monomers such as HEMA and DMA. Alcohol is used as a solvent to aid the miscibility of these ingredients and is then extracted following polymerization. High-molecular-weight PVP is the internal wetting agent (the 'Hydraclear') used in these lenses, which is entangled and

therefore 'entrapped' within the lens matrix, and allows them to be manufactured without requiring a surface treatment.[43,44] The PVP essentially works by shielding the silicone from the tear film at the lens interface.

The Biofinity lens (comfilcon A) is not based on TRIS chemistry. It comprises solely silicon-containing macromers and requires no surface treatment or wetting agent. The patents surrounding the material refer to a monofunctional macromer (containing only one double bond which takes part in the polymerization process) being combined with another rubber-like siloxy macromer resulting in a material with much longer chains (higher molecular weight) compared to the other silicone hydrogels.[45,46] The patents also discuss other hydrophilic monomers which are presumably the key to why these materials do not need to be surface treated. The material chemistry of this lens provides a higher than expected oxygen transmissibility for its water content. The introduction of these 'second generation' lenses has also seen a significant rise in the number of silicone hydrogel lenses being prescribed on a daily wear basis.

6.633.5. Classification of Soft Contact Lens Materials

There are three main classification systems for soft contact lens materials. Two are well established: the UK Association of Contact Lens Manufacturers (ACLM) classification system and the US Food and Drug (FDA) classification system. A third classification system has been put forward in a British and International Standard.[8,9] These classification systems are expanded upon in Appendix A.

6.633.6. Soft Contact Lens Manufacture

Three techniques can be employed to manufacture soft contact lenses – lathe cutting, spin casting, and cast molding. As medical devices that rest against the highly sensitive eyeball, contact lenses need to be of the highest quality in terms of their physical construction. As devices that correct optical defocus, the optical quality of contact lenses must also be of the highest order. At the same time, it must be recognized that companies will only manufacture contact lenses if they are profitable; the dominant forces in the market dictate that these high-quality products must be delivered at minimal cost, and one consequence of this is a simplification of lens parameters to streamline the high-volume process.

A key requisite of any technology employed to manufacture a medical appliance is that the final product is safe, predictable, and of high quality, so that it meets the intended need. The three technologies discussed below have been developed to meet these requirements.

6.633.6.1. Lathe Cutting

This process essentially involves the use of a special contact lens lathe to cut an anhydrous cylindrical button of material (xerogel) into the required shape, and then hydrating this to form the finished soft lens. Lathe manufacture ranges from labor-intensive, manual-based cutting systems to sophisticated and fully automated manufacturing lines, depending on the capital budget or skill levels available. Even with the use of automation, however, the number and variability of manufacturing steps, which are necessary for lathe cutting, means that manufacturing soft lenses using this technology is necessarily more expensive than that using spin casting or cast molding.

Therefore, lathe cutting is generally reserved for the production of custom-ordered or extreme range lenses that contain design features not amenable to mass production, such as lenses of high spherical power and/or high toric power, and more recently, aberration-correcting soft lenses for keratoconus.[47]

The raw xerogel is supplied to the lens manufacturer in the form of 'rods' or 'buttons.' A rod is a solid cylindrical piece of xerogel, about 16 mm in diameter and 400 mm long. The rod is then sliced, tangentially to the long axis, into buttons about 10 mm thick. More commonly, the xerogels are fabricated and supplied in button form. When this occurs, buttons have usually been pretrimmed to a industry standard size so that it can be machined in most of the available lathes.

The button is first secured to a back surface lathe in a clamp or 'collet,' and this assembly is set spinning at a high rate (typically 8000–12000 rpm) about its central axis. A diamond-tipped tool cuts the posterior surface lens shape into the button. A second diamond tool advances from the side to reduce the diameter to the required size. The surface is rendered smooth by either fine machining or polishing. Modern sophisticated lathes are capable of cutting xerogel surfaces to a tolerance of 8–15 nm. Such smooth surface finishing precludes the need for polishing and is preferred when nonspherical surface geometries are being generated. This approach also serves to preserve the consistency of one surface to the next. The dimensions of the lathed surface are calculated to allow for eventual expansion when the xerogel is later hydrated.

The button is removed from the collet and the cut posterior surface of the button is mounted onto a support tool of a front surface lathe, using low melting point wax. It is essential during this process that the button is mounted and fixed in an absolutely concentric and level aspect to the support tool in order to minimize unwanted prism being introduced by the front surface cutting. A diamond-tipped tool cuts the anterior surface down to the required thickness, and the surface is smoothed. The most advanced lathes now offer 'W' axis cutting options that can generate rotationally nonsymmetric surfaces while the primary front surface is being cut. Polishing tools may be used to smooth the lens edge, although some advanced lathes obviate this step.

After inspecting and measuring all relevant dry lens parameters, the lens is hydrated in normal, unpreserved saline until it is fully equilibrated and impurities have been extracted. The hydrated lens is reinspected for final wet parameter conformity, sealed in small glass vials and autoclaved at 120 °C for 15 min to effect sterilization. Advances in lathing technology and computer-controlled processing have led to the development of semiautomatic systems whereby stacks of buttons are automatically fed into lathes; however, even this technology cannot match the mass-production capabilities of cast molding.

Figure 8 is a schematic flow diagram illustrating the process of manufacturing a soft contact lens using lathe cutting technology.

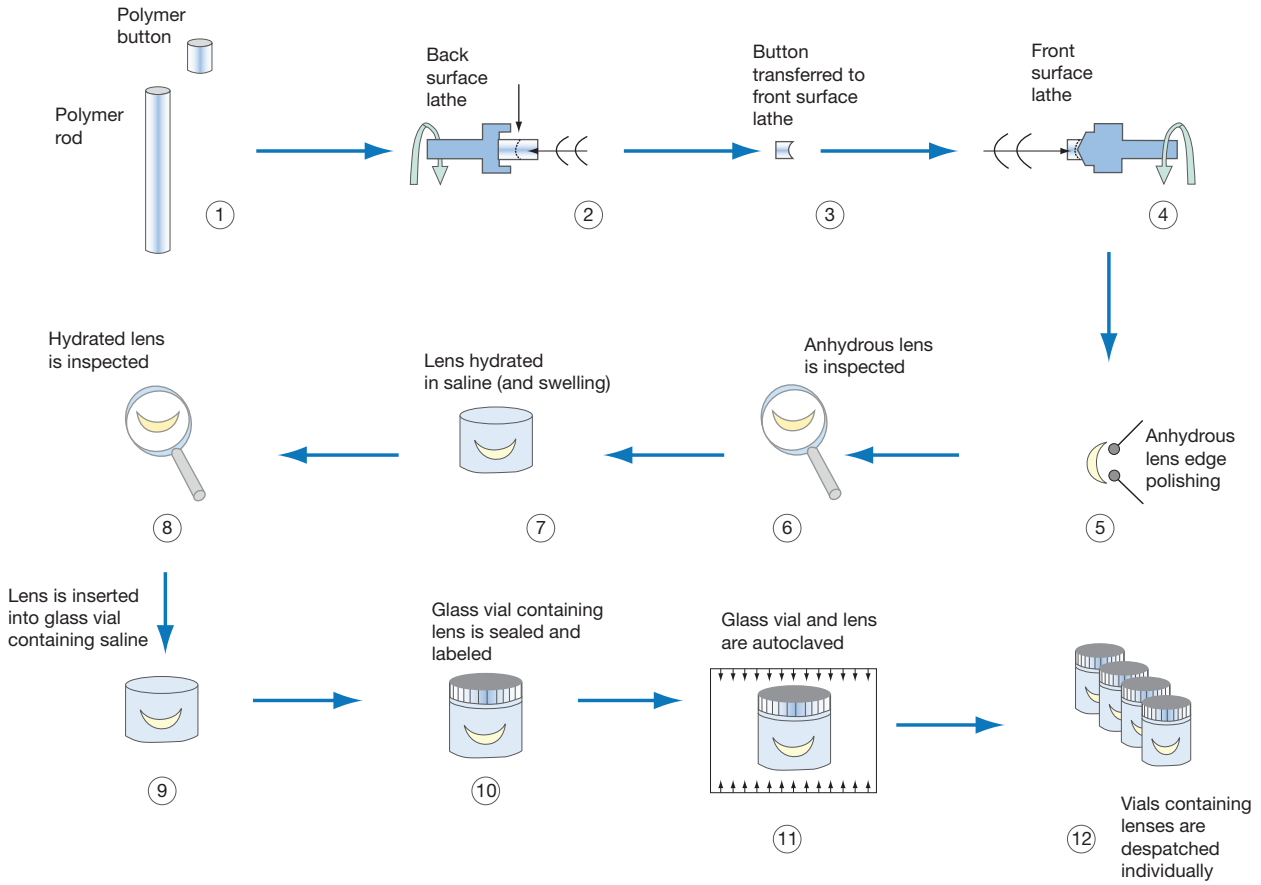

Figure 8 The process of manufacturing a soft contact lens by lathe cutting. (1) The dry polymer is supplied as a rod or button. (2) A polymer button is placed on a lathe; the button spins and a diamond knife is advanced toward the button to generate the lens back surface. (3) The button is released from the back surface lathe. (4) The button is mounted on a front surface lathe with adhesive wax; the button spins and a diamond knife is advanced toward the button to generate the lens front surface. (5) The dry lens is removed from the lathe and the edges are polished. (6) The lens is inspected at 10× magnification. (7) The dry lens is placed in saline to hydrate the lens, which swells to its final soft lens form. (8) The hydrated soft lens is inspected at 10× magnification. (9) The soft lens is inserted into a glass vial containing saline. (10) The glass vial is sealed and labeled. (11) The sealed glass vial containing the lens is sterilized in an autoclave. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 87.

6.633.6.2. Spin Casting

In this process, a convex 'male-shaped' stainless steel tool, or 'insert,' is produced on a high-precision engineering lathe and lapped to provide an accurate surface that matches the dry dimensions of the proposed anterior surface of the contact lens (Figure 9). Modern nonferrous materials are also suitable for producing the mold tool and these materials can be generated on 'nano-accurate' single point turning lathes. These lathes can cut mold tools to a surface finish which renders polishing unnecessary. The final surface shape of the master mold tool is verified using interferometry or other similar noncontact measuring methods. Any given tool is used to make millions of molds.

The steel tool is impressed against heated liquid polypropylene or polyvinyl chloride (PVC), which then cools and sets to form a solid plastic concave female mold. A series of about eight tools is used to produce eight molds simultaneously. The molding methods and tooling used must be very accurate in

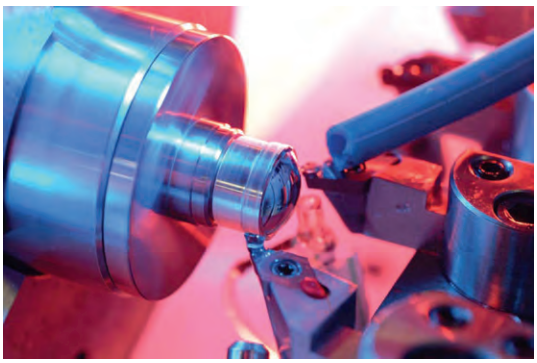

Figure 9 A male-shaped stainless steel tool being cut to shape using a high precision lathe. This tool will be used to form female molds. Reprinted with permission from Efron, N.; Newman, S. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 89.

order to preserve the concentricity of the resultant plastic part. Any molding run out will create unwanted prism in the lens during the spinning process. This sort of injection cast molding is generally conducted in a controlled environment. It is imperative for a spin cast manufacturing process to control the level of potential contaminants to a minimum as it is an open molding system.

The xerogel lens form is created by pouring liquid monomers into the concave molds, which spin at a high rate about the central mold axis.

This spinning takes place in a controlled atmosphere of carbon dioxide or similar oxygen deprived atmosphere. This is necessary as the spin mold is an open system and thus exposes one surface of the lens (posterior) to air as it is being cured. Oxygen in air is a natural scavenger of the initiator and will ultimately inhibit the polymerization process.

The speed of rotation, combined with both the mold tool shape and monomer dose, ultimately determines the final lens parameters. The shape of the back surface is governed by centrifugal force generated by the rate of spin of the mold, surface tension and friction forces between the mold and polymer, and the effects of gravity. A greater speed of rotation of the mold will result in more polymer mass being shifted toward the lens periphery, and more negative lens power. Because of this system of manufacture, certain process controls such as monomer dosing must be more accurate than those found in full cast molding of contact lenses.

As the mold spin rate stabilizes, ultraviolet radiation and/or heat is introduced to initiate polymerization. The lens is removed from the mold, and the mold is discarded. Certain spinning processes hydrate the lens in the original plastic mold, which is never removed. Such a process has been proven advantageous and cost-effective for the mass production of daily lenses.

Other spinning systems still require that the edges of the lens are polished and that the lens be inspected, hydrated, reinspected, packaged, and autoclaved. Spin casting can produce a much higher output volume than lathe cutting, and in the latest systems, can match the high volume of lenses that can be produced by cast molding. The primary restriction of spin cast manufacture lies in its inability to generate a fully formed edge from the posterior to anterior surface; however, sophisticated design modeling, combined with accurate tooling, has largely mitigated this limitation. The process of spin casting is illustrated in Figure 10.

6.633.6.3. Cast Molding

Cast molding has become the dominant technology in high-volume lens manufacture. As with spin casting, a series of highly polished steel tools is used to fabricate polypropylene molds; however, matching male and female molds are required for cast molding. Again, modern nonferrous materials are suitable for producing the mold tool and can be generated to extremely fine levels of accuracy and surface finish. These master tools are used to make millions of male and female molds (Figure 11).

The variations found in different manufacturing facilities around the world, however, attest to significant development in challenging this norm. Modern molding machines can create reproducible results (a critical requirement for the high-volume production of contact lenses, particularly daily disposable lenses) with higher numbers of tools. Some machines can successfully carry as high as 36 cavities (18 males and 18 females) in one mold base. Molding parameters, tool accuracy, cooling, and balancing are critical if this is to be successful. The manufacturer will seek a balance between output and accuracy with the molding process.

Cast molding generally takes place in a continuous, automated production line (Figure 12). Monomer in liquid form is introduced into a concave female mold, which defines the shape of the lens front surface. An ultraviolet-transparent male mold is mated to the female mold and the two are clamped together in a carefully controlled environment.

The contact lens edge is formed when the two sides of the mold come together. There is considerable science and art in the control of the polymerization process and the pressure that is applied to the mold to form the lens. A crucial aspect of this process is to arrange for the excess polymer (so-called 'flash') to be squeezed out while leaving the edge intact.

Once the polymer is encapsulated in the mold, it is 'cured'– a process in which the assembled molds are exposed to either UV light or thermal radiation, or a combination of both, to effect polymerization so as to form the dry contact lens. Most cast-molding processes are designed so that when the dry lens is removed from the mold there is no need to polish the edge. The molds are disassembled and discarded, and the lens that is released from the molds – still in rigid form – is hydrated in saline.

Inspection is undertaken either manually (Figure 13) or using automated video-based computer-controlled image analysis. Finally, the lens blister packs are sealed, labeled (Figure 14), autoclaved, and packaged in boxes. Figure 15 is a flow diagram of the cast-molding process.

It should be recognized that the above descriptions are highly simplified accounts of sophisticated engineering processes. Various manufacturers have introduced a number of unique variations, such as wet-state polymerization, the employment of reusable glass molds,[48] and use of the male half of the mold for final lens packaging. Also, toric and bifocal lenses can be manufactured using either spin-casting or cast-molding technology by engineering the master tools to contain the desired lens forms; these design elements will then be faithfully transposed to the molds and then to the final lens.

6.633.6.4. Reproducibility and Quality of Mass-Produced Lenses

Practitioners who prescribe lenses, and patients who wear lenses, need to be assured of the reproducibility of lenses that have been manufactured using mass-production techniques. Young *et al.*[49] determined the reproducibility of 24 lenses in three lens powers (−1.00D, −3.00D, and −6.00D) of eight common frequent replacement spherical soft contact lens types. They found that the mean power of all the lenses was higher than their labeled powers, although all were within the tolerance ranges. Reproducibility was observed to be worse for all lenses at higher powers. All but two lens types had mean diameters within tolerance. A slight reduction of optical quality at high powers was noted. Measures of back optic zone radius, center thickness, and overall diameter showed reasonably good repeatability.

In a similar study conducted on three brands of daily disposable contact lenses, Efron *et al.*[50] found that 450 lenses

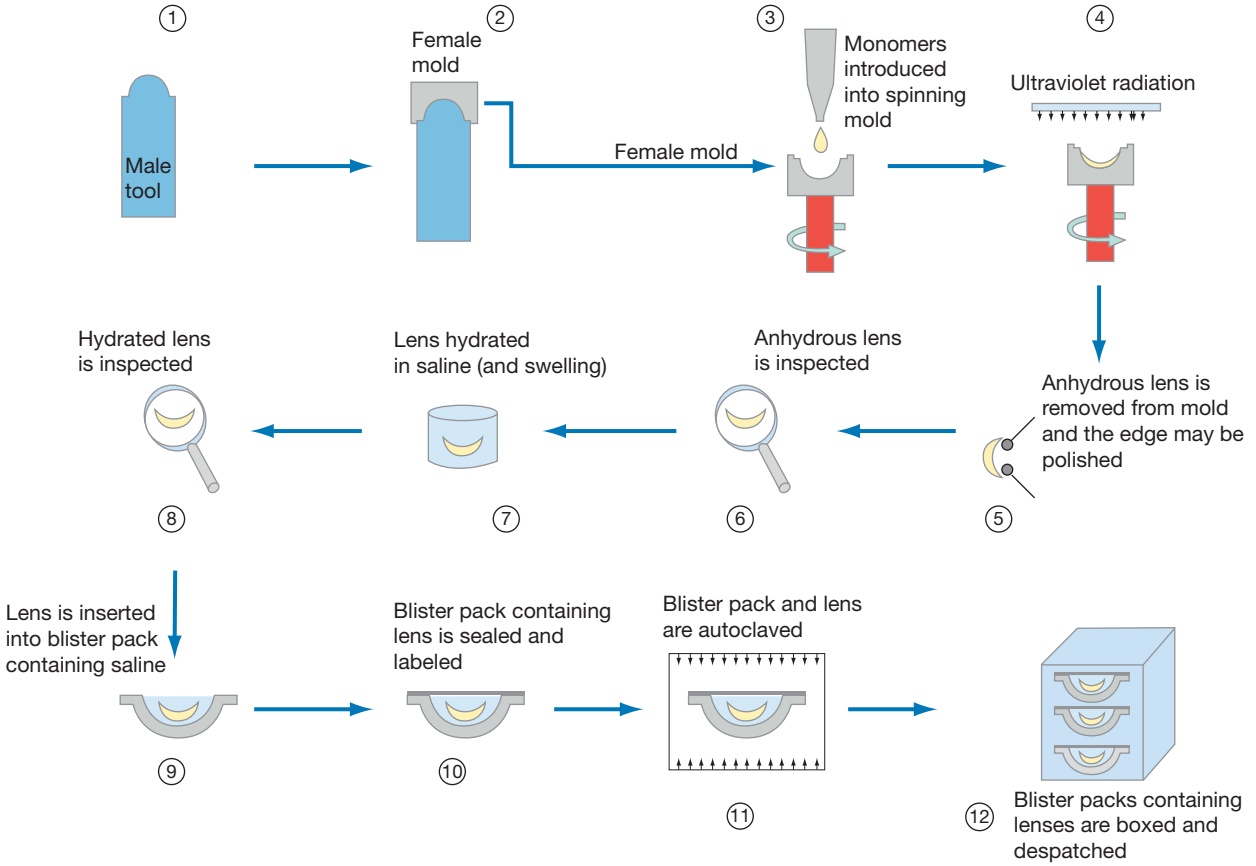

Figure 10 The process of manufacturing a soft contact lens by spin casting. (1) A male tool is machined from stainless steel; the contour of the tool head will define the shape of the anterior lens surface. The same tool is used to make millions of molds. (2) A female mold is made by pressing the male tool into molten polypropylene, which cools and sets. (3) The female mold is mounted, with the concavity facing upward, in a spindle that spins about the lens axis, and liquid monomers are introduced into the spinning mold. (4) The monomers in the spinning mold are irradiated with ultraviolet light to initiate lens polymerization. (5) The dry lens is removed from the mold, the lens edge is polished, and the mold is discarded. (6) The edge of the dry lens is inspected at 10× magnification. (7) The dry lens is placed in saline, which hydrates the lens, causing it to swell to its final soft lens form. (8) The hydrated soft lens is inspected at 10× magnification. (9) The soft lens is inserted into a blister pack containing saline. (10) The blister pack is sealed with a special foil, and a label is stuck onto this. (11) The sealed blister pack containing the lens is sterilized in an autoclave. (12) The individual blister packs are inserted into packages, typically in multiples of either three or six lenses. Reprinted with permission from Efron, N.; Newman, S. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 89.

of −3.00D in power displayed an overall high degree of accuracy and reproducibility. They concluded that, with a single inconsequential exception, all measured parameters were found to fall well within clinically acceptable limits for providing wearers of these lenses with consistent vision and fit.

Efron and Veys[51] examined the quality of three types of early generation disposable lenses and observed a high prevalence of nicks, tears, roughness, and blemishes. At the time, other authors reported similar findings.[52–54] These studies accorded a valuable service to the contact lens industry in the early 1990s as they focused attention on the importance of the quality of mass-produced lenses, especially edge quality. Advances in cast-molding manufacturing technology over the past two decades, fuelled by the attention drawn to the above issues, have led to a substantial overall improvement in lens quality.

At a microscopic, subclinical level, it can be observed that different manufacturing techniques can have a significant effect on the finished lens surface. Fine concentric rings can often be seen on the surface of soft lenses that have been manufactured by lathe cutting; these 'lathe marks' are often visible under high magnification using the slit-lamp biomicroscope. Using atomic force microscopy, Bhatia *et al.*[55] observed that the surface of unused cast-molded lenses varied from smooth to rough with surface features unique to the polymers and manufacturing process.

Maldonado-Codina and Efron[56] investigated the impact of manufacturing method and material composition on the surface characteristics of five types of hydrogel contact lenses: three pHEMA lenses, each manufactured by a different technique, namely, lathing, spin casting, and cast molding, a HEMA/MAA cast-molded lens, and a HEMA/glycerol methacrylate cast-molded lens. Front and back lens surfaces were examined using scanning electron microscopy (SEM) and atomic force microscopy (AFM). The surfaces of the lathed lenses were covered in lathing/polishing marks. In general, at a microscopic level, the anterior surface appeared rougher. All three cast-molded lenses

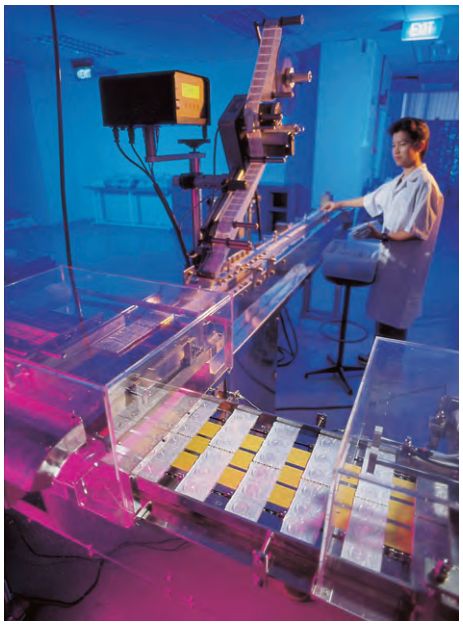

Figure 14 Automated contact lens labeling. Reprinted with permission from Efron, N.; Newman, S. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 90.

had more processing debris than the lathed and spun-cast pHEMA lenses. Overall, the surfaces of the lathed lens were 'rougher' than those of the cast-molded lens. Maldonado-Codina and Efron[56] concluded that surface topographies of hydrogel contact lenses are dependent on method of manufacture. They also noted that cast-molded lenses are associated with apparently 'stickier' surfaces, which may be indicative of surface degradation during the manufacturing process.

Maldonado-Codina and Efron[57] measured high- and low-contrast visual acuity, and the level of protein deposition, in patients wearing HEMA lenses made by three manufacturing methods. They found that spun-cast HEMA lenses deposited less protein than cast-molded or lathed HEMA lenses; however, the differences in the amount of protein deposited did not affect visual function.

The impact of manufacturing method on the PLTF of soft HEMA contact lenses was also investigated by Maldonado-Codina and Efron.[56] Manufacturing method was found to have only a minor effect on the quality and stability of the PLTF in HEMA lenses. The authors concluded that PLTF structure is likely to be more related to material and patient characteristics than manufacturing method.

6.633.7. Clinical Ramifications of Polymer and Manufacturing Developments

As with all developments in the field of biomaterials, technological innovations and improvements are ultimately driven by the needs of clinicians working in the specific fields

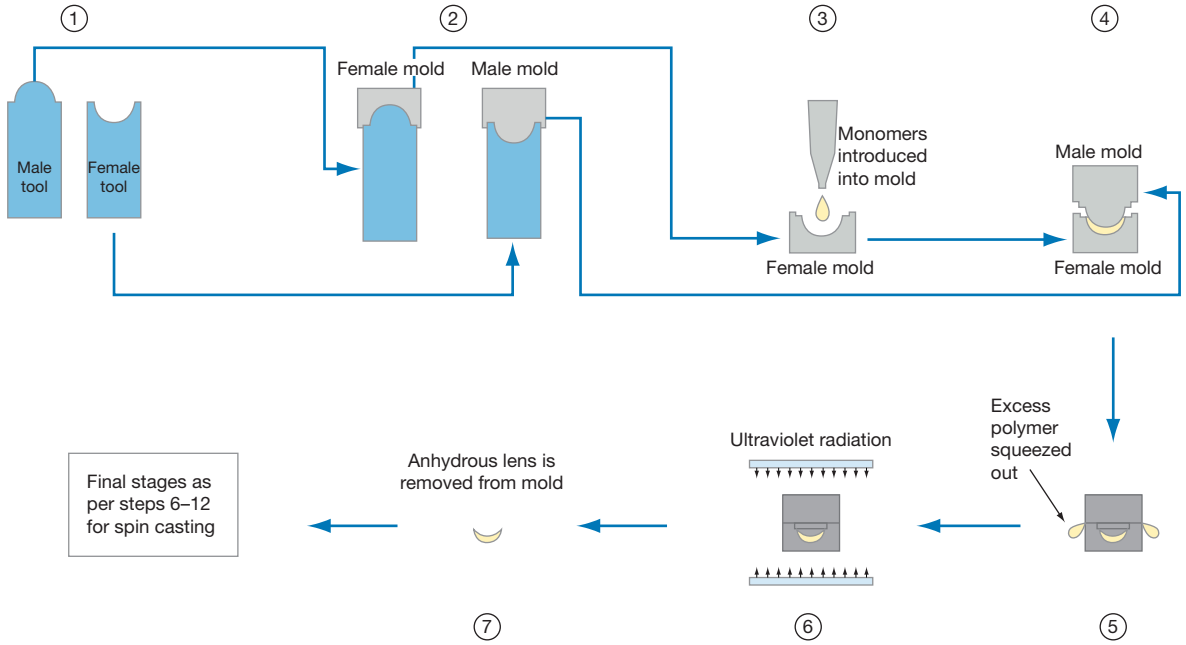

Figure 15 The process of manufacturing a soft contact lens by cast molding. (1) Male and female tools are machined from stainless steel; the contour of the male tool head will define the shape of the anterior lens surface, and the contour of the female tool head will define the shape of the posterior lens surface. The same tools are used to make millions of molds. (2) Male and female molds are made by pressing the tools into molten polypropylene, which cools and sets. (3) The female mold is mounted on a conveyer belt, with the concavity facing upward, and liquid monomers are introduced into the concavity. (4) The male mold is registered over the female mold and the two molds are clipped together. (5) Excess polymer is squeezed out from the sides of the mold. (6) The monomers inside the mold assembly are irradiated with ultraviolet light to initiate lens polymerization. (7) The dry lens is removed from the mold and the molds are discarded. The final stages of lens production are essentially the same as for spin casting, which is illustrated in steps 6–12 in **Figure 10**. Reprinted with permission from Efron, N.; Newman, S. In *Contact Lens Practice*, 2nd ed.; Efron, N., Ed.; Butterworth-Heinemann/Elsevier: Maryland Heights, MO, 2010; p 91.

to which the biomaterials relate. In the early stages of the development of soft contact lenses (i.e., throughout the 1970s and 1980s), two critical problems adversely impacted upon the biocompatibility of contact lenses: insufficient oxygenation of the cornea to sustain normal metabolic processes during lens wear, and problems relating to the buildup of deposits on the lens (and absorbed into the lens matrix) over time.

This section will provide an overview of ramifications of developments in polymer chemistry and manufacturing technology that have essentially solved the problems of poor corneal oxygenation and long-term deposit buildup. Although evidence had slowly been accumulating in the ophthalmic literature throughout the 1970s and 1980s of the imperative of developing soft lenses that could alleviate hypoxia and avoid deposit formation, the definitive work to address this issue was the celebrated 1985 report that became known as the 'Gothenburg study.'[58] This landmark publication is one of the most highly cited papers in the field of contact lenses. It provided a clear rationale of the imperative of solving these two problems, and pointed toward the likely solutions.

The Gothenburg study – so named because the research was undertaken in Gothenburg, Sweden – assessed the effects of long-term extended wear of soft contact lenses on the human cornea. This was achieved by examining 27 patients who had worn a high water content hydrogel contact lens in one eye only for an average of 62 ± 29 months (mean $\pm$ standard deviation). The other eye, which was either emmetropic or amblyopic, acted as a control. Thus, any difference between the two eyes could be attributed to the long-term effects of soft lens extended wear.

The lens-wearing eye showed a 14.8% reduction in epithelial oxygen uptake ($p < 0.001$), a 5.6% reduction in epithelial thickness ($p < 0.05$), a 2.3% reduction in stromal thickness ($p < 0.05$), the induction of epithelial microcysts, and a 22.0% increase in endothelial polymegethism ($p < 0.001$). Endothelial cell density was unaffected by extended lens wear. No interocular differences in any of these physiological characteristics were found in a matched control group of anisometropic and amblyopic subjects who did not wear contact lenses, which validated the use of the contralateral eye as a control in this experiment.

The patients ceased lens wear for up to 1 month and recovery of corneal function was monitored during this period. Epithelial oxygen uptake and thickness recovered within 33 days of lens removal. The number of microcysts increased over the first 7 days, but decreased thereafter; some microcysts were still present 33 days after lens removal. Recovery from stromal thinning had not occurred after 33 days following lens removal. There was a slight reduction in polymegethism in some patients, but overall this was not statistically significant. These findings establish (1) that the extended wear of hydrogel lenses induces significant changes in all layers of the cornea; (2) that lens wear suppresses aerobic epithelial metabolism, which may compromise the epithelial barrier to infection; and (3) that changes to the stroma and endothelium are long lasting.

The authors of the Gothenburg study concluded – on the basis of the outcome a regression analysis of the data – that lens-induced effects on corneal physiology can be minimized by fitting lenses that (1) are more frequently removed, (2) have greater oxygen transmissibility, (3) are more regularly replaced, and (4) are more mobile on the eye.[58] This conclusion became the blueprint for contact lens development over the next quarter of a century, and to this day remains the single most important set of doctrines governing technological refinements in the field.

The first requirement – that lenses should be more frequently removed – was easily solved by advising those using lenses on an extended wear basis (i.e., wearing lenses continuously day and night) of the imperative of wearing lenses continuously for no more than 30 days. This now represents standard advice worldwide, and is entrenched in legislation in the United States via directives from the FDA. In the early days of extended wear, it was thought that it might be possible to use lenses on an extended wear basis indefinitely, but it was gradually realized (and confirmed by the Gothenburg study) that the longer lenses were worn continuously, the greater was the adverse physiological impact.

The second requirement – that lenses have greater oxygen transmissibility – was a far more difficult problem to address, as it pointed toward the need to develop new materials with an oxygen permeability approaching an order of magnitude greater than existed at the time of the Gothenburg study. The answer to this was the development of silicone hydrogel materials, as discussed in Section 6.633.4. The clinical ramification of the introduction of these materials is discussed below in Section 6.633.7.

The requirement that contact lenses should be more regularly replaced – the third edict of the Gothenburg study – pointed toward the need to develop manufacturing processes that would allow mass production of high-quality contact lenses. The inventor of soft contact lenses, Otto Wichterle, had attempted to fabricate lenses using cast molding, but was unhappy with the resultant quality of the lens edge, so he developed an alternative spin-casting technique.[14] It was not until the mid-1980s that cast molding became commercially viable, and this heralded the development of regular replacement disposable lenses. The cast-molding manufacturing process has been discussed in Section 6.633.6.3, and clinical impact of this technology is discussed in Section 6.633.7.

The fourth requirement of the Gothenburg study – that lenses should be more mobile on the eye – relates to the need to constantly flush out debris that accumulates behind a contact lens during wear. At the time of the Gothenburg study, increased lens mobility was the only strategy possible to enhance tear exchange beneath the lens surface. However, other strategies are possible, so this requirement, which has yet to be solved, is perhaps better stated today as a need for greater postlens tear exchange.

The requirement for a greater postlens tear exchange is especially critical for overnight wear, when metabolic byproducts, tear-film components such as lipid and mucin, and naturally desquamating epithelial cells accumulate in the postlens tear film and form a potential 'breeding ground' for microorganisms, leading to an increased risk of inflammation and infection.[25,26] Various strategies for increasing greater postlens tear exchange have been investigated, such as (a) introducing channels, patterns, or grooves in the posterior surface of the lens, to act as conduits of hydraulic flow;[59,60] (b) designing lenses to facilitate a form of pumping action, whereby the lens would move closer to, and further from, the plane of the cornea; or (c) introducing fenestrations (small holes) in the lens.[61] While theoretical models point toward an enhancement of postlens tear exchange using these strategies, practical solutions remain elusive.

6.633.7.1. Polymer Developments: Enhanced Corneal Oxygenation

Arguably, the question of corneal oxygenation has been the most important driver of technological developments in the contact lens field. In fact, this problem was signaled at the very time a contact lens was fitted for the correction of myopia. This was in 1889; a 25-year-old medical student named August Müller (1864–1949) submitted the results of his final year project, entitled 'Brillenglüser und Hornhautlinsen' (Spectacle Lenses and Cornea Lenses), to the University of Kiel in Germany.[62] As can be seen from Figure 16, Müller wore spectacles to correct high myopia.

In what must have been perceived as a bold and perhaps dangerous experiment, Müller fitted himself with large, thick glass lenses (known as 'haptic' lenses); however, he was only able to wear them for half an hour, and provided the following graphic description of his experience:

> Gradually, about a quarter of an hour after insertion, a sensation of pressure and burning appeared, which could not be localized exactly. After a further quarter of an hour, the sensation became so agonizing that I had to remove the lenses. Upon their removal, the violent pain immediately stopped and a short while after I could use the eyes again.

Müller was so disappointed with the results of his experiments that he gave up the idea of becoming an eye specialist and went on to practice as an orthopedic surgeon.[62]

This pioneering work signaled the beginning of the battle to develop contact lenses that could be worn comfortably and continually for many hours. As it turned out, Müller was

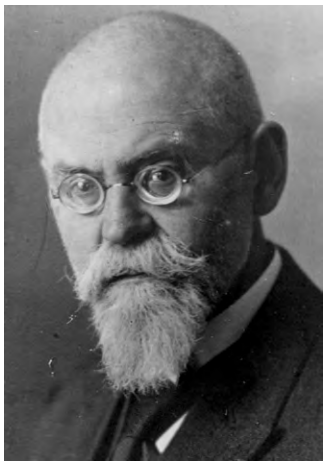

Figure 16 August Müller.

entirely correct in ascribing the failure of his own lens-wearing experiments to "... a disturbance of nourishment of corneal tissue." Unlike all other tissues in the body, the cornea does not contain blood vessels (so that it can remain optically transparent); therefore, in order to respire normally, it must obtain oxygen directly from, and eliminate carbon dioxide directly to, the atmosphere. Although he did not know it at the time, Müller's haptic lenses prevented this necessary exchange of respiratory gases.

If a contact lens blocks off the normal oxygen supply, the corneal epithelium will become hypoxic and will begin to respire anaerobically. This leads to a buildup of lactic acid, which diffuses into the corneal stroma, creating an osmotic force that draws in water. The cornea then develops edema and becomes less transparent, and the eye becomes uncomfortable. Carbon dioxide that is prevented by a contact lens from escaping from the corneal surface dissolves in the tears forming carbonic acid (Figure 17). The resulting acidosis compromises the physiological integrity of the cornea to a small extent – but the effects of hypoxia are far more critical.[63]

The solution to the problem of hypoxia is to design contact lenses that maximize corneal oxygenation during lens wear, as explained in Section 6.633.2.5. Because soft contact lenses completely cover the cornea, the only option for preventing hypoxia is to use soft materials that are permeable to oxygen. As explained in Section 6.633.2.5, the ease with which oxygen can diffuse through a contact lens (defined by the term 'oxygen transmissibility') is a function of the oxygen permeability of the hydrogel material from which the lens is made and the thickness of the lens. A thinner lens provides less resistance to oxygen flow; however, nothing much can be done about lens thickness, because a lens must have a certain thickness profile to achieve the desired optical power for vision correction. Furthermore, if a lens is made too thin, it will fall apart. This leaves material oxygen permeability as the only variable, and the introduction of silicone hydrogel materials this century has essentially solved this problem.

During the waking hours, silicone hydrogel lenses supply the cornea with enough oxygen to avoid excessive edema.[64] However, there is a small but significant minority of patients who need or desire to sleep in lenses, due to the convenience of being able to wake up, either in the morning or in the middle of the night, and have instantly clear vision. As well, sleeping in lenses for an extended period obviated the need for routine daily lens cleaning and maintenance, which is necessary for all daily wear lenses with the exception of daily disposable lenses (see Section 6.633.7.2).

Whereas oxygen reaches the cornea during open eye wear by diffusing from the atmosphere, through the lens to the cornea, the closed eyelid blocks off this oxygen supply when the eyes are closed. The rich plexus of capillary vessels in the conjunctiva on the inside of the eyelid (the superior palpebral conjunctiva) becomes the main source of oxygen for the cornea during sleep; however, the partial pressure of oxygen in the superior palpebral conjunctiva is about one-third of that in the atmosphere.[65] Therefore, the oxygen supply to the cornea is markedly reduced during sleep.

Many changes can be observed in the cornea in association with chronic low level hypoxia and edema, as they occur during sleep. The most critical of these chronic changes is a structural and metabolic weakening of the corneal epithelium. An intact epithelium provides a vital defense against invasion by potentially pathogenic microorganisms that could either enter the eye by chance or in a lens wearer, via contaminated fingers and/or contact lens storage solutions. Opportunistic pathogenic microorganisms – such as pseudomonas aeruginosa or acanthamoeba – can invade the epithelium and establish a potentially sight-threatening corneal infection.

Recent epidemiological studies have demonstrated that, despite the introduction of highly oxygen permeable silicone

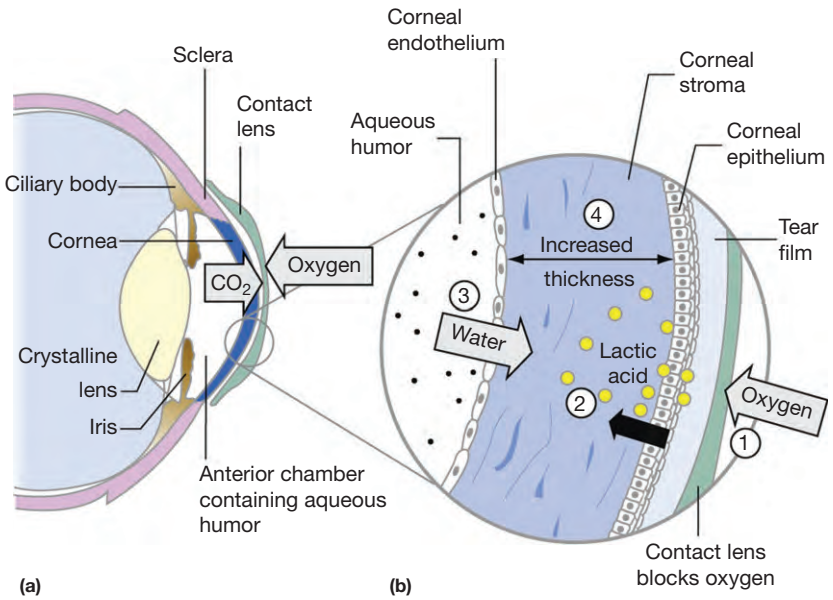

Figure 17 (a) Cross-section of an eye wearing a contact lens, which impedes ingress of oxygen into, and the egress of carbon dioxide from, the cornea. (b) The contact lens blocks oxygen supply to the cornea (1), causing lactic acid to accumulate in the stroma (2). This draws in water (3), leading to stromal edema (4). Adapted from Efron, N. *Biol. Sci. Rev.* **1997**, *9*, 29–31.

hydrogel contact lenses, the incidence of severe corneal infections (microbial keratitis) with extended wear silicone hydrogel lenses is about five times greater than for daily hydrogel lens wear.[66] Accordingly, overnight lens wear is discouraged by many eye care practitioners. Certainly, those who do sleep in lenses must be informed of the extra risks of adverse complications. If a problem is encountered and treatment is delayed, the consequent infection can be extremely painful and lead to some loss of sight (although true 'blindness' is extremely rare). Most of the sensational reports that occasionally appear in newspapers describing problems with contact lenses can be traced to patients sleeping in lenses.

Notwithstanding concerns about extended contact lens wear as outlined above, there is now an abundance of evidence demonstrating the health benefits of silicone hydrogel lenses for daily contact lens wear.[42,67] This lens material has essentially eliminated hypoxia-related contact lens complications, making daily contact lens wear a healthy vision correction option.

Most of the problems encountered today relating to contact lens wear can be traced to patient noncompliance, whereby lens wearers fail to adhere to advice and guidelines offered by their practitioners or the lens manufacturers. Noncompliant behaviors include improper lens maintenance, failing to replace lenses according to the prescribed replacement frequency, or sleeping in lenses designed for daily wear only.

6.633.7.2. Manufacturing Developments: Planned Lens Replacement

'Planned replacement' refers to lens replacement at intervals from 1 day to 12 months and therefore, includes all 'disposable lenses,' which are defined as lenses replaced at least monthly. The first disposable lenses were released internationally in the mid-1980s. The acceptance of disposability by practitioners and patients has been one of the most significant changes in the worldwide contact lens market over the past two decades. By 2005, UK practitioners were fitting 99% of their new soft lens patients with disposable lenses, compared with 61% 10 years before.[68]

The rationale for the planned replacement of soft contact lenses is simple: cleaner lenses should produce fewer adverse ocular effects. A significant proportion of clinical problems relating to the wear of soft contact lenses can be attributed to deposition on the lens surface with tear-derived substances. Contact lens deposits result in reduced acuity, comfort, and wettability and increased inflammatory complications such as papillary conjunctivitis and acute red eye.[69]

All soft contact lenses suffer gradual spoliation from the environment and tear-film components over time. Daily cleaning and periodic protein removal can slow this rate of deposition but not prevent its occurrence. By ensuring that soft lenses are replaced at a suitable predetermined interval, one of the most enduring medical management axioms – that of prevention being better than cure – is brought to bear. In practice, patients who replace lenses regularly report fewer symptoms and exhibit less physiological changes in most instances,[70–75] compared with patients who do not replace lenses regularly. Specific benefits arise from the use of planned replacement lenses;[76] these are so compelling that any decision not to prescribe soft lenses on this basis requires special justification, such as parameter and/or design unavailability, and should be a comparatively rare event.

While the need to clean and disinfect multiuse soft lenses is self-evident, a powerful argument for prolonging the life of lenses with elaborate lens care systems emerged in the early days of soft lenses because of their relatively high cost of production. By the start of the 1980s, soft lenses were becoming the preferred option in many countries. To achieve the then lens life norm of at least a year, a minimum of three lens care product types were needed. Daily cleaners were used to remove loose deposits and microorganisms from the lens surface; disinfecting solutions were used to kill any remaining microorganisms; and protein removal treatments were used to reduce the buildup of tear proteins on the lens surface. The ongoing cost of these products was often found to be more than that of the contact lenses themselves.

Planned replacement lenses (excluding daily disposable lenses) still need high standards of lens care to ensure safe wear, but the shorter replacement cycles allow some scope for simplification. It should not be necessary to deproteinize lenses changed at least monthly. In cases where lens surface spoliation is a problem with monthly replacement, shortening the replacement interval to 2 weeks or even 1 day is likely to be a superior option – at least in terms of patient convenience and therefore compliance – than adding a protein removal step to the care regime.

While mechanical daily cleaning, rinsing, and disinfection are still essential in the care of 2-weekly and monthly replacement lenses, in most cases these functions can be effectively achieved with a single lens care product, namely a multipurpose solution.[77] Daily disposable lenses, which are discarded each day following lens removal, by definition require no lens maintenance.

Because planned replacement lenses are supplied in multipacks, it follows that the loss or damage of a lens should not, in most cases, be an inconvenience to a patient. Practices fitting disposable lenses are also likely to have numerous trial lenses, and even stocks of the more popular parameters, on the premises, which enable rapid replacement if lens loss or damage occurs.

Planned replacement protocols require patients to return at regular intervals for fresh lenses. Aftercare visits can be scheduled to coincide with lens collection, which is a further benefit of prescribing this modality. However, regular repurchasing does not necessarily imply compliance with the wearing schedule.[78,79]

Prior to the introduction of disposable lenses, practitioners maintained sets of 'trial lenses' which were used to assess the fit of a lens on a given patient, and then cleaned and reused on subsequent patients. In the case of disposable lenses, new diagnostic or trial lenses are used with each patient, and disposed of thereafter. This eliminates the risk of cross-infection from a previous wearer of the lens. It also has the advantages of eliminating the time-consuming chore of trial lens cleaning, disinfection, and storage.

With the ready availability of a comprehensive stock of trial lenses, it is nearly always possible to undertake a lens-wearing trial on a prospective disposable lens patient with the required lens parameters, especially with respect to lens power. This was not the case prior to the introduction of disposable lenses,

when practitioners could only maintain a trial set with a limited range of parameters. Trial fitting with a lens with parameters that closely match the requirement of the patient allows for a realistic subjective impression of lens wear and assists the practitioner to accurately assess the fit of what is likely to be the final lens specification in many instances. For certain specialist fittings, such as presbyopia, trial fitting is more meaningful if the appropriate lens powers for the refractive condition of the patient are used.

By the very nature of planned replacement, it is straightforward to modify the prescription of a patient, particularly with respect to changes in refractive error. From a practice management viewpoint, it is advisable to carry out the annual aftercare appointment prior to the dispensing of the next supply of lenses for the patient. Any alteration in lens power can then be made without the need to exchange unwanted lenses.

There are probably no clinical disadvantages in prescribing planned, as opposed to unplanned, replacement lenses. However, there are some points to bear in mind that may have negative implications. The potential for practitioner and patient noncompliance with the designated replacement frequency is ever present.[80]

Provided lens fitting, aftercare, and patient education are of a good standard, there are no compelling reasons for avoiding planned replacement, as long as the required parameters are available.

With any lens replaced at least monthly, it is not practical for each lens to be inspected in detail, either prior to insertion or in the eye of the patient. For planned replacement to be successful, it is a requirement that lenses are sufficiently consistent in quality such that the patient will not notice any change in comfort, fit, or visual acuity from lens to lens. Certainly, the various types of molding systems used to produce most disposable lenses are developed on the principle of building quality into the product, as the traditional manual methods previously used by manufacturers to examine conventional lenses would not be cost-effective with a mass-produced lens.

Wider quality issues are also important when the patient is using many lenses each year. Consistency of packaging and labeling are of great significance when the patient is supplied with unopened packages. If patients find that some blister packs are empty or dry, or contain more than one lens, their confidence in the product is likely to be reduced.

Notwithstanding the above considerations, the recent literature is free of descriptions of complications attributable to poor disposable lens quality; nevertheless, patients should be advised to inspect visually all lenses prior to insertion and discard any lenses exhibiting surface or edge defects, or lenses that are persistently uncomfortable, cause significant eye redness, or provide poor vision.

6.633.8. Conclusions

Soft contact lenses have come a long way since the pioneering efforts of Professor Otto Wichterle in the late 1950s in terms of material, design, and the way they are manufactured. Thick pHEMA lenses which were replaced every few years are now a thing of the past.

Hypoxia-related problems with conventional hydrogels were alleviated to some degree by reducing the thickness of the lenses and/or utilizing more hydrophilic monomers. However, these materials still fell far short of the oxygen requirements needed for truly safe continuous wear.

Although the various hypoxia-related problems associated with contact lens wear appear to have been resolved with the new breed of silicone hydrogel materials, a number of mechanical and surface material-related complications still remain, despite the introduction of 'second generation' silicone hydrogel polymers. Future development of soft contact lens materials is likely to concentrate on trying to resolve the issues of inflammation and infection, improving lens comfort, enhancing postlens tear exchange, and improving surface wettability.

The three primary methods of manufacturing soft contact lenses are lathe cutting, spin casting, and cast molding. The technique of cast molding has become the dominant form of soft contact lens manufacture, because it is capable of producing sufficient quantities of high-quality lenses so as to meet the intense clinical demand for affordable planned replacement and disposable lens-wearing modalities. Modern soft lens manufacturing techniques produce lenses of high quality and good reproducibility.

Planned contact lens replacement, especially in the form of disposable soft lenses, has transformed contact lens practice over the past two decades. This approach is clearly justified in terms of clinical performance, increased convenience, and practice profitability. With the increasing popularity of daily disposable lenses, it is likely that this lens type will be used with greater frequency, and it may not be long before all contact lenses are supplied on this basis. Indeed, we predict that by the year 2020, the vast majority of contact lenses will be daily disposable products made of advanced silicone hydrogel materials.

Appendix A. Classification of Soft Lens Materials

A.1. FDA Classification System

The FDA classification system for soft lens materials is shown in Table A.1. The classification system has four groups. The main drawback with this system is that different materials containing different monomers can be classified within the same material group.

A.2. ACLM Classification System

The ACLM classification has two main groups: *focon* for rigid lens materials and *filcon* for soft lens materials. Each group is further subdivided depending on how much ionizable

Table A.1 FDA classification system for soft lens materials

Group	*Material*
I	Low water content (<50%), nonionic polymers
II	High water content (>50%), nonionic polymers
III	Low water content (<50%), ionic polymers
IV	High water content (>50%), ionic polymers

Table A.2 FDA classification system for soft lens materials

Group	*Material*
1a	Essentially poly 2-HEMA, but ≤0.2% by weight of any ionizable chemical (e.g., MA)
1b	Essentially poly 2-HEMA, but >0.2% by weight of any ionizable chemical
2a	A copolymer of 2-HEMA and/or other hydroxyalkylmethacrylates, dihydroxyalkylmethacrylates, and alkylmethacrylates, but ≤0.2% by weight of any ionizable chemical
2b	As in group 2a, but >0.2% by weight ionizable chemicals
3a	A copolymer of 2-HEMAwith an *N*-vinyl lactam and/or an alkyl acrylamide but ≤0.2% by weight of any ionizable chemical
3b	As in group 3a, but >0.2% by weight of ionizable chemicals
4a	A copolymer of alkyl methacrylate and *N*-vinyl lactam and/or an alkyl acrylamide, but ≤0.2% by weight of any ionizable chemical
4b	As in group 4a but >0.2% by weight of ionizable chemical
5	Soft lens materials formed from polysiloxanes

Table A.3 BS EN ISO hydrogel suffix groups

Group suffix	*Material*
I	Low water content, nonionic: materials which contain less than 50% water and 1% or less (expressed as mole fraction) of monomers that are ionic at pH 7.2
II	Medium and high water content, nonionic: materials which contain 50% water or more and 1% or less (expressed as mole fraction) of monomers that are ionic at pH 7.2
III	Low water content, ionic: materials which contain less than 50% water and greater than 1% (expressed as mole fraction) of monomers that are ionic at pH 7.2
IV	Medium and high water content, ionic: materials which contain 50% water or more and greater than 1% (expressed as mole fraction) of monomers that are ionic at pH 7.2

monomer is present in the material. The classification system is shown in Table A.2.

A.3. BS EN ISO 18369-1: 2006

The specific classification of a contact lens or contact lens material is given as a six-part code as follows:

(prefix) (stem) (series suffix) (group suffix) (*Dk* range) (modification code)

For soft lens materials, the classification denotes whether the material is ionic and the range in which the water content of the material lies. The presence or absence of surface modifications is also indicated.

The prefix is a term assigned to a material to designate a specific chemical formulation. Use of this prefix, which is administered by the United States Adopted Names (USAN) Council, is optional for all countries other than the United States.

Two types of *stems* are used. The filcon stem is affixed to the prefix and is applied for materials which contain <10% water by mass (hydrogel materials). Focon is applied to materials containing <10% water by mass (i.e., nonhydrogel materials).

Table A.4 BS EN ISO hydrogel *Dk* groups

Group	Dk *range*
0	<1 *Dk* unit
1	1–15 *Dk* units
2	16–30 *Dk* units
3	31–60 *Dk* units
4	61–100 *Dk* units
5	101–150 *Dk* units
6	151–200 *Dk* units
7 etc.	Increasing in increments of 50 *Dk* units

The *Series suffix* is also administered by the USAN council, and is used in cases in which the original ratio of the monomers of an existing contact lens polymeric material is changed to make a new material. In this case, the capital letter 'A' is added after the stem designation. Subsequent changes in monomer ratio are designated by the next letter of the alphabet. These letters are used to differentiate copolymers of unchanged monomer units, but with different ratios.

The Group suffix, represented by a Roman numeral, indicates the range of water content and ionic character of the material (Table A.3).

Table A.4 shows how the *oxygen permeability* of the materials is classified.

The *Modification* code, designated by a letter 'm' denotes whether the lens has a surface modification which renders the surface characteristics different from that of the bulk material. Such treatments include plasma treatment, acid/base hydrolysis, and incorporation of a material which migrates to the surface. Certain types of tinted lenses may also be considered surface modified. In the case of an unmodified surface, this suffix is omitted.

A.3.1. Example

In order to demonstrate the BS EN ISO classification system, the Acuvue 2 lens would be classified as follows:

Prefix – eta
Stem – filcon
Series suffix – A
Group suffix – IV
Dk range – 1
Modification code – none

The lens can, therefore, be classified *as* (*etafilcon A*) (IV) (1).

Glossary

Hemodialysis membrane A synthetic membrane used in dialysis, which is used to separate toxins from the blood through a diffusion-dominated process.

Hemofiltration membrane A synthetic membrane used in filtration of the blood to remove toxins in a process dominated by hydraulic pressure.

High-flux membrane A membrane used in hemofiltration, with larger pores and higher hydraulic conductivity than conventional membranes, which allows for the removal of higher molecular weight toxins.

Synthetic membrane A fabricated structure that allows for the separation of mixtures. Conventional membranes accomplish this separation based on molecular size, as lower molecular weight species are able to pass through pores in the membrane.

Abbreviations

AKI	Acute kidney injury
APACHE	Acute physiology, age, chronic health evaluation

6.634.1. Overview of Renal Replacement

The kidneys are vital organs, which play critical excretory and regulatory roles in maintaining water and electrolyte homeostasis in the body. In addition, the kidneys provide an essential endocrine function as they secrete important signaling molecules that interact with the cardiovascular, skeletal, and immune systems. As one of the most highly specialized, vascularized, and metabolically active tissues in the body, the demands placed on the kidneys cause organ failure at a rate higher than rates for many of the other vital organs of the body. The kidney was the first organ to be successfully transplanted, and a kidney transplant is one of the most common and effective transplantation surgeries performed in the world. However, global shortages of donor kidneys have proven to be a major barrier to the treatment of kidney disease, leaving millions of chronic kidney disease patients without total functional replacement.

The kidney was the first organ to have its function partially substituted by an artificial device. Current dialysis therapies, including hemodialysis (HD), peritoneal dialysis (PD), hemofiltration (HF), and hemodiafiltration (HDF), replace the blood filtration function of the kidney by removing waste products and excess electrolytes using artificial or natural semipermeable membranes. All these methodologies address water and electrolyte-balance functional replacement of the kidney. However, they fail to provide for the lost endocrine function. The long and storied history of medical technologies for kidney function replacement gives hope that a bioartifical kidney will be the first tissue-engineered device to fully replace a complex organ's function.

6.634.1.1. Ultrafiltration and Small-Solute Clearance

The basic functional element of the kidney is the nephron. There are approximately 1 million nephrons in each human kidney. Each nephron comprises three major parts, as shown in Figure 1: the glomerulus, the tubule, and the collecting duct. The glomerulus consists of a tuft of small, highly permeable capillaries interposed between the afferent and efferent arterioles and located inside a hollow structure called the Bowman's capsule. The Bowman's capsule opens out into a series of tubules – the proximal tubule, loop of Henle, distal tubule – and then into the collecting duct, all of which are lined by a continuous layer of epithelial cells.

The first step in the excretory process of the nephron is the generation of an ultrafiltrate (UF) of plasma across the glomerulus into the Bowman's space. The glomerulus is designed to provide efficient ultrafiltration of as much as one-third of the plasma entering it, removing waste products of metabolism from the circulation but retaining important circulating components such as albumin. This high rate of ultrafiltration across the glomerular capillary results from hydraulic pressure generated by the heart and vascular tone of the preglomerular and postglomerular arterioles and from the high hydraulic permeability of the glomerular capillary wall. To achieve the required semipermeability characteristics and extremely high ultrafiltration rates, the glomerular membrane evolved into a complex structure comprising a specialized fenestrated endothelium, a charged basement membrane, and highly differentiated epithelial cells called podocytes. Together, these components impart to the glomerular membrane its extraordinary characteristics, currently unmatched by artificial membranes.

6.634.1.2. Tubular Reabsorption and Secretion

The UF is modified in two ways: by reabsorption and by secretion while passing through the series of tubules and the collecting duct. Reabsorption refers to the removal of a substance or water from the UF, whereas secretion refers to the addition of a substance to the UF. The different tubular segments and the collecting duct make various contributions to these processes. In normal human kidneys, ultrafiltration by the glomerulus produces approximately 130 l day^{-1}; daily urinary volume is roughly 2 l. Thus, more than 98% of the glomerular UF is reabsorbed by the renal tubules. The bulk of reabsorption, 50–65%, occurs along the proximal tubule. As in glomerular filtration, fluid movement across the renal proximal tubule cell is governed by physical forces. Unlike the fluid transfer across the glomerular capillary wall, however, tubular fluid flux is principally driven by osmotic and oncotic pressures rather than hydraulic pressure. Renal proximal tubule fluid reabsorption is based on active Na^+ transport, requiring the energy-dependent Na^+/K^+-ATPase located along the basolateral membrane of the renal tubule cell to promote a small degree of osmotic difference (2–3 mOsml kg^{-1} H_2O) across the renal tubule, sufficient to drive isotonic fluid reabsorption due to the very high diffusive water permeability of the renal tubule cell membrane. Once across the renal proximal tubule cell, the transported fluid is taken up by the peritubular capillary bed because of the high oncotic pressure gradient that results from the high rate of protein-free filtrate formed in the proximate glomerular capillary bed. As can be appreciated, an elegant system has evolved in the nephron to filter and reabsorb large amounts of fluid in bulk to attain high rates of metabolic product excretion while maintaining regulatory salt and water balance. When functioning properly, all kidney components work together to ensure the removal of toxic compounds from plasma while retaining useful components (e.g., glucose and proteins), maintaining appropriate fluid volumes, controlling the levels of ions, and regulating the function of other organs in the body. It is also important to note that evolution ensured that the kidney fulfills its role even under stress, during conditions of high toxin load. As a result, only a small portion of the overall excretory capacity of the kidneys is required under normal conditions and for sustaining life.

6.634.1.3. Metabolic and Endocrine Function

The kidney is responsible for the secretion of hormones that are critical in maintaining hemodynamics (renin, angiotension II, prostaglandins, nitric oxide, endothelin, and bradykinin), red blood cell production (erythropoietin), and bone metabolism (1,25-$(OH)_2$-vitD_3 or calcitriol).[1] It synthesizes glutathione (GSH) and free-radical scavenging enzymes and provides gluconeogenic and ammoniagenic capabilities.[2,3] Catabolism of low-molecular-weight proteins, including peptide hormones, cytokines, and growth factors, is also accomplished by the kidney.[4] The kidney also has a less-recognized immunoregulatory function. The mammalian renal proximal tubule cells are immunologically active. They are antigen-presenting cells[5] that have costimulatory molecules[6] that synthesize and process a variety of inflammatory cytokines.[6,7] The roles of the renal tubule cells in GSH metabolism,[2] regulation of vitamin D, and production and catabolism of multiple cytokines[1] are critical to immunoregulation to maintain tissue integrity and host defense under stress conditions.[8]

6.634.2. Membranes for Small-Solute Clearance

Filtration by the glomerulus is the first step in the excretory process in normal kidney. The glomerulus removes solutes from the blood by convective transport. Then, in the tubules of the nephron, solutes are removed or reclaimed based on diffusion. The water and solute balance function of the kidney is practically replaced by conventional dialysis or filtration. In these processes, synthetic membranes are used to selectively remove water and solutes based on diffusive or convective transport. In HD, where solute removal from the blood is driven by a concentration gradient of the solute across a membrane, the process is dominated by diffusion. However, solute transfer also occurs, to a lesser extent, convectively by a process of ultrafiltration, where water and solutes move across the membrane.[9] This process is leveraged further in HF, where pores in semipermeable membranes allow water and solutes across the membrane independent of the concentration gradient, and predominantly on the hydraulic pressure gradient across the membrane, which mimics the filtration function of the nephron. HDF combines HD and HF processes, where both diffusion and hydraulic pressure are used as driving forces.

6.634.2.1. Dialysis

Dialysis is a process of removing toxins and metabolic byproducts from the bloodstream based on diffusion and, to a lesser extent, ultrafiltration across a membrane. Dialysis is currently carried out by either HD or PD. In HD, blood exits the body through a catheter, and heparinized silicone tubing delivers the blood to the dialysis unit (**Figure 2**).

$$J/L_pS = \left[\left(P_{dialysate} - P_{blood}\right) - \left(\pi_{dialysate} - \pi_{blood}\right) = P_{effective}\right] \quad [1]$$

Equation [1] describes this process, where J is the flux of the solute across the semipermeable membrane, L_p is the permeability of the membrane to the solute, S is the surface area, $P_{dialysate}$ and P_{blood} are hydraulic pressures, and $\pi_{dialysate}$ and π_{blood} are oncotic pressures, the dominant diffusive driving forces. Within the dialyzer, blood interacts with a semipermeable membrane, which allows for small solutes such as urea, creatinine, potassium, and phosphorous to pass through, while retaining blood cells and critical large proteins such as albumin and immunoglobulin (**Figure 3**). Dialysate, the fluid that flows opposite the blood on the other side of the semipermeable membrane, is an aqueous solution with various concentrations of solutes that dictate the driving force to remove, retain, or add to solute concentrations in the blood. Movement of the solute is directed from high concentration to low concentration. For example, excess bicarbonate can be added to the initial dialysis solution to insure that bicarbonate moves according to this concentration gradient from the high concentration of bicarbonate in dialysate to the lower concentration in blood, resulting in a total net movement of bicarbonate into blood.

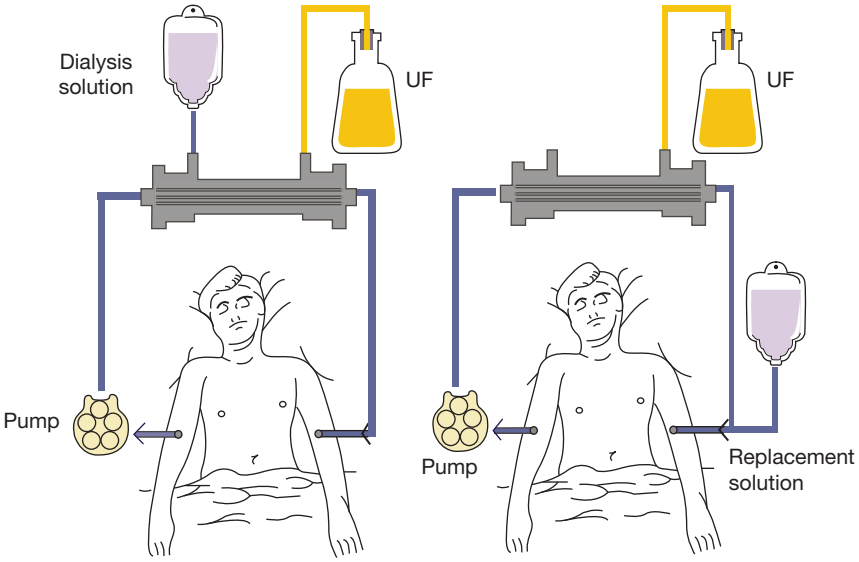

Figure 2 Schematic representations of hemodialysis (left) and hemofiltration (right).

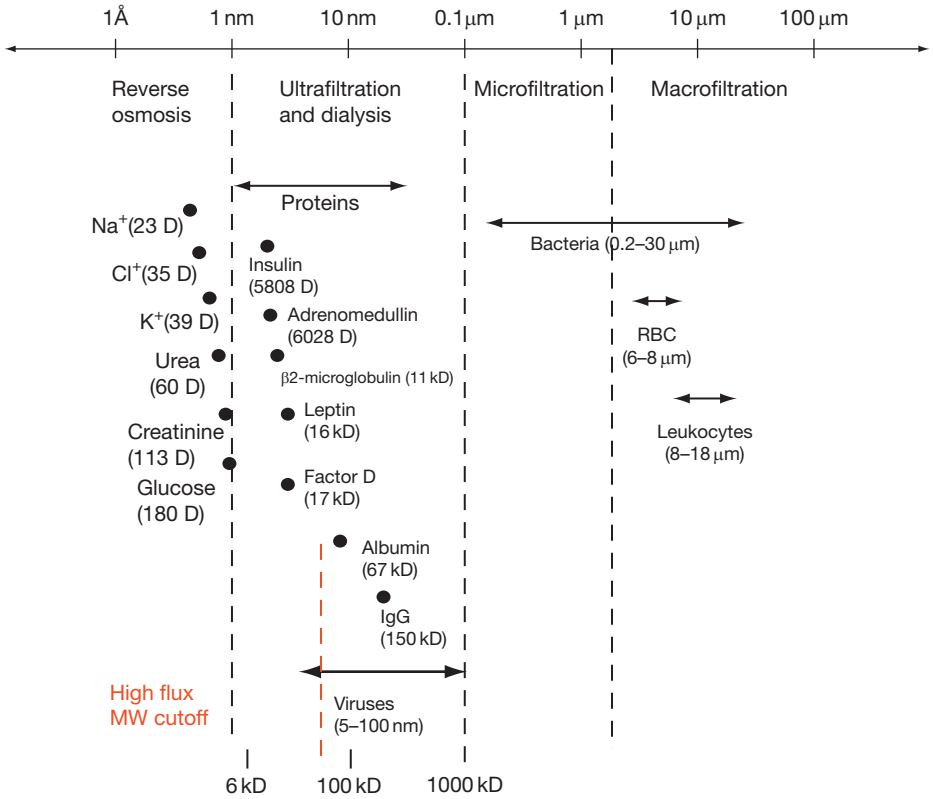

Figure 3 Separation methods: macrofiltration, microfiltration, ultrafiltration, and reverse osmosis, with molecules, pathogens, and cells of interest to dialysis technologies.

Graham first introduced the idea of substituting the clearance function of the kidney by the use of a semipermeable membrane to remove small solutes and water.[10] The first human HD treatment with collodion tube membranes, a cellulose-based material, allowed for the concentration of small solutes in dialysate.[11] Kolff and Berk later used a long cellophane tube spirally wrapped around a cylinder that rotated in a stationary dialysate bath.[12] There were several later designs of dialyzers, including coil and parallel flow dialyzers, before the widespread use of hollow-fiber dialyzers as

the current formulation for HD treatment.[13] The original development of hollow-fiber dialyzers in the 1960s utilized regenerated cellulose as the principal membrane material.

Membrane materials for separation processes are diverse, ranging from metals and ceramics to polymers. Critical to the choice of materials for current dialysis membranes, biocompatibility with blood is a major concern, as well as cost and manufacturing. Synthetic polymers have been the dominant membrane materials used for separation processes due a combination of these factors (see **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**). The most common polymers in the manufacturing of synthetic membranes are nondegradable polymers, cellulose derivatives, nitrates, esters; polysulfones; polyacrylonitrile derivatives; polyamides; polyimides; polyolefins such as polyethylene, polypropylene, or polyvinylchloride; and fluorinated polymers such as polytetrafluoroethylene and polyvinylidine fluoride.

Biocompatibility of HD membranes with blood is complex and depends on material properties that influence multiple failure mechanisms when in contact with blood, such as hemolysis, clotting, inflammation, and membrane fouling. The material properties that determine biocompatibility also play critical roles in governing separation kinetics. Solute partitioning is affected by hydrophobic/hydrophilic balance (HLB) and surface charges, which are also involved in chemical resistance and binding affinity. When many high molecular weight molecules, such as proteins, adsorb to a membrane's surface, this phenomenon is called membrane fouling. In general, high surface hydrophilicity favors better wettability and decreases fouling (see **Chapter 2.204, Peptoids: Synthesis, Characterization, and Nanostructures**).

Many membrane polymers are grafted, custom modified, or produced as copolymers to improve their properties.[14] For example, concerns about the bioincompatibility of widely used cellulose membranes stemmed from the hydroxyl groups within the cellulose structure. This led to the development of another membrane material, called modified cellulose, with improved biocompatibility. The hydroxyl groups in these modified membranes were masked either by replacing them with other chemical structures, such as acetyl derivatives, or by bonding with potentially advantageous compounds, such as vitamin E or heparin. The use of vitamin E-bonded membranes was recently developed to further improve biocompatibility and minimize HD-associated oxidant stress, thereby modifying the excessive inflammatory state of end-stage renal disease (ESRD).[15]

Current commercially available hemodialyzers are listed in **Table 1**, along with their constituent polymers.

6.634.2.2. Hemofiltration

HF is the ultrafiltration of the blood utilizing a pressure difference to drive water and solutes across a semipermeable membrane and into the filtrate compartment. This can be accomplished by applying a positive pressure to the blood

Table 1 Commercially available hemodialyzers and their respective materials

Company	*Product name*	*Material*	*Chemical structure*

compartment or a negative pressure to the filtrate compartment. Because this process is solely dependent on convection and not diffusion, the resulting filtrate consists of both small and large molecular weight solutes in contrast to dialysate where larger molecular weight solutes are limited due to slow diffusion. Solute movement due to hydraulic pressure driving forces can be expressed in the equation:

$$J/L_pS = [(P_{filtrate} - P_{blood})] \quad [2]$$

In this equation, J is the flux of the solute across the semipermeable membrane, Lp is the permeability of the membrane to the solute, S is the surface area, and $P_{filtrate}$ and P_{blood} are hydraulic pressures.

No dialysate solution is used in HF; rather, the filtrate is collected and discarded, and ultrapure replacement solution is administered to the patient to maintain water/solute balance, as shown in comparison to dialysis in Figure 2.

In order for the artificial hemofilter to replicate the ability of the kidney glomerulus to efficiently remove blood toxins, the artificial membrane permeability must be high enough to permit pressure-driven ultrafiltration flux of the toxins, while retaining the important high molecular weight molecules such as proteins. Ultrafiltration removes water and effectively clears solutes that are within the molecular weight cutoff of the membrane. In contrast, clearance by diffusion depends on concentration gradients and solute mobility. As a result, diffusion is ineffective for the removal of large and/or highly dilute solutes.

Both diffusive and convective processes occur during traditional HD, but most solute movement is achieved via diffusion. Recognition of the inherent limitations in diffusive transport has led to the development of membranes with high hydraulic permeability and therapeutic extracorporeal modalities for renal failure, including HDF and HF in which blood cleansing is achieved via convective HF rather than diffusive HD. Removal of uremic toxins, predominantly by the convective process, has several distinct advantages because it initiates the glomerular process of toxin removal with increased clearance of higher molecular weight solutes and removal of all solutes (up to its molecular weight cutoff) at the same rate. Distinct differences are apparent between diffusive and convective transport across a semipermeable membrane. The clearance of a molecule by diffusion is inversely correlated with the size of the molecule (eqn [3]):

$$D = \frac{K_B T}{6\pi\mu R_H} \quad [3]$$

where D is a molecule's diffusion coefficient ($m^2\,s^{-1}$), which is inversely related to the Stokes–Einstein hydrodynamic radius (R_H). K_B is the Boltzman constant, T is temperature in Kelvin, and μ is the viscosity of the transport media.

In contrast, clearance of a solute by convection depends only on the molecular weight cutoff of the membrane. The bulk movement of water carries passable solutes along with it in approximately the same concentration as in the fluid, allowing for the removal of even dilute toxins.

Current commercially available hemofilters are listed in Table 2, along with their constituent polymers.

6.634.2.3. Advancements in Membrane Technology

Besides improvements in biocompatibility, HD membranes have been developed to better reproduce the physiologic process of glomerular ultrafiltration. It has long been recognized that dialysis membrane clearance was based on concentration differences rather than convective separation of small solutes and low-molecular-weight proteins from large serum proteins and blood elements. In an attempt to replicate glomerular ultrafiltration and removal of 'middle molecules,' synthetic membranes with larger pore sizes and higher water permeability compared to cellulosic membranes were developed. These so-called high-flux membranes are prepared with hydrophobic base materials, including polyacrylonitrile, polysulfone, polyethersulfone, or polymide, with various hydrophilic components. These have supplemented cellulosic membranes owing to manufacturing processes that can mass produce membranes with wide ranges of hydraulic permeabilities for various treatment modalities.[16]

Pore size is another critical issue in hemofilter design. Conventional polymeric membranes are typically cast or spun from polymers in solution, resulting in a dispersion of pore sizes and geometries in a single fiber or sheet that causes incomplete molecular weight cutoff in convective transport. New techniques using a nanocontrol spinning procedure could help solve this problem by producing high-flux membranes in which

Table 2 Commercially available hemofilters and their respective materials

Company	*Product name*	*Material*	*Chemical structure*
Fresenius	Ultraflux F400	Polysulfone	Minntech	Renaflo II	Polysulfone	Gambro	Prismaflex M150	Polyacrylonitrile	
the porosity of the inner layer is finely controlled at the nanoscale level, resulting in an increased number of pores while the spectrum of pore diameters is narrowed and concentrated near the desired values.[17] However, polymeric membranes are basically thick and require high hydraulic pressure gradients to produce UF when compared to the glomerulus.

Based upon this technology, the main focus of recent membrane development has been to increase pore size while sharpening the molecular weight cutoff of high-flux membranes to maximize removal of low-molecular-weight proteins. This direction is based upon the idea that removal of a distinct class of uremic toxins, such as β2-microglobulin, factor D, leptin, and adrenomedullin (**Figure 3**), while minimizing the loss of albumin, could improve treatment outcomes of patients with ESRD. Further work has evolved with superflux or protein-leaking membranes. These membranes provide greater clearances for low-molecular-weight proteins and small protein-bound solutes, such as homocysteine and advanced glycation end products, but with significantly higher loss of albumin than high-flux dialysis membranes. The overall benefits for patients on chronic HD still require more extensive evaluation.[18] Nonmembrane-related determinants of dialyzer performance, including fiber bundle configuration, spacing, and sterilization techniques, also deserve further study.[19]

Current polymer membranes used in dialysis and ultrafiltration have been extensively studied. The pores in such membranes are formed by extrusion and solvent-casting techniques. The geometry and surface chemistry of the pores arise from the chemistry of the polymers and the fluid dynamics of the casting process. In general, the hollow-fiber membranes are fairly thick or employ a multilayer scaffold for mechanical support, and have a distribution of pore sizes rather than a regular array of uniform pores. Pores in conventional polymeric membranes tend to be roughly cylindrical, have a round orifice terminating in a larger channel, or have a structure resembling an open-cell sponge. Extensive descriptions of porous structures used in commercial ultrafiltration and microfiltration have been published.[14,20] It is not clear whether any of these structures provide optimal geometries for membrane filtration, for two reasons. First, a wide dispersion in pore sizes within a membrane leads to imperfect retention of molecules larger than the mean pore size of the membrane. This problem is remedied in practice by engineering the mean pore size of the membrane to be so small that negligibly few pores are large enough to allow passage of a solute above the desired molecular weight cutoff of the membrane. This solution, however, has the undesired effect of reducing the mean pore size in the membrane and thus reducing the hydraulic permeability of the membrane. Engineering narrower pore size distributions ameliorates this dilemma, allowing sharper transitions from passage to retention and maximizing the mean pore size of the membrane.

Second, the round shape of conventional pores dictates a fourth-power dependence of hydraulic permeability on pore radius:

$$\frac{Q}{\Delta P} = \frac{\pi r^4}{8uL} \qquad [4]$$

where Q denotes volumetric flow, P is hydrostatic pressure, r is the radius of the pore, μ is viscosity, and L is the length of the pore, which may or may not be the same as the thickness of the membrane. A pore that is slit-shaped allows steric hindrance to solute passage dictated by the smallest critical dimension of the pore, while increasing hydraulic permeability by a factor of the long dimension of the pore:

$$\frac{Q}{\Delta P} = \frac{wh^3}{12uL} \qquad [5]$$

where w is the long dimension of the slit, h is the thickness of the slit, and L is again the length of the pore. Consequently, it might be predicted that filtration structures with parallel slit-shaped pores might have superior performance when compared to structures with round pores. With that in mind, it is interesting but speculative to note that natural selection has produced filtration structures with elongated, slit-shaped geometries in the kidney.

Turning from steric hindrance to electrostatic effects, it has long been argued that the glomerular filtration barrier imposes an electrostatic restriction on solute passage.[21] This function has been variously attributed to the proteins within the slit diaphragm, the glomerular basement membrane, and the glycocalyx of the glomerular endothelial cell (EC).[22] At physiologic pH, many materials, such as glass, have an anionic surface charge, which can be neutralized at lower pH or possibly increased at higher pH. The net charge density on a microfluidic substrate in contact with an aqueous solution gives rise to an electrical double layer in the aqueous solution. This shielding layer is commonly known as the Debye layer or electrical double layer. For nanometer-scale pores, the thickness of the electrical double layer is in the same order of magnitude as the pore size itself and can contribute to the rejection of charged solutes by the pore.

Although HF can be achieved successfully with purely artificial membranes, new research in biomaterials and tissue engineering holds promise for significant future improvements. Modern membranes are used reliably all over the world in countless HD, HF, and HDF procedures. Typically, membranes are used in the form of hollow-fiber modules and are based on cellulose or synthetic polymers, including polysulfone, polyacrylonitrile, and polyamide, used as such or modified with a variety of agents.[23–25] A major limitation of current membrane technology is diminution of filtration rate owing to protein deposition on the membrane and thrombotic occlusion of the hollow fibers. These problems reduce the durability of the filtration membrane. Current technology introduces considerable advances in a number of areas, including biocompatibility and consistency of pore size. However, there is much room for improvement in the performance of current membranes. Conventional membranes remove solutes only on the basis of molecular size, whereas the glomerulus also employs charge selectivity by the basement membrane. This nonselective nature of conventional membranes is another limitation to overcome. One possible solution to this problem is the growth of basement membrane cells on the hemofilter membrane. Another approach is the design of 'smart' membranes that have selective transport characteristics and contain a predetermined number and size of nonpassive nanoengineered pores that have specific interactions with solutes and solvents at the atomic level.[26]

A membrane composed of slit-shaped pores can separately regulate steric and electrostatic hindrance with extremely high hydraulic permeability. These insights into structure–function relationships in the kidney have motivated the design and construction of a silicon membrane with slit-shaped pores, the dimensions of which approximate the dimensions of the glomerular slit diaphragm. Silicon nanopore membranes (SNMs) with 10–100 nm × 45 μm slit pores were designed and fabricated at the Cleveland Clinic Foundation and Case Western Reserve University. Initial hydraulic characterization of these membranes has been completed.[27] Silicon chips bearing 1 × 1 mm arrays of approximately 10^4 slit pores were fabricated via sacrificial layer techniques.[28] The pore structure is defined by deposition and patterning of a polysilicon film on the silicon wafer. The critical submicron pore dimension is defined by the thickness of a sacrificial SiO_2 layer, which can be grown with unprecedented control to within ±1 nm. The oxide layer is etched away in the final processing step to create the porous polysilicon membrane. The hydraulic permeability to gas, deionized water, and phosphate-buffered saline (PBS) of these novel membranes was tested in a custom-engineered ultrafiltration cell. Gas flow data were well fitted by transitional flow models, consistent with pore sizes approximating the mean free path of the gas molecule. Liquid flow was almost perfectly predicted by conventional Navier–Stokes predictions.

Rejection of charged proteins in solution by SNMs was examined in the same ultrafiltration cell. Briefly, solutions of three proteins (carbonic anhydrase, 25 kDa, bovine serum albumin (BSA), 66 kDa, and sweet potato amylase, 200 kDa) in 1× PBS (150 mM) and 10× PBS (1500 mM) were subjected to ultrafiltration by SNMs. Even for membranes with pore sizes much larger than the molecular radii of the proteins, some rejection of the proteins by the membrane was observed, but this effect was abrogated in high ionic strength solutions, strongly suggesting an electrostatic barrier to passage. Further definition of steric and electrostatic barriers to passage is an area of active research.

6.634.3. Renal Epithelial Cell Therapy

Improvements in membrane biocompatibility have reduced inflammatory reactions, but off-the-shelf polymeric materials still induce a cascade of biochemical events leading to blood coagulation, thrombus formation, and frequently complement activation and inflammation (see **Chapter 4.401, The Concept of Biocompatibility**). Thus, anticoagulation, most commonly the systemic administration of heparin, is required to solve these problems. The use of anticoagulants, however, may lead to additional complications such as hemorrhage, and therefore researchers are trying to improve anticoagulation therapy by finding alternative antithrombotic agents, such as hirudin,[29] and methods of administration, such as direct incorporation onto the polymeric membrane.[30]

The incorporation of a confluent cell monolayer on a synthetic membrane may provide a solution to the membrane/blood compatibility problems and form the basis for the development of a bioartificial hemofilter (BAHF). In addition to improved biocompatibility, a bioartificial membrane is inherently better suited to replicate glomerular filtration and thus provide a complete functional replacement for the glomerulus.

Owing to the relative clinical success of HD treatments and the complexity inherent in tissue engineering for kidney replacement, the literature is devoid of promising efforts to develop a BAHF. Nevertheless, the feasibility of the BAHF concept is supported by many existing studies. For example, the endothelial seeding of synthetic vascular grafts may inhibit long-term deposition of platelets and formation of thrombus,[31] and improve long-term patency after implantation.[32] In addition, the antithrombotic properties of endothelialized grafts may be further improved by ECs engineered to secrete anticoagulation factors.[33] Accordingly, ECs engineered to express an anticoagulant factor could be utilized to coat vascular grafts and stents,[34,35] and semipermeable membranes and thus improve long-term performance *in vivo*. The same approaches can be extended to improve the patency of endothelialized HF membranes.

The disease state arising from renal failure is the result of more than just the loss of blood volume regulation and the clearance of small solutes and toxins, which are replaced by conventional dialysis therapy. Survival rates of renal transplant recipients far exceed those of dialysis patients awaiting transplant,[36] suggesting that the other metabolic and endocrine functions of the kidney not replaced by dialysis account for the poor outcomes of patients receiving conventional dialysis treatment. A new approach using renal progenitor/stem cells to form a monolayer in tissue-engineered devices to supplement or replace the metabolic, endocrine, and immunomodulatory functions of the kidneys when used in conjunction with dialysis addresses these shortcomings (see **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**).

6.634.3.1. Device Design and Fabrication

6.634.3.1.1. Renal assist device

The tissue engineering of a bioartificial renal tubule as a cell therapy device to replace reclamation, metabolic, and endocrine functions of the kidney component is an approach that utilizes living cells supported on appropriate synthetic scaffolds (see **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design**; **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**; **Chapter 5.539, From Tissue to Organ Engineering** and **Chapter 5.540, Kidney Tissue Engineering**).[37] Because the scaffolding material provides the required physical support for the tubule cells, it should not degrade considerably over the life of the bioartificial construct. Furthermore, it should permit the unhindered transport of solutes reclaimed by the tubule cells on one side to the filtered blood circulating at the other side, provide a large surface area to facilitate this mass transport, be compatible with blood, and not leach cytotoxic products into the circulation. Therefore, a bioartificial tubule can be constructed utilizing renal tubule progenitor cells[38,39] cultured on semipermeable polymeric hollow-fiber membranes (polysulfone) on which an extracellular matrix has been layered to enhance the attachment and growth of the epithelial cells.[40] These hollow-fiber synthetic membranes not only provide the architectural scaffold for these cells but also allow for differentiated vectorial transport

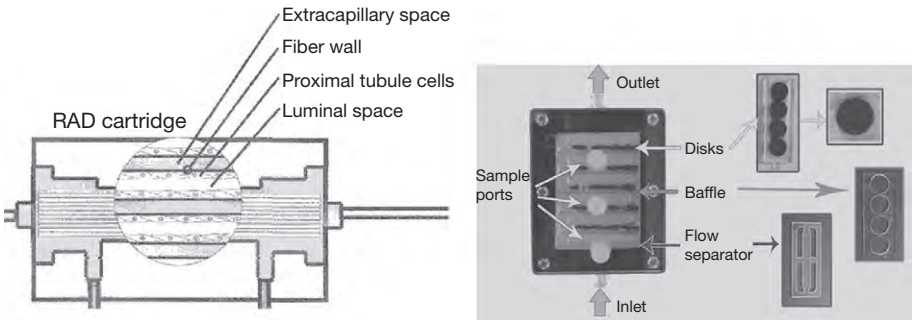

Figure 4 Designs of the renal assist device (RAD) and the bioartificial renal epithelial cell system (BRECS).

and metabolic and endocrine activity and provide immunoprotection, as has been observed in the long-term implantation of the bioartificial pancreas in a xenogeneic host.[41] With appropriate membranes and biomatrices, immunoprotection of cultured progenitor cells can be achieved concurrent with long-term functional performance as long as conditions support tubule cell viability.[37] The technical feasibility of an epithelial cell system derived from cells grown as a monolayer along the luminal surface of a single polymeric hollow fiber, called a bioreactor, has been achieved, as shown on the left in Figure 4.[42]

6.634.3.1.2. Bioartificial renal epithelial cell system

A major obstacle to the widespread adoption of renal cell therapy is the lack of a cryopreservable system to enable distribution, storage, and therapeutic use at point-of-care facilities. The bioartificial renal epithelial cell system (BRECS), shown on the right in Figure 4, is the first all-in-one culture vessel, cryostorage device, and cell therapy delivery system.

The BRECS was designed with the capability to support up to tenfold more cells in less than one-third of the volume of previous renal assist device (RAD) designs, along with the capacity to cryopreserve the full unit in order to facilitate distribution. The polysulfone hollow fibers used as the scaffold in previous RAD designs were limited in cell attachment surface area, and were prone to fracture during cryopreservation and reconstitution, a critical element for storage and distribution of a cell therapy device. The cell-seeding scaffold for the BRECS, niobium-coated carbon disks (Cytomatrix, Woburn, MA), was selected based on its biologically inert, nonbiodegradable and favorable thermomechanical properties for cryopreservation. Cell culture media containing oxygen and nutrients was perfused through and around the porous disks housed within the BRECS. Growth of adequate cell numbers to achieve a therapeutic impact was possible due to the disks' high surface area. High porosity (80–90%) allowed for sufficient, homogeneous delivery of oxygen and nutrients to the cells on the disks through a balance of convective and diffusive flows across and through the scaffold. The other BRECS components, the polycarbonate housing, the gasket, nuts, bolts, and access ports, were carefully selected and thoroughly tested for the ability to withstand cryogenic temperatures, while still maintaining an uncompromised, sterile internal BRECS environment. The BRECS casing consisted of a top lid and a bottom chambered piece, which defined the internal volume where the cell-covered disks were loaded. A single gasket (ethylene propylene diene monomer) was used to tightly seal the pieces together when assembled with external nuts and bolts (Figure 4). The inlet and outlet of the BRECS were standard polycarbonate female luers, which connect with male luers of tubing lines that deliver externally pumped perfusion media. To enable sampling of the BRECS for cell assessment, three sterile sampling ports were integrated into the lid. To insure a homogenous flow profile across the BRECS, a flow separator was used at the inlet, and a set of flow baffles was used to direct a significant amount of the flow directly through each cell-covered disk. At tested flow rates, no significant pressure drop was measured across the BRECS, demonstrating that incorporation of the BRECS into an extracorporeal circuit would not restrict flow. Perfusion was visualized using dilute dye showing a uniform flow distribution throughout the BRECS. During *in vitro* perfusion, all the components remained intact, with no indication of degradation over 6 months.

6.634.3.2. Metabolic Replacement

6.634.3.2.1. In vitro evaluation of the RAD

In vitro experiments have tested transport and metabolic functions of the RAD, utilizing porcine renal proximal tubule progenitor cells grown intraluminally within these cartridges with membrane surface areas of 97 cm^2 to 0.7 m^2, resulting in a device containing up to 10^8–10^9 cells.[43] Porcine cells were used because the pig is currently considered the best source of organs for both human xenotransplantation and immunoisolation cell therapy due to its anatomic and physiologic similarities to human tissue and the relative ease of breeding pigs in large numbers. The nonbiodegradability and pore size of the hollow fibers allow the membranes to act as scaffolds for the cells and as immunoprotective barriers as well. Studies of the RAD have demonstrated that the confluent monolayer cells exhibited morphological characteristics (e.g., apical microvilli, endocytic vesicles, and tight junctional complexes) typical for differentiated tubule epithelia, as well as differentiated active transport properties, differentiated metabolic activities, and important endocrine processes.[43] In particular, these *in vitro* studies demonstrated the ability of the RAD to actively transport sodium, glucose, bicarbonate, and organic anions. The RAD also reabsorbed significant amounts of water in response to oncotic and osmotic pressure gradients.

Vectorial transport of sodium and water across the monolayers was assessed by perfusion of the lumen and the

extracapillary space (ECS) with calibrated flows of culture media and measurement of timed collections of media from each flow. The RAD was tested to see if transport could be increased by creating an oncotic driving force across the monolayer, and if that increase could be abrogated by ouabain (a specific inhibitor of Na^+/K^+-ATPase), the enzyme responsible for the bulk of sodium transport across the luminal surface of the cell. Results suggested that the transport was an active process, rather than passive flow governed by Starling forces across a semipermeable membrane. To increase the oncotic pressure, BSA was added to the ECS perfusate, followed by addition of ouabain as well. As expected, the transport was active and mediated by Na^+/K^+-ATPase.[43] The metabolic characteristics of the cultured proximal tubule cells and the transport of glucose, bicarbonate, and GSH were explored and the data expressed in terms of fractional reabsorption accomplished by the RAD. For each molecule, fractional excretion was measured in the absence or presence of a known inhibitor of an enzyme essential for the reabsorption. In the case of glucose, the compound phlorizin was used; for bicarbonate, a carbonic anhydrase inhibitor (acetazolamide) was used; and for GSH, an inhibitor of γ-glutamyl transpeptidase (acivicin) was used. In each case, there was evidence of active transport and specific inhibition.[43]

In addition, renal proximal tubule cells cultured in the RAD or in culture plates maintained their ability to synthesize and excrete ammonia (a function critical for the maintenance of acid–base homeostasis in the body), produce 1,25-$(OH)_2$-$vitD_3$ (the active form of vitamin D), and, through metabolic degradation and transport of its constituent amino acids, remove GSH from the perfusate. It is thus evident that the RAD has the ability to replicate the major differentiated transport, and the metabolic and secretory functions performed by the healthy renal proximal tubule.

6.634.3.2.2. In vitro *evaluation of the BRECS*

Similar *in vitro* evaluation was undertaken with the BRECS. Cell viability and metabolic activity were confirmed in the BRECS by measuring lactate production and oxygen consumption (Figure 5). Both metrics of metabolism were consistent throughout the duration of perfusion culture, with an interpolated total cell number of 2×10^8 cells. The average oxygen consumption rate of 2–3 nmol O_2/min 10^6 cells is similar to previously reported values for metabolically active cells.[37] To determine if RECs in BRECS maintained renal differentiated phenotypic characteristics over time in perfusion culture, human REC-seeded disks from BRECS units were processed for immunohistochemical (IHC) analysis of selected renal cell differentiated markers acetylated tubulin (AT-1) and zona occludens (ZO-1). AT-1, a marker for apical central cilia of proximal tubule cells, exhibited regular staining in central regions of cells grown on disks (Figure 5, bottom left and middle). ZO-1, a marker for epithelial tight junctions, displayed strong expression along the surface of the cells. ZO-1-positive tight junctions and punctate AT-1-positive central cilia are indicative of polarized epithelium and were evident in all the disks tested.

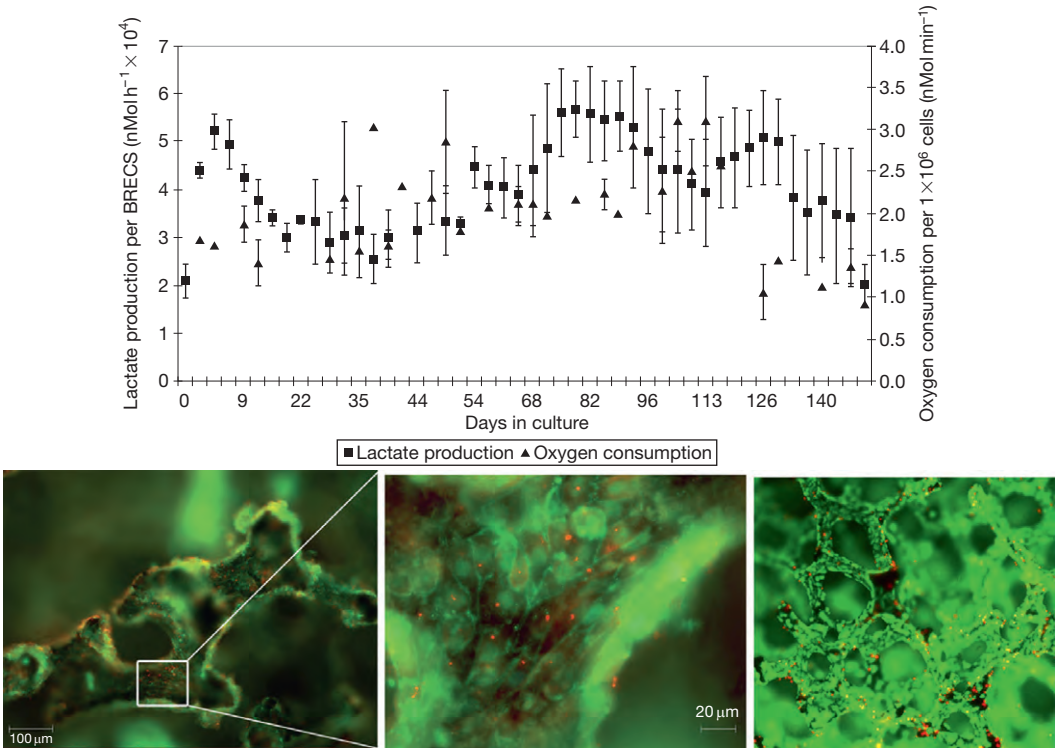

Figure 5 *In vitro* evaluation of the BRECS. Metabolic activity of renal cells was evaluated by measuring lactate production and oxygen consumption (top panel). Immunohistochemical analysis demonstrated that renal cells maintain a differentiated state with the expression of tight junction protein ZO-1 (green) and a central cilia protein, AT-1 (red, left and center panels). Cells maintain high viability both during culture and after reconstitution of cryopreserved BRECS, as demonstrated by a stain of living cells with fluorescein diacetate (green) and dead cells with propidium iodide (red, right panel).

A nondestructive GSH degradation assay was chosen to assess specific renal cell catabolic function in the BRECS units over time. Exogenous GSH was supplemented in the BRECS perfusion media, and metabolic degradation of GSH was measured over a 60-min period. GSH degradation rates in BRECS remained stable, ranging between 600 and 1200 nmol/h/BRECS over a 90-day period, indicative of sustained differentiated renal cell function in the device.

To assess the cryopreservation of RECs in the BRECS units, studies were conducted on single cryopreservable disks. In initial studies, many cryopreservation media performed well with hardy lamb and pig REC cells. However, human REC cells were more susceptible to lower viability after thaw. Of the commercially available and Food and Drug Administration (FDA)-approved cryopreservation media tested, postthaw cell retention and subsequent cell metabolic activity was highest with CryoStor 10 (#640222, Biolife Solutions, Bothell, WA). Immediate postcryopreservation cell retention was optimized when HTS-Purge solution (#637112, Biolife Solutions, Bothell, WA), a hypothermic solution used to prepare cells for the extreme conditions of cryopreservation, was utilized as a precryopreservation rinse buffer. An average cell retention of greater than 90% was achieved on porcine ($n = 4$) and lamb ($n = 2$) REC-seeded disks. Furthermore, this cryopreservation procedure yielded an average cell viability of approximately 90% for human REC-seeded disks (Figure 5, far right).

6.634.3.3. Immunomodulation

Our research group is now focused on the role of the kidney as an immunomodulatory organ and the possibility of renal bioreplacement therapy for the systemic treatment of inflammatory dysregulation. Current renal replacement therapy has poor patient prognosis due to the acute tubular necrosis (ATN) that results in the loss of the kidney's immunoregulatory function. Cell therapy is a potential approach to provide immunomodulation. Loss of immunoregulation results in a propensity to develop systemic inflammatory response syndrome (SIRS), sepsis, multiple organ failure (MOF), and a high risk of death because of systemic immunologic or inflammatory imbalance (Figure 6). Activation and release of inflammatory proteins from circulating activated leukocytes and imbalance between pro- and anti-inflammatory proteins are provoked and aggravated by kidney cell injury and possibly by dialysis. These conditions play a central role in the proinflammatory state in acute kidney injury (AKI) with SIRS and/or MOF.

SIRS is a catastrophic sequela of a variety of clinical insults and is usually present with AKI. In the past decade, a large constellation of data has provided new insights into the inflammatory response that seems to underlie the MOF syndrome. There are now data linking patient outcome to initial plasma levels of tumor necrosis factor (TNF)-α, interleukin (IL)-6, and other proinflammatory cytokines.[44–46] Septic shock is an acute syndrome that is characterized by hypotension, coagulopathy, and eventual MOF, primarily due to ischemic tissue injury. This disorder is associated with dramatic elevations in inflammatory cytokines, including TNF-α, IL-1β, IL-6, IL-8, and interferon-γ.[2] This reactive and uncontrolled inflammatory response results in the adverse hemodynamic and metabolic disturbances in septic shock. In the event of a loss of balance between pro- and anti-inflammatory mediators, the patient may proceed to cardiovascular collapse if proinflammatory processes are excessive, or develop profound immunosuppression with increased risk of recurrent or continuing infection if the anti-inflammatory cascade overreacts.[45,46]

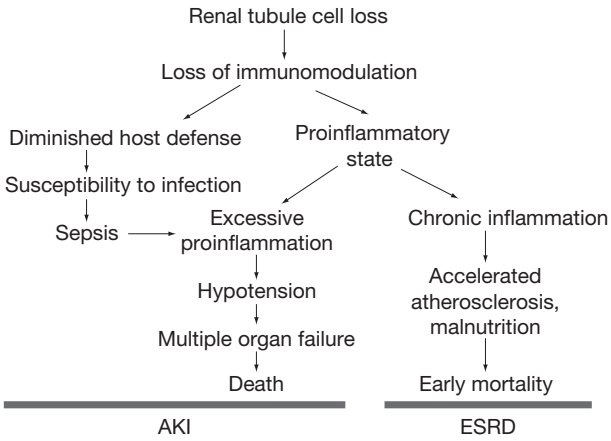

Figure 6 Schematic representation of the sequences of inflammatory dysregulation in acute kidney injury (AKI) and end-stage renal disease (ESRD). The intervention of renal cell therapy may interrupt the pathophysiologic spiral that leads to death in AKI, and may possibly interrupt the chronic proinflammatory state of patients with ESRD. Reprinted from Song, J. H.; Humes, H. D. *Semin. Dial.* **2009**, *22*, 603–609.

The disorder of ESRD is characterized by immune dysregulation presenting with clinical and biological immune deficiency despite chronic activation of immunocompetent cells, especially circulating neutrophils and monocytes.[47] This immune dysregulation develops in patients with chronic renal injury (CRI) prior to the initiation of chronic dialysis therapy, although dialysis causes further inflammatory activation.[48] This chronic inflammatory disease state is characterized by both neutrophil and monocyte dysfunction. Neutrophil phagocytosis and microbe killing are reduced in ESRD patients compared to normal individuals in the presence of spontaneous neutrophil and monocyte activation and reactive oxygen species generation.[49–51] High levels of proinflammatory cytokine serum levels, including IL-6, TNF-α, and IL-1β, are found in ESRD patients, with high levels of production observed in isolated monocytes in these patients.[51] In fact, serum levels of IL-6 correlate well with IL-6 production rates of isolated monocytes from individual ESRD patients.[52,53]

The clinical ramifications of this dysregulated immune state in CRI and ESRD have profound implications. The neutrophil dysfunction translates into the fact that infection is the second most common cause of death in HD patients, approaching 25% of the annual mortality rate.[54] This rate of infection complication is not diminished with a higher dialysis dose or high-flux membrane utilization.[55] Mortality due to sepsis occurs approximately 250-fold more commonly in these patients compared to the general population.[56] The chronic proinflammatory state, as reflected by elevated biomarkers, specifically C-reactive protein (CRP) and IL-6, as well as activation of circulating leukocytes,[57–60] is also highly correlated with accelerated atherosclerosis and early mortality in ESRD patients. Cardiovascular disease processes account for roughly 50% of the annual

mortality rates in Europe and the United States. In fact, the discrepancy between the vascular and chronologic ages of ESRD patients reflects the accelerated atherosclerotic process that develops in these patients.[61]

The immune dysregulated state of CRI and ESRD is also manifested in other ways. ESRD patients exhibit high rates of autoimmune diseases and neoplasia. They demonstate cutaneous anergy in delayed hypersensitivity reactions and respond poorly to vaccination.[62] An improved understanding of these immunologic processes should provide insight into new approaches to treating this immunologic disturbance.

Leukocytes are major contributors to the pathogenesis and progression of many clinical inflammatory disorders, including acute and chronic renal failure. Many therapeutic approaches are under investigation to limit the activation and tissue accumulation of leukocytes at sites of inflammation so that tissue destruction and disease progression can be minimized.[63,64] A synthetic membrane device with the ability to bind and inhibit activated leukocytes along a continuous renal replacement extracorporeal circuit has been developed and is called the selective cytopheretic inhibitory device (SCD). This device incorporates a low-velocity and low-shear-force blood path around a bundled collection of dialysis hollow fibers. In conjunction with regional citrate anticoagulation, this coupling of events within the device results in the sequestration of activated leukocytes in conjunction with a low ionized-calcium (Ca_i) environment due to citrate in the blood circuit to inhibit the release of inflammatory and destructive enzymes and cytokines from the membrane-bound neutrophils and monocytes.[65,66]

Other clinical inflammatory disorders, including SIRS, ischemia/reperfusion injury and adult respiratory distress syndrome (ARDS), are also strong candidate disease states for treatment with renal cell therapy or selective cytopheretic inhibition.[63,64] A large number of therapeutic approaches are under investigation to limit the activation and tissue accumulation of leukocytes at sites of inflammation in order to minimize tissue destruction and disease progression. For example, cardiopulmonary bypass (CPB) is a strong inducer of SIRS, with activation of complement and coagulation systems, and stimulation of cytokine production, and lung and kidney damage can be ameliorated during CPB surgery with the use of leukocyte-depletion filters.[67] Disruption of the activation process of circulating leukocytes may limit microvascular damage and multiorgan dysfunction.

6.634.4. Preclinical Evaluation of Bioartificial Kidney

6.634.4.1. Acute Renal Failure

A bioartificial tubule unit is clearly feasible when conceived as a combination of living cells supported on polymeric substrata, which act as scaffolds for the cells. Renal tubule progenitor cells can be cultured on the biomatrix-coated hollow-fiber membranes of a standard high-flux hemofilter. Dialysate from a conventional dialysis circuit can be passed into the bioartificial tubule as a nutrient and oxygen source for the cells grown on the membrane. The membrane is both water- and solute-permeable, allowing for differentiated vectorial transport and metabolic and endocrine activity provided by the cells, and processed dialysate is discarded. Immunoprotection of cultured progenitor cells is achieved concurrent with long-term functional performance as long as conditions support tubule cell viability.[9] Large-animal studies using an RAD consisting of renal proximal tubule progenitor cells have demonstrated that this device replaces filtration, transport, metabolic, and endocrine functions of the kidney in acutely uremic dogs, following bilateral nephrectomies.[43,68,69] A series of additional animal experiments investigated the impact of treatment with this device on the high mortality of sepsis complicated by AKI. Studies in both dogs and pigs have demonstrated that RAD treatment in a bioartificial kidney circuit improves cardiovascular performance associated with changes in cytokine profiles and confers a significant survival advantage in septic or endotoxin animal models.[70–72]

A noncell therapy, immunomodulatory approach was taken using an SCD, a standard polysulphone HF cartridge (F40, Fresenius AG, Bad Hamburg, Germany) set up in series with an HD circuit. The proprietary circuit[66] was designed to diminish the shear stress (SS) of blood along the hollow fibers from greater than arterial SS ($>30\,\text{dynes}\,\text{cm}^{-2}$) in the first cartridge, to levels below venular SS ($<1\,\text{dynes}\,\text{cm}^{-2}$) in the SCD cartridge to provide an environment for leukocyte adherence.[73] The SCD was evaluated in a porcine model of *Escherichia coli*-induced septic shock and demonstrated increased survival time for SCD-treated groups,[74] along with an ability to lower neutrophil activity (serum myeloperoxidase and CD11b cell-surface expression) and diminish neutrophil tissue invasion.[65]

6.634.4.2. End-Stage Renal Disease

A cell therapy approach to ESRD has a number of technical challenges due to the critical requirement of a durable cell therapy for chronic application. One approach by our group is a wearable bioartifical kidney (WEBAK), utilizing the BRECS and sorbent technology to regenerate peritoneal dialysate to improve therapy for ESRD. Similar to the use of the RAD and BRECS in acute renal failure (ARF), dialysate is used as a nutrient and oxygen source for the cells in the BRECS. A large-animal model was developed to evaluate these BRECS units using PD. PD catheters were placed in 40-kg sheep ($n = 5$). One week postop, 1–2 l of dialysate was infused into the abdomen, followed by continuous PD via catheter connection to the BRECS. In three sheep, the BRECS was used for 6–14 days; in two other sheep, a BRECS unit was not added due to catheter obstruction or peritonitis. No changes in hemodynamics were observed. Oxygen consumption increased by an average of 16% in the BRECS sheep, with a maximum of 63%, compared to *in vitro* averages. When placed into the extracorporeal circuit where PD fluid was the source for nutrients and O_2 delivery, the cells had consistently gluconeogenic properties. Glucose levels increased within the BRECS to an average of $30\,\text{mg}\,\text{dl}^{-1}$.[75] These initial findings are promising as cell durability is critical in cell therapies for chronic applications such as ESRD.

6.634.5. Clinical Evaluation of Bioartificial Kidney

AKI affects up to 200 000 people in the United States annually, and approximately 5% of all long-term hospital patients.

The development of AKI in a hospitalized patient results in a five- to eightfold higher risk of death.[76] The cause of death subsequent to AKI is generally the development of SIRS, frequently secondary to bacterial infection or sepsis, resulting in cardiovascular collapse and ischemic damage to vital organs, and culminating in MOF.[77]

In the United States, 452 000 patients were listed as having ESRD by the 2005 USRDS database, of whom 324 826 were receiving maintenance dialysis.[36] The prevalence of ESRD in the United States is rising by approximately 8% annually.[36,78] The financial cost of dialysis is immense, estimated at USD 64 614/HD patient/year and USD 47 384/PD patient/year. In contrast, transplant patients cost an average of USD 22 142/patient/year.[36,78] The higher cost of maintenance dialysis compared with transplantation does not translate into better results; annual mortality for patients listed for transplant and awaiting a kidney is 6.3%, compared with only 3.8% for patients listed for transplant who do receive a kidney. These statistics compare favorably with the 16.7% annual mortality for ESRD patients not listed for transplant.[79] Transplantation, despite its advantages in terms of cost, morbidity, and mortality, is severely limited by the scarcity of donor organs. In 2006, there were over 300 000 patients on dialysis and 72 983 patients on the kidney waiting list. Only 4096 renal transplants were performed in the first quarter of 2006, based on the Organ Procurement and Transplantation data as of 9 June 2006.

Current dialysis therapies are suboptimal for both AKI and ESRD. These therapies do not meet the medical need to reduce mortality from AKI. Even in ESRD, the outcomes of patients receiving chronic dialysis therapy are still disappointing, with an annual mortality exceeding 25%, on average, and a drastically shortened life expectancy of only 5 years.[36] Several groups have reported that the survival of critically ill patients with AKI could be improved by intensifying the dose of renal replacement therapy,[80–82] but the initial excitement generated by these reports has waned following studies demonstrating that dialysis dose is not closely related to outcomes.[83–85]

6.634.5.1. Acute Renal Failure

The pathophysiology of AKI is due to toxic and/or ischemic damage to the lining epithelium of the renal tubules, which promotes acute organ failure. If the patient can be maintained over the subsequent 7–10 days, the renal epithelium has the ability to regenerate and repair the organ. Extracorporeal cell therapy was implemented to bridge the patient from regenerative repair to baseline health. Renal epithelial cell therapy during an episode of AKI, in conjunction with HF, provides more complete renal replacement therapy as compared to dialysis treatment alone.

6.634.5.1.1. Phase I clinical studies of the RAD

Encouraging preclinical animal data led to an FDA-approved phase I/II clinical trial to evaluate the safety and efficacy of the RAD on ten critically ill patients with ARF and multiorgan dysfunction syndrome (MODS) who were receiving continuous venovenous hemofiltration (CVVH).[86] The predicted hospital mortality rates for these patients, as assessed with acute physiology, age, chronic health evaluation (APACHE) III scores, averaged 85%. The devices used in this study were seeded with human renal proximal tubule cells isolated from kidneys donated for cadaveric transplantation but found to be unsuitable for transplantation due to anatomic or fibrotic defects. The RAD perfusion pump system was connected in series to a CVVH extracorporeal pump system, following the principle tested in the preclinical animal studies, but with a minor adaptation of the circuit to maintain the original CVVH prescription in terms of blood flow rate from the patient and UF rate from the hemofilter.

The results of this clinical trial demonstrated that the experimental treatment could be delivered safely under study protocol guidelines for up to 24 h when used in conjunction with CVVH. The clinical data also indicate that the RAD maintains and exhibits viability, durability, and functionality in this clinical setting. Cardiovascular stability of the patients was maintained, and increased native kidney function, as determined by elevated urine outputs, which was temporally correlated with RAD treatment. The device also demonstrated differentiated metabolic and endocrinologic activity, with ammoniagenesis, GSH reclamation, and endocrinologic conversion of 25-OH-vitD$_3$, to the active form 1,25-(OH)$_2$-vitD$_3$.[87] All but one treated patient with more than a 3-day follow-up showed improvement, as assessed by acute physiologic scores. Six of the 10 treated patients survived past 28 days with kidney function recovery, although only 1 was expected to survive by the predicted mortality scoring system. Of interest, plasma cytokine levels suggested that RAD therapy produces dynamic and individualized responses in patients, depending on their unique pathophysiologic conditions. For the subset of patients who had excessive proinflammatory levels, RAD treatment resulted in significant declines in granulocyte colony-stimulating factor, IL-6, IL-10, and especially IL-6/IL-10 ratios, suggesting a greater decline in IL-6 compared to IL-10 levels and a less proinflammatory state.

6.634.5.1.2. Phase II clinical studies of the RAD

These favorable phase I/II trial results led to an FDA-approved, randomized, controlled, open-label phase II investigation at ten clinical sites to determine whether this cell therapy approach alters patient mortality.[88] Fifty-eight patients (age 18–80 years) with ARF requiring conventional renal replacement therapy (CRRT) in the intensive care unit (ICU) were randomized (2:1) to receive CVVH and RAD ($n = 40$) or CRRT alone ($n = 18$). The primary endpoints were all-cause mortality at days 28, 90, and 180, time to recovery of renal function, time to ICU and hospital discharge, and safety. Baseline demographics and clinical characteristics were well balanced between treatment groups. Mean SOFA renal organ dysfunction subscores were 2.9 and 2.7 in the RAD and CRRT groups, respectively. Acute physiology and chronic health evaluation (APACHE) II scores were slightly, but not significantly, higher in the CRRT-alone group. By most key clinical laboratory parameters, the RAD group had higher degrees of disease severity and MOF than the CRRT-alone group (but no significant differences). A higher proportion of patients in the RAD group completed the study (21 of 40, 53%) compared to patients who received CRRT alone (4 of 18, 22%). Median time on RAD therapy was 35.9 h with a range of 1.8–72.1 h. At day 28, the mortality rate was 33% in the RAD group and 61% in the CRRT group ($p = 0.082$); these 28-day results did not reach statistical

significance. Survival through day 180, however, was significantly improved in the RAD group ($p = 0.034$), and the Cox hazard ratio indicated that the risk of death was approximately 50% of that observed in the CRRT-alone group. By day 28, 21 (53%) of the 40 patients in the RAD group had recovered renal function, ten (25%) had died before renal recovery, eight (20%) remained on renal support, and one (3%) had withdrawn consent. In the CRRT-alone group, a lower proportion of patients had recovered renal function (5 of 18, 28%) by day 28, a higher proportion had died prior to recovery (9 of 18, 50%), and a similar proportion remained on renal support (4 of 18, 22%) compared to the RAD group. Subgroup analyses, including severity of illness (SOFA and APACHE scores), number of organ failures and presence of sepsis at study entry were evaluated. Consistently higher survival rates at 28 days were observed in the RAD group compared to the CRRT-alone group, regardless of the number of organ failures (Figure 7). The incidence of sepsis in the two groups was high, at 73 and 67% in RAD and CRRT-alone groups, respectively. RAD therapy decreased the mortality rate in the patients with sepsis from 67% in the CRRT-alone group to 34%. Of note, patients with five or more failed organs had a 60% mortality rate in the RAD group compared to a 100% rate in CRRT alone. Thus, it appears from these small sample sizes that RAD treatment effects may be more pronounced with greater illness severity at baseline. These promising data suggest that the addition of renal tubule cell therapy to CVVH results in a substantive clinical impact on survival, and that RAD treatment demonstrates an acceptable safety profile.

6.634.5.2. End-Stage Renal Disease

Though the WEBAK has not yet been evaluated in clinical studies for long-term use in ESRD, clinical studies with renal cell therapy paired with CRRT in an extracorporeal circuit have shown promise in the treatment of ARF. As noted previously, ESRD patients on CRRT are at high risk for cardiovascular and infectious diseases. A recent clinical trial failed to show survival benefit from increased doses of HD above what is now standard care.[89] This suggests that there are important metabolic derangements not adequately treated with conventional dialysis treatment. Data from the survival of renal transplant recipients, which far exceed those from the survival of age-, sex-, and risk-matched controls awaiting transplant, also suggest that there is some metabolic function provided by the kidney that transcends this organ's filtration function. Patients with ESRD display elevated levels of CRP (an emerging clinical marker) and proinflammatory cytokines, including IL-1, IL-6, and TNF.[57,58,90] All of these parameters are associated with enhanced mortality in ESRD patients. Specifically, IL-6 has been identified as a single predictive factor closely correlated with mortality in HD patients.[57] Although all ESRD patients could conceivably benefit from a bioartificial kidney, patients in the inflammatory stage who display elevated levels of certain markers of chronic inflammation (most notably IL-6 and CRP) would likely benefit most and will be the target population for clinical study in the near future. Clinical translation from preclinical studies will address long-term cell durability, biocompatibility, and administration protocols.

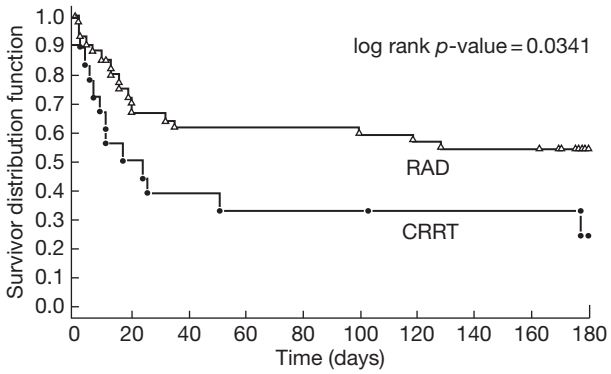

Figure 7 Kaplan–Meier estimates of survival of patients treated with either RAD cell therapy or conventional renal replacement therapy (CRRT). Reprinted from Tumlin, J.; Wali, R.; Williams, W.; *et al. J. Am. Soc. Nephrol.* **2008**, *19*, 1034–1040.

The SCD may provide a novel approach to the immune dysregulation in ESRD. Accordingly, our group has recently evaluated the SCD in a group of chronic HD patients with elevated CRP values. The SCD was placed in series with a hemodialyzer cartridge in a conventional dialysis pump system. Fifteen chronic HD patients were treated for 4 h under standard HD and SCD therapy to ameliorate leukocyte activation. Leukocyte activation parameters were assessed before, during, and after treatment with flow cytometry, along with blood cytokines before and after standard and SCD dialysis therapy. During SCD treatment, multiple leukocyte activation parameters were altered. SCD treatment also lowered proinflammatory cytokines and elevated anti-inflammatory cytokines. Ongoing studies are evaluating dose response effects and the mechanism of action of this device. This approach may be further tested in clinical studies as an innovative intervention to ameliorate the chronic proinflammatory state of ESRD and retard the accelerated atherogenesis associated with chronic renal failure.[91]

6.634.6. Future Prospects

Conventional renal replacement therapies are continuing to advance in the areas of increased feedback control of HD and HF for automated dialysis, ease of use for home treatment, and miniaturization for ambulatory treatments. The promise of renal cell therapy for both acute and chronic applications also opens up new avenues for advances, including implantable bioartificial kidneys.

6.634.6.1. Microelectromechanical System and Extracellular Fluid Volume Sensing

Critical to the success of an automated dialysis platform is online real-time estimation of extracellular fluid (ECF) volume, a complex engineering problem in its own right. Esophageal Doppler monitoring (EDM), pulmonary-artery catheters, and peripheral waveform analysis all provide measures of central hemodynamic parameters. Bioimpedance and hematocrit monitoring may provide estimates of changes in blood volume. Various volume estimation techniques have been deployed in

outpatient maintenance HD.[92] Blood volume monitors have yielded mixed results in clinical trials. An implanted right ventricular pressure monitor appeared to provide valuable clinical information over and above clinical judgment in a very small series.[93]

Ideally, a bioartificial kidney suitable for long-term use in ESRD patients would be capable of performing continuously, like the native kidney, to reduce risks from fluctuations in volume status, electrolytes, and solute concentrations and to maintain acid–base and uremic toxin regulation. As in ARF, cell therapy currently can be administered only intermittently. These additional functions require the eventual design and manufacture of a compact implantable or wearable bioartificial kidney. The advent of silicon bulk and surface micromachining offers hope for the development of such a device.[94] Microelectromechanical systems (MEMS) have traditionally referred to miniature components integrating sensors, actuators, and electronics (see **Chapter 3.315, Biological Microelectromechanical Systems (BioMEMS) Devices**).[95] These devices are produced using many of the same microfabrication techniques as those used to manufacture integrated circuits on silicon substrates. This manufacturing strategy enables the mass production of miniature, high-performance, mechanical, fluidic, and optical components that can be integrated with electronics at low unit cost. These technologies allow the fabrication of pores, beams, gears, and pressure sensors and the patterned deposition of cells in engineered micro- and nanoenvironments. Surface micromachining has been used to provide capillary-like conduits for blood flow in hepatocyte tissue cultures, and micropatterning has been used to control cell growth and differentiation.[96,97]

The telemetric application of MEMS sensor technology to hemodialytic systems has two component requirements: (1) sensing and (2) data transmission. If no internal power source is to be used, external powering of the system becomes a requirement, as well. This can be accomplished via inductive coupling, using radiofrequency transmission from an external source, the charging of a capacitor located on the implanted MEMS chip, and the releasing of the energy to power the MEMS chip and circuit in order to transmit sensed data to an external receiving source. An alternate, and even simpler, scheme is suitable for capacitive MEMS sensors, where changes in the sensing parameter can be translated into capacitance variations of the MEMS sensor. In such cases, the MEMS sensor can be configured into a passive tank circuit that is composed of the variable capacitor and a fixed inductor. This tank circuit exhibits a characteristic resonant frequency that varies as the capacitance changes. An external probe can be used to detect the resonant frequency of the implanted sensor without the use of any circuit in the implanted chip. Millimeter-scale continuous-reading wireless probes have been demonstrated for use within deep tissues, and could be adapted for continuous monitoring of hemodynamic parameters, permitting closed-loop cardiovascular feedback for autonomous HF systems.[98]

6.634.6.2. Wearable Artificial Kidney

The fill volume and footprint of cartridge-based artificial kidney devices continue to become more portable, which allows for future incorporation into a wearable dialysis system. Though no current wearable dialysis system exists, recent advancements in pump miniaturization and technology to reduce the volume of regenerated dialysate during continuous PD are important steps to an engineered solution.[99–102] In this regard, the durability of current cell-based therapy suggests that this therapy could be maintained for at least 6 months in a continuous PD circuit without need for replacement, ideal for a chronic use application such as ESRD.[75]

6.634.6.3. Implantable Artificial Kidney

The aforementioned extracorporeal BRECS is the first step toward a fully implantable artificial kidney. As the technical aspects of the durability of cells are being assessed in the BRECS, an initial proof of concept of the implantable artificial kidney was undertaken. An implantable BAHF to initiate new tissue formation with a capillary bed surrounding synthetic hollow fibers without EC lining was successfully fabricated and implanted. UF draining into an artificial bladder in a rat with protein permselective properties was produced from this implant device.[103] Long-term biocompatibility of the implantable artificial kidney and maintenance of the associated capillary bed are key technical hurdles to be addressed. Although research into the ideal implantable artificial kidney is ongoing, this is a promising future approach.

Glossary

Adhesiolysis Removal of adhesions (by dissolution).
Anastomosis Surgically made joint in an organ or tissue.
Fibrinolysis Dissolution of fibrin gel (by enzymes).
Peritoneal cavity Nominally the same as the peritoneum, but often implying the whole abdominal cavity.
Peritoneum The gap between the peritoneal membrane inner surfaces (outer surfaces of the relevant organs).

FDA Food and Drug Administration (USA)
PTFE Poly(tetrafluoroethylene)
TGF-β Tissue-derived growth factor-beta
tPA Tissue plasminogen activator
USD United States Dollars
VEGF Vascular endothelial growth factor

6.635.1. Introduction

There are a number of organs and tissues that move significantly with respect to the surrounding structures. The intestines and visceral organs, the female reproductive organs, tendons, the heart, lungs, muscles, skin, and the brain are some of the major organs that have significant movement. For most of these organ systems, movement is vital to proper function, and the body has

developed several structures, including serous membranes, adventitia, and fascia layers, to allow this movement.

Adhesions are collagenous, fibrous structures that result from the body's wound-healing system and tether the moving organ to the surrounding tissue, or surround an organ, such as the intestine, and constrict it. The net effect of the adhesion can range from mild to catastrophic. Unfortunately, it is not possible to predict which adhesions will have severe to catastrophic effects on organ function.

Although adhesions may occur naturally from inflammatory disease, most adhesions are the result of surgical intervention, especially abdominal surgery. Ellis[1] gives a highly readable account of the history of the development of interest in surgical adhesions, their potential causes, and the effects on patients and society. According to Ellis, the rate of serious complications requiring reoperation is fairly small, generally around 1–9% (also see Grant *et al.*[2]), although there is a high degree of variability depending on operation type, and complications may take many years or decades to show up. However, abdominal operations are so common that one report[3,4] estimated that the total cost of adhesiolysis in the United States in 1988 alone was over USD1 billion, rising to USD1.3 billion by 1994! This does not include the cost of litigation.

Recently, Park *et al.*[5] in their study reported a 4.6% rate of serious complications following colorectal surgery. However, adhesion formation of all degrees of severity would appear to be in the high 90% range.[6] Not surprisingly, there have been many attempts to develop techniques and materials to prevent or reduce the occurrence of adhesions. One major approach is the use of (bio)materials as barriers to the development of fibrous adhesions between the serous membrane and the organ. This chapter examines some of the materials, and other approaches, used for adhesion prevention.

What is the benefit/advantage of using barrier biomaterials to prevent adhesion formation? The prevailing assumption from all the reviews and studies would appear to be that physical prevention of fibrous scar formation between the organ and the surrounding membrane will prevent the serious complications that are associated with a relatively low proportion of cases of actual fibrous adhesion formation. The prevailing practice is also to use resorbable materials (see **Section 6.635.3.1.1**), although there are some nonresorbable materials that have been used (**Section 6.635.3.1.2**).

There are a number of materials in clinical use and many more experimental composite materials, mostly centering around a limited set of base polymers. Both clinical and animal studies have increased our knowledge and understanding, and have led to improved surgical techniques and methods to reduce the overall level of adhesions.[5]

It is interesting to note that adhesions are not necessarily bad in abdominal surgery. Ellis[1] reports that previous experimental data on rats show that adhesions are a necessary source of revascularization of ischemic areas of the bowel. Indeed, retrospective analysis[7] of a number of studies involving a resorbable barrier shows an improvement in the rate of higher severity adhesions but no statistical improvement in serious complications. However, there is a statistical increase in abscess formation and anastomotic leakage, and the authors conclude that the anastomosis should not be covered by the barrier.

Zawaneh and Putnam[8] have provided a significant review, up to 2007 of the field of biomaterials for adhesion and seroma prevention. This chapter does not intend to repeat their work, and readers are referred to the review for details. This chapter will rather look at the more recent work (mainly 2007–2009), mostly animal studies, with some overview to enable an appropriate understanding of the context.

Although the concept of adhesion barriers and prevention is deceptively simple, the many decades of work on the subject have not yielded the desired outcome of prevention of serious sequelae from adhesions following surgery.[9]

> ... adhesions still remain a significant, unresolved postoperative complication. (Lim *et al.*, 2009)

6.635.2. Formation of Adhesions and Major Areas of Concern

6.635.2.1. Pathophysiology of Adhesion Formation

Adhesion formation is a natural, if unwelcome, consequence of the body's wound-healing response. Early events following wounding involve filling of the wound site with a fibrin clot. This clot, initially, is a weak hydrogel that fills space and is designed to prevent further loss of blood. As a hydrogel, it also allows invasion by the cells of the innate immune system (mainly neutrophils and granulocytes) to clean out the wound. As the wound-healing process continues, macrophages invade the clot and begin removing debris and bacteria. Finally, fibroblasts and cells from the regenerating local tissue invade, once the inflammatory (wound cleaning) phase has abated. The fibrin clot is eventually removed by fibrolytic enzymes and by the invading cells as relevant local tissue is regenerated.

Stiffening of the clot due to cross-linking occurs mechanically relatively early, and then as fibrinolysis occurs, the clot becomes less and less stiff. In the ideal case, fibrinolysis should be well advanced prior to fibroblast invasion.

Fibrin also acts as a sink, when whole, and as a source, as it is lysed, for a large number of growth factors that regulate the inflammatory process and for revascularization of the resolving tissue.

In the nonideal case, fibroblasts arrive in the clot while the inflammatory process is still under way and before substantial net fibrinolysis can occur. Under these circumstances, the fibroblasts receive information on the local mechanical and biochemical environment. In terms of biochemical environment, a fibrin clot is neutral, and therefore, it is reasonable to conjecture that the fibroblasts will tend to follow the local mechanical cues, and not the local tissue regeneration biochemical cues, which are usually too remote on a biochemical gradient basis to affect cellular behavior. The result will, therefore, be a scar, with collagen fibers oriented mostly to resist the local mechanical stress. An adhesion is formed where this scar tissue surrounds or adheres to an organ that moves (visceral organs, female reproductive organs, heart, tendons, brain). If the adhesion prevents necessary movement of the organ, or by constriction causes organ failure, a pathological condition is created.

Invasion by fibroblasts and regeneration of tissue is a natural competition. In the case of abdominal surgery, the

regenerating tissue of interest is the mesothelial layer that lines the inside of the peritoneal membrane. Coverage of damaged areas of mesothelium with new cells would appear to be essential to the prevention or limitation of adhesions.[1] This would appear to occur fairly quickly, with most damaged areas recovering in 3–7 days.[10] The timeline for fibroblast appearance in the fibrin clot is also around 1 day to 1 week.[10,11]

Figure 1 outlines the competitive processes and approximate timelines in the wound-healing system. The crucial time would appear to be around days 3–5 during which if fibrinolysis is sufficiently advanced, indicating mesothelial repair, adhesions will not form. If inflammation or irritation continues and the regrowth of the mesothelial layer is inhibited, then the conditions are set for adhesions to form. For more detailed descriptions of the associated biochemical factors and cellular invasion, the reader is referred to Thompson *et al.*,[12] diZerega and Campeau,[10] and Cheong *et al.*[11]

Irritants prolong the inflammatory stage, as demonstrated by the problems of powder on surgical gloves, first, talc, and then starch, in enhancing adhesions in abdominal surgery.[1]

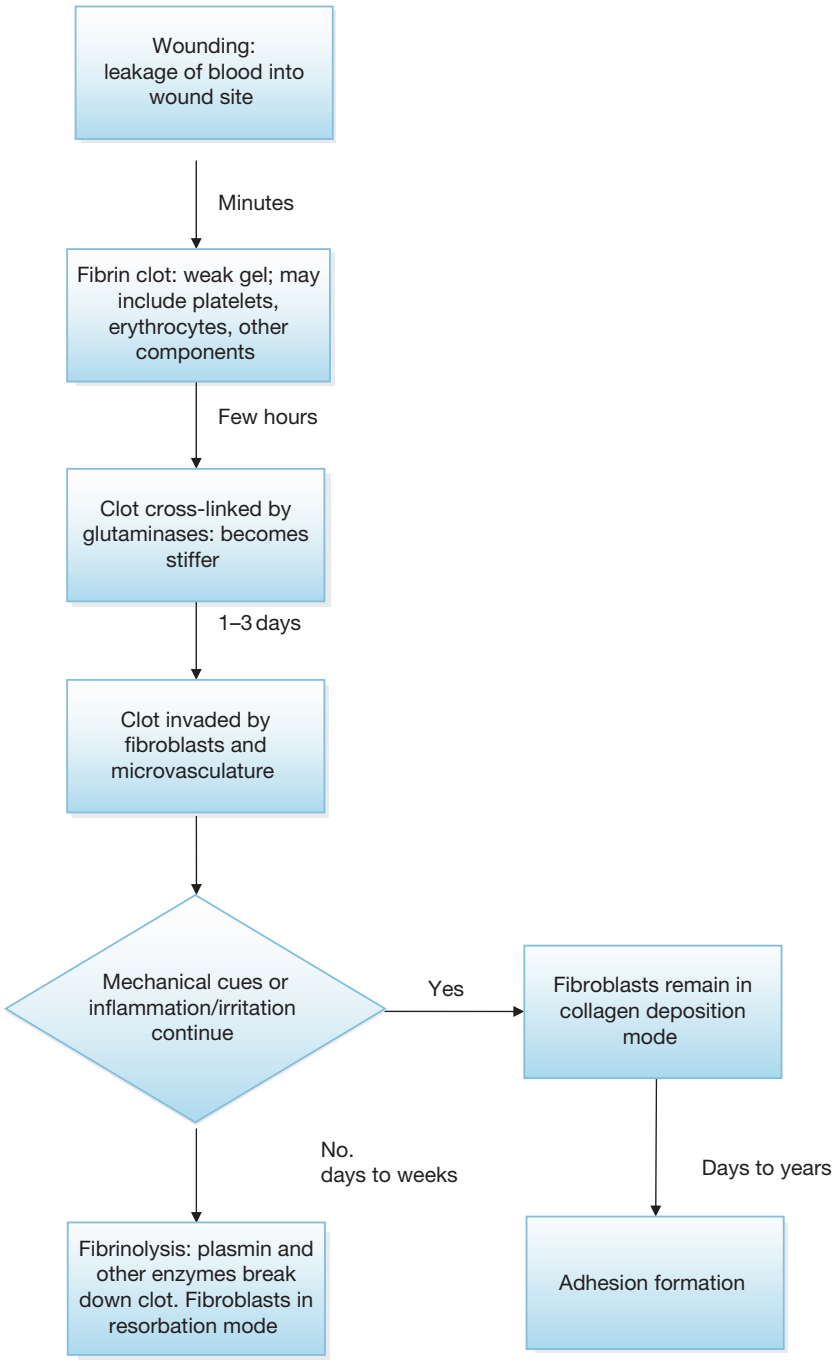

Figure 1 Flowchart, with approximate timeline, of the repair or adhesion development pathways.

Other irritants, such as sutures, would also appear to have a significant effect, and Ellis notes the final recommendation to avoid attempting to suture the damaged mesothelium and underlying membrane to reduce the deficit in the layer.

With prolonged irritation comes prolonged inflammation, addition to the fibrin clot (through increased vascular permeability), reduced fibrin degradation (through reduced tissue plasminogen activator (tPA) concentration[12]), and reduced mesothelial cell recovery. This means that fibrinolysis will not have proceeded far enough for the mechanical cues to the fibroblasts to be reduced and to cause them to gene-switch to resorption rather than collagen deposition. Mechanical stimulation has been shown to be a significant factor in the switch by fibroblasts between collagen deposition (strained) and matrix resorption (unstrained).[13]

Other tissues, such as the pleura, the dura mater/arachnoid mater/pia mater around the brain, and the pericardium are serous membranes that perform comparably to the pericardium. The tendon is surrounded by a synovial membrane that also performs a similar set of functions. In all these situations, wounding either by surgery, trauma, or infection can lead to adhesion formation by very similar mechanisms.

It should be noted again here that adhesions and scar tissue contain vasculature and can provide necessary nutrition to the organs to which they adhere[1] if the local vasculature has been damaged by the surgery. Indeed, Ellis[14] earlier proposed that ischemia, rather than wounding *per se*, was the cause of adhesions. Ischemia may still be a major cause of adhesions, as the lack of oxygen in the region will prolong the inflammatory response and provide cytokines that encourage vascular ingrowth through the repairing mesothelial layer.

Readers interested in more detail on wound healing, fibroproliferative diseases, and tissue regeneration may find the following general references useful:

Eming *et al.*[15] review the association of an advanced and active immune system on tissue regeneration;

Levin[16] takes a geometry-based overview of regeneration and sounds some warnings about attempting to micromanage regeneration that could well be applicable to attempts to control adhesions; and

Fusi[17] provides a generalized mathematical model that may be applied to wound healing and fibroproliferative disorders.

6.635.2.2. Peritoneum and Urinary and Reproductive

6.635.2.2.1. Peritoneum

The peritoneal cavity (abdominal cavity or coelum) contains, largely, the visceral organs including the liver, stomach, small and large intestines, and associated smaller organs. In women, the uterus, Fallopian tubes, and ovaries also protrude into the peritoneal cavity.

The peritoneal membrane (peritoneum) is a serous membrane that performs the functions of separating the visceral organs from the bulk of the body and each other, providing lubrication for the movement of the visceral organs,[18] and providing nutrition to the outer layers of the visceral organs and preventing the vasculature from connecting between the main part of the body and the moving visceral organs. As a serous membrane, it has a layer of connective tissue with a single cell thickness of mesothelial cells that secrete a lubricating liquid into the space between the layers. As most of the organs in the peritoneal cavity are coated with peritoneum, the peritoneum effectively provides the lubricated surface that allows the organs to move within the cavity.

The healing of the peritoneum is different from the process of general wound healing of the tissues or epidermal epithelium of the skin in that the areas of the peritoneum that have lost cells rapidly repopulate all over the denuded surface from precursor cells.[10] Major body tissues and skin epithelium repopulate from the edge of the wound only.

As mentioned in the previous section, the area of the denuded surface is also associated with a fibrin clot and the general wound-healing process, which may lead to fibrous tissue formation instead of tissue regeneration. The formation of an adhesion, in effect a bridge of tissue between the underlying layers of tissue, prevents the restoration of the original mesothelial layer. The opposite is also the case with a restored mesothelium preventing adhesions. The complexity of the competition between these processes in the early postoperative phase may well be the cause for a number of authors such as Tulandi[19] to conclude that aspects of the healing process are still unclear.

What is clear, however, is that complications due to adhesions in the peritoneal cavity may be severe, including obstruction of the small intestine (by forming a ring around the intestine and preventing peristalsis), and pelvic and intra-abdominal pain; that these complications may not occur until many years postoperatively[1,19]; and that these complications are sufficiently common and their intervention sufficiently costly to require the development of methods to reduce them.

A variety of approaches have been made in attempting to understand the causes of adhesion and complications. In terms of breadth of cause, Vural *et al.*[20] examined the role of neutrophils in adhesion formation, as these cells are major initiators of the inflammatory response, whereas Cahill and Redmond[21] have proposed anti-VEGF therapy in order to reduce the formation of blood vessels in the fibrin clot/adhesion and therefore the severity and longevity of the adhesion. Ellis[1] remains a strong promoter of tPA therapy, and there is some evidence that long and extensive abdominal surgery can result in lowered tPA levels in the peritoneal fluid.[22,23]

Cheung *et al.*[24] have conducted a recent review of adhesion prevention methods and clinical outcomes. Their conclusion is equivocal, citing expense and higher rates of complications for one material barrier, despite that barrier performing best in reducing adhesions at the site of surgery.

6.635.2.2.2. Urinary and reproductive

The top of the bladder and, in females, the uterus, Fallopian tubes, and ovaries, have peritoneal membrane surfaces. Gynecological surgery has been associated with fibrous adhesions affecting the small bowel as well as the reproductive organs. Conversely, an association between infertility and adhesions has been known for many years.[19] Adhesions from surgery in the lower abdomen can interfere significantly with egg translation to the Fallopian tube. The problems of specialization are commented upon by Tulandi, who remarks that gynecologists seem to forget that later onset bowel obstruction, a potentially fatal complication, could be associated with the gynecological surgery.

Nappi *et al.*[25] have reviewed a large number of techniques related to gynecological surgery and minimization of complications and equivocally concluded that there are benefits to the uses of barrier materials, liquids, or drug treatments at the time of operation.

In an interesting aside, Sjosten *et al.*,[26] using a rabbit model, found that starch granules placed in the vagina could lead to adhesions in the lower abdomen, as the granules were able to travel through the uterus and Fallopian tubes and then into the peritoneal cavity. This unlikely route to adhesion development gives cause for thought about other routes for inflammatory particles to reach the peritoneum, especially with the recent prevalence of nanoparticles that may be taken up by a number of cell types.

6.635.2.3. Tendon, Ligament, and Joint

Tendons connect the muscle body to the bone on which the muscle acts. As tendons must be able to move considerable distances, relatively, as the muscle body contracts, they lie within a synovial sheath structure that provides both lubrication and nutrition to the tendon.

The major repairs to tendons are usually those of the hand and the Achilles tendon at the ankle. Tendon reconstruction often is required following trauma to the hand or wrist, or as a result of 'snapping' of the Achilles tendon during exercise. Fibrous adhesions are a common complication of tendon repair,[27] and there have been a large number of studies on ways to prevent or minimize such adhesions, as they affect movement of the associated bone and, hence, the overall function of the associated joint.

The most common treatment to attempt to prevent adhesions is by use of passive movement. However, this is not always practicable, and the strength of the tendon repair is not always sufficient to allow passive movement over the whole range of motion of the joint. In addition, there seems to be some variation in the likelihood of adhesion formation with different styles of repair of the tendon and the tendon sheath, and the size of the deficit in the tendon sheath.

Ligaments and joints are also subject to adhesion formation in the synovial space after trauma or surgery. The degree of damage to the synovial membrane and time of immobilization are two of the major contributors.[28]

A number of barrier materials have been tried in tendon and joint repair in animal models with limited results. These include pericardium,[29,30] oxidized regenerated cellulose,[31] hyaluronic acid derivatives,[32] intestinal submucosa,[33] carboxymethylcellulose,[34] PTFE and e-PTFE,[35] hydroxyapatite and alumina,[36] and others listed by Ozturk *et al.*[37] Few have made it to clinical trial or clinical use.

6.635.2.4. Pericardium

The pericardium is the membrane surrounding the heart. Adhesions between the pericardium and the heart tissue are mainly due to open-heart surgery. Although adhesion-related complications are relatively rare, complications associated with reopening of the pericardium are more common and potentially life-threatening. Adhesions from previous surgery obscure the heart and graft structures, and dissection of the adhesions may lead to accidental damage to the grafts or to the heart muscle. Mortality rates from iatrogenic damage to the graft or the heart may range up to 56% with an incidence rate of 4–9% of reoperations.[38]

The number of coronary operations is increasing with the aging population and increasing longevity. Consequently, there is a need for systems to reduce adhesions in the pericardium if the reoperation rate is on the order of 10%.[38]

Recent experimental work has looked at a number of approaches, including carboxymethyl chitosan,[39] oxidized regenerated cellulose (Interceed®),[38] and hyaluronic acid derivatives.[40] All show reduced numbers or density of adhesions with the use of a barrier material. The current alternative for pericardial applications is pharmaceutical, with investigations including keratinocyte growth factor, an activator of mesothelium regeneration,[41] and chymase inhibitor, which reduces the activation of TGF-β1, an activator of fibroblasts and fibrosis.[42] Whether either of these approaches will attain clinical acceptance is still unknown.

6.635.3. Barriers to Adhesion: Current Clinical Practice

Barriers that physically separate serosal surfaces aim to prevent the occurrence of tissue adhesion after surgery. Currently, there are only two FDA-approved clinical membrane products, Interceed® (Johnson & Johnson) and Seprafilm® (Genzyme Corp), that are available for use for adhesion prevention.[43]

An overview of current resorbable and nonresorbable barrier methods including solid membrane/mechanical barriers, spray-on, gel and liquid barriers is presented. Emerging nonbarrier therapies such as those employing pharmacologic agents have also been included, but methods such as drainage and dissection techniques, and surgical and mechanical treatments are outside the scope of this chapter.

6.635.3.1. Solid Barriers (Membranes/Mechanical Barriers)

6.635.3.1.1. Resorbables

6.635.3.1.1.1. Polysaccharide-based

Table 1 lists recent work with resorbable barrier materials manufactured from cross-linked polysaccharides.

6.635.3.1.1.2. PEG-based (polyethylene glycol)

Polyethylene glycol-based resorbable barrier materials have been used in a variety of forms. Table 2 lists the recent studies.

6.635.3.1.1.3. Other polymers

Although polysaccharide- and PEG-based materials predominate in barrier applications, some other common biomaterial polymers are also used, as shown in Table 3.

6.635.3.1.1.4. Other

Among the resorbable solid barriers, there are some barriers made from animal tissue, listed in Table 4.

6.635.3.1.2. Nonresorbables

6.635.3.1.2.1. Polytetrafluoroethylene

Polytetrafluoroethylene (Teflon®) has been used in a large number of medical applications and elicits a very small inflammatory response. This has seen its continued use as a barrier

Table 1 Polysaccharide-based materials

Base material	*Product name*	*Manufacturer*	*Description*	*Application/procedure*
Hyaluronic acid	CMHA-SX or Carbylan-SX	Carbylan Biosurgery Inc.	Chemically modified, *in situ* cross-linkable derivative of hyaluronan	Pericardiotomy[40] Cecum–abdominal wall[56] Uterine horn[56]
Carboxymethyl cellulose (CMC)	Seprafilm	Genzyme Corp.	Made from chemically modified sodium hyaluronate and CMC	Ovarian and Fallopian tube laparatomy[57] Peritoneal laparatomy[57] Peritoneal midline incision[6] Ileostomy closure[58] Cecum–abdominal wall[59] Cecal abrasion[60] Radical colorectal resection[5]
	N/A	N/A	Made from Fe^{3+} cross-linked CMC	Achilles tendon abrasion[34]
Chitosan	N/A	N/A	Polypropylene mesh coated with a chitosan membrane	Cecal abrasion, parietal peritoneum incisions[46]
Cellulose	Interceed®	Johnson & Johnson	Made from oxidized regenerated cellulose	Achilles tendon repair[31] Pericardial excision[38]

material (Table 5), even though it must be sutured in place and removed by a subsequent surgery.

6.635.3.1.2.2. Polypropylene

Polypropylene is a widely used polymer in the production of prosthetic materials due to its low cost and *in situ* nondegradation. A number of commercially available meshes generally used intraperitoneally for intra-abdominal hernia repair are given in Table 6.

There are a number of problems associated with mesh use. The implant can undergo pronounced *in situ* shrinkage.[44] Seroma and hematoma formation can occur between the

Proceed™	PP mesh with a layer of polydioxanone polymer film and a layer of absorbable oxidized regenerated cellulose	Ethicon, Johnson & Johnson
Prolene®	PP mesh	Ethicon, Johnson & Johnson
Parietex™ Composite	Polyester mesh with a layer of absorbable collagen–polyethylene glycol–glycerol	Covidien Healthcare
Parietene™ Composite	PP mesh with a layer of absorbable collagen–polyethylene glycol–glycerol	Covidien Healthcare
TiMESH®	PP mesh with a titanium surface	GfE Medizintechnik GmbH
Ultrapro®	PP mesh with an absorbable polyglycolide/e-caprolactone coating	Ethicon, Johnson & Johnson

Table 7 Other

Base material	*Product name*	*Manufacturer*	*Description*	*Application/procedure*
Small intestinal submucosa	N/A	N/A	Porcine small intestinal submucosa	Patellar tendon defect[33]
Polyvinyl alcohol and CMC	A-Part®	Aesculap	40-μm thick membrane made of PVA and CMC in various ratios	Cecum–abdominal wall[50]

mesh and the abdominal wall. Mesh migration to neighboring organs can occur. Intraperitoneal mesh use can induce an inflammatory reaction, which can lead to excessive fibrosis and adhesion formation,[45] and direct contact between the mesh and the intestinal loops can promote enterocutaneous fistulas and visceral erosions.[46] Resistant infection and postoperative pain have also been reported.

The polypropylene base mesh/membrane is often coated with a biocompatible absorbable material in an attempt to limit direct contact between the polypropylene and the peritoneal surface. The aim of the coating is to resorb when it is no longer required to reduce the amount of foreign material left in the body. The coating can take the form of a gel, film, or membrane.

Comparative studies have explored the differences between the commercially available meshes.[43,45] A reduction in adhesion formation is seen with a reduction in polypropylene and a change in pore size.[47] Currently, no ideal mesh is available.[48]

6.635.3.1.2.3. Other

Table 7 lists a couple of other partially or nonresorbable membranes that have been trialed.

6.635.3.2. Resorbable Spray-on, Gel, and Liquid Barriers

Barriers may also be applied as gelling sprays, direct sprays, or as viscous liquids, as this reduces the amount of work required to get the barrier in place. However, there are problems with the length of time the barrier remains in place and the specificity of placement.

6.635.3.2.1. Spray-on

Table 8 lists recent work with spray-on gelling liquids.

6.635.3.2.2. Gel

There are a substantial number of gels available and a lot of recent work as shown in Table 9.

6.635.3.2.3. Liquid

Liquid barriers are largely based on corn starch (icodextrin) and hyaluronic acid (Table 10).

6.635.3.3. Nonbarrier Methods

6.635.3.3.1. Hybrid systems

There has been little recent reported work on drug-delivering barrier systems (Table 11).

6.635.3.3.2. Transgene/drug/pharmacologic agent therapies

Table 12 lists a variety of other agents, used to try to limit adhesion formation, from pharmaceuticals to gene therapy.

Table 8 Spray-on barriers

Hyaluronic acid	Hyaloglide®	Fidia Advanced Biopolymers	Made from hyaluronic acid and utilizes an auto-cross-linking process	Flexor tendon repair[72]
	Hyalobarrier® GEL × ENDO	Fidia Advanced Biopolymers	Made from hyaluronic acid and utilizes an auto-cross-linking process	Laparoscopic myomectomy[73]
	Intergel	Lifecore Biomedical Inc.	Made from cross-linking carboxylate groups on the HA molecules by chelation with ferric ions to make a 0.5% ferric hyaluronate gel	Abdominal colorectal surgery, ileostomy reversal[74]
	Incert®-S	Anika Therapeutics	Composed of chemically cross-linked pure hyaluronic acid	Uterine horn[75]
Sodium CMC	Poly(p-dioxanone)/ NaCMC/Tranilast	Polymed (Tranilast) Hercules (CMC) BENECEL (CMC)	Tranilast was combined with a CMC gel and encapsulated using poly(p-dioxanone) for a sustained release	Sidewall abrasion, uterine horn abrasion, laminectomy, tendon[43]
Chitosan	N/A	N/A	Made from chitosan, hyaluronic acid and chemically modified 1,2-butylene oxide	Cecal abrasion[76]
Carboxymethyl chitosan	N/A	Dayang Chemicals Co (CMC powder)	Made from carboxymethyl chitosan	Percardiotomy[39]

Table 10 Liquids

Base material	*Product*	*Manufacturer*	*Description*	*Application/procedure*
Icodextrin derived from cornstarch	ADEPT®	Innovata plc	4% Icodextrin solution	Adhesive small intestine occlusion[77]
Hyaluronic acid	Sepracoat® (formerly HAL-C™)	Genzyme Corp.	Composed of chemically derived sodium hyaluronate and carboxymethyl cellulose	Abdominal wall defect[78]

Table 11 Drug-delivery films

Agent	*Product*	*Manufacturer*	*Description/mode of delivery*	*Application/procedure*
Insulin	N/A	N/A	Ibuprofen-loaded poly(L-lactic acid) and polyethylene diblock copolymer films used for defect repair	Cecum–peritoneal wall defects[63]

6.635.4. Barriers to Adhesion: Current Research

While a number of techniques have been employed to address unwanted postsurgical tissue adhesion, a great deal of attention has been paid to barrier methods. It has been attested that compared with other materials or substances used for the reduction or elimination of adhesion, barrier products are the only effective products currently available.[19,23] In spite of this fact, it should be noted that there still remains no unequivocally effective method, be it a surgical technique, pharmacological agent, material or barrier, to prevent adhesion formation.[19]

There are a number of limitations and concerns associated with current barriers. Many of the products are only suitable for specific anatomical locations, and outside of these areas have been shown to cause further complications. They are also dependent on application through particular surgical methods, and are not always suitable for minimally invasive laparoscopic procedures, which may be preferred.

Table 12 Gene and soluble drug delivery

Agent	*Product*	*Manufacturer*	*Description/Mode of delivery*	*Application/Procedure*
Smad7	pTRE-m2*Smad7*	N/A	Delivered to peritoneal cavity via a nonviral ultrasound-microbubble-mediated naked gene transfection system	Cecum and parietal peritoneum abrasions[79]
Melatonin	N/A	Details not given	Postsurgical daily single dose via orogastric gavage	Pinealectomy followed by cecum incision[80]
Kombucha mushroom	Kombucha fermented tea	N/A	Intraoperative intraperitoneal administration	Intestinal and peritoneal defects[81]
Neurokinin-1 receptor antagonist	CJ-12-255	Pfizer	Intraoperative intraperitoneal administration (intraperitoneal lavage)	Peritoneal side wall defects[82]
Metformin and atorvastatin	Metformin (Glucophage®); Atorvastatin (Lipitor®)	Merck Sante SAS; Pfizer	Oral delivery starting on the day of surgery	Uterine horn[83]
Keratinocyte growth factor	Recombinant human keratinocyte growth factor	Sigma	Solution in saline, injected into pericardial cavity postoperatively	Pericardial cavity (abrasion, blood instillation, and desiccation)[84]
Chymase inhibitor	Suc-Val-Pro-Phe^{p} $(OPh)_2$	Details not given	Solution in saline, sprayed topically into pericardial cavity	Epicardium abraded[42]

Barriers that are nonresorbable may require a second surgery to remove the implant. If the implant is not sufficiently anchored, it may move *in situ*, potentially resulting in further complications. Nonresorbable barriers can also degrade over time, and this breakdown can litter the area with aggravating debris.

Methods that utilize human tissue contain the risk of cross-infection, which in turn limits their use.

Ideally, a barrier should possess characteristics and prerequisites such as being inert to the surrounding tissue, with excellent biocompatibility; promoting fibrinolysis prior to fibroblast invasion; not encouraging clot formation which in turn will prevent/reduce fibroblast reaction; reliably avoiding the formation of adhesions; adhering to the desired tissue for as long as required[49]; possessing good handling characteristics[50]; being applicable to a number of anatomical sites; and being applicable by both open and laparoscopic procedures.[49]

Even if all these criteria are suitably satisfied, a shortcoming of barrier methods that will remain will be reliance on the surgeon for predicting potential sites of adhesion and subsequent placement of the barrier.[51]

The current approach for barriers is focused on one of two options, to make modifications to preexisting products in the hope of improvement, or for the use of new materials,[52] which have often been used in other *in situ* applications. These approaches are tested using various animal models (usually small animals), with different injury types attempting to mimic clinical surgical procedures. These models have variable degrees of trauma, with and without blood exposure. Comparison between studies can be difficult due to subjective grading systems used to gauge adhesion,[53] and reported results are sometimes found to be contradictory.

The use of small animal models, while practical from a laboratory point of view, does not necessarily provide accurate clinical predictions with success[49] for a number of reasons. There are differences in surgical procedures, and methods such as abrasion, incisions, and electrocautery are used to mimic surgical injury. Differences in scale and physiological forces also exist between small animals (mice, rats, and rabbits) and humans. The desire to eliminate some of these factors has led researchers toward porcine and canine models, particularly for pelvic surgery. While there is an increase in organ size, allowing more similarities in surgical procedure, there are the drawbacks of comparing the human anatomy with that of four-legged animals.

6.635.5. Uses for Adhesion

Adhesions and the process of adhesion formation are not necessarily always deleterious. There are a number of occasions where the formation of an adhesion may be necessary or may be utilized for beneficial purposes.

Many medical devices that are not directly bonded to bone require fixation in position, as migration around the body may cause significant problems. Pacemakers, heart valves, hernia reinforcement, and breast implants are probably the most common implants requiring fixation. Lack of fixation allows movement within the body, and many early devices failed because of the lack of appropriate fixation in one anatomical position. Although not intuitive, devices implanted in any of the planes between organs or tissues are not constrained in their ability to move in that plane. General body motion results in uneven forces on the device and consequent motion within the body.

Large diameter blood vessels, especially those made from Dacron® velour, utilize the body's chronic inflammatory reaction to the material to develop scar tissue analogous to adhesions elsewhere. This helps seal the graft and anchor it into position.

In the peritoneal region, adhesions are central to the use of meshes to reinforce weak areas prone to herniation. The development of a strong collagenous matrix on the tissue side of the mesh is essential to prevent the abdominal wall from failing and extruding the mesh and the viscera.

As mentioned previously, adhesions, or at least the associated vasculature, may be required to provide nutrients to the healing bowel.[1] This aspect of adhesion formation should not be overlooked when examining the clinical use of adhesion barriers.

6.635.6. Discussion

From the available literature, adhesion barriers do work to reduce the number and severity of adhesions in most clinical applications, generally without increasing the incidence of complications or producing new complications. There is the exception of use around the anastomosis site in bowel surgery where barrier materials may slow or impede healing. The rate of severe complications does not appear to be altered by the use of barrier materials, and one must question the tacit assumption that the severe complications are directly related to the adhesions.

At least for cardiac surgery, the complications appear to be related to the severity of the adhesions and not to the long-term sequelae. Adhesion barriers should do well in this situation, even if they do not reduce complication rates for abdominal surgery.

6.635.6.1. Complications of Barrier Films

Adhesion barrier materials are largely seen to be benign. However, there are some potential complications arising from their use in surgery.

6.635.6.1.1. Inflammation

The degradation of most resorbable biomaterials is by random hydrolysis of the bulk material. This results in the material losing strength well before it begins to lose mass. A consequence of this loss of strength is that the material should break up into pieces, especially in a mechanically active environment. Little work appears to have been done on this aspect of material degradation, although Ishii and coworkers[54] have demonstrated fragmentation of nanofibers of poly-L-lactic acid in an animal model.

Particles of polymeric material, especially around 0.1–1 μm size, contribute highly to macrophage activation,[55] so it is conceivable that the degradation of resorbable barrier materials may well result in inflammation as the material breaks up into small pieces late in the life of the barrier.

6.635.6.1.2. Nutrient deprivation

Most barriers are relatively thick, greater than 200 μm, and even the hydrogels will restrict diffusion of oxygen and nutrients. Where provision of nutrients to the wound site is dependent on the serosal (e.g., peritoneal) fluid or where the local vasculature has been compromised by surgery, the barrier material may well act as a barrier to nutrition and oxygen and thereby restrict the ability of the local tissue to heal. This scenario would lead to the finding of Zeng *et al.*[7] of increased leakage of anastomoses when covered by barrier materials.

6.635.6.1.3. Potential late adhesion development

A sufficiently robust inflammatory response to degrading barrier material may also generate local damage to the mesothelial layer and therefore cause renewed conditions conducive to adhesion development.

6.635.6.2. Design of New Barrier Films

In the design of barrier materials, the long-term goals of the material, its short- and long-term behavior, and the body's response need to be included in an interrelated manner.

Some criteria for the design of new materials are discussed in the following sections.

6.635.6.2.1. Drug-eluting barrier materials to reduce inflammation and increase fibrinolysis

Adhesions require a fibrin clot in which to develop and are exacerbated by the inflammatory response to the wound. Several researchers have proposed using anti-inflammatory, and even anticancer, drugs to reduce inflammation as an antiadhesion strategy (see **Section 6.635.3.3.2**). Profibrinolytic drugs, such as tPA which converts plasminogen to the enzyme plasmin that lyses cross-linked fibrin gels, can also reduce the mechanical stiffness or remove the fibrin clot. A drug-elution strategy from the adhesion barrier material that encourages fibrinolysis at around day 3–5 and has an anti-inflammatory effect at the same time as well as when the material is in the final stages of degradation could be a potential step forward in reducing complications.

6.635.6.2.2. Allow penetration of nutrients and removal of waste (MW > 1 M)

As nutrition is an essential function of the serous fluid (e.g., peritoneal fluid) pumped into the peritoneum, reduction in the diffusion barrier properties of the membrane while maintaining the cell-excluding properties is another strategy. This could be achieved by increasing the permeability of the membrane to a molecular weight of 1 million Daltons or more, and decreasing the thickness of the material.

6.635.6.2.3. Bioresorbable, but does not form microscopic pieces on degradation (inflammatory)

An alternative strategy for dealing with the long-term degradation behavior of the barrier materials is to make them surface eroding, rather than bulk eroding. This may be difficult for hydrogels, unless the mechanism of degradation is related to the surface activity of the material.

6.635.6.3. Technique and Assessment

Appropriate animal and (retrospective) clinical trials need to be undertaken to evaluate the use of barrier materials for inhibiting long-term complications. This will require the development of an animal model that simulates the conditions that lead to severe complications in humans.

In addition, assay systems that look at the entire degradation behavior of the materials and not just the first few days' behavior will need to be employed.

6.635.6.4. Summary

In summary, most resorbable barrier materials work to reduce adhesion formation. However, in abdominal surgery, there are severe complications that may occur months or years after surgery, the incidence of which does not seem to be affected by the use of adhesion barriers. We should question the

assumption that all severe complications arise as a direct result of those adhesions and look for a more complete understanding of the processes leading to bowel obstruction, as these should modify the strategy for the design of the material. New technologies and new materials should also be investigated if the benefits of adhesion barriers are to be increased to include late-onset complications.

However, barrier materials have a clinical use now in situations where the number and severity of adhesions is important (heart surgery, and protection of the uterus and Fallopian tubes). Most barrier materials would appear to be reasonably safe for use if used in the appropriate settings.

6.636.1. Introduction

Suture materials play an important role in wound repair by providing support to healing tissues. Closure of skin wounds is only one application of suture material. Sutures are used for closure of fascia, hemostasis, intestinal anastomosis and enterotomy, urogenital tract surgery, surgery of the musculoskeletal system, vascular surgery, ocular surgery, plastic surgery, and neurosurgery, amongst other applications. Selection of a suture material should be based on an understanding of the physical and biological properties of the material, assessment of the wound, the healing rate of different tissues, and the patient's physical condition. Too often, selection has been governed by the personal preference and training experience of the surgeon and by economic reasons. Continued technological improvement in suture materials has seen an increase in the variety of sutures available. At the same time, there has been a refinement in suture needles leading to a greater range of options with more tissue-specific applications. The development of surgical staples and various tissue adhesives has also provided an alternative to sutures for wound closure. The challenge for surgeons now is to comprehend the enormous choice available and stay abreast of new developments.

The general performance of a suture material is based on its physical properties, handling characteristics, and biological properties. The ideal suture material could be utilized for any purpose and would be characterized by good handling characteristics, have good knot security and tensile strength, would be sterile, nonelectrolytic, nonferromagnetic, noncapillary, nonallergenic, and noncarcinogenic, and would not provide a medium for bacterial growth. It should be resistant to shrinkage and absorbed with minimal tissue reaction, easy to sterilize without alterations to its properties and be economical to use.[1]

There is no ideal suture material. A compromise on the selection of the best suture material for a specific application is made by the surgeon and is based on the circumstances. The selection of suture material will be influenced by the age, weight, and health status of the patient and the site of the wound. Tissue varies throughout the body in thickness, elasticity, speed of healing, and the tendency to scar. Concurrent diseases such as diabetes, heart disease, dermatitis, and the systemic use of medications such as steroids may affect healing. The presence of infection and individual wound characteristics may all influence the choice of suture material. Surgeons should aim to select a material that has a high strength to diameter ratio, is of consistent diameter, sterile, pliable, and has optimal tissue acceptance and predictability of performance.

6.636.2. Properties of Suture Materials

6.636.2.1. Tensile Strength

Tensile strength is defined by the US Pharmacopeia (USP) as the weight necessary to break a suture divided by the cross-sectional area of the suture.[2–4] The relationship between the weight necessary to break a suture and the suture's diameter is not linear.[5] Tensile strength can be measured using either dry or wet sutures. The tensile strength of wet sutures is more clinically relevant, given that sutures are implanted into tissue comprised of extracellular fluid. Effective tensile strength is an additional measurement that evaluates the tensile strength of a looped and knotted suture. Effective tensile strength will vary with suture material and knot type.[5–7] A suture should have and maintain adequate tensile strength for its specified purpose.[4]

6.636.2.2. Tissue Absorption

Absorption is a characteristic that refers to the ability of the body to degrade the suture over time. Absorbable sutures lose tensile strength as they undergo degradation and absorption. Nonabsorbable sutures are resistant, although susceptible, to degradation and, therefore, maintain their tensile strength longer. Generally speaking, absorbable sutures are often defined as sutures that lose most of their tensile strength within 60 days after implantation, while nonabsorbable sutures maintain their tensile strength for more than 60 days. However, the loss of tensile strength is independent of absorption.[8] For example, an absorbable suture may lose tensile strength rapidly but be absorbed slowly. Most foreign materials will eventually undergo some degree of degradation over time. The use of absorbable or nonabsorbable sutures and their rates of absorption are particularly relevant to the development of suture-related complications such as wound dehiscence, suture sinus formation and granulomas.[9]

Absorbable sutures are most commonly used in deeper tissues from where they are fully absorbed and are unlikely to cause long-term complications. Nonabsorbable sutures are most commonly used in the skin where they can be removed after they have completely supported healing.[10] Nonabsorbable sutures may be used in deeper tissues when there is systemic disease or impaired healing and extended support is required. Common situations where wound healing may be delayed include diabetes, corticosteroid therapy, malnutrition, stress, and systemic disease. If nonabsorbable sutures are used in these cases it is preferable that these be placed such that the sutures can be removed when healing is complete in order to avoid suture sinua formation.

6.636.2.3. Cross-Sectional Diameter

When selecting suture size, the smallest diameter required, according to the estimated tension on the suture line and natural tissue strength, is recommended.[3] A suture does not need to be stronger than the sutured tissues. Selecting the smallest diameter required will minimize trauma as the suture passes through tissue and will reduce the amount of foreign material left in the wound. The number of sutures placed will depend on the suture pattern. The aim is to appose the skin edges with the minimum number and the smallest diameter of sutures.

The most commonly used standard for recording suture size is that of the USP which denotes dimensions in a numerical scale. Suture diameters are specified in a descending grade when followed by 0 such that 2-0 is larger than 5-0. However, once the 0 is dropped suture size increases numerically such that number 3 suture is larger than number 1.

6.636.2.4. Coefficient of Friction

The coefficient of friction is a measure of how easily a suture passes through tissue[8] and relates to the amount of tissue trauma a suture causes. Smooth surfaces cause less trauma and are particularly relevant in delicate tissues like the eye. However, smoother sutures require greater tension to ensure good apposition of tissues and have lower knot security.

6.636.2.5. Knot Security and Strength

The least reliable component of any suture is the knot.[3] A knot should hold securely without fraying or cutting. Knot strength is determined by calculating the force necessary to make a knot slip or break.[2,8] This measure is directly proportional to the coefficient of friction. A knot stays tied because of the friction produced by one throw of the knot acting on another. A suture material with a high coefficient of friction has good knot security but tends to be abrasive and experiences unwelcome resistance or drag when being pulled through tissues.[11]

Knot security reflects that characteristic of a suture which allows it to be tied securely with a minimum number of throws per knot.[12] For safety, a knot should be tied with at least three throws with 3 mm ends. Extra throws should be employed when sutures with smoother surfaces are used so that the knot holds securely without fraying, cutting, or slipping.

Effective tensile strength denotes the force a suture strand can withstand before it breaks after it is knotted. Greater effective tensile strength acts to minimize the risk of wound dehiscence; however, the tensile strength of the knotted suture should not greatly exceed the tensile strength of the tissue.

Irrespective of the knot configuration and material, the weakest point in a surgical suture is the knot and the weakest point is the point immediately adjacent to the knot. The reduction in tensile strength may be 35–95%, depending on the suture material used.[7,13,14] When functional biomechanics are considered this is not surprising, given the effects of slippage of suture material through the knot and the unavoidable suture elongation that occurs as the knot is formed and tightened.

Due to excessive relative wound tension on the knot and the concern for suture failure due to knot slippage, there is a tendency to overcome these concerns by tying excessively tight knots. However, if tied too tight, surgical knots can cause local tissue necrosis, inhibit fibroblast proliferation, and cause excessive tissue overlap, which may all lead to reduced strength in the healed wound.[15]

A surgical knot represents the highest density of foreign material within a suture and the volume of the knot is directly related to the amount of surrounding inflammatory reaction.[13] If minimizing the inflammatory reaction is integral to wound healing and minimal scarring, the surgeon should minimize knot sizes without compromising the tensile strength of the suture line. This may mean selecting a different suture type.

6.636.2.6. Elasticity

Elasticity is the ability of a material to stretch during wound edema and return to its original length after the edema subsides.[8] Elasticity is a desirable property for a suture material. High elasticity allows the suture to stretch as wounds swell without cutting through the tissue edges and then to regain its normal shape and length as swelling subsides. This maintains good tissue apposition throughout healing.

6.636.2.7. Plasticity

Plasticity and elasticity are interrelated. Plasticity is defined as the capacity of a suture to stretch with wound edema but remain permanently altered or deformed after edema subsides.[2,8] Like elastic sutures, sutures with high plasticity do not cut through the tissue edges as a wound swells. However unlike elasticity, plasticity is generally an undesirable characteristic. Sutures with high plasticity may become too loose when swollen wounds return to normal, leading to impaired wound healing and wound dehiscence.

6.636.2.8. Memory

Memory is the capacity of a suture to assume a stable linear configuration after removal from packaging and after stretching. Sutures with greater memory are not pliable. This results in a suture with poor surgical handling characteristics and poor knot security.[5]

6.636.2.9. Handling

Elasticity, plasticity, and memory all contribute to handling quality or flexibility of the suture material.[3] The material should handle comfortably and naturally. Silk is the standard by which other sutures are compared because of its exceptional handling and ease of knot tying.[3,10] Flexible sutures are indicated for ligating vessels or performing continuous sutures while less flexible sutures like wire are not suitable for these purposes.

6.636.2.10. Tissue Reactivity

All suture materials are foreign materials and may elicit a tissue response, usually inflammation, which interferes with wound healing and potentially increases the risk of infection.[3]

The severity and duration of the reaction are related to the type, quantity, origins, and presentation of the suture.[5,16] An ideal suture material should be nonelectrolytic, noncapillary, nonallergenic, and noncarcinogenic, thus minimizing tissue reaction.

6.636.2.11. Origin and Physical Configuration

The USP has defined and standardized caliber which denotes dimensions from fine to coarse.[2] The caliber of a suture, as defined by the USP, is determined in millimeters and its size is expressed in a numeric scale where 10-0 is the smallest and 7 is the largest. Zero is the baseline average size suture. The smaller the caliber of the suture the more zeros. For example, 10-0 is the smallest size available and has a finer diameter than a 4-0 suture. Sutures larger than 1-0 are numbered 1–7. USP 7 is the largest suture available.

Suture material may be either natural or synthetic. Natural fibers such as surgical gut and silk cause a more intense inflammatory reaction compared to synthetic materials such as polypropylene. Sutures may be single stranded (monofilament) or multistranded (multifilament). Monofilament sutures are strong, have low tissue drag, are less likely to harbor infection, and are associated with significantly lower wound infection rates compared to multifilament sutures.[8,9] However, the handling characteristics of monofilament sutures are not as good as those of the multifilament sutures. Multifilament sutures can be braided or twisted, which improves handling but also increases tissue reactivity and infection by virtue of its increased capillarity.[12] Bacteria can be protected in the crevices of braided sutures, thus escaping phagocytosis.

6.636.2.12. Capillarity

Capillarity is the ability of sutures to spread liquid along their length and this becomes important when bacteria are present. Neutrophils and macrophages are too large to enter the interstices of the fibers, and so infection may persist even in the presence of systemically administered antimicrobials. Monofilaments show no capillarity while multifilament sutures have variable capillarity which is related to their composition. A braided nylon suture could harbor up to three times as many bacteria as a monofilament nylon suture.[9] Braided polyester has capillarity and the potential to promote the spread of infection while braided silk, coated with wax, does not do so.[17] Coating a suture with teflon, silicone, wax, paraffin-wax, and calcium stearate can reduce its capillarity and its coefficient of friction.

6.636.2.13. Fluid Absorption

Fluid absorption is different from capillarity but both contribute to an increased risk of bacterial contamination and its spread. Chromic gut and plain gut sutures, which are both monofilament sutures with no capillarity, have the highest fluid absorption.[17] The chemical nature and physical structure of a suture determine the level of fluid absorption; however, the chemical nature appears to be more important than the physical structure.[9] Natural sutures have greater capacity to absorb fluid compared to synthetic sutures which are more hydrophobic. Nevertheless, generally speaking, multifilament sutures have higher fluid absorption than monofilament sutures.[9]

6.636.2.14. Ease of Removal and Color

Sutures come dyed or undyed. Dying makes the suture more visible and easier to remove. Where removal is not necessary, undyed sutures may be less conspicuous.

6.636.3. Sutures

Suture material may be absorbable or nonabsorbable, natural or synthetic, monofilament or multifilament, according to its composition and structure. Absorbable sutures are generally defined as materials that lose their tensile strength within 60 days of implantation.[18] Natural materials are absorbed through enzymatic degradation, while newer synthetic absorbable sutures are absorbed by nonenzymatic hydrolysis. During nonenzymatic hydrolysis, the polymers are divided into monomers by direct water cleavage and the monomers are metabolized to carbon dioxide and water.[19] The advantage of the new synthetic sutures is that their rates of absorption during the process of nonenzymatic hydrolysis are not affected by the presence of inflammation or infection.[20]

Nonabsorbable suture materials are those materials that are not significantly degraded after implantation. These sutures are normally used where extended support is required. The preference is usually toward synthetic materials, which are less reactive than natural fibers. Natural fibers invoke a more significant inflammatory reaction.

The use of absorbable sutures can be beneficial when suture support is required only for a short time or when removal of the sutures is likely to be painful or difficult due to its anatomical location. Monofilament nonabsorbable sutures are preferred to multifilament varieties, particularly when infection may be a problem. The capillarity of multifilament suture increases the attraction and retention of bacteria thereby increasing the risk of infection and the subsequent development of draining sinus tracts from the wound.

6.636.3.1. Absorbable Suture Materials (Table 1)

6.636.3.1.1. Surgical gut

Surgical gut comes in many varieties and can be plain, chromic, or fast absorbing. These are natural absorbable multifilament sutures and are prepared from purified connective tissue derived from either the submucosa of sheep intestines or the serosal layer of bovine intestines. Strands of, mostly, purified collagen are twisted together to form sutures. Surgical gut was an early standard in surgery but has lost favor today because it has poor tensile strength and knot security compared to the newer synthetic suture materials.[12] In Europe, it is no longer used because of the risk of bovine spongiform encephalitis. Although it is predominantly collagen, surgical gut invokes a moderate inflammatory reaction in tissues that is probably associated with miscellaneous muscle fibers and mucoprotein that are also present within the suture.[21] It is broken down rapidly by a combination of enzymatic degradation and

Table 1 Characteristics and applications of absorbable suture materials

Suture type	*Strand*	*Raw material*	*Properties*	*Use*	*Disadvantages*
Surgical gut	Multifilament				
Plain (Gut)		Ovine intestinal submucosa or serosa of bovine intestine	Absorbed quickly by proteases. Retains strength for 7 days. Fully absorbed by 14 days Invokes moderate inflammatory reaction	Rarely	Sets up an inflammatory reaction Absorption increased in infected tissues Short holding time
Chromic (chromic gut)		Same as plain but treated with chromium salts to improve strength and decrease reactivity	Absorbed more slowly Retains strength for 14 days and absorbed at 21 days	Good handling characteristics Used in rapidly healing tissues like subcutaneous tissue May be desirable where inflammatory reactions and fibrous tissue are desired	Inflammatory reaction Poor knot security Variable absorption rate Loss of tensile strength High capillarity Occasional reaction
Polyglactin 910 (Vicryl)	Braided multifilament	Copolymer of glycolic and lactic acid coated with calcium stearate	Retains 65% of strength at 2 weeks and loses all strength at 3 weeks	Easier to handle than gut, minimal tissue reaction, higher strength, and can be used in infected wounds	May cut through friable tissue
Vicryl			Absorption by hydrolysis complete at 60–90 days		
Vicryl Rapide		Polyglactin 910 partially hydrolyzed in buffer	50% of tensile strength lost at 7–14 days and absorbed at 21 days	Designed to mimic performance of gut without the inflammatory reaction	
Polyglycolic acid (Dexon, Dexon II)	Braided multifilament	Synthetic homopolymer of glycolic acid. Dexon II is coated with polycaprolate	Retains 89% of strength at 7 days, 63% at 14 days 17% at 21 days and absorbed at 90–120 days by hydrolysis	Similar properties to Vicryl. Wide variety of uses in normal and contaminated tissues. Useful for cesarean and intestinal anastomosis	Breakdown enhanced in urine and oral cavity. Uncoated form has high coefficient of friction
Poliglecaprone 25 (Monocryl)	Monofilament	Copolymer of glycolide and epsilon-caprolactone	Looses 30–40% of strength at 14 days, no strength at 3 weeks and absorbed at 90–120 days by hydrolysis	Easy to handle, good knot security, and minimal tissues reactivity. General tissue approximation	Should not be used in area of delayed healing
Polydioxanone (PDS II)	Monofilament	Polymer of paradioxanone	Retains 74% of tensile strength at 2 weeks and 25% at 6 weeks. Absorbed at 6–7 months by hydrolysis	Used where approximation of tissues needed for extended periods. Useful in infected tissues	Poor knot security and poor handling characteristics because of stiffness and memory
Polyglycolide–trimethylene carbonate (Maxon)	Monofilament	Copolymer of glycolic acid and trimethylene	Retains tensile strength for 42–92 days compared to 64–80 days for PDS. Absorbed by hydrolysis at 6 months	Better knot security than PDS II. Similar applications to PDS II	Poorer handling characteristics compared to PDS II
Caprosyn (caprosyn)	Monofilament	Composite of glycolide, caprolactone, trimethylene carbonate and lactide	Retains 50–60% tensile strength at 5 days and 0% at 3 weeks. Fully absorbed by 56 days	Superior handling, tensile strength, and knot security compared to gut and greater resistance to infection	Short retention time confined its use to plastic surgery, obstetrics and gynecology where rapid absorption and minimal scarring are important

phagocytosis. Plain gut also attracts small lymphocytes which enhance absorption.[22,23] The rate of absorption is significantly increased in the presence of infection and in tissues with high levels of proteolytic enzymes.[24]

Plain gut is an untreated preparation that retains its strength for 7 days and is fully absorbed in 10–14 days. Chromic gut is tanned with chromic salts to reduce the tissue reaction and to delay its breakdown. This treatment increases the holding time to ~14 days and delays absorption to 21 days. Chromic gut is difficult to handle, has a tendency to fray and has poor knot security when wet.[1] It is important to place four throws at the start of a continuous suture and five throws at the end.[25] Fast absorbing plain gut is heat treated to increase its rate of absorption; however, this also reduces suture strength compared to similar gauge, plain gut. It is commonly used in epidermal suturing where sutures are required for only 5–7 days and suture removal is difficult. Gut is generally inexpensive, making it economically attractive, but has now largely been superseded by newer synthetic absorbable sutures that have fewer complications.

6.636.3.1.2. Polyglactin 910 (coated Vicryl, Vicryl Rapide, and coated Vicryl Plus)

Vicryl was the second synthetic absorbable suture introduced after Dexon (polyglycolic acid). Vicryl is a synthetic, braided, absorbable suture made of polyglactin 910, a copolymer of L-lactide (10%) and glycolide (90%), and is coated with calcium stearate (**Figure 1**). Vicryl is sterilized by ethylene oxide. It comes in both clear and dyed forms. Vicryl is similar to Dexon in many of its characteristics. It has a greater initial tensile strength than surgical gut but is only marginally stronger than Dexon. This difference is clinically insignificant. Vicyl retains 50–65% of its tensile strength at 2 weeks, but by 3 weeks has no residual strength.[9,26] It elicits a minimal inflammatory reaction with complete absorption occurring by hydrolysis in 60–90 days. It has good handling characteristics and size to strength ratio, making it suitable for use in a variety of tissues, including infected wounds.[26] It comes in a range of sizes.

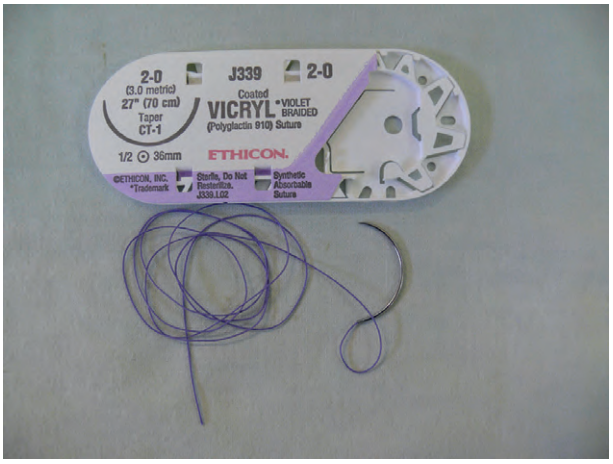

Figure 1 Polyglactin 910 is a commonly used absorbable braided multifilament suture which has better handling characteristics and is stronger than surgical gut.

Vicryl Rapide is a synthetic, absorbable, multifilament suture derived from polyglactin 910 that is partially hydrolyzed in a buffer solution and sterilized with gamma radiation. This processing enhances its absorption.[9] It has approximately 66% of the initial tensile strength of coated Vicryl.[27] It loses its tensile strength much faster than Vicryl and is used in the oral cavity as it will start to slough in 7–10 days.[1] In other tissues, strength is lost in 7–14 days and its absorption is complete by 21 days. It was designed to mimic the performance characteristics of surgical gut without inciting the inflammatory reaction associated with gut. It is suitable for tissues that heal with a rapid increase in tensile strength and long-term support is not required, such as in the gastrointestinal and urinary tracts.[1]

Coated Vicryl Plus employs a coating of the antimicrobial Triclosan which is thought to inhibit bacterial colonization of the braided suture and thus minimize the pain associated with subclinical infection.[8,9] It is often used in pediatric surgery because its antibacterial properties reduce the effects of pain in infants.

6.636.3.1.3. Polyglycolic acid (Dexon, Dexon II)

Polyglycolic acid was the first commercially available absorbable synthetic suture. It is a braided, synthetic absorbable suture made from a synthetic homopolymer of glycolic (hydroacetic) acid.[26] Dexon II has a coating of polycaprolate which enhances its handling characteristics by reducing the coefficient of friction. Polyglycolic acid is initially stronger than surgical gut but has less tensile strength compared to other synthetic absorbable sutures. It retains 89% of its tensile strength at 7 days, 63% at 14 days, 17% at 21 days, and is completely absorbed by 90–120 days.[28] Dexon loses its functional properties faster and has a lower knot breaking strength compared to Vicryl.[9]

Dexon is broken down by hydrolysis rather than enzymatic breakdown, thus leading to less tissue reaction and delayed absorption compared to surgical gut. The end products of breakdown do not provide growth materials for bacteria.[29,30] Polyglycolic acid has been reported to be unsuitable for use in the oral cavity or in the presence of infected urine as the alkaline pH increases its rate of breakdown.[29,30] It is suitable for use where extended approximation of tissues under stress is not required, such as intestinal anastomosis or a cesarean section.[31,32]

6.636.3.1.4. Poliglecaprone (Monocryl)

Poliglecaprone is a synthetic monofilament absorbable suture made of a copolymer of glycolide and ε-caprolactone. The lubricant coating decreases the coefficient of friction. It is available in the dyed or the undyed form. It is one of the strongest absorbable suture materials available, allowing the selection of suture sizes that are one to two times smaller than would ordinarily be chosen.[8,33] However, it rapidly loses its strength after implantation.[24] Dyed monocryl retains 30–40% of its tensile strength at 2 weeks whereas undyed monocryl retains only 25% at 2 weeks. By 3 weeks, there is no residual strength, absorption is by hydrolysis and is complete by 90–120 days.[9]

Monocryl elicits minimal tissue reaction, has good knot security and excellent handling characteristics as it lacks stiffness, and has less memory compared to other synthetic

absorbable sutures. Compared to Vicryl Rapide in a subcuticular closure, monocryl resulted in significantly smaller, less reactive scars, and a reduced tendency to produce hypertrophic scar formation.[34] It is recommended for general soft tissue approximation, including subcutaneous closures.

6.636.3.1.5. Polydioxanone

Polydioxanone (PDS II) is a synthetic, absorbable, monofilament suture made from a polymer of paradioxanone (Figure 2). It has greater initial tensile strength than polyglycolic acid and polyglactin 910 but has the poorest knot security of all the synthetic absorbable sutures.[24] The suture retains 74% of its tensile strength after 2 weeks, 50% after 4 weeks, and 25% after 6 weeks. There is minimal absorption by 90 days and absorption is not complete until 6–7 months after implantation.[9] This retention of strength after implantation is an advantage over other synthetic absorbable sutures and is useful wherever extended approximation of tissues (up to 6 weeks), under tension, is required.[35] PDS II is stiff and more difficult to handle than Dexon or Vicryl, but slides easily through tissue. PDS II was developed to improve the handling characteristics of the original form. It has low reactivity and maintains integrity in infected tissues and in urine and is often used in bladder surgery.[36] Its long retention time may act as a nidus for calculus formation in patients with a history of urinary calculi. However, it is suitable for use in a wide variety of tissues.[1]

6.636.3.1.6. Polyglycolide–trimethylene carbosnate (Maxon)

Maxon is a synthetic, absorbable, monofilament copolymer of glycolide and trimethylene carbonate. It has better handling properties than polyglactin 910 and polypropylene but is considered more difficult to handle than polydioxanone.[37,38]. Maxon is reported to have better knot security than PDS II.[38] It has greater initial tensile strength after implantation than most other absorbable sutures, but after implantation, the decrease in tensile strength is 81% at 14 days, 59% at 28 days, and 30% at 42 days, which is similar to PDS II.[12,39] On an average, Maxon retains its tensile strength for 42–92 days compared to 64–80 days for PDS II.[9] It is absorbed by hydrolysis like the other synthetic absorbable sutures and, like PDS II, loss of tensile strength occurs well before there is a significant reduction in mass. Absorption is complete by 6 months.[8]

Figure 2 Polydioxanone is a commonly used absorbable monofilament suture useful in infected tissues where approximation of tissues for extended periods is desired. However, it is stiff and has poor handling characteristics and knot security.

6.636.3.1.7. Caprosyn

Caprosyn is a monofilament, synthetic, absorbable suture prepared from polyglytone 6211 synthetic polyester which is composed of glycolide, caprolactone, trimethylene carbonate, and lactide.[40] This recently developed suture material undergoes rapid absorption. Caprosyn retains a minimum of 50–60% of knot strength at 5 days postimplantation and a minimum of 20–30% of knot strength at 10 days. All of its tensile strength is lost by 21 days after implantation and it is fully absorbed by 56 days. Caprosyn has been compared to chromic gut.[40] Caprosyn is superior in tensile strength to chromic gut but has comparable resistance to wound disruption. Caprosyn has far superior handling characteristics, better tissue approximation, and improved knot security. Caprosyn and chromic gut are absorbed at a similar rate but caprosyn has a greater resistance to infection. It is designed for plastic surgery, obstetrics and gynecology, and urology, where the benefits of rapid absorption and minimal scarring may be important.

6.636.3.2. Nonabsorbable Suture Materials (Table 2)

6.636.3.2.1. Silk (Mersilk, Perma-Hand)

Silk was introduced in the late 1800s as an alternative to gut. It is a natural nonabsorbable braided suture, produced by silkworm larvae, and made of protein filaments. These are braided for ease of handling and dyed for greater visibility. Silk evokes an inflammatory response that is second only to surgical gut and has significant capillarity. Silk may be coated by immersion in oil, wax, or silicone. Coating silk reduces capillarity at the expense of knot security.[18] Silk has superb handling characteristics and is the benchmark for comparison of handling characteristics of other suture materials. It has higher initial tensile strength compared to gut but is not as strong as most of the synthetic sutures. It retains 50% of tensile strength at 1 year and complete absorption may occur by 2 years.[9,24] Its braided configuration allows blood and serum to accumulate between its fibers and this predisposes it to infection and tissue ingrowth. Along with its tendency to produce an inflammatory reaction, it has also been shown to enhance the development of *Staphylococcal* spp. infection by up to 1000 times.[24] It may cause ulceration if used in the intestine or other hollow viscera and predisposes to calculi formation in the bladder and bile duct.[41] It is often used as a stay suture for retraction during surgery and for cutaneous surgery around the lips and eyelids.[2,5,12]

6.636.3.2.2. Polybutester (Novafil)

Polybutester is formed from a monofilament of polybutylene terephthalate and polytetramethylene ether glycol.[1,24] It was designed to combine the advantages of polypropylene and polyester. It has greater strength, less stiffness, and a lower coefficient of friction than either polypropylene or nylon.[12] It displays good handling characteristics and knot security

Table 2 Characteristics and applications for nonabsorbable suture materials

Suture type	*Strand*	*Raw material*	*Properties*	*Use*	*Disadvantages*
Silk (Mersilk, Permahand)	Braided multifilament	Protein filaments spun by silkworm larvae. May come coated in wax, silicone or immersion in oil	Looses 50% tensile strength at 1 year and complete absorption by 2 years	Excellent handling characteristics but invokes a marked inflammatory response. High capillarity. Used in ophthalmic surgery and as stay sutures	Not for use in contaminated tissues or intestinal anastomosis. Enhances infection in tissues
Polybutester (Novafil)	Monofilament	Copolymer of polybutylene terephthalate and polytetramethylene ether glycol	No appreciable loss of tensile strength. Designed to combine advantages of polypropylene and polyester	Excellent strength, elastic, good handling characteristics, good knot security while eliciting little tissue reaction. Useful in tendons and slow healing tissues	
Polyester (Mersilene, Ethibond, Surgilene, Surgidac)	Braided multifilament	Synthetic material made from condensation and polymerization. May be coated with polybutilate	Tensile strength second only to metallic sutures. No appreciable loss of strength. Good handling and knot security	Used to support slow healing tissues	Noncoated forms have high coefficient of friction. Not to be used in contaminated tissues, expensive
Nylon (Ethilon, Nurolon, Dermalon, Monsof, Supramid, Monosol, Surgilon)	Monofilament or multifilament	Polyamide thermoplastic made from hexamethylenediamine and adipic acid	Monofilament retains 72% of tensile strength after implantation and lose up to 50% by 2 years. Multifilament looses all strength by 6 months. Absorbed by hydrolysis	Inert, excellent elasticity makes it excellent in skin. Low capillarity and hydrolyses to antibacterial products so good in contaminated tissues	Poor handling characteristics, significant memory, and poor knot security. Multifilament forms have improved handling characteristics
Polypropylene (Prolene)	Monofilament	Catalytic polymerization of polypropylene	Retains tensile strength after implantation. Low tissue reactivity, least thrombogenic of all sutures. High plasticity	Excellent for skin and often used in vascular surgery	Poor knot security and poor handling characteristics
ePFTE Gore-Tex CV4	Monofilament	Polytetrafluroethylene	Retains tensile strength and is not degraded	Excellent handling characteristics	
Stainless steel	Monofilament or multifilament	Chromium and molybdenum alloy	Biologically inert and offers the greatest strength of all suture materials	Commonly used in orthopedic surgery and tendon and ligament repair Useful in slow healing or infected tissues	Can cut through tissues so not useful in highly mobile sites, poor handling characteristics

while eliciting only minimal tissue reaction.[42] As it is a monofilament it is less likely to harbor bacteria. It has a high degree of elastic stretch under low loads, thus offering distinct advantages over other nonabsorbable sutures.[43] It is able to stretch to 50% of its original length at a load of 25% of its breaking point.[12,43] This elasticity provides clinical advantages as it allows substantial swelling without cutting into tissue and maintains tissue approximation throughout healing. Polybutester is suitable for repair of tissues such as tendons where its elastic properties may be an advantage, particularly in the early phases of healing.[1]

6.636.3.2.3. Braided polyester (Mersilene, Ethibond, Surgidac)

Polyester is a nonabsorbable multifilament suture material formed by condensation polymerization (Figure 3). It may come coated with polybutilate (Ethibond) or in the uncoated (Mersilene) form. The uncoated forms have a high coefficient of friction and drag through tissue. The coated form was developed to overcome this problem but the coating has been noted to crack after implantation and may induce inflammatory reactions.[2,9,27] Braided polyesters were developed to induce minimal tissue reactivity while maintaining the good handling properties of braided multifilament sutures. While showing reduced tissue reactivity compared to other multifilament sutures, these braided polyesters do not match the inert qualities of other synthetic nonabsorbable monofilament sutures.[1] They generally show poor knot security, particularly the coated forms, with five throws suggested as a minimum number.[1] Braided polyesters are stronger than silk or gut and are second in tensile strength only to metal sutures.[44] They lose little tensile strength over time. They are more expensive than most other sutures and provide no significant advantages over other less expensive sutures, and so are not commonly used. Braided polyesters should not be used in the presence of contamination and infection as bacteria may become trapped between the fibers and isolated from phagocytic cells, leading to draining sinus tracts.

Ethibond suture material has a polybutilate coating which improves the handling characteristics and reduces the high coefficient of friction compared to uncoated forms. Polyester sutures show no significant loss of tensile strength over time.

6.636.3.2.4. Nylon (Ethilon, Monosof, Nurolon, Surgilon, Supramid)

Nylon is a synthetic, nonabsorbable, monofilament made of a chemically inert polyamide thermoplastic made from hexamethylenediamine and adipic acid.[1] It is available as either a monofilament (Ethilon, Monosof) or as a multifilament (Nurolon, Surgilon, Supramid) suture. The monofilament form is far more common and less susceptible to infection (Figure 4). The monofilament retains 72% of its tensile strength immediately after implantation, after which the degradation stabilizes.[45,46] It will lose up to 30–50% of its tensile strength by 2 years due to progressive hydrolysis over time.[1,9,47] Owing to nylon's chemically inert characteristics and slow hydrolysis, it induces less of an inflammatory reaction than polyglycolic acid sutures.[45] It maintains a high level of elasticity after implantation in tissue, an important consideration if tissue edema and inflammation develop. These properties make nylon the most commonly used skin suture.[10] The main disadvantages of nylon are its poor handling characteristics and knot security.[35] Nylon has significant memory and is not very pliable making it difficult to work with. Alcohol-soaked monofilaments improve handling. Multifilament forms tend to have improved handling characteristics and knot security, but at the expense of capillarity.[27]

Supramid is a twisted multifilament, polymerized caprolactam enclosed in a smooth sheet of proteinaceous material. It has superior tensile strength compared to other nylon products but tends to have poorer knot security.[24]

6.636.3.2.5. Polypropylene (Prolene, Surgilene)

This product is a synthetic, nonabsorbable, monofilament suture made by the catalytic polymerization of polypropylene (Figure 5). Polypropylene has the greatest tensile strength of all synthetic nonabsorbable suture materials and no appreciable reduction in strength after implantation.[47,48] It has low tissue

Figure 3 Polyester suture is a braided multifilament, nonabsorbable suture with tensile strength second only to metallic sutures. Polyester is commonly used to support slow healing tissues.

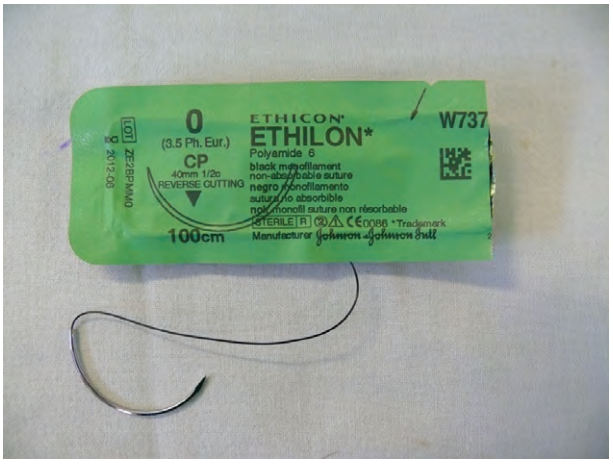

Figure 4 Nylon is a nonabsorbable monofilament suture which is most commonly used for skin closure. It has excellent elasticity, low capillarity, and hydrolyses to antibacterial products so is useful in contaminated tissues. However, it has poor handling characteristics, significant memory, and poor knot security.

reactivity and is the least thrombogenic suture material, and is, therefore, often used in vascular surgery.[49] Polypropylene has high plasticity and is useful in accommodating wound edema or swelling without cutting through the skin; however, once it is stretched it does lose its form. It has a very smooth surface giving it a low coefficient of friction; however, this feature along with high memory contributes to lower knot security.[27] If the knots are set firmly, polypropylene will flatten where strands cross each other and provide greater knot stability and greater knot strength. The longevity without significant loss of tensile strength, its resistance to infection and low tissue reactivity make it a suitable suture for the skin.[20]

6.636.3.2.6. ePFTE (Gore-Tex CV4)

Gore-Tex CV4 is a synthetic, nonabsorbable monofilament suture made from polytetrafluroethylene that has been expanded to produce a porous microstructure that is 50% air by volume. This suture is white in color and provokes minimal tissue response with cellular ingrowth. The tensile strength does not change *in vivo*. It is soft and supple, affording excellent handling characteristics. Gore-Tex CV4 does not degrade in the presence of infection and is not subject to the action of tissue enzymes.[9]

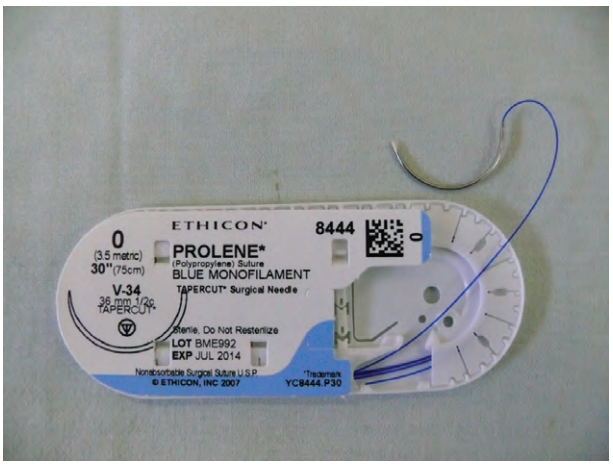

Figure 5 Polypropylene is a nonabsorbable monofilament suture that is commonly used in skin. It retains tensile strength after implantation and has low tissue reactivity making it the least thrombogenic of all sutures and useful for vascular surgery. It has high plasticity, poor handling characteristics, and poor knot security.

6.636.3.2.7. Stainless steel

Stainless steel is an alloy of chromium and molybdenum, available as either a monofilament or a multifilament suture. It is biologically inert and offers the greatest strength of all the suture materials.[27] It is most commonly used in orthopedic surgery but has also been used in tendon or ligament repair. It is used in contaminated and infected wounds such as abdominal wall hernias following wound infection in horses.[1,29,50,51] Stainless steel sutures have a tendency to cut through tissue and have poor handling characteristics.[35] Movement over the ends of the knot can cause tissue necrosis.[26]

6.636.3.3. Other Sutures

6.636.3.3.1. Barbed suture (Quill SRS, Monderm, Coveidin)

This is a knotless, synthetic suture that is available in a variety of nonabsorbable and absorbable materials; however, to date, all sutures are monofilaments. The first approved barbed suture was a bidirectional barbed polydioxanone. From that time onwards, bidirectional barbed suture has also become available in poliglecaprone 25, and is now available as a nonabsorbable suture in nylon and polypropylene.

Barbed sutures are effective due to their bidirectional fixation within the wound. The barbs are arranged around the suture, in opposite directions, on each side of a short retainer free segment. This is achieved by a micromachining technique that cuts barbs into the monofilament fibers around the circumference in a helical pattern. The barbs are separated by a distance of 0.88–0.98 mm. Closure begins at the midpoint of the wound and the suturing extendsin two directions

Table 3 Suggested suture selection for specific tissues

Skin	Monofilament nonabsorbable sutures such as nylon, polypropylene, and polybutester are recommended. Alternatively, the monofilament absorbable sutures with longer retention times such as polydioxanone or polyglycolide–trimethylene carbonate may be used where removal of sutures may be difficult. Stainless steel staples save time in larger incisions Avoid reactive or high capillarity sutures
Subcutis	Any of the synthetic absorbable sutures. Where approximation of tissues is required only for a short time polyglycolic acid or polyglactin 910 are commonly used. Where longer retention time for slower healing tissues then polydioxanone or polyglycolide–trimethylene carbonate may be used
Fascia	Synthetic, absorbable sutures with are recommended. Applications for subcuticular tissues apply. If prolonged strength is required, synthetic nonabsorbable sutures can be used but run the risk of suture sinus formation if contaminated. They should be placed so that they can be easily removed if needed
Muscle	Synthetic absorbable or nonabsorbable sutures may be used. Nylon and polypropylene are recommended for use in cardiac muscle because of their superior mechanical properties
Hollow viscus	Polyglycolic acid, polyglactin 910, polydioxanone, polyglycolide–trimethylene carbonate, poliglecaprone 25, caprosyn, and monofilament nonabsorbable sutures may be used in viscera. Polyglycolic acid is generally considered unsuitable for the bladder because it loses its tensile strength faster in urine. Polydioxanone may act as a nidus for calculi production because of its long half-life
Tendon	Nylon and stainless steel are often recommended. Polydioxanone, polyglycolide–trimethylene carbonate and polybutester may also be used where adhesion formation associated with prolonged presence of suture is a potential complication
Blood vessel	Polypropylene is the least thrombogenic of all sutures and is recommended. Nylon and coated polyester have also been used
Nerve	Nylon and polypropylene are used because they have the least tissues reactivity

with needles swaged onto each end. Barbs within the suture distribute tension evenly across the wound, thus eliminating the need for knots.[9] This material facilitates the use of a continuous suturing technique rather than the simple interrupted sutures in deeper tissue layers, thereby increasing the ease, speed, and economy of placement. As the barbs cannot slip backward, they do not leave gaps in areas of tension, allowing subcuticular closure with fewer primary buried sutures and significant time saving.

Owing to a decrease in the effective diameter during micromachining, generally, a barbed suture is rated as equivalent to 1 USP suture size greater than its conventional equivalent. So a 2-0 barbed suture will rate as a 3-0 conventional suture. However, it is worth noting that conventional sutures lose tensile strength at and around the knots while a barbed suture is knotless and is not predisposed to weak areas. When corrected for size, a barbed suture demonstrates equal, if not better, *in vivo* wound breaking strengths compared to conventional monofilament sutures.[13] Furthermore, elimination of the knot reduces the amount of foreign material within the wound and tissue reaction. The holding power and apposition of tissue are improved because the tension is distributed more evenly across the suture. This is expected to create a more watertight seal and can avoid uneven healing across the suture line.[13]

More recently, a unidirectional barbed suture has been released, which has a loop at the distal end for initial suture fastening. There is some conjecture that necrosis of the tissue at the loop end could limit the wound strength of this configuration of suture. Currently available barbed sutures are produced only in a limited number of suture materials and in limited suture and needle sizes.

6.636.4. Staples

Tissue staples provide a quick and effective alternative to manual suturing.[52] They are used in procedures such as gastrointestinal surgery, liver and lung resection, and reproductive surgery but may have wider applications. Skin staplers place individual rectangular-shaped sutures in a single row while staples used in other tissues place at least a double row of staples in a staggered 'B' configuration.[27] Stapling instruments reduce tissue handling, decrease surgery time, minimize contamination, provide secure visceral, vascular, and dermal closures, and preserve blood supply.[24] However, they may be ineffective if used on excessively thick tissues, and provide ineffective haemostasis in large blood vessels.[1]

6.636.4.1. Skin Staples

Skin staples come in both nonabsorbable and absorbable forms.

6.636.4.1.1. Nonabsorbable staples (Proximate, Royal Autosuture)

These staples are made of stainless steel and have the highest tensile strength. An additional advantage is that they come with low tissue reactivity.[12] Metal staples come in two sizes, regular (4.8–6.1 mm) and wide (6.5–7 mm), and are discharged from lightweight cartridges (Figure 6). Prior to application they have a straight cross member and straight or curved legs. After discharge, the cross member is bent over, thus crimping it at two sites and bringing the legs together to form a rectangular shape that is narrower than the original staple.[53] They provide a faster method of closure compared to sutures and evert wound edges without strangulation of tissue, thereby reducing the incidence of cross hatch scarring.[9,54] Staples may provide a superior cosmetic result in some circumstances and have a lower incidence of complications in contaminated wounds.[9]

6.636.4.1.2. Absorbable staples (Insorb)

This staple is made of an absorbable copolymer, consisting predominantly of polylactide and a lesser component of polyglycolide. These subcuticular staples provide a novel method of skin closure. They lose 60% of their holding strength within 2 weeks and have a half-life of 10 weeks.[53] They produce less severe inflammation at 7–21 days after surgery compared to subcuticular suture or stainless steel skin staples.[55] They are useful in contaminated wounds where, compared to Vicryl sutures, they have a lower incidence of infection.[8] Many studies have produced variable results when comparing the performance of absorbable and stainless steel staples with respect to wound infection.[9]

6.636.4.2. Ligatures

Instruments for vascular ligations are designed for vascular bundles that can be compressed to 5 or 7 mm. The device is pistol-shaped and, when activated, fires two stainless steel, titanium, or absorbable copolymer staples. The device transects the vessel between the two staples. These U-shaped staples come in two sizes, regular and wide. Regular staples are 5.79 mm wide and 5.23 mm tall, closing to a width of 5.33 mm. Wide staples are 8 mm wide and 7.22 mm tall,

Figure 6 Autosuturing devices contain stainless steel staples useful for skin closure. These staples have high tensile strength and low tissue reactivity and provide faster closure of surgical wounds. After discharge, the cross member of the original staple is bent over crimping it at two sites bringing the legs together to form a shape that is narrower than the original staple.

with a final closure width of 7.3 mm. Regular staples are set 6.35 mm apart and the wide staples are set 9.53 mm apart. Vascular clips are useful in procedures which require rapid or extensive vascular occlusion, such as during splenectomies or in intestinal resections where extensive ligation of mesenteric vessels may be required. The vessel should be isolated from the surrounding tissue to allow the most effective discharge of the device. If double ligation is required or if the vessel cannot be crushed to 7.5 mm the advantage of the ligatures (LDS) may be lost.

6.636.4.3. Stapling Devices in Abdominal and Thoracic Surgery

These devices come as disposable or reusable instruments that create an inverted or everted tissue closure that is secured by two or more rows of B-shaped stainless steel, titanium, or, occasionally, absorbable staples. The B-shaped configuration is noncrushing while compressing tissues, thereby creating some hemostasis without necrosis.

The GIA (gastrointestinal anastomosis) or ILA (intestinal linear anastomosis) devices come with disposable cartridges that fire two double rows of staggered titanium staples (Figure 7). The staple lines are set 3.5 mm apart and the device cuts between the second and third rows of staples, creating an incision length 8 mm short of the last staple at the distal end.[53,56] The GIA cartridges come in a variety of sizes, including 50, 60, 80, and 90 mm lengths (Figure 8), while the ILA cartridges are available in 52 and 100 mm lengths. Staples are 4.0 mm wide and come in 4.8 and 3.8 mm leg lengths that compress to 2.0 and 1.5 mm, respectively.[53] Discharge of the device results in an inverting, side-to-side anastomosis of two hollow organs such as the small intestine. However, these devices have also been used to resect diseased tissues in various organs, including the lung and intestine. The device is placed across the junction between the healthy and diseased tissues to seal both sides with a double row of staples. The diseased portion of tissue can be removed safely without leakage of body fluids. The sealed stump of the healthy tissue can then be oversewn, if required, to reinforce the seal.

Circular stapling devices are also available for intestinal anastomosis. The end-to-end anastomosing (EEA) devices contain 4-mm-wide staples with 4.8-mm leg length that close down to a height of 2.0 mm. Reusable staple devices are straight and come in lengths of 25, 28, and 31 mm. A circular cartridge is attached to the arm and these are available in diameters of 25, 28.6, and 31.6 mm with knife diameters of 15, 18, and 21.2 mm, respectively. Single use curved EEA devices come with circular cartridge diameters of 21.3, 25, 28.7, 31.6, and 34.1 mm and with knife diameters of 11.5, 15, 18, 21.2, and 23.6 mm.[53] The appropriate size of instrument for the lumen is gauged by ovoid sizers which can also be used to stretch the intestine. Once the correct diameter is determined, the device is passed into the lumen of the intestine, and the two edges of the intestine to be anastomosed are secured around the cartridge using a purse string suture. The device fires a circumferential double row of B-shaped titanium staples creating an inverted anastomosis between the two ends. The redundant tissue inside the staple line is removed simultaneously by the knife.

The TA (thoracoabdominal) staplers fire two or more rows of B-shaped titanium staples to seal the thoracic and abdominal organs. Cartridge sizes are 30, 55, or 90 mm for reusable devices and 30, 45, 60, and 90 mm for disposable devices. The cartridges generally fire two rows of staples; however, the 90 mm cartridges are also available with three or four rows of staples. The staples are 4.0 mm in width but have a leg length of 4.8 and 3.5 mm, closing down to 2 and 1.5 mm, respectively. The cartridges come in a U-shaped configuration that can be inserted into a long-handled device, allowing access to difficult areas (Figure 9). These devices are available with rotating and articulating heads which further improve access in tight areas.[57] The device does not automatically cut, however, after

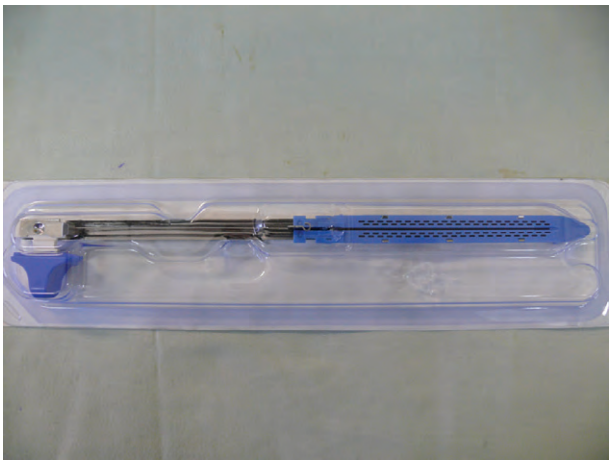

Figure 7 The disposable cartridges for the gastrointestinal anastomosing device contain two rows of staples either with 3.8 or 4.8 mm leg lengths. The staples are set 3.5 mm apart. When fired the staples compress to 1.5 and 2.0 mm, respectively. A blade cuts between the second and third rows of the staples creating a stoma 8 mm short of the last staple.

Figure 8 The gastrointestinal anastomosing (GIA) device comes in a variety of lengths with disposable cartridges that result in an inverting side-to-side anastomosis of tow hollow organs such as small intestine. They can also be used to resect and remove diseased tissues without leakage of body fluids.

Figure 9 The thoracoabdominal (TA) staplers come in a variety of sizes. The cartridges usually fire two rows of staples; however, the 90 mm cartridges are also available with three or four rows of staples. The devices come with a leg length of 3.8 or 4.8 mm closing down to 1.5 and 2 cm, respectively. The design of the handles allow access to difficult areas and devices are available with rotating and articulating heads further improving access to tight area.

discharging the staples; the instrument head can be used as a guide for transection, particularly in inaccessible areas.[53]

6.636.5. Surgical Needles

Needles are manufactured from stainless steel alloys which have excellent resistance to corrosion.[58] All true stainless steels contain a small amount of chromium which allows a thin protective surface layer of chromium oxide to form when the steel is exposed to oxygen. Maraging stainless steel with nickel provides a combination of high strength and toughness. The basic principle of maraging centers around strengthening the martenistic matrices so that the planes of atoms in the stainless steel are prevented from sliding over each other. A high nickel maraging stainless steel like S45500 is composed of 7.5–9.5% nickel, 0.8–1.4% titanium, and 11–25% chromium. High nickel maraging stainless steel is used to create surgical needles with greater strength and ductility. These needles show greater resistance to bending and breakage than stainless steel needles without nickel.

Surgical needles have a distinctive anatomy and characteristics such as shape, size, point, and method of suture attachment. Ideally, needles should be made of high quality stainless steel and be suitable to meet the needs of the surgery. They should be of the smallest diameter required to penetrate the tissue without bending, be able to be passed through both sides of the incision with minimal tissue trauma, be sharp enough to penetrate tissue with minimal resistance, be stable in the needle holder, and be sterile and corrosion resistant to minimize chances of infection. Some needles may be coated with silicone to enhance passage through tissue. When selecting a needle the surgeon should consider the thickness and accessibility of the tissue to be sutured, the importance of attaining a good cosmetic result, and the size of the suture material.[9,41]

6.636.5.1. Anatomy of a Needle

Needles have distinct features. The needle point is the portion of the needle that extends from the tip to the maximum cross-section of the body. The body incorporates most of the needle length. The importance of the body is that it is the point of engagement between the needle and needle holder during the transmission of force from the needle to the tip. Diameter, radius, geometry, and the material of the needle are all features of the body that determine bending moment, ultimate moment, surgical yield moment, and needle ductility.

Needles are available as eyed needles where the suture needs to be threaded onto the needles or as swaged needles where the suture is attached to the end. A channel swage is where the needle is created with a channel into which the suture is introduced and the channel is crimped on the suture. The swage, in this configuration, is wider than the body of the needle. A drill swage is where the material is removed from the center of the needle and the needle is crimped onto the suture. In this case, the swage is of a smaller diameter than the body of the needle. Swaged needles are less traumatic to tissues, easier to handle, and are always sharp because they are used once and then discarded.[41]

Eyed needles are reusable and less expensive than swaged needles, but cause greater trauma during suture placement. The larger diameter of the eye compared to the body of the needle and the need to loop a double strand of suture creates substantial trauma as the suture is pulled through the tissue. This effect is compounded when the needle becomes dull with reuse. The eye may be closed or French. A closed eye may be round, oblong, or square. A French eye is open to the end of the needle through a slit with ridges that catch and hold the suture in place. Increased handling of suture when threading a nonswaged needle can weaken the suture, or cause fraying or damage. Nonswaged needles are also less likely to become unthreaded during suturing compared to swaged needles.

Each needle is identified by various measurements. Chord length is the direct linear distance from the point of the curved needle to the swage (bite width). The needle length is the distance measured along the needle from the point to the swage. Needle length is the measurement supplied on suture packages. The radius is the distance from the body of the needle to the center of the circle along which the needle curves. The diameter is the thickness of the needle.

6.636.5.2. Point Types

The ability of the needle to penetrate tissue depends on the shape of the point and body of the needle.[41]

- Cutting

  A cutting needle has at least two, opposing, cutting edges because the point is usually triangular. Cutting needles are designed for penetration through dense, irregular, and relatively thick tissues. They are ideal for skin sutures. Conventional cutting needles have three cutting edges arranged in a triangle. The third cutting edge is on the inner or concave curvature.

  Reverse cutting needles are the same as conventional cutting needles except that the third cutting edge is on the

outside or convex curvature. These needles are stronger than the conventional cutting needles and have a lower chance of cutting through the edge of the tissue. They are designed for tough tissues but are also beneficial for cosmetic and ophthalmic surgery because, by cutting, they cause minimal trauma.

The taper cut needle combines the reverse cutting design at the point with a round shaft that is useful in delicate fibrous tissue.

Side-cutting needles have two cutting edges on each side of the needle and flat convex and concave surfaces. This maximizes passage through tissues while minimizing trauma.

The special K needle is similar to the taper cut needle but has a shorter and stronger cutting tip, making it useful in tough dense tissues such as cartilage.

- Taper point

  This is a round body needle with a sharp point that passes through tissue by stretching rather than cutting. These needles are not suitable for tissues that are hard to penetrate. They are usually used on nonfibrous soft tissues like abdominal viscera to minimize risk to adjacent vessels and nerves. The sharpness of the point is determined by the taper ratio (8–12.1) and tip angle (20–35°). Sharper needles have higher taper ratios and lower tip angles.
- Beveled, conventional, and cutting edge needles

  These needles are designed to repair lacerations. The angle of presentation of the cutting edge is decreased and this enhances the sharpness. They are composed of a stainless steel (ASTM 45500) that is heat treated after the curving process which enhances their resistance to bending. They are reported to have superior performance characteristics over conventional cutting edge needles.[59]
- Blunt point needles

  The point of these needles is blunt and rounded making them suitable for tissues like the kidneys or liver. This needle dissects tissues rather than cutting them.

6.636.5.3. Body Types

When choosing a needle shape, wound depth, size, and accessibility are the factors that should be considered.

- Straight

  This body type is used where tissue is easily accessed and the needle can be manipulated by hand, such as for skin, tendon, and gastrointestinal tract repair. It is also useful for nerve and vessel microsurgery.
- Half-curved ski

  This body type is not commonly used. It has a straight body and curved point such that the straight body does not follow the curved point making it difficult to handle.
- Curved

  This body type is commonly used and is useful in tight spaces. The path of the needle through tissues is predictable, optimizing passage through tissues. It comes in a variety of curves (quarter-inch, three-eighths-inch, half-inch, and five-eighths-inch). The three-eighths-inch is commonly used for skin closure while the half-inch is designed for tight spaces. The tighter the curve the greater the wrist manipulation that is required by the surgeon to place the suture.
- Compound curved

  This is an unusual needle with a tight 80° curvature at the tip which becomes a 45° curvature through the remainder of the body. It was originally designed for ophthalmic surgery but is now sometimes employed in microvascular surgery to approximate vessels.

6.636.5.4. Selection of Needles

There is no standardized sizing system for needles. Factors that should be considered when choosing a needle include:

- the hole made by the needle should only be large enough to permit suture passage so the needle does not weaken the tissue;
- the design and diameter of the needle should result in minimal tissue damage while minimizing the risk of needle breakage;
- the needle should have the appropriate size, shape, and diameter to permit rapid, accurate, and precise suturing.

In tissues that are easy to penetrate, a taper needle is usually sufficient, while cutting needles are typically reserved for tougher tissues. Cutting needles are usually used for the skin while taper needles are more suited to other tissues such as subcutaneous tissues and visceral organs such as the intestine.[41]

The length, diameter, and curvature of the needle will influence the surgeon's ability to place a suture and will be determined by the accessibility of the tissues. With swaged needles, the needle diameter will usually be preselected by the supplier according to the suture size. Needles are passed through tissues using needle holders. The jaws of the needle holder should be appropriate for the size of the needle to ensure that the needle is held securely to prevent rocking, turning, and twisting but at the same time there should not be excessive force which can cause bending or breakage of the needle.

6.636.6. Conclusions

Suture materials play an important role in wound repair by providing support to healing tissues. The number of options available to the surgeon has increased over the past 30 years. There is no ideal suture material available and the surgeon must make a decision based on scientific principles rather than by anecdote or tradition. Assessment of the wound, the healing properties of the tissues, and the patient's physical condition need to be matched to the physical and biological properties of the materials available. While the number of materials available has increased, within the variety of absorbable and nonabsorbable sutures available, there is a relatively consistent and stable range of established materials that cover most of the applications. With experience and excellent technical execution, different methods of closure may achieve similar high-quality results. However, with continued technological advances in suture materials, needles, and alternative approaches to wound closure, the challenge for the surgeon will be to stay abreast of new technology.

PGA Polyglycolic acid
PTFE Polytetrafluoroethylene
SIS Small intestinal submucosa

6.637.1. Introduction

Intestinal resections and reconstruction by anastomosis are one of the most common procedures performed in abdominal surgery. The anastomosis can be either hand-sewn or stapled. Multiple studies have demonstrated that the complications associated with stapled anastomosis versus hand-sewn anastomosis seem comparable.[1] As complications associated with intestinal anastomosis have significant consequences, staple line reinforcement techniques have been developed to strengthen the anastomosis when this is performed with a stapled technique. Owing to the success of the use of staple line reinforcement in lung resections, varieties of studies have adapted this concept for GI resection. Morbidity and mortality after GI anastomosis is mainly due to anastomosis leakage. Leak rates may vary from 7% to 13%, and mortality following this complication can range from 6% to 40% because of abdominal sepsis and multiple organ failure. Formation of abscesses and fistulae because of dehiscence are also considered major complications and are often difficult to treat.[2,3]

Staple line reinforcement techniques have been shown to increase the burst pressure of the stapled anastomosis and, furthermore, to reduce the risk of hemorrhage. Despite several studies that have been performed regarding the use of these reinforcement materials, no final answers have been found for the prevention of leaks. However, no large prospective comparative studies have been performed up till now in order to prove the advantage of reinforcement of stapled anastomoses. Moreover, several materials are currently available and these materials are all accompanied by their individual approach. Thus, no consensus exists among surgeons who therefore remain divided in their opinion if stapled anastomosis or staple lines should be reinforced with buttress materials, have to be oversewed, or do not have to be reinforced at all.

This chapter aims to summarize the available literature on staple line reinforcement techniques after GI resections and provides an overview of the currently available evidence of the advantages and disadvantages of the usage of these materials.

6.637.2. Staple Line Reinforcement

6.637.2.1. Etiology of Anastomotic Complications

Anastomotic complications, whether they occur after hand-sewn or stapled anastomosis, are severe complications that can lead to life-threatening conditions of the patient. Several studies have shown that the incidence of the major complications associated with anastomotic formation (which is anastomotic leakage, hemorrhage, fistula formation, and abscess) are comparable between hand-sewn and stapled anastomosis.[1] Therefore, the use of staple armentarium for GI reconstruction after resection seems to increase, as they are easy to use and may save time.

Many causes of anastomotic leaks can be identified, but they mainly fall into two categories: mechanical and ischemic factors. Overall, leaks are more likely to occur when the intraluminal pressure exceeds the strength of the tissue and the staple line, resulting in a leak. Classically, anastomotic leakage occurs in the first 5–7 days postoperatively and is due to tissue ischemia. This may occur when the wound healing is between the inflammatory and fibrosis phases. Early leaks, in the first several postoperative days, are usually due to the mechanical failure of the staple line or technical hand-sewn anastomotic method flaws.[2]

6.637.2.2. Buttress Material Properties

Application of reinforcement material in the staple line is thought to moderate the tension of the staple line because it acts as a neutralization plate. Furthermore, the buttressing material seals off the staple holes and narrows the spaces between each staple. Thus, leakage, bleeding, and tearing at the staple line may be reduced.[4]

The buttress material is generally made up of two regions, one of which serves primarily to secure the buttress material to the stapler prior to actuation, and one of which serves primarily to form the improved seal. The buttress material is adapted to be stably positioned upon the staple cartridge or anvil components of the stapler prior to, or at the time of, use.

6.637.3. Reinforcement Materials

Different forms of staple line reinforcement are available. Reinforcement methods are material applied exogenously to the staple line or incorporated into the staple line. Reinforcement materials can be non-, semi-, or absorbable.

6.637.3.1. Absorbable Material

6.637.3.1.1. Fibrin glue

Fibrin glue is a material applied directly to the staple line. Fibrin sealants have been used to achieve hemostasis and tissue adhesion in surgical specialties. It contains fibrinogen, fibronectin, factor XIII, thrombin, ionized calcium, and aprotinin. In the presence of calcium, thrombin facilitates the activated factor XIII to polymerize the fibrin monomers to form an insoluble fibrin clot. The process mimics the last step of the coagulation cascade and is independent of the patient's coagulation status.

The process of fibrinolysis breaks down the fibrin glue material. New fibrin sealant materials with added antifibrinolytic agents are developed to slow down the material degradation. Most available sealants contain human plasma products and bovine-derived components and thus carry the potential but very rare risk of seroconversion.[5]

There are different types of fibrin sealant available on the market, and three are mentioned below:

1. Tisseel VH®/Tissucol® Fibrin Sealant (Baxter International, Inc., IL, USA)
   This sealant is mainly applied as an adjunct to hemostasis in procedures concerning parenchymatous organs and cardiopulmonary surgery. It is also applied as a sealant during the closure of several types of anastomoses and staple lines after gastric sleeve resection. This adjunct is completely resorbed during wound healing within 10–14 days.[6]
2. Vivostat® Autologous Fibrin Sealant (Vivolution, DK)
   Vivostat® is currently being used in a wide range of abdominal procedures, including liver and colorectal surgery.[6]
3. LifeSeal™ (LifeBond Ltd., Israel)
   This mixed sealant is applied to anastomosis staple line junctures in the GI tract and, thus, may fortify the attachment leading to a reduction of leakage.[6]

6.637.3.1.2. Cellulose

Cellulose was originally developed as a wound dressing. It is synthesized by *Acetobacter xylinum* and has a nonwoven, multilayered three-dimensional structure that is not found in synthetic polymeric materials. The manufacturing process ensures that the product is nonpyrogenic and biocompatible. This biosynthesized cellulose has been processed into a resorbable form. It demonstrates a fluid-holding capacity up to 100 times its dry weight and is four times stronger than organic fibers.

The available cellulose product is made by Xylos® (Xylos Corp., Langhorne, USA).[6]

6.637.3.1.3. Polyglycolic acid/trimethylene carbonate

Biodegradable polymers have proved to be of significance in medical applications. Polymers prepared from glycolic acid and lactic acid have found a multitude of uses in the medical industry, starting with the biodegradable sutures first approved in the 1960s. Since that time, many products have been accepted for use as medical devices. The ideal polymer has mechanical properties that match the application, remaining sufficiently strong until the surrounding tissue has healed and does not invoke an inflammatory or toxic response. It should be metabolized in the body after fulfilling its purpose and is easily processable into the final product form.

An example of bioabsorbable polyglycolic acid (PGA) is Seamguard® (W.L. Gore & Associates, Flagstaff, AZ, USA). This is made of a porous fibrous structure composed of poly copolymer. It retains measurable strength for 4–5 weeks and is completely absorbed within 6 months. The Seamguard is formed like a sleeve to be fitted over the stapler arm. After firing, a slipknot suture is pulled to unravel the sutures that secure the strips that hold the sleeve in place. It is available for both open and endoscopic procedures.[6,7]

6.637.3.1.4. Polysaccharidic polyglycuronates biopolymers

This buttressing material is made of highly purified fractions from calcium alginates, originating from seaweeds, with documented hemostatic and healing properties. The product available with this material is called FOREseal™ (Laboratoires Brothier, Nanterre, France) and is only to be used in pulmonary resections.

It consists of preformed coated knitted bioabsorbable sheets held into the form of sleeves sized to fit onto the forks of the surgical stapler. The sleeve preserves as a large strip of material, intended to overlap to the lung parenchyma widely, beyond both sides of the reinforced staple line.[6]

6.637.3.2. Semiabsorbable Material

C-seal® (Colon-seal) (Polyganics BV, The Netherlands).

The C-seal is a biodegradable synthetic fragmentable colorectal drain developed to protect anastomotic leakage in colorectal anastomosis. The C-seal is a single-use device, designed for circular stapler devices. It is stapled to the inner lining of the anastomosis. As a result, the anastomosis is protected and sealed for 10–15 days. The degraded material will be secreted from the body together with the GI contents. C-seal is still in its development stage.[6,8]

Bovine Pericardium Strips, Peri-strips Dry® (BPS) (Synovis Life Technologies, Inc., St. Paul, MN, USA)

BPS comprises two vacuum-dried strips of biological tissue derived from bovine pericardium. It is biocompatible and acellular but is semiabsorbable because of the glutaraldehyde treatment in the manufacturing process. It is designed to provide adequate strength while promoting angiogenesis and cellular ingrowth. A polydioxanone synthetic absorbable gel, an adhesive hydrogel, is applied to the inner surface of both stapler arms after which the stapler is positioned over the bovine pericardium strips and locked. With the bovine pericardium facing the tissue, the stapler device is fired and the tissue is cut after which the stapler can be removed. The remaining material will be incorporated by host tissue after healing. BPS can be used for reinforcement of staple lines during pulmonary, mesentery, and GI procedures.[6]

Porcine Small Intestinal Submucosa (SIS), Surgisis® Staple Line Reinforcement (Cook Biotech, Inc., West Lafayette, IN, USA)

SIS is an acellular xenograft. The material provides a bioscaffold for tissue growth. Following implantation, tissue adjacent to the SIS matrix begins to invade the SIS matrix. SIS is gradually replaced as the host system reinforces and rebuilds the weakened site. The body's tissue grows completely into the surgical site while SIS maintains the needed tissue support. It can be applied for many purposes such as lung and gastric resections and pelvic floor reconstructions.[6,9]

6.637.3.3. Nonabsorbable Material

ePTFE, Seamguard staple line reinforcement material® (W.L. Gore & Associates, Flagstaff, AZ, USA).

This product is made of expanded polytetrafluoroethylene and is intended to be used as a prosthesis for surgical repair of soft tissue deficiencies using linear surgical staplers. It was the first synthetic material used for staple line buttressing. The material is constructed like a sleeve that can be slid over the jaws of the stapling device, without the need for additional fixing to the stapler before firing. After firing, the material is released from the arms by pulling a ripcord. If necessary, the excess material can be trimmed. The use of ePTFE has been shown to have an effect in pulmonary resection, but there are no studies confirming the advantage of ePTFE in GI resection.[6]

6.637.4. Discussion

The use of staplers during reconstruction after GI resection seems to have increased in the past years as it is easy to use and generally shortens operating time. The ultimate goal, however, was to reduce the incidence of major complications associated with the formation of an intestinal anastomosis because the risk of technical failures was thought to be minimized, which is relatively high during hand-sewn anastomosis. A decrease in incidence of these severe complications, that is, anastomotic leakage and hemorrhage, ultimately may result in less postoperative morbidity, surgical reinterventions, and mortality. Several studies, however, have shown comparable results postoperative outcomes after hand-sewn versus stapled anastomosis.[1–3,10] Although these studies were carried out properly, it has to be taken into account that a difference between these techniques may still be present but may be small, necessitating prospective studies with large patient populations undergoing standardized surgical procedures. Such a study has not been performed up till now.

Staple line reinforcement techniques were developed[9,11] because anastomotic leakage and severe bleeding from the site of the staple line or anastomosis can be life threatening.

Several reports in the literature support the burst pressure as the most important factor in assessing the quality of a fresh intestinal suture.[12] Data support that staple line reinforcement increases the burst pressures.[13–16] This may suggest prevention or at least a reduced rate of postoperative leaks and bleeding. Polytetrafluorethylene (PTFE) was the first synthetic material used for staple line buttressing. Although popular with some surgeons, there are no randomized controlled trials evaluating its effectiveness in GI surgery. This accounts, however, for all studies performed on the possible advantages of staple line reinforcement materials as they mostly are carried out retrospectively and concern studies in small patient populations. The use of nonabsorbable staple line reinforcement materials in a contaminated environment during GI reconstruction may raise the question if this may lead to an increase in indolent infection, fistula formation, and erosion. As various small pilot studies suggest a reduction in complications after the use of absorbable staple line reinforcement materials, this has not led to any hesitancy regarding the use of these materials.[9,11,17] Consequently, absorbable staple line reinforcement is applied worldwide for many indications.

Another frequently applied method for reducing the risk of postoperative hemorrhage is an exogenous suspended material as fibrin glue. This is mainly used in obesity surgery such as gastric sleeve resection where fibrin glue is used as a hemostatic

agent. Unfortunately, there are no clinical or animal comparative studies specifically addressing whether hemorrhage was actually reduced by the use of fibrin sealant. A review article about the applications of fibrin sealant in surgery demonstrated that fibrin sealants help to strengthen the stapled or sutured anastomosis and seal microscopic leaks at the anastomosis, but no data exist if morbidity is reduced after surgery in clinical studies.[5] Fibrin glue promotes the formation of granulation tissue and changes its composition by increasing the density of fibroblasts that occur with angioblasts.[18] The pathways, by which fibrin glue accelerates granulation tissue formation, as well as vessel density, are unknown. Silecchia *et al.* have reported data from a rather small randomized prospective clinical trial, assessing safety and efficacy of fibrin glue, suggesting that the use of fibrin sealant in laparoscopic Roux-Y gastric bypass may be beneficial in reducing the reintervention rate for major perioperative complications.[19] Unequivocal beneficial data, however, are lacking.

Regarding absorbable staple line reinforcement materials, two separate prospective studies have been published.[20,21] One of these studies investigated Seamguard in gastric resections as part of bariatric procedures and showed a significant reduction in blood loss. No differences were seen for leakage at intra- and postoperative testing. Another study concerned a pilot study of 30 patients in which all anastomosis were performed with a linear stapler, reinforced with Seamguard.[22,23] Consistent with the former study, no differences were seen in the incidence of anastomotic leakage in this small population. Recently, Chen *et al*. also described no reduction in leak rates after reinforcement of the staple line. In his conclusion, he reported, just as in the previous studies, a decrease in hemorrhage.[24] Buttressing the staple line is also used during pancreatic resection with the objective to reduce pancreatic leakage from the staple line. Reports suggest that Seamguard® may decrease pancreatic fistulas in distal pancreatic resections as postoperative leakage was reduced.[4,25,26] Conversely, other recent studies found an increase in pancreatic fistulas after pancreatic resection with staple line reinforcement with absorbable materials.[27,28] Although these studies seem to conflict, it has to be emphasized that they suffer from major methodological flaws. To determine definitive conclusions, prospective trials are needed with large patient numbers to detect possible small differences.

We performed an extensive literature review and found no large comparative studies on the use of staple line reinforcement materials. Although no conclusions could be drawn regarding the effect of these techniques on a possible reduction of anastomotic or staple line leakage, it does seem beneficial in reducing the risk of postoperative bleeding. Two small studies routinely using bioabsorbable Seamguard® during laparoscopic colorectal resection showed a significant reduction in staple line bleeding sites.[22,23] Therefore, the incidence of GI hemorrhage may be minimized with the use of staple line reinforcement during, for example, gastric sleeve resection or the transection of large vessels during laparoscopic surgery.[29,30] Regarding anastomotic leakage, several small studies have been published, but they all could not provide clear data on a possible reduction of this complication.

This chapter has provided an overview of all currently available materials to reinforce staple lines during the construction of anastomoses or transection of organs and vessels. Furthermore, the literature has been reviewed on possible clinical relevant advantages of these materials during GI surgery. As no high-level prospective studies exist, it remains unclear at this moment if staple line reinforcement reduced the incidence of anastomotic leakage. However, the use of these materials, especially fibrin glue, does seem to minimize the risk of bleeding from the anastomotic or transection site.

Glossary

Bioprostheses A prostheses made of biological material.
Elasticity It is the physical property of a material when returning to its original shape after the stress (typically arising from external forces) that made it to deform is removed.
Intraperitoneal Within the peritoneal cavity, the area that contains the abdominal organs.
Laparoscopy An operation performed in the abdomen or pelvis through small incisions (usually 0.5–1.5 cm) with the aid of a camera.
Tensile strength The tensile strength of a material is the maximum amount of tensile stress that it can take before failure.

6.638.1. Introduction

6.638.1.1. Why Are Biomaterials Essential in Hernia Surgery?

Billroth stated as early as in 1878, "If we could artificially produce tissues of the density and toughness of fascia and tendon, the secret of the radical cure of hernia would be discovered."[1] The grandmaster of surgery realized – more than a 100 years ago – that abdominal wall herniae were poorly reinforced by mere closure or the use of endogenous tissue. Recurrence rates of more than 50% for ventral herniae[2,3] and 15% for groin hernia[4] – reported in the recent published literature – clearly illustrate the problem of hernia treatment without the use of a foreign body for reinforcement.

Polymeric synthetics such as polypropylene or polyester possess the qualities demanded by Billroth and are being successfully used for the treatment of groin and ventral herniae for about 20 years now. By the use of surgical techniques with mesh reinforcement, recurrence rates in groin hernia surgery have been reduced to 1–2%[5,6] and those for ventral hernia surgery to about 10%.[2,7]

6.638.1.2. Limitations of Biomaterials in the Field of Hernia Surgery

In addition to their advantages these meshes cause, in part, very unpleasant foreign body reactions, which may culminate in stiffening of the abdominal wall in rare cases. The patients are then unable to perform simple activities of daily living such as tying their shoelaces. Klinge *et al.*[8,9] recognized the problem of meshes of the first generation, whose pore size was too small. This caused extensive scar plates, which rendered the ventral abdominal wall immobile. A subsequent advancement were meshes with a pore size of at least 1 mm, which caused the scar to be bridged with loose connective tissue (also known as the bridging phenomenon)[9–11] (**Figure 1**). The mobility of the abdominal wall was not limited by this procedure. Therefore, meshes with large pores are given preference, especially in the treatment of ventral abdominal wall herniae.

6.638.2. History of Biomaterials in Hernia Surgery

6.638.2.1. Initially Used Materials

In 1889, Witzel used silver wire meshes for abdominal wall herniae. However, due to the severity and high rate of complications (such as perforation of the bowel, skin necrosis, etc.), these foreign materials proved as unsuccessful as rubber sponges or stainless steel wire meshes.[12,13] It was in the middle of the twentieth century that synthetic materials such as nylon started to be employed for hernia closure. In 1952 Cumberland reported on the use of 'meshes' for herniae.[14] The first large application studies concerning the use of polyester and polypropylene meshes were published by Usher and coworkers in 1959.[15,16] However, this mesh reinforcement surgery was not widely accepted at that time and was rarely used. It was Irvin Lichtenstein in the United States who developed his own surgical method in 1989, using polypropylene for tissue reinforcement.[17] Shortly afterwards, laparoscopic groin hernia procedures employing synthetic implants were developed.[18]

6.638.2.2. Averseness to Biomaterials

Owing to potential complications such as wound infection or chronic pain, herniologists at the time initially adopted a very skeptical approach toward synthetic implants.[19,20] The latter were rated as hazardous foreign materials which, in the worst case, might cause cancer. Such fears have been clearly disproved in the last few years.[21,22]

6.638.2.3. Acceptance of Biomaterials

It was realized that implantation of foreign material provides the required tissue reinforcement for hernia surgery. Since the introduction of laparoscopy in the early 1990s, meshes are being increasingly used for various open as well as laparoscopic surgical procedures. Hernia recurrence rates have been markedly reduced by these procedures and the acceptance of the meshes increased rapidly. Currently, more than three-fourths of operations for abdominal wall herniae are performed by the use of mesh reinforcement.[23] Worldwide about 25 million hernia operations and nearly 20 million mesh implantations are performed per year (Table 1).

6.638.3. Materials Used in Hernia Surgery

6.638.3.1. Synthetic Fiber Polymers

As regards hernia meshes which have been used million-fold in the last 20 years, those of the first generation were replaced by recent ones. The first meshes were very close knit and had a pore size of >800 μm. This led to the formation of scar plates, which markedly reduced mobility, especially in cases of herniae in the anterior abdominal wall.[8] Klinge and coworkers[9–11] established the formation of connective tissue around the threads – which were a foreign body – as the reason for this phenomenon (Figure 1). Therefore, meshes with pore sizes of 1.5 mm or more were produced: these had a larger distance between the individual threads. The so-called bridging phenomenon prevented the formation of extensive scar tissue. Limitations in mobility such as those reported for synthetic meshes could be avoided by this approach.

The formation of scar plates also led to shrinkage of the meshes, followed by folding and waving of the meshes, and occasionally resulted in insufficient hernia repair.

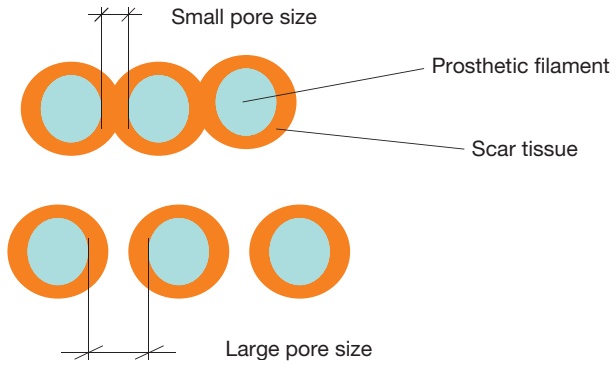

Figure 1 Diagram showing the scarring process provoked by the different pore sizes of the meshes. With small pores a continues scar plate occur.

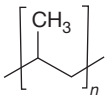
Table 1 Hernia operations per year

USA	1 000 000
Europe	1 000 000
Worldwide	25 000 000

Such shrinkage of meshes of the first generation could be largely reduced and even avoided by the use of modern meshes with large pores.

In histological specimens one finds foreign body tissue reactions which, in the early phase, were marked by a monocyte-dominated acute form of inflammation. These were followed by chronic foreign body reactions, which were primarily granulomatous in nature.[24]

6.638.3.1.1. Polypropylene (e.g., Marlex®, Prolene®)

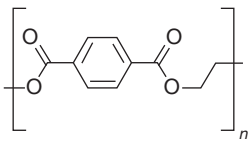


The most frequently used meshes in hernia surgery today are those made of polypropylene. Many companies produce hernia meshes made of polypropylene, which is an economical material. About 100 different designs, manufactured with different quantities of material, pore sizes, and elastic properties are offered in the market. Polypropylene meshes are largely monofilamentous (Figure 2), whereas polyester meshes usually possess a multifilamentous thread structure (Figure 2). The microporosity of the multifilamentous structure is about 10 μm. This thread design was presumed to be the reason for the high infection rates registered in earlier studies.[25] However, this hypothesis was disproved in recent investigations comprising large case numbers, because no difference in infection rates was found between monofilamentous and multifilamentous synthetics.[26,27]

Monofilamentous polypropylene meshes, which were used by Usher as early as in 1962,[15] are still used today. To achieve better ductility and elasticity, the initially woven meshes were replaced with knitted constructions. Modern polypropylene meshes are very stable and are associated with a low rate of accompanying inflammation.[28,29]

Nevertheless, polypropylene causes adhesion to intestinal organs. Therefore, contact with these organs should be painstakingly avoided.[30,31] In some techniques, polymeric meshes are introduced in the abdominal cavity in order to reinforce the abdominal wall. These are provided with a special antiadhesive coat,[32] ensuring satisfactory ingrowth of the polypropylene layer in the abdominal wall[33] on the one hand, and preventing adhesion of the mesh to abdominal organs such as the bowel or stomach[34,35] on the other.

6.638.3.1.2. Polyester



Multifilamentous mesh constructions made of ethylene glycol and terephthalate are highly flexible and also provide a high degree of mechanical stability.[36] They were rarely used in the past (almost exclusively in France) because a study published in 1998[37] advised against the use of polyester meshes due to their instability and the formation of fistulas. However, this statement was not confirmed in many recent studies.[27,36]

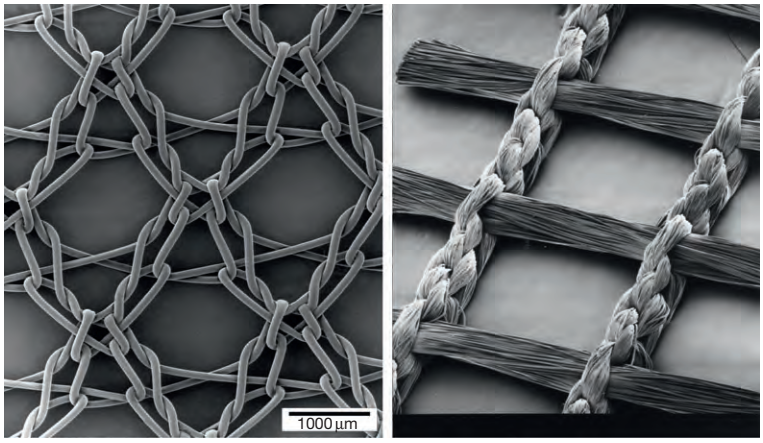


Figure 2 Electron microscopic view of a polypropylene mesh (left side) versus a polyester mesh (right side).

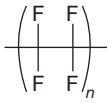
Currently, polyester and polypropylene are considered equally suitable for use in hernia surgery.

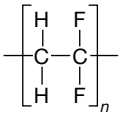
6.638.3.1.3. Polytetrafluorethylene



This product is available as a film and is therefore associated with poor healing, marked shrinkage of the scar, and a high propensity for infection. It is rather firm and not very elastic. Complete integration into host tissue does not occur. Rather, a scarred capsule is formed around the implant.[38] The prosthesis' poor ingrowth behavior is attributed to its film-like structure, its hydrophobic surface, and the negatively charged polytetrafluorethylene (PTFE). Anchorage in the surrounding tissue did not occur even after several years. However, as this material was shown to possess antiadhesive properties in a few studies, the films were initially used in intraperitoneal location. However, they were gradually ousted from the market by competitor products (such as polyester or polypropylene meshes with an antiadhesive coat) for this indication as well.

Besides, these 'meshes' were disproportionately expensive and were therefore rarely used from the very start.

6.638.3.1.4. Polyvinylidene fluoride



Hernia meshes made of polyvinylidene fluoride (PVDF) are being used to an increasing extent in the last few years. PVDF, an inert material, is being used as suture material for a long time now. It is marked by a high degree of biocompatibility – similar to that of polypropylene or polyester. In some studies it was shown that, due to its low rate of inflammatory and fibrotic foreign body reactions and low shrinkage after implantation, PVDF serves as a useful alternative to conventional materials such as polypropylene and polyester.[39,40]

6.638.3.1.5. Composite meshes

The concept underlying this mesh made of a combination of nonabsorbable and absorbable material is self-evident. After implantation one initially achieves a high degree of mesh stability. After absorption of one component, only a small quantity of residual foreign material remains. These meshes are usually composed of combinations of polypropylene and absorbable polyglactin (Vypro II) or absorbable poly-L-lactic acid. However, after absorption the meshes cause a significant foreign body reaction. Therefore, the overall reaction of the body to these synthetic materials is not markedly different from that of meshes composed of a single component.

In order to achieve better biocompatibility, polypropylene meshes are coated with a very thin layer of titanium (TiMesh). In the recent published literature, opinions about the advantages of this titanium coat are diverse as to whether this alteration of the surface does actually cause better tissue tolerance.[24,41]

6.638.3.2. Biological Materials

A disadvantage of all polypropylene meshes is the impossibility of mesh implantation in an infected wound. Synthetic materials are extremely susceptible to bacteria because the latter adhere to the mesh structures and form an impermeable biofilm for the body's immunological defense and for antibiotic treatment.[25] Therefore, infected meshes have to be removed in many cases. The film-like structure of polytetraflourethylene meshes renders them inaccessible to treatment with local or systemic antibiotics in case of infection, and the meshes have to be removed in nearly all cases. On the other hand, modern large-pore meshes can be successfully overcome by the body's own defense and treated by antibiotics in case of bacterial infection. They can be retained in more than one half of cases.

Biological meshes were developed to achieve reinforcement even in cases of infected or potentially infected wounds, because they are associated with a much higher degree of tolerance to infection.

Biological meshes have been used for the past few years and in very rare cases of groin herniae. They can be obtained from various donors: porcine, bovine, or human. All cellular

elements are removed from tissue rich in collagen, especially the skin, the pericardium or the intestinal submucosa, so that only the intact collagen and elastin framework remains. The following biological meshes are currently available:

Alloderm® is produced from foreign human skin (chemically unchanged)
Veriats® consists of acellular bovine pericardium
Peri Guard® is also obtained from the bovine pericardium (chemically modified)
Permacol® contains reinforced porcine collagen
Surgisis® is produced from the acellular freeze-dried tissue matrix of porcine submucosa.

In order to prevent rapid degradation of meshes by collagenases, the collagen framework of some meshes is altered or linked differently through chemical processes. This is achieved by blocking the collagenase-binding sites, which renders the prostheses capable of withstanding degradation and absorption by the body for a longer period of time than untreated bioprostheses. Chemically pretreated prostheses are known as cross-linked bioprostheses and differ from untreated non-cross-linked bioprostheses. The higher resistance of cross-linked bioprostheses to collagenases[42,43] as well as the rapid degeneration of non-cross-linked (Surgisis®) prostheses[44,45] have been proven in several studies.

Regardless of chemical pretreatment, after a certain period of time the implant becomes integrated in the host tissue. The structure of the prosthesis is markedly altered by this process, which is hence known as remodeling.

The clinical value of biological meshes cannot be estimated at the present time, because degradation of the implant and ingrowth of collagenic connective tissue for hernia reinforcement are still difficult to assess. Degradation of the mesh prior to the formation of adequate connective tissue causes hernia recurrence. Likewise, mechanical stabilities after several months or years are currently unknown. Therefore, at the present time these meshes can only be used as tissue reinforcement in cases of infected wounds. As biological meshes cost about 10 times more than synthetic meshes, the bioprostheses will be used in carefully selected cases in the next few years as well.

6.638.4. Hernia Surgery with Prostheses

Today about two-thirds of all abdominal wall herniae are treated with mesh reinforcement and the numbers are increasing. This is especially because suture techniques lead to high tension at the suture base, which frequently causes the suture to tear out of tissue and leads to recurrence of abdominal wall hernia. In addition to markedly lower recurrence rates, mesh reinforcement techniques permit early load bearing and cause chronic pain in very rare cases.

6.638.4.1. Inguinal Herniae

6.638.4.1.1. Open techniques with mesh

6.638.4.1.1.1. Lichtenstein

The procedure named after Irvin Lichtenstein is the most frequently used surgical technique for groin hernia throughout the world. As early as in 1986 Lichtenstein and Shulman[17] realized the advantages of mesh reinforcement through tension-free hernia treatment and therefore named it the 'tensionless' technique. The gap in the groin is not closed with sutures, as was done earlier, but is covered with synthetic material. The foreign body reaction induced by polypropylene – a foreign body – leads to the formation of a resilient scar plate. Recurrence rates could thus be significantly reduced from 15% to 1–2% (Figure 3).

6.638.4.1.1.2. Plug and patch repair

This technique was modified by Rutkow and Robbins[46] in that the gap was additionally narrowed by the use of an umbrella-like plug (Figure 4). A synthetic mesh is then introduced between the internal and external musculature, as in the Lichtenstein technique. This procedure is especially popular in the United States.

6.638.4.1.2. Laparoscopic techniques (TAPP and TEP)

Following the introduction of laparoscopy at the start of the 1990s, laparoscopic techniques were also developed from the treatment of groin hernia. Flat placement of a synthetic mesh measuring about 15 cm × 10 cm in the preperitoneal space (Figure 5), between the peritoneum and the musculature, became widely accepted. The hernia is not closed under tension but is covered with synthetic material, as is done in the Lichtenstein procedure. This tensionless technique is given preference in cases of surgery for hernia recurrence and also for bilateral groin herniae.[47] Depending on the access used to approach the preperitoneal space, a distinction is made between the transabdominal preperitoneal (TAPP) and the

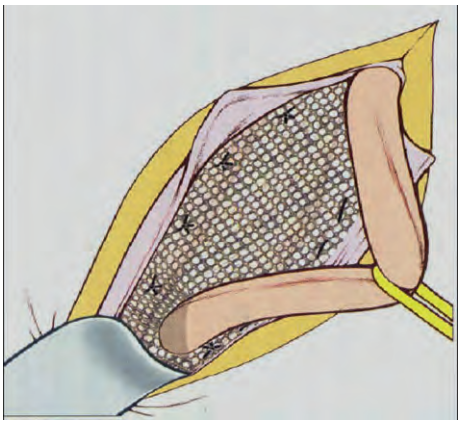


Figure 3 The Lichtenstein technique.

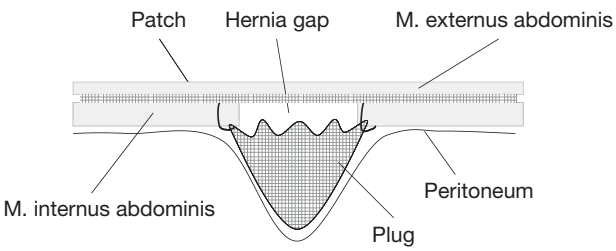

Figure 4 The Rutkow technique.

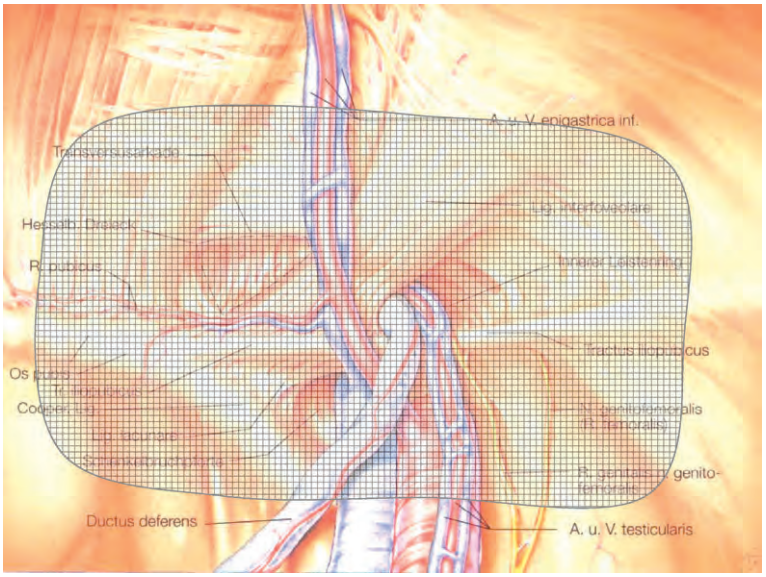

Figure 5 The laparoscopic view of a groin region. All possible groin defects are covered with a 15 cm × 10 cm mesh.

total extraperitoneal (TEP) technique. The advantage of the laparoscopic technique is especially the low degree of surgical trauma (small incisions of only 5 mm), because of which the patients are able to fully withstand loads after a mere 10 or 14 days.

6.638.4.2. Ventral Hernia Repair

6.638.4.2.1. Open mesh techniques

Treatment of the anterior abdominal wall is a much greater problem than treatment of groin hernia. This is clearly demonstrated by recurrence rates, which are about 50% after the suture technique and about 15% after mesh reinforcement[2,7] – which is still much higher than the recurrence rate of about 1% for groin herniae after the TAPP technique.[5,6] This may be explained by the fact that ventral herniae achieve enormous dimensions of up to 20 cm or may be composed of huge hernia sacs containing several intestinal loops (Figure 6). The mesh reinforcements required in cases of such large herniae are not only advantageous, but may also cause limitation of movement – as was true for meshes of the first generation – or even stiffening of the anterior abdominal wall. Large-pored meshes were developed to counteract this problem. Due to the bridging phenomenon they do not impair the mobility of the abdominal wall after implantation. Additionally, these herniae are usually highly susceptible to infection because of the large wound surface. Therefore, quite often it is necessary to remove the infected synthetic mesh. As these herniae cause major problems for the surgeon, a wide range of techniques are used for this condition, depending on the type of hernia and the patient's characteristics.

6.638.4.2.1.1. Onlay technique

By this technique the mesh is fixed to the anterior rectus sheath. The procedure is advantageous because it is very simple to perform, but is associated with a high rate (~15%) of infection

Figure 6 Huge ventral hernia reaching the knees of the patient.

of the foreign body.[48] The recurrence rate of 15% is an additional disadvantage as opposed to alternative techniques.[48]

6.638.4.2.1.2. Sublay technique

Due to the problems of the onlay technique, the sublay technique is given increasing preference. The mesh is introduced between the rectus muscle and the posterior rectus sheath and thus reinforces the midline. However, due to the position of the mesh, this rather laborious surgical technique is marked by a lower recurrence rate than the onlay technique.[48–50]

6.638.4.2.2. Laparoscopic technique (IPOM)

In the last few years, laparoscopic treatment of incisional herniae by the use of special meshes has been established as an

equally effective surgical technique as open procedures.[51–53] The meshes are fixed to the peritoneum by the laparoscopic technique (intraperitoneal onlay mesh) and bridge the abdominal wall defect on the side facing intraperitoneal pressure (Figure 7). As polyester, polypropylene, or other polymeric materials cause massive adhesions to abdominal organs,[30,31] these synthetics are coated with an antiadhesive layer (Figure 7). The coating may be made of porcine collagen for instance, and is absorbed after about 10 days. As a neoperitoneum will have formed by this time, adhesions to abdominal organs are avoided to a large extent.[33,54,55] Especially in cases of so-called Swiss cheese incisional herniae, which are usually composed of several small herniae, the scar tissue between the hernia gaps persists and holds the mesh in position like an abutment. However, large herniae may cause the mesh to bulge and are therefore commonly treated by open techniques.

The low degree of tissue trauma is an advantage of the Intraperitoneal onlay technique (IPOM); it is also associated with a low rate of wound infection and minimal postoperative pain.[51–53] A disadvantage at the current time is the possibility of the mesh becoming adherent to the abdominal organs despite the antiadhesive coat, because of its intraperitoneal position.[56]

6.638.4.3. Hiatus Hernia Repair with Mesh

In cases of large diaphgramatic herniae, reinforcement is achieved by adaptation of the diaphragm using a mesh. As the very sensitive esophagus and stomach are directly adjacent to the mesh in this region, even self-coated meshes are rarely used at the present time.[57] Due to rapid advancements in mesh technology, synthetic meshes will probably conquer this field as well.

6.638.5. Forces Acting on Hernia Meshes

The forces acting on this mesh are of various intensities, depending on the surgical method used. A basic distinction is made between two techniques, namely whether the mesh is used in addition to closure of the hernia for reinforcement of tissue, or whether the defect is merely covered with the mesh.

6.638.5.1. Biomaterial Reinforces a Closed Defect

After closure of the hernia the mesh is placed in order to reinforce the tissue (e.g., the onlay technique) or between the layers of the abdominal wall (e.g., sublay technique). However, closure of the hernia causes high tension on the hernia margins. Horizontal forces are especially strong in cases of ventral hernia because of the oblique muscles of the abdominal wall (external oblique muscles, internal oblique muscles, and transverse muscles of the abdomen). Thus, the linea alba is able to withstand horizontal loads of 10 N mm^{-2}, but vertical loads of only 5 N mm^{-2} until rupture occurs.[58] Due to the mesh, the load on the scar or the midline is shared by the polymer mesh. Recurrence rates have been markedly reduced by this approach.[2,7] However, as the majority of meshes were found to withstand loads of 100–200 N cm^{-1} when a strip of mesh was exposed to tensile loads (according to DIN 53587) – these values being well above their physiological load-bearing capacity – failure of the construction always causes mesh tear-off rather than rupture of the material. As the mesh is fixed on muscle or fascia, shear forces by far exceed the fixation strength of the mesh during mesh tear-off (Figure 8).

6.638.5.2. Biomaterial Covers Defect

By this technique the defect is not closed but merely covered with a mesh. This approach has been very successfully employed in laparoscopic groin hernia surgery (TAPP or TEP technique). In the last few years it has also been used for ventral herniae. Even large defects can be bridged with the mesh (Figure 7). Here as well, shear forces between the prosthesis and the abdominal wall are of decisive importance for successful hernioplasty (Figure 7). When shear forces exceed the mesh's retention strength, the mesh glides into the opening and the abdominal wall hernia is reexposed. Furthermore, soft materials may cause wide bulging so that the abdominal organs may reenter at the level of the abdominal wall and cause hernia recurrence (Figure 9).

6.638.6. Requirements for Hernia Meshes

The challenge for hernia meshes lies in the various requirements that a foreign body must fulfill in order to reinforce

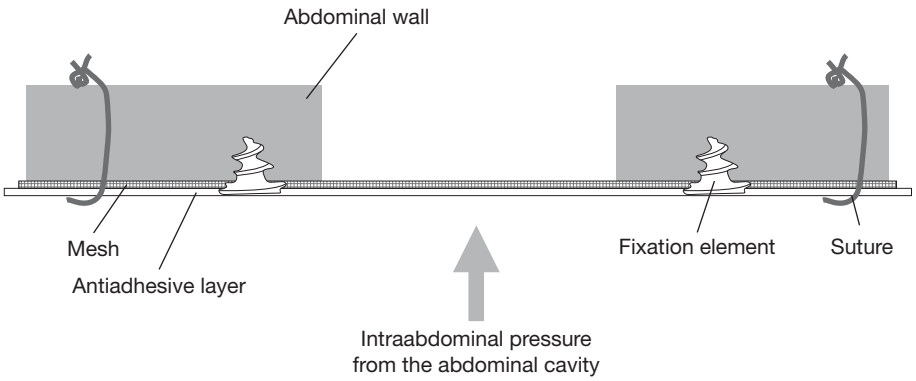

Figure 7 IPOM (Intraperitoneal onlay technique).

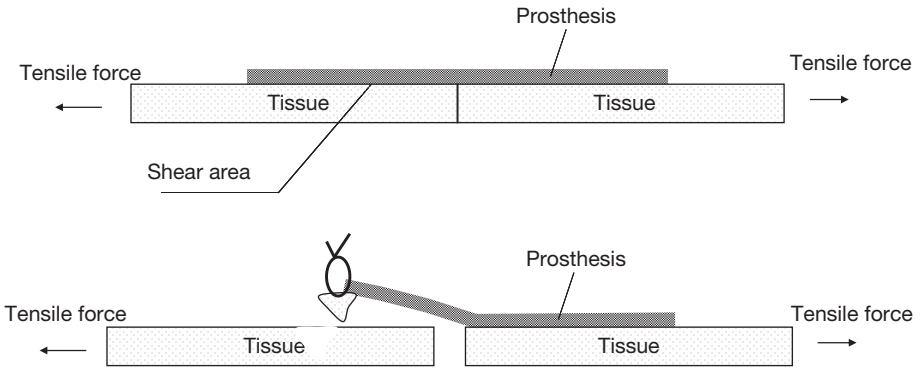

Figure 8 Recurrence after mesh repair always arise due to mesh tear-off rather than mesh rupture.

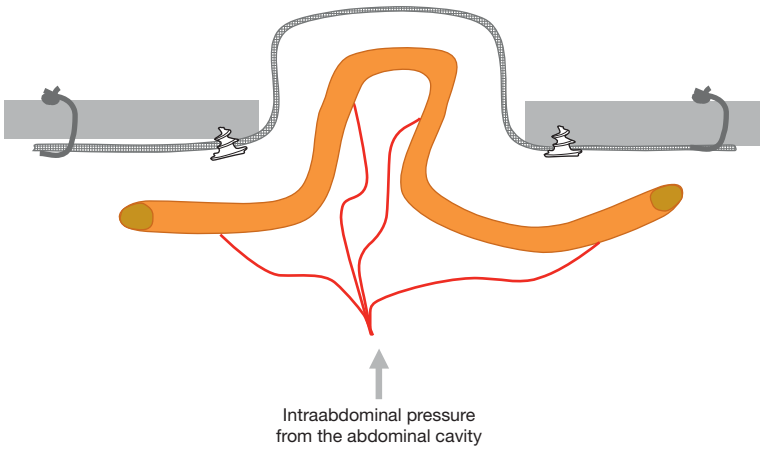

Figure 9 The mesh bulge into the opening and cause hernia recurrence.

the abdominal wall. These demands on the mesh are, in part, contradictory. The surgeon is therefore compelled to make a compromise as regards the properties of the mesh. The required criteria for polymers used in hernia surgery are listed in the following sections.

6.638.6.1. Physical Stability to Tissue Secretions

Hernia meshes should not be absorbable. When meshes started to be widely used some 20 years ago, fully absorbable meshes were used in order to leave no residual foreign substances in the body. After absorption of the meshes, however, the newly formed scar tissue was not sufficiently stable. Nearly all of the herniae reappeared.[59] Only partially absorbable meshes such as those made of polypropylene and polyglactin (e.g., Vicryl and Vicryl II) achieve sufficient stability because of their polypropylene content. Therefore, these meshes expand the spectrum of otherwise nonabsorbable hernia meshes.[60,61]

6.638.6.2. Biocompatibility

Polymers cause an inflammatory reaction in the body directly after implantation.[24] In hernia surgery we try to use meshes that cause minimal and brief inflammatory reactions in the body. Acute as well as chronic pain can be minimized by this approach.

6.638.6.3. No Carcinogenicity

Some of the polymers employed in hernia surgery have been in use for about 50 years (polypropylene and polyester) and have, to date, caused no carcinoma – neither in studies nor in clinical application. Meshes are therefore considered to be noncarcinogenic.[21,22]

6.638.6.4. Tensile Strength

Currently used meshes were shown to possess a tensile strength of 50–200 N when a 1 cm strip of mesh was subjected to tensile loads (DIN 53857) until it ruptured. One of the reasons for this diversity is the fact that the required stability of synthetic meshes has not been clearly established among hernia specialists.[10,58] Furthermore, the mesh stabilities required for various applications are very diverse. In cases of midline herniae one may anticipate horizontal loads of up to 10 N mm^{-2} which are mainly exerted on the oblique muscles of the abdominal wall. Several surgical techniques for midline closure are aided by the use of a synthetic mesh. As it is positioned on fascia or between muscle and fascia, the mesh is primarily subjected to shear forces. Meshes used at the present time are sufficiently resilient to tensile forces. Mesh rupture is practically nonexistent whereas mesh tear-off from tissue is more likely to occur. Therefore, in addition to the tensile strength of meshes, the

problem of fixation should be given greater attention in the field of technical advancement because an enormous improvement potential exists in this area.

In contrast, in the groin the synthetic mesh is fixed nearly exclusively through intraperitoneal pressure in the preperitoneal cavity. Therefore, tensile loads on the mesh in this region are of secondary importance.

6.638.6.5. Elasticity

Due to their large pores (>1.5 mm), modern meshes are very elastic and remain so even after incorporation. This is especially important in cases of ventral herniae because stiffening of the anterior abdominal wall would cause significant limitation of mobility. Likewise, the marked ductility of the mesh reduces the load on fixations. Therefore, mesh tear-off is a rare occurrence.

6.638.6.6. Thickness and Bending Properties

The thickness of the mesh markedly influences its flexion behavior. Especially for those surgical techniques in which the gap remains open and the mesh is only placed on the hernia, its thickness is inversely proportional to its flexion.[62] Very thin meshes of 0.2 or 0.3 mm are therefore unsuitable to cover large defects. In these cases, more stable meshes (in terms of flexion) of 0.4–0.6 mm should be used.[62]

6.638.6.7. Mesh Weight

Depending on their weight, a distinction is made between light (up to 45 g m^{-2}), moderate (45–75 g m^{-2}), and heavy (>75 g m^{-2}) meshes. In some studies, light-weight meshes proved valuable in terms of causing less postoperative pain than heavy meshes.[63] They are preferentially used for small and mid-sized herniae. Owing to their poor stability in terms of flexion, excessively thin meshes are overstrained when used for large herniae. In the latter case, more stable meshes of moderate to heavy weight should be used in order to avoid bulging.[62]

6.638.6.8. Surface Properties

The mesh's surface properties are responsible for the severity and duration of the foreign body reaction, especially in the adjacent tissue. The surface consistency also determines the mesh's friction properties. Especially in the first few postsurgery days, when connective tissue ingrowth of the mesh has not yet started, it is more likely to slip. After this time it is stably fixed in the surrounding connective tissue. Therefore, friction is only significant during the first few postsurgery days.

6.638.6.8.1. Mesh coating

In order to minimize the foreign body reaction, one manufacturer developed a fine titanium coat for the polypropylene mesh (Figure 10). As titanium is an inert substance, the coating was expected to reduce the tissue's reaction to polypropylene. The published literature contains studies that confirm this theory as well as others that provide no indication of the efficacy of this titanium coat in respect of foreign body reaction.[24,41]

6.638.6.8.2. Microhooks

To avoid dislocation, meshes with microhooks made of polylactic acid on their underside were developed (Figure 11). These are stably fixed to the surrounding tissue so that additional fixation elements are not required. In a study on rats it was shown that these microhooks achieve the tensile strength of fixation elements (such as the hernia stapler).[64] The advantage of these polylactin microhooks (Figure 12) is their absorbability – they are degraded within 1 year and cause no chronic nerve irritation, which is occasionally encountered when fixation elements are used.[65]

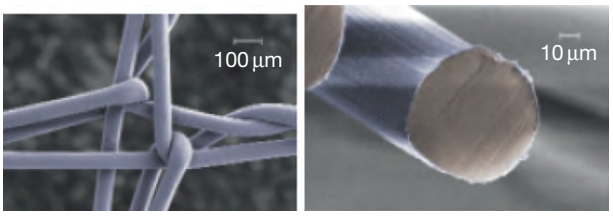

Figure 10 TiMesh: a thin layer of Titan coats the polypropylene.

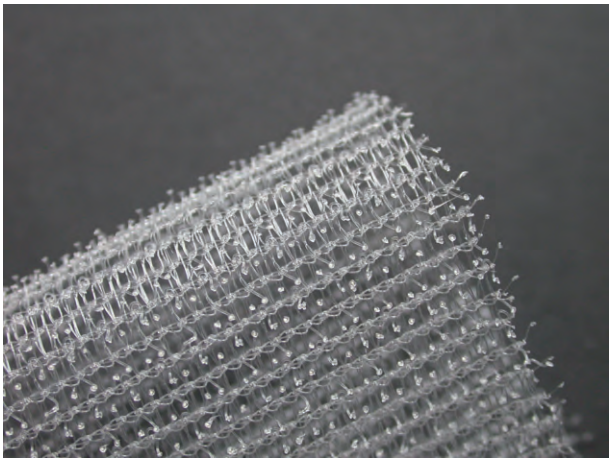

Figure 11 Mesh with microhooks on their underside.

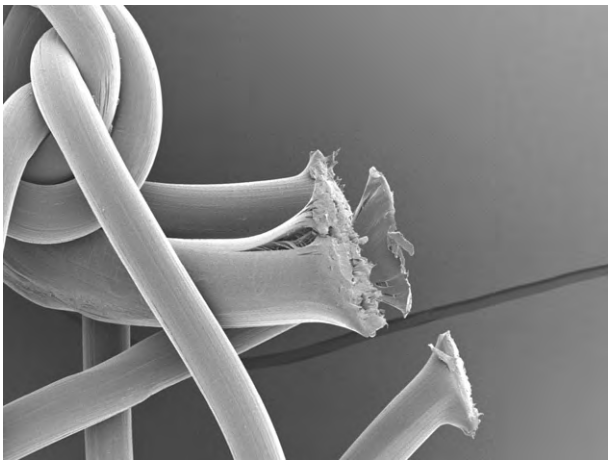

Figure 12 Electron microscopic view of the mesh-microhooks.

6.638.6.8.3. Antiadhesive coat

Meshes for intraperitoneal use are provided with an absorbable coat; one of the materials used to produce the coat is porcine collagen. Adhesion of internal organs such as the bowel, stomach, or liver is largely avoided by this measure (also see Section 6.638.4.2.2).

6.638.6.9. Mesh to Hernia Size Relation

Meshes that overlap the hernia margin should be directly proportional to the size of the hernia. Initially this point was underestimated. Many recurrences occurred because the mesh became detached from the margin and slipped into the hernia. Likewise, recurrences occurred when static friction was inferior to tensile loads because of the small size of the overlapping surface and poor fixation of the mesh.[38,66]

6.638.6.9.1. Surgical techniques with closure of the hernia

For reinforcement of the closed hernia, currently an overlap of at least 4–5 cm on each side is recommended.[38,67] In cases of ventral herniae, the fact that horizontal tensile forces are twofold higher than vertical tensile forces should be taken into account: the defect should be overlapped generously on its sides.[58]

6.638.6.9.2. The mesh overlaps the defect

This type of hernia treatment is given preference, especially when using laparoscopic techniques, and is associated with a low recurrence rate of about 1% in the treatment of groin herniae.[5,6] These favorable results are attributed to the fact that defects in this region are usually <2 cm in diameter and larger herniae are rarely encountered in this location. In the groin, the mesh is inserted in the preperitoneal space and fixed on both sides through the abdominal wall and through the peritoneum. In cases of ventral herniae, even large defects are treated by this approach, although the recurrence rate for these herniae is much higher than 10%.[68] This is due to insufficient lateral mesh overlap which, for anatomical reasons, frequently does not achieve the required dimensions. The mesh is fixed on the peritoneum so that ingrowth of the material is confined to the side facing the abdominal wall. Mesh dislocation and slippage into the hernia are the most common causes of recurrence when this technique is used. Despite stable and widespread fixation, hernia recurrence cannot be avoided. Therefore, in cases of very large defects the indication for laparoscopic IPOM should be established very stringently.

6.638.6.10. Costs of Meshes

Polypropylene and polyester meshes measuring 15 cm × 15 cm cost about 100€ at the present time (this is a rough estimate). Freudenberg *et al.*'s study is noteworthy in respect of mesh costs. In their study in Burkina Faso they showed that sterilized nylon mosquito nets achieve equivalent results as commercially used polypropylene meshes (Ultrapro®).[69] The sole difference was the price – which was 0.0043 US dollars for locally purchased nylon meshes compared to 108 US dollars for the commercial mesh. Therefore, Kingsnorth[70] has emphasized the importance of nylon mosquito meshes in developing countries.

Coated meshes are much more expensive because the protective antiadhesive coat is laborious and costly in terms of production. Meshes measuring 15 cm × 15 cm cost about 300–400€. Biological meshes made of porcine acellular collagen or bovine pericardium are very expensive – a mesh of the above mentioned size costs more than 1000€. This is one of the main reasons why biological hernia meshes are very rarely used at the present time.

6.638.7. Mesh Fixations

As currently used meshes do not tear under physiological loads, hernia recurrence is caused by mesh tear-off or dislocation. Fixation of the mesh in tissue is therefore of decisive importance. Particularly in the early postoperative phase, the prosthesis is stabilized by the fixation elements alone. Additional connective tissue ingrowth of the mesh occurs after about 2 weeks. Once the prosthesis has been well incorporated into the surrounding tissue, recurrences secondary to this structural reinforcement usually do not occur.

6.638.7.1. Nonabsorbable Devices

Early mesh fixations were made of nonabsorbable material in order to ensure sustained fixation.

6.638.7.1.1. Suture

The nonabsorbable suture is still an important tool for fixation of the prosthesis. As it permits fixation through several layers of the abdominal wall, it is the type of fixation that is able to withstand by far the greatest tensile loads.[33] Quite often it is combined with other fixation elements in order to achieve widespread attachment of the prosthesis.[71,72]

6.638.7.1.2. Hernia stapler

These fixation elements are similar to an ordinary desk stapler and function in the same manner. The two metal ends penetrate the tissue by about 4 mm and are then bent by the stapler device when pressed (Figure 13). The prosthesis is thus fixed into the tissue. This fixation technique has been in use for

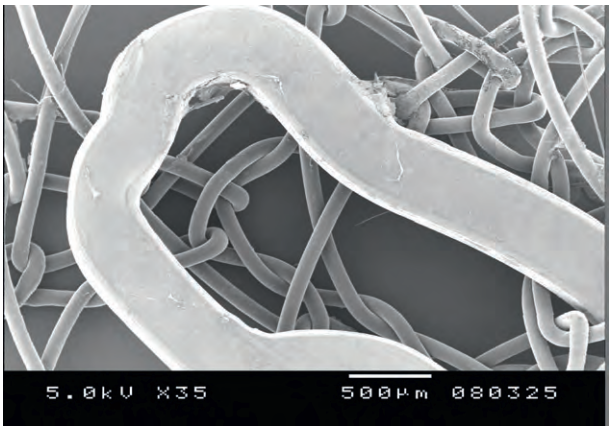

Figure 13 Electron microscopic view of a mesh fixed with a hernia stapler.

about 20 years and is gradually being replaced with more innovative devices. This is because stapler fixation may be associated with a few disadvantages. The nonabsorbable elements may cause chronic pain due to nerve irritation.[73] Likewise, 12 mm trocars are needed to introduce the staples. The high cost of the method has been another reason for developing absorbable and more economical fixation techniques.

6.638.7.1.3. Spiral tacker

These spiral fixation elements have been in use for more than 10 years and achieve stable fixation.[74] They are particularly suitable for fixation of the prosthesis in bone, such as the symphysis or the xiphoid process. Their marked tendency toward adhesion when used in intraperitoneal location is a disadvantage.[33,75]

6.638.7.2. Absorbable Fixation Systems

Absorbable fixation techniques were developed to avoid chronic foreign body reactions and chronic pain.

6.638.7.2.1. Absorba tack

These fixation elements consist of 4-mm-long screws made of polylactic acid and are fully degraded after about 1 year. The formation of adhesions to intraperitoneal organs is thus markedly reduced. Therefore, the elements are given preference when using the IPOM technique for widespread mesh fixation. In respect of retention strength they are as effective as spiral fixation elements.[35]

6.638.7.2.2. Microhooks

These small barbed hooks made of polyactic acid are fixed on the underside of the prosthesis and are equivalent to the hernia stapler in terms of retention strength.[64] The meshes (Progrip®) are used to treat groin herniae.

6.638.7.2.3. Fibrin glue

Fibrin glue is marked by its low rate of complications. Chronic pain due to nerve irritation is avoided by this fixation technique.[73] The prosthesis can be fixed well over a large surface. However, stable fixation of the mesh in tissue immediately after surgery (i.e., in the vulnerable phase) could not be proven in all studies.[64]

6.638.7.2.4. Suture

Nonabsorbable sutures complete the list of fixation techniques. They are preferentially used in those areas in which stable fixation of the prosthesis in tissue is anticipated. Furthermore, to bridge the first few postsurgery months, they provide additional retention and promote integration of tissue into the prosthesis. Nonabsorbable sutures for margins subjected to tensile loads are frequently combined with absorbable sutures for widespread fixation of the prosthesis.[72]

6.638.8. Potential Complications of Hernia Meshes

The advantage of reducing recurrence rates by providing tissue reinforcement must be viewed in the light of a few potential complications.

6.638.8.1. Perioperative Complications

6.638.8.1.1. Rejection

Rejection or intolerance of the prosthesis are extremely rare events and have been reported in isolated cases.[76–78]

6.638.8.1.2. Infection

Infection of the prosthesis is a much more frequent and very unpleasant complication (Lit). Especially when using open techniques,[79] skin pathogens may collect on the prosthesis and necessitate its removal in many cases.[80] To avoid this complication, antibiotics are administered perioperatively to protect the prosthesis when using open techniques.

6.638.8.2. Chronic Complications

6.638.8.2.1. Hernia recurrence

Hernia recurrence rates have been significantly reduced by the use of mesh techniques as opposed to suture techniques. Nevertheless, the treatment of ventral herniae is still reported to be associated with high recurrence rates. Therefore, surgical techniques for this type of hernia need to be optimized.

6.638.8.2.2. Chronic pain

Apart from hernia recurrence, chronic pain after mesh implantation must be avoided. The use of modern meshes and modern fixation techniques has reduced the number of patients who experience chronic pain to about 5%. In cases of proven nerve irritation due to the mesh or mesh fixation, the cause of pain should be eliminated by surgery. Success rates for this type of pain treatment, however, are still unsatisfactory.[81]

6.638.8.2.3. Stiffening of the abdominal wall

Stiffening of the ventral abdominal wall has occurred after implantation of small-pore meshes. This complication can be largely avoided by the use of modern large-pore meshes: the patient is able to move the abdominal wall in all directions despite widespread reinforcement of the abdominal wall with the mesh.

6.638.9. Conclusion and Future Perspectives

6.638.9.1. Further Developments

A wide spectrum of options for improvement exist, especially in the field of prosthesis fixation. Fixation elements or sutures of maximum ductility could markedly reduce mesh tear-off. More exact determination of the forces acting on the prosthesis might enhance our understanding of tensile loads on the foreign body and consequently optimize the characteristics of the prosthesis as well as its dimensions.

6.638.9.2. Conclusion

Hernia meshes have become an integral aspect of surgical techniques for the treatment of abdominal wall herniae and are currently used in two-thirds of all hernia operations. Synthetic meshes represent the artificial fascia and tendons aspired for by Billroth, and have significantly improved the outcome of hernia surgery. Nevertheless, a long pathway of research lies ahead of us if we wish to reduce, or even eliminate, the accompanying negative effects of synthetic meshes.
