Walnut Creek Treatment Plants. With growth driving the sewer treatment needs, the South Austin Regional and Walnut Creek plants were built along with large diameter interceptor sewers that flow west to east picking up the flows from the different watersheds. Besides treating the sanitary flows, the City also reuses the sludge created by the plants to generate a compost product called "Dillo Dirt" at the Hornsby Bend Biosolids facility.

Currently, the city owns and operates its water and wastewater system providing service to a population of 820,765 (766,428 retail and 54,337 wholesale) through 187,000 service connections. The city's utility service area of 538 square miles consists of 2,500 miles of pipelines, 124 city maintained wastewater lift stations, over 45,000 manholes, two major wastewater treatment plants with a total treatment capacity of 135 million gallons per day (MGD) and one central biosolids processing plant.

In 1998, a lightning-induced failure at a wastewater lift station just north of Austin resulted in a discharge into Brushy Creek. The episode drew attention to wastewater overflows and resulted in the United States Environmental Protection Agency (USEPA) issuing an Administrative Order (AO) on September 11, 1998. The AO included a finding of violation and an order for compliance noting that the City had also reported 129 unauthorized discharges in the preceding three years. While the September 1998 AO was specific to the violation on Brushy Creek, a subsequent AO was issued in 1999 that required the City to eliminate sanitary sewer overflows by 2009.

APPROACH

The task was tackled by in a step by step flow down process that started by looking at the entire City, then looking closer at areas of the highest inflow and infiltration (I&I) to identify and prioritize specific problems and finally to replace or make improvements to deficient parts of the wastewater system. The City-wide portion of the analysis was accomplished with three large scale I&I studies. A sanitary sewer evaluation survey (SSES) was completed for the areas of the highest I&I. Findings from the SSES were clarified, studied, and used to make recommendations for improvements in Technical Memorandums and grouped into construction projects in Administrative Order Reports. The steps in this process are described in more detail in the following paragraphs.

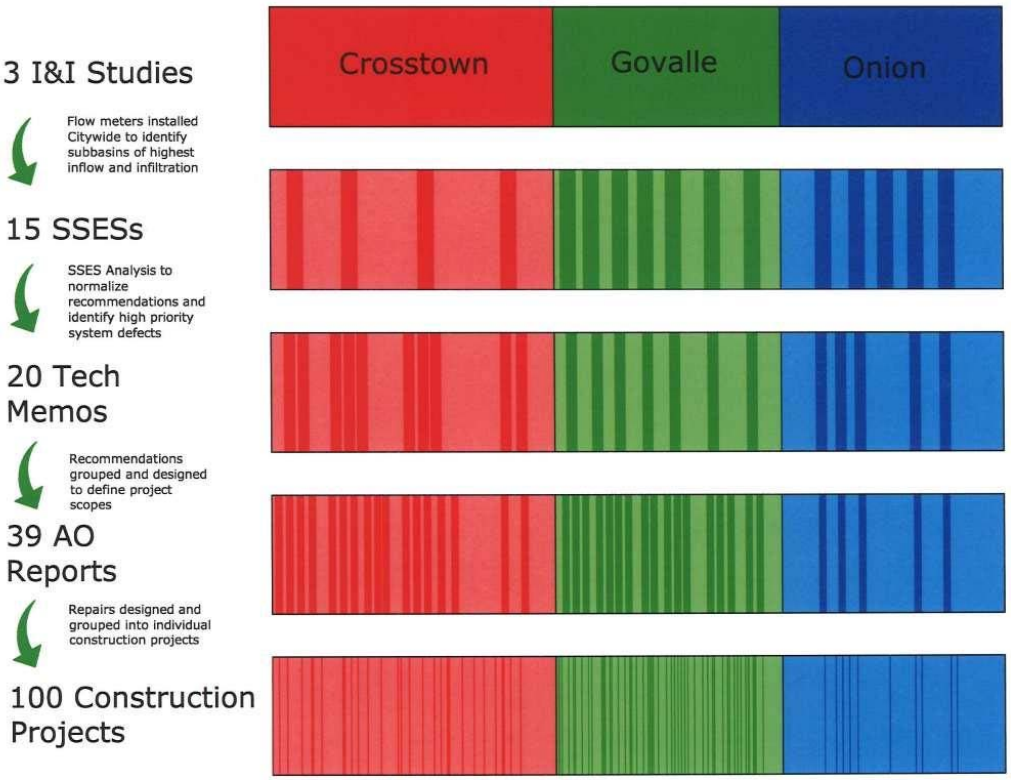

Figure 1. Process of Identifying and Replacing Priority Wastewater Deficiencies.

INFLOW AND INFILTRATION STUDIES

To begin to approach the Sanitary Sewer Overflow question in Austin, Inflow and Infiltration Studies were conducted to determine the areas of the City most impacted by I&I. The City is divided into three major sewer basins by sewer network configuration and topology. There is a main tunnel draining each of the major sewer basins.

North – Crosstown Basin (Crosstown Tunnel)
Central – Govalle Basin (Govalle Tunnel)
South – Onion Basin (Onion Creek Tunnel)

The extent and locations of the major sewer basins is shown in Figure 2.

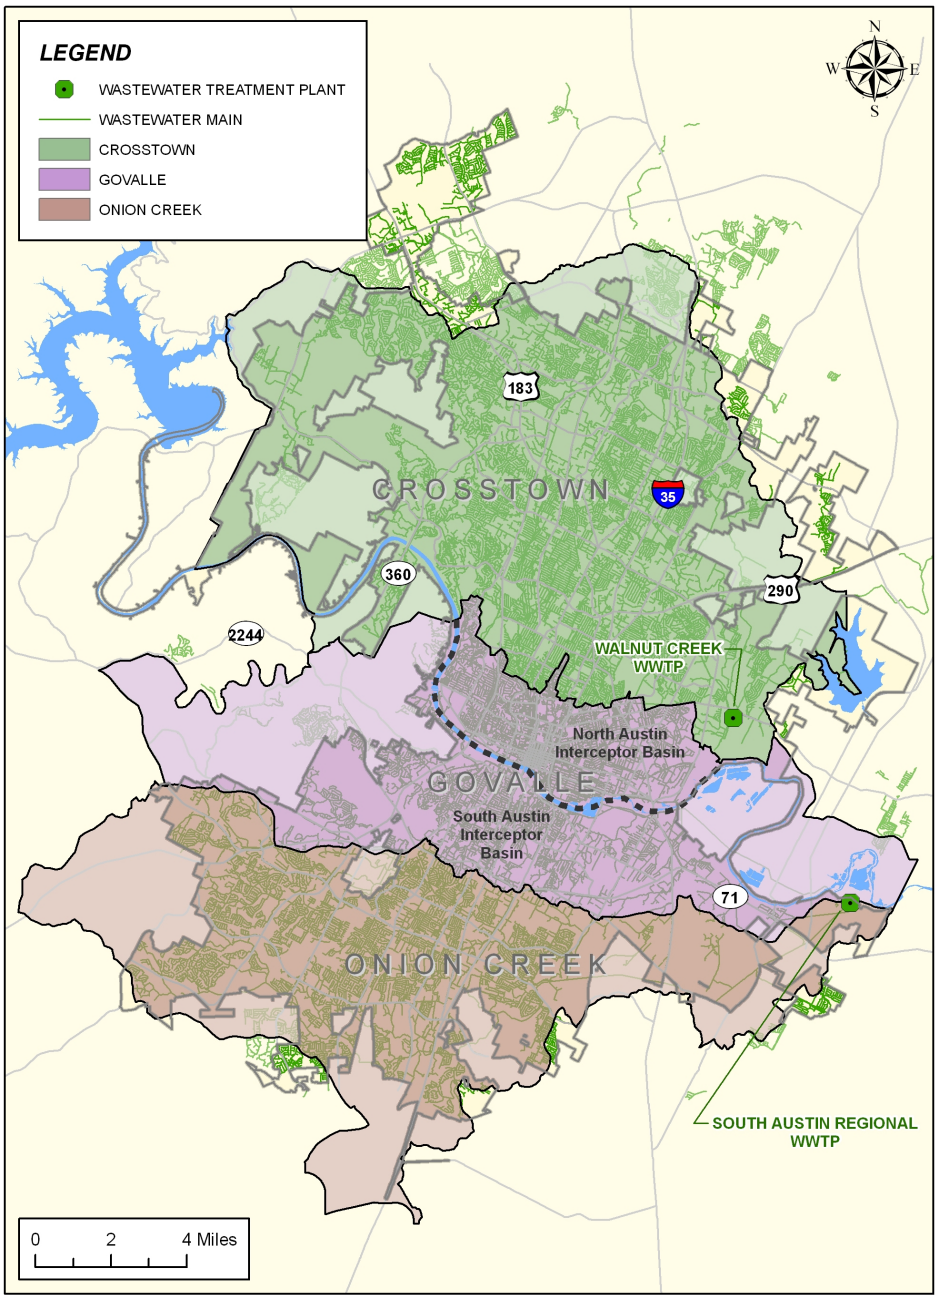

Figure 2. Austin Water Utility Wastewater Basins

An I&I study was performed in each of the three major sewer basins by monitoring flow at all of the major interceptors in each major basin. This divided the City's sewer system into sewer basins that were tributary to each interceptor. The I&I studies ranked the sewer basins based on evidence of high I&I in the sewer basin using flow monitoring studies. The sewer basins with the highest evidence of I&I were identified to be studied more thorough with an SSES study. The I&I studies monitored flows in approximately 94 basins and approximately 28 basins were recommended to be studied further.

SANITARY SEWER EVALUATION SURVEY STUDIES

The SSES studies were used to derive Capital Improvements Program (CIP) projects to address problems and minimize overflows. The SSES studies were conducted by consulting engineers hired directly by the City. Each SSES report included:

Hydraulic Modeling
Flow Monitoring
Smoke testing
CCTV investigation
Manhole inspections
Survey and Mapping of the Wastewater Collection System

A typical SSES report usually included a project area description, results of field investigations, a hydraulic model, a prioritization of suggested improvements, and recommended improvements with cost estimates.

The SSES studies were to prioritize recommended improvements with the following prioritization scheme.
Priority 1 - SSO Elimination, including hydraulic deficiencies and structural defects that result in overflows.
Priority 2 - Rehabilitation of assets with moderate to severe structural defects and I/I deficiencies not attributable to SSOs.
Priority 3 - Scheduled Preventive Maintenance, including the evaluation of all remaining pipe segments on a phased schedule.
Priority 4 - Rehabilitation of infrastructure identified in Priority 3.

Oversight and a clear understanding of the scope of the SSES studies appeared to be lacking and several of the SSES studies were not ready to be used for their intended purpose as submitted. In some sub-basins, supporting documentation and detail was omitted. Most hydraulic models prepared by the SSES consultants did not account for future growth in their evaluation and recommendations and had limited flow meter data. Very few of the SSES recommendations gave consideration to systems planning or moving wastewater pipes out of creeks. Some the SSES recommended improvements were not very cost effective. It was determined that the information in the SSES studies needed to be refined to best determine which improvements were Priority 1 and needed to be fixed during the ACWP.

TECHNICAL MEMORANDUMS AND AO REPORTS

As the SSES studies were performed by various consultants without a lot of specific direction the reports varied. The ACWP Team performed an in depth review of each SSES studies to develop Technical Memorandums (TM) to normalize the SSES reports. This process involved

- hydraulic model review and recalibration
- application of a consistent design storm to the hydraulic models

- application of 2020 future population to the hydraulic models
- re-evaluation of CCTV tapes to look at them critically with a better understanding of the overall condition of the wastewater collection system
- field visits to verify and investigate unresolved questions

A TM was prepared for each SSES basin to summarize recommended Priority 1 improvements based on further investigation and normalizing the findings of the SSES studies. During the preparation of the TMs some suggested improvements that were not identified by the SSES consultant but were known to be trouble spots in the collection system by City staff or were identified as causing a recent overflow were added to the list of suggested improvements. Alternative, more cost effective solutions such as CIPP lining, spot repairs and manhole replacements were also suggested as part of the TMs prepared for each basin.

Suggested Priority 1 improvements from the TMs were grouped together to form construction projects that were to be designed by consulting engineers. Suggested improvements were grouped together in the form of an AO report that was intended to outline each design project. The AO reports further clarified and suggested the improvements that were needed for each repair. Projects were usually grouped geographically when possible with approximate dollar amounts in mind that were appropriate size for a construction project. During the preparation of the AOs further recommendations by the City Staff and SSO investigation staff was also added to the list of Priority 1 improvements. The AO reports contained preliminary engineering analysis, cost estimates, environmental constraints maps and suggestions for coordination with other projects and improvements being planned in the City (water lines, street resurfacing, and channel stabilization). These reports were used as scoping documents in the COA's task of bidding CIP Projects.

CONSTRUCTION PROJECTS

By 2004 the Priority 1 Construction Projects had been identified from the process. These projects were designed by separate consulting engineers with oversight from the City and ACWP staff starting in 2002 with the last design completed in the fall of 2007. These projects total $350 million in design and construction fees and 75 miles of improvements to the wastewater system. The locations of these projects within Austin are indicated in Figure 3. The program is on track for final completion of all construction by April 30, 2009. The ACWP was the largest construction program ever taken on by the City and it has accomplished many much needed improvements the wastewater collection system. The Priority 2-4 problems with the system remain or will develop and are planned to be improved as part of an ongoing maintenance program.

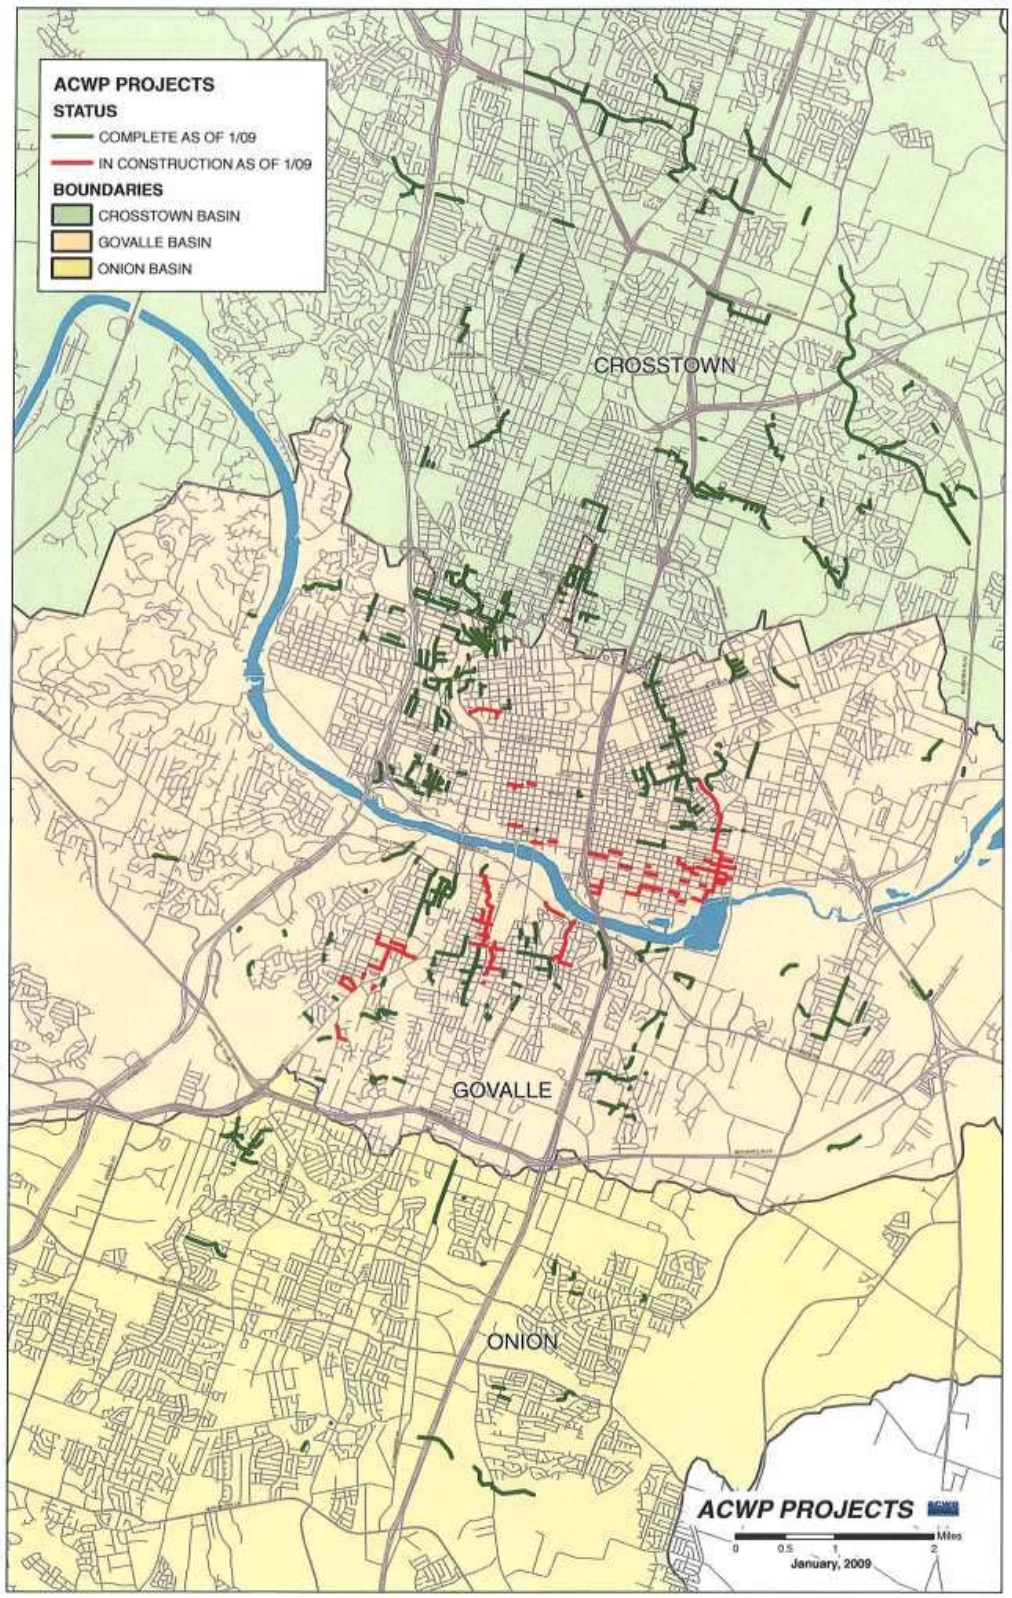

Figure 3. ACWP Construction Project Status Map (January 2009)

CONCLUSION

In 2001, the City of Austin and the Austin Clean Water Program was faced with the daunting task of determining how to eliminate a pervasive sewer overflow problem within its wastewater collection system. The terms of its USEPA Administrative Order required quick and decisive action. The analysis started at the major basin level and drilled down to the construction project level through a logical sequence of steps. The ACWP employed a systematic process of analyzing flow data, field surveys, CCTV, smoke testing, computer modeling, and inspection to determine the highest priority wastewater improvements that would maximize the reduction in sanitary sewer overflows. This process led to one hundred construction projects that have already lead to a remarkable reduction in recorded overflows. This decision making approach could be applied in any City facing a similar mandate and should be considered as a possible procedure for addressing widespread sewer overflows elsewhere.

Spatial Evolutionary Algorithms for Characterizing Large-scale Spatial Groundwater-Vegetation Dynamics in Arid Region

Jihua Wang, Ximing Cai, Albert J. Valocchi

Hydrosystems Laboratory, Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, Urbana, 61801. E-mail: xmcai@uiuc.edu, jwang41@uiuc.edu, valocchi@uiuc.edu

Abstract

Vegetation in arid riparian zones heavily depends on groundwater, meanwhile the distribution of vegetation impacts the groundwater flow in the area. This study describes a methodology to characterize groundwater-vegetation dynamics using a spatial evolutionary algorithm (SEA). It incorporates spatial knowledge of groundwater and vegetation to facilitate the optimal search of vegetation distribution compatible to groundwater flow. Unlike a regular EA for spatial models, the SEA employs a hierarchical tree structure to represent spatial variables in a more efficient way. Furthermore, special crossover and mutation operators are designed in accordance with the tree representation. In this paper, the SEA is applied to searching for the maximum vegetation coverage associated with a distributed groundwater system in an arid region. The results of computational experiments demonstrate the efficiency of SEA for large-scale spatial optimization problems. Extension of the algorithm for other water resources management problems is discussed.

Keywords: spatial evolutionary algorithms (SEA); large-scale; vegetation-groundwater interactions; spatial optimization; ecosystem management

1 Introduction

In many arid regions of the world, surface water-groundwater interactions are critically important for the health of the riparian ecosystem (Grimm et al., 1997; Le Maitre et al., 1999; Zhu et al., 2004). The main scientific issues relevant to the study of riparian ecosystem include the nonlinear feedback and interactions among the surface water, groundwater and vegetation system. In arid regions where plant growth is limited by groundwater availability, the spatial pattern of vegetation is the result of preexisting environmental heterogeneity, such as groundwater depth. Meanwhile, the distribution of vegetation impacts the groundwater flow in the area.

The groundwater-vegetation dynamics is essentially characterized with spatial patterns of groundwater and vegetation. The simulation of the dynamics as well as the decisions on optimal human controls for groundwater management and vegetation maintenance has a significant spatial dimension. This motivates a modeling analysis of vegetation management within a spatial analytical framework. This study describes a methodology to characterize the large-scale, groundwater-vegetation dynamics using a spatial evolutionary algorithm (SEA). The SEA uses spatial knowledge of groundwater and vegetation to support the optimal search of vegetation distribution compatible to groundwater flow. A computational experiment shows the effectiveness and efficiency of this approach for large-scale spatial optimization problems.

In this paper, a conceptual model of the research problem is proposed and the

assumptions discussed. The components of the SEA are then addressed in detail, including the hierarchical encoding scheme, the formulation of the spatial fitness function, and the enhanced crossover and mutation operators. Both the newly-developed SEA and the regular evolutionary algorithms (REA) are applied to the ground water in the computational experiments and the performances are compared. At the end, the differences between SEA and REA are summarized.

2 Conceptual model of the study problem

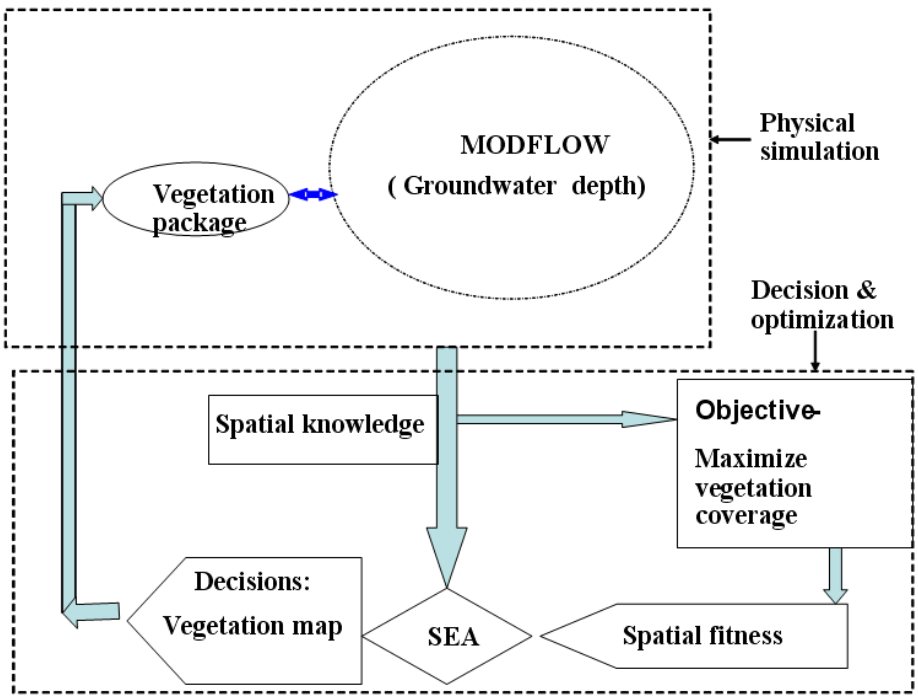

Fig1. Conceptual model of the study problem

The study problem can be formulated as an integrated simulation and optimization model as shown in Fig. 1. The assumption is, in arid regions with little precipitation, vegetation is mainly sustained by ground water. Where there is more ground water, there is more vegetation. Fig. 1 shows the systematic combination of models, management objectives and decision variables.

The spatial parameters to be assessed, such as the distributions of vegetation and groundwater and their dynamic interactions, distinguish this problem from regular optimization-simulation problems. The developed methodology will subsequently focus on exploring the interactions of the spatial patterns of vegetation and groundwater, and further on how to take advantage of these to solve the large-scale optimization-simulation problem.

3 Overview of SEA

Water resources systems contain numerous hydrological features which are inherently spatial and as such can be considered “large-scale spatial systems”. They present challenges because large-scale problems are computationally expensive for traditional

optimization methods and spatial patterns are not easily represented in the quantitative models. Meanwhile large-scale spatial systems provide some opportunities for the optimization method. This presents a motivation to design SEA to meet the challenges and take advantages of the specialty of the systems. The tree structure is employed to depict the interesting subsets of the whole system, which could save much computational time for large-scale problem. Meanwhile the spatial knowledge of a system is incorporated into the SEA framework to improve the performance of the optimal search.

3.1 Flowchart of SEA

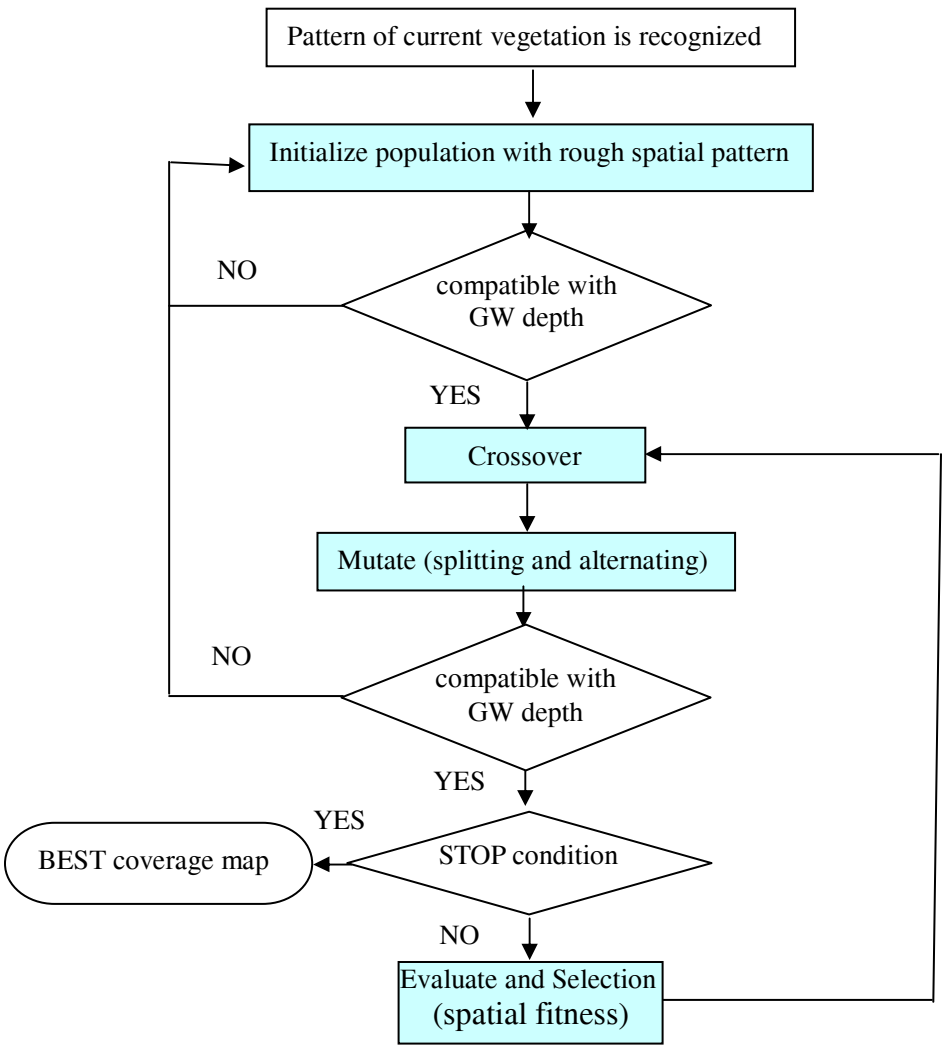

Fig. 2. Flowchart of SEA

As shown in Fig. 2., SEA starts from initialization of population and then moves to crossover, mutation, selection and terminates when the stop condition is satisfied. The enhanced components have been marked in blue and will be discussed in more detail later. The left loop of the flowchart checks the feasibility of the solution using the physical simulation model to determine whether groundwater can support this coverage solution.

The right loop represents the generations of SEA, and the evolution will not stop until (1) generation reaches the maximum generations, (2) there is no improvement within a specified number of generations, and (3) a specified percentage of the population reaches the maximum depth of the tree structure. The third stop condition is designed specifically for the hierarchical tree structure of SEA. The maximum level can be determined by the modeler's experience or by the constraints of the simulation model. Taking the vegetation for example, since the simulation model is constructed with Modflow, maximum depth depends on the grid numbers used in Modflow. The evolution will stop when specified percentage of population reaches the maximum depth.

3.2 The hierarchical encoding scheme

Encoding schemes for decision variables are fundamental to all EAs. In a regular EA, solutions are encoded with binary strings (Holland, 1975), real numbers (De Jong, 1998) or finite state machines (Fogel, 2000). Generally, the encoding method of the solutions is dependent on the context of the problem: EA designers normally select the most suitable encoding scheme for their problems.

To solve large-scale spatial optimization problems, two essential requirements present for the design of the encoding scheme. Firstly, since large-scale problems are computationally expensive if every grid of a map is encoded as a decision variable, it is necessary for the encoding of the population to represent the spatial characters with limited data volume. Secondly, the spatial solutions must be represented by a well-defined spatial data structure that can be easily handled by the EA operators.

To meet these requirements, the tree structure is employed to represent the spatial population solution because it has been shown to capture spatial characters with reduced data volume (Samet, 1990). In addition, the operators of crossover and mutation can be easily manipulated on the tree structure. More details about operators will be given in the following subsections. In this paper, I use a quadtree to represent the map of vegetation converge. For other water resources applications, the tree structure can be modified in accordance with the specialty of those spatial problems.

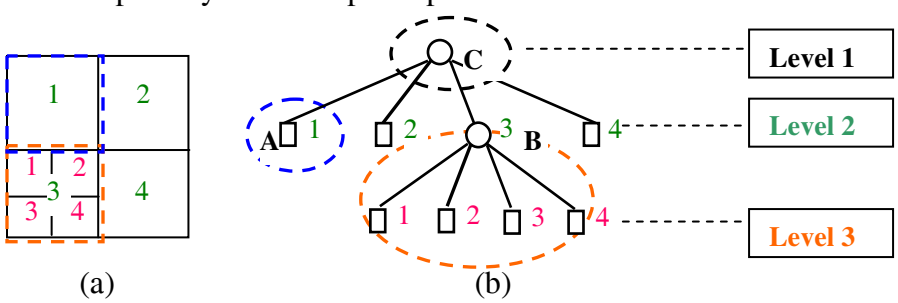

Fig. 3. Encoding a spatial population (a) with a quadtree (b)

Taking the vegetation coverage for example, every population of the coverage is encoded as a quadtree. Every leaf without a predecessor in the quadtree (like A in Fig. 3(b)) is for a uniform coverage in the population map(orange square in Fig. 3(a)) while a node (like B in Fig. 3(b)) represents 4 different coverages(blue square in Fig. 3(a)).

The tree structure of SEA offers flexibility for modelers to get various degrees of accuracy of the optimization solution for a large-scale spatial problem. The quadtree starts from a rough pattern and then further refines the map. The quadtree in Fig. 3(b), for

example, starts from a uniform map and is constructed from level 1, as node C shows. If the refinement of the map leads to an improvement of the optimization objective, node C splits, and the depth of quadtree goes to level 2 and leads to more variations in the corresponding map. If we want to increase the accuracy further, node B in level 2 splits again, the depth of quadtree goes to level 3, and the corresponding map shows more details(Fig. 3(a)). Refinement is prohibited unless necessary, and hence SEA is computationally efficient for large-scale problems.

SEA works like a top-down method: it starts from a rough pattern and then further refines the map. It is flexible and efficient for large-scale problems since the accuracy depends on what you need. This top-down method can balance the tradeoff between accuracy and computation.

3.3 Initial Population generation

To solve the vegetation problem, a rough pattern of the current vegetation coverage is used as the basis for initialization because vegetation coverage is relatively consistent and there is no abrupt change. Since the final result should be much closer to the current coverage than to a randomized coverage map, significantly fewer generations are required to reach the optimized coverage from the current coverage.

3.4 Spatial fitness

Spatial patterns of the study problem contain much important information about the specialties and characters of the problem. So it is essential to incorporate them into the model. However, one challenge for spatial optimization problems is that it is usually difficult to represent spatial patterns explicitly in the models. Hence, it is the modelers' responsibility to apply their professional experience and insight when they try to recognize the spatial patterns, interpret them as spatial knowledge and incorporate the knowledge into quantitative models.

In arid regions with little precipitation, we assume that vegetation is mainly supported by groundwater and hence the distribution of the vegetation coverage is highly correlated with that of the saturated thickness of groundwater. The spatial pattern of the correlation is further interpreted by a quantitative index like the spatial cross-covariance between vegetation coverage and groundwater depth. The spatial fitness of the vegetation problem can then be defined as

$$\text{Max} \underbrace{\text{total coverage}}_{(a)} + \lambda * \underbrace{(\text{cross-covariance})}_{(b)} \qquad \text{Equation (1)}$$

Besides the original objective (a), the spatial fitness has an extra component (b) to incorporate spatial patterns into the optimization models. Lambda (λ), the Lagrange multiplier, can be determined by modeler's experiences. With spatial fitness it is relatively easy to incorporate spatial patterns into the optimization models.

In this paper, spatial patterns are incorporated into the spatial fitness function to represent the preference for the compatible vegetation coverage. It must be mentioned that spatial knowledge can be incorporated into fitness or work as a strict spatial constraint like the boundary of locations for a site selection problem. Since the preference for specific

vegetation coverage is implicit and not as strict as the boundary condition, the spatial knowledge is incorporated into the fitness to guide the search for compatible vegetation.

3.5 Crossover operator

Since we encoded the solution with a quadtree rather than the conventional string, the crossover and mutation operators must also be modified to meet the spatial specialty of the tree structure and guarantee that the results from the two operations are still legal quadtrees. Swapping has been widely used in genetic programming (GP) to exchange the nodes, and has been shown to be efficient in many applications. In this paper, swapping is employed to change the nodes within the same area between individuals.

The crossover of SEA is operated on the nodes of a tree rather than on the grid of a map as in regular EA, which is computationally efficient for large-scale problems. Unlike the crossover in GP which can be operated at different areas or within the same individual, the crossover in SEA swaps nodes within the same area and is only applied between individuals. The main benefit of this operational constraint in SEA is that the swap of the nodes within the same area between individuals can pass the locally good information to the next generation. Since a good neighborhood or distribution in one location may not make sense for another location, the crossover is only applied between individuals and not within the same individual.

3.6 Mutation operator

Mutation is important to introduce new information into a population. The conventional mutation is not efficient for large-scale problem size because randomly changing some parts of the population without the guidance of spatial knowledge may be computational expensive before convergence for a large-scale problem.

Three criteria are used for designing the mutation operator of SEA. First of all, the mutation is able to be efficiently implemented on the large-scale problem with the help of spatial knowledge extracted from the study problem. Secondly, some randomness must be included to keep the diversity of the population and balance exploration and exploitation. Thirdly, the resultant offspring is required to be a legal quadtree for the consistency of the encoding in the next generation.

SEA employs two kinds of mutation: splitting and alternating. Both are operated on the leaves of a tree. Similar to the conventional mutation operator, alternating randomly selects a number of leaves and changes their values. Splitting, which is based on the sensitivity of the leaves to the fitness improvement, focuses the computations on interesting subsets of the whole large volume of data.

Similar to the promising index in nested partition methods (Shi et al, 1999), sensitivity, a good quantifiable index of spatial knowledge, works as a guide for concentrated computations on the most promising parts of the large volume of data and saves computations on those insensitive/insignificant parts. Fortunately the hierarchical character of the tree structure offers the flexibility of focus and concentration. As discussed in 2.3, splitting, together with the tree structure, make computational efficiency and flexibility possible for large-scale problems.

However, splitting is not totally dependent on sensitivity: some insensitive regions are also selected randomly for splitting to maintain the diversity of the population and reduce the risks of pre-convergence. More diversity of the leaves is also introduced by randomly alternating some leaves based on the specific probability. Both the splitting and alternating will obviously preserve the quadtree structure.

4 Computational experiment

To test the efficiency of this algorithm, both SEA and REA are applied to the same conceptual GW model. All the shared parameters of these two algorithms and the initialized maps (starting point for evolution) are the same for SEA and REA in order to get a fair comparison. The same GW model is used as the test issue and the GW constraints are also the same.

The specific aim of this experiment is to examine whether SEA sustains its effectiveness as problem sizes increases. Five different resolutions of the same GW model are designed for the experiment. As the problem sizes increases, the grid size of the GW models decreases and the number of decision variables (complexity of optimization model) increase.

Three scenarios are tested: (1) to compare the optimized pattern of vegetation coverage, run both algorithms with unlimited computational time until model converges. (2) Run algorithms with similar computational time and compare the fitness and (3) compare the computational time when both models reach the same fitness.

4.1.Run algorithms until model converges

As the problem size increases, both SEA and REA takes more time to converge because GW model needs more simulation time and the number of decision variables also increases. However, SEA reaches a better fitness with less total generations than REA. Table 1 and Fig. 4 show that SEA obtains nearly twice fitness using about 60% of the computational time with the REA.

Fig. 5 shows SEA finds a more compatible vegetation pattern with GW depth for 128*128 grids: the vegetation coverage is higher nearing the river since river is the main water supplier recharging this aquifer under arid climate. The optimized vegetation converge with REA has no clear pattern and may be dominated by randomness because of the huge computational complexity caused by decision variables.

Table 1. Comparison of computational time and fitness when model converges

	Generations		Time[min]		Max Fitness (Average density)		SEA/REA	
Size	REA	SEA	REA	SEA	REA	SEA	time ratio	fitness ratio
8*8	601	330	77	47	0.33	0.70	**0.61**	**2.12**
16*16	601	329	103	53	0.41	0.62	**0.51**	**1.51**
32*32	601	301	163	89	0.38	0.59	**0.55**	**1.55**
64*64	601	301	287	150	0.28	0.66	**0.52**	**2.36**
128*128	481	301	670	452	0.23	0.63	**0.67**	**2.74**

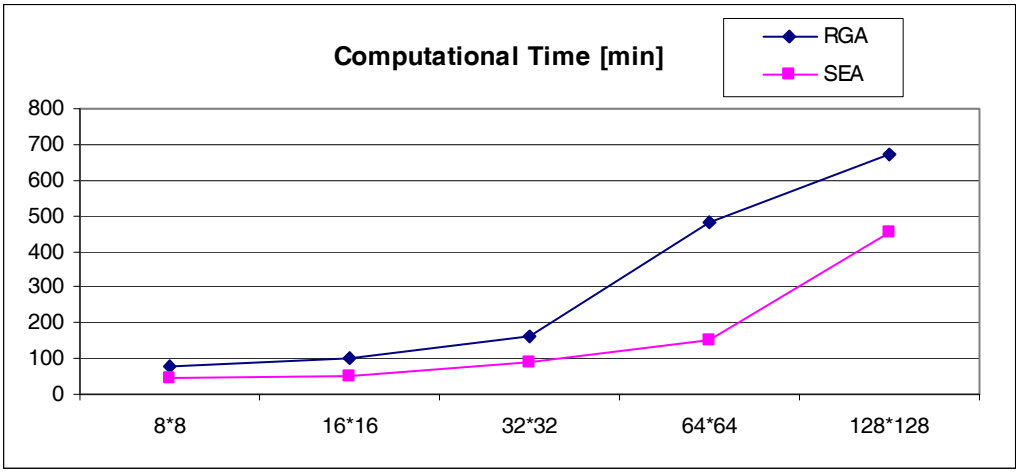

Fig. 4. Comparison of computational time when model converges

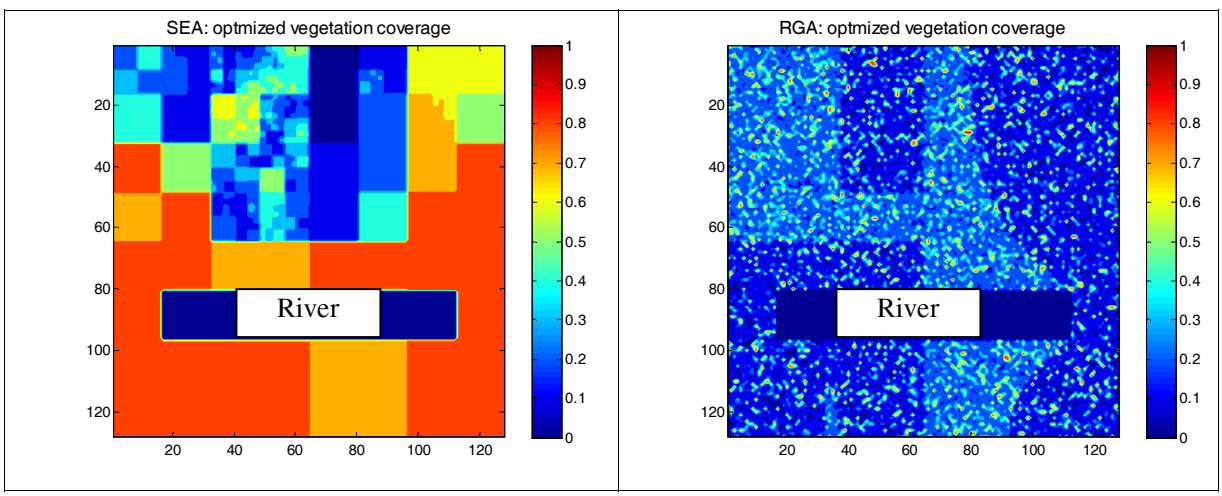

Fig. 5. Optimized vegetation converge when model converges

4.2.Run algorithms with similar computational time

With similar computational time, SEA obtains twice fitness as REA, which shows SEA is more efficient for large-scale optimization problem.

Table 2. Comparison of fitness with similar computational time

Problem Size	Generations		Time[min]		Max Fitness		SEA/REA	
	REA	SEA	REA	SEA	REA	SEA	time ratio	fitness ratio
8*8	99	101	13	13	0.29	0.57	0.99	**1.98**
16*16	110	101	17	17	0.23	0.63	0.99	**2.80**
32*32	107	101	25	25	0.29	0.55	1.00	**1.93**
64*64	120	101	48	47	0.27	0.59	0.99	**2.17**
128*128	113	101	131	130	0.23	0.60	0.99	**2.66**

4.3.Run algorithms when both reach similar fitness

When both algorithms reach the similar fitness, SEA takes no more than 1% computational time as REA. This time ratio is reasonable since REA evolves slowly when the model has a large number of decision variables.

Table 3. Comparison computational time when both algorithms reach similar fitness

Problem Size	Generations		Time[min]		Max Fitness		SEA/REA	
	REA	SEA	REA	SEA	REA	SEA	time ratio	fitness ratio
8*8	5001	5	684	2	0.47	0.53	0.002	1.11
16*16	5001	3	841	2	0.42	0.46	0.002	1.10
32*32	3691	4	1062	6	0.41	0.43	0.006	1.04
64*64	3001	4	1387	6	0.45	0.48	0.004	1.06
128*128	1021	2	1477	14	0.46	0.48	0.009	1.04

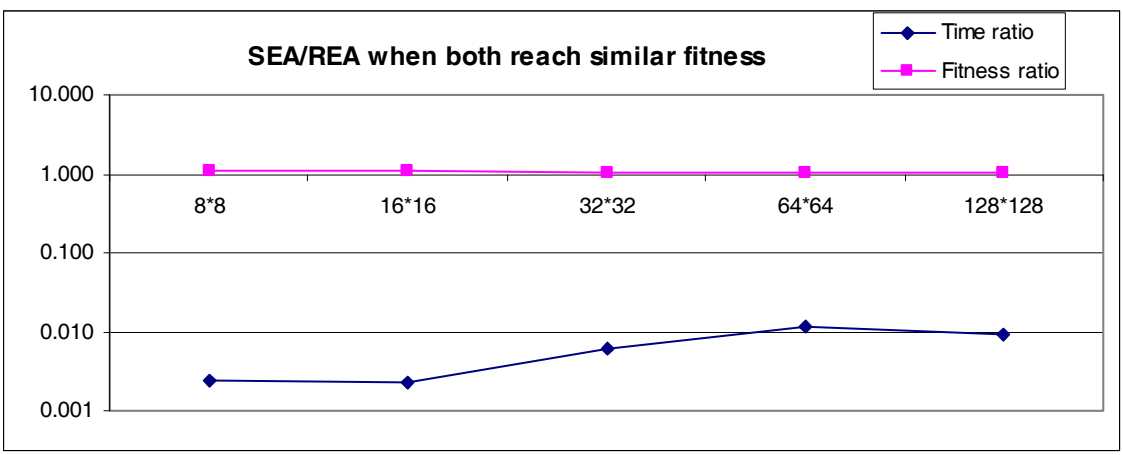

Fig. 6. Optimized vegetation converge when model converges

5 Conclusion

The main components of SEA, encoding, initialization, fitness and operators, have been modified to meet the challenges and also to make use of the characters of large-scale spatial problems. The spatial knowledge used in crossover, mutation and fitness together with a tree structure for encoding, distinguishes the SEA from a regular EA and increases flexibility and computational efficiency for large-scale spatial problems. In summary, the SEA has the following merits:

- The tree structure and initialization procedure increase the computational efficiency for large-scale spatial problems;
- Splitting, based on sensitivity in the mutation operation, introduces more exploitation into mutation and helps to speed up the optimal search for solutions to large-scale problems;
- Crossover swaps the nodes within the same area between individuals, maintains locally good information and passes it on to future generations;
- Spatial knowledge is interpreted from the spatial patterns of the study problem and helps to modify the crossover, mutation and fitness function of SEA.

Study on the Water Value Conversion between Economy and Ecology and Countermeasures of Water Resources Distribution for Coordinated Development of Economy and Ecology

Hongzhen Ni[1], Hao Wang[1], Bo Zhao[1], Dangxian Wang[1]

[1]China institute of water resources and hydropower research, Fuxing road, Haidian district, Beijing, 100038 ; PH (86)010-68785703; FAX (86)010-68483367; email:nihongzhen@163.com

Abstracts: Taking Beijing as an example, the paper studies response mechanisms to water quantity and quality of economy and environment, calculates water value and studies the conversion law of water value, measuring the gains and losses of the water conversion between economy and ecology. On this basis of analysis, the paper tries to give some suggestions for water sustainable utilization. The example gives us some conclusions: (1) in Beijing 2000, the water value of economy is more than ecologic, and in the low level of life, the man could pay more attention to economic water use; (2)if 4.04×10^9 m^3 used by social economy in 2000 are reallocated between environment and economy, following utility maximum principle, 24.76 million m^3 could be used by economy which is far less than actual, comprehensive water price is RMB 8.01/m^3 which is more than actual price 2.81, present water price cannot promote water reasonable allocation and sustainable utilization.

The social economy fast development caused the economical water consumption sharply increased. It has gone beyond the natural water resources bearing capacity, which occupied the natural ecosystem water used, broke the natural biosphere water demand balance, and then initiated the humanity to live the interdependence ecological environment worsening. However, with the economics growing and the material wealth increasing, the human energetic culture demand promotes quickly, so the higher qualities of life pursue needs support of superior environment. Therefore how to rationally allocate the limited water resources between economic society and the ecological environment, and how to make water resources utility value most superior display, has now become an extremely thorny pair of contradictory in water resources management.

Beijing is China's capital, located at Huabei Plain, where is serious scarcity of water.

In this article, we take Beijing as an example; analyze the water value and influence factors and the countermeasure of water resources reasonable distribution.

1 Basic data of study region

In 2000, the Beijing GDP reached 2478.76 hundred million Yuan, the total population achieved 12,779,000 people, the land area was 16807.8 square kilometers, the waters area was 9.70 square kilometers, and the urban garden greening area was 20600 hectare [1]. According to 2000 Beijing water resources bulletin[2], in 2000, the total water use in economic and society in Beijing is 40.40 hundred million m^3, went far beyond water resources supply quantity 16.86 hundred million m^3 in the same year. Compared last year the surface water resources depletion quantity approximately was 6.91 hundred million m^3, and the groundwater resources depletion quantity approximately was 5.89 hundred million m^3. In 2000 the total sewage discharge was 13.55 hundred million m^3, in which the industrial sewage discharge reached 5.79 hundred million m^3, and the domestic sewage (including the tertiary industry) reached 7.76 hundred million m^3. Conversions [3] according to the water quality condition is that the comprehensive surface water quality rank weakened from 3.58 to 3.62 by the beginning of the year, and corresponding the synthesis ground water from 3.46 to 3.6. Calculating according to the 2000 year price, Beijing investment costs per year on water resources management, maintenance, plan, and water source projects was 0.6 Yuan /m^3; The tap water supply volume is totally 7.54 hundred million m^3,and its total cost is12.54 hundred million Yuan.

2 The eco-environment value accounting of water resources

2.1 The eco-environment value of surface water

(1) The eco-environmental water demand and deficit calculation of surface water

In Beijing, the eco-environmental water demand is mainly influenced by the eco-environmental water demand inside the rivers, the lake's eco-environmental water demand in the city and the eco-environmental water demand of the urban green spaces.

① Eco-environmental water demand inside the rivers

There are five main rivers in Beijing, in turn from west to east is Juma River, Yongding river, northern canal, Chaobai River and Ju river, and they separately belong to Daqing river system、Yongding river system、northern canal system、Chaobai river system and Ji canal system.

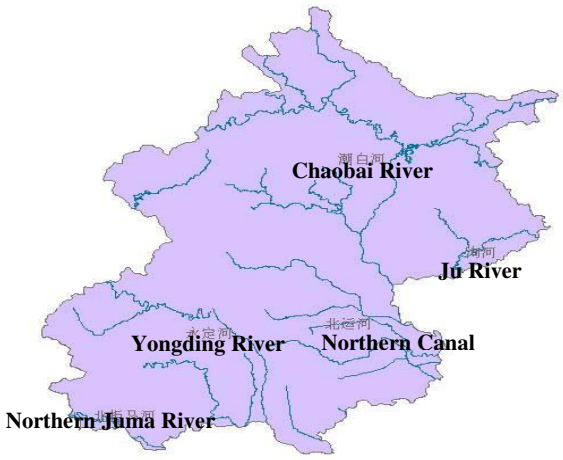

Figure 1. Distribution map of main rivers in Beijing

Here the calculating is directed towards to the five rivers in Beijing, and the eco-environmental water demand inside the river should meet three requirements: 1) to maintain the minimum flow of river; 2) to satisfy the water surface evaporation in river; 3) for the groundwater level in Beijing now falls generally and seriously, the water demand should also contains the channel leakage.

$$Q = Q_1 + Q_2 + Q_3 \quad (1)$$

which: Q Stands for the minimum eco-environmental water demand inside river;

Q_1 Stands for the water volume to maintain the minimum flow of river;

Q_2 stands for the water volume to satisfy the surface evaporation;

Q_3 stands for the water volume to satisfy the channel leakage;

The calculation of Q_1, take Guanting, Tongxian and Suzhuang stations as the controlling stations of Yongding River, Northern canal and Chaobai river systems. For the three stations locate on the main streams, they can stands for the changes of each water systems in Beijing. And other three stations, as shown in Table 1, Zhangfang station use the extrapolate formula in Hai river project; Ju river is a sub steam of Ji Canal, so here take the average flow in minimum month of Ju river's Sanhe station in the 1960s. The results are shown in Table1. The water volume to maintain the minimum flow of river in Beijing is 0.124 hundred million.

Q_2 The annual average surface evaporation in Beijing is 1100mm, according to the relationship between surface water wide and flow, we can obtain the water surface wide to each water system's minimum flow. So the total surface evaporation volume in Beijing is 6.473 hundred million. The results are shown in Table 1.

Q_3's calculation formula :

$$Q_3 = K\ F \quad (2)$$

K is empirical coefficient, F stands for water surface area.

Considering Beijing area is in the plain before the mountain, seepage property is worse

from west to east, therefore take Northern Juma River and the Yongding River's K value as 1.5, take northern canal and Chaobaihe River as 1, and take Ji Canal as 0.8. After computation the year river leakage quantity is 6.389 hundred million m^3, see Table 1.

Table 1. The eco-environmental water demand and water deficit of river

River name	Northern Juma River	Yongding River	Northern Canal	Chaobai River	Ju River	Total
River system	Daqing River	Yongding River	Northern Canal	Chaobai River	Ji Canal	
Control stations	Zhangfang	Guanting	Tongxian	Songzhuange	Sanhe	
River length（km）	51	240	339	680	85	
River water surface wide(m)	40	35	50	45	10	
Minimum ecological flow(m^3/s)	1.67	4.46	1.42	6.37	0.4	
Flow percentage (%)	7.22	7.4	12.1	10.5		
Water volume to maintain the minimum flow of river Q_1 (hundred million m^3)	0.014	0.039	0.012	0.055	0.004	0.124
Water volume to satisfy the surface evaporation Q_2 (hundred million m^3)	0.224	0.924	1.865	3.366	0.094	6.473
Water volume to satisfy the channel leakage Q_3 (hundred million m^3)	0.306	1.26	1.695	3.06	0.068	6.389
Total (hundred million m^3)	0.545	2.223	3.572	6.481	0.165	12.986
Status water volume （hundred million m^3）	0.40	1.64	2.64	2.98	0.12	7.78
Water deficit (hundred million m^3)	0.14	0.58	0.94	3.51	0.04	5.21

According to major achievement of the tenth five-year plan projects torch-plan countries -- China's regional ecological water use standard research, by 2000 correlation controlling stations' actual flow analysis, calculated that the rivers' extant water volume is 7.78 hundred million m^3, and get the result in the present situation that rivers ecological environment water deficit finally is 5.2 hundred million m^3.

② Eco-environmental water demand of the urban green spaces

According to each kind of material, Beijing city green space vegetation water used fixed quantity: Yearly average $1m^3/m^2$, so calculated that the urban vegetation green space need man-power water supply 2.06 hundred million m^3. According to investigates Beijing city green space vegetation's real water supply is $0.25m^3/m^2$, and the urban green space actual water used total quantity is 0.52 m^3, so the water scarcity is 1.54 hundred million m^3.

③ The lake eco-environmental water demand in the city

According to "Ecological environmental Water demand Theory, Method And Practice" (Yang Zhifeng and so on, Scientific Publishing house, 2003) (in city limit's lake and artificial river) the smallest eco-environmental water demand is 0.70 hundred million m^3.See Table 2.

Table 2. the minimum lake eco-environmental water demand in Beijing in 2000 (hundred million m^3)

Evaporation	Seepage	Habitat	Water recharge	Based flow	Total
0.0328	0.0064	0.0205	0.0137	0.6307	0.7041

In 2000, the actual water supply is 0.43 hundred million m^3, water storage capacity is

0.980 hundred million m^3 in the beginning, and the ecological environment water scarcity is 0.17 hundred million m^3.

Table3. the minimum surface water eco-environmental demand in Beijing in 2000(hundred million m^3)

	Channel	River and lake	Green vegetation	Total
Water demand	12.98	0.70	2.06	15.74
Water consumption	7.78	0.53	0.52	8.83
Water scarcity	5.20	0.17	1.54	6.91

(2) Surface water eco-environmental demand value and water scarcity loss accounting

①Value of eco-environmental water demanded and water scarcity loss accounting in channel

Use Haihe river's basin data 1.35 Yuan /m^3 to calculate the Beijing rivers' dilution value, the result is 17.52 hundred million Yuan /a.

According to Costanza etc.（1997），and if according to the price index in 2000 the conversion price is 3488.26 Yuan /hm^2, considered that the ecological environment value's increment effect, take the growth factor is 3%, then it results in 3811.72 Yuan /hm^2, then Beijing river eco-environmental water for biodiversity value is 0.21 hundred million Yuan /a, converted 0.02 Yuan /m^3.The surface water can adjustment temperature and saves the energy, the parameter is 56.67 Yuan /m^3.a, so Beijing's rivers adjustment climate and save energy 366.63 hundred million Yuan /a.

②Value of rivers and lakes eco-environmental water demanded and water scarcity loss accounting

According to the dilution ability[3] (1.35 Yuan /m^3) and the channel cleanout effect (refers to "15" research projects " Key technologies of Ecology Water Computation Research", 5.12 Yuan /m^3) the water's value is 6.47 Yuan /m^3, the river-lake eco-environmental water demand value is 4.53hundred million Yuan, and the water scarcity loses 1.10 hundred million Yuan.

③Value of the urban green vegetation eco-environmental water demanded and water scarcity loss accounting

The country "85" research project "Beijing City Botanical garden Ecological benefit's Research" indicate that vegetation can absorb CO_2 228.72t/hm^2, and release O_2 159.13t/hm^2 and so on, so the urban green vegetation eco-environmental water demand value and water scarcity loss is as Table 4.

About the green space water holding capacity, through the former experiments take 25% as the proportion of interception rainfall. With the shadow project method to calculate the water conservation value computation, the investment which namely the construction same storage capacity's storage facility (for example reservoir) needs, the value = water-holding capacity×the unit storage capacity cost. According to 2000's price the reservoir's cost to construct is 5.714 Yuan /m^3 , converted by Beijing city green space area, Beijing green space for water conservation's value can reach 0.295 hundred million Yuan.

According to related green vegetation improvement mass of atmosphere value correlation data: Antiseptic value 875 Yuan / hm^2•a, increases negative oxygen ion

value is 55.0 Yuan / hm^2•a, the storage preserves soil moisture value is 1065.6 Yuan / hm^2•a, humidification and adjusting temperature value is 278.0 Yuan / hm^2•a, so Beijing green vegetation value that make purification mass of atmosphere is 0.47 hundred million Yuan (in 2000 price).

Through the accounting, the green space eco-environmental water value is as Table4. According to normal water demand 2.06 hundred million m^3 of existing construction area green space in Beijing in 2000, the value converts for 5.92 Yuan/ m^3. And there are also large green spaces need artificially recharge water, so green space water scarcity loss is 9.12 hundred million Yuan. According to the value contribution, of water resources to the green space, takes the water used benefit sharing coefficient as 0.5, so the net value of green space's eco-environmental water used was 6.1 hundred million Yuan in 2000 in Beijing, and per m^3 water's value contribute to green vegetations is 2.96 Yuan, the green space water scarcity creates loss 4.56 hundred million Yuan.

Table 4. Eco-environmental water use value of green spaces in Beijing

Function	Amount of dust absorption	Absorb CO_2	Release O_2	Improve Air quality	Water conservation	Total
Value(hundred million Yuan)	0.19	7.95	3.28	0.47	0.30	12.19

According to the ecological and environmental experts' opinion, municipal reservoir constructions in Beijing destroyed the natural river 's ecological equilibrium, the reservoir's eco-environmental benefit did not arrive at original natural river system displaying the ecological environment benefits as river mouth, therefore did not calculate the value of reservoir's ecology water used adding to the total eco-environmental value in Beijing. And based on the water resources disposition, the surface water eco-environmental demand value and water scarcity loss accounting is as Table 5. The conversion for per m^3 water's value is 23.11 Yuan /m^3.

Table 5. The value and water scarcity loss on the satisfaction to minimum surface water eco-environmental demand in 2000 in Beijing

Classification	Channel	River and lake	Green spaces	Sum
Value (Yuan/m^3)	29.61	6.47	2.56	
Total value(Hundred million Yuan)	384.36	4.53	6.10	394.99
Water scarcity loss (Hundred million Yuan)	154.27	1.1	4.56	159.93

2.2 Eco-environmental value of ground water

Beijing ground water's ecological environment value can be calculate mainly through the value which prevent the surface subsidence and the value maintaining the bearing pressure of water-bearing to prevent the ground water form being polluted. As a result of the material limit, the ground water ecological environment's value is taken by: max {economic loss which avoids reducing ground water ultra exploitation, ground water recharging cost}.

According to Chinese Geology University's "City Groundwater resources Sustainable Mining Model Study" report, that in 2000 Beijing land subsidence surpassed 0.15m, and average economic loss of unit area will reach 4.5 Yuan /m^2. In 2000 in Beijing the most greatly land subsidence surpassed 0.59m, the area of influence surpassed 600km^2.Estimating from this, the eco-environmental loss which for the ground water ultra exploitation creates 27 hundred million Yuan in 2000 in Beijing. And in 2000 the

ground water ultra exploitation is 11.97 hundred million m^3, ultra exploitation the per m^3 water loss is 2.26 Yuan /m^3. (If according to the multi-annual means 24.55, in 2000 the ground water ultra exploitation is 2.6 hundred million m^3, and the unit water loss is 10.38 Yuan /m^3.)

Beijing is in Huabei region, if take the Shandong Province cost which recharges ground water to restores the ground water's eco-environment as references, considering the price factor and the time effect, the eco-environmental value in 2000 in Beijing is 4.43 Yuan /m^3.

2.3 Ecological environment value of water resources

The eco-environmental water used value in Beijing in 2000 is: surface water is 23.11 Yuan/m^3,ground water is 4.43Yuan/m^3，and the comprehensive value is 10.56 Yuan/m^3。

3 Value accounting of economic water use

The water resources' social and economy value calculation includes the effective and the disadvantageous consequence which caused by all social economy water use, which embody the advantageous and disadvantageous effect or the utility that the water resources produce in economic society (including ecological environment loss and water pollution economic loss).

3.1 Economic society water use accounting

The total water use volume of economic society in 2000 in Beijing is 40.40 hundred million m^3， including 13.25 hundred million m^3 surface water and 27.15 hundred million m^3 groundwater，which far beyond the water supply volume 16.86hundred million m^3。According to the basic data of Beijing, the accounting results are as shown in Table 6.

Table 6. Water resources use condition in 2000 in Beijing (Hundred million m^3)

Sub item		Industry	City life	River and lake	Agricultural use	Sum
Water use volume		10.52	9.76	0.43	19.69	40.4
Water source classification	Surface water	5.27	4.45	0.43	3.1	13.25
	Ground water	5.25	5.31		16.59	27.15

3.2 Positive effectiveness of economic society water use

The effectiveness economic society water use manifests in water used benefit shares among various departments. Because the lack on data information, it is difficult to establish the detailed relations between water use volume and production volume in minute department, so from the entire society national economy production angle, established Douglas production function which take capital, labor force and water as the essential factors, to analyze the production water supply utility value.

The total water volume in 2000 year in Beijing is 40.4 hundred million m^3, GDP is

2478.76 hundred million Yuan. The value that unit water shared in GDP is 61.355 Yuan /m^3. By the total water consumption, GDP, total capital and employed population during 1988~2002 year economic society, when caring about factor in which the water used efficiency, the capital enhance use efficiency and the labor force level developing along with the time, obtains the entire social product function through fitting as follows:

$$GDP = 0.0023K^{0.528}L^{0.545}W^{0.242} \quad (3)$$

By the functional relations, in the situation which capital, labor force and so on essential factors are invariable, increasing per m^3 water used value in the economic society to GDP is 14.73 Yuan /m3.

3.3 The water polluted cost caused by economy society water use

(1) Surface water polluted cost caused by economy society water use

According to the water quality ~ economical loss factor function in economic society water use [3], the surface water polluted cost caused by economy society water use in 2000 in Beijing is 112.32 hundred million Yuan; the estimate result is as shown in Table 7.

Table7. Water polluted cost caused by economy society water use in 2000 in Beijing

Sub item	Agriculture	Industry	City life	Tourist industry	Town planning	Sum	Total water (hundred million m^3)	Per m^3 water loss (Yuan/m^3)
Loss(hundred million Yuan)	12.59	8.43	43.99	23.94	23.36	112.32	40.4	2.78

(2)Ground water polluted cost caused by economy society water use

Ground water polluted cost caused by economy society water use in 2000 in Beijing is 2.25 hundred million Yuan[3], and the per m^3 water loss is 0.06 Yuan/m^3。

Generalized analyzing, the ecological environmental loss caused by the economic society water use sums as 114.57 hundred million Yuan, according to same year economic society water use 40.4 hundred million m^3,the shared per m^3 water use cost is 2.84 Yuan /m^3.

3.4 Value and loss of economic society water use

Considering each loss calculation achievement, the accounting results are as shown in Table 8. The total ecological environmental loss caused by the economic society water use sums as 327.95 hundred million Yuan, the shared per m^3 water use cost is 8.11 Yuan /m^3.

Table 8 Environment and resources accounting evaluation indexes of economic society water use

Idem	Total (hundred million Yuan)	Percentage of GDP	Per capital volume (Ten thousand Yuan)
1. Environment loss index	114.57	4.62%	0.090
Surface water polluted loss	112.32	4.53%	0.088
Ground water polluted loss	2.25	0.09%	0.002
2. Resources depletion index	213.02	8.59%	0.167
Surface water depletion loss	159.93	6.45%	0.125
Ground water depletion loss	53.09	2.14%	0.042
Sum of two index	327.59	13.21%	0.257

Through the green account of water resources, the eco-environmental synthesized water used value was 10.56 Yuan /m^3 in 2000 in Beijing, the economic society synthesized water used value is 14.73 Yuan /m^3, and the environment economy synthesis loss was 8.11 Yuan /m^3.

4. The conversion of water value and analysis of gains and loss

If ignoring the negative effect or loss caused by economy water use, Driven by interest, the economic man should be in the pursuit of economic development as a main goal because of the water use benefits of economy outweighing environment. Furthermore, the local people are still in the low level life, and the role and value of water used in ecological environment is still in the senses, not completely and deeply. Similarly, now many propaganda material also just stay in scattered, rather than the profound information, could not to hit and shock the theory of driven by interest which is in the souls deeply. The economic man only values the positive benefits of economic water use, not from the overall social welfare including direct and indirect, tangible and intangible, positive and negative, short-term and long-term, economy and natural environment, to study and evaluate, and make an optimal decision. Therefore, in the life level below or at the primary stage of rich, especially in state of paying less attention to high quality requirements in ecological environment and its demand weakening, or the destruction of ecological environment due to water scarce not endangering the survival, the economic man will be yet driven by interest to consider economic water use at first, although the ecological environment water use and benefits can get attention gradually, it is also in secondary demand status.

At present, people's knowledge is not enough to calculate the value of ecological water use completely. From the simple arithmetic, social welfare value of economic water use is still positive, namely 6.62 yuan/m^3. If seeing the problem in a shortsighted view, it is profitable to economic occupying ecological water. But 6.62 yuan/m^3 < 10.56 yuan/m^3, the net benefits of economic water use are less than the value of environmental water use; water does not reach the optimal allocation and utilization.

5 Economical regulation analysis of water resources optimal allocation

In the view of social welfare, put environment and economy into a virtual water market (not exist yet), use the market water price mechanism to study the allocation of Beijing economic water use in 2000, according to the optimal allocation principle. Applying the theory of partial equilibrium analysis, studies the effect of water price.

5.1 Water demand equation

The budgetary expenditures of water consumption *M*, according to the coefficients of development stage [5] and the international average standard: the charge of living water is about 3% of water incomes; the charge of industrial water could be 5% of total industrial output value.

According to the 2000 Engel's coefficient 36.3% [1], Beijing economic development stage coefficient $l = \frac{1}{1+e^{-1/0.363+3}}$=0.44. The proportion of expenditure budget of living water consumption for income: 3%×0.44＝1.32%; The proportion of expenditure budget of industrial water use for total industrial output value: 5%×0.44=2.2%. In 2000, the second industrial output value of Beijing is 3878.35 billion Yuan [1], the budgetary expenditures of water consumption are for 85.324 billion Yuan; According to the 6.5% (international rate) of output value of the tertiary industry and the coefficient of development stage, budgetary expenditures of the tertiary industry water consumption are: 3952.92[1]×6.5%×0.44＝113.05 billion Yuan; Income of resident is 695.5 billion Yuan [1], the budgetary expenditures of the water consumption are for 9.18 billion Yuan; According to 1.32% of GDP (same as living), the budgetary expenditures of the agriculture water consumption are for 195.18 [1] ×1.32%＝2.58 billion Yuan. The budgetary expenditures of whole society total up to 210.14 billion Yuan, namely 8.5% of GDP.

According to value, economic water utility preference coefficient set as 0.6, the ecological environment water utility preference coefficient set as 0.4.

Based on the analysis of water use in 2000, the ecological environment basic water demanded cannot be guaranteed and lack 6.91 billion m^3. According to the basic human "water" (BRW) 50L for each day [7], the basic water of life to safeguard should be 230 million m^3/a. To establish the utility maximization equation of water demand.

$$\begin{cases} \max U = 0.6\ln(Q_s - 2.3) + 0.4\ln(Q_e) \\ p_s Q_s = M = 0.085GDP = 210.14 \\ 2.3 \le Q_s + Q_e \le 40.4 \\ Q_s, Q_e, p_s \ge 0 \end{cases} \tag{4}$$

U is the utility of total water use, Q_S is the water demanded by economic society, Q_e is water demanded by ecological environment, p_s is the price of economic water use.

5.2 Water supply equation

From the water supply, according to the market mechanism, take the profit maximization of water supply as an aim, the equation is as follow:

$$\begin{aligned} \max\ \pi &= v_e Q_e + p_s Q_s - C \\ &= 10.56 \times (40.4 - Q_s) + p_s Q_s - C \end{aligned} \tag{5}$$

π is the profits of water supply, v_e is the value of ecological water use, C is the total cost of water supply to economy and ecological loss due to economic water use not rationally.

When to meet the basic water demanded by ecological environment, the water 40.4-6.91 =33.49 billion m^3 might be use by economy. With the whole cost accounting of economic society water use, setting the quantity of tap water supply as a constant, by the analysis of the financial costs in Beijing 2000, the relationship between whole cost of social economic water use and water consumption is as bellow:

$$\begin{cases} C = 8.11 Q_s + 0.6(Q_s - 7.54) + 12.54 & Q_s > 33.49 \\ C = 2.84 Q_s + 0.6(Q_s - 7.54) + 12.54 & Q_s \le 33.49 \end{cases} \tag{6}$$

Taking the simultaneous equations of water supply and demand, do the iterative computation. In 2000, the total water 40.4 billion m^3 used by social economy are reallocated between ecological environment and social economy, the result is that comprehensive water price is RMB 8.01/m^3 under maximum utility of water use, 24.76 million m^3 could be used by social economy, water quantity available for ecological environment is 15.64 billion m^3, the optimal comprehensive benefits of economic and environmental water use is 440 billion Yuan. Through analysis, it can be found if the ecological basic water demanded can not be satisfied, with the bear ability of social economy, all the cost caused by social economy water use would not be recovered.

In 2000, Beijing actual comprehensive price is 2.81 yuan/m^3 that cannot promote reasonable allocation and sustainable utilization of water resources.

6 Counter measures of water reasonable allocation

Beijing water failed to reach optimal allocation, the main reason is not only market failure, such as water price etc., but also water management and macro-control measures problems. Therefore, for the optimal allocation of water resources rationally, many kinds of methods combined are necessary. Overall, mainly these points should be taken seriously as following.

(1) To strengthen ecological water right management. Considering the ecological benefits enjoyed by the human as a right, set up the water resources management control system which rights and obligation is peer to peer. The basic standard of ecological environment water demanded should be taken scientifically, to ensure social economy and ecological environment coordinated development.

(2) Use the preferential policy encouraged, promote economic sectors saving water, and then protect the ecological water use. Through the priority development, tax cuts and subsidies, encourage cleaning production and saving water.

(3) Fully exert the market mechanism, scientifically make water price to allocating water rationally and optimally. With the passage of time, the ability to shoulder economically cost of water use and scarce degree of water resources will change, water price must dynamically be adjusted accordingly, in order to guarantee their normal adjustment ability of supply and demand of water resources. With the water became restriction of production and life environment beautification more and more seriously, it can be consider to gradually set price of ecological environment water use relating to human welfare, changes the view of ignoring value of ecological water use, promote to value ecological water use as well as economics'.

ABSTRACT

One of the most fundamental assumptions in statistical analysis is whether the random variable of interest is continuous or discrete. Natural processes such as streamflow are considered to be continuous random variables, able to take on an unlimited number of possible values. However, to reflect data accuracy, reported streamflow values are generally rounded. For example, the U.S. Geological Survey (USGS) reports mean daily streamflow values less than 1 cubic foot per second (ft^3/s) to the nearest hundredth place (0.01), resulting in only 99 possible values for streamflows between 0 and 1 ft^3/s available for statistical analyses. The limits of the data subsequently result in the discretization of a continuous variable; the effects of discretization on the statistical properties of the data could affect applications such as moment estimation, regional frequency analysis, and distribution fitting, particularly for low flows where rounding could substantially reduce the number of possible values. In an effort to determine the effects of discretization, large samples of independent data were generated from a generalized probability distribution to the sixteenth decimal place. The synthesized data was then rounded according to USGS streamflow-reporting standards. Initial comparisons of the original synthesized data and the rounded data show that estimates of the sample mean and standard deviation only differed slightly. Additional experiments will explore the effects of rounded data in other statistical analyses as well as for autocorrelated data.

INTRODUCTION

A common technique to estimate flow-duration-curve quantiles at ungaged locations is to develop regional regression equations that relate measurable basin characteristics to streamflows

at the quantiles of interest. In southern New England, it is a well-documented feature of these regional-regression equations that the prediction error and uncertainty in the regression equations increase with increasing exceedance probability (see Reis and Friesz, 2000 and Archfield and others, 2007). It is commonly hypothesized that this phenomenon occurs because there does not yet exist a set of explanatory variables capable of adequately estimating low flows. The purpose of this paper is to explore the streamflow estimates themselves as an alternative explanation for the increased prediction error and uncertainty in low-flow regional-regression equations. In particular, this paper begins to explore the effect that U.S. Geological Survey (USGS) reporting standards for streamflow have on the estimation of streamflow quantiles.

U.S. GEOLOGICAL SURVEY STANDARDS FOR REPORTING STREAMFLOW DATA

The USGS rules for reporting streamflow values are given in table 1 (U.S. Geological Survey, 2009). Given those reporting rules, there are only a limited number of values that exist for streamflows less than 1,000. Notably, there are only 99 possible unique values for streamflows less than 1 cubic foot per second and 90 possible unique values for streamflows between 1.0 and 10 cubic foot per second. The reporting rules have the effect of discretizing streamflow - a continuous random variable - into a discrete random variable. Because the effects of this reporting standard are most pronounced for streamflows less than 10 cubic feet per second, it is hypothesized that the reporting standard has some effect on any statistical analysis performed with the discretized values.

Table 1. U.S. Geological Survey rules for reporting streamflow values

Range of streamflow values, in cubic feet per second	Reporting rule for streamflow values
Less than 1	Nearest hundredth
Between 1.0 and 10	Nearest tenth
Between 10 and 1,000	Whole numbers
Greater than 1,000	Three significant figures

STUDY AREA AND STREAMFLOW-GAGING STATIONS

We begin by exploring the impact of the reporting rules in Table 1 on actual streamflow records. We consider the 66 gaged basins shown in Figure 1 all of which do not contain major water withdrawals or return flows and the predominant land cover in the basin is forest; however, the presence of dams within the basins was not considered in the identification of minimally-impacted sites. Daily, continuous streamflow observations at the gages ranged from 10 to 86 years, with 47 gages containing greater than 20 years of continuous record and the drought of the 1960s, which is considered to be the drought-of-record in New England (fig. 1). Armstrong and others (2008) provide a detailed description of the geologic, hydrologic and climatic conditions of the study area as well as information on water use, land cover, and the presence of dams within the study basins.

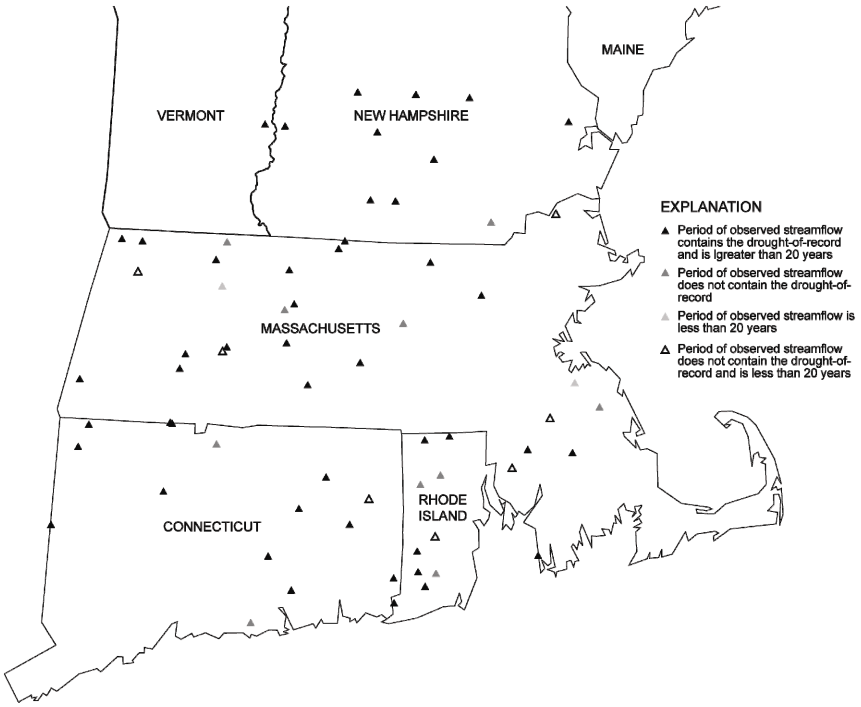

Figure 1. Locations of 66 minimally-impacted streamflow gages in southern New England.

CHARACTERIZATION OF STREAMFLOW DATA

The effects of the USGS reporting standard (table 1) is evident from a simple count of the number of unique values that occur in each of the streamflow records at the 66 study gages shown in figure 1. The average record length of the study gages is 15,655 daily streamflow values; however, the average number of unique streamflow values is only 547. One of the more dramatic cases is the Moss Brook at Wendell Depot, MA streamflow gage, which has over 24,400 daily streamflow observations but only 361 unique streamflow values. In general, at most only 8 percent of the reported observed flow values across all of the study gages were unique values and the number of unique values in a particular streamflow record tends to increases with the median streamflow computed from the gage's period of record as shown in fig. 2.

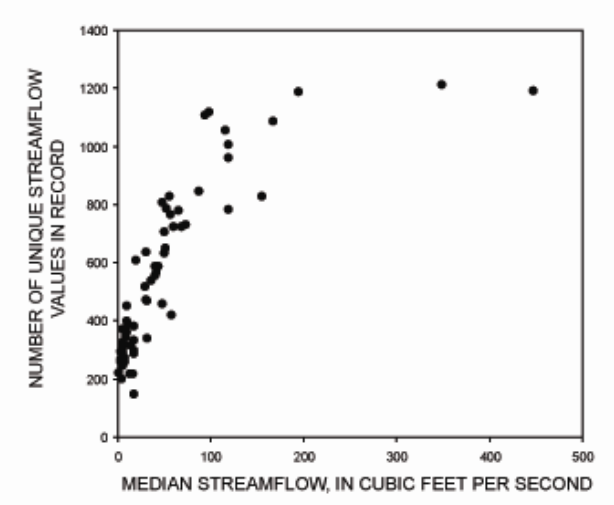

Figure 2. Relation between the numbers of unique streamflow values and the median streamflow for 66 study gages in southern New England.

SIMULATION EXPERIMENT AND RESULTS

To begin to understand the effects of the USGS reporting standard on quantiles and moments of streamflow estimated from the discretized streamflow values, 66 samples of 20,000 independent streamflow values were generated from a 3-parameter generalized Pareto (GP) distribution using the parameter sets estimated from the 66 observed streamflow records (fig. 1). Vogel and Fennessey (1993) found that a GP distribution provides a good approximation to the distribution of daily streamflows in Massachusetts. More recently Archfield et al. (2007) determined a kappa distribution to be a more appropriate distribution than the GP for representing the distribution of daily streamflow, however, the GP distribution was used in this analysis to avoid complications in parameter estimation that is introduced by use of the kappa distribution.

Simulated data were then rounded according to the USGS reporting rules shown in table 1. The mean, median and standard deviation of the simulated data and simulated-then-rounded data were compared. Differences in the estimated means and standard deviations varied only slightly; however, it is interesting to note the USGS reporting rules do not preserve the sample mean and variance of the data. When the median values were compared, the simulated data and simulated-then-rounded data differed by as much as 4 percent. A difference of up to 4 percent was also observed when a comparison of the data at the 90- and 95-percent exceedence probabilities was made. Such large exceedance probabilities, associated with low streamflows are where we expected the most significant differences to occur. The difference is more pronounced when one takes the natural log of the streamflows, as is commonly done in regional-regression analysis. In fact, more than a 15-percent difference was observed when comparing the log-transformed simulated data and rounded-simulated data for 3 samples.

DISCUSSION

Reported values are rounded based solely on the magnitude of the streamflows; independent of the measurement or rating errors. The reporting rules do not appear to be based on any error or uncertainty analyses, making it unclear why these rules are practiced. The experiment presented in this paper only considers an independent random variable; whereas, daily streamflow is highly autocorrelated. The autocorrelation in daily streamflow will only exacerbate the number of non-unique values, particularly for low flows where the number of possible values is much smaller. In the experiment presented in this paper, we were unable to simulate a record that contained a similar number of non-unique values as the observed streamflow records; this is because the samples we generated were independently generated. Future experiments will generate daily streamflow data based on an autocorrelated process. Additional work will explore the effects of this reporting standard in other statistical analyses, such as distribution fitting and regional frequency analysis. Future work will also explore the use and utility of quantile estimators presented in Vogel and Fennessey (1994). These estimators show promise in smoothing the flow-duration curve and thus converting discretized data into a continuous streamflow series. . It is also unclear if the effects of this reporting standard are more pronounced for smaller sample sizes than the 20,000 used here. We expect to report on all of the above issues in much greater detail at our oral presentation at the 2009 EWRI conference in Kansas City.

Whose Idea Was This to Use Risk and Uncertainty Analysis in Water Resources?

Many of the ideas presented in this paper have been around for numerous years. The main proponent of this approach for use in water resources subjects is the U.S. Army Corps of Engineers (COE) and it use is mandated for COE flood control projects. In the early 1990s, the COE and other entities re-examined the concept of freeboard for their flood control projects and felt that the use of Risk and Uncertainty concepts would help quantify the additional required protection above the design elevation instead of adding a somewhat arbitrary value (NRC, 2000). This paper presents the concepts of Risk and Uncertainty Analysis (affectionately termed as RU) as applicable to floodplain management and issues. It also goes over some of the important aspects of RU analysis that should be understood by water resources engineers and floodplain managers. Within about 5 years, floodplain managers will be required to be knowledgeable on the subject of Risk and Uncertainty!

Types of Uncertainties (adapted from Pappenberger, et.al., 2006; NRC, 2000)

1. Natural Uncertainty (Variability) - Refers to inherent variability in the physical world
2. Uncertainties that stem from the assumed inherent randomness and basic unpredictability in the natural world
3. Characterized by the variability in known or observable populations
4. Knowledge Uncertainty - Lack of scientific understanding of natural processes and events in a physical system.

   - Process model uncertainty – Models (e.g., HEC-RAS and HEC-HMS) are an abstraction of reality and can never be considered true. Measured data versus modeled data gives an insight into the extent of model uncertainty.
   - Statistical inference uncertainty - Quantification of the uncertainty of estimating the population from a sample. The uncertainty is related to the extent of data and variability of the data that make up the sample.

5. Statistical model uncertainty - Associated with the data fitting of a statistical model. If two different models fit a set of data equally well but have different extrapolations/interpolations, then it is not valid - statistical model uncertainty.

Some Definitions used in Uncertainty Analysis

1. Deterministic Analysis: Uses single values for key variables, e.g., use of an expected flow to determine a single water surface elevation.
2. Probabilistic Analysis: Uses a probability distribution rather than a single value for key variables - captures and describes uncertainty of the variable, e.g., expected flow including a range of possible flows to determine a range of possible water surface elevations.
3. Annual Exceedance Probability (AEP): Measures "the probability of getting flooded" in any given year, considering the full range of floods that can occur – uses only the peak discharge of each year.
4. Conditional Annual Non-Exceedance Probability - CNP (Assurance): The probability that a project will provide protection from a possible distribution of a specified event. For levees, includes the chance of capacity exceedance and the chance of failure at lesser stages. CNP is computed by determining the expected exceedance/failures at top of levee (levee will not fail before overtopping); or application of levee elevation failure probability curve (chance of failure prior to overtopping).

Who is Monte Carlo and Why are We Afraid of Him?

The Monte Carlo techniques are integral to RU analyses. Monte Carlo methods are a class of computational algorithms that iteratively evaluates deterministic model results using input of random numbers. The methods are used when it is infeasible or impossible to compute an exact result with a deterministic algorithm. There is no single Monte Carlo method; instead, the term describes a large and widely-used class of approaches. These approaches tend to follow a particular pattern:

1. Define a domain of possible inputs (e.g., average and standard deviation).
2. Generate inputs randomly from the domain, and perform a deterministic computation on them.
3. Aggregate the results of the individual computations into the final result.

Example of the Monte Carlo Techniques: Determine π by Random Darts

A simple example of the Monte Carlo method can be seen in a classic experiment, using random dart throws to determine an approximate value of π. First, take a quarter of a circle and place it within a square (see Figure 1). If one randomly throws darts at that square (disregard any that fell out of the square), some would land within the circle, and some would land outside. The proportion of darts that landed in the circle to darts that landed outside would be roughly one-fourth of π (see equations below).

$$\frac{\#\text{ darts hitting shaded area}}{\#\text{ darts hitting inside square}} = \frac{\frac{1}{4}\pi r^2}{r^2} = \frac{1}{4}\pi$$

or

$$\pi = 4\frac{\#\text{ darts hitting shaded area}}{\#\text{ darts hitting inside square}}$$

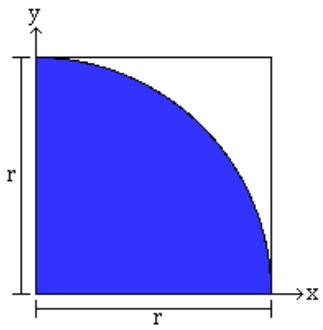

Figure 1. ¼ Circle Within a Square

If only a few darts are thrown, the results of the throws would not lead to a very accurate value for π. As in most Monte Carlo simulations, thousands or millions of trials must be made so that outliers do not affect the accuracy of the results.

Parameter Value and Possible Range

To perform a Monte Carlo simulation, the parameter(s) of interest must be valued and the variation of that value determined. This is illustrated in Figure 2 in which a parameter can have a "best guess" value and a probability of its range of values. This is termed a probability density function (PDF). This PDF can be transformed into a Cumulative Probability Distribution Function (CDF) as illustrated in Figure 3.

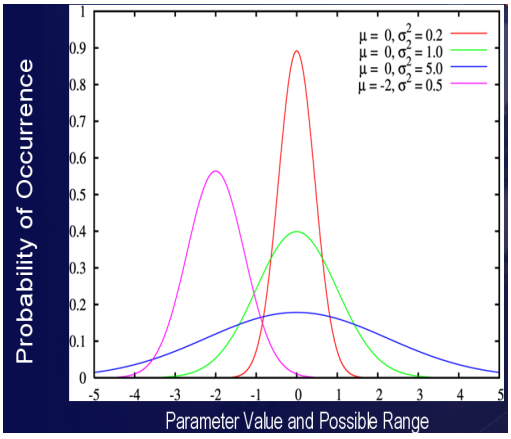

Figure 2, Example of a Probability Density Function

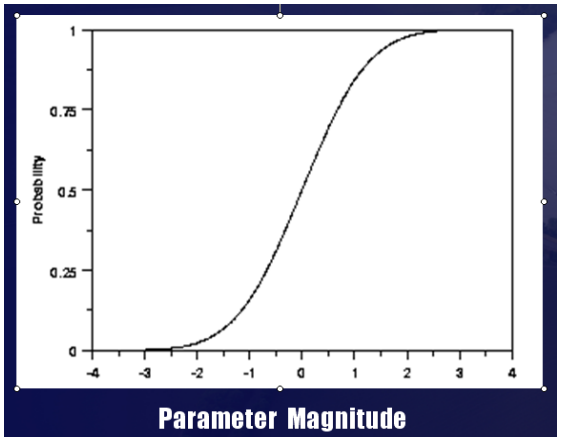

Figure 3. Example of a Cumulative Probability Distribution Function

Determining the Answer Using Monte Carlo

Once the CDF of a parameter is determined, it is randomly sampled and each sample value and its associated probability are noted. These values can be input to a model for simulation (e.g., precipitation depth in HEC-HMS) and the result of the simulation (e.g., peak discharge) has the associated probability of the input value, resulting in another CPD. In this example, the probability distribution of the peak

discharge. The following procedure is applicable to Hydrology and Hydraulics using RU Analysis. Results can be used for a variety of floodplain management strategies.

1. Determine the CDF for a given discharge
2. Determine the CDF of the parameters affecting the water surface elevations in a hydraulic model
3. Use Monte Carlo to develop a CDF of the water surface elevation versus discharge relationship, combining the hydrologic and hydraulic CDFs
4. Results are associated probability for each water surface elevations for the given discharge

How Do We Determine the Hydrologic Parameters and Their Variations?

For hydrology, frequency analysis of discharges can be used from gage data and statistically determine the mean and variation of the peak annual discharge. The standard error of flood discharges from gaging station data can be determined as described by Kite (1988). The standard error of gaging station estimates can also be determined using the 84-percent one-sided confidence limits as described in Bulletin 17B (WRC, 1981). The approach by Kite (1988) is favored because it considers the uncertainty in the skew coefficient while the Bulletin 17B approach does not.

The standard errors of estimate or prediction of the USGS regression equations can also be obtained from regional flood frequency reports (e.g., Dillow, 1996). The standard error of rainfall-runoff model estimates is not usually known. WRC report (1981) suggested that it is larger then the standard error of regression estimates in part because rainfall-runoff models based on a single-event design storm are not usually calibrated to regional data.

Confidence limits or standard errors of flood discharges from rainfall-runoff models can be estimated if an equivalent years of record is assumed for the flood discharges - USACE (1996b). However, no established practice of estimating the uncertainty of flood estimates from rainfall-runoff models.

How Do We Determine the Hydraulic Parameters and Their Variations?

Variations in water stage can be done by observation of the stage vs. discharge relationship. The uncertainty in stage for ungaged locations can be estimated by the following (COE, 1996b):

$$S = [0.07208 + 0.04936\ I_{Bed} - 2.2626x10^{-7}A_{Basin} + 0.02164\ H_{Range} + 1.4194 \times 10^{-5}Q_{100}]^2$$

Table 5-1
Bed Identifiers

Material	Identifier
Rock/Resistant Clay	0
Boulders	1
Cobbles	2
Gravels	3
Sands	4

Where: S = standard deviation in meters, H = maximum expected stage
A = basin area in sq km, Q = 100 year discharge, I = from Table 5-1

Hydraulic models can be used and the parameters that could be varied are:

- Expansion and contraction ratios (usually important only at bridges and culverts)
- Other parameters influences on the stage vs. discharge relationship are very small
- Manning's "n" values – requires a mean value, maximum and minimum, and an assumed distribution (usually a normal "Gaussian" distribution): this is the most common parameter to be varied. See Figure 4 for example.

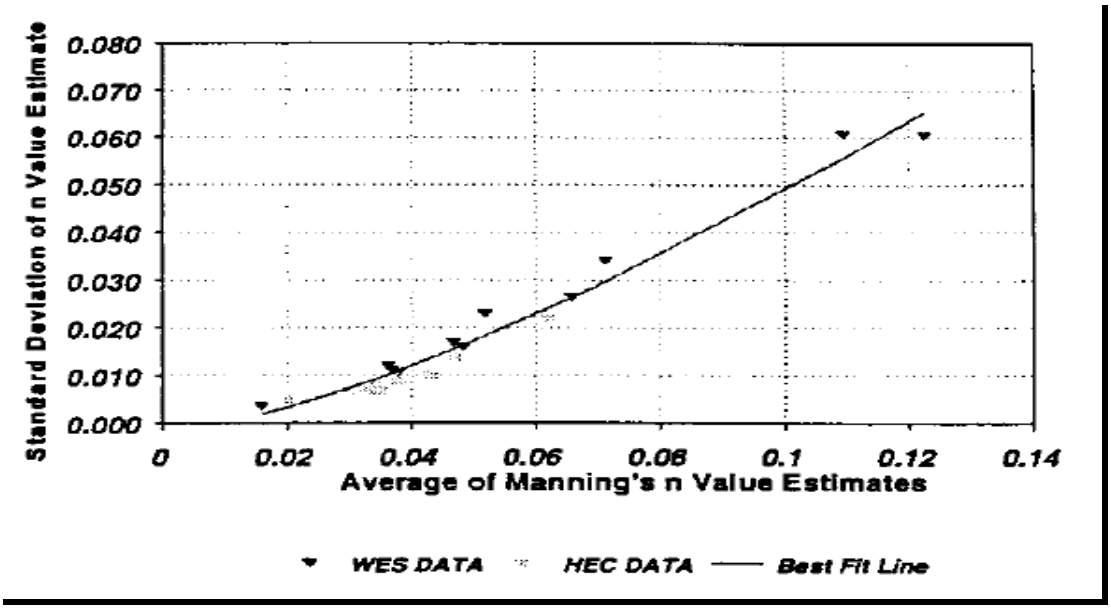

Figure 4. Estimation of the variation in Manning's "n" (COE, 1996b)

What Does The Results Look Like?

The variation in discharge can be used to determine the variation in stage (with in-bedded Monte Carlo simulation in the hydraulic model) and then used to determine the variation in stage, as illustrated in Figure 5. The variation of the stage for a single probability is illustrated in Figure 6.

Hydrologic and Hydraulic Model Linkages and Stochastic Modeling

The Corps of Engineers' Engineering and Research and Development Center (ERDC) sponsors the development of WMS 7.0, which is an interface of various hydrologic models. Within WMS 7.0, the ability to link an HEC-1 hydrologic analysis to a HEC-RAS model has been developed. HEC-HMS is planned for later. The user defines certain modeling parameters for both models within a range of probable values and then runs the linked simulations. Only CN and Precipitation are currently

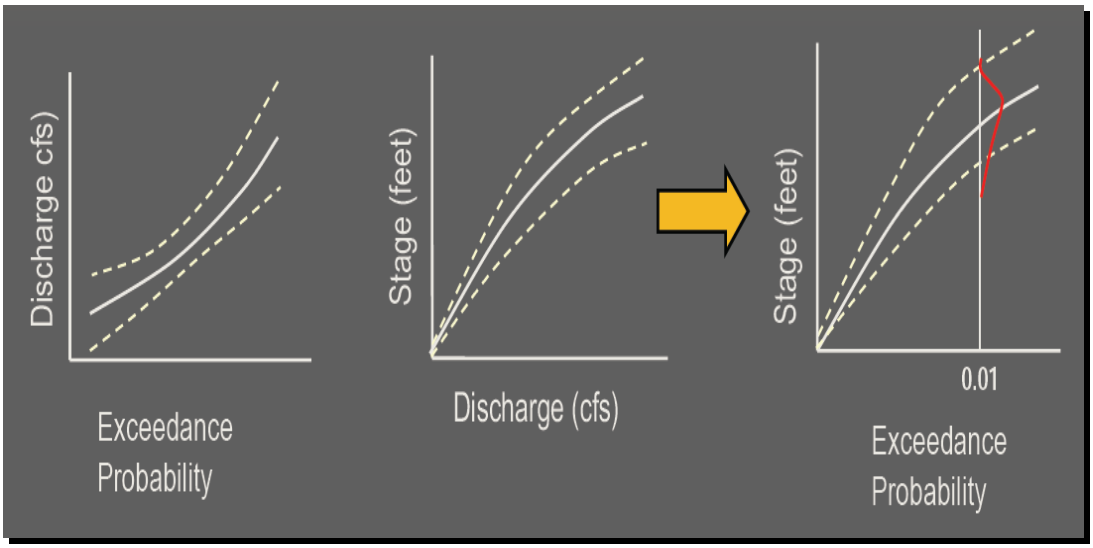

Figure 5. Determination of Stage Uncertainty (Deering, 2007

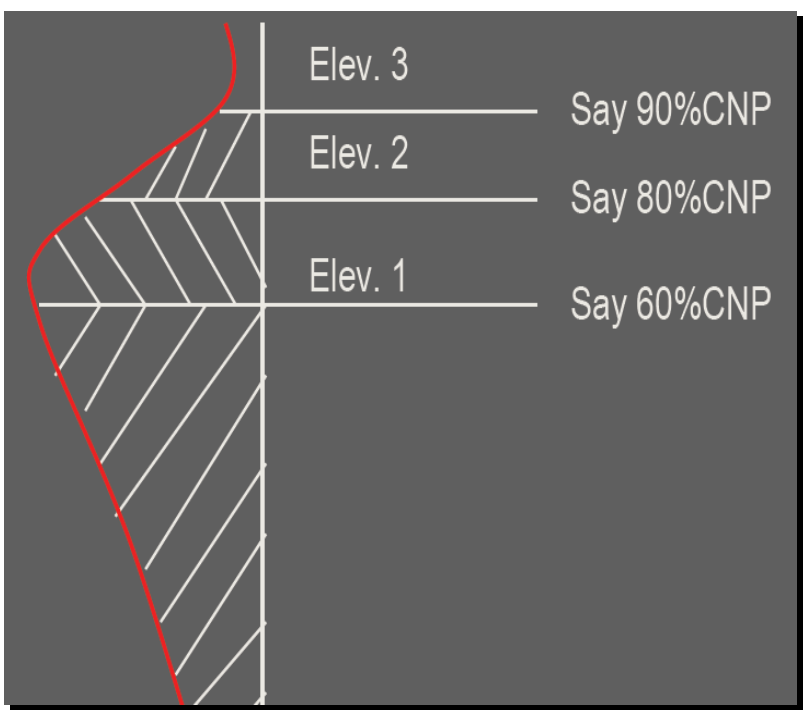

Figure 6. Stage Variation for a Single Probability (Deering, 2007)

the possible parameters for HEC-1 models and Mannings roughness for HEC-RAS models. Additional parameters will be added to both models.

What Are Some Applications of RU to Levees?

The traditional design for top of levees includes freeboard (to account for uncertainties) added to the design water surface elevations. If the uncertainties can be quantified as a range of probabilities, the freeboard can be determined if a certain

CNP can be agreed upon (say 90 or 95% CNP). The lower the acceptable risk (want less risk of failure), the higher the CNP and the higher the top of levee above the traditional deterministic water surface elevation.

What is the Corps policy on RU and Levees?

The US Army Corps of Engineers (COE) has guidelines for computing an aggregated annual exceedance probability (AEP) in the floodplain for levee certification (see USACE, 1996a, 1996b and NRC, 2000). The COE (since 1996) does not use "freeboard" but uses the concept of the CNP elevation above the deterministic elevation. In the NRC (2000) report, it states that the COE approach to levee certification is well thought out, but is still lacking in certain areas. Two recommendations for improving the current methods (NRC 2000) are: (1) consider spatial variability in flood studies and (2) use the AEP more widely as the measure of levee performance for both COE and FEMA.

What about FEMA, Corps, Levees and RU?

In 1996, FEMA and the Corps proposal combined FEMA's old criteria with the Corps RU methodology. This supplements 44 CFR 65.10. The Corps and FEMA agreed to certify a levee if its elevation was at least:

- (1) at the 90 percent CNP elevation if it is greater than 3 feet.
- (2) at the 95 percent CNP elevation if it is greater than 2 feet
- (3) at 3 feet if it is between the CNP of 90 percent and 95 percent.

Why bother with RU for levees? (Davis, 2007)

Consider these situations:

Situation 1. Flat gradient, flow/stage variability low, long flow/stage record, high integrity existing levee.
Situation 2. Steep gradient, flow/stage variability high, short record, uncertain integrity existing levee.

Traditional methods would give one value for freeboard, but risk analysis explicitly quantifies difference between these situations and reflects residual risk. From an HEC study of 13 levee systems, the following observations were made:

- FEMA standard of 3 feet of freeboard provides a median expected level of protection of approximately 230 years, range of <100 years to >10,000 years
- Corps – FEMA 90% - 3ft - 95% criterion provides an average of 3.3 feet of freeboard and yields a median expected level of protection of approximately 250 years, range of 190 to 10,000 years
- The 90 percent CNP has an average of 3.0 feet of freeboard and a median expected level of protection of approximately 230 years, range of 170 to 5,000 years
- The 95 percent CNP has an average of 4.0 feet of freeboard and a median expected level of protection of approximately 370 years, range of 210 to 10,000 years.

Use of RU and CNP for Levee Elevation Determinations

We can use the results of the RU analysis to determine inundation extents for any CNP. From the CNP elevations for a given AEP (say 100 year event), we can map the floodplain inundation areas for a given CNP. Smemoe (2004) has proposed using uncertainty analysis for this purpose. This can aid the floodplain managers in regulation of the floodplain. Flood insurance rates within contour intervals could be determined by a more realistic and physically based methodology

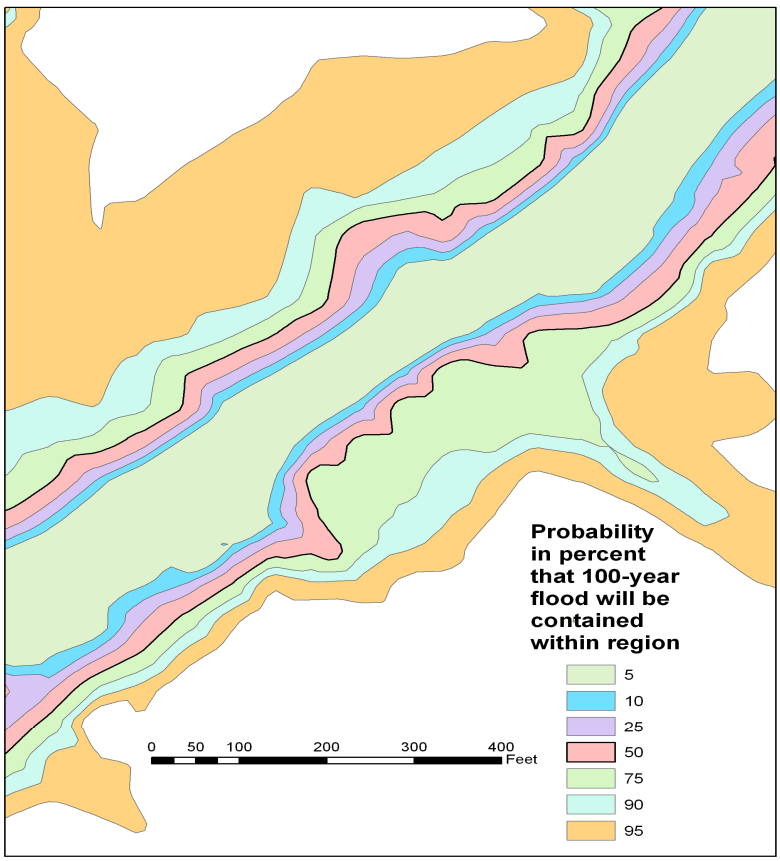

Figure 7. Example Floodplain Probability Contours

RU Design Issues

Much of the uncertainty that is required for an R&U analysis is difficult to define with any accuracy; e.g., standard deviation of the water surface elevation for a given flow, coincident probabilities of stage and wind for a wave calculation, coincident timing of flood peaks for two different size drainage areas upstream from the project, etc. Deterministic assumptions are made on these items and because designers have been trained to analyze "worse" case conditions, they establish "Base" case or most likely conditions that are far more extreme than the most likely. The RU analysis therefore begins with a significant bias that is unrecognized.

In flood control, the greatest uncertainty lies in the estimation of the flow frequency curve and/or stage frequency function. Engineers and Hydrologists have relied upon Confidence Interval calculations found in Bulletin 17B (WRC 1981b) to estimate this uncertainty. It has been shown that this procedure can vastly overestimate the uncertainty because it does not recognize physical limitations of a watershed (PMF, etc). Therefore, the assurance level calculations based on Bulletin 17B Confidence Interval calculation can be extremely misleading.

Current procedures used by the Corps to establish "90% Assurance" levels that are not based on Bulletin 17B are quite sensitive to changes in the 1.1 and 2-year flood levels when calculating the 200-year 90% Assurance level. This is unexplainable.

A levee project designed with R&U will have a design top of levee but no design water surface elevation. This makes operation and maintenance requirements for the channel unknowable.

Levee system performance assumptions for an R&U analysis have not been determined. If there is 1100 miles of levee upstream from the project, a true RU analysis must consider the possibility that upstream levees will fail. Upstream levee failure will impact the stage frequency function at the project location. A deterministic design may assume upstream levees do not fail and this assumption becomes just another of the "worse case" assumptions associated with deterministic design. A no failure assumption destroys the basic assumption of RU analysis.

In the Sacramento Valley, numerous levee failures have occurred over the years and before the levees overtop. Is it reasonable to assume for instance that 80+ miles of levee would overtop during a 500-year flood and not fail? A "No Failure" assumption for an R&U analysis would vastly overestimate the flood risk.

There is a requirement to determine "when" and "how" a levee will fail. A levee that fails after the peak flows and stages have occurred has a much different impact on flood stages than a levee that fails before or at the peak flow and stage condition. History has provided numerous examples of all three failure conditions.

The "How" assumption is also significant. A 25 foot wide levee break has a different impact than a 1000 foot wide break. It is necessary that a hydraulic model can be programmed to execute the desired failure scenarios. At this time, the models are limited in their capability to simulate varying assumptions of this type.

A Risk Analysis methodology that incorporates "Worse" case assumptions as the base case significantly overstate the risks associated with a project and could potentially lead to bad decision making.

A requirement to use RU procedures when correcting project defects has been stated as a Corps 408 permit requirement but with no definitive guidance provided. What does it mean and how to implement it is a very significant policy issue.

Abstract

Traditional measures of sensitivity in watershed modeling are based upon a framework wherein parameters are specified externally to a model, so one can independently investigate the impact of uncertainty in each parameter on model output. However, when parameter estimates results from a joint calibration to observed data, the resulting parameter estimators are interdependent and different procedures should be employed. For example, over some range, evaporation rates may be adjusted to correct for changes in a runoff coefficient, and vice versa. As a result, descriptions of the precision of such parameters may be very large individually, even though their joint response is well defined by the calibration data. These issues are illustrated with the simple abc rainfall-runoff model. In fitting the abc model to data from the Pigeon River Watershed (North Carolina), our analysis explicitly accounts for rainfall measurement errors so as to adequately rpresent the likelihood function for the data given the major source of errors causing lack of fit.

1. Introduction

Traditionally the parameters of most watershed and ecological models were estimated as part of an extensive calibration process conducted by experienced models. Currently, the trend in the profession is to make much greater use of automated calibration procedures (Yapo et al., 1996; Boyle et al., 2000; Duan et al., 2003; Bekele and Nicklow, 2007). This eliminates the tedious and subjective trial-and-error exercises that modelers conducted in earlier years. However, without the need to conduct such trial-and-error analyses, a modeler can lose the previous insight into how well different parameters can be resolved, and how they interact. Uncertainty and sensitivity analyses need to provide such insight for model development and calibration, and well as the appropriate confidence to attach to model predictions.

How to obtain appropriate parameters for any modeling study is an issue which has faced considerable attention within the hydrologic community and has motivated many studies. Gupta et al. (2003) offer an interesting reflection on recent advances in automatic calibration of watershed models. Attractive algorithms of uncertainty analysis for highly non-linear models with multi-dimensional parameter spaces are presented in Mugunthan and Shoemaker (2006) and Blasone et al. (2008a). A multi-step automatic scheme (MACS) that emulates the thought processes of expert-manual calibration of Sacramento model is described by Hogue et al. (2003). The combined impacts of

parameter uncertainty and model error have been well documented (Kuzcera et al., 2006; Clark and Vrugt, 2006; Ajami et al., 2007).

Many hydrological studies have embraced the Bayesian credo and have derived different model specification schemes that characterize uncertainties and which reflect such uncertainties in prediction limits on the simulated model outputs. These approaches include classical Bayesian schemes (Kuczera and Parent, 1998; Bates and Campbell, 2001; Thiemann et al., 2001; Thyer and Kuczera, 2003; Marshall et al., 2005a; Choi and Beven, 2007; Yang et al., 2007; Stedinger et al., 2008).

In this study, we review the sensitivity analysis for watershed models when parameters are calibrated. In Section 2, we discuss traditional sensitivity and uncertainty analyses measures. Sections 3, 4 and 5 discuss the appropriated definitions of parameter uncertainty when data is used to calibrate several parameters jointly. Finally, Section 6 uses the abc model with a likelihood function that reflects the critical rainfall estimation errors to illustrate different sensitivity analysis approaches and a posterior Bayesian evaluation of parameter uncertainty.

2. Traditional Measures of Sensitivity

Morgan and Henrion (1990) provide definitions and motivation for traditional sensitivity analysis and uncertainty analysis:

"It is usually not immediately obvious which assumptions and uncertainties may significantly affect the conclusions. The purpose of sensitivity and uncertainty analysis is to find out. *Sensitivity analysis* is the computation of the effect of changes in input values or assumptions (including boundaries and model functional form) on the outputs. *Uncertainty analysis* is the computation of the total uncertainty induced in the output by quantified uncertainty in the inputs and models, and the attributes of the relative importance of the input uncertainty in terms of their contributions. Failure to engage in systematic sensitivity and uncertainty analysis leaves both analysts and users unable to judge the adequacy of the analysis, and the conclusions reached."

Several metrics have been employed by different investigators for sensitivity and uncertainty analysis; they include:

- one-at-a-time analysis of each factor
- joint analysis changing several factors at a time
- parametric analysis of selected parameter ranges
- probabilistic analysis that can use correlation, regression, or other approaches to examine how much of the uncertainty in the output is attributable to uncertainty in each parameter input.

Morgan and Henrion (1990, pp. 174-176) describe metrics used to quantitative describe sensitivity, as do Loucks and Stedinger (1994); Saltelli et al. (2000); Frey and Patil (2002); Loucks et al. (2005); and Benaman et al. (2005).

3. Sensitivity Analysis with Calibrated Parameters

The traditional measures of sensitivity described in Section 2 are based upon the concept that parameters are determined externally to a model, so one can independently

investigate the impact of uncertainty in those parameters on the output of the model. Figure 1 represents a conceptualization of a modeling process when this is appropriate.

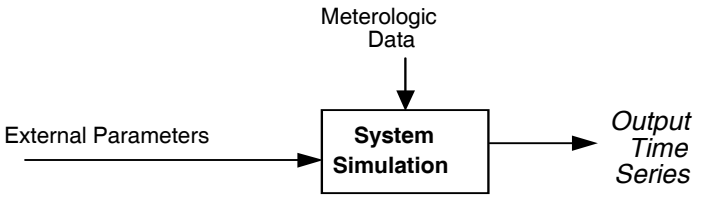

Figure 1: Simple conceptualization of modeling process.

However, it is important to recognize that hydrologic models have many key parameters that are estimated in the calibration process. That means that these "calibrated parameters" are estimated as best one can to make the model output time series match observed flow and stage series when the model is run with the corresponding historical meteorological data. This is important for at least three reasons (Madsen, 2000; Kavetski et al. 2003):

1. Any errors in external parameters may have been compensated for by adjustment of calibrated parameters so that the model output matches observed values. For example, if depression storage is over-estimated, the runoff coefficient may be underestimated in the calibration process so that the resulting model better estimates observed runoff. Thus calibrated parameters may have errors that compensate for errors in external parameters.

2. Because calibrated parameters are estimated jointly, errors may be interdependent. For example, it may be difficult for the model to exactly estimate a detention storage parameter and a runoff coefficient: over some range almost the same model output can be obtained with a higher detention storage parameter and a lower runoff coefficient, and visa versa. Thus when the calibration procedure attaches to detentions storage a standard deviation σ_d, that value implicitly assumes that such variations in detentions storage goes with corresponding and compensating variations in the runoff coefficient. Thus it is no longer appropriate in a sensitivity analysis to independently vary detention storage by ± 2 σ_d without making the corresponding adjustments in other parameters.

3. The mathematical model is not a perfect representation of reality. The calibration set providing flow and stage data and some groundwater elevations is not without measurement error and does not exactly match the spatial and time averages with which it is compared. Thus the match between the model predictions and the calibration data will not be perfect making it impossible to precisely resolve the values of calibrated parameters.

Initially, before serious calibration of the model, traditional sensitivity analysis that varies one parameter at a time can have an important role revealing or documenting when, where, and which parameters have a large impact on model predictions. Benaman et al. (2005) discuss such procedures. However, after a model is calibrated, a different concept of sensitivity analysis is appropriate that reflects the interdependence among possible errors that remain after the calibration process.

4. Calibration and Parameter Uncertainty

Figure 2 presents an appropriate conceptualization of the modeling process when parameters are calibrated with available data describing watershed behavior .

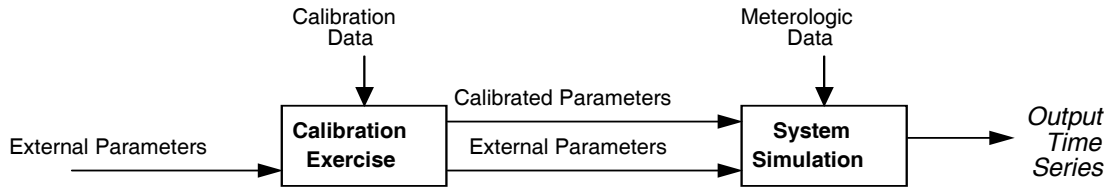

Figure 2: Conceptualization of modeling process when calibration data is employed to estimate some parameters.

Given the values of external parameters, calibration data is never sufficient to accurately resolve all of the parameters of complex watershed and environmental models. Thus in considering the conceptualization of the modeling process above, one recognizes that conditional on the assumed model structure and the external parameter values, there can be significant uncertainty in the calibrated parameters. Furthermore, errors in different parameters of complex models are often interrelated. Thus we desire to consider the uncertainty in the calibrated parameters, and the resulting uncertainty in the simulation model output time series and statistics based upon that time series.

5. Bayesian Approach

Figure 3 describes a Bayesian conceptualization of the modeling process. Here no distinction need be made between external and calibrated parameters. What were before external parameters are now parameters for which external data is thought to provide very precise information; as a result their values will not change during the calibration process: the size of canals, the dimension of cells, and the area of land in different crops would be examples. Still the values of these parameters could be adjusted during the calibration process if a much better fit could be obtained, though it is also possible to prohibit such adjustments.

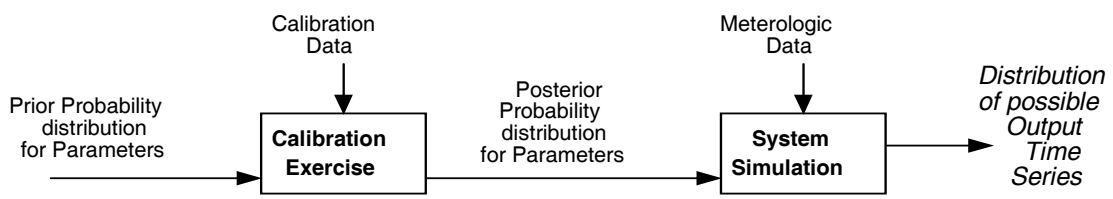

Figure 3: Bayesian conceptualization of modeling process when calibration data is employed to improve the understanding of the likely values of the parameters.

Moreover, there are now no internal parameters whose values are only determined by calibration. Such calibrated parameters initially have some prior distribution representing conceptual reasonableness, physical appropriateness, and experience elsewhere with similar natural systems. However, if such prior information does not result in a relatively precise resolution of the values of such parameters, then the information about system performance introduced in the calibration process is likely to be the major determinant of the value of such parameters.

In Figure 3, having derived the posterior distribution for the model parameters, the results of system simulation is a distribution of possible system performance time series. This distribution represents how the system might operate with the ranges of parameters that are reasonable given both prior information and the information added in the calibration process. In practice the distribution of parameters is described by a large number of generated values, perhaps with different weights (probabilities), which yield an equal number of simulation time series, with the same weights (probabilities). Stedinger et al. (2008) cite examples.

6. Case Study

6.1 The abc model

This study focuses on the abc model introduced by Fiering (1967) as a pedagogical tool. See also Kuczera and Parent (1998). The abc model uses two linear equations with only three parameters to describe a water balance between precipitation, evaportranspiration, groundwater storage and streamflow. The initial value S_0 of the aquifer storage variable S_t must be specified. The model is driven by the rainfall P_t:

$$Q_t = (1-a-b)P_t + cS_{t-1} \quad (1)$$
$$S_t = (1-c)S_{t-1} + aP_t$$

Here Q_t is the streamflow output and S_t is the groundwater storage at given time t. The abc model partitions rainfall P_t into evapotranspiration bP_t, recharge to the groundwater store aP_t, and quickflow to the stream $(1\text{-}a\text{-}b)P_t$. The parameter c is the fraction of groundwater storage released as baseflow in each period.

6.2 Data

A 2-year record (water year: 1 Jan. 2003-31 Dec. 2004) for the Pigeon watershed, North Carolina (USGS Cataloging Unit: 06010106), was employed consisting of daily precipitation from a rainfall USGS raingage station 03455773, and mean daily streamflow discharge rate from USGS streamflow station 03456500. Some precipitation was shifted a day to obtain a better fit to the daily flow data.

6.3 Calibration and rainfall errors

With just a single point-rainfall gage, or even the average of several gages in or near a watershed, there will exist a potentially large error in basin-wide average precipitation. This is especially important for large storm events which provide the bulk of the water entering this hydrologic system. Errors in this storm rainfall input can be very important, resulting in misrepresentation of streamflows, and yield correlated residual errors as observed in the calibration process. In order to reflect likely rainfall errors in large storms, the abc model was rewritten to include errors as:

$$Q_t = (1-a-b)P_t \exp(\delta_i) + cS_{t-1} \quad (2)$$
$$S_t = (1-c)S_{t-1} + aP_t \exp(\delta_i)$$

where δ_i is a normally distributed error for storm event P_t ; δ_i has mean 0 and standard deviation σ_δ.

In this study, the objective function is to minimize the sum-of-squared errors so as to identify maximum likelihood estimators (MLE); based on the assumption that the flow

and rainfall measurement errors are lognormally distributed, the negative of the log-likelihood function is:

$$L = \sum_{t=1}^{n} \frac{(\ln Q_t - \ln \hat{Q}_t)^2}{2\sigma_e^2} + \frac{n}{2} \ln 2\pi\sigma_e^2 + \sum_{i=1}^{I} \frac{\delta_i^2}{2\sigma_\delta^2} + \frac{I}{2} \ln 2\pi\sigma_\delta^2 \qquad (3)$$

where n is the number of days of data available for calibration, I is the number of storm events modeled as having an error, and σ_e^2 is a constant model error variance.

Figure 4 shows that the match between observed and simulated streamflow. Here one observes that the rainfall error calibration approach produces nearly identical results to the observed streamflow data using 4 estimated parameters, and 26 storm errors for the days with the largest precipitation totals. The correlation between the observed and predicted streamflows is 0.918. Without the 26 precipitation errors, the best calibration yields a correlation between observed and predicted flows of 0.820. With precipitation errors, the autocorrelation of the prediction errors was 0.206, whereas without precipitation errors, the autocorrelation of the prediction errors as 0.301.

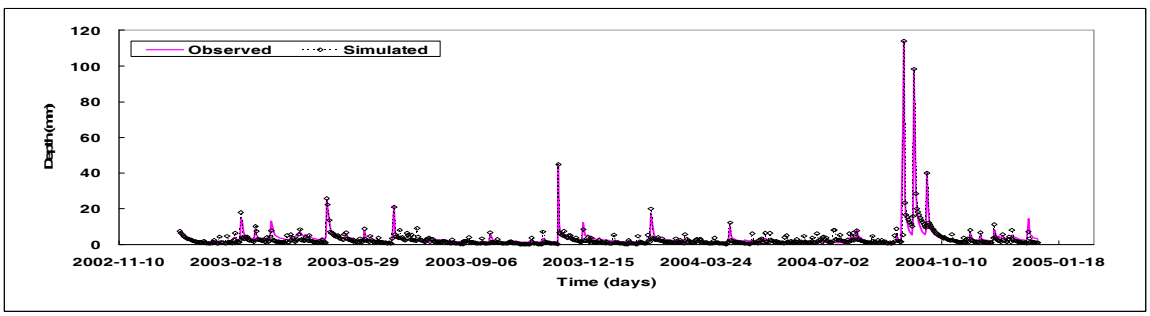

Figure 4: Observed streamflow and the simulated flow at calibration period.

6.4 Parameter uncertainty through MCMC

In this study the Bayesian posterior distribution of the model parameters was represented using 10,000 iterations of a Monte Carlo Markov Chain Gibbs sampler algorithm (Geman and Geman, 1984); the first 1,000 samples generated were removed to forget the initial parameter set. Figure 5 describes the relationships between two pairs of parameters, a and b, and b and c. From the scatter plot of b and c, one sees that the evapotranspiration parameter, b, has a wider range for small baseflow parameter c. It means that the uncertainty of parameter c is smaller than the others with small standard deviation. We also see that there is a strong linear relationship between the recharge and evapotranspiration parameters, a and b. These scatter plots show the relationships among parameters when calibrated parameters are estimated jointly. Table 1 summarizes posterior correlations among the three estimated parameters.

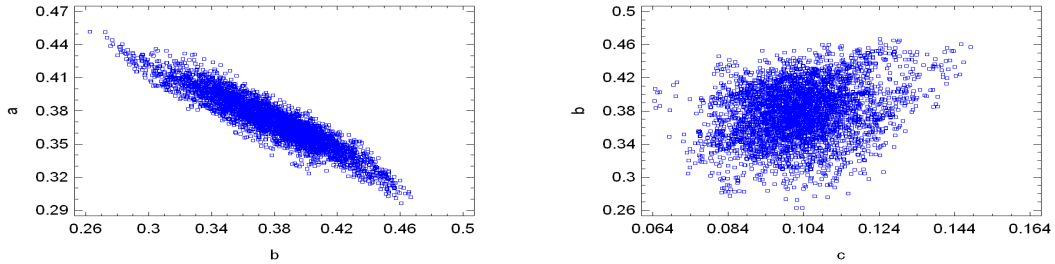

Figure 5: Scatter plots of parameter pairs generated by the Bayesian MCMC analysis.

Table 1. Correlations between the estimated parameters and MCMC posterior moments.

Parameter	Correlation			Mean	St. Dev.	MLE*
	a	*b*	*c*			
a	1			0.371	0.023	0.394
b	-0.930	1		0.379	0.034	0.349
c	-0.435	0.232	1	0.103	0.012	0.095

* Values of maximum likelihood estimators; σ_δ=0.135 and σ_e= 0.074.

6.5 The sensitivity index

Two sets of sensitivity indices were evaluated to illustrate the important of reflecting interdependences in calibrated parameters in a sensitivity analysis.

1) *Simple sensitivity index:* This represents a simple conceptualization of a sensitivity analysis as described in Figure 1. A dimensionless one-at-a-time sensitivity index for each parameter β_i is

$$e = \beta_i / Flow \,.\, \partial Flow / \partial \beta_i \Big|_{\beta_j \, fixed} \tag{4}$$

where $\partial\beta_i$ is a change in parameter *i* from the nominal value and $\partial Flow_i$ is the corresponding change in flow, or some other output value of our interest. In this study, the outputs of interest were the lowest streamflow, the mean streamflow, the peak flow, and the sum of square errors. For the total sum of square errors, sensitivity index (4) is generally not of interest, because at the optimized parameter, equation (4) is zero. Thus a critical statistic that would be of interest is the normalized second derivative

$$d_{SS}^2 = \beta_i^2 / SS \,.\, \partial^2 SS / \partial \beta_i^2 \tag{5}$$

where ∂SS is the change of sum of square errors which describes how well a model fits a calibration data set.

2) *Sensitivity index with parameter interaction:* A sensitivity index for when parameters are calibrated as described in Figure 2 is:

$$e_C = \beta_i / Flow \,.\, \partial Flow / \partial \beta_i \Big|_{\beta_j optimized} \tag{6}$$

This index describes the sensitivity of parameter β_i when other parameters β_j (j≠i) are adjusted to retain the best fit possible; thus other parameters β_j will be re-optimized to consider the interrelation of different parameters of the model. One can also compute the value of d_{SS}^2 when the other parameters are simultaneously re-optimized.

6.6 Sensitivity analysis

Sensitivity analysis can consider basic input data, model structure, initial conditions (S_0) or weather parameters. Here our focus is on calibrated model parameters, specifically *a*, *b* and *c*. Figure 6 provides the results of the two sensitivity analyses for the 3 parameters. The sensitivity analyses consider the lowest flow, mean flow, the peak flow, and the sum of squares. The lowest and peak flows were considered as the averages of the lowest and highest in each of the two years respectively. The indices of sensitivity were measured with +/-1 % changes in each parameter. Both sensitivity analysis statistics

indicate that *a* (recharge from rainfall) is potentially the most important parameter. Both statistics indicate *a* is critical to low flows, though the new statistic attributes to *a* twice the impact; however, they disagree about *a*'s impact on high flow. The traditional statistics indicate *a* is important to floods, as a simplistic analysis would indicate. But recalibration of *b* compensates for variations in *a* so that model predictions of floods are little effected by errors in *a*. However, such changes in *a* have a critical impact on low flows and also the mean flow. The traditional sensitivity analysis indices miss entirely the link between errors in *a* and the mean flow. Parameter *c* (base flow from storage) is the next most important, and both statistics indicate that it has a critical impact on low flows. Overall, as shown by the sensitivity analysis indices for the sum of squares, *a* is the most important parameter, *c* is next most critical, and *b* (evapotranspiration) has the smallest impact on model performance. The sensitivity analysis index for the sum of squares without recalibration ranks *b* before *c*, but this makes little sense. These results show that the simple sensitivity analysis that does not reflect parameter interactions when parameters are calibrated fails to capture several critical issues.

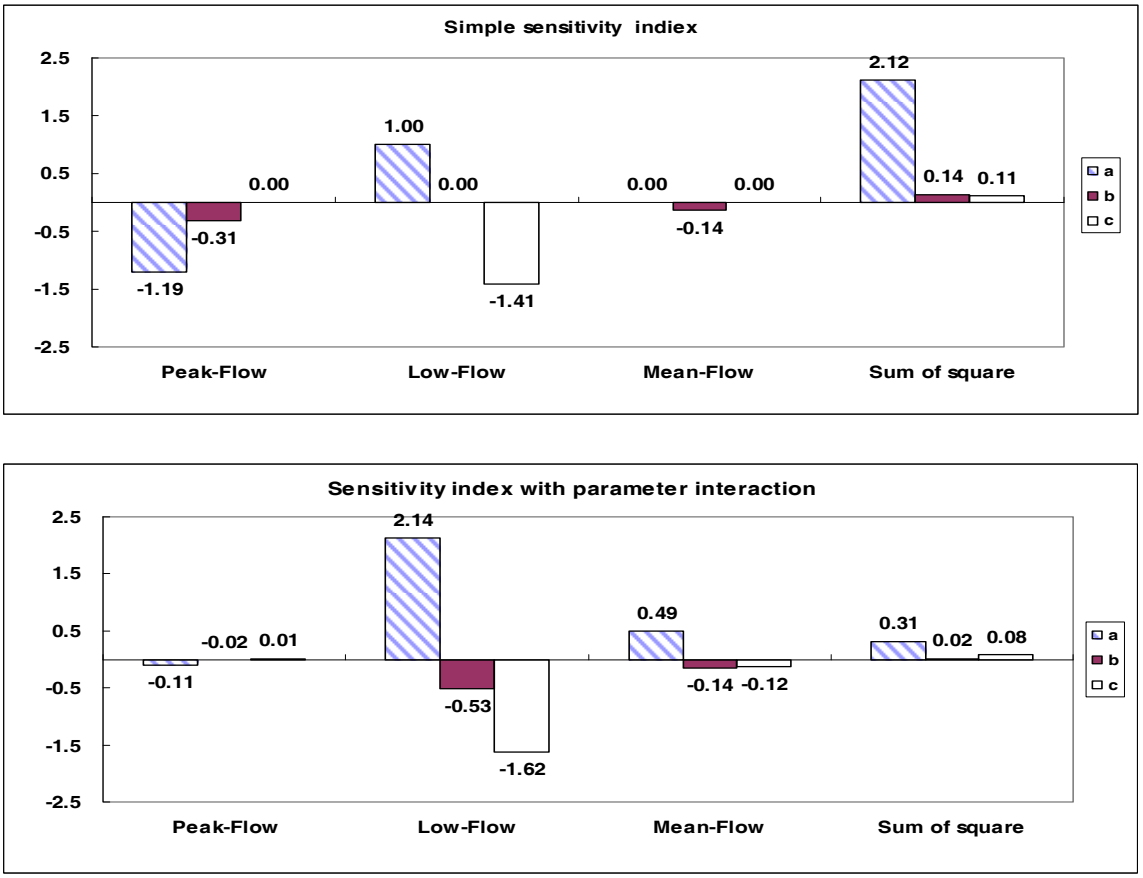

Figure 6: Sensitivity results with two different sensitivity indices.

7. Conclusions

In this study, we analyzed the importance of watershed parameters using one-at-a-time sensitivity index and sensitivity index considering parameter interactions. The one-at-a-time sensitivity analysis can misrepresent critical issues when parameters are jointly

calibrated. For this example, the new sensitivity analysis indices capture critical issues reflecting the interaction among the parameters in the calibration process.

To improve the reliability of a model and its ability to be understood, it is important to be explicit about precision and uncertainty throughout the model calibration and verification processes. This includes recognizing the precision of data, which are generally point measurements used to represent spatial and time averages. Clearly the daily precipitation from one gauge employed in this study provided an imperfect description of basin precipitation, and precipitation errors resulted in correlation among flow errors and degraded the goodness of fit. As part of the calibration process, quantitative measures of the precision of estimated parameters should be developed. Similarly, sensitivity and uncertainty analyses can be used to quantify the impact of parameter uncertainty on the precision of simulated measures of system performance.

VULNERABILITY OF THE HYDRAULIC RESOURCES OF THE RIVER BASIN OF THE SAN JUAN-BRAVE RIVER WITH THE GLOBAL CLIMATIC CHANGE

Rodríguez García José Luis[1] y Cardoso Landa Guillermo[1]

[1]Land Sciences Department, Instituto Tecnológico de Chilpancingo, Av. J. F. Ruiz Massieu # 5, Col. Villa Moderna, C. P. 39000, Chilpancingo, Gro., México; PH (747)4725899; e-mail: gclanda@prodigy.net.mx

ABSTRACT

All the countries are exposed the devastating consequences of the climatic change. For such reason it is necessary to implement political that not only they help to resist the phenomenon but that also help to adapt to the new climatic conditions and to diminish the vulnerability to extreme the climatic events such as droughts, floods, changes in precipitation regimes, among others. This global problem has local solutions. For the analysis and effects of this one phenomenon a region of the barren zone has been selected to the North of our country that is the river basin of the Bravo river, in where the pressures become more evident on the resource water due to different factors on the one hand from their shortage and on the other hand from the demand by the use of the water, situations that difficult the diverse uses of the water. Specifically the river basin of the San Juan-Brave River was studied, that is a sub river basin of the river basin of the Bravo River.

A general diagnosis of the River basin of the San Juan-Brave River appears, showing its basic characteristics as they are: geographic location, physical frame, climate, physiographic, edafology, geology, orography, pluvial precipitation, evaporation, temperature, flora, fauna, economic policy and industrialization, hydraulic infrastructure, cattle agriculture, activities, forest activities, quality of the superficial water, pick up, problematic, in addition a general explanation to integration and operation of a GIS based on Internet at the moment in operation.

10 stations by their distribution in the river basin were selected and its greater number of years of registry and is used the method of polygons of Thiessen in addition of which the maximum precipitations in 24 calculate hours for different periods from return by means of 8 functions of probability and the one of smaller error is chosen to use it in the method of the Triangular Unitary Hidrogram.

The precipitation regimes are quantified and analyzed that will in the future appear due to the global climatic change for the 4 different scenes proposed by Intergovernmental Group of Experts on Climatic Change for years 2050 and 2080. The equations of the variation of the percentage of diminution of the cost with respect to the percentage of diminution of the precipitation are obtained doing a regression analysis.

INTRODUCTION

The evolution of the activities of the man has brought like result important modifications of the means in which it lives and it is developed, the atmosphere as it leaves from this one is not the exception. The phenomenon of the effect conservatory is the main cause of the global heating, although several gases exist that produce the effect conservatory such as they are the water steam, ozone (O_3), nitrous oxide (N_2O), methane (CH_4), the chlorofluorocarbons (CFCs) and mainly carbon dioxide (CO_2) which the hypothesis more widely accepted at the present time is come off that talks about to that we journeyed by a period of heating, due to the increasing carbon dioxide concentration (CO_2) in the atmosphere.

As a result of the global heating they have come appearing effects such as the increase of temperature, the increase in the mean sea level, the variation in the precipitation regimes, and in addition the extreme phenomena have been become serious such as the calls El Niño, La Niña, the prolonged droughts, the intense precipitations, the hurricanes, among others with potential catastrophic effects in many regions of the planet. The incidence of these phenomena and their different levels from affectation, the currents contamination of and channel are aggravated by, and the low productivity and inefficiencies in the use of the water in agriculture and the urban services. These effects hit in the resource water in the hydrological river basins, in individual in those sensible river basins to these changes like the located ones in the arid zones or the coasts, as it is the case of the river basin of the Bravo River and in individual one of his sub river basins the river basin of the San Juan River.

Intergovernmental panel on climatic change (IPCC)

During the decade of the Eighties the scientific evidence of the possibility of the global climatic change grew, bringing a great concern between governmental scientists and heads, by its possible consequences. Recognizing the problem of the potential global climatic change World Meteorological Organization (WMO) and the Program of the Nations United for Ambient (PNUMA) established the Panel Intergovernmental on Climatic Change (IPCC) in 1988, with the purpose of:

a. To evaluate the information available on climatic change,
b. To evaluate the environmental and socioeconomic impacts of the climatic change and
c. To formulate answer strategies.

The IPCC has three work groups and one significant task that next it is explained:

- ✓ Work group I, evaluates the scientific aspects of the climatic system and climatic change.
- ✓ Work group II, analyzes the negative and positive vulnerability of socioeconomic and natural systems before the climatic change, consequences of the climatic change, and options of adaptation.
- ✓ Work group III, evaluates options to limit the emissions of effect gases conservatory and to mitigate the climatic change on the other hand.

- ✓ The significant task in National Gas Inventories of Effect Conservatory consists of watching the National Program of Inventory of Gases of Effect Conservatory.

Models of general circulation

At the present time, the most reliable tool for the investigation of the climate, their fluctuations and variations, is the models of general circulation of the atmosphere (MGC). A MGC is approximated a space and temporary representation of the main physical processes that happen in the atmosphere and of its interactions with the other components of environment . Essentially, it is constituted by a system of equations derived differentials in partial. These equations express the physical laws that govern the system. Most important they are 7 and they are: Canadian Climate Center Model (CCCM), United Kingdom Meteorological Office Model (UKMO), United Kingdom Office Model run 1989 (UK89), Goddard for Institute Space Studies (GISS), Geophysical Fluid Dynamics Laboratory (GFDL), Harley Centre Models (HADCMGHG and HADCMGHS).

BOUNDARY AND BASIC CHARACTERISTICS OF THE ZONE OF STUDY

Geographic location

This affluent of the Bravo River is the second in importance of the Mexican effluents to that international current. Its confluence happens to 58 km waters underneath the curtain of the Imprisoned Falcon, 38 km waters underneath the entrance of the Álamo River, 25 km waters underneath the City Miguel Alemán and 383 km waters above of the opening in the Gulf of Mexico.

The extreme limits of the river basin are confined inside of parallels 24° the 50' and 26° 25' of North latitude and by the meridians 98° 45' and 101° 59' of length WG.

This river is one of most important of the Northeast region of the country, by the category of the zone in which this nailed, including the territory of three states that are: Coahuila with 13.123 km^2, Nuevo León with 18.860 km^2 and Tamaulipas with 989 km^2. Within its river basin several important cities have left such as Forecastle, Coahuila, Monterrey, Nuevo León and Camargo, Tamaulipas. They excel the following advantages in its river basin: Dam Rodrigo Gómez (the Mouth), Dam Marte R. Gómez, Dam "El Cuchillo" and System of Potable Water Dowry to Monterrey.

Given to its location the river basin of the San Juan River it is exposed to strong cyclonal disturbances of the Gulf, those that periodically they have caused increasing of importance between most remarkable is the one of year 1967.

Physical Marco

The River basin of the San Juan River - Brave it has a surface of 32, 763,43 km^2 and it is located in parts of three States of the Republic: Coahuila, Nuevo León and Tamaulipas, but the greater area belongs again to the State Leon, so that it is possible to be affirmed that the dominant policy in the zone is certain reason why it occurs in this organization.

43 Municipalities are in the zone, of which 35 are in Nuevo León and registering the greater number of inhabitants of the economically active population and of services and industries of the River basin, in addition to the 4 Municipalities of Coahuila and the 4 Municipalities of Tamaulipas. This zone of the River basin of the San Juan River is constituted by the Metropolitan Area of Monterrey whose economic dynamics turns it one of the five strategic zones for the growth of the country.

Climate

The climatic characterization has to be considered under the vision of the climatic classification of Köpen modified by Enriqueta García. The great climate groups that cover to the River basin; the tempering, happening through semiwarm subhumid (A) the C (Wo) until subhumid semicold C (E) X'; and the dry one from the semidry Bs1Kw tempering to the very dry BWhw.

Physiographic

More significant the physiographic rank constitutes the folding that undergoes the Mountain range Eastern Mother to the height of the city of Monterrey, from which acquires a general direction East-West. To the north of this folding the orographic elements become spaced and the less narrow geologic structures more, in addition the relief diminishes gradually to the east, until constituting the coastal plain of the Gulf.

Edaphologhy

The present types of ground in the area of study and its zone of influence are: Xerosol Háplico, and Lúvico, Vertisol Calcárico, Fluvisol Calcárico, Yermosoles Háplicos and Cálcicos, Castañozems Calcic, Regosol Eútrico, Rendzina, Planosol Mólico and Litosoles.

Pluvial precipitation, evaporation, temperature

Taking solely from reference the 10 selected climatologic stations, the precipitation is low and irregular with an annual average value of 524,31 mm; the temperature it has an average value of 17.27 °C, and the evaporation it has an annual average value of 1.812 mm.

Flora

In general terms it can say that there are two types of predominant vegetation: the forests and the scrubs; in the first case it dominates the pine forest, with some species like: Pinus cembroides (piñonero Pine), Pinus sp (Pine), Pinus pseudostrobus (Pine), Pinus teocote (Pine), combined with Shrubs jalapensis (madroño), Quercus polymorpha (encino), Mexican Quercus (encino) among others.

Fauna

In the Mountain ranges is puma (concolor Felis), the Texan deer white tail (Odocoileus virginianus), the wild cat (Lynx rufus), as well as some squirrels (Ammospermophilus leucurus, Scirus alleni, Spermophilus mexicanus, Spermophilus

spilósoma). In the little mountains and plains small mammals like coyote exist (Canis latrans), four species of rabbit, between these the rabbit of the desert (Silvilagus audubonii), the raccoon (lotor Portion), six species of tlacuaches, three species of thorny mice, 17 species of mice and rates of field, three species of zorrillo and pecari of necklace (Dicotyles tajacu). As far as the birds, in the zone corresponding to Tamaulipas there are several anátidos species of, like the texano duck (Anas fulvigula), duck of necklace (platyrnynchos Anas), and mainly doves like: the one of white wings (Asian Zenaida), the arroyera dove (Leptotila verreauxi), the dove huilota (Zenaida macrcura) among others.

Economic policy and industrialization

In general terms politically speaking, in the country there is a tendency to industrialization, but focused that industry of high exportability since the country is interested in the currency pick up; this has given like result that the North border strip of the country becomes more interesting the geographic place for the industrial investment, by its proximity with the great potential market that represents the United States of North America and thanks to the Free Trade Agreement.

Agriculture

The weather agriculture is disperses in all the River basin. In this type of agriculture, the maize and the sorghum are the annual culture that emphasize more in the States of Tamaulipas and Nuevo León, in the State of Coahuila is the wheat the most important culture. The irrigation agriculture is located essentially in the States again Leon and Tamaulipas. It is possible to mention that in addition to the maize and sorghum, perennial cultures in the State Leon are registered again. The Municipalities of Montemorelos and Terán General are accountants, since they represent one of the more important citric zones of the country.

GIS based on Internet

It was helpful the consultations of the GIS for the river basin of the San Juan River that has been modeled under the model Relational of Data bases, and introduced in tables with different attributes according to which it is wanted to present/display and the requirements of each data set, as well as the sobreposition of maps of different characteristics before mentioned that they were put simultaneously in different layers up to three.

DEVELOPMENT

10 stations by their distribution in the river basin were selected and their greater number of years of registry and their areas of influence by means of the method of polygons of Thiessen calculate in addition of which the maximum precipitations in 24 calculate hrs. for different periods from return by means of 8 functions of probability among them they are: Exponential, Range 2 parameters, Gumbel, Gumbel two populations, Log-Normal, Nash, Normal and Pearson III, the distribution Gumbel, takes the best model, taking into account its smaller standard error of adjustment and applying the factors of adjustment of the precipitation per

fixed period of observation (Fd) and by area (Fa) to each one of the climatologic stations and is used the method of the Triangular Unitary Hydrogram.

Next the process of calculation of the crescents of design of the river basin of the site in study is described.

Table 1 Characteristics and parameters of the river basin of the San Juan River

Area of river basin (km^2)	32763.43	One calculated by means of AutoCAD.
Length of the main channel (km)	295.75	The main channel calculated by means of the measurement of a thread following and applying the scale.
Slope of the channel (Taylor-Schwarz)	0.00631068	One calculated removing to the pending average dividing the length overall between the difference from unevennesses.
Time of concentration (h), Kirpich	37.22	One calculated by means of the application of the propose formula by Kirpich.
Number of draining	77	It is considered according to the type of ground.
Constant ***e*** of Kuichling	0.5225	One calculated by means of the propose formula by Kuichling.
Constant ***n*** of the HUT	22.54	One calculated previously with the described formula.
Adopted model of Distribution	Several	One calculated depending on that it had less error.

In Table 2 are the maximum expenses, assigned to different periods from return, using the weighted average by means of the polygons of Thiessen of the Maxim precipitation in 24 hours.

Table 2 Calculation of maximum expenses assigned to different return periods

The precipitation regimes are quantified and analyzed that will appear in the future due to the global climatic change for the 4 different scenes proposed by Intergovernmental Panel on the Climatic Change for years 2050 and 2080. The results of the presented/displayed variation of the precipitation for our country they were obtained from the average answer of a sample of ten recent models of simulation for global climates. These simulations were made by seven located climatic laboratories in 6 different countries. Most of the climatic models they indicate a drought process on the continental part of Central America and in the islands of the Caribbean, being the most significant changes for the continent that stops the islands. Giving as result for the zone of study the following percentage of variation: -4%, -5%, -7%, -8% and -12%.

Applying these percentages to the Maxima precipitation in 24 hours the following results presented in tables 3, 4, 5, 6 and 7 are obtained:

CONCLUSIONS

As it is appraised in the results, the waited for global climatic change for years 2050 and 2080 and the 4 different scenes proposed in relation to the precipitation does not leave to the margin the area drained by the fluvial system of the San Juan River, their hydrologic cycle will even be affected of significant way in the availability of the resource water, in individual due to the influence of the city of Monterrey. Therefore still it is time to take, at least, some local measures as the ecological conservation of the geographic space and a more rational use of the vital liquid in order that this change repels with smaller severity.

Making an analysis of correlation and regression with the method of square minimums, with the percentage of resulting variation of the precipitation the following equations of variation of the percentage of diminution of the cost with respect to the percentage of diminution of the precipitation was obtained:

· For a period of return of 2 years:
%VQ = (1.882) (%VP) + 0.3147 (Linear)
%VQ = (- 0,0058) $(\%VP)^2$ + (1.9752) (%VP) - 0,012 (Polynomial of second degree)
· For a period of return of 5 years:
%VQ = (1.5822) (%VP) + 0.1459 (Linear)
%VQ = (- 0,0027) $(\%VP)^2$ + (1.6257) (%VP) - 0,0068 (Polynomial of second degree)
· For a period of return of 10 years:
%VQ = (1.4568) (%VP) + 0.092 (Linear)
%VQ = (- 0,0017) $(\%VP)^2$ + (1.4844) (%VP) - 0,0047 (Polynomial of second degree)
· For a period of return of 20 years:
%VQ = (1.3849) (%VP) + 0.0662 (Linear)
%VQ = (- 0,0012) $(\%VP)^2$ + (1.4048) (%VP) - 0,0036 (Polynomial of second degree)
· Para un periodo de retorno de 50 años:
%VQ = (1.3212) (%VP) + 0.0466 (Linear)
%VQ = (- 0,0009) $(\%VP)^2$ + (1.3352) (%VP) - 0,0026 (Polynomial of second degree)
· For a period of return of 80 years:
%VQ = (1.2963) (%VP) + 0.0398 (Linear)
%VQ = (- 0,0007) $(\%VP)^2$ + (1.3082) (%VP) - 0,0023 (Polynomial of second degree)

· For a period of return of 100 years:
%VQ = (1.2859) (%VP) + 0.0371 (Linear)
%VQ = (- 0,007) (%VP) ^{2} + (1.2971) (%VP) - 0,0022 (Polynomial of second degree)
· For a period of return of 500 years:
%VQ = (1.2294) (%VP) + 0.0241 (Linear)
%VQ = (- 0,005) (%VP) ^{2} + (1.2367) (%VP) - 0,0015 (Polynomial of second degree)

Where:
%VQ = Percentage of diminution of the cost.
%VP = Percentage of diminution of the precipitation.

The regression with less error is the polynomial of second degree; nevertheless the linear regression gives very acceptable results. As it is possible to be appreciated in the results, the effects that the diminution of the precipitation produces magnify in relation to the cost.

ABSTRACT

In order to ensure the adequate and sustainable water management for the city of the future, the impact of the global change pressures and sources of uncertainties should be analyzed appropriately. This paper presents a model for forecasting the future water demand addressing the uncertainties associated to the climate change, population and economic growth. It uses the historic time series records of water consumption for forecasting the future water demand, and applies the Monte Carlo sampling, Latin hypercube sampling and bootstrap methods to describe the associated uncertainties. The model was applied in Birmingham, UK to analyse the water demand for year 2035. Results showed that future water demand in Birmingham will be governed by the socio-economic factors not by the climate change impact. There is a very high likely risk of not meeting the future water demand from the existing supply sources.

Key words: Global change pressures, uncertainties, scenarios, forecasting, sampling

INTRODUCTION

Forecasting of water demand is a crucial component in the successful operation of water supply system. Accurately forecasted water demand either in short-term, or medium-term, or long-term time horizons can be very useful for capacity planning, scheduling of maintenance, future financial planning and rate adjustment, and optimization of the operations of a water system In addition, adequately forecasted demand will be a basis for the strategically decision making on future water sources selection, upgrading of the available water sources and designing for the future water demand management options, so that water resources are not exhausted, and competing users have adequate access to those resources.

Most of the previous studies on water demand forecasting are based on the three approaches: end-use forecasting, econometric forecasting, and time series forecasting. End use forecasting is an approach that bases the forecast of water demand on a forecast of uses for water, which requires tremendous amounts of data and assumptions. The econometric approach is based on statistically estimating historical

relationships between different factors (independent variables) and water consumption (the dependent variable) assuming that those relationships will continue into the future. Time series approach forecasts water consumption directly, without having to forecast other factors on which water consumption depends (Zhou *et al.*, 2000).

Many climatic variables, such as rainfall, air temperature, sunshine duration, relative humidity, wind speed, historical water uses were considered for developing a linear regression to the artificial neural network model for forecasting the water demand studies. Linear regression models developed by Jain et al. (2001) uses weekly maximum air temperature, weekly rainfall amount, weekly past water demand, and the occurrence and non-occurrence of rainfall as dependent parameters. The linear regression models developed by Graeser (1958) have the number of previous days with maximum air temperature above 100°F, and the number of weeks from last occurrence of one inch of rainfall as dependent variables. Box and Jenkins models were developed by Maidment *et al*. (1985) to predict the daily municipal water use. In more recent studies, artificial neural network (ANN) model are becoming prominent for water demand forecast as the neural network was found to outperform the regression and time-series models in some studies (Bougadis *et al.*, 2005; Ghiassi *et al.*, 2008). Similarly, a Takagi Sugeno fuzzy method for predicting future monthly water consumption values from three antecedent water consumption amounts was developed by Altukaynak *et al.,* (2005) for future demand forecasting.

Some other studies have included economic, demographic, and weather factors in their water demand models. Billings & Agthe (1998) used the marginal price of water and personal income per capita in their model. Zhoua *et al* (2000) modelled daily water consumption by splitting it into two components: base (weather-insensitive) and seasonal (weather-sensitive) uses for Melbourne water supply. Arbués *et al* (2003) have reviewed the main variables that can affect demand and highlighted the water price, income, or household composition as the crucial determinants of residential consumption. Moreover, there are many studies done on water demand forecasting and impacts analysis in urban scale, catchments scale & regional scale, for examples see (Arnell, 2004; Arnell & Delaney, 2006; Bradley, 2004; Ruth *et al.*, 2007; Sophocleous, 2004; Vörösmarty *et al.*, 2000).

Most of those studies are focusing on the future demand forecasting without considering the uncertainties associated to the future change pressures. The future changes pressures; such as climate changes and variability, population growth and urbanisation, changes in public behaviours and socio-economic condition, ageing and deterioration of buried infrastructures, increased rate of leakage, technological development, increased demand for water to maintain in stream ecosystems, alter in water quality, and (Khatri & Vairavamoorthy, 2007) and their impacts are highly uncertain. Consequently, without dealing with these future change drivers and associated uncertainties, the predicted forecast will not be reliable and sufficient for the planning and management of water supply system.

The objective of this paper is to explore the different sources of uncertainties in future water demand forecasting due to climate changes, population growth, and changes in public behaviour, and assess the risks. We apply the computing tool to describe,

propagate and forecast the domestic demand considering these change variables, and apply in the real case of Birmingham, UK. It also attempts to assess the main governing drivers' for the future water demand (i.e. climatic or socioeconomic) in Birmingham city.

The paper is organized to address each of these topics in six sections. The second section presents the main sources of uncertainties associated to these change pressures. Third section presents the methodology applied for describing the uncertainties during the demand forecasting process. The fourth section introduces the case study area, and fifth section will present the current and potential future climatic and social condition of the Birmingham city followed by analysis. Finally, a brief discussion and conclusions of the study will be presented in the sixth section.

SOURCES OF UNCERTAINTIES

The sources of uncertainty refer to the causes that give rise to uncertainty in the forecasted state of the system that is modelled (Krzysztofowciz, 2001; Mannina *et al.*, 2006; McIntyre *et al.*, 2003; Paté-Cornell, 1996). A complete assessment of impacts caused by the future change pressures in water demand forecasting is being impossible either due to the complexities, or incomplete knowledge, or unknowable knowledge leading to a range of uncertainties. It may be either data uncertainty, or model uncertainty, or parameter uncertainty, or natural and operational uncertainty, or all. Here, we are exploring the sources of parameters uncertainties subjected to the future water demand forecasting.

Climate Change

Most of the climate change studies including IPCC (2007) had already concluded the greater impacts of climate change on water resources. Climate variability and change affect the availability of demand and quality of water, and runoff or temperature extremes. Different sources of uncertainties stemming from the climate change; such as future temperature, precipitation, sunshine duration, wind speed, relative humidity, evaporation rate, transpiration rate, soil moisture content will have significant impact on future water consumption. The extreme events (drought or frequent flood) will have also considerable impact on future demand. Therefore, how these climatic parameters changes in future will govern to water demand forecasting.

However, prediction of future climate change and impacts contains the series of uncertainties, which cascades from scenarios to impacts studies. Such as future scenarios of how the future (complex non-linear dynamic system) will be; emission generated, natural process, and variability; different global climatic models for the prediction and their capacity; downscaling and error; uncertainties associated to hydrological modelling; and finally uncertainties associated to the impact model. These associated uncertainties are due to the incomplete knowledge or unknowable knowledge to be articulate and quantified (Berliner, 2003; Carter *et al.*, 1999; New & Hulme, 2000). Planning for the future with less or no regret strategy against climate change impact, will be possible only if associated uncertainties are well described.

Population Growth

Urbanisation and population growth follow a very complex process and affected by a range of economic, political, social, cultural, and environmental factors. Traditional population forecasting techniques are based on the assumption that three components (fertility, mortality and migration) of population growth will be smooth and follow a monotonic path for future trends. However, demographic situation is neither known perfectly in the present, nor future trends in births, deaths, and net migrants are predictable. Future population growth can be influenced by affecting birth, death, or migration rates due to social, economic, political, technological, and scientific developments. We do not know whether new diseases, or drug-resistant strains of old diseases, will raise mortality in the future. We do not know whether migration toward industrial countries will accelerate or abate (Lee & Tuljapurkar, 1994; O'Neill *et al.*, 2001).

The two approaches commonly used for characterizing uncertainty in demographic forecasting are scenario and probabilistic. Scenario uses to describe its projections in consistent story in which fertility, mortality, and migration assumptions are embedded to provide a comprehensive picture of what the future might be. Building alternative scenarios to assess and communicate the uncertainty associated with their projections, is common in national forecasts. An alternative to scenarios as a means of communicating uncertainty is probability distributions. It explicitly accounts for uncertainty in projected trends of fertility, mortality, and migration; and derives the resulting probability distributions for projected population size and age structure. Further details on these areas can be found elsewhere (Keilman *et al.*, 2002; Lee & Tuljapurkar, 1994; National Research Council (NRC), 2000; Wilson & Bell, 2004).

Socio-economic Changes

Many previous studies have revealed that there is a strong correlation between water consumption and socio-economic changes. Examples are changing life style, changing housing type and household size, acceptability, and market penetration of water efficient appliances alternative sources of water, economic development, employment opportunities, education level, and water pricing (Bradley, 2004; Clarke *et al.*, 1997; Schneider & Whitlatch, 1991). Forecasting and describing these parameters are subjected to uncertainties.

It has been recognised that economic prosperity, type of housing, occupancy, climate and technical developments in water-using devices influences the micro-components of water uses (Herrington, 1995). Micro-components of water demand typically uses water for the devices; such as toilets, showers, bath, washing machines, dishwashers, internal and external taps are considered and assessed separately. Future domestic water consumption will be decided by how these micro-component changes, which will be based on change in life styles, emerging new technology, ecological awareness and economic reason (Hensher *et al.*, 2005).

DESCRIPTION OF UNCERTAINTY

In this study, we purpose a risk based approach for analysing the uncertainties while forecasting the future water demand. We are applying, therefore scenario approach,

random sampling techniques (Monte Carlo simulation and Latin Hypercube sampling), and bootstrapping techniques for describing the uncertainties. Domestic water demand will be forecasted based on the micro-components of water demand analysis and total population in the future. Impacts of climatic variables will be assessed using the regression models developed from historic time series records.

Monte Carlo Simulation (MCS) will be applied for prediction of total future population with uncertainty. MCS is a well established and tested method of overall assessment of the uncertainty relies on the central limit theorem. MCS technique generates an estimate of the overall uncertainty in the predictions due to all the uncertainties in the input parameters (Macdonald & Strachan, 2001). Time series population data will be used for trend analysis, moving average technique for the smoothing in forecasting, and lognormal distribution for the future probabilistic simulation of total population using MC simulation (see section 5). Population forecasted with a large numbers of random simulations and predicted population in 95% confidence interval will describe the uncertainty ranges in total future population.

Latin Hypercube Sampling (LHS) technique will be used to analyse the micro - components of water demand and to get the distribution for per capita water consumption. Latin Hypercube Sampling (LHS) is a stratified sampling procedure, and converges more quickly than other stratified sampling procedures. It produces the more precise results than MCS results for same numbers of model runs in case of linear and monotonic problems (Ferson *et al.*, 2004; McKay, 1992). Uniform distribution will be developed for per capita water consumption considering the occupant numbers and ACRON (see section 5), and get the present water demand distribution. Secondly, micro-component of water demand will be classified in 8 – groups with uniform probability distribution. Future per capita water use will be obtained after LHS sampling. The ranges of micro-components water demand values were selected based on UK study results.

Bootstrap technique will be applied to describe the uncertainties in future average temperature and precipitation. The bootstrap is the simplest technique for simulating the probability distribution of any statistic, without making any assumptions or estimating any parameters. Bootstrapping amounts to re-sampling a record, with replacement, to generate (B) bootstrap samples, from which one can simulate B estimates of a given statistic, leading to an empirical probability distribution of the statistic. In order to resample the records assuring the temporal and spatial covariance structure of the original time series, moving block bootstrap techniques is applied. In a moving-blocks bootstrap, one chooses a block length $\lambda \approx n/k$, where n is the record length and k is the number of blocks to resample. The idea is to choose a large enough block length λ, so that observations more than λ time units apart will be nearly independent. Details on bootstrap and moving block bootstrap can be found in (Efron & R. J. Tibshirani, 1993; Hidalgo, 2003; Ku¨nsch, 1989; Vogel, 1996).

Similarly, scenario approach will be considered for the climate change impacts analysis. We considered the different emission scenarios and predicted climatic variables. Wide spectrum of possible climate change scenarios, prediction and their

impact in water demand will cover the associated uncertainties. We have used the predicted results obtained after downscaling from climate impact study UKCIP02.

CASE STUDY: BIRMINGHAM

Birmingham is the second most populated British city after London. It is situated in 52° 29′ 1″ N, 1° 54′ 23″ W, having total area 267.77 km2; average elevation of 150 to 350 m; and population 1113600 (city council, 2008 estimate). The City of Birmingham forms part of the larger West Midlands conurbation and includes several neighbouring towns and cities; such as Solihull, Wolver Hampton and the towns of the Black Country. Although Birmingham's industrial importance has declined, it has developed into a national commercial centre, being named as the third best place in the UK to locate a business, and the 21st best in Europe and fourth most visited city by foreign visitors in the UK.

Severn Trent Water Limited (STWL) and South Staffordshire Water (SSW) Company are responsible for supplying drinking water, managing waste water and environment within the Birmingham. STWL provides water from the Birmingham water resource zone (WRZ) - one of the six water resource zone (Figure 1). The Birmingham WRZ includes most of the city of Birmingham, which is principally supplied from the Elan Valley reservoirs in mid Wales, via a 70 mile long aqueduct. The estimated total population within this zone was 1125183 in 2007. There is no raw water abstracted from within this resource zone. The deployable output of this zone is approximately 329.6 Mega liters per day (ML/d), and there is approximately 314.9 ML/d of water available for use. The service area has an average occupancy rate of 2.2 per household, and per capita water consumption of 146.98 litres (STWL, 2008).

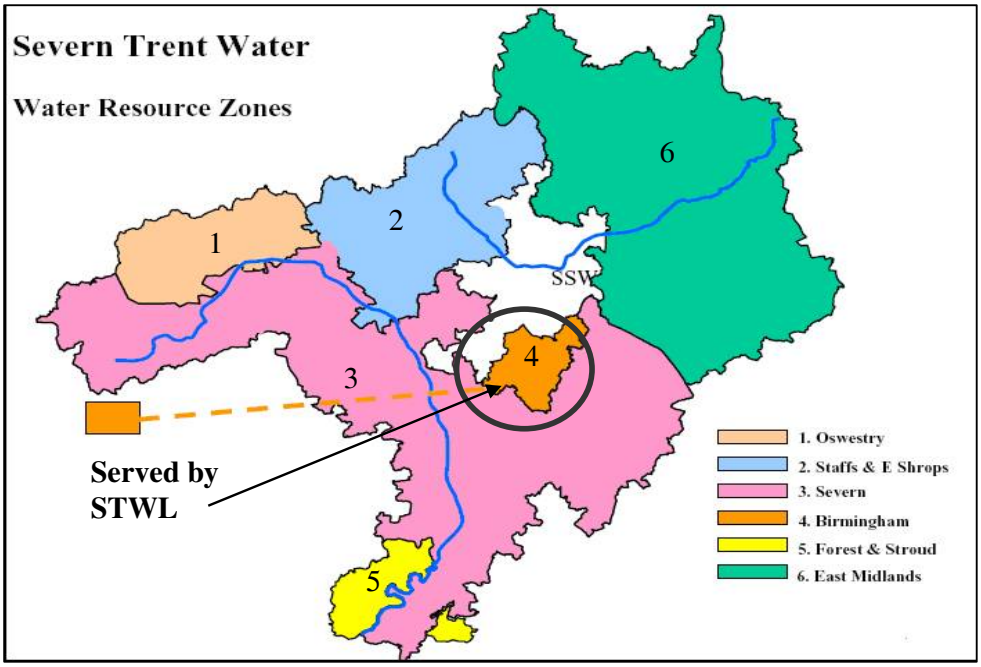

Fig. 1. Severn Trent Water resource Zones and supply area for Birmingham

DATA, LIMITATION AND ANALYSIS

Water Demand

We obtained water consumption data for this analysis from STWL from Jan 1996 to March 2005 (see Figure 2). We have only total consumption data, so we are unable to distinguish water use for residential, commercial, and industrial sectors. For the monthly analysis, we aggregated the data into monthly totals, normalizing each total for the length of the month so that all data assume a 30.416 day month. We don't have sufficient data on total population served from year 1996, so adjustment for water consumption to a per capita basis was not possible.

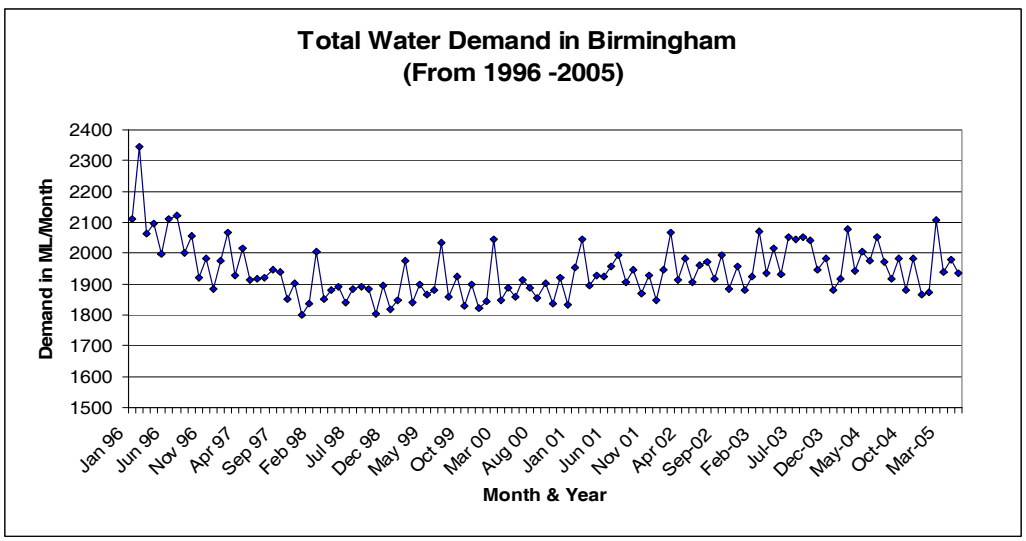

Fig. 2. Total Water consumption per month in Birmingham served by STWL

In the time series records, water demand is decreasing from 2111 ML/Month in January 1996 to 1837 ML/Month in January 1998. Although, we lack the data on water demand by sector, the reduction in demand might be due to decreasing numbers of industries. From 1998 to 2001, there is no considerable increase in water demand with average rate of 1943 ML/month. Average water consumption during the winter appears fairly consistent and summer time consumption figures are well above normal. Apparently, the peak demand is increasing in a warmest summer month of the year compared to normal year, such as year 1996.

Historical and Future Climate Change Scenarios

Historical time series records for the temperature and precipitation parameters for two rain gauge stations (Sutton Bonnington, Nottingham shire and Penkridge, Shropshire) was provided by STWL. The average value of the two stations was used for the case of Birmingham. Although water demand has direct affect of rainfall patterns, air temperature, sunshine duration, relative humidity and wind speed, we are limiting our work only on temperature and precipitation due to unavailability of data.

In order to correlate the temperature and precipitation affect on water demand, a linear regression model was developed from year 2001 as shown in Figure 3 (a) & (b). From the regression results, water demand is negatively correlated with precipitation $Y = 1.9934 * 1000000 - 0.0006 * P$ with adjusted regression coefficient of R^2 = 0.26, having standard error in repressors of 0.3369. Temperature is positively correlated $Y = 1.9389 * 1000000 + 0.0021 * T$ with adjusted coefficient of R^2 = 0.19, standard error of 0.0533. Although there is lower correlation of variables to the prediction, we have applied here single linear regression technique to estimate the future implication in water demand from available information.

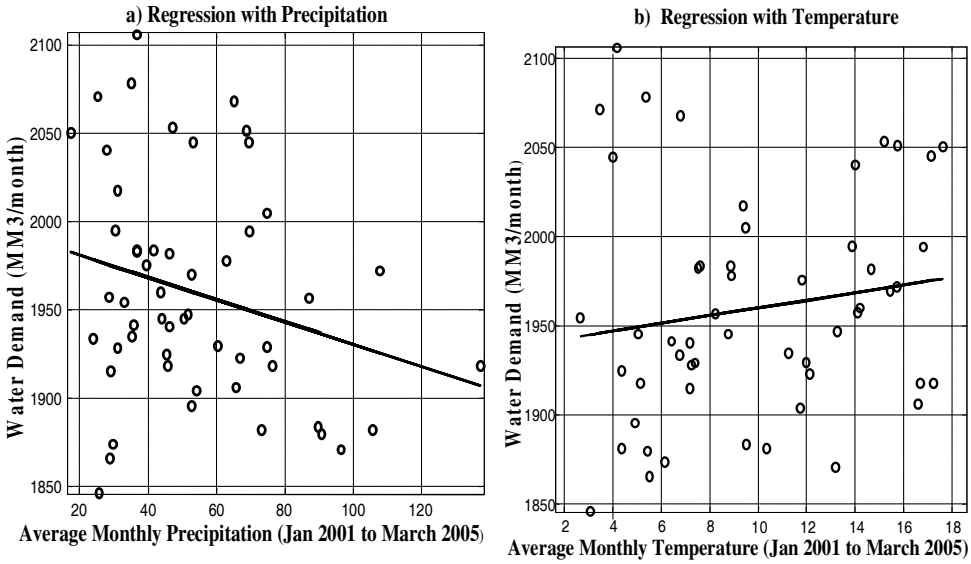

Fig.3 Regression results on water demand and average precipitation (a) and temperature (b)

Future climate change scenarios for Birmingham are based on the scenarios developed and studied by the UK Climate Impacts Programme-2002 (UKCIP02). UKCIP02 uses the Hadley Global Climate Model (GCM) of the atmosphere including a dynamic ocean circulation model (see www.ukcip.org.uk). It provides climate change database for three time slices 2020s (predictions for 2011 to 2040), 2050s (predictions for 2041 to 2070), 2080s (predictions for 2071 to 2100) and for four core emissions scenarios (Low, Medium-Low, Medium-High, and High) at both 50Km and 5Km resolutions. In this case, we are using the temperature and precipitation parameters for four emissions scenarios for time 2020s at 50Km resolutions (Table 1 & 2).

For the future water demand prediction, we are considering the two cases of climatic variables. Firstly, average monthly temperature and total change in precipitation for four scenarios (Table: 1&2) was analysed using moving block bootstrapping. We grouped data of the predicted values in three months (block length) time periods for the four scenarios. After bootstrapping by moving block for 1000 times, a seasonal average value with 95% confidence intervals was estimated (see Table 3). It embeds a wide range of possible intra - and inter-annual variation in climate. Average future demand will be predicted with respect to these mean values. There are uncertainties in

future extreme events of drought; however the average values will provide a sufficient base for the future planning.

Population Growth and Socio-economic Changes

Population trends of Birmingham city was obtained from the Birmingham City council. However, STWL covers the partial area of Birmingham, and includes the additional neighbouring area, so population figures obtained from STWL is different than total city population. For the probabilistic population forecasting, demographic data of total population obtained from city council was used to find the best distribution of total population growth. The lognormal distribution was obtained as the best fit from total population and applied for the population forecasting in STWL

service area. Future forecasted population was smoothened by moving average method with 5- year time steps. Sufficient MCS was run (1000 times) to get the future total population for STWL area with 95% confidence interval (see Figure 4).

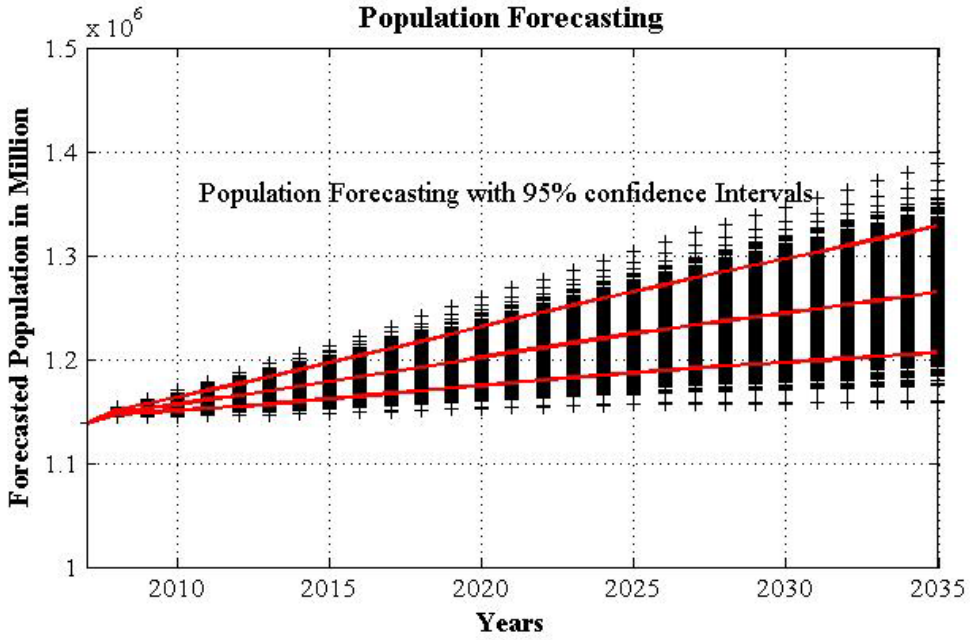

Fig. 4. Total population forecasted for Birmingham (served by STWL)

We consider the micro-component of water demand and geo-demographic classification to assess the future water demand. ACRON is a geo-demographic classification of population used in UK. It groups the entire UK population into 5 categories, 17 groups and 56 types using more than 400 variables (see www.caci.co.uk). The water consumption according to the ACRON number (1 to 5) and family size (1 to 5) obtained from STWL was used for the analysis. Water consumption patterns per capita, for different ACRON types for Birmingham is shown in Figure 5.

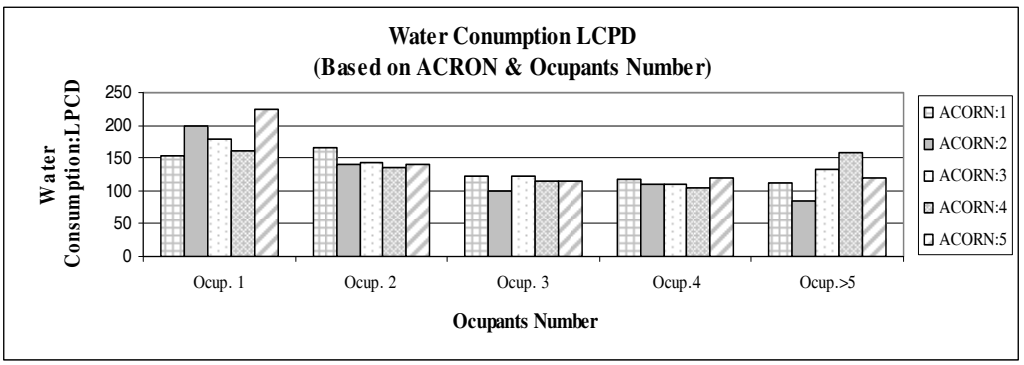

Fig. 5. Per capita water consumption based on ACRON

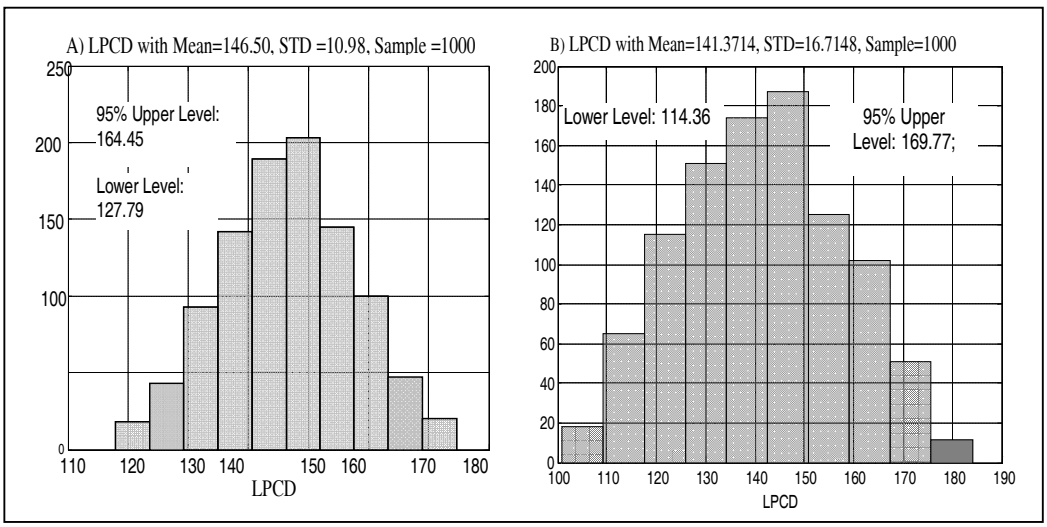
From the water consumption for ACRON (1 to 5), we assumed uniform distribution for different occupants' numbers (ACRON: 1(120-167); ACRON: 2(85-200) ACRON: 3(110-178): ACRON: 4(104-160): ACRON: 5(115-226)). Using LHS, we sampled random samples (1000 simulations) and finally, we got a distribution, which gives the most likely value 146.50 LPCD, and 95% confidence intervals (see Figure 6(A)).



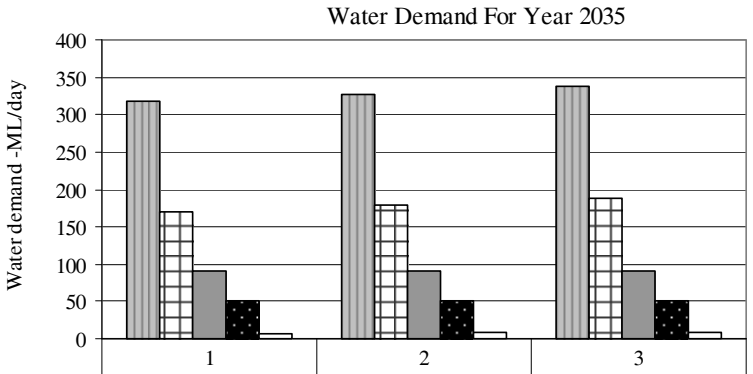


Fig. 6. Water consumption based on ACRON for preset (A) and for the future (B)

We divide the micro-components of water consumption in 8-groups (WC:(10-40%), Washing Machine(10-20%), Dish wash:(5-8%), Bath(10-20%), Shower: (4-8%), Sink Kitchen:(8-20%), Wash basin: (4-12%), and outside and losses(10-15%) as a uniform distribution of present LPCD, and future water per capita was forecasted in terms of distribution applying the LHS techniques (see Figure 6(b)). The range of micro-components was considered based on the STWL survey results and Environmental Agency study in UK.

Future Water Consumption

We have population forecasted with confidence intervals, LPCD forecasted for the future (considering the micro-components of the water demand) which will give the future domestic demand. Regression models on temperature and precipitation shows-there will be 2.10% increase and 0.06 % reduction in total monthly demand, if temperature increases by 1ºC, and rainfall increases by 1mm/Month. We are forecasting the climatic affect for year 2035, considering the average value obtained in Table 3. We have no detailed data base on non - domestic demand, and leakage but we are using information available from STWL. From this analysis, water demand situation in Birmingham for year 2035 is shown in Figure 7.

	1	2	3
Total demand	318.0717	327.8076	338.0925
Domestic	170.5629	178.7765	187.7676
Leakage	90.0000	90.0000	90.0000
Non domestic	50.7500	50.7500	50.7500
Climatic	6.7588	8.2811	9.5748

Fig. 7. Future water demand for three scenarios (minimum, average and maximum)

DISCUSSION AND CONCLUSIONS

This study is limited by numbers of constraints. First, the unavailability of sector-specific data, social data (exact population coverage and GDP rate), water price data, leakage rate, and climatic data in smaller time scale lacks the better understanding of these variables and representation into the model including description and propagation of the uncertainties. As a reason, we limited our analysis only in domestic demand, which is most uncertain part for the future water demand. We could not be able to assess the water demand affect due to climate change. Second, the monthly time step does not allow us to see whether climate characteristics that occur within months (which most extreme events are likely to be) will threaten the city's ability to maintain adequate reserves of drinking water. Regardless, this paper demonstrates and emphasises on uncertainties associated to the future and future change pressures. We cannot describe the future water demand deterministically as those change pressures are highly uncertain, and new study on demand forecasting should have significant emphasise on associated uncertainties description, which can be described either by scenarios approach, or probabilistically. Our efforts in this regards will be new insights for the future planning for the Birmingham or similar cities.

From the analysis, it is clear that future water demand (at the monthly aggregate level) is largely driven by change in population and socio-economic changes rather than climate changes. From the analysis, we found average water demand for year 2035 318.07<327.87<338.09 ML/day having supply side risk of not meeting the future demand from present sources of 314.9 ML/day (water available for use). The role of Birmingham is changing from industrial city to commercial city, which will have different demand characteristics in the future than simply projected by Water Company. We recommend for the further detailed analysis on future water demand

forecasting in Birmingham, and apply appropriate planning options for maintaining the sustainable management of future water demand in Birmingham STWL service area.

ACKNOWLEDGEMENT

The authors would like to express their kind appreciation for the useful data and information provided by the Severn Trent Water Limited, Birmingham, UK, especially to Business Strategy Manager Frank Grimshaw.

ABSTRACT

Crop and fertilizer prices have increased dramatically in the past few years. These prices, together with existing demand for carbon trading allowances, affect farmers' decisions. It is useful to assess the effect of varying crop, fertilizer and carbon prices on farmers' decisions, and in turn, the effect of these decisions on surface water quality, specifically the nitrate load from the watershed. To achieve the objectives of this study, a mixed integer optimization model incorporating a hydrologic model of a test site is developed. The Salt Creek watershed in East Central Illinois has been selected as the test site for this study. Simulation results indicate that there is a higher tendency for farmers to produce corn in 2007 and 2008 than in previous years. Consequently, the average fertilizer use in that period is relatively high, causing greater levels of nitrate runoff. Results also indicate that at current carbon prices, carbon trading is ineffective in reducing nitrate runoff.

INTRODUCTION

With the growing demand for biofuels and general worldwide pressure on cereal grain supplies, crop prices have increased dramatically in the past few years. At the same time, fertilizer prices have also been increasing due to rising energy costs. These prices, together with existing demand for carbon trading allowances, affect farmers' decisions. On one hand, high crop prices create greater motivation for farmers to adopt more aggressive production practices. On the other hand, rising fertilizer prices cause farmers to be more conservative in their use of fertilizer. Similarly, carbon trading gives incentive for farmers to implement certain best management practices (BMPs) that may negatively affect crop production. In this study, carbon trading is modeled after the Illinois Conservation and Climate Initiative (ICCI) (www.illinoisclimate.org) program, through which farmers may sell carbon credits on the Chicago Climate Exchange (CCX) (www.chicagoclimatex.com).

It is useful to assess the effect of varying crop, fertilizer and carbon prices on farmers' decisions, and in turn, the effect of these decisions on surface water quality. A better understanding of this will facilitate the formulation of more informed

policies to control agricultural runoff, which is a major source of nutrient loading in surface waters and a direct contributor to hypoxia in many coastal ecosystems.

The Salt Creek watershed in East Central Illinois has been selected as the test site for this study. It is typical of most Midwestern agricultural watersheds and like many of these systems, experiences excessive nutrient loads in its waters.

METHOD

To meet the objective of this study, a hydrologic model of the Salt Creek watershed in East-Central Illinois is developed and linked to an economic model to estimate farmers' decisions- subject to crop, fertilizer and carbon prices- and subsequently, the effect of those decisions on water quality.

Hydrologic model

The Salt Creek watershed model is developed using the Soil and Water Assessment Tool (SWAT) (www.brc.tamus.edu/swat/). SWAT is a watershed-scale hydrologic model to simulate the environmental effects of land and agricultural practices. It is public domain software supported by the US Department of Agriculture (USDA) Agricultural Research Service (ARS) and is widely accepted in both academia and government (Gassman et al., 2007).

Input data for the watershed model include elevation, land use, soil type, temperature and precipitation data, which are obtained from online databases maintained by the USDA, US Geological Survey (USGS) and National Oceanic and Atmospheric Administration (NOAA).

The watershed is delineated into a hundred subbasins of varying sizes with the average being 48 km^2. The soil type and land use within each subbasin is assumed homogenous throughout it. Two of the subbasins representing the area in and around the City of Bloomington are urban, while the remaining subbasins are agricultural with corn and soybean as their primary crops.

The watershed model is calibrated and validated against observed data for daily stream flow, monthly riverine nitrate load and annual corn and soybean yields. The observed data are from various sources including the USGS, Illinois Environmental Protection Agency (IEPA) and USDA National Agricultural Statistics Service (NASS). Results show a good fit between simulated and observed values based on their coefficients of determination (R^2) and Nash-Sutcliffe coefficients (NSE).

Economic model

The economic model to predict farmers' decisions as a function of crop, fertilizer and carbon prices can be described as follows. A farmer has to choose the right crop (corn or soybean), best level of fertilizer input and/or whether or not to adopt certain BMPs to generate carbon offsets for sale. In this study, two types of BMPs are considered, i.e. grass planting and conservation tillage.

The farmer stands to gain from crop sales. He also stands to gain from selling carbon credits should he choose to participate in that. However, he has to weigh these potential gains against the costs of fertilizer, pesticide, labor, energy, equipment etc. To identify the most optimal balance that maximizes his overall profit, he will have to refer to the current year's crop, carbon and fertilizer prices.

In making his decisions, the farmer also has to consider the "rotation effect", where a crop planted continuously is more vulnerable to pest and disease than if planted in rotation with another crop (Turco et al., 1990; Katsvairo and Cox, 2000). Thus, it is generally costlier to plant a crop after itself than after another crop.

If assuming rational behavior and perfect information on the part of the farmer, the problem can be framed as a mixed integer optimization model and linked to the SWAT hydrologic model to obtain predictions of the farmer's decisions.

RESULTS AND DISCUSSION

Simulations are carried out to estimate farmers' decisions for the years 1999 to 2008 and the effect of those decisions on riverine nitrate load at the outlet of the Salt Creek watershed. For each of the agricultural subbasins in the SWAT watershed model of the system, the optimal combination of crop choice, fertilizer input and BMP application is computed.

To maintain a common basis for comparison, all simulations are carried out using the same set of climate data (2002 data). For the same reason, the initial condition of the system is also maintained constant across the years. Here, the initial condition refers to the previous year's crop and BMP selection; and is assumed as approximately half the watershed cultivating corn and half soybean with zero implementation of conservation tillage or grass planting.

Preliminary simulation results show that there is a greater tendency for farmers to plant corn in 2007 and 2008 than in previous years. This is due to record high corn prices in those years; and is in spite of the rotation effect. Corn acreage in both years exceeds 80% of the watershed, which is high considering that the ten-year average is 56%.

These results are a cause of concern as corn is a more polluting crop than soybean. Corn requires greater levels of fertilizer input that causes serious water quality problems when washed into surface waters. Indeed, the simulated average fertilizer use in 2007 and 2008 is relatively high and correspondingly, so is the nitrate load coming out of the watershed. This is the case even though fertilizer prices for those years are unusually high when compared to historical values.

Another item of interest is the price of a carbon dioxide equivalent. At current carbon prices (as determined by the CCX), carbon trading does provide some additional incentive, on top of the savings they gain, to farmers to practice conservation tillage. However, the prices are not competitive enough to provide any incentive to farmers to adopt grass planting, which requires them to give up their crops. This means that at current prices, carbon trading is not a viable policy instrument to mitigate nitrogen runoff from agriculture; as conservation tillage is ineffective in reducing nitrogen loss where there is subsurface drainage (Bjorneberg et al., 1996) (as is the case of the Salt Creek watershed and much of the Midwest).

CONCLUSIONS

A hydrologic model of the Salt Creek watershed in East Central Illinois is developed and linked to a mixed integer economic model to predict farmers' decisions subject to crop, fertilizer and carbon prices; and the effect of those decisions on water quality, specifically the nitrate load from the watershed. The results obtained indicate that there is a greater tendency for farmers to produce corn (versus soybean) in 2007 and 2008 than in previous years. Consequently, the average fertilizer use in that period is relatively high, causing greater levels of nitrate runoff. Results also indicate that at current carbon prices, carbon trading is ineffective in reducing nitrate runoff.

All this suggests that should 2007 or 2008 conditions prevail, there is a real possibility of farmers switching from their current corn-soybean rotation schedule to a continuous corn schedule permanently; at the expense of the environment. Suitable policies, beside or on top of carbon trading, will have to be implemented to control the increases in nitrate runoff that will be inevitable.

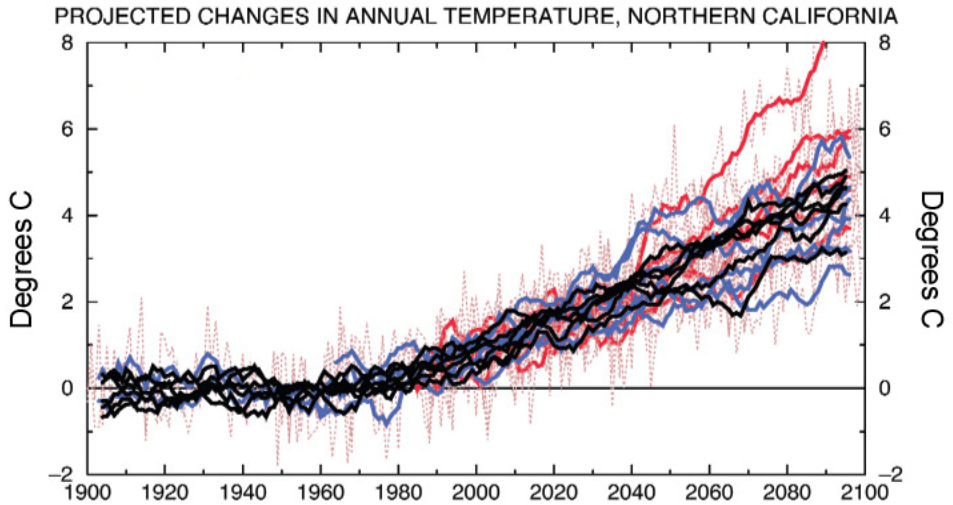
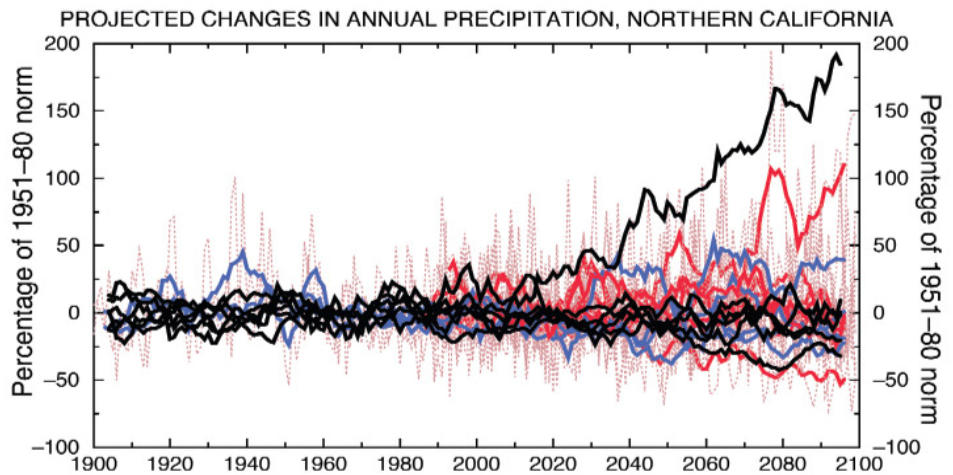
ABSTRACT

Milly et al. in a recent article (Science, Vol319, 1February, 2008, pp573-574) declared that "stationarity is dead and should no longer serve as a central, default assumption in water-resources risk assessment and planning." They went on stating, "Finding a suitable successor is crucial for human adaptation to changing climate." Noting that the fundamental cause of this climatic change is the warming temperature and further noting no apparent change in the runoff volume for the last century, the authors hypothesize that a temperature based hydrology can explain most of the non-stationary behavior of the runoff in a snow dominant watershed like the Upper Feather Basin in California. The observation of the historical temperature data suggests that this region is warming consistent with the global trend. The projections of precipitation by various GCM's are wide spread and uncertainties on the wetness (or dryness) abound whereas the future temperature projections, through also widely spread, are unanimous in directional sense—going up or getting warmer over time. Noting this robust nature of the future temperature projections and also noting that the cause of the future precipitation changes between rain and snow is due to the rising temperature, the authors take an approach that the temperature, rather than the precipitation, should be the commencing point in the development of the changing future hydrology. We claim that the main cause of the "death" of the stationarity in a snow dominant watershed may be the warming temperature. Therefore, by commencing with the temperature in the hydrologic process, either the form of precipitation or the melting of the accumulated snow can be simulated and the non-stationary aspects of the future hydrology can be captured for more adequate water resources planning and management. The USGS under a contract to the California Department of Water Resources completed development of the Precipitation-Runoff Modeling System (PRMS) application for simulating daily streamflow for the Upper Feather River Basin. PRMS simulates all the major snowmelt/precipitation related physical processes including snowpack accumulation/melting, sublimation, evapotranspiration, surface runoff, subsurface flow, and ground water flow. The calibrated model simulates Water Years 1971-2001. This analysis perturbs the historical period daily minimum and maximum



temperatures by 1°C, 2°C, 3°C, and 4°C, respectively, to determine the impact on snowmelt/runoff processes and ultimately streamflow at Oroville; all other parameters were unchanged from the historical simulation (Base Case). Precipitation spatial and temporal distribution was unchanged. Model output parameters studied include evapotranspiration, groundwater flow, groundwater recharge, interception evaporation, precipitation (rain/snow), runoff, snow cover percent, snow evaporation/sublimation, snowmelt, snowpack water equivalent, surface streamflow, subsurface flow, and subsurface recharge. For these varying degrees of warming, the outflows of the Basin were examined and compared to the base historical simulation. The timing of the center of the mass, the April through July runoff as a percent of the annual runoff, and the April snowpack water equivalent are shown to change appreciably with rising temperature.

INTRODUCTION



The assumption of stationarity of a hydrological time series is fundamental to long term water resources planning. In a snow dominant watershed, hydrological series such as temperature and precipitation (both snow and rainfall) have a direct impact on snowmelt and rainfall-runoff processes impacting stream flows which is crucial for planning and operating large surface water reservoirs receiving such flows. Global climate change studies suggest that such an implicit assumption of stationarity may not be true anymore. Milly et al. in a recent article (Milly et al, 2008) declared that "stationarity is dead and should no longer serve as a central, default assumption in water-resources risk assessment and planning." They went on stating, "Finding a suitable successor is crucial for human adaptation to changing climate."

Noting that the fundamental cause of this climatic change is the warming temperature and further noting no apparent change in the runoff volume for the last century, the authors hypothesize that a temperature based hydrology can explain most of the non-stationary behavior of the runoff in snow dominant watersheds in California. The observation of the historical temperature data suggests that these regions are warming consistent with the global trend. The projections of precipitation by various GCM's are wide spread and uncertainties on the wetness (or dryness) abound whereas the future temperature projections, through also widely spread, are unanimous in directional sense—going up or getting warmer over time (Figure 1 and Figure 2).

Noting this robust nature of the future temperature projections and also noting that the cause of the future precipitation changes between rain and snow is due to the rising temperature, the authors take an approach that the temperature, rather than the precipitation, should be the commencing point in the development of the changing future hydrology. We claim that the main cause of the "death" of the stationarity in a snow dominant watershed may be the warming temperature. Therefore, by commencing with the temperature in the hydrologic process, either the form of precipitation or the melting of the accumulated snow can be simulated and the non-stationary aspects of the future hydrology can be captured for more adequate water resources planning and management.

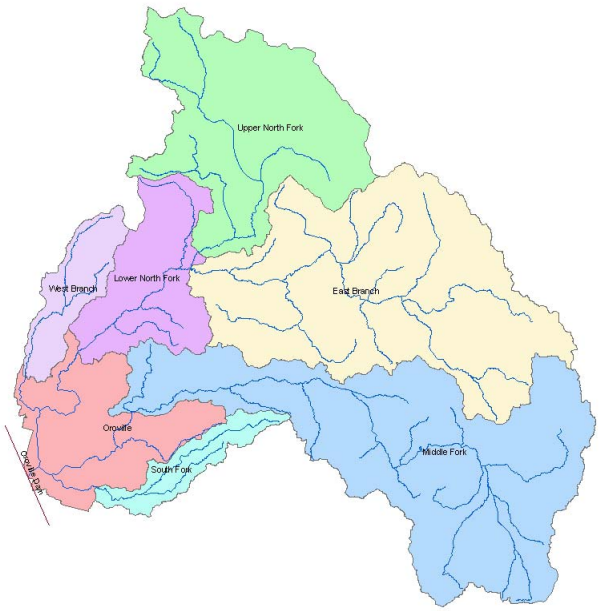
UPPER FEATHER RIVER BASIN

The Upper Feather River Basin is a 3600 square mile drainage area whose runoff flows into Oroville reservoir, a key component of California's State Water Project (Figure 3 and Figure 4). Altitudes for the basin range from 843 feet (above Mean Sea Level) at Oroville to 9525 feet near Mount Lassen. The average snowline altitude is 5500 feet. The geology is volcanic rocks in the north and west, and granitic sedimentary rocks in the south. The climate is Mediterranean with warm dry summers and cool wet winters and springs. Most of the basin lies at altitudes where winter temperature can easily vary from below to above freezing. Daily temperatures at the lowest station range from 46°F to 71°F, whereas at the highest station it ranges from 33°F to 60°F. The lapse rate is approximately 3.6°F per 1000 feet of altitude change. The average April through July runoff for the watershed for water years 1922 through 2003 averages 1992 thousand acre-feet (TAF) and is approximately 45% of the total annual runoff of 4394 TAF. Lake Oroville, the backbone of the SWP, receives much of its inflow from the upper Feather River

basin in the Sierra Nevada mountain range. Sierra Nevada means “snowy mountains” in Spanish, and, true to this name, snowpack that accumulates from October through March in the upper Feather Basin provides the majority of the spring and summer runoff that eventually flows into Lake Oroville. Because snow melting and sublimation is heavily dependant on temperatures, it is important to the operation of Lake Oroville to know how projected future climate conditions can affect both the timing and quantity of flows arriving there. This study uses a physical model of the upper Feather Basin to better understand the effects of increasing air temperature on precipitation, snowpack, and runoff.

Figure 3: Upper Feather River Basin and State Water Project



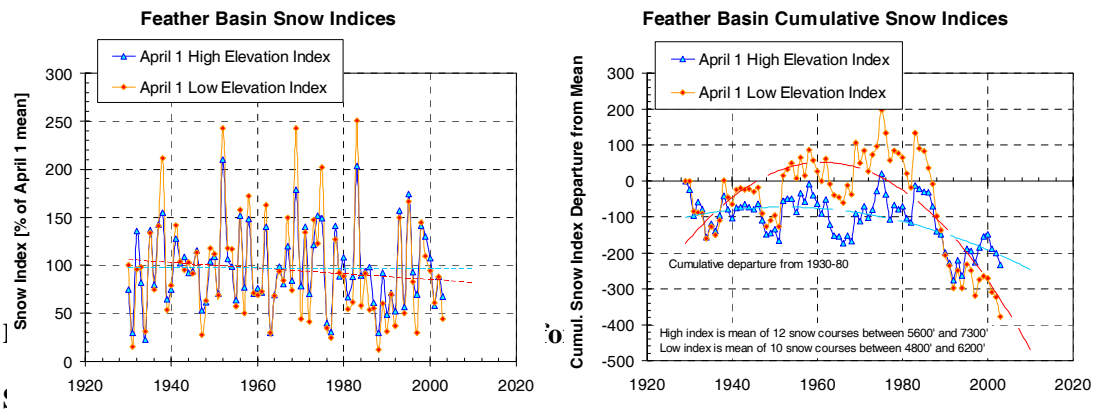


Figure 4: Major Sub-basins within the Upper Feather River Basin

A key hydrological parameter to note for the basin is the snow indices measured for the historical period and shown in Figure 5.

The Precipitation-Runoff Modeling System PRMS is a physically based precipitation-runoff model developed by the USGS (Figure 6). The model simulates all the major snowmelt and precipitation-related physical processes, including snowpack accumulation or melting, sublimation, evapotranspiration, surface runoff, subsurface flow, and groundwater flow. It was applied to the Upper Feather River Basin in a study by the USGS for the California Department of Water Resources DWR (Koczot et al. 2004). The model simulates the historical period water

years 1972–1997 (which is also the calibration period), and has since been extended through water year 2001.

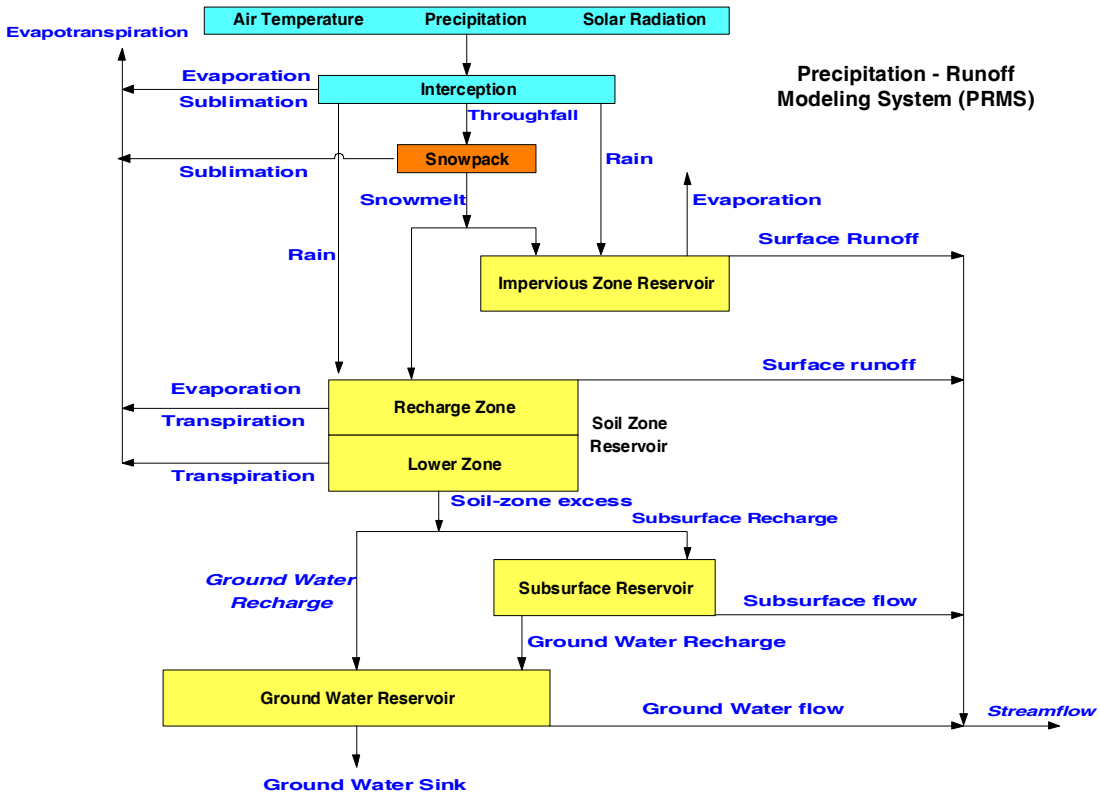

Figure 6: The Precipitation-Runoff Modeling System by USGS

A sensitivity analysis was conducted using the PRMS for the Upper Feather River Basin to quantify the effects of increasing daily minimum and maximum ambient air temperature by 1°C, 2°C, 3°C, and 4°C (1.8°F, 3.6°F, 5.4°F, and 7.2°F) on snowmelt and runoff processes in the basin and impact on inflow into Oroville reservoir. The daily minimum and maximum temperatures for the 324 Hydrologic Response Units over the 30-year historical period (water years 1972-2001) were increased and impacts on the hydrological components, including streamflow and base flow were analyzed by comparing the alternative scenarios with the historical base scenario.Air temperature was the only parameter that changed for each simulation. Spatial and temporal distributions of precipitation and all other model parameters were the same for each simulation. The results below compared alternative air temperature scenarios with the historical base scenario.

KEY FINDINGS

In California, April has traditionally been considered as the time when snowpack is at its peak. The majority of the snowmelt runoff is assumed to occur in April through July. As air

temperatures increase, these traditional assumptions may no longer be valid, and water planning practices may need to be revised**.** Figure 7 shows the dramatic decrease in the April Snow Water Equivalent with increasing temperatures.

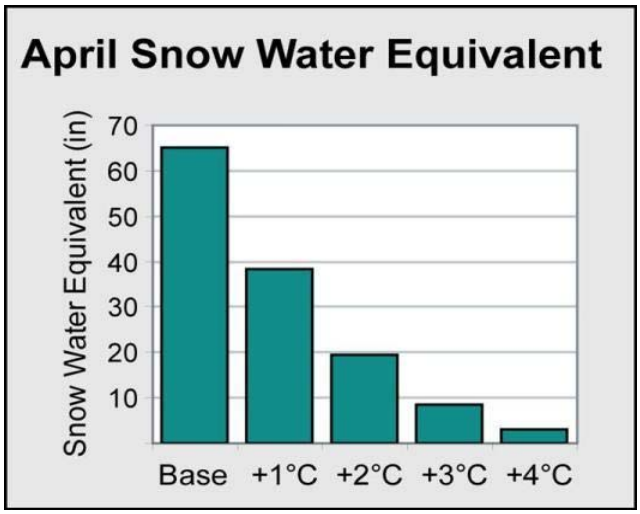

Figure 7: April Snow Water Equivalent for Upper Feather River Basin

Figure 8 shows how the day in the water year when 50% of the annual inflow arrives in Lake Oroville moves earlier in the year as air temperature increases. Figure 9 shows the fraction of annual runoff that occurs during the traditional runoff period of April through July decreases through time for all scenarios (including the base scenario) and decreases as air temperatures increase. These changes can have important impacts on current Water Year classifications (e.g., Sacramento Valley Water Year Type Index) and associated regulatory standards.

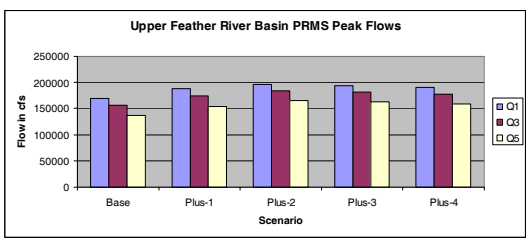

Figure 12: Impact on Q1, Q3, and Q5 Events and Peak Flows Exceeding 99th Percentile for Upper Feather River Basin

CONCLUSIONS

Using global climate change studies indications of increasing trends in temperature but with uncertain trends in precipitation, the sensitivity analysis of increasing ambient air temperatures conducted using PRMS on the Upper Feather River Basin in California to determine impacts of increasing ambient air temperatures showed significant impacts on hydrological processes such as April snow water equivalent, % snow cover, timing of center of mass for flow into Oroville, snowpack water equivalent, and Q1, Q3, Q5 events exceeding 99th percentile flow for Oroville. Use of the physically based PRMS model is superior to empirical based approaches from downscaled GCM results though more expensive to conduct and more resource intensive.

ABSTRACT

Energy and water resources are inextricably linked: the production of energy requires large volumes of water; and reciprocally, the treatment and distribution of water relies on available, affordable energy. This paper reviews technology trends, identifies regulatory and technical challenges to the electrical energy industry, provides case studies based on work by Black & Veatch that explores methods for the sustainable provision of energy and water to communities, and discusses the ongoing research and development efforts as related to utilities and regional stakeholders.

INTRODUCTION

Water and energy resources have stimulated unprecedented economic growth and development in the United States. A growing population has also contributed to competition for resources; together these demands affect the value and availability of energy and water. The Census Bureau projects US population will grow by about 70 million, from just over 300 million, in the next 25 years. During that time, electricity demands are estimated to increase by 50% (EIA, 2006). Energy and water resources are inextricably linked. The production of energy requires large volumes of water, and reciprocally, the treatment and distribution of water relies on available, affordable energy.

In the United States, the USGS estimates that 136 billion gallons of freshwater are withdrawn and 10 billion gallons of freshwater are consumed each day for thermoelectric generation (Hutson, 2004). Approximately 3% of overall electrical usage, 56 billion kilowatt-hours, is used for water and wastewater treatment and distribution annually (EPRI, 2001). Municipal electrical usage, however, is largely connected to a community's need for water infrastructure. For the City of Kansas City, Missouri, municipal water and wastewater treatment and distribution accounts for approximately 29% of the City's annual energy budget (Kansas City, 2007). The health of economies and populations in developed and developing countries around the world will hinge on the availability of clean and cost-effective energy and water resources.

TECHNOLOGY TRENDS

Water is integral to the production of energy. Water is used during resource extraction, refining, processing, and transportation, and water systems dominate the cooling and emissions scrubbing in thermoelectric power plants. Thermoelectric power plants, such as coal, oil, natural gas, and nuclear fueled power generators that use a steam turbine system based on the Rankine thermodynamic cycle, require significant quantities of water for generating electrical energy. The thermoelectric power generation market is the single largest user of freshwater in the US, accounting for 48% of the freshwater withdrawals in

the country annually. Most of the water that is withdrawn is returned at the end of the process at a higher temperature and with other changes in quality; however, it is available for subsequent use. Water consumption data refers to the loss of water as an available resource, often through evaporation. Figure 1 illustrates the water processes within a thermoelectric power plant, demonstrating that cooling is the most water consumptive process.

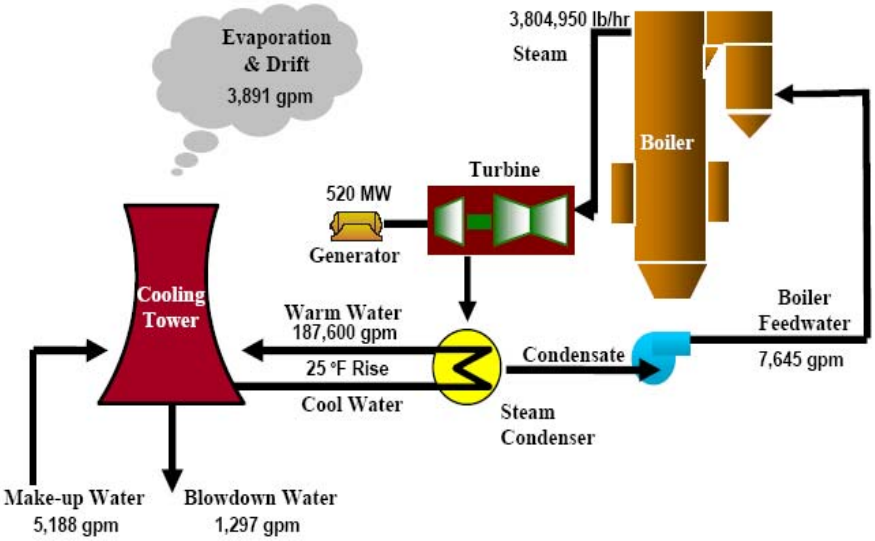

Figure 1. Thermoelectric Power Plant Schematic (Feeley, 2007)

Water for thermoelectric plants is withdrawn primarily from large volume sources, such as reservoirs, rivers, oceans, or underground aquifers. Approximately 70% of withdrawals are from freshwater sources. The volume of water withdrawn and consumed is dependent on the allowable temperature rise of the cooling water and the cooling technology. Industry typically uses three cooling water system designs: once-through, wet recirculating, and dry recirculating. In once-through cooling systems, water is withdrawn from a local water source and returned after passing through a condenser. On average, these systems withdraw a relatively high volume of water, but they consume only a small percentage, 0.25% of water withdrawn, in evaporative losses (Feeley, 2005). Wet recirculating systems recycle cooling water after dissipating the heat from warmed cooling water to the ambient air. The systems incorporate cooling towers, ponds, or canals for heat dissipation. On average, wet recirculating systems withdraw less water than once-through systems, but lose a larger percentage to evaporation, 92% of water withdrawn (Feeley, 2005). Dry recirculating cooling systems prevent evaporative losses by integrating a closed-loop heat exchanger to conduct heat from the used cooling water to the ambient air. These systems are not frequently constructed due to high capital and operating costs, and slowed energy generation is the trade-off for greater water efficiency. Figure 2 shows the number of existing cooling systems at US steam plants for 2005 and average total cost. Environmental regulations and permitting will continue to drive developers to choose options that are less water intensive.

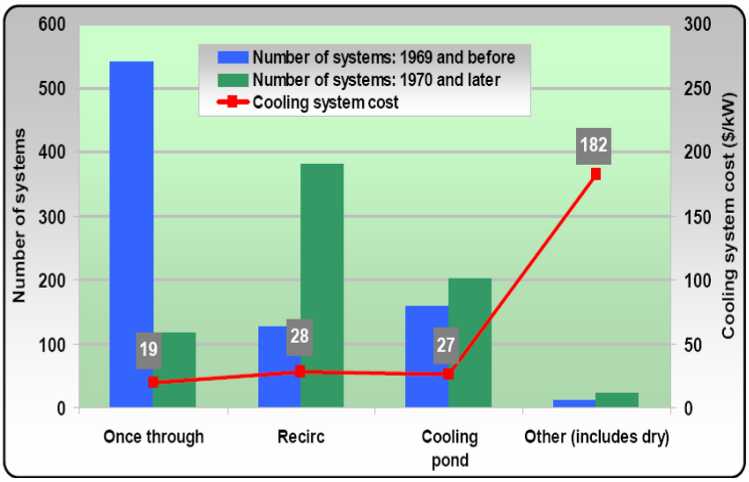

Figure 2. Cooling Technology Trends (Gerdes, 2008)

The cooling water system has the most substantial effect on the water requirements of a generation technology. Flue gas desulfurization (FGD) in coal-fired power plants also affects the withdrawal and consumption of water. The National Energy Technology Laboratory (NETL) developed national average water withdrawal and consumption factors for model thermoelectric power plants based on 2005 data. The team compared five types of generation: coal, nuclear, oil and natural gas, natural gas combined cycle, and integrated combined cycle systems. Their results also demonstrate the water efficiency of alternative cooling systems, boiler types, and FGD methods. A condensed summary of their results is presented in Table 1.

Table 1. Average Water Withdrawal and Consumption (Feeley, 2008)

Generation Type	Cooling water system type	Withdrawal factor (gal/kWh)	Consumption factor (gal/kWh)
Coal	Once-through	24.83	0.102
	Wet cooling tower	0.57	0.461
	Cooling Pond	16.46	0.405
Nuclear	Once-through	31.49	0.137
	Wet cooling tower	1.01	0.624
Oil & NG	Once through	22.74	0.09
	Wet cooling tower	0.25	0.16
	Cooling pond	7.89	0.11
NGCC	Once through	9.01	0.002
NGCC	Wet cooling tower	0.15	0.13
	Cooling pond	5.95	0.24
	Air cooled	0.004	0.004
IGCC	Wet cooling tower	0.226	0.173

The comprehensive assessment of withdrawal and consumption presented above is based on national averages; however, consumption rates and prevalent technology vary significantly by region. There are two major alternating current power grids in North America: the Eastern Connection and the Western Connection. The separation provides a

way to assess the water intensity of power generation on a regional basis, as presented in Table 2.

Table 2. Water Consumption by Region (Torcellini, 2003)

Power Provider	Thermoelectric *Gallons Evaporated per kWh*	Hydroelectric Plants *Gallons Evaporated per kWh*	Aggregate *Gallons Evaporated per kWh*
Western Interconnect	0.38	12.40	4.42
Eastern Interconnect	0.49	55.10	2.33
Texas Interconnect	0.44	0.00	0.43
U.S. Aggregate	**0.47**	**18.00**	**2.00**

If practices go unchanged, thermoelectric power plants will increasingly compete for freshwater with other sectors such as domestic, commercial, agricultural, industrial, and in-stream use – particularly in regions of the country with limited freshwater supplies. At times, energy generation is competing against protection of drinking water resources. Thermoelectric generating capacity is expected to increase by nearly 22% between 2005 and 2040, based on the Energy Information Administrations Annual Energy Outlook 2007 projections.

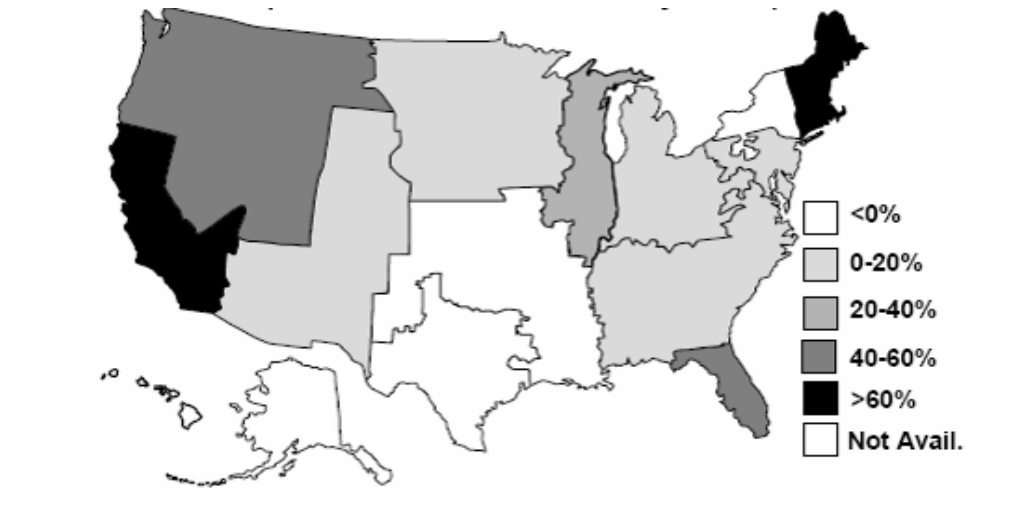

Figure 3. Percentage Increase in Power Plant Water Consumption (EPRI, 2002)

A water needs analysis conducted by NETL suggests that regional water demands may be significant as freshwater consumption increases. Figure 3, suggests that regions with very constrained water resources, such as the west coast and southeast, project the largest increases in power plant water consumption between 2000 and 2020.

OPPORTUNITIES FOR INTEGRATION

Overall, the existing thermoelectric power plant industry operates, on average, at 32% efficiency (Nichols, 2008). The designed efficiency of a power plant partially reflects the price of fuel at the time of construction. As fuel prices and operating costs have increased, greater consideration has been given to the efficiency of generation and transmission. Improvements in efficiency, alternative system designs, and demand side

management to reduce peak loading have implications for the water requirements of a power generation facility.

The following Black & Veatch projects demonstrate a broad range of options for integrated decision making, regional planning, and technological innovation:

Energy Recovery Opportunities in Water Infrastructure

San Diego County Water Authority: Rancho Penasquitos Hydroelectric Facility

The public San Diego County Water Authority serves the San Diego region as a wholesale supplier of water from the Colorado River and Northern California. The Rancho Penasquitos Pressure Control and Hydroelectric Facility (PCHF), located in the City of San Diego, was designed to facilitate delivery of untreated water to Authority member agency facilities. The RPPCHF is part of the extensive water distribution system that the Water Authority owns and operates in San Diego County. Located along a major aqueduct and connected to a 108-inch-diameter untreated-water pipeline, the facility was designed not only to control water pressure and flow but also to generate renewable energy through a turbine-generator sized at 4.5 megawatts, enough power for approximately 5,000 homes. The San Diego community benefits from this green renewable energy, which takes full advantage of the excess pressure at the project site. Planning, designing, and constructing a single facility that serves dual purposes was a challenge, because different processes, equipment, and engineering skills were needed to control water pressure and flow and simultaneously generate electricity in an environmentally responsible manner.

Decentralized Power Generation Options for Water Processes

Hybrid Water and Power Innovation (HWPi) Desalination Plant

Desalination of sea or brackish water often involves a power plant and a water plant. To increase efficiency and reduce the cost of this traditional approach, the project team incorporated product innovations and plant design improvements resulting from an integrated facility. GE's newest and most efficient gas turbine, the LMS100, was united with Black & Veatch's innovation in integrated thermal desalination. The gas turbine employs off-engine intercooling technology with an external heat exchanger, making it an efficient simple cycle turbine. It provides enough power to operate the 10 MGD desalination plants and simultaneously provide 105 MW of electricity to consumers. Paired with the advanced membrane technology and flexible modes of operation, this hybrid solution provides safe and reliable water and power to growing communities with a smaller carbon and water footprint.

A variety of renewable technologies may be utilized for decentralized applications as well. For example, wastewater utilities, as well as being a consumer of energy, can use anaerobic digesters to generate reliable, cost effective power. Biogas from these digesters can be used in a combined heat and power (CHP) system as "free" fuel to generate reliable electricity and power. Renewable energy represents about 2.4% of the fuel source mix in the United States and non-hydroelectric renewable electricity generation is expected to quadruple by 2030 (EIA, 2008). The operation of non-

hydroelectric renewable energy generation is dependent on very little, if any, water withdrawal and consumption.

Progressing the Understanding of Wastewater Recovery for Energy Generation Processes

Western Corridor Water Recycling

As a result of a long-standing drought in South East Queensland, Australia, diversifying water supply sources, including the advanced treatment of wastewater, is integral to ensuring sustainable water availability in the region. However, alternative treatment technologies and transport of water supplies increase the energy intensity of water. Historically, the region has depended on dams and other low-energy infrastructure for water supply. The program focus is to guarantee water supplies by managing demand effectively, resolving regional supply gaps, and carefully addressing agricultural and industrial needs.

The Bundamba Advanced Water Treatment (AWT) plant, designed by Black & Veatch in 2008, produces nearly 20ML per day of purified recycled water, replacing a facility that previously discharged a lower quality effluent into the nearby river. The purified recycled water from Bundamba AWT plant is piped from the plant via a 7.3 kilometre, 800 millimetre diameter pipeline into a lake at the CS Energy Swanbank Power Station near Ipswich. The continual water flow reduces the power station's reliance on the drought-affected Wivenhoe Dam and ensures that the power station remains available to support Southeast Queensland's growing electricity needs in the midst of severe water shortages. The design incorporated the latest membrane and advanced oxidation technologies to provide purified recycled water for both municipal water supply and cooling demands at the Swanbank Power Station. Main treatment steps – ultra-filtration membranes, reverse osmosis membranes followed by advanced oxidation using ultra-violet irradiation and hydrogen peroxide employed at the plant – present a high standard for water reclamation. The Bundamba plant is part of the Western Corridor project, a network of 200 kilometres of underground pipelines and three new advanced water treatment plants. The diversified supply plan will help secure water resources in Queensland into the future, while moving forward the discussion and practical applications of waste recovery technology.

Regional Water and Energy Resource Planning

Colorado River Long-Term Augmentation

Drought conditions on the Colorado River coupled with population growth in the region are driving long-range measures to manage the River water supply and augment its flow. Colorado River water allocations are regulated by a series of interstate and national contracts, approved in 1922, that specify a base river flow. The River has the most complete allocation of water resources of any river in the world and a highly-complex regulatory environment.

In 2007, Black & Veatch utilized extensive stakeholder outreach to provide a strategic plan for the long-term management and augmentation of the Colorado River water supply. Twelve potential long-term options were developed and evaluated by these standards: water quality, technical implementation, environmental considerations, permitting, relative costs, and projected water yield. The expert panel documented that

large volumes of water were withdrawn from the river system for cooling water at conventional thermoelectric power generation facilities. Their study evaluated the potential water saving if power plants withdrawing from the Colorado River water supply would convert existing cooling processes to non-evaporative systems. The team projected a potential savings as great as 160,000 acre-feet per year – demonstrating both the effectiveness of regional infrastructure planning and the significance of technological innovation to preserve water supplies while maintaining energy production.

In the past, water supply planning focused on identifying quality surface or groundwater supplies to meet needs for a specific community or small region. In managing water scarcity, however, a larger regional and holistic approach can integrate alternative water supplies and needs into a plan that optimizes the water balance of a region for a wide range of stakeholders. This project demonstrates the benefits of regional water planning, decision support, and technology selection.

Figure 4. Colorado River Valley

ONGOING RESEARCH AND INTERESTING CHALLENGES

Multiple agencies and associations across the nation are conducting research and development regarding the energy-water nexus. NETL, as part of the Department of Energy (DOE), hosts an integrated expansive energy-water research and development program. The Water Energy Technology Team (WETT) at Lawrence Berkeley National Laboratory is promoting new technologies and practices for key players by comparing technical feasibility and economic efficiency of newly developing technologies, practices, and policies to existing ones, and optimizing new technologies that promote water and energy sustainability. The Sandia National Laboratories support a program that integrates three components: prediction and decision support, science and technological innovation, and technology transfer and implementation. Decision support tools rely on access to information and the development of high-performance computer models that link the many systems that influence water and energy resources, including climate changes, land uses, regional hydrology, population growth, energy use, and regulatory constraints. These systems are meant to provide an unprecedented level of detail to optimize the balance of water use among stakeholders. The DOE drive toward technological innovation will focus on minimizing the impact of energy production on water quality and availability and in parallel, reducing the amount of energy necessary for the treatment and distribution of water. Stakeholder teams will provide real world feedback by testing decision support systems and prototyping technological innovations. The program's short term goal is to reduce freshwater consumption and withdrawal, in terms of gallons/kWh: 50% by 2015 and 70% by 2020. Many organizations supplement this research endeavor, providing forums for discussion of applications. These programs

share a common goal of ensuring sustainable supplies of energy and water by reducing impact on the environment and engaging in regionally based planning.

Resource Planning

The 2006 DOE Report to Congress on the Interdependency of Energy and Water highlights collaboration in resource planning to ensure proper evaluation and valuation of water resources for all needs regionally (inclusive of energy development and generation, agriculture, domestic, etc.). The report emphasizes that significant improvements in conservation and efficiency can be achieved through energy water infrastructure synergies – innovative processes or technologies, co-location of energy/water facilities, and improvements to infrastructure.

In addition to technological innovation and regional planning, the broad application of sustainability assessments across sectors may provide a comprehensive resource and tool for both water and energy utilities. As energy utilities experience increased regulatory requirements and consumer demand for responsible resource management, they are recognizing that environmental performance is linked to financial success (DeBono, 2004). Energy utilities are given the challenging task of powering a community while simultaneously supporting emissions reductions. Increasingly, the energy industry has shifted focus from supply management to demand management and increasing efficiency. Similarly, efficient water utilities must anticipate the need to improve treatment capacity while decreasing energy consumption during the process. Sustainability assessments and metrics provide a useful tool for benchmarking and determining success.

Reducing Carbon Emissions

In 2007, nearly half of the total generation of the United States was produced by coal-fired power plants. These plants are associated with 82% of the power sector carbon dioxide emissions and are expected to continue servicing communities over the next few decades. Utilities may reduce emissions by improving plant efficiency with additional technology, operational practices, maintenance, and by augmenting carbon dioxide recovery processes (CDR). The most widely applied CDR process at coal-fired power plants and natural gas combined cycle plants is a monoethanolamine (MEA) recovery unit.

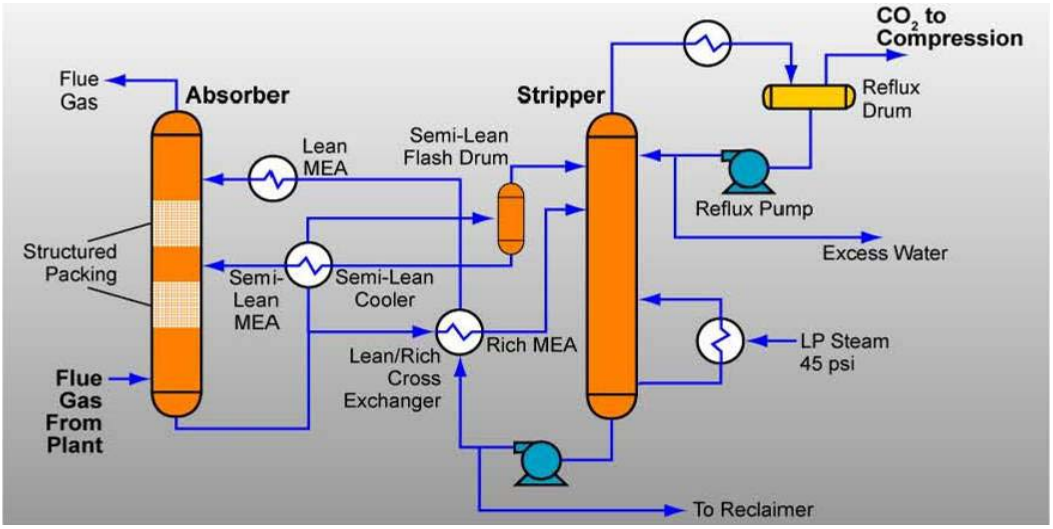

Figure 5. MEA Carbon Recovery Process (Gerdes, DOE)

This chemical process, illustrated in Figure 5, is based on cooling flue gases, allowing the MEA to absorb CO_2, and steam-heating the CO_2-laden MEA to release the CO_2 for compression and shipment. Each of the sub-processes requires significant volumes of cooling water (Gerdes, 2008). A greater concentration of CO_2 increases the efficiency of the process in an integrated gasification combined cycle facility. Other technologies to recover CO_2 include water shift reactors and physical absorption based scrubbers. Similar to FGD, installation of CDR processes in a thermoelectric power plant actually decreases plant efficiency. Much like the energy intensity of advanced treatment of pollutants in water, the need for carbon-capture technology comes with an energy and water penalty.

CONCLUSIONS

Despite the claims of others, the provision of energy and water resources to a society is perhaps the oldest profession. The significance of research and investment in systems that appreciate and optimize the energy-water nexus is critical. Future projections suggest the reality of resource scarcity. Current technology often demands a compromise between the efficient uses of available resources. Yet, research institutions and engineering firms have demonstrated that thoughtful applications of technology and broad-based resource planning can result in solutions that sustain a community. With growing concerns about the effects that greenhouse gases, such as carbon dioxide from fossil fuel combustion, are having and will continue to have on the climate, the attention given to synergies between energy and water resources is timely.

WATERSHED MANAGEMENT IN THE INDIAN HIMALAYAN REGION: ISSUES AND CHALLENGES

Samagra Rana [1], Vaibhav Gupta [1]
[1]G. B. Pant University of Agriculture and Technology

Abstract

Indian population constitutes about 15 % of the world's population, whereas its land area and water resources are about 2 % and 4 % of the world's total, respectively. In the last 50 years, the per capita availability of fresh water has been reduced by about 90 %, and the same trend is still going on with the increase in population, urbanization, and industrialization. At the national level, the irrigation alone consumes about 83 % of the available water resources. About 30 % of the total geographical area is drought prone due to erratic pattern of rainfall and out of about 148 million hectare cultivable land about 72 % is rain fed.

The economy of the Himalayan region is predominantly agrarian. More than 4/5th of the working population is directly engaged in agriculture. Though Himalayan region gave birth to several perennial rivers and streams, the inhabitants face the problems of drinking water and irrigation. Even though only 12.5% of the total land area is under agriculture, only 11% of the cultivable area is irrigated, almost 64% of which is fed by natural springs. The topography of the region is steep; the average annual rainfall is high (1200-1600 mm) and the soils range from sandy to sandy loam causing very high percolation losses of rainwater from individual farmers' terraced fields. The soil does not hold water for long and consequently in the absence of available soil moisture, the crops suffer badly due to moisture stresses at different stages of crop growth during post-monsoon period. About 60 % population in hilly region depends on natural water springs to fulfill their day to day water needs for drinking, sanitation, irrigation etc. About half of the perennial springs have either dried-up or have become seasonal due to ecological imbalance and environmental degradation during last two decades. Nearly 8000 villages mostly located in upper and mid hills have been facing acute shortage of drinking water.

Keeping the above facts in mind, the only way to enhance socio-economic status of the inhabitants of the Himalayan region is to adopt appropriate strategies on a watershed basis, which ensures proper utilization of land, water and vegetative resources in a rational manner. From the engineering point of view, the land and water resources development and management strategies must emphasize application of appropriate technical measures for the development of watershed. Using GIS and remote sensing digital analysis for the land use and terrain analysis will have to be incorporated; such data provides an important link between intensive, localized ecological research and management of biological diversity. Studies conducted in the mid- and high-hills have revealed that the land has to be used as per its capability and sincere efforts have to be made to develop and conserve the existing water resources on sustainable basis. Hence, the adopted technologies have to be location specific, cost effective and easily maintainable by the farmers themselves.

Introduction

The Himalayas are amongst one of the youngest folded mountainous formations of the world, and the youngest in India. The Aravallis, Nilgiris, and the Eastern Ghats are 1500 to 2500 million years old, and the Vindhyachals around 1000 million years old (Swaminathan, 1992). By comparison the Himalayas date back to only 40-45 million years. They traverse an arc for about 2500 km between the Indus and the Brahmaputra. The average width of this mountain range along the entire longitudinal extension ranges from 100 to 400 km. Upadhyay (1995) estimated that the Himalayas cover an area of 4.6 million sq. km. above 1500 m, 3.2 million sq. km. above 3000 m and 0.56 million sq. km. above 5400 m. The Himalayas extend from west to east, from the Pamit Knot in the northwest to the valley of the Brahmaputra River in the east. The range passes through Afghanistan, Pakistan, India (Jammu and Kashmir, Himachal Pradesh, Uttaranchal, Sikkim, Assam, Arunachal Pradesh, Manipur, Meghalaya, Mizoram, Nagaland, Tripura and Darjeeling district of West Bengal), China, Nepal, Bhutan, Bangladesh and Myanmar.

The birth of the Himalayas is the result of a calamitous event of break-up of the peninsular part of present India (the Deccan Plateau) from the supercontinent Gondwanaland, 140 million years ago. The peninsular Indian Plate, having its original locale proximal to Madagascar and South Africa, started drifting northward about 15 cm per year, across what is now the Indian Ocean. Around 15 million years ago, it collided into the Asian continent near the present state of Assam in India. This crashing of the peninsular Plate against the

Southern edge of the Asian continental plate led to the rise of the Himalayas (Khoshoo, 1992). The Indian Plate continues to move northward at the rate of 2 cm per year. The Himalayas are still geologically active and structurally unstable. For this reason, earthquakes continue to be a frequent occurrence in the entire Himalayan region. Being the worlds' highest mountain chain, the Himalayas is characterized by a complex geologic structure, snowcapped peaks, large valley glaciers, deep river gorges and rich vegetation. A complex interplay of climatic and geological processes, patterns of resource use and economic conditions have led to resource degradation and associated environmental consequences in the Himalayan ecosystem (Jodha, 2001).

The paper is an attempt towards an analysis of the major ecological concerns, the underlying driving factors (both human and natural processes), socio-economic impacts and the responses in trying to cope with these, both at the micro/community level and at the national or international levels. We begin with a glimpse of the social and economic structure of the Himalayan region, which constitutes a critical basis for the ensuing analyses. This is followed by an overview of the state of the environment in the region and a detailed analysis of key environmental issues: water resources and their sharing, biodiversity loss, glacier recession, deforestation, land degradation and agriculture systems, natural disasters and solid waste management.

Socio-economic background

The Himalayan mountainous belt is inhabited by 51 million people, covering 18% of the geographical area and 6% of population of India. The mountain range, with its richness of resources, has been contributing to the economic development of

mainland India since times immemorial. However, conventional parameters of development are not the best measures for understanding the social and economic status of the hill communities. The prevalence of traditional lifestyles, barter trade and common property resources
tend to hide the level of poverty or prosperity of the highland people. The following discussion is structured around the key social and economic themes that have had ramifications for the state of environment and ecology of the mountain belt.
The trade-off between meeting subsistence needs and commercial interests is engendering newer forms of social tensions. The privatization of the traditionally common property land along the " fruit-belt" of the Mussoorie-Chamba road in Tehri Garhwal district has led to commoditization of local activities, use of migrant labor and changing working relationships.

Overview of the state of the environment

The Himalayan region is characterized not only by ecological fragility but also by a deep and historical geopolitical sensitivity (Stone, 1992). An ecosystem based natural resource management approach is difficult to achieve as many countries share the resources of this mountain system.

The Himalayas are full of natural wealth, both renewable and non-renewable resources. Amongst its non-renewable resources are deposits of boron, lead, lithium, coal, chromium, ores of iron, copper, tungsten, zinc and deposits of building material like limestone, dolomite and marble. These deposits occur across the length and breadth of the Himalayas cutting across international boundaries. Though the Himalayas have substantial mineral wealth, the common image of resources there is that of water and forests (Stone, 1992). The Himalayas present a storehouse of bio-diversity, where flora and fauna vary extensively with climate diversity from one region to the other. If an attempt is made to divide the forests types based on the standard classification of tropical, sub-tropical, temperate and alpine, it becomes difficult to describe the rich diversity of the Himalayan forests. However, extensive commercial felling of forest for timber has been reported in the region, especially in the last few decades when urban centers began to grow in areas near the forests. While the forests, farmlands and grasslands are of extreme importance for the a grip a store economy within the Himalayan region, the other renewable resource, water, has always been crucial for thickly populated plains further down in the south and east. The Himalayas has one of the highest hydropower potentials of the world which includes three of the mightiest rivers of the world, i.e. Indus, Ganga and Brahmaputra. Besides, water resources, vast extended grasslands and dense forests in some highland parts and in the foothills of the Himalayas have certain specific advantages such as a tremendous potential for tourism. However, extreme climate variations and inaccessible terrain make it difficult to exploit and utilize all the natural resources of the great Himalayas. Climatic extremes like cloudbursts, hailstorms and earthquakes play a critical role as an environmental constraint. Global warming is effecting ice and glacier cover in the region. Furthermore, due to inaccessibility of the region, it is difficult to quantify and assess the damage caused by these natural events. The environmental constraints against the exploitation of natural resource also include other natural phenomena like mass wasting, high seismic activity, landslides, glacial lake outburst floods, erosion and sedimentation. Soil erosion is one of the major environmental constraints, which results in frequent

flooding in the plains downstream and damage to agriculture, life and infrastructure. The livestock population in the region has also increased during the recent past and problem of grazing in the high altitudes has acquired serious dimension, as a result the vegetative cover is decreasing which has resulted in the loss of top soil due to excessive erosion. The relatively soft rocks and favorable climatic conditions are the factors behind quick weathering followed by mass wasting and landslides. Intense monsoon rainfall also accelerates soil erosion in the region. The Himalayan Rivers also carry a very heavy sediment load especially during summer and rainy season, which provides conditions for river shifting.

Water resources

This section assesses the water resources of the Himalayan region, the impact of climate change on hydrological balance and stresses on the crucial issue of water sharing between countries in the South Asian region. Finally, the mechanisms for management of water resources in the Himalayan region, at the national, regional and international level are discussed. The term “Himalaya” has been derived from a Sanskrit word meaning “the Abode of snow”. The region is characterized by intense rainfall in the east and heavy snowfall in the western reaches, which feed some of the longest glacier systems in the world and are the source of major rivers (Stone, 1992). The region is home to Cherrapunji, the second highest rainfall region in the world. The water resources of the Himalayan region are a crucial part of the lives of millions of people living in the hills and the plains. Rivers originating in the Himalayas bring fertile silt and irrigation water, which is essential to the development of the agro-economy in the plains. This dependence of the neighboring plains on mountain water resources has led to the description of the South Asian civilization as a 'hydraulic society' (Stone, 1992). The Himalayas contain over half the permanent snow and ice-fields outside the Polar Regions and it is estimated that roughly 50,000 sq. km of glaciers feed into the world’s largest water drainage system of the Indus, Ganga and Brahmaputra rivers. This perennial river system of the Himalayas is fed by melt water contributions from snow cover, glaciers and permafrost regions. The total amount of water flowing from the Himalayas to the plains of the Indian subcontinent is estimated to be about 8.6 x 106 m3 per year (IPCC, 2001). The contribution of snow to the runoff of major rivers in the eastern Himalayas is about 10% (Sharma, 1993) but more than 60% in the Western Himalayas (Vohra, 1981). Natural lakes exist at high altitude regions ranging from 600-5600 m, and are of freshwater as well as saline in nature. Two of the world’s largest rivers, the Indus and Brahmaputra originate from these glacial lake systems. The average annual run-off of Indus, Ganga and Brahmaputra rivers is 208, 494 and 510 km3 per year, respectively. Varying estimates of water resources in the Himalayan region have been made. Murthy (1978) estimated Himalayan water resources around 245 km3 per year, Gupta (1983) and Kawosa (1988) estimated the total amount of water flowing from the Himalayas to the plains to be around 8643 km3 per year. Bahadur (1998a) re-evaluated his earlier estimates of 200–500 km3 per year as 400-800 km3 per year as melt water contributions from the snow and glacier fields in the high mountain region. Despite these widely differing estimates of the water resource of the Himalayan region, the

water output could be the highest from any single mountain range in the world (Stone, 1992). In recent decades the hydrological characteristics of watersheds in the Himalayan region have undergone substantial changes due to land use changes leading to more frequent hydrological disasters, enhanced variability in rainfall and runoff, extensive reservoir sedimentation and pollution of lakes (Ives and Messerli, 1989). Water availability, in terms of temporal as well as spatial distribution, is expected to be highly vulnerable to anticipated climate change (IPCC, 2001). Changes in the snowfall pattern have been observed in the Himalayas (Verghese and Iyer, 1993). These changes will have a marked impact on the monsoon regime, seasonal run-off and vegetation cover, including agriculture (IPCC, 2001). Because the melting season of snow coincides with the summer monsoon season, any intensification of the monsoon is likely to contribute to flood disasters in the Himalayan catchments (IPCC, 2001). Such impacts will be observed more in the Western Himalayas than in the Eastern Himalayas because of the higher contribution of snowmelt runoff in the west (Sharma, K P 1997).

The effect of climate change on hydrology of the region will be multifaceted: ranging from regional variations in precipitation characteristics, glacial shifts, mean run-off frequency and intensity of droughts and floods, soil moisture, water supplies for irrigation and hydroelectric generation. The Himalayas play a critical role in providing water to continental monsoon Asia. Increased temperatures and enhanced seasonal variability in precipitation are expected to result in glacier recession and increasing danger from glacier lake outburst floods. A reduction in average flow of snow-fed rivers, together with increase in peak flows and sediment yields would have a major impact on hydropower generation, urban water supply and agriculture. Studies of one catchment in the Western Himalayas (the Chenab, a tributary of the Indus) show that the average snowmelt and glacier-melt contribution to the annual flow of water is 49.1%; a significant proportion of run-off is derived from snow in the dry season, when water demand is highest (Singh et al., 1997).

If the rainfall pattern in the Himalayas changes due to climate change, the impact could be felt in downstream countries such as Bangladesh. The water and agriculture sectors are likely to be most sensitive to climate change-induced impacts in Himalayas. Catchments in Nepal supply about 70% of the dry-season flow of the Ganges River, and the tributaries of the Brahmaputra river originating in Bhutan supply around 15% of the total annual flow of that river. If climate change disrupts these resources and alters mountain hydrological regimes, the effect will be felt not only in the montane core of Tropical Asia but also downstream, in countries that are dependent on this water resource.

Water Resource Management for sustainable agriculture production in Himalayan Region

Water resources hold the key for socio-economic development mountain region. Indian Himalayan has two distinct geopolitical sub regions, viz., north east hills and north west hills. Despite adequate rainfall in both the flanks of Himalayas, there is a shortage of water not only for raising the crop but also for drinking. Against this backdrop, it becomes imperative to study various options for increasing the crop water productivity i.e. more crop per drop, and also for meeting the basic

requirements of water to the community for various purposes. So, there is a need for various technological options for the betterment of the water supply and conservation, restoration of links between forests and water, construction of water harvesting structure, agronomical measures for improving water use efficiency, watershed approach for water management.

The Watershed Concept

The watershed approach enables planners to harmonize the use of soil, water and vegetation in a way that conserves these resources and maximize their productivity. The watershed is the appropriate hydrological unit for technical efforts to manage water and soil resources for production and conservation. But watershed management is complicated by the fact that watersheds rarely correspond to human-defined boundaries. The fundamental social problem of watershed development is that it often distributes benefits and costs unevenly, making it a likely source of disagreement and conflict. Mostly, watershed projects distribute costs and benefits unevenly, with costs incurred disproportionately upstream, typically among the poorer farmers, and benefits realized disproportionately downstream, where water use is concentrated and richer farmers own most of the land. The challenge is to internalize the costs and the benefits in such a way that all the stakeholders are part of a win-win scenario.

The impact and control of water Erosion and natural soil resources

Soil erosion is critical issue on hills due to steep slopes. Soil loss from cultivated slopes is quite high particularly during first two to three years of cultivation. It has been expected that concerning 6 million hectare of land require careful conservation measures in Himalayan and sub Himalayan regions. The havoc of erosion has been becoming a burning problem due to accelerated activities against nature by human beings viz. Cutting of hillocks, deforestation etc.

Natural resources management and control of erosion on hills

1. **Contour Farming**: The ridges of same depth are called as contours. The crop is sown on the ridges and water is provided through the furrows. This encourages more water infiltration into the soil the soil profile.
2. **Conservation Tillage**: Now days, the concept of conservation tillage (zero tillage, no tillage) is coming up to overcome the problem of soil erosion.
3. **Riparian Fencing**: Fencing of waterways will prevent grazing of land and trampling of river banks by herbivores. Moreover, tree plantation on river sides also reduces river bank erosion.
4. **Grassed Waterways**: Grassing over the shallow waterways, in most cases is found to be effective in preventing soil loss from it. Grass leaves act as a barrier against the speed of water current and reduce the erodibility of soil.
5. **Shelterbelts:** They provide roots at the boundaries of the fields, sheltering the soil and supply organic matter.
6. **Spaced Tree Planting:** Trees provide deep roots that hold the soil; Cycle

deep nutrients and loss nutrients also provide good amount of organic matter to the soil. Trees must compete with highly metabolizing grassland, thus should be fast growing and deciduous.

7. **Retirement Fencing:** Fencing is an absolute must to encourage natural growth and to protect tree planting.
8. **Topdressing:** Fertilizing of soil leads to rapid growth of vegetations, is the best remedy against soil erosion.
9. **Forest Fire Control**: Forest Fire destroys vegetation cover up to various extent. There is also change in the amount of light, pH of soil and destruction of soil organism. As a result soil productivity is reduced.
10. **Cultivation of fruits**: Fruits such as oranges, pineapple, Jack fruit, banana and papaya reduce soil erosion as well as provide income to the people of this region.
11. **Bench Terracing**: On steeply sloping (16% to 33%) and undulated land, intensive farming is possible. The field is made into a series of benches by excavating of the soil from upper part of the terrace and felling in the lower part.
12. **Anti-seep Collar**: An impermeable diaphragm of sheet metal or concrete constructed at intervals within the zone of saturation along the conduit of a principle spillway to increase the seepage length along the conduit thereby preventing piping and seepage.
13. **Debris Dams:** They check the movement of water in steep gullies. They should not be used in slow flowing waterways. Any kind of debris would do but natural products such as tree stumps, braches, planting are better.

Judicious Use of Excess Water in Hilly Regions

Himalayas are considered as the source of water but rain or the availability of water for irrigation purpose is not up to the mark in adjoining regions as many places are either rain-fed or having heavy rain with temporal and spatial variability. Dry spells are direct consequences of spatial and temporal variability, and these hamper the success of rain-fed agriculture by causing crop yield reduction and crop failure in many regions a number of times. Water conservations and storage techniques are essential in these regions for sustainable agriculture. Water harvesting is not a new concept however generally the water harvesting techniques are used to harvest only rain water which is not available throughout the year. Therefore an attempt has been made to study the applicability of poly tanks for water harvesting in the region. The construction of poly tank is very cheap and successful to save the crop at the time of acute water shortage if they are constructed at proper site.

Present Scenario In the region

Though most areas receive good annual rainfall, its intensity and distribution is quite erratic and causes severe drought spells to hamper the growth of timely sown winter crops and subsequent planting of spring crops due to lack of soil moisture. This

situation forces the farmers to risk their winter crops at germination and ripening stages of growth. The average annual rainfall in this region varies from 700 mm to 3000 mm of which about 70 % occurs during monsoon months of June to September. The existing rivers, streams and natural springs have been drying up fast due to systematic environmental degradation by humans and natural calamities. Presently, only few perennial natural springs exist in the mid-Himalayan region, while most springs have become seasonal due to lack of continuous recharge. Therefore, the inhabitants generally suffer from shortage of water for drinking and household activities, and to irrigate their crops at critical times. The crops suffer badly due to moisture stresses at different stages of crop growth during post-monsoon period and long dry spells during rainy season. Because of lack of sufficient moisture, the seeds remain dormant from October to December until winter rainfall/snowfall occurs. Usually, the amount and distribution of rainfall does not coincide with the water requirements at critical stages of crop growth. Frequent and long dry spells also retard the growth, fruit size and yield of important fruit crops like apple, plum, peach, apricot etc.

Agricultural Scenario in Uttarakhand Hills

- Population engaged in agriculture > 90 %
- Status of agriculture
  - Irrigated 11 % (Valleys)
  - Rainfed 89 %
  - Land holding
    - Marginal (< 1 ha) 70 % (Scattered)
    - Small (1 – 2 ha) 17 %
  - Cropping intensity 102 %
- Frequent natural/man-made hazards Soil erosion, landslide, drought, cloud-burst, forest fire.

- About 60 % population in hilly region depends on natural water springs to fulfill their day to day water needs.
- About half of the perennial springs have either dried-up or have become seasonal due to ecological imbalance and environmental degradation during last two decades.
- Nearly 8000 villages mostly located in upper and mid hills have been facing acute shortage of drinking water.
- If scientifically appropriate biological and engineering measures to rejuvenate the existing springs are not taken in time, the remaining springs will also die sooner than later.
- Low spring discharge, if collected and stored in a suitable tank/pond, will create a huge water resource for use by the local people to fulfill their household and agricultural needs.
- Flowing rivers (24), streams, lakes (16) and glaciers (38)
- Flowing natural water springs (perennial & seasonal)

- Overland runoff during rainfall

Runoff through roof-tops of houses during rainfall

Modernizing irrigation water management

FAO has defined modernization as "a process of technical and managerial upgrading of irrigation schemes combined with institutional reforms, if required, with the objective to improve resource utilization and water delivery service to farms" (Facon and Renault, 1999). In this sense, modernization offers a means of institutional reform with a purpose, not just reform for its own sake. It is systemic and practical without asking that all institutional elements change and it needs to be applied where irrigated agriculture has a clear comparative advantage.

Irrigation institutions need to adopt a service orientation and improve their performance in economic and environmental terms. This entails: adopting new technologies; modernizing infrastructure; applying improved administrative principles and techniques; and promoting the participation of water users. Irrigation-sector institutions need to link their central task of providing irrigation services to agricultural production and to integrate their water demands and uses with other users at basin level. An enhanced appreciation of the water cascades and flows across landscapes and the circulation of groundwater within aquifers will lead to informed decisions on the use and reuse of agricultural water.

Development of Small Hydropower System in the region and GIS applications in Energy Sector

Hydropower, hydraulic power or water power is power that is derived from the force or energy of moving water, which may be harnessed for useful purposes. Prior to the widespread availability of commercial electric power, hydropower was used for irrigation, and operation of various machines, such as watermills, textile machines, and sawmills. A tromp produces compressed air from falling water, which could then be used to power other machinery at a distance from the water. Small scale hydro has been increasingly used as an alternative energy source, especially in remote areas where other power sources are not viable. Small scale hydro power systems can be installed in small rivers or streams with little or no discernible environmental effect on things such as fish migration. Most small scale hydro power systems make no use of a dam or major water diversion, but rather use water wheels.

There are some considerations in a small-hydro system installation. The amount of water flow available on a consistent basis, since lack of rain can affect plant

operation. Head, or the amount of drop between the intake and the exit. The more head, the more power that can be generated. There can be legal and regulatory issues, since most countries, cities, and states have regulations about water rights and easements. Over the last few years, the Government of India has increased support for alternative power generation. Many resources such as grants, loans, and tax benefits are available for small scale hydro systems. Small-hydro power can be used directly as "shaft power" for many industrial applications. Alternatively, the preferred option for domestic energy supply is to generate electricity with a generator or a reversed electric motor which, while less efficient, is likely to be available locally and cheaply. Small-scale hydropower systems are those that generate between .01 to 30 MW of electricity.

Application of Geographical Information System in Small Hydropower

The technology of GIS provides a means of introducing information and knowledge from various data sources in to the decision-making process and help in handling and manipulating the classified remotely sensed data. Entire information is stored in the database in GIS environment as separate thematic layers and hence it becomes easy to handle the entire data.

A GIS stores a representation of the world in the form of layers connected by a common geographical frame of reference. Each of the features required for hydropower projects, has a unique identifier, which distinguishes it from the rest of the features on the layer, and allow us to relate it to relevant information stored in external databases, etc and to capture only those elements of the world that are of interest to us, like catchment area, under forestation, covered under snow etc. GIS is also used to input, store, retrieve, manipulate, analyze and output geographically referenced data or geospatial data, in order to support decision making for planning and management of land use, natural resources, environment, transportation, urban facilities, and other administrative records.

GIS based Watershed Management System

GIS and Remote sensing techniques are used to generate action plans for conservation of land and water resources. Spatial database on soils, land use, contours, geology, drainage etc. is created using Survey of India topographical maps, cadastral maps, ground truth and remotely sensed data obtained from various sources using state of art GIS software. This primary resource data is used to derive secondary vector layers and quad trees (data structures) corresponding to slope, erosion class, soil depth, land capability etc. Rules are framed to arrive at certain suitable solutions to each of the area-specific problems identified for the watershed. Further a number of macro-level and location-specific action plan maps are generated based on the secondary derived maps and the action plans framed.

A resource inventory towards the development of an efficient and an effective Watershed Management System is created. Suitable decision rules are framed and the same are used in conjunction with the resource inventory to arrive at certain suitable solutions in the form of action-plan and treatment-plan maps to each of the area-specific problems identified for the Watershed.

Conclusion

Environmental sustainability of the Himalayan region is critical to the well being of millions of people in the Indian subcontinent who are directly or indirectly dependent on its resources. Increased accessibility, population pressures, economic development and the concomitant excessive utilization of the regions resources have resulted in a threat to the health of this mountain ecosystem and its inhabitants.

Integrated watershed management in these regions requires adoption of innovative soil conservation and crop management techniques to prevent land degradation, maintain soil fertility and ensure environmental security for achieving sustainable productivity. Experience of integrated watershed development programs in hilly and valley regions has indicated that they greatly helped in moderating floods in downstream areas, improve in-situ moisture conservation and groundwater recharge for increased biomass production and were economically viable with tremendous environmental externalities.

Water harvesting and groundwater recharge, location-specific and cost-effective technologies for erosion control and flood moderation, suitable plant materials and integrated farming systems for higher production and conservation of natural resources, contingency planning for undertaking calamity relief works for generating productive employment and diversification for new market opportunities based on demand-driven growth need to be promoted. Modern tools and procedures should be deployed for planning of watersheds and provide better opportunities to the marginalized and inaccessible hilly situations.

WHATEVER IT TAKES
FROM WATER AVAILABILITY MODEL TO COST OF WATER

Alfredo Rodriguez[1]

[1] Sr. Water Resources Engineer, Water Resources Division, Aurora Water, Aurora, Colorado 80012 (303) 739-7334; email: drodrigu@auroragov.org

Abstract. This paper summarizes ongoing efforts by the Water Resources Division at Aurora Water to determine the cost of Raw Water for the City of Aurora. Aurora is currently developing, at a cost of approximately 700 million dollars, a new water supply and delivery system, the Prairie Waters Project (PWP). This project will act as an additional source of water supply. The project is designed to divert Aurora's reusable return flows from the lower South Platte River, pump them back to the City, and, after suitable treatment, reintroduce them into the City's potable water system. In addition, Aurora Water staff is diligently pursuing the acquisition of storage and agricultural water rights in the South Platte River north of the Denver Metropolitan Area. Purchased agricultural water will be transferred to municipal use to supplement reclaimed water in order to provide for future population growth. Using results from the water availability model, and established budgeting procedures, staff at Aurora Water is taking the necessary steps to determine the cost of raw water.

This complex system of water supply raises the following question: What is the actual cost of water? Finding the answer to that question is not a small task.

Information to establish the cost of water is obtained by combining data from the Aurora Water adopted budget, the proposed construction costs and the cost of acquiring water rights and storage in the lower South Platte River.

1. Introduction

The City of Aurora encompasses a service area of approximately 151 square miles directly east of the City and County of Denver. Aurora Water has a complex water supply system and water rights portfolio.

Water is delivered to the City from the Arkansas, Colorado, and South Platte River basins and treated at two 80 MGD treatment facilities before distribution to the end users (see Figure 1.) In addition, the City is building the Prairie Waters Project and diligently pursuing the acquisition of additional water rights in the lower South Platte River Basin (Figure 2).

Water diverted through the Prairie Water Project to the City will be treated at a 50 MGD treatment facility (Prairie Water WPF) as indicated in Figure 2

[1] DISCLAIMER: **Cost values shown in this document are for illustrational purposes only and are not intended to reflect actual City of Aurora water costs.**

Population growth has been estimated at a constant rate of 1.75% per year. Table 1 summarizes the long-range official growth projections through the year 2055. At this rate, the population of Aurora is expected to more than double in the next 50 years.

Portions of the water supply system are built and have been debt free for a while, some have been built and are being paid off either through revenue bonds or through general obligation bonds, and other portions of the system are under construction and will be paid off through the issuance of bonds. In addition, there are a series of other proposed projects being considered for future expansions.

Table 1 – City of Aurora Long-Range Population Projection

Year	Official Population Projection
2000	276,393
2005	303,833
2010	323,777
2015	351,967
2020	382,612
2025	415,924
2030	452,137
2035	491,503
2040	534,296
2045	580,815
2050	631,384
2055	686,356

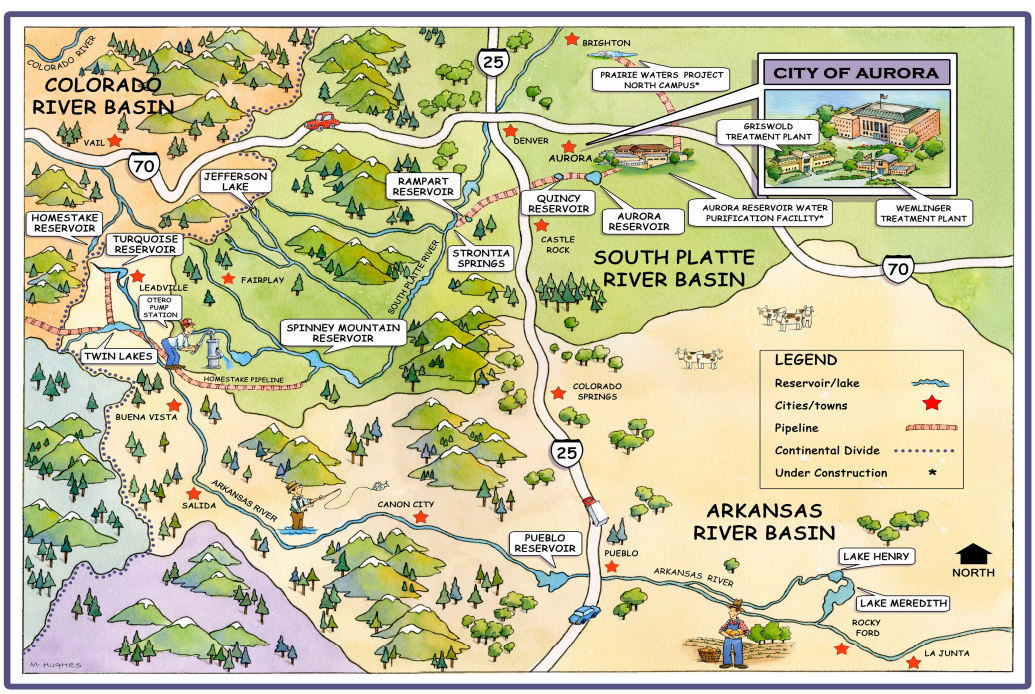

Figure 1 - City of Aurora Water Supply System

Figure 2 - Prairie Waters Project

Because of the complexity of the system, the cost of water in the Arkansas and Colorado basins is calculated by facility (i.e. a reservoir) and by water right as explained below. In the South Platte Basin, the cost of water is determined by facility and by type of water (i.e. reusable water).

The Aurora Water Availability Model is used to determine the amount of water yielded by the City using pre-established conditions (i.e. expected infrastructure during the year 2015). and the price

Results from the Aurora Water Availability Model are copied into an Excel Workbook and the cost of water is calculated using adopted City budgets for existing facilities and proposed construction and operational costs for future facilities.

The cost of water per acre-foot in the Economic Model is based on the amount of water yielded by the system and not on the total amount of water moved through each facility. In addition, the cost is calculated for both the raw portion and the treated portion as explained in the following sections.

ARKANSAS/COLORADO BASIN COSTS

Cost of Water by Facility

Cost of water per acre-feet for each of the facilities (i.e. Colorado Canal, Homestake Reservoir) is determined based on the amount of water coming into (inflows) and leaving (outflows) a particular facility.

In each facility, the main component is the water that is either yielded or moved through that facility via exchanges or leases.

The Colorado/Arkansas basin has the following water supply systems as shown in Table 2, some of which are proposed projects as noted:

Table 2 – Arkansas/Colorado Water Supply Systems

Facility Name	Size/Amount/Capacity	Condition
Holbrook Reservoir	4,000 AF	Existing
Timpas Creek Reservoir	4,000 AF	Proposed
Valco Gravel Pit	10,000 AF	Proposed
Colorado Canal	9,117	Existing
LaFarge Gravel Pit	10,000 AF	Proposed
Pueblo Reservoir	10,000 AF	Existing (Lease)
Otero Pump Station	75 cfs	Existing
Twin Lakes	2,724 AF	Existing
Box Creek Reservoir	20,000 AF	Proposed
Turquoise Reservoir	20,000 AF	Existing
Homestake Collection	21,441 AF	Existing

The following table shows an example of a calculated average cost of water from the Arkansas/Colorado Basin by facility. In this example, the average annual cost of water was estimated at $906.87 per acre-foot.

Table 3 – Average Annual Cost of Water for the Colorado/ Arkansas System by Facility.

ECONOMIC OPTIMIZATION MODEL
AURORA WATER COST SUMMARY BY FACILITY

WATER SYSTEM	INFLOW TO SYSTEM (AF)	COST PER ACRE-FOOT ($/AF)	TOTAL COST
BOX CREEK RESERVOIR SYSTEM	0	$0.00	$0
HOLBROOK RESERVOIR SYSTEM	4,804	$268.92	$1,291,841

NATIVE YIELD	**1,047**		**$202,419**
TOTAL WATER LEASES	**2,196**		**$424,609**
OTHER SOURCES OF WATER	**13,173**		**$2,546,641**
TURQUOISE CF&I ACCOUNT	8,570	$196.94	$1,687,693
HOMESTAKE SYSTEM	**6,165**		**$1,214,191**
BUSK-IVANHOE SYSTEM	**1,411**		**$277,907**
EXCHANGES AND LEASES	**993**		**$195,596**
HOMESTAKE COLLECTION SYSTEM	13,579	$275.95	$3,746,981
COLUMBINE/WURTZ/EWING DITCH SYSTE	0	$0.00	$0
TOTAL ANNUAL COST OF THE COLORADO/ARKANSAS SYSTEM			**$27,958,167**
AVERAGE ANNUAL COST OF WATER PER AF FOR THE COL/ARK SYSTEM			**$906.87**
COST OF WATER FOR THE COL/ARK SYSTEM ($/1,000 Gallons)			**$2.78**

The methodology used throughout the Aurora Water system is shown in the following example.

Example: Pueblo Reservoir System

In the following example, the cost per acre-foot of water at Pueblo Reservoir was estimated at $273.39. The following graph shows the Pueblo Reservoir Facility.

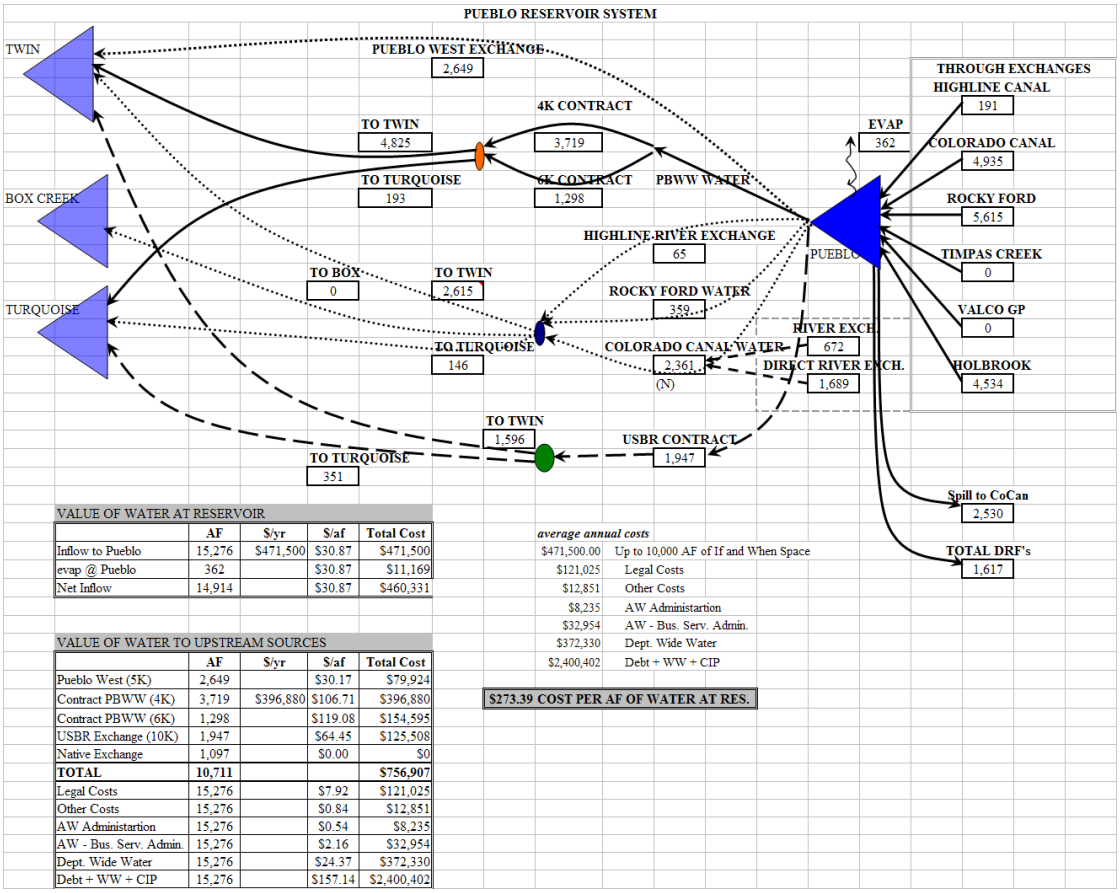

Figure 3 - Pueblo Reservoir System - Cost Calculation

Inflows to Pueblo:

The cost of moving water into the Reservoir is calculated to be $30.87 per acre-foot as follows:

The total estimated average annual amount of Aurora water moved, via exchanges, from the different sources into the reservoir is 15,275 AF as follows:

1. 4,935 AF from the Colorado Canal
2. 5,615 AF from the Rocky Ford Ditch
3. 4,434 AF from the Holbrook Reservoir
4. 191 AF from the Highline Canal Lease

Aurora Water pays an annual assessment of $471,500 for the right to used 10,000 AF of **If-and-When** space in the reservoir. Therefore, $471,500/15,275 AF = $30.87.

Outflows from the System:

The cost of moving water out of the Reservoir has been estimated as $70.67 per acre-foot as follows:

1. 2,649 AF of water is moved through the Pueblo West Contract exchange at $30.17 per acre-foot.
2. 3,719 AF of water is moved through a 4,000 AF contract exchange with the Pueblo Board of Water Works. The annual payment for the right to exchange this water is $396,880. The cost per acre-foot is estimated at $106.71.
3. 1,298 AF of water is moved through a 6,000 AF contract exchange with the Pueblo Board of Water Works. The cost of this contract exchange is $119.08 per acre-foot.
4. 1,947 AF of water is moved through a 10,000 AF contract exchange with the U.S. Bureau of Reclamation. The cost of this contract exchange is $64.45 per acre-foot.
5. 1,097 AF of water was moved via a Native Exchange for which there is no cost to Aurora Water.

Therefore, $756,907/10,711 AF = $70.67

Other Costs at Pueblo Reservoir:

In addition to the cost of moving water through a reservoir, there are additional cost such as Legal, Administrative and other costs that the City incurs due to its day to day operations.

In the case of this example, Total Other costs at Pueblo Reservoir were estimated at $192.97 per acre-foot

Cost of Water by Water Right

Cost of water per acre-foot for each of Aurora's Water Rights (i.e. decreed or contracted) is estimated based on the total amount of water moved through the Otero Pump facility for each water right or water contract.

Aurora Water has the following water rights in the Colorado/Arkansas basin:

Table 4 –Aurora's Water Rights in the Colorado/Arkansas River Basins

Water Right	Type
Homestake	Decreed
Busk-Ivanhoe	Decreed
Twin Lakes	Decreed
Upper Ranches	Decreed
Rocky Ford	Decreed
Colorado Canal	Decreed
Lake Creek Ranch Lease	Contract
Eagle River Lease	Contract
Climax Water Lease	Contract
Pueblo West Lease	Contract
PBWW Lease	Contract
Highline Canal	Contract
Columbine/Ewing/Wurtz Ditches	Contract

The following table shows the average cost of water from the Arkansas/Colorado Basin by water right. In this example, the average annual cost of water in the Colorado/Arkansas basins is estimated to be $906.93 per acre-foot

Table 5 – Average Annual Cost of Water for the Colorado/ Arkansas System by Water Right.

AURORA WATER

ECONOMIC OPTIMIZATION MODEL
AURORA WATER COST SUMMARY BY WATER RIGHT

WATER RIGHT	AMOUNT DELIVERED TO OTERO (AF)	COST PER ACRE-FOOT ($/AF)	TOTAL COST
Homestake	12,082	$587.48	$7,097,786
Busk-Ivanhoe	1,387	$429.52	$595,796
Twin Lakes	1,045	$407.63	$425,973

Highline lease	233	$7,332.36	$1,711,928
Columbine/Ewing/Wurtz Leases	0	$0.00	$0
TOTAL ANNUAL COST OF THE COLORADO/ARKANSAS SYSTEM			**$27,959,414**
AVERAGE ANNUAL COST OF WATER PER AF FOR THE COL/ARK SYSTEM			**$906.83**
COST OF WATER FOR THE COL/ARK SYSTEM ($/1,000 Gallons)			**$2.78**

SOUTH PLATTE BASIN COSTS

Costs in the South Platte Basin are divided into two components, the first one includes the existing system (from Spinney Mountain Reservoir to the City's Treatment Facilities), and the second one includes the Prairie Waters Project (from the Metro Wastewater Treatment Plant to the Aurora Reservoir Water Purification Facility) presently under construction and the costs of acquiring agricultural water rights.

In addition, costs are divided into Raw Water costs (from source to treatment) and Treated Water costs (from a treatment plant to the end consumer), see example below.

In the calculation of treated water from the City treatment facilities, the following annual organizational budget and account numbers are included:

Cost of Water by Facility

Cost of water per acre-feet for each of the facilities in the South Platte Basin, as in the case of the Arkansas/Colorado basins, were determined based on the amount of water coming into (inflows) and leaving (outflows) at a particular facility (i.e. Wemlinger Treatment Plant, Aurora Reservoir, etc.)

Table 6 below shows the summary of the cost of raw water in the South Platte Basin. In this example, the cost per acre-foot of raw water was estimated at $4,160.76.

The example shown below, includes the calculation of raw water cost and treated water cost for one of the water treatment facilities at the City of Aurora.

Example: Wemlinger Water Treatment Facility

The following example, shown on Figure 4, includes the calculation of the raw water and the treated water portions of the system at the Wemlinger Treatment Facility.

The cost of raw water at the Treatment Facility has been estimated to be $248.79 per acre-foot while the cost of treated water from the facility has been estimated to be $458.68 per acre-foot.

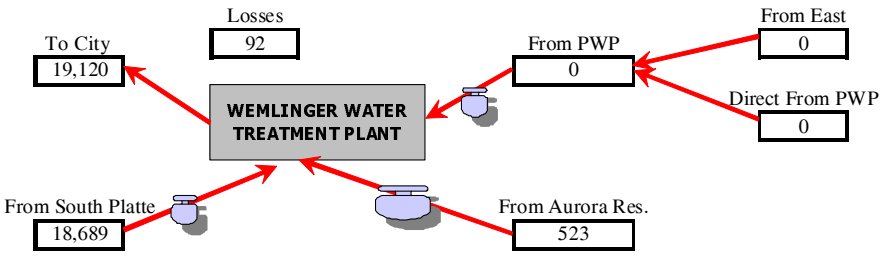

Table 6 – Average Annual Cost of Water for the South Platte System by Facility.

AURORA WATER TOTAL WATER SYSTEM COSTS

Having determined the cost of raw water for both the Arkansas/Colorado and the South Platte River Basins, as well as the cost of treatment and distribution of the treated portion, then the total water system cost con be calculated as shown on Table 8.

Using the example in this document, the total cost of the system for the City of Aurora has been calculated to be $2,516 per acre-foot, of which $2062 per acre-foot is the cost of raw water and $454 per acre-foot the cost of treated water

Table 8 – Aurora Water System Cost Summary

ECONOMIC OPTIMIZATION MODEL
AURORA WATER SYSTEM COST SUMMARY

Aurora Water System	Total Yield (AF)	Total Cost ($)	Cost of Water ($/AF)	Cost of Water ($/1,000 Gal.)
South Platte River Basin Raw Water Cost	16,971	70,611,106	$4,161	$12.77
Arkansas/Colorado River Basins Raw Water Cost	30,829	27,958,167	$907	$2.78
Total Aurora Water Annual Cost of Raw Water	**47,800**	**98,569,272**	**$2,062**	**$6.33**
Aurora Water Treated Water Cost	47,798	$21,689,293	$454	$1.39
Annual Cost of Water for Aurora Water System	**47,800**	**120,258,566**	**$2,516**	**$7.72**

Final Remarks

Aurora Water's Water Resources Division recognizes that this is a continuous project and that the results will vary according to an specific condition or conditions set in its water availability model.

Additional work needs to be accomplished to include electrical cost for the operation of the Prairie Waters Project.

The results of this project can be used to determined the base charge for water in case of a potential sale of water to a third party.

CURRENT WATER MANAGEMENT PRACTICES AND THE EFFECTS OF CLIMATE CHANGE ON THE COLORADO RIVER BASIN

J. Brandon Klenzendorf, Student Member

Graduate Student, Civil Engineering Department, University of Texas at Austin, Austin, TX, jbklenz@mail.utexas.edu

ABSTRACT

The Colorado River Basin (CRB) reservoir system is one of the most over-allocated systems in the world. Due to recent drought conditions within the past decade, reservoir storage has been decreasing and shows no sign of increasing in the near future. The allocated demands from the system are greater than the average streamflow into the system. Furthermore, it is expected that climate change will only make the situation more severe in the near future. Various modeling techniques show that climate change will decrease precipitation in the CRB while increasing evaporation. This combination results in decreased runoff and streamflow which provides the majority of water in the CRB. However, the more significant problem is the over-allocation of the river. The allocations and water usage can be controlled much easier and have a much greater impact on the reliability of the reservoir system than global climate change. This paper will highlight some of the major flaws in the water allocations utilized in the CRB and reasons for mistakes made in the past. Previous studies on the reliability of the CRB reservoir system are investigated, and the general impacts of climate change on the hydrologic cycle are briefly discussed.

INTRODUCTION

The reservoir system of the Colorado River Basin (CRB) consists of over 90 reservoirs, of which Lake Mead (created by the Hoover Dam) and Lake Powell (created by the Glen Canyon Dam) account for 51.9 million acre-feet (MAF) of storage, or roughly 85% of the total CRB reservoir storage volume (Christensen et al., 2004). Lake Mead is the largest man-made reservoir in the United States and is the main focus of this study. The lake is located in the Lower CRB and provides water to roughly 8 million people in the southwestern United States and parts of Mexico. It contains about 16 MAF of capacity for the joint use of water supply, irrigation and power, and 10 MAF for inactive storage (USBR, 2008b). Figure 1 shows the water surface elevation of Lake Mead through time since its construction in 1936. Several important elevations are listed to give an idea of when the lake will no longer produce hydropower and

when water can no longer be extracted by gravity for municipal use. A water level below 1,125 feet is considered to be drought conditions; Lake Mead has experienced three significant droughts during its life. The short drought around 1965 was impacted by the construction and subsequent filling of Lake Powell (in the Upper CRB) upstream of Lake Mead. The lake is currently experiencing drought conditions.

The following statistics and characteristics of the CRB were taken from Christensen et al. (2004). The total drainage area of the CRB is 243,000 square miles. The annual average streamflow is around 15.1 MAF based on gage data collected since 1906. Of this streamflow value, 90% of the flow is generated in the Upper Basin, which is designated as the area upstream of Lees Ferry, Arizona. 70% of the flow generated in the Upper Basin comes from snow pack which also controls the seasonal timing of streamflow. The average annual precipitation of the entire CRB is 14.0 inches, of which approximately 12.2 in. evaporates, which leaves 1.8 in. of water available for runoff. Therefore, only 13% of the precipitation becomes runoff and contributes to streamflow and water storage. This low runoff value, together with the low precipitation and high water demands show why water resources are a major concern in this part of the country.

OBJECTIVES

The main objective of this paper is to investigate the surface water availability and management practices within the CRB, which is currently experiencing drought conditions. Lake Mead will be used as an indicator of the total water availability issues in the CRB due to its large storage volume. A brief inspection of the reliability of the CRB reservoir system is provided based on previous studies available in the literature. Furthermore, the possible impacts

of global climate change are investigated based on projected changes to the hydrologic cycle. Specifically, the influence of climate change on precipitation, evaporation, and runoff are necessary to determine surface water availability in the future. Finally, the overall water availability within the CRB is summarized based on current water management practices and the possible impacts of global climate change.

WATER AVAILABILITY AND MANAGEMENT PRACTICES

Water resources management in the CRB is governed by the "Law of the River", which is a collection of over 50 international treaties, interstate compacts, court decisions, and other legislation that has occurred over the years (Harding et al., 1995). The Law of the River allocates an annual amount of water of 7.5 MAF for the Upper Basin, 7.5 MAF for the Lower Basin with an additional 1.0 MAF if needed, and 1.5 MAF for Mexico. This combines for an allocated annual streamflow total of up to 17.5 MAF. However, this does not account for the minor water rights that are reserved for such uses as endangered fishes and Indian tribes (MacDonnell et al., 1995). Therefore, the total allocated water in the entire basin is approximately 18 MAF per year.

The value of annual allocated water must be provided by the combination of reservoir storage and streamflow. The average annual streamflow varies depending on what data source is considered. Gage streamflow data taken beginning in 1906 by the United States Bureau of Reclamation (USBR) estimate an annual average streamflow of 15.1 MAF. However, historical streamflow records have been estimated based on tree ring reconstructions dating back to the early 1500s. The tree ring records suggest an average annual streamflow as low as 13.5 MAF (Christensen et al., 2004). Figure 2 shows one collection of tree ring reconstructions at the location of Lees Ferry, Arizona presented as 10-year averaged streamflow values (Woodhouse et al., 2006) together with the averaged gage data monitored since 1906. Lees Ferry is the dividing point between the Upper and Lower Basins, and is a good representation of the total water in the entire CRB since the Upper Basin accounts for 90% of the total flow. The important point of these data is to point out that the observed streamflow values since 1906 show a higher average annual streamflow value than suggested by the tree ring reconstructions. Furthermore, allocations of water in the CRB, governed by Law of the River, total up to 18 MAF per year. When these allocations were made in the 1920s, the CRB was experiencing a high annual average streamflow value equal to this allocation value, possibly the highest streamflow over the past 500 years. Therefore, allocations were made based on the observed 18 MAF annual average at the time, as opposed to the more likely 13.5 MAF annual average suggested by the tree ring reconstructions. Currently, 90% of the allocated water is actually being utilized, so that roughly 16 MAF of water each year is being used by the residents in the CRB, with little indication of this number decreasing in the future unless changes to the water resources management practices are made. Clearly, this over-allocation of water is the major problem associated with water resources management in the southwest United States. As shown in Figure 2, there have been only four possible times when an annual allocation of 18 MAF could actually be provided by streamflow alone.

The CRB is one of the most over-allocated river systems in the world. An annual allocation of 18 MAF is provided by the Law of the River. Over 16 MAF of water is actually being used each

year. The average annual streamflow of record is 15.1 MAF, with a possible average closer to 13.5 MAF as suggested by tree ring reconstructions. Therefore, since the outflow to water users is greater than the inflow to the reservoir system, the reservoirs have been consistently draining in recent years with no indication of filling in the near future. This suggests that the entire system is destined to fail in the future unless drastic water resources management changes are made.

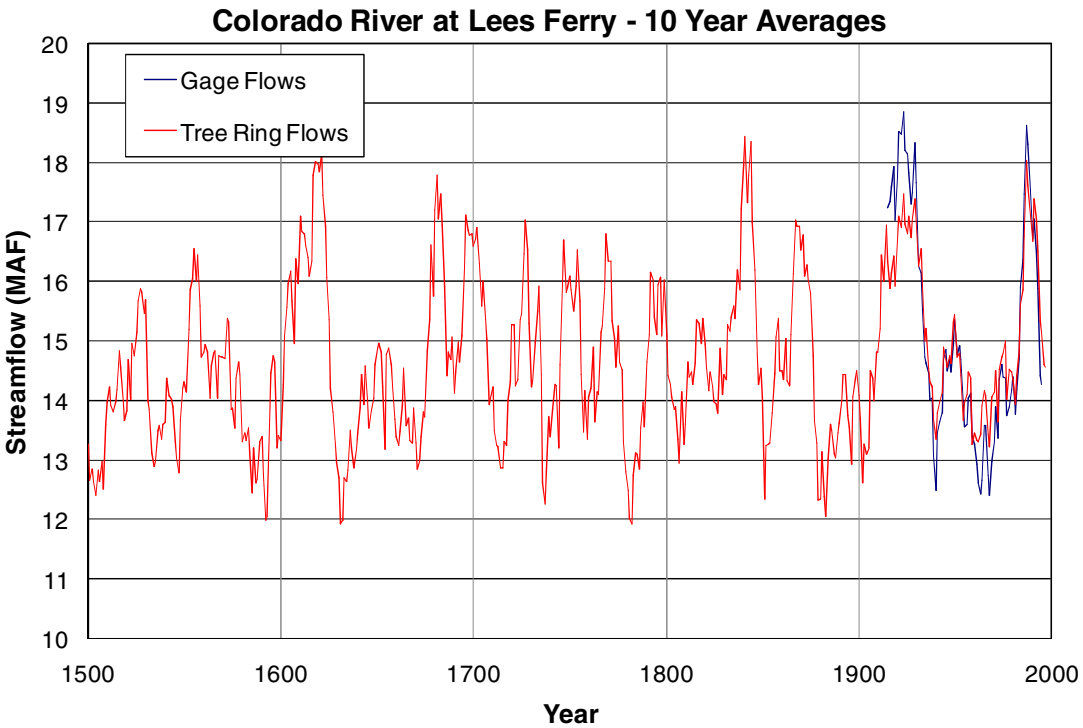

Figure 2 – 10-year average annual streamflow values in the CRB (data: NOAA, 2008)

RELIABILITY OF RESERVOIR SYSTEM

Many previous studies have investigated the reliability of the reservoir system in the CRB. This issue has been important due to the fact that the system supplies water to a large population. Previous studies prior to the current drought conditions have shown that the reservoir system is very reliable. However, more recent studies suggest the reservoir system is not as reliable and likely could go dry in the future.

Tarboton (1995) examined the impacts of three scenarios of severe sustained droughts on the CRB. The first drought scenario is the "Colorado Drought of Historic Record" which occurred from 1943 to 1964 and is likely to occur again. The second scenario is the "Colorado Severe Drought" which is the worst drought from tree ring reconstructed flows and occurred from 1579 to 1600. The third drought is the "Colorado Rearranged Severe Drought" where the annual flows in the "Colorado Severe Drought" are rearranged in descending order so that this is a worst case scenario. The major finding is that only the most severe drought ("Colorado Rearranged Severe Drought") must take place before any extreme consequences are felt. Therefore, the

other two scenarios will not significantly impact the water resources in the region in the long run. This study did not take into account any climate effects but only considered actual streamflow values that have occurred in the CRB. In a similar study, Harding et al. (1995) found that a severe sustained drought would have little impact on the Lower Basin, but would heavily strain the water resources on the Upper Basin. These studies prior to the recent drought showed that the reservoir system of the CRB is very resilient to severe sustained drought.

More recent studies suggest the reservoir system is likely to go dry in the future. Barnett and Pierce (2008) are the first to attempt to predict the time at which decreased water availability will begin to impact the residents of the CRB. They looked at various scenarios and developed cumulative distribution functions of when the active storage in Lakes Mead and Powell will disappear based on Monte Carlo simulations of a water balance model for the entire basin. They found that the net inflow (inflow minus outflow) for the year 2008 is -0.2 MAF per year based on the average inflow of 15.1 MAF. This is consistent with the above description in the previous section of the outflow from the system being greater than the inflow. The simulations of current conditions, with no impact of climate change, showed that by the year 2060 the net inflow would be -1.2 MAF per year. This suggests that even without the impacts of climate change, the system is destined to fail under current conditions due to continued increased water demand. However, these values are based on the higher observed annual streamflow average. If the lower tree ring reconstruction flows are used, the actual net inflow for the year 2008 may be closer to -1.0 MAF. The current value of negative net inflow for the CRB reservoir system is what distinguishes the results from more recent studies when compared to older studies. In the older studies, the reservoir system was experiencing positive net inflow which suggested that the system could withstand large droughts. Due to the recent shift to negative net inflow as a result of over-allocation of the available water, the system is much more likely to fail in the future.

One major finding in Barnett and Pierce (2008) is that in the early twenty-first century, the probability that the reservoir system will run dry is more likely than the chance that the reservoir system will fill back up. This is shown in Figure 3 (taken from Barnett and Pierce, 2008), where the curves show the probability of the system going dry or filling within the following 20 years. For example, in the year 1960, around the construction of Lake Powell, there was virtually no chance of the system going dry by the year 1980. On the other hand, around 2005, there is about a 25% chance that the system will go dry by 2025, and similarly a 25% chance the system will fill up by 2025. Beyond this year, the probability of going dry is greater than the probability that the system will fill back up. This shift, corresponding with the change to negative net inflow, again shows why earlier studies on the CRB determined that the reservoir system was very reliable.

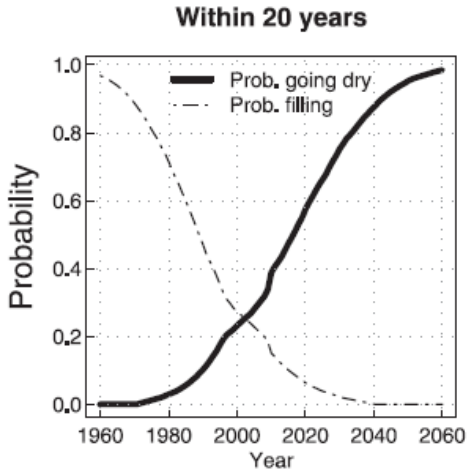

Figure 3 – Probability of system running dry or filling up in the following 20 years (source: Barnett and Pierce, 2008)

All of these studies show that the current allocations and water management practices in the CRB, together with possible decreases in runoff due to climate change, are destined to fail the reservoir system. Therefore, drastic change in reservoir operating policies is necessary in order to ensure the longevity of the system. However, this does not include other possible water sources of water such as groundwater and importing water from other basins. These could be two possible courses of action in order to maintain the surface water use in the CRB. This problem has become even more strained due to the possible impacts of climate change on the region. Assuming that the global temperature will increase in the future, this change will impact both the timing and amount of water in the CRB. Increased temperatures will impact the amount of snowfall that occurs in the Colorado River headwaters. Since snow pack accounts for 70% of the annual streamflow, this change can have major effects. Increased temperatures will cause more precipitation to fall as rain as opposed to snow. Also, the higher temperatures will cause the snow packs to melt earlier in the spring, which will alter the timing of streamflow downstream. Finally, increased temperatures will result in higher evaporation, which will cause an even greater loss of water to the atmosphere than in the past. This increase in temperature will, in turn, increase the demand of water for such uses as irrigation and hydropower.

IMPACTS OF CLIMATE CHANGE

The issue of global climate change has been a concern for many years. However, this issue has gained more attention in recent years. The possibility of increasing global temperatures can have a drastic effect on the hydrologic cycle which controls much of the water resources throughout the world. A very brief description of the mechanics of climate change deal with the continued increase in emissions of CO_2 and other greenhouse gases, such as water vapor, that have been shown to absorb infrared thermal radiation emitted from the surface of the Earth and radiate it back towards the surface where it is reabsorbed. This leads to an increase in infrared radiation at the surface that must be balanced by the loss of energy through increased latent heat and sensible heat (Boer, 1993). Increased latent heat results in an increased evaporation rate at the surface, whereas increased sensible heat results in increased temperature at the surface.

The most important impact of climate change for the CRB is the impact on evaporation and precipitation. As mentioned above, evaporation is expected to increase globally due to climate change. However, the impact on precipitation is more difficult to determine. Boer (1993) found that the precipitation over land does not increase as much as evaporation. Therefore, more rain will fall over the oceans, which will result in a decrease in runoff of 5.2% on land. Multiple studies have attempted to model the change in runoff (precipitation minus evaporation) over the entire Earth. Figure 4 (modified from Held and Soden, 2006) shows the average percent change of runoff, δ(P-E), based on latitude. This is for a scenario of twice the current concentrations of CO_2 in the atmosphere using two separate modeling techniques. Over the tropics near the equator, runoff increases drastically. Runoff is expected to decrease over the mid-latitudes where the CRB is located. Finally, runoff increases over the high latitudes. These trends follow the predications associated with changes in precipitation, which correspond to the current distribution of precipitation over the Earth. This suggests that precipitation will increase where it is already high and decrease where it is already low. The reason for this trend is that the locations of high precipitation are controlled by the air circulation in the atmosphere, which is not expected to change considerably due to global climate change. In general, precipitation is likely to occur where there is a rising air mass, such as at the equator and high latitudes. At the mid-latitudes, there is in general a falling dry air mass, so precipitation is expected to decrease. Overall, the pattern of runoff is exaggerated with increased temperatures. This means that current areas of low runoff are expected to have even lower runoff, and areas of high runoff are expected to have even higher runoff with increased temperature.

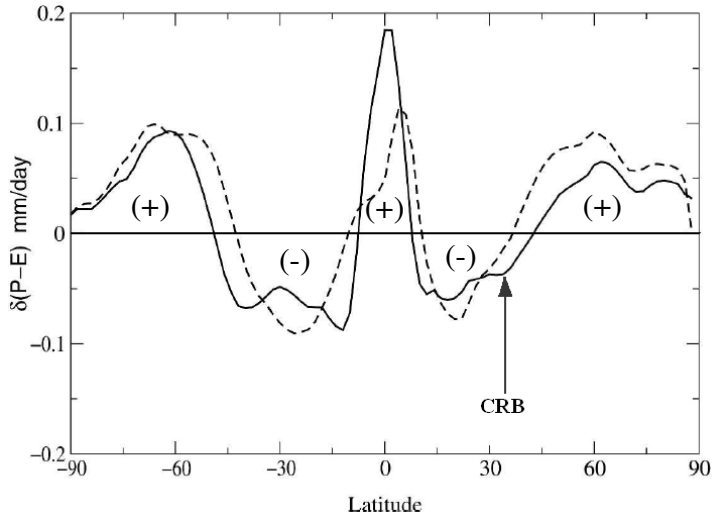

Figure 4 – Change in runoff versus latitude (modified from: Held and Soden, 2006)

Various studies have attempted to model the impacts of global climate change using general circulation models. Studies such as Christensen et al. (2004), Milly et al. (2005), Christensen and Lettenmaier (2007), and McCabe and Wolock (2007), among others, have investigated these changes either on a global scale, or specifically for the CRB. There are common trends seen in all of these studies which suggest an increase in temperature and evaporation, resulting in a decrease in runoff available for streamflow within the CRB.

SUMMARY AND CONCLUSIONS

The Colorado River Basin reservoir system is one of the most over-allocated systems in the world. It supports a very large population and is the major source of water for much of the southwestern United States. Due to the large demands placed on the system and recent drought conditions, reservoir storage has been decreasing for the past decade and shows no sign of increasing in the near future. The water allocation demands from the system are greater than the average streamflow into the system. Therefore, if decreases in allocations are not made in the near future, the system will eventually run dry and fail to provide water even if drought conditions decline. The recent change to negative net inflow has made the system more vulnerable than ever before.

In addition to these problems, it is expected that climate change will only make the situation more severe. Various modeling techniques show that climate change will decrease precipitation in the CRB and increase evaporation. This combination results in a decrease in runoff and streamflow in the CRB. Therefore, not only is water use in the CRB currently greater than the supply by streamflow, but climate change is expected to decrease the available streamflow.

In conclusion, climate change is expected to further decrease the reliability of the reservoir system in the CRB. However, the more significant problem is the over-allocation of the river. The allocations and water usage can be controlled much easier and have a much greater impact on the reliability of the reservoir system than global climate change does. The high water usage and over-allocation is the first problem that should be addressed in order to maintain a reliable water supply in the CRB. The current allocations were made during an unusually wet period, and therefore are not representative of the actual amount of water available for distribution. Reallocating the water, together with obtaining water from different sources is necessary to ensure the longevity of a reliable water system in the Colorado River Basin.

DOES POLYMER HAVE AN EFFECT ON BACTERIAL REGROWTH IN ANAEROBICALLY DIGESTED BIOSOLIDS?

Jean M. Ryan, Student Member

Undergraduate Student, Environmental Engineering Department, Penn State, Harrisburg, PA, jmr5190@psu.edu

ABSTRACT

Recently more attention is being given to the regrowth of bacteria in treated biosolids. It has been found that in many anaerobically treated biosolids, bacterial regrowth occurs between digestion and the point in which the biosolids are disposed of or used for land application. This experiment examines the possible effect of polymer usage on bacterial regrowth in anaerobically digested biosolids. In order to examine this possible effect, a control sample, a sample with newly-reconstituted polymer, and a sample with pre-constituted polymer (several days old) were compared for their effects on bacterial regrowth using an MPN test. Each sample was 300mL, and a weight ratio of 1mg: 185kg, assuming 2% solids, was used to add polymer to all of the samples, excluding the controls. These samples were then compared at 0, 1, and 2 days of incubation. As a whole, the MPN values increased with one and two days of incubation at room temperature. However it was also found that the control samples had a higher MPN than the samples treated with the old and new polymer after one and two days of incubation, which suggests that polymer does not have an effect on the increase of fecal coliforms in biosolids.

INTRODUCTION

The proper treatment and disposal of sewage sludge has not always been common practice. Years ago, the effects that sludge may have caused on the environment were not considered. However as people became more aware of environmental issues, attention was directed towards the importance of properly handling and disposing of sewage sludge. Because of this attention, many countries, including the United States, have regulations that are required for the treatment of sewage sludge. In the United States, the Environmental Protection Agency (EPA) issued the "Standards for the Use or Disposal of Sewage Sludge" which lays out general requirements, pollutant limits, operation standards, and management practices, as well as frequency of monitoring, record keeping, and reporting requirements (U.S.

EPA, 1994). These regulations serve to classify biosolids by their level of treatment and describe their future use in an environmentally safe manner.

Some of the regulations that are in place deal directly with sludge stabilization and the amount of pathogen reduction that is required in the treatment of sludge (U.S. EPA, 1994). Pathogen reduction is considered to be one of the parameters used to determine sewage sludge quality (U.S. EPA, 1994). This pathogen reduction is done so that biosolids can be designated as either Class A or Class B biosolids. The EPA's Part 503 regulation contains two classes of pathogen reduction, which are Class A and Class B biosolids (U.S. EPA, 1994). Class A biosolids are considered to be nearly pathogen free and must have a fecal coliform density of less than 1000MPN per gram of biosolids (dry weight basis) after they are treated (U.S. EPA, 2003). On the other hand, biosolids must have a fecal coliform density of less than 2 million MPN per gram of biosolids to be classified as Class B biosolids (U.S. EPA, 2003). Therefore it is necessary that Class B biosolids require further regulations in order to prevent any sort of harmful contamination.

There are three ways for pathogen requirements to be met so that biosolids can be considered Class B biosolids (U.S. EPA, 2003). These methods are the monitoring of fecal coliform, using a process to significantly reduce pathogens (PSRP), or using a process that is equivalent to a PSRP (U.S. EPA, 2003). There are five types of PSRPs that are used for pathogen reduction. They are aerobic digestion, air drying, anaerobic digestion, composting, and lime stabilization (U.S. EPA, 2007). Of these five PSRPs, anaerobic digestion is the most commonly used in treatment facilities (Qi et al., 2007). By treating biosolids at a certain temperature and for a given length of time, anaerobic digestion can meet the proper criteria for pathogen reduction (U.S. EPA, 2003). Once this criterion is met, the treated biosolids are considered to be Class B solids and can be used for land application.

The problem with these requirements is that treated biosolids are characterized immediately after digestion rather than when they are used or disposed of (Qi et al., 2007). Between the digestion process and the disposal of biosolids, processes such as conditioning and dewatering occur (Qi et al., 2007). While these processes have not been expected to have any effect on bacterial density, recent studies suggest that this is not the case (Higgins et al., 2007). Over the past several years research has shown that after mechanical dewatering, there are higher concentrations of fecal coliforms than there are after the anaerobic digestion step (Higgins et al., 2007). This creates a problem in that the regrowth of fecal indicators in the treated biosolids may no longer fall within the U.S. EPA's standards (Chen et al., 2007). By failing to meet the set regulations, these biosolids are no longer eligible for land application (Chen et al., 2007). These biosolids must then be disposed of, which in turn is more costly than if they had been applied to the land.

There have been several different theories presented in order to explain the increase of fecal coliforms in dewatered sludge. One potential explanation is the regrowth of fecal coliforms (Higgins et al., 2007). It has also been suggested that the difference

in enumeration between the liquid and cake was due to sample matrix effects. This idea is similar to the idea that the shearing effect on solids that are exposed to high solids centrifugation, improves the "release" of bacteria from the floc matrix (Higgins et al., 2007). Because of this, the amount of bacteria that can be cultured will increase when compared to the amount of culturable bacteria before the dewatering process (Higgins et al., 2007). It has also been suggested that contamination with fecal coliforms could also explain the high counts that are found after dewatering (Higgins et al., 2007). Finally it has also been proposed that bacteria enter a nonculturable state during digestion, and that dewatering can "resuscitate" the bacteria allowing them to grow once again (Higgins et al., 2007).

It has also been shown that the regrowth of fecal coliforms in anaerobically digested biosolids is associated with odor production (Chen et al., 2007). This odor production is a result of food release and oxygen exposure that occurs during centrifuge dewatering (Chen et al., 2007). However, it is also possible that polymer, which is a chemical coagulant composed mainly of hydrocarbons, used for dewatering can serve as food source for regrowth. The use of polymer in dewatering has been common in the treatment process in order to improve the efficiency and reduce the cost of both transporting and handling sludge (Wu et al., 1997). Still any link between the addition of polymer and bacterial regrowth is still unclear. While it has been proposed that polymer is indeed partially biodegradable and therefore a possible food source for bacterial regrowth, it has yet to proven. Therefore the goal of this paper is to examine the possible relationship between the addition of polymer and bacterial regrowth in anaerobically digested biosolids, and see whether or not polymer is being used as a food source for bacterial regrowth.

METHODOLOGY

Sample Collection

The biosolids used were from the Highspire (Pennsylvania) Wastewater Treatment Plant, a conventional municipal activated sludge plant (Figure 2). The biosolids were collected after digestion and storage and before centrifuge dewatering. The biosolids were anaerobically digested at a temperature of 95-98°F for a period of approximately 35 days. They were stored (for approximately three days) in sterilized and sealed plastic containers at room temperature until just before experimentation.

Polymer Addition Testing

The biosolids were separated into nine plastic containers, which had been sterilized with bleach and sterile water, with 300mL in each of the containers. Three containers were used for controls (no polymer added), three were treated with three day old polymer, and three were treated with newly constituted polymer. The polymer used was Claifloc NE-1200 from Polydyne Inc. located in Riceboro, GA, and it is a

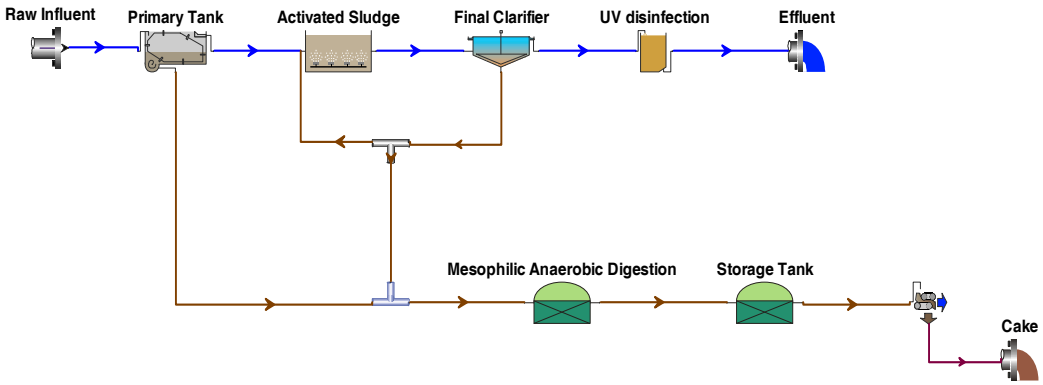

Figure 1. Flow Chart of Highspire Wastewater Treatment Plant completed using BioWin

medium charge cationic polyacrylamide. The polymer, which was made using a ratio of 2.7g to 500mL of tap water, was added to the biosolids at a dry weight ratio of 1mg of polymer per 185kg of sludge. The identical ratio was also used to add distilled water to the control samples in order to keep the volumes of each sample the same. Testing was done on the biosolids immediately and at one and two days of incubation at room temperature by using one of each type of sample- a control, a sample treated with old polymer, and a sample treated with new polymer- at each different day of incubation.

MPN Enumeration of Fecal Coliform

The three samples of biosolids that were to be tested immediately were individually placed into autoclaved blenders and blended on high for two minutes as laid out by the U.S. EPA under 40 CFR Part 503 (U.S. EPA, 2003). Each sample was then diluted using a dilution buffer to obtain five separate dilutions. A traditional Most Probable Number (MPN) test, which was based on the U.S. EPA Method 1680, was performed for each of the each of the samples with five trials done for each serial dilution. (U.S. EPA, 2006). The MPN tubes were stored in an incubator at 37°C for two days. The positive results, which can be determined by the color change from purple to yellow of the Lauryl Tryptose Broth, were then transferred using a sterile transfer loop to a MPN tube containing EC Medium and a Durham tube. The Durham tubes were used in order to examine the gas production in the test tubes after one day in a warm water bath. Calculations were then based off of the Standard Methods table (U.S. EPA, 2006).

RESULTS AND DISCUSSION:

The hypothesis of this experiment was that polymer addition affected bacterial regrowth in biosolids. It was expected that there would be higher bacterial densities in biosolids treated with old polymer compared to those treated with new polymer and the control samples used in the experiment. It also was expected that incubation of the biosolids would also increase the bacterial density in the sludge.

The results of the experiment can be found in Figure 2. The MPN values of the samples of biosolids at their various days of incubation were plotted using a bar graph to allow for visual comparison. As expected it can be seen that the MPN in all of the samples increased with incubation. Yet, the differences between the control, the new polymer, and the old polymer samples, were not what they were hypothesized to be. While initially (no incubation), the old polymer sample had a slightly higher MPN than both the control and new polymer samples, after just one day of incubation the control had a higher MPN than both the new and old polymer. This was also the case for two days of incubation. However these differences were not significant and the error bars on the graph account for the differences between the samples. Given these results it could be suggested that polymer does not have an effect on bacterial regrowth in anaerobically digested biosolids.

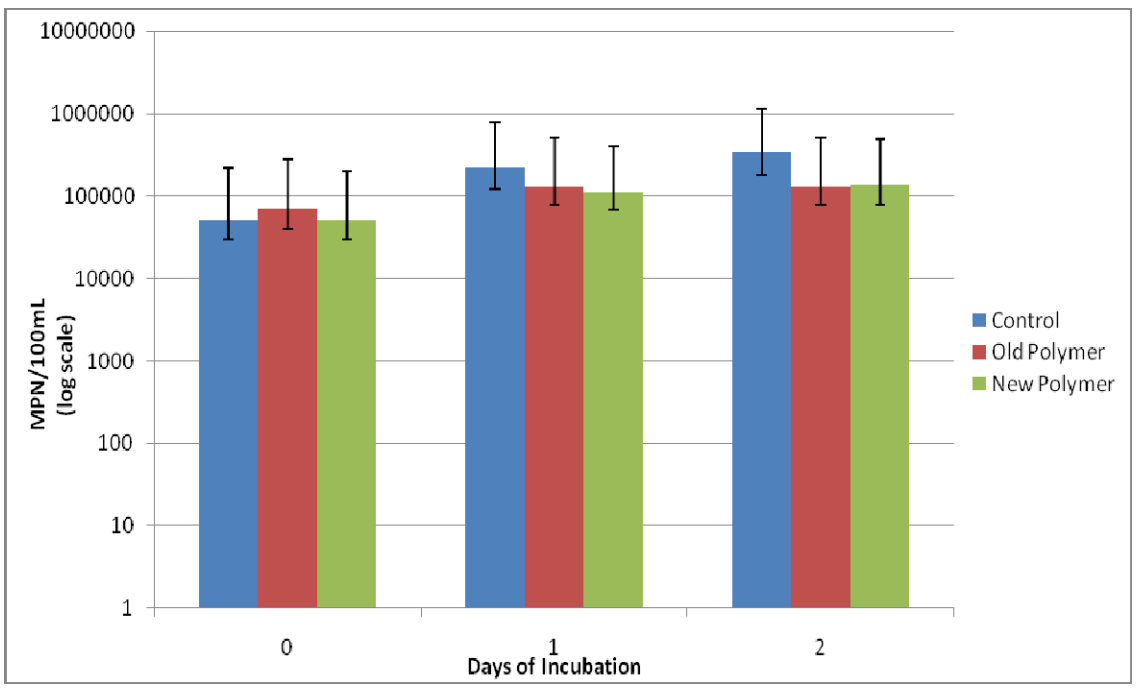

Figure 2. Represents the MPN/100mL of fecal coliform bacteria in anaerobically digested biosolids at various days of incubation. The error bars represent the 95% confidence interval

A study in which it is shown that polymer may contribute significantly to bacterial regrowth is the study done by Qi et al. In this study it was suggested that a higher polymer dosage led to an increase in the number of fecal coliforms and therefore a larger MPN value (Qi et al., 2007). In that study a weight ratio of 1:100 and 1:10 were experimented with (Qi et al., 2007). In the biosolids treated with a 1:10 ratio of polymer, a significant increase of two orders of magnitude in the MPN value was found. There was also a slight increase in MPN in the biosolids treated with the ratio of 1:100. It is also important to note that in the Qi et al. study, the treated biosolids were incubated at 37°C versus the room temperature in which the biosolids were incubated at in this experiment. The increase in temperature would allow for the bacteria to grow more quickly as it is a temperature in which they tend to thrive.

The main problem with this study is that while it shows a significant increase in biosolids treated at a 1:10 ratio, these biosolids are overdosed with polymer. Polymer overdosing can lead to an increase in the bound water content of the biosolids (Wu et al., 1997). Treating biosolids with excess amounts of polymer can also lead to a significant increase in the diameter of a conditioned sludge floc as well as a decrease in floc density (Wu et al., 1997). This is because when biosolids are overdosed with polymer, the flocs of bacteria that have been formed can actually separate back into single cells (Wu et al., 1997). It is therefore possible that overdosing with polymer can lead to an observed increase in the MPN values of the biosolids. This is because more bacteria cells are available to culture in the MPN media.

In this experiment a ratio of 1:184 was used to treat the biosolids, which is around the typical dosage used in conditioning. As stated previously, no significant increases in the biosolids treated with polymer both before and after incubation were shown. This suggests that polymer is not being used as a food source for bacterial regrowth. It would also suggest that the results of the Qi et al. study were the result of polymer overdosing, in which the bacterial cells were separated from their flocs to individual cells, rather than polymer being used as a food source for the bacteria. This would then serve to explain the difference in MPN values observed in the treated biosolids of that study.

In this experiment it was also found that after incubation the control had higher MPN values though these increases were not significant. This is most likely because polymer is a coagulant and as previously mentioned causes bacteria to form flocs. In the control samples no polymer was added and therefore the bacteria did not form flocs and showed higher MPN values as the bacteria cells were more readily available like they are in biosolids that have been overdosed with polymer. Running the experiment again could be useful to verify these results and see if the controls have higher MPN values than the treated samples or if once again the results are insignificant. Performing the experiment again would also help to verify the results that polymer does not contribute to the regrowth of bacteria.

Further research should be done to verify these results aside from the possibility of running the experiment again. A Bushnell-Haas test on a pure culture could be done to see if fecal coliform can grow on polymer. Comparing their growth on polymer to their growth on a known carbon source such as Dextrose would allow for another observation on whether or not polymer can be used as a possible food source for the bacteria. Further research could also be done in order to examine the possible effects that treating biosolids with excess polymer may have. In order to do this the same type of experimental procedure could be used though various polymer dosages should be tested in the samples rather than the old and new polymer dosages which were done in this experiment.

CONCLUSION

From the results of this seed project it can not be said that the addition of polymer increases the number of fecal coliforms present in anaerobically digested biosolids. The results of the experiment suggest that polymer does not have an effect on bacterial regrowth and that polymer is not used as a food source for bacteria in treated biosolids. However, further testing is required in order to verify these results. By performing the experiment again the results can be verified to make sure there was no error in the experimental procedure. Another type of test such as the Bushnell-Haas test can also be done in order to determine if polymer can be used as a food source for bacteria. Further research on the possible effects of polymer overdosing may also prove of interest by observing the effect that it has on the regrowth of bacteria in treated biosolids.

EFFECT OF ACID MINE DRAINAGE ON ALUMINUM RELEASE FROM CLAY MINERALS

Oscar Vazquez, Student Member

Civil and Environmental Engineering Department, University of Pittsburgh, Pittsburgh, PA, ocv1+@pitt.edu

ABSTRACT

Aluminum is an environmentally toxic material found in some acid mine drainage (AMD) locations. Data reported from over 150 different mine drainage samples across USA showed that over 30% of these locations presented minimum dissolved aluminum concentrations of 50 mg/L, elucidating that aluminum pollution must be taken seriously. Research underway at the University of Pittsburgh involves an AMD site where a former trout fishery stream has been ruined. The evolution of the aluminum in this AMD, released from a subsurface environment, suggested a first stage dominated by first order kinetics of exchange reactions on clay surfaces, followed by a second stage dominated by dissolution processes with lower rates that exist over a long term. Results from a batch experiment involving synthetic AMD and kaolin minerals were in concordance with this analysis.

Further research, taking into consideration factors such as pH, AMD characteristics, type of clay minerals and retention time, is necessary in order to better understand the effect of AMD on the aluminum release from clay minerals. Such understanding is necessary for prediction of short-term and long-term impacts of AMD on aquatic ecosystems and will assist in the design and selection of treatment systems leading to practical remediation strategies.

INTRODUCTION

Aluminum is an environmentally toxic material found in some acid mine drainage (AMD) locations. Data reported from over 150 different mine drainage samples across USA showed that over 30% of these locations presented minimum dissolved aluminum concentrations of 50 mg/L (Watzlaf, 2004). Aluminum is typically found in AMD when the underground geology is characterized by the presence of clay and other aluminum bearing minerals. The problem is aggravated at low pH values, as reported by Cravotta (2006), who showed the median aluminum concentrations in mine discharge samples from 140 abandoned coal mines collected

in Pennsylvania in summer and fall 1999. Over 50% of the 140 abandoned mine discharges sampled presented median dissolved aluminum concentrations over 1 mg/L. The highest concentrations of aluminum were found in the acidic range of pH 2-5 with values between 1-50 mg/L of aluminum.

Elevated aluminum levels in AMD often occur when subsurface soils contain high concentrations of aluminum. Typical of such soils include clays containing the mineral kaolinite [$Al_2Si_2O_5(OH)_4$] (Smoke, 2007; Sidenko et al, 2005). Galan et al (1999) showed that kaolinite could be a possible reaction product of the dissolution of unstable smectite under acidic conditions. Smectite [$(Ca, Na, H)(Al, Mg, Fe, Zn)_2(Si, Al)_4O_{10}(OH)_2 - xH_2O$] is another clay mineral present worldwide, particularly extended in the northern hemisphere and commonly found in US soils (Astudillo, 2004). The Appalachian region including Pennsylvania and West Virginia historically support high mining activities and have elevated potentials for the generation of AMD with high concentrations of aluminum due to the abundance of smectite, and possibly other clay minerals.

In the scenario of AMD generation, when the oxidation of pyrite takes place in a location with a high presence of alumino-silicate materials (clays) and under strong acidic conditions (pH<5), the release of aluminum may typically be caused by ion-exchange (Tan, 2000) and dissolution of clay processes (Essington, 2004).

The purpose of this study was to explore the interactions between AMD and clay minerals under conditions typically found in the Pennsylvanian and Appalachian region. The study was focused on the effect of AMD cations including iron, Fe, and brackish groundwater with sodium, Na^+, and potassium, K^+, salts on the release of aluminum, Al, from clay minerals. In order to accomplish this goal the following objectives were set forth: (1) evaluate the evolution of aluminum in AMD released from aluminum-bearing soils after interaction with AMD; (2) explore the effect of synthetic AMD, including iron and sodium and potassium salts on the release of aluminum from clay minerals.

METHODS AND MATERIALS

The following tasks were performed to accomplish these goals: (1) analysis of the field data from an actual case of AMD pollution; (2) batch experiments to explore the effect of synthetic AMD on the release of aluminum from clay minerals.

A previous study at the University of Pittsburgh (Smoke, 2007), reported low concentrations of dissolved iron, high concentrations of dissolved aluminum and minimal concentrations of particulate aluminum in AMD affecting the Jonathan Run stream in Centre County, PA. Field data from this AMD discharge, which was sampled and tested from 1999-2008 (Hedin, 2003; GAI, 2007; Neufeld et al, 2007), was collected and further analyzed.

Two different weights of kaolin samples, $Al_2Si_2O_5(OH)_4$, (2 g and 16 g) were shook for a 67-hour period with a prepared pH 2.6 solution and two synthetic AMD solutions with different characteristics (Table 1) and further analyzed. The kaolin powder sample used to conduct this experiment was supplied by Fisher Scientific Company. $FeSO_4$ $7H_2O$ and H_2SO_4, also supplied by Fisher Scientific Company, were used to prepare the synthetic AMD solutions. KCl and NaCl used to prepare the synthetic AMD 2 solution were supplied by Mallinchrod. The suspensions were shaken for 67 hours and then centrifuged. The pH was determined before filtration by using a pH meter. Afterwards the centrifuged samples were filtrated through 0.45 µm nitrocellulose membrane filters supplied by Millipore Corporation and the extracts were stored at 4°C for further analysis. Standard Methods (2005) was used to determine the concentrations of Al, Fe, K^+ and Na^+. The concentrations of Al, Fe, K^+ and Na^+ were determined by flame atomic absorption spectrometry.

RESULTS

Data showing the aluminum concentration from the major surface seep polluting the Jonathan Run stream in Centre County, PA, from 1999 to 2008, is shown on Figure 1. The values represented in this figure are quarterly aluminum averaged values. The data appear to follow two different trends from 1999-2003 and from 2003-2008. The averaged aluminum concentrations released from the main source of pollution, as shown in Table 2, were 104.6 mg/L and 47.6 mg/L for the stages 1999-2003 and 2003-2008, respectively, with the second stage reaching and apparent steady state of about 48 mg/L. The field pH values averaged 4.1 and 3.5, as shown in Table 2, for the stages 1999-2003 and 2003-2008, respectively, and were rather consistent in each period, as shown in Figure 2.

The results of the release of aluminum from the kaolin mineral when exposed to solutions with different characteristics for a 67-hour period are shown in Table 1. The release of aluminum from the clay mineral, when exposed to an acid solution (pH 2.6), was not detectable. Conversely, when the clay mineral was exposed to synthetic AMD 1 with Fe concentrations over 600 mg/L, the release of aluminum was significant, reaching 6.3 mg/L when the soil(g):solution(ml) ratio was 16:40. The release of aluminum from the clay mineral increased up to 12.2 mg/L when the soil (g): solution (ml) ratio was 16:40 and the solution (AMD2) contained K^+ and Na^+. The initial iron concentration in AMD 1 was 660 mg/L, as shown in Table 1. After 67 hours of interaction with the clay mineral, a decrease in the iron concentration was observed; 555 mg/L and 335 mg/L for the 2:40 and 16:40 suspensions (susp.), respectively. In a similar way, the initial K^+ concentration in AMD 2 was 600 mg/L. After 67 hours of interaction with the clay mineral, a decrease in the K^+ concentration was observed; 400 mg/L and 400 mg/L for the 2:40 and 16:40 susp., respectively. The concentrations of Na^+ in the soil solution remained constant, 1000 mg/L, as shown in Table 1.

Table 1. pH, Al, Fe, Na^+ and K^+ concentrations in the initial synthetic AMD and pH 2.6 solutions and in the soil solution after 67 hours of experiment.

DISCUSSION

The dissolution reaction rates of clay minerals are generally slow in contrast to the exchange reactions rates which are typically fast (Li, 2006). Huertas (1999) studied the proton-promoted dissolution kinetics of kaolinite using batch reactors at 25°C in the pH range 1-13. In his experiment, 80 mg of kaolinite and 40 ml of solution were placed in continuously shaken reaction vessels to maintain the solid phase in suspension. At pH 3, after more than 400 days of experiment, the concentration of aluminum released from the clay mineral was below 35 μM. This slow rate of release of aluminum seems to follow a similar pattern to the second stage illustrated in Figure 1, which appear to follow a zero order rate expression once the aqueous aluminum concentration reached an apparent steady-state of about 48 mg/L in the field. Likewise, the first stage of aluminum release shown in Figure 1 may be approximated by a first order differential equation:

$$d[Al]/dt = - 0.29\ [Al]$$

where [Al] = aluminum concentration (mg/L) and
t = time (years)

These results suggest that an early stage of aluminum release could be dominated by exchange reaction processes with high rates of aluminum release appearing to be first order with time, and a second stage of aluminum release dominated by longer term dissolution processes, with lower rates of aluminum release.

The results from the batch experiments involving synthetic AMD and kaolin minerals seemed to be in concordance with the analysis of the field data from the actual case of AMD pollution. The release of aluminum from the kaolin mineral, when exposed to the acidic solution (pH 2.6), was slow (not detectable) if compared with the release of aluminum when exposed to the synthetic AMD, with iron concentrations of about 600 mg/L, at the same pH value of 2.6 (Table 1). The release of aluminum from the clay mineral seemed to be influenced by the content of iron and potassium cations in the synthetic AMD. The decreases in K^+ and Fe concentrations in the soil solution after a 67-hour period were a common feature. This was presumable due to adsorption and/or cation exchange between the solutions and the kaolin mineral. The potassium concentration in the soil solution decreased over 30% after the 67-hour period. Despite of this change, the potassium remained constant with the

soil(g):solution(ml) ratio and thus seemed not to play a role in the change of aluminum release when changing the soil(g):solution(ml) ratio. Sodium ions seemed not to cause any effect on the aluminum release within the experimental conditions. The sodium concentrations remained constant, 1000 mg/L throughout the experiment. The adsorption and exchange behavior of the alkali metals in soils and other exchange media is strongly a function of their hydrated radii, according to the selectivity rule for the same valence cations. This resulted in K^+ being retained in preference to Na^+. The ratio of soil (g): solution (ml) seemed to play a significant role in the release of aluminum from the clay. The results suggested that the aluminum released increased with increasing the amount of kaolin in the solution.

CONCLUSIONS

When a clay mineral interacted with a synthetic AMD, it influenced the chemical composition of the synthetic AMD. Processes such as ion exchange, adsorption, hydrolysis and dissolution took place. The release of aluminum from the clay mineral when exposed to an acidic solution (pH 2.6) was not detectable after 67 hours of experiment but when the clay mineral was exposed to synthetic AMD solutions, with iron and potassium concentrations in equivalent conditions of pH (around 2.6), the release of aluminum became significant. Although the results of this experiment may differ in the magnitude of the impacts that would occur in the field environment, qualitatively, they seem to be in concordance with the evolution of the aluminum concentrations, as shown in Figure 1, for an actual case of pollution of a stream by aluminum-containing AMD. These results suggested that two types of processes, cation exchange and dissolution processes, may take place when AMD meets an argillic area. In order to better understand the effect of AMD on the aluminum release from clay minerals and the resulting AMD characteristics, further research taking into consideration factors such as pH and content of AMD, type and amounts of aluminum bearing minerals and retention time, need to be conducted . Such understanding is necessary for prediction of short-term and long-term impacts of AMD on aquatic and terrestrial ecosystems and will assist in the design and selection of treatment systems leading to practical remediation systems and ultimately, to a better management of AMD in locations where the underground geology, due to the presence of clay and another aluminum bearing minerals, is right for the in-situ generation of aluminum discharges.

SENSITIVITY ANALYSIS OF HEC-HMS HYDROLOGIC MODEL TO THE NUMBER OF SUB-BASINS: CASE STUDY

Osama Z. Al-Hamdan, Student Member

Graduate Student, Civil and Environmental Engineering Department, University of Alabama in Huntsville, Huntsville, AL, alo@uah.edu

ABSTRACT

This paper presents a sensitivity analysis of the hydrologic model HEC-HMS to the number of sub-basins for the McDonald Creek watershed in Huntsville, Alabama. ArcGIS was used to estimate the parameters needed for the model. The sensitivity analysis of HEC-HMS runoff results was evaluated for two cases, namely, Case 1 and Case 2. The number of sub-basins of the watershed was 3 and 5 for Case 1 and 2, respectively. This study implements kinematic wave method to model the overland flow transform and Muskingum-Cunge method for channel routing. The loss rate was estimated using both Green-Ampt and SCS curve number methods. The results demonstrated that the number of sub-basins did not significantly affect the discharge results. However, increasing the number of sub-basins changed the discharge peak values. The results also showed that HEC-HMS model was sensitive to the input slope parameter when the SCS method was used, while it was not in case of using the Green-Ampt method.

INTRODUCTION

Watershed models have become an essential tool for water resources planning, development, and management (Singh and Woolhiser, 2002). There are several well known watershed models in current use in the United States and one of these models is the Hydraulic Engineering Center Hydrologic Modeling System (HEC-HMS). HEC-HMS is considered the standard model in the private sector in the United States for the design of drainage systems and quantifying the effect of land use change on flooding (Singh and Woolhiser, 2002).

HEC-HMS was developed by the U.S. Army Corps of Engineers for rainfall-runoff simulation processes of networking watershed systems. HEC-HMS consists of meteorological, hydrologic and hydraulic functional components, including losses, runoff transform, open-channel routing, analysis of meteorological data, rainfall-runoff simulation, and parameter estimation. In order to estimate the runoff and basin

outflow, the hydrologic elements of HEC-HMS, including sub-basins, reaches, junctions, reservoirs, diversions, sources, and sinks are connected in a network. HEC-HMS utilizes several methods for transforming excess precipitation into surface runoff such as unit hydrograph and the kinematic wave method with multiple planes and channels. The runoff computation in HEC-HMS proceeds from upstream elements in a downstream direction. For infiltration losses simulations, HEC-HMS utilizes several methods including the initial constant, Soil Conservation Service (SCS) curve number, and Green-Ampt. For more details about the model, see U.S. Army Corps of Engineers HEC-HMS user's manual (2005).

In HEC-HMS, the watershed can be represented in hydrologic elements. These elements are used to break the watershed into manageable pieces that are connected together in a network to form a representation of a stream system. By creating multiple representations of the same watershed, different development scenarios or management alternatives can be evaluated. Hence, HEC-HMS simulation results could be sensitive to the number of sub-basins that assemble the representations as the sub-basin hydrologic parameters might vary in each representation. Therefore, this paper studies the effect of number of sub-basins on the outflow discharge by using two different representations of a watershed.

METHODOLOGY

The study area belongs to the watershed of McDonald Creek in Huntsville, Alabama. The drainage basin area is 2.16 square mile and consists of a second order main stream. The drainage basin is mostly of urban type, covered sparsely with lawn-type vegetation. The average annual precipitation of the watershed is 57.5 inch.

In order to evaluate the sensitivity of HEC-HMS model to the number of sub-basins, the model was used to estimate the runoff discharge of McDonald Creek for two cases. The watershed was divided into 3 and 5 sub-basins for Case 1 and 2, respectively. In Case 1, the sub-basin areas are 0.937, 0.543, and 0.680 square mile for Sub-basin I, II, and III, respectively. In Case 2, the sub-basin areas are 0.301, 0.637, 0.246, 0.296 and 0.680 square mile for Sub-basin I, II, III, IV, and V, respectively. In both cases, the sub-basins were divided to two planes as seen in Figure 1. HEC-HMS simulation discharge results were studied at the exit of the watershed as well as at the conjunction point of sub-basins I and II for Case 1, and sub-basins I, II, III and IV for Case 2.

This study implements kinematic wave method to model the overland flow transform and Muskingum-Cunge method for channel routing. The loss rate was estimated using both Green-Ampt and SCS curve number methods with the assumption of no base flow. In order to study the sensitivity of the discharge results to the input watershed parameters, the model was also run for both cases for the following four conditions: (1) all parameters in Case 2 are different than the corresponding parameters in Case 1 (i.e., smaller planes in Case 2 than in Case 1); (2) all parameters in Case 2 are same as the corresponding parameters in Case 1 except for the slope; (3) all parameters in Case 2 are same as the corresponding parameters in Case 1 except

for the imperviousness; and (4) all parameters in Case 2 are same as the corresponding parameters in Case 1 except for the soil type. The discharge results of Case 1 and 2 were statistically compared for all four conditions.

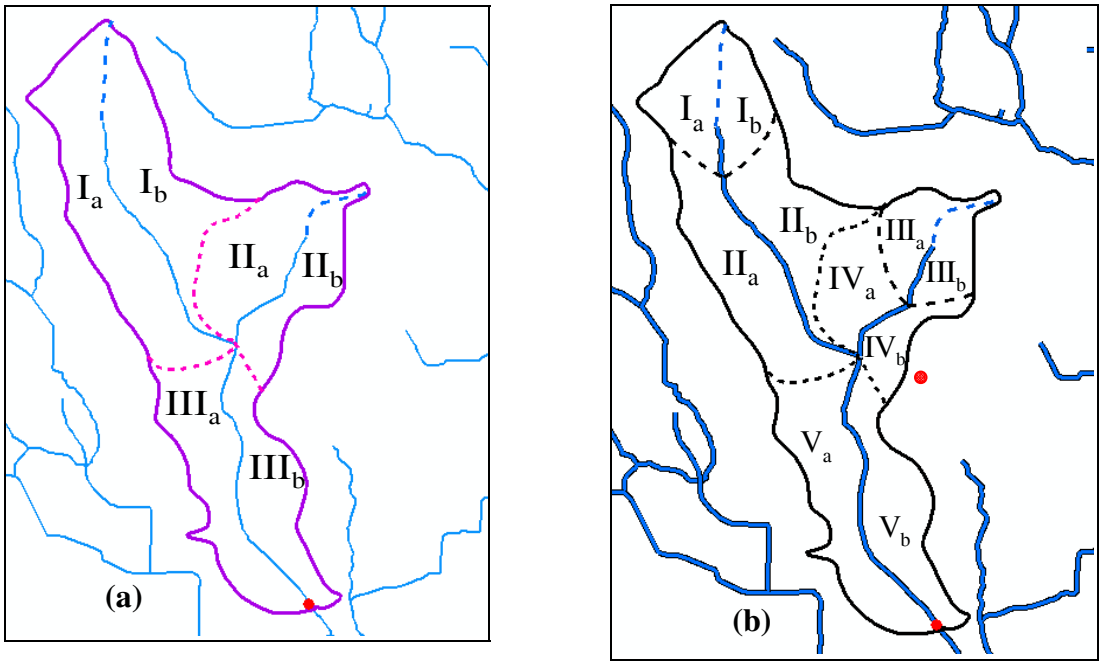

Figure 1. McDonald Creek watershed: (a) Case 1 (b) Case 2.

Data Collection

In order to determine the runoff discharges using HEC-HMS, the model requires different types of watershed data, such as precipitation, soil type, topography, and land cover. The rainfall hyetograph used in this study is depicted in Figure 2 (USGS, 2005). The topographical data were obtained from the digital elevation model (DEM) files downloaded from the US Geological Survey website (USGS, 2004). The soil types of the watershed were obtained from the Soil Survey Geographic (SSURGO) database of the National Resources Conservation Service (NRCS) (NRCS, 2004). The land cover data were obtained from the NRCS website (NRCS, 2004).

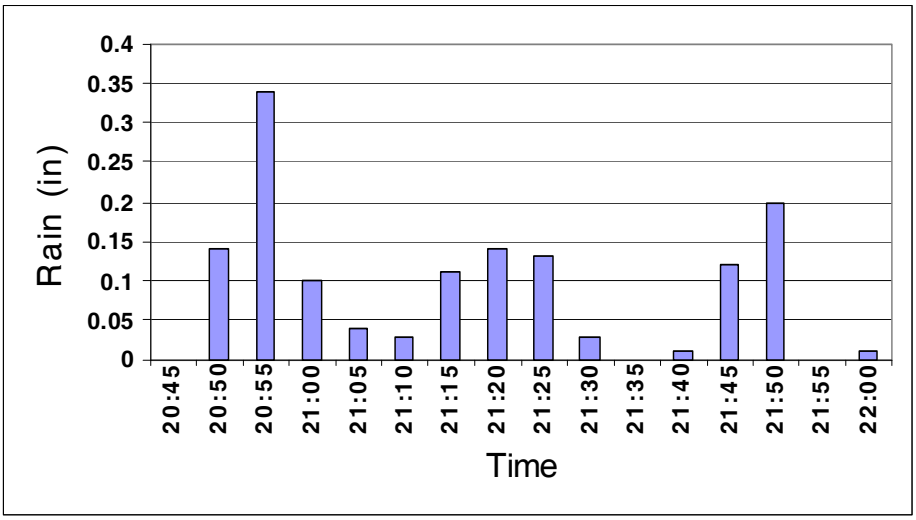

Figure 2. Hyetograph of the selected storm used in this study (USGS, 2005a).

The collected input data were then imported into ArcGIS software to estimate the parameters required for running the HEC-HMS model. The watershed was delineated using ArcGIS. The slopes of the watershed planes and streams were calculated using ArcGIS as seen in Figure 3a. The estimated physical properties data of McDonald Creek planes and streams are illustrated in Table 1 and 2, respectively. The soil properties (hydraulic conductivity and head suction), imperviousness, Manning's n values, and the land use SCS curve numbers were obtained from Chow (1959) and Chow et al. (1988) based on the SSURGO soil and land cove maps. The SSURGO map classifies the soil to more than 50 types. In this study, the soil types were simplified and classified based on the soil texture into eight major groups, namely, clay, clay loam, loam, loamy sand, sandy loam, silt loam, silty clay, and silty clay loam (Figure 3b). In order to determine the SCS curve number, the soil groups were categorized using ArcGIS into four SCS hydrologic soil groups as seen in Figure 4. The calculated soil properties data and the land use SCS curve numbers of the studied watershed are presented in Table 3. The values in Table 3 represent the weighted average properties of each plane. For calibration purposes, the Manning's n value of the planes was assumed to be 0.1.

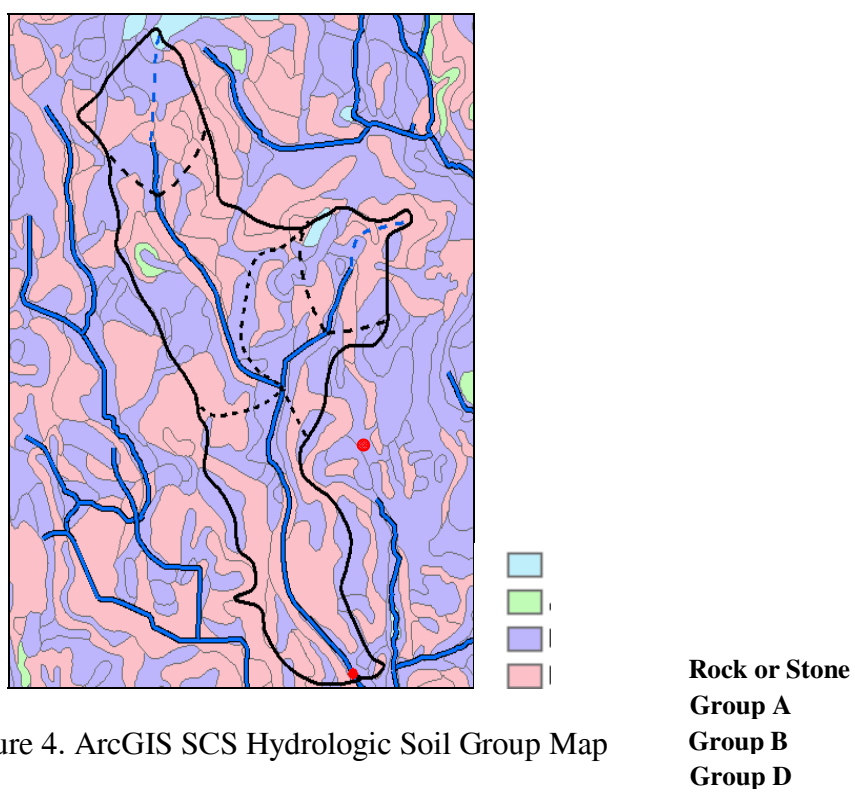

Figure 4. ArcGIS SCS Hydrologic Soil Group Map

RESULTS

The HEC-HMS discharge results of Case 1 and 2 for all conditions as described above were statistically compared using paired T-test. The analysis was also performed using two different methods for rate loss determinations, namely, Green-Ampt method and SCS method. The null hypothesis in the T-test is that the means of the modeled discharges are equal for both cases. The differences in peak discharge values, concentration times to the peak, and the total discharge volumes were also measured for each studied condition. The statistical analysis results are shown in Tables 4 and 5.

Table 4. P-value and differences of discharge results at the watershed exist and the conjunction point using Green-Ampt method.

Outflow point	Condition	P-value	Peak value Difference (%)	Difference in Time of peak (min)	Difference in Volume (%)
Watershed Exit	1	0.768	-4.5	0	-0.7
	2	0.858	-4.2	0	-0.4
	3	0.633	-0.4	0	-0.2
	4	0.856	-2.8	0	-0.4
Conjunction Point	1	0.758	-6.2	0	-1.0
	2	0.854	-5.6	0	-0.6
	3	0.636	-1.1	0	-0.3
	4	0.85	-3.4	0	-0.6

Table 5. P-value and differences of discharge results for at the watershed exit and conjunction point using SCS method.

Outflow point	Condition	P-value	Peak value Difference (%)	Difference in Time of peak (min)	Difference in Volume (%)
Watershed Exit	1	0.875	-5.9	+ 5	0.3
	2	0.912	-7.1	+5	-0.2
	3	0.072	0.3	0	0.6
Conjunction Point	1	0.872	-6.0	+ 5	0.5
	2	0.911	-8.0	+5	-0.3
	3	0.095	-1.6	0	-0.9

For all conditions at the watershed exit and conjunction point, the T-test results show that the null hypothesis with an α-level of 0.05 could not be rejected (i.e., p-value > 0.05). In other words, the means of the discharge values for Case 1 and 2 are likely the same. Moreover, the number of sub-basins does not significantly affect the discharge results. However, the number of sub-basins changed the discharge peak values in all conditions.

The results also demonstrate that the discharge peak difference increased from 4.5% at the watershed exit to 6.2% at the conjunction point. Also, the difference in the total discharge volume increased from 0.7% at the watershed exit to 1% at the conjunction point. The increase in these differences indicates that the effect of sub-basin number increase from 2 to 4 is higher than from 3 to 5 as Sub-basin III in Case 1 and Sub-basin V in Case 2 are identical.

In case of implementing the SCS method in HEC-HMS model, the results of the peak difference values and the difference in time of peak for condition 1 and 2 at the watershed exit and conjunction point are almost the same; indicating that that HEC-HMS model is more sensitive to the input slope parameter than the imperviousness when using the SCS method. While in case of implementing the Green-Ampt method in HEC-HMS model, the results show that the time of the peak did not change for all conditions; indicating that HEC-HMS is not likely sensitive to the slope parameter when using Green-Ampt method.

CONCLUSIONS

This study shows that ArcGIS facilitates the estimation of the parameters that needed for running the hydrologic model and makes it faster in creating representations of the same watershed in larger number of sub-basins. The results of this study demonstrate that the number of sub-basins did not significantly affect the discharge results. This study also shows that HEC-HMS model was sensitive to the input slope parameter when the SCS method was used, while it was not in case of using the Green-Ampt method.

STUDY OF LOW DOSAGE PRE-OZONATION ON SAND FILTRATION EFFICIENCY

Walter Lee Ellenburg, Student Member

Undergraduate Student, Civil and Environmental Engineering Department, University of Alabama in Huntsville, Huntsville, lee.ellenburg@uah.edu

ABSTRACT

The most traditional method for water filtration is the sand filter. Sand filters consist of sand, some type of activated carbon, and a more coarse aggregate such as gravel. Particles too large are then filtered out. Suspended particles too small for sand to catch are thus the problem, therefore different techniques are used to increase the efficiency of sand filters, these techniques are called pre-filtration. The goal of pre treatment is to coagulate, or clump together; the small suspended solids so that they may be caught in the filter. Current water treatment plants use many different types of pre-filtration: ferric, aluminum salts, or cationic polymers.

One form of pre-treatment is ozonation. By electrically charging oxygen and allowing a third molecule to join, ozone, (O_3), is created. Ozonation is the process of applying ozone to cause the small suspended particles in a given sample to coagulate. It has been studied and experimented for many years, proving a significant increase in coagulation and thus allowing the sand filtration to be more effective. As longer treatments of ozone are applied, the taste and odor may also be neutralized. In addition to the benefits previously stated, ozone may also be used as a disinfectant. In fact ozone oxidizes thousands times faster than that of chlorine. However, the production of ozone is somewhat energy intensive, and therefore an option that is sometimes over looked.

In this experiment, pre-ozonation will be examined in low dosages to see if the effects of coagulation are as beneficial as those exposed to longer periods of time. These smaller exposures would be more economical and a more realistic alternative for coagulation. If this hypothesis proves correct, the pre-treatment of ozone may be more appealing than other alternatives such as Alum and other chemical treatments which may stay longer in the water thus causing rising concerns in health related issues.

The result of this experiment proved that compared to previous tests with high amounts of ozone, small amounts of ozone will also reduce the suspended solids with time. The suspended solids were reduced by 1% with a five minute exposure and rapidly increased to a reduction of 7% over a 45 minute time period. From 45 minutes on the percent of decreased suspended solids slowly increased to 8%.

BACKGROUND

Direct filtration is a filtration process that treats direct surface runoff. This process usually includes the adding of a coagulant, rapid mixing, flocculation and filtration. Flocculation however, can usually be sidestepped. When the flocculation tank is omitted, it is usually called direct in line filtration, where the flocculation occurs in the filter itself. In the direct filtration process there is no need for sediment tanks, and it usually requires less chemical coagulant. These, among others, are key factors in the popularity of direct filtration. Direct filtration appears to be the most economical form of surface water filtration; however its inability to handle waters with high turbidity and operating challenges provides room for other filtration methods. The most common of these direct filtration methods are those using sand as the primary filter and therefore will be the direct filtration method used in this experiment. Larger aggregates and activated carbon will also be used as ingredients of the filter to best mimic the local Huntsville city water treatment system [Pontius, 1990].

Coagulation is the interaction of colloids and particulate with a destabilization agent. To agglomerate these particles and colloids is the central purpose for coagulation. These small particulates and colloids are also referred to as suspended solids. Suspended solids range in size and weight and can settle quite quickly, in a matter of hours or could take years. This bundling process is referred to as the destabilization of colloidal systems. These suspended solids usually have a maximum diameter of 10μm. Their rate of settling is usually no more than 10^{-2}cm/s [Faust, et al., 1982]. To achieve an increase the sedimentation of these suspended solids, a chemical coagulant is added. Ozone is one of many different types of coagulants used in water treatments. This process of pre-treating water with ozone before it is filtered is called Pre-Ozonation. Pre-Ozonation is a technique using Ozone, O_3, to cause the small suspended particles in the water sample to coagulate. Once these particles begin to coagulate, or bundle together, they begin to gain mass and surface area and therefore gain in sedimentation velocity and start to sink to the bottom of the container. Since direct in line filtration will be used in this experiment, the ability to sediment the particles is trivial. However, as the suspended particles begin to agglomerate; their surface area begins to increase, thus allowing more of the suspended solids to be filtered out [Gottschalk, et al., 2000].

When comparing a sample of ozonated water and un-treated filtered water, there should be a noticeable difference in the visible suspended solids and turbidity, along with the color and odor. This can be observed due to the oxidizing capability of ozone. Ozone is a gas that is unstable and therefore must be generated at the point of

use. Ozone can be created by a number of different methods. These methods include electrical, electrochemical, photochemical, thermal, and by radiation. The electrical discharge ozone generator is the most common used and will be used in this experiment. This process of generating ozone begins with first producing ionized molecular oxygen by applying high powered alternating current to oxygen. Ozone is then formed by the recombination of the ionized oxygen atoms and the unionized oxygen. Basically, the oxygen atom is charged and a third oxygen is combined then to create O_3, ozone. Differing amounts are capable of production depending on the air pressure and the pureness. The ozone generator used in this experiment produces 2.5 mg every 30 minutes.

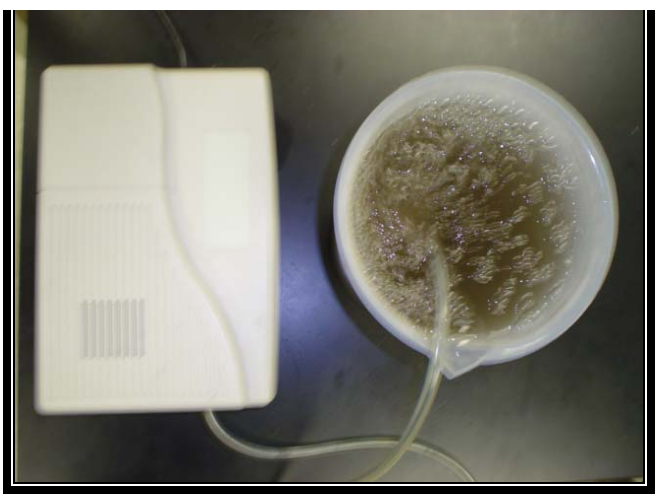

Figure1: Ozone generator
Source: Image taken by author

For this study, inline direct filtration was used to examine the effects of ozone as a coagulant aid in low dosages. Specifically, this experiment will compare several doses to examine how pre-ozonation affects coagulation. These smaller doses would be more economical and a more realistic alternative for chemical coagulation. Tests for suspended solids, TSS, will be conducted to determine the effectiveness of the proposed pre-filtration method [Faust, et al., 1982]

EXPERIMENTAL

In this experiment a simulated surface water model sample was prepared. The simulated water sample was mixed exactly the same for each experiment of differing ozone levels. The sample was created by mixing a commercially available composted cow manure, which is naturally high in organic matter, in water. It was mixed with de-ionized water at 150 grams per liter. The mixture was then mixed thoroughly and allowed to settle for two hours. Before filtration a small net was skimmed over the surface to remove large floating suspended solids to keep the filters from clogging. Once the surface water sample was allowed to settle, the control sample was then passed through the sand filter without any ozone exposure. Once the control was

established differing amounts of ozone were applied then filtered. First a small exposure of 5 minutes per 5 liter container was measured for a dosage of 1 mg/L. The next experiment conducted was an ozone exposure of 10 minutes for a 2 mg/L dose. Next increments of 15 minutes were test up to 45 minutes. Then one, two and three hours of exposure were tested. In each of these tests, TSS were conducted in accordance with standard methods for the examination of water and wastewater. Four different samples were taken from each sample before exposure and four after the ozone exposure to obtain a valid average analytical result for each parameter studied.

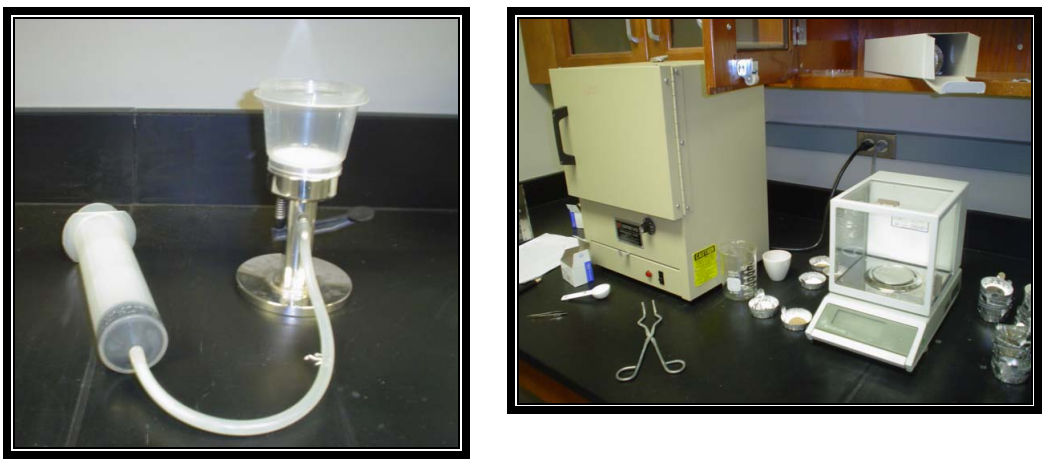

Figure 2: Suspended solids apparatus used (left); Oven and scale (right)
Source: Image taken by author.

The filter used was built to model the sand filtration water treatment plant currently used by the City of Huntsville. The laboratory sand column was built using a 4 inch diameter, 2 foot long, polyethylene tube with six holes drilled out of the bottom to allow for the water sample to percolate steadily through. The media consisted of a two inch (2") layer of large aggregate at the bottom, a two inch (2") layer of activated carbon and eighteen inches (18") of sand. The sand was obtained from the water treatment plant so that the experiment would be as realistic as possible. The sand was first washed and layered out to dry, then placed into the tubes on the larger rock and activated carbon layers. As designed, the water will first percolate though the sand, then the activated carbon, and finally though the large rocks, which is similar to the configuration at the actual plant.

Figure 3: Filtration apparatus Source: Image taken by author

DISCUSSION

The results of this experiment proved the initial hypothesis correct. Specifically, the amount of suspended solids in the sand filter effluent decreased with the amount of ozone applied as shown in Figure 4. However the decline was not linear and the results seem to hit a minimum increasing dosage.

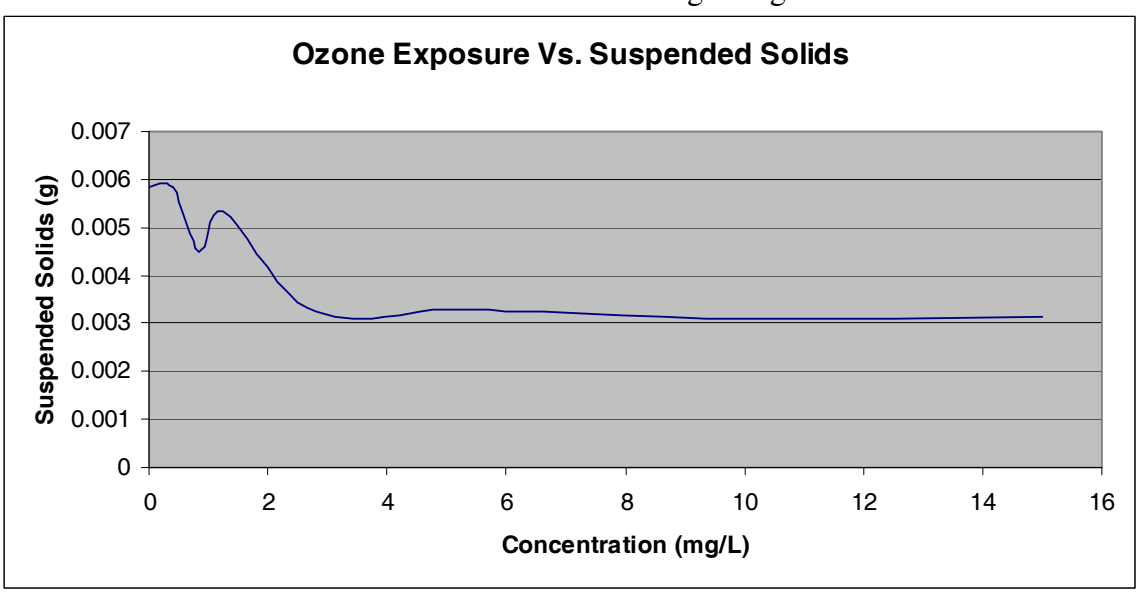

Figure 4: Ozone Exposure Vs. Suspended Solids

As one can clearly see the suspended solids dropped rapidly with the 1 mg/L dose. After 4 mg/L the suspended solids in the effluent remained relatively constant. When the percent of decrease of the suspended solids were analyzed a similar trend resulted, however the rapid increase occurred with the 0.83 mg/L dose. This data is the more accurate, since the percentage is considered. This trend can be seen below in

Figure 5.

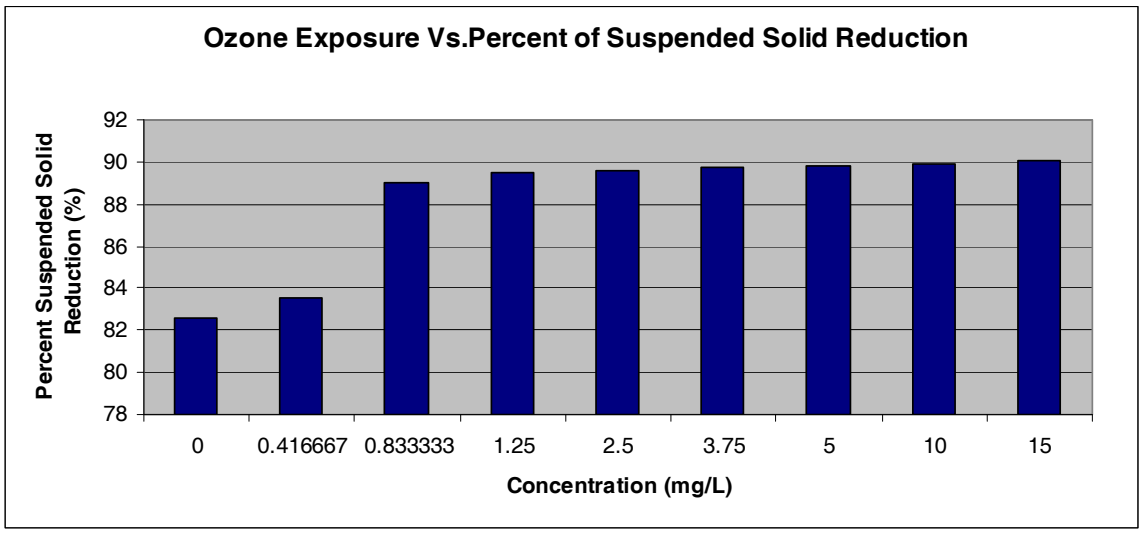

Figure 5: Ozone Exposure Vs. Percent of Suspended Solid Reduction

From simple visual observation, see Figure 6, one can see the reduction of suspended solids and the reduction in color. It was also noticed that the water became clearer throughout the experiment as the ozone concentrations increased. However, as the data suggest, it's only in the first few small concentrations of ozone that a significant reduction in suspended solids were measured. It is noted that sand filtration depends greatly on the type of surface water that is to be filtered. As stated previously, direct filtration cannot handle waters with high turbidity or color.

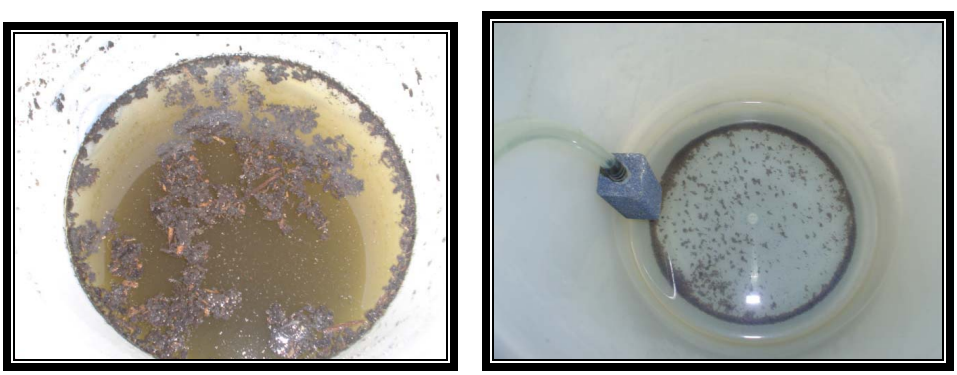

Figure 6: Before (left) and after (right) of Pre-Ozonation.

CONCLUSION

This experiment was successful in learning that small amount of ozone as a pre-treatment will reduce the suspended solids. The experiment analyzing the effects of low amounts of ozone exposure prior to sand filters resulted in a marked decrease in suspended solids. The best results occurred at approximately 0.83 to 1.0 mg/L dose. Higher doses did not seem to make any difference in this study. The maximum

reduction in suspended solids was 89 percent. The control sample of reduced suspended solids by simple filtration was 82 percent. Thus pre-ozonation removed over 7% of additional SS than the traditional sand filters.

It is recommended that further studies should be pursued to develop more exact results on optimizing ozone dosages. If turbidity were examined along with the suspended solids and compared, more conclusions could be made. Also, when this experiment was conducted small variations in the organic matter that simulated the surface water could have taken place. If the experiment used an actual surface sample and was conducted in a concentrated time, more accurate results may be obtained.

THE DUBAI PALMS: CONSTRUCTION AND ENVIRONMENTAL CONSEQUENCES

Ethan Poole, Student Member

Undergraduate Student, University of Tennessee, Knoxville, Knoxville, TN
epoole1@utk.edu

ABSTRACT

Virtually every western news agency and even the Discovery Chanel have produced ever growing pieces about the engineering accomplishments of the small Middle Eastern country of The United Arab Emirates (UAE). In an attempt to create tourism, Dubai, UAE, has created some impressive structures, but now, it is creating land itself. Five artificial islands are being reclaimed from the Persian Gulf — one of which, the Palm Jumeirah, takes the shape of a date palm, and will be the focus of this paper. Reaching several hundred meters into the gulf, and standing several above the water line, the Palm Jumeirah is so large it can be seen from space. While an impressive creation, a reclamation project of this size could easily have a negative effect on the environment. Upon researching the project, it became clear that the UAE was in such a rush to build the islands that the proper planning and environmental studies were not conducted, thus resulting in the destruction of the Persian Gulf's eco-system. While most projects do tend to negatively effect the surrounding environment in some form, the islands, due to their shear size, have completely destroyed an already fragile eco-system in a manner that may be irreversible. After introducing the reader to some basic information regarding the construction of Dubai's Palm Jumeirah, this paper will examine some of the major environmental effects that have occurred as a result of the Palm Jumeirah project.

INTRODUCTION

In the late twentieth century, the Middle Eastern nation of the United Arab Emirates (UAE) began to make plans to distance itself from the petroleum industry that dominates most of the Persia. Driven by the fact that internal experts believe the country's oil reserves will be depleted by the year 2012, the UAE is attempting to transition to a service industry, with a major focus on tourism, retail, and entertainment. In order to transform its economy, the UAE is first focusing of the

already advanced city of Dubai, which is the first tax free, centrally-planned, free-market capitalist society in the Middle East (1). With an economy valued at over forty six billion dollars, the city of Dubai is, by far, the most economically powerful city in that part of the world. Yet it has virtually no ties to the commanding petroleum industry (2).

The UAE is in the process of spending trillions of dollars transforming Dubai into an engineering marvel. Of all of the structures that the emirate has recently created, including the tallest structure in the world and a revolving skyscraper, this report will focus on the largest land reclamation project to date, the manmade island formed in the shape of a date palm. The island, which Dubai has already termed "the eighth wonder of the world," adds almost 1,600 km (1,000 mi) of additional coastline to Dubai, and is formally called the Palm Jumeirah (3). While it is an engineering marvel, without extensive research and planning, the creation of such an island chain could have severely affected the local environment and coastal eco-system. Unfortunately, the UAE did not have time or patience for such research and planning, and therefore, the repercussions of such a large scale project have been devastating. This report will first give the reader some background on the Palm Jumeirah project and will then discuss some of the environmental repercussions of this large land reclamation project.

Palm Jumeirah Background

The Palm Jumeirah was designed and created by the state owned development company, The Nakheel Corporation. Formed in the shape of a Date Palm, Jumeirah consists of a trunk measuring 457 m (1500 ft) wide, 2.5 km (1.6 miles) long, and surrounded by an expansive canopy of seventeen fronds. Once complete, the palm will support over sixty luxury hotels, over 5,000 residential villas and apartments, several marinas, and various forms of entertainment (4).

Engineering Information

The engineering of this island was done in four major steps, first the breakwater was raised from the gulf. Next the center crescent was created, followed by the fronds. Currently, the newly formed dry land is being populated with amazing structures. Preliminary plans did not call for the large protective breakwater, but fortunately the executives realized the palm island must be protected by such a structure in order to abate the flow of the gulf.

Constructing the Breakwater

The breakwater was constructed where the water had a depth greater than 10 m (33 ft). It is 11 km (6.8 mi) long and 200 m (656 ft) wide, and rises 4 m (13 ft) out of the water. The barrier was made up of reclaimed sand from the bed of the surrounding area. In order to stop erosion, a cap structure was added. Engineers topped the breakwaters with two separate layers of massive rocks on the top, and three layers for the subsurface sections. Each rock was precisely sanded, shaped, and individually placed to form a wall-type structure that would remain sturdy (5).

Creating the Actual Palm

The island itself was created in a similar fashion. In order to provide support for the immense weight that will be added upon completion, the ground layer consists of enormous rocks blasted from far away mountains. Next, layers of soft sea sand that was covered with an erosive-preventing water-permeable geo-textile formed the bulk of the structure (6). This sand was, for the most part, dredged from the bottom of the gulf about 35 m (115 ft) from the breakwater. One-ton rocks sit atop this sand layer and create a cap that breaches the surface of the water.

At this point, the island began to show shape, but rose only several feet above the surface of the water. The final step was to dredge over 8,500,000 m^3 (302,000,000 ft^3) of ocean sand onto the top of the base structure in order to create habitable islands. This sea sand increased the island's height to 4 m (13 ft) above low tide (6). In order to quickly, yet precisely acquire and distribute the sand, fleets of dredging vessels and massive transport/delivery ships were brought from a European manufacturer.

Dredging

In dredging millions of cubic meters of sea bed, the project used specialized cutter suction dredgers in order to apply the sand to the desired surface. A cutter suction dredger, according to the European Dredging Association (EuDA), is a large rig with a powerful underwater suction tube generally 10 - 100 cm in diameter extended angularly from the centroid of the vessel with a large crane extending from the rear of the ship to stabilize the tube (7). Due to the dense makeup of the Persian Gulf, the dredgers had a cutting head at the base of the tube. This head chews through the rock bed with over 5,000kW cutting power. It was equipped with a massive jet dredge system powered by a submerged pump attached to the tube to help pull the destroyed bedrock into the ship (8 & 9). The jet dredge systems create an extreme negative pressure in the pipe, which creates a basic Bernoulli venturie tube effect. The negative tube pressure created uses the weight of the surrounding sea to force the debris up the tube and into the vessel at an incredible rate (Hughes 8).

Environmental Effects: Introduction

As the island was being built, global praise and awe far outweighed environmental concern, but once the initial amazement had worn off, many critics began voicing their concerns. In response, Nakheel continually issued publications from their scientific board and assertions stating that the ecosystem was not, and would not be, adversely affected. In many reports, they even claimed that the ecosystem would benefit from the construction (10). While the company did make some concessions, which are described below, the project ultimately resulted in extreme environmental destruction. The new archipelago not only completely changed the shape and makeup of the gulf, but the dredging and construction itself had even worse effects on the local environment.

The Positive Environmental Points

The company's environmental impact plan did have some positive points. They did modify the breakwater by adding two 3 m (9.8 ft) deep channels cut about a quarter of the way into the structure on each side. This design change allows additional currents to enter the island's channels, thus greatly reducing the internal water renewal time to about fifteen days (11). It also provides nutrients to the inner ecosystem and reduces the occurrence of stagnation which would allow bacteria to thrive. The company also spent two months transplanting 1,869 marine animals from an area where the sub-sea transit tunnel was to be placed (12). In addition, they employed two oceanographic experts to study the effects of the new islands on the environment and help design several different kinds of artificial reefs throughout the archipelago in order to replace the original habitat.

Impact on Construction on the Pre-Existing Landscape

While some considerations toward the environment were made, the result of creating a land mass with an area of 25,000 m^2 (270,000 ft^2) at an average depth of 10 m (33 ft) was nothing short of catastrophic for the environment. The creation of the Palm Jumeirah has influenced the ecosystem enough to alter the landscape of the preexisting beaches. Stable beaches go through transformations every day. As alluvial sand is relatively unconsolidated, the sand is constantly eroding with each undercurrent, but that erosion is usually counteracted as the natural currents and waves regularly re-deposit sand lifted off of the sea floor. Once the island was constructed, it disrupted the natural currents that move along the coast of the UAE, essentially acting as a large jetty. By dampening the force of the waves several miles out, the island current is not able to deposit enough sand on the natural beaches. This causes severe depletion of the beach soil. According to Dr. Tom Williams, Nakheel's Former Senior Technical Advisor, by 2006, the Palm Island had drastically reduced sediment deposits along almost 41 km (25 mi) of Dubai's shoreline (4).

The Direct Impact of Construction on the Marine Life

In addition to damaging the existing coastline, the Palm Jumeirah has proved deadly to most of the marine species in the area. Due to its extreme temperatures, salinity, and fierce storms, the Persian Gulf is already a high stress ecosystem with the marine life that exists there held in a delicate balance. The plentiful yet fragile sea grass, biota, algae, and microorganisms form the basis of life as they are one of the few stable food sources in the region. This food source attracts varieties of small fish that have limited territories. They are restricted to areas with ample food and protection from predators. Generally, the only form of protection in the coastal areas of the Persian Gulf is coral reefs. Obviously, it is these small fish that then in turn attract the larger, more mobile and nomadic predatory marine life.

Creating an intricate island chain like the Palm Jumeirah was a slow process and Nakheel reasoned that most of the aquatic life would have adequate time to relocate. This proved to be an accurate assumption for most of the larger organisms. However, the majority of the immobile flora, algae and coral reefs that support life, as well as those fauna that lived within the reefs were either dredged, permanently dislodged, or completely buried under the new island itself. Nakheel's environmental impact study found that about 10% of the area under and around the Palm contained

coral reefs. While that may sound like a small amount, given the shear size of the project, it totals to over 1.2 km^2 (300 acres) of coral, and all life sustained therein, directly destroyed (4). In addition, much of the sea grass and microorganisms located on the perimeter of the construction zone would have easily been sucked up by the jet pumps, ripped out of the sea floor by the excessive turbulence, or just choked out by the immense disturbance. Even those species originally located in the construction site that attempted to flee would have had to travel over 4.8 km (3 mi) into the gulf or almost 35.5 km (22 mi) along the coast to escape the construction.

The Indirect Impact of Construction on Marine Life

While the direct impact of the construction site decimated the marine population located in or close to the construction site, the indirect impact was far worse. Since the majority of the islands were formed using either bedrock or sea sand, the dredgers and transport vessels pulled up hundreds of millions of tons of sand and sprayed it back into the sea in a technique called rainbowing, which, according to a Dubai environmental protection agency, resulted in "substantial re-suspension of finer sediments, and the consequent siltation of [marine] communities in the general region of each development" (13). Plumes of sedimentation from the sprayed sand and the disrupted bed spread more than 25,000 m^2 (6 acres) acres in each direction, thus making the total area affected by over-sedimentation greater than 75,000 m^2 (18.5 acres): an area larger than the state of West Virginia. Nakheel stated that the silt would settle in a few months, but that was not the case as the construction and rainbowing lasted several years. The result was the burial or asphyxiation of any organism that could not travel that distance in time.

CONCLUSION

The creation of the Palm Jumeirah island community is an undeniable marvel of engineering. The Nakheel Corporation was able to successfully create an immense and intricately designed island that required accuracy to the centimeter. It is a testament to the fact that with proper design techniques and an attention to detail, a trained engineer can create awe inspiring structures. However, it is also a prime example of how unguided ambition can have catastrophic windfall. The damage to the local aquatic environment, and possibly that of the entire Persian Gulf may be permanent. Today, seven years after construction began, the water around the Palm Jumeirah is still murky and the fine sediments become re-suspended every time a storm comes through. The coastal beaches, which historically lost 10,000 – 15,000 m^3 per year of sand due to natural erosion, have already lost over 3,500,000 m^3 (14). According to fish counts, less than half of the 35 species of fish have returned to the site. Every single species of fauna that once existed at the site were destroyed during construction, and fewer than 30 of the original 106 species have returned. The Palm Jumeirah may be a structure that will stand the test of time and revolutionize coastal development, but the loss of a unique ecosystem may prove to have been too high of a price to pay.

ABSTRACT

The purpose of this study was to evaluate the feasibility of developing stormwater management retrofit demonstration projects for application in the public right-of-way (ROW) in form of "Green Streets." This study responded a motion issued by the City Council of Cincinnati to create a plan for a Green Streets Pilot Project, targeting specific downtown streets for the implementation of methods to address stormwater runoff generated by the public right-of-way and to assess their feasibility to reduce combined sewer overflows.

The study developed conceptual prototype stormwater controls to fit into common features in the public right-of-way and adjacent impervious features for four (4) street segments in the central business district of Cincinnati, Ohio. CH2M HILL's Low Impact Feasibility and Evaluation (LIFE) model was applied to evaluate each of the BMP concepts in terms of runoff reductions resulting from the planned level of storage, infiltration into the subsurface soils, and evapotranspiration. Cost estimates were developed to assess runoff reduction efficiency.

Introduction Background and Purpose

Many urban communities served by combined sewers have struggled for years to find an economically viable solution to mitigate the impacts of wet weather overflows. Most of the applied technology has focused on increasing the capacity of the conveyance system, adding storage to detain storm flows until treatment capacity returns, or providing some form of water quality treatment to the overflow discharges.

Alternate approaches seek to reduce the volume of stormwater runoff entering the combined sewer system. Various stormwater management technologies developed over the past three decades have been given closer consideration for application in the urban environment. Measures that infiltrate (porous pavements, linear infiltration systems, and tree trenches); measures that transpire and reduce energy demand (vegetated roofs); measures that infiltrate and transpire (rain gardens and planter boxes); and measures that capture and reuse rainfall (rain barrels and grey water systems) have all evolved in different regions around the globe, depending on the local ecology and water resource requirements or limitations.

This study responded to the City of Cincinnati Council Motion of May 29, 2007, which required "that the administration create a plan for a Green Streets Pilot Project, targeting specific Downtown Streets for the implementation of methods to address stormwater runoff." The purpose of this study was to evaluate the feasibility of these measures for application in the public right-of-way in the form of "Green Streets." Various terms have evolved to describe the application of such solutions in the urban environment, with the word "green"

providing a popular and acceptable label. In fact, the use of vegetative systems as an integral part of the engineered designs provides hydrologic, hydraulic, water quality, and aesthetic benefits.

Project Area

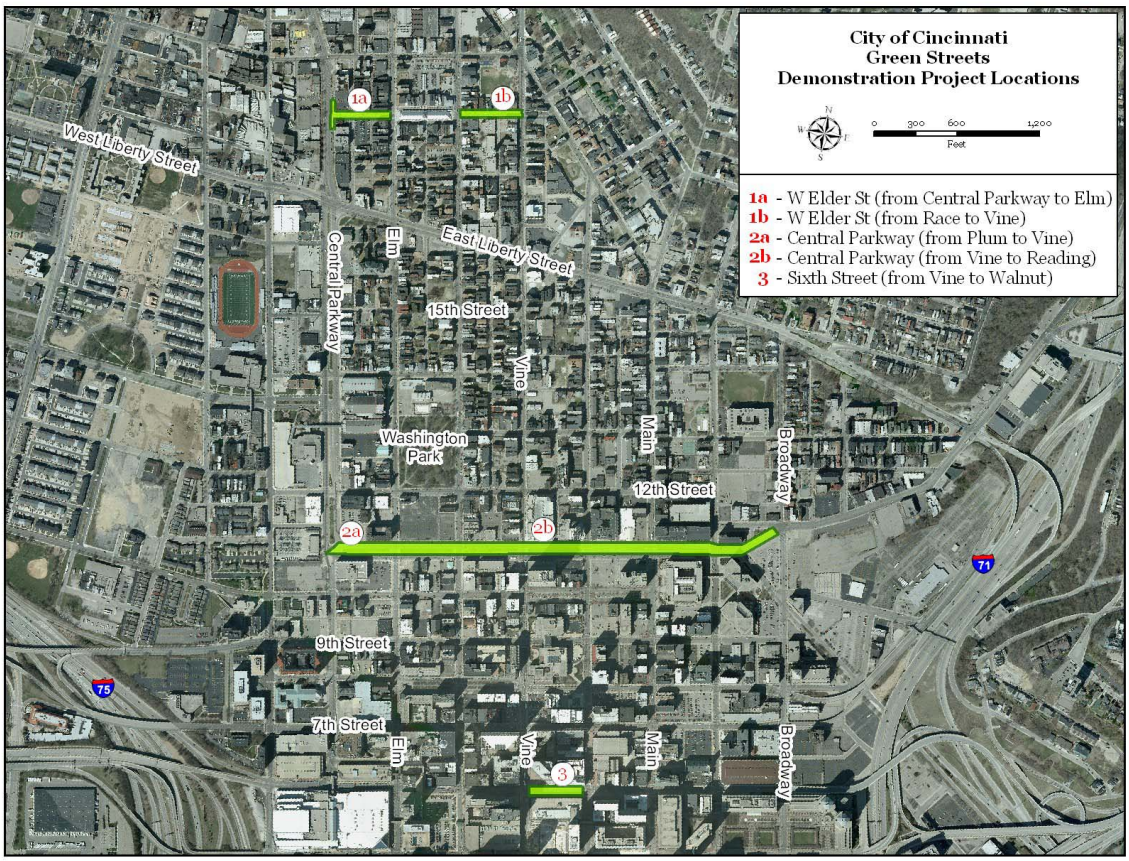

Figure 1 - Street Areas Selected for Feasibility Analysis

The Stormwater Management Utility (SMU), the Department of Transportation Engineering (DOTE), and the Parks Department collaborated to develop a set of ranking criteria to select viable street segments for the feasibility study. Based upon this criteria, the streets shown in the project area map in Figure 1 were selected for the feasibility analysis.

BMP Concept Development

Early on the process, the project team held a workshop meeting with SMU, the Parks Department, and DOTE to develop evaluation criteria, to conduct onsite reconnaissance of the proposed project areas, and to discuss potential concepts with City staff in the field. The workshop presented and critiqued relevant stormwater control technologies and their potential applicability to the City streetscape. The technologies drew from case studies that had been successfully implemented in other areas of the country, many with similar hydrologic characteristics to those found in Cincinnati. The technologies that were considered for application in the Green Streets program include the following:

- Porous pavements
- Subsurface infiltration
- Infiltration trench
- Bioretention
- Vegetated planter box
- Vegetated (green) roof

Using the knowledge obtained at the initial field visit and through analysis of the available source data (CAGIS, anecdotal observations from key staff, soil survey data), opportunities and constraints were identified for the street sections. The basic procedure entailed developing generic Green Street "retrofit" concepts or prototypes, as well as additional low impact development (LID) concepts for sustainable stormwater management in the adjacent areas, including concepts that managed runoff from adjacent parcels. While the focus of this work effort was clearly on the streets themselves, it is important to understand opportunities to further reduce runoff by "retrofitting" the adjacent areas, which included some publicly-owned impervious areas. Concepts were also developed for a limited number of these areas for comparison purposes.

In order to organize the various Green Street "retrofit" concepts into a framework specific to the City of Cincinnati, the project team developed a classification system of prototypes. This prototype classification is unique to this project and allowed the project team to group different "green" stormwater practices and technologies into unified Green Street concepts. Specifically, the following five Prototypes were developed:

- Prototype 1: vegetated curb extensions, infiltration under standard pavement parking lane, continuous tree trench, and porous concrete sidewalk with infiltration
- Prototype 2: vegetated curb extensions, infiltration under standard pavement parking lane, and continuous tree trench
- Prototype 3: vegetated curb extensions and infiltration under standard pavement parking lane
- Prototype 4: vegetated curb extensions
- Prototype 5: porous pavement parking lane and tree trench

Prototype 1 included all four elements of a comprehensive Green Street design that seeks to maximize runoff capture by using all available elements of the streetscape. Prototypes 2, 3 and 4 represent variations on Prototype 1, by subtracting one element from the preceding design prototype. The common elements in these four Prototypes are the vegetated curb extensions, which represents the minimum level of stormwater treatment. Prototype 5 provides a variation on Prototype 4 by substituting porous pavement with a stone infiltration bed for the vegetated curb extensions in the parking lane. Green Street design is most efficient when it utilizes either vegetated

curb extensions or porous pavement parking lanes, rather than using the two practices in combination. With porous pavement parking lanes, little runoff, if any, would ever reach the vegetated areas, which allows for direct comparison of vegetated measures with the porous pavement technologies.

For Prototypes 1 through 4, the vegetated curb extensions (or bioretention areas) will receive runoff from the streets and, in some cases, adjacent impervious areas (sidewalks, awnings, etc.) and allow it to be filtered, treated, and evapotranspired prior to it draining into a subsurface aggregate infiltration system. In this way, the curb extensions will serve at least three stormwater treatment functions: pretreatment, evapotranspiration, and infiltration. The underlying aggregate infiltration system will actually extend beneath all elements in the particular prototype. (For the purpose of this study, these prototypes were considered as unified "systems", as opposed to separate, individual elements.) In addition, it has been previously demonstrated at other locations that these measures can provide traffic calming benefits and soften the aesthetics of the streetscape.

For Prototype 5, runoff from the streets and, in some cases, adjacent impervious areas will drain directly through the porous pavement, which will have to be vacuum-swept on a biannual basis to maintain porosity, and into the subsurface infiltration system. For all the prototypes, runoff will be temporarily stored both on the surface and in the voids of the underlying aggregate (typically 40 percent) until it has had an opportunity to exfiltrate into the subsoil. In the event of a larger rain events (> 1 inch), the full design of the prototype would incorporate controlled overflow mechanisms (weirs, constricted outlet orifices, overflow pipes, etc.) to allow for excess flows to pass on to the existing combined sewer system.

Drainage Areas for the four streets were delineated digital aerial photos, site photographs, field notes, and utility information obtained from CAGIS (Cincinnati Area Geographic Information System). The drainage areas tributary to each BMP concept were delineated using a combination of GIS features (inlets, manholes, catchments, contours, etc.) and field investigation (verification of street crown, inferred ground slope). Estimates of the pervious and impervious areas to each BMP were recorded in summary tables. In several cases, it was assumed that minor modifications could be made to existing street inlets either to allow more runoff to enter the various concepts or to allow runoff to overflow from the concepts into the existing sewer system. This provided a comparison of how Green Street features could be used to capture additional runoff and at what cost.

Using the drainage area delineations, runoff volumes were calculated from the 0.5 inch, 0.75 inch, and 1.0 inch rainfall events. Based on these volumes, the various BMP concepts were sized to hold the runoff volume resulting from a 1.0 inch storm as "dead storage" either on the surface or in the aggregate voids (typically 40 percent) in the case of a gravel bed. Infiltration and evapotranspiration were not considered at this conceptual sizing stage.

The benefits of these hydrologic functions were evaluated as part of the modeling evaluation of the BMP performance. Based upon the results of the modeling analysis, it is likely that some of these concepts could be downsized and still provide capture for the first inch of rainfall. It should be noted that in situ soil permeability testing should be used as the basis for the final design sizing. Tables 1 and 2 provide an example of the BMP Sizing analysis, in this case for West Elder Street.

For all rain events, the impact of stormwater runoff on the combined sewer system (and overflows) will be reduced through the application of these prototypes. The runoff reductions associated with each prototype were quantified in this study, but the simulation of the specific overflow reductions occurring at the downstream CSO were beyond the scope of this effort. It is also important to note that the five prototypes and other LID concepts considered for this project are only conceptual in nature and would require full engineering and detailed site investigation prior to implementation. Soil permeability testing, deep pit excavations, utilities investigation, and topographic surveying would have to be performed to ensure the effectiveness of the various designs and the minimization of risks to adjacent structures.

This effort also considered demonstrating the use of porous concrete at several bus stop locations throughout the project area. Based upon input from DOTE, concrete bus stop pads were indicated to be failing in some locations throughout the City and in need of replacement. Thus, the project team evaluated the potential stormwater benefit of an existing transportation feature that inherently possesses a large, deep stone bed for structural stability. This 18-inch stone base could also provide useful stormwater storage that can be utilized in one of two ways: porous pavement or connection of an inlet or area drain to the stone void space (typically 40%).

LIFE™ Model

CH2M HILL's Low Impact Feasibility and Evaluation (LIFE) model was applied to evaluate each of the BMP concepts in terms of runoff reductions resulting from the planned level of storage, infiltration into the subsurface soils, and evapotranspiration for measures that had a vegetative component. The LIFE™ model is a physically-based hydrologic and water quality simulation tool that was developed to evaluate the performance of various LID techniques (e.g., bioretention, infiltration systems, rainwater capture/reuse systems, permeable pavement, green roofs, etc). It is well suited to site-level analysis of spatially distributed stormwater source controls (i.e., LID techniques).

Table 3 - LIFE™ Model Evaluation of Runoff Reduction and Cost Efficiency - West Elder Street - Findlay Market

			Annual Runoff Volumes				Unit Runoff Reduction Cost	
Location	BMP ID	BMP Type	Existing Condition (ft^3)	With BMP (ft^3)	Volume Reduction (ft^3)	Percent Reduction	$ / Gallon (Low)	$ / Gallon (High)

Prototype 4 - Vegetated curb extensions
Prototype 5 - Porous parking spaces and tree trenches
BMP ID - Scenario b - Denotes an alternative where an available adjacent impervious area (roof leader, parking lot, etc.) was routed to the BMP

The LIFE™ model provides a continuous simulation of the runoff, interflow, infiltration, and baseflow from a developed area given the following inputs:

- *Continuous rainfall data* (typically in time increments of one hour or less) and *evapotranspiration data* (daily), typically for a time period of one year or more. Evapotranspiration (ET) can also be calculated from temperature data.
- *Site design parameters and land cover characteristics* for each land use type being modeled (e.g., road width, rooftop coverage, surface parking coverage).

- *Information on LID techniques* that are applied for each land use type, including:
  - Extent of source control application (e.g., fractions of road and of building coverage with certain types of source controls)
  - Source control design parameters (e.g., area and depth of infiltration facilities, soil depth for green roofs or absorbent landscaping, volume of rainwater re-use cisterns)
- *Soils information, including:*
  - Surface soil parameters (e.g., maximum water content, vegetation rooting depth)
  - Sub-surface soil parameters (e.g., saturated hydraulic conductivity)

LIFE™ calculates runoff and pollutant loads under a variety of weather conditions, land uses, and soil types and has more robust representation of infiltration processes than commonly applied planning models such as the U.S. Environmental Protection Agency's (EPA) Stormwater Management Model (SWMM). Final LIFE™ hydrographs for the Green Streets project scenarios can be fully incorporated into the City's EPA SWMM models of the combined sewer system to scale site benefits for evaluating the impact of system-wide implementation. These benefits would typically be reflected in runoff volume, recharge, peak flow, and water quality.

In the case of some project locations, such as West Elder Street, two scenarios were tested. In Scenario A, the proposed control measures were modeled as if they would treat only their immediate drainage areas. In Scenario B, additional impervious area was added to these control measures, given the assumption that nearby inlets and pipes could be practically modified. Table 3 and Figure 2 provide an example of the LIFE™ model results and corresponding cost estimates ($/Gallon reduction), in this case for West Elder Street.

According to the results summarized in Figure 2, the three primary BMPs (represented as DA1 Scenario A, DA1 Scenario B, DA2 Scenario A, DA2 Scenario B, and DA3) reduced total runoff volumes by 22 to 31 percent. These represent the best opportunities for retrofits based on public ownership of and access to their proposed locations. If two additional "secondary" BMPs were added (DA 4 and DA 5), the annual runoff volumes could be reduced an additional 32 to 36 percent. The LIFE™ model also indicates that several control measures are probably over-sized either in terms of surface area or storage depth. The proposed BMPs for both DA 2 and DA 4 removed all but 286 ft^3 of their combined annual runoff volume. Sizing of individual control measures was not part of the modeling process and should be revisited in any future design process.

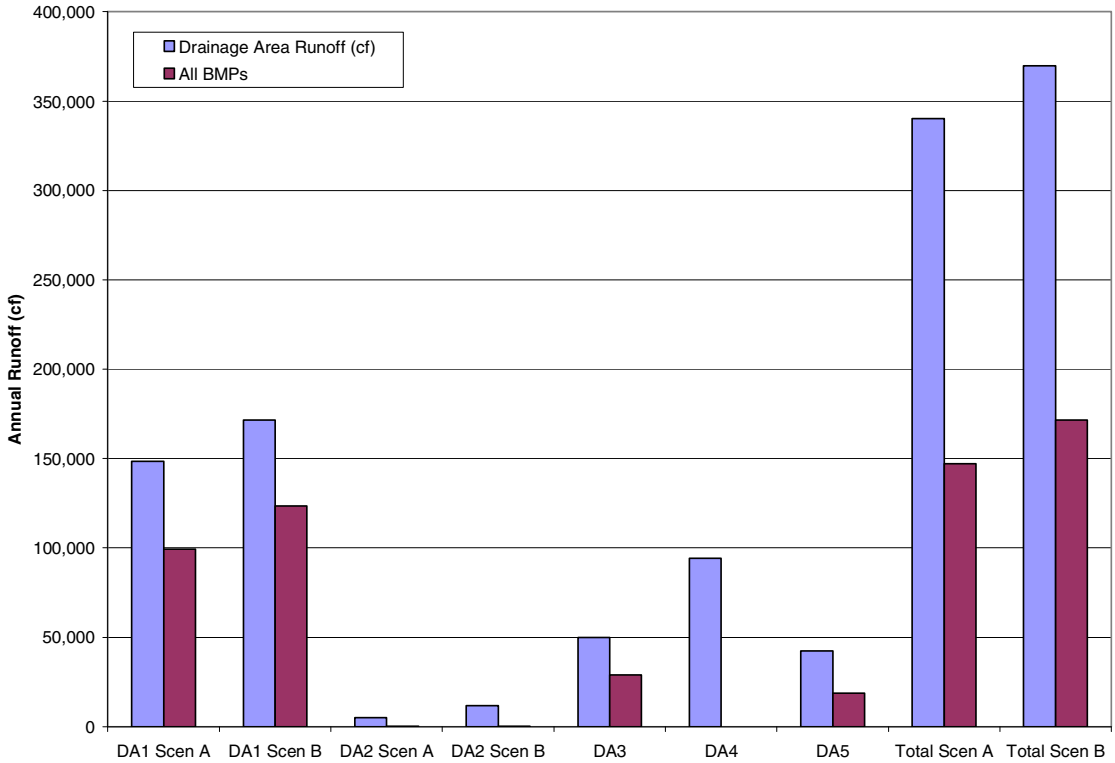

Figure 2 - Comparison of Runoff Reduction for each Drainage Area – BMP Combination - West Elder St. Cincinnati, OH.

Cost Analysis

After selecting and sizing the various Green Street and LID concepts described above, conceptual cost estimates were developed both for construction and ongoing operation and maintenance (O&M). For each concept, the project team specifically considered the following probable cost items: pavement demolition, excavation, aggregate, geotextile, standard pavement, porous pavement (asphalt or concrete), pipes and cleanouts/catch basins, existing inlet modifications, planting soil, curbing, bioretention vegetation, street trees, tree grates, and vegetated roof material. Unit costs for these various items were based on several sources, including the project team's recent construction experiences, the latest version of "R.S. Means Construction Costs", and other published data. A 20 percent contingency was applied to the total cost of each concept.

Two construction cost scenarios were developed to provide a "high" and "low" cost for each project concept. For the "high" cost scenario, all of the line items listed above were included. For comparison, the "low" cost scenario considered the case where several line items are not directly related to stormwater management. In other words, these components would have to undergo some level of routine maintenance and rehabilitation as part of maintaining the street infrastructure. These items included the following: standard asphalt pavement, porous asphalt and concrete pavement (only the cost increase over standard asphalt and concrete was considered),

curbing, street trees, and tree grates. The "low" cost estimate would illustrate the benefit of integrating the timing of green streets projects with renewal of the street ROW as part of a broader infrastructure renewal need.

The expected primary maintenance tasks for the various Green Street and LID Concepts include the following: cleaning out cleanouts/catch basins, pruning/weeding/watering/etc of bioretention vegetation during establishment period (if and when required), removing trash/sediment/debris from bioretention curb extensions and planter boxes, vacuum-sweeping the porous pavement, and irrigating the vegetated roof material during the establishment period. It is important to note that the O&M cost analysis did not factor in the current costs of drainage maintenance (removal of trash/sediment/debris from inlets and gutter lines) incurred by the City, in so much as they exist and would presumably continue with or without the Green Streets project. Therefore, the costs summarized in the tables below, either as actual dollar amounts or as "high", "medium", or "low", are likely to be rather conservative.

Project Implementation Plan

A basic prioritization scheme was developed to select projects for implementation. The projects were ranked according to a set of criteria and criteria weights that reflected the goals adopted by the project team. The project concepts were evaluated with respect to the above evaluation criteria. Weighting factors were developed for each of the main ranking criteria as follows:

- Community Amenity / Education (40%)
- Reduction of Runoff and CSO volume (90%)
- Complements / Integrates Multiple Existing Projects (70%)
- Constructability - How easy is it to build? (50%)

The projects were then ranked according to the criteria and weighting scores and the top ranked projects were recommended to move on to design development and were incorporated into the Long Term Control Plan Strategy for the Metropolitan Sewer District of Greater Cincinnati. The next phase of this effort is expected to occur in 2009 and will entail implementation of one or more of the proposed Green Street projects.

Implementation and Performance of Stormwater Best Management Practice Retrofits in Wilmington, NC

J. D. Wright[1], W. F. Hunt[1], M. R. Burchell II[1], C. A. Perrin[2] E.R. McCoy[3]

Abstract. *Burnt Mill Creek, located within downtown Wilmington, NC, is on the EPA's 303(d) list for impairment due in large part to urban stormwater runoff. The urban nature of the watershed presents challenges for restoration because of the varying land uses including single and multi-family residential areas, recreational parks, and commercial and industrial areas. Restoration efforts are multiplying in Burnt Mill Creek as a result of passionate involvement from local community leaders, and partnerships with state organizations. The Watershed Education for Communities and Local Officials (WECO) coordinated a partnership, with NCSU BAE, the City of Wilmington, as well as several other key state and local organizations and citizens groups, to obtain an EPA 319 grant that addresses stormwater management in the watershed. Community involvement has led to several retrofit BMP opportunities, including pervious pavement and rain gardens at a local YMCA, two bioretention cells installed in the parking lot at Port City Java's corporate headquarters, a stormwater wetland in a city owned communal area, and several residential scale rain gardens in an urban low income community. Twelve rain gardens and twenty four rain barrels were installed at citizen's private residences in an urban neighborhood in downtown Wilmington. Although restoration takes time, momentum continues to build in the Burnt Mill Creek watershed as resources are devoted to thoughtful education and engagement with the public.*

Keywords. Stormwater, BMPs, Urban Retrofits, Bioretention, Wetlands, Permeable Pavement

Introduction

Burnt Mill Creek watershed is located in downtown Wilmington in New Hanover County, North Carolina, and is on the EPA 303(d) list of impaired streams for impacts from stormwater runoff. In 2002, the NC Ecosystem Enhancement Program completed a watershed plan for Burnt Mill Creek and adjacent Smith Creek. The NCEEP plan indicated general impacts resulting from increased stormwater discharges and associated pollutants. More recently, NCDWQ's Assessment Report (2004) of the Burnt Mill Creek watershed identified toxic impacts from polycyclic aromatic hydrocarbons (PAHs) as the primary cause of biological impairment, with secondary and cumulative causes being sedimentation, and nutrient enrichment. Research conducted by the University of North Carolina at Wilmington (UNC-W) found all PAH samples exceeded concentrations that would cause harmful effects in aquatic communities (Mallin, et al; 2006). The same report identifies fecal coliform counts well in excess of the State standard for human contact waters at all but one sampling station. Stormwater runoff generated by development will continue to degrade the creek unless measures are taken to manage stormwater runoff.

WECO coordinated a partnership including the North Carolina State University Department of Biological and Agricultural Engineering, City of Wilmington Stormwater Services, Cape

[1] Department of Biological and Agricultural Engineering, North Carolina State University, Campus Box 7625, Raleigh, NC 27695
[2] Agricultural and Resource Economics, North Carolina State University, Campus Box 8109, Raleigh, NC 27695
[3] Department of Landscape Architecture, College of Design, North Carolina State University, Campus Box 7701, Raleigh, NC 27695

Fear Riverwatch, UNC-Wilmington, New Hanover County Planning Department and Soil and Water Conservation District, NCEEP, and citizens that received an EPA 319 grant to address stormwater management in the watershed. The focus of the grant was to install six BMPs throughout the Burnt Mill Creek Watershed, involve the community through education and involvement installing several residential BMPs, and water quality monitoring. BMP sites were identified by project cooperators and concerned citizens through community meetings and workshops.

BMP retrofits were installed at seven sites in the Burnt Mill Creek Watershed, four of which are described herein. A gravel parking lot at the Wilmington Family YMCA was a substantial source of sediment into Burnt Mill Creek. The gravel was replaced with porous concrete, two rain gardens, and grassed landscaping. The porous concrete and rain gardens improved infiltration and the rain gardens provided some pollutant removal trough filtration and plant uptake. Runoff from the parking lot at the Port City Java headquarters was intercepted by a sod bioretention area designed to reduce peak flow and improve water quality through filtration and plant uptake. A stormwater wetland was constructed to treat a 5.5 acre watershed, comprised mainly of single family residential, that drains through City of Wilmington owned open space, referred to as Mary Bridgers' Park, on the banks of Burnt Mill Creek. The wetland will reduce peak flow and provide treatment for the design storm.

The Bottom Neighborhood Empowerment Association (BNEA) is a group of citizens living in the bottom area who are striving to improve the quality of life in their neighborhood. The bottom area, called the bottom because it is one of the lowest points in the watershed, is a dense urban neighborhood where many residents have incomes lower than the median income of Wilmington and New Hanover County (Wilmington median income is $42,000, New Hanover County $41,000; areas in BMC between $22,000 and $34,000 depending on census tract) (NC Census, 2000). Cooperation with BNEA has led to several educational and LID retrofit opportunities including three educational workshops held in the community, installation of twelve rain gardens in community areas and private residences, and distribution of twenty-four 246 L (65 gallon) rain barrels.

Methods

Wilmington Family YMCA

Site Description

A gravel area at the Wilmington Family YMCA was being used as an overflow parking area for members of the YMCA (Figure 1). Because of the areas use for parking the gravel had become compacted such that is was nearly impermeable. Roof top runoff from half of the roof was also directed into the parking lot causing runoff from rain events to wash a substantial amount of sediment into the stormwater system. Two best management practices were used as a treatment system to manage stormwater on this site. Porous concrete was installed to stabilize the site and two rain gardens were used to treat the roof top runoff (Figure 2). Porous concrete will allow the rainfall that falls on the surface to infiltrate preventing runoff. Some storage is also available within and in the materials below the porous concrete. Rain gardens serve to store and infiltrate the stormwater removing pollutants through filtration and plant uptake.

Porous Concrete

The site was excavated 30 cm (1 ft) below the existing grade. Due to the concern for the rain fall infiltrating through the porous concrete impacting the foundation of the building, a buffer of at least 2.4 m (8 ft) was maintained between the building and the edge of the porous concrete. Typically a buffer of 3 m (10 ft) would be recommended, however, because of the extremely high infiltration rates it was determined that 2.4 m would be sufficient. Because

Figure 1 Gravel Parking Area

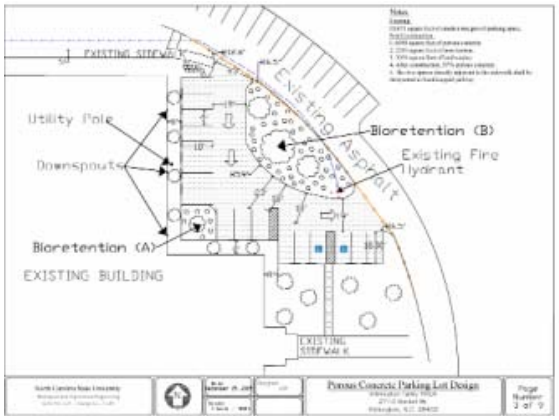

Figure 2 YMCA Design

the site was extremely sandy there was no concern about compacting the insitu soils. Fifteen cm (6 in) of washed no 57 stone was spread through the bottom of the excavated area. Thirty cm (12 in) curb and gutter was used to separate the porous concrete from the rain gardens and prevent vehicles from driving into the rain gardens. Two curb cuts were installed in the curb and gutter around each of the rain gardens to allow for over flow into the parking area utilizing the storage capacity of the porous concrete. Each load of porous concrete was inspected to verify that the moisture content of the porous concrete was at an optimum level. The porous concrete was then covered in plastic overnight to retain moisture and prevent it from drying to quickly. Immediately after the porous concrete was in place sod was installed around the edges of the parking area to stabilize the site and prevent soil from washing onto and potentially clogging the porous concrete (Figure 3). A standard concrete strip was installed between the asphalt and the porous concrete to provide a sturdy transition between the two materials. The porous concrete area was closed to all vehicles for 14 days as recommended by the Carolina Ready Mix Concrete Association (2004) to allow adequate time for the porous concrete to cure. The parking lot was then marked in accordance with standards enforced by the City of Wilmington.

Rain Gardens

Two rain gardens were installed to capture the runoff from half of the roof of the YMCA. Three downspouts were connected with 10 cm (4 in) plastic corrugated pipe to a drop inlet installed in the porous concrete parking area. The drop inlet was installed below the bottom of the downspouts so that water will not back up into the downspouts if the capacity of the rain garden is exceeded. The run off was gravity fed from the drop inlet into the rain garden through a 20 cm (8 in) smooth walled corrugated pipe. The rain garden was excavated in a bowl shape with the lowest elevation being 25 cm (10 in) below the level of the porous concrete parking area. The larger rain garden was 200 m^2 (1255 ft^2) and the smaller rain garden was 36 m^2 (390 ft^2). The two rain gardens are large enough to store and treat 2.5 cm (1 in) of rain fall from the roof. The rain gardens were both filled with 5 cm (2 in) of topsoil that was mixed into the top 20 cm (8 in) of the existing soil. Triple shredded hardwood mulch was spread 7.5 cm (3 in) deep and appropriate vegetation was added (Figure 4). Table 1 shows the vegetation that was planted in the rain gardens.

Port City Java (PCJ)

Site Description

Port City Java corporate headquarters were located on the bank of Burnt Mill Creek. The stormwater from the 1,435 m^2 (15,450 ft^2) parking lot drains directly into the creek. Two bioretention cells 110 m^2 (1180 ft^2) total were installed in the parking lot to intercept the stormwater before it flowed into existing storm inlets (Figure 5). The bioretention areas were

designed to store runoff from 2.5 cm (1 in) of rainfall. Bioretention areas have been shown to reducing peak flows (Davis, 2007, Hunt et al. 2008) and reduce pollutant concentrations and loads (Hunt et al., 2006, Dietz and Clausen 2006).

Bioretention Areas

Two bioretention cells were installed as a retrofit in an existing parking lot, therefore, 123.5 m^2 (1,330 ft^2) of asphalt had to be removed from the parking area (Figure 6). The cells were each in the shape of a "T." The tail was 1.5 m (5 ft) wide and expanded at the end to an area equivalent to two parking spaces. Because this was a retrofit, the parking lot had to meet city standards requiring that the distance between curb stops installed between spaces be no more

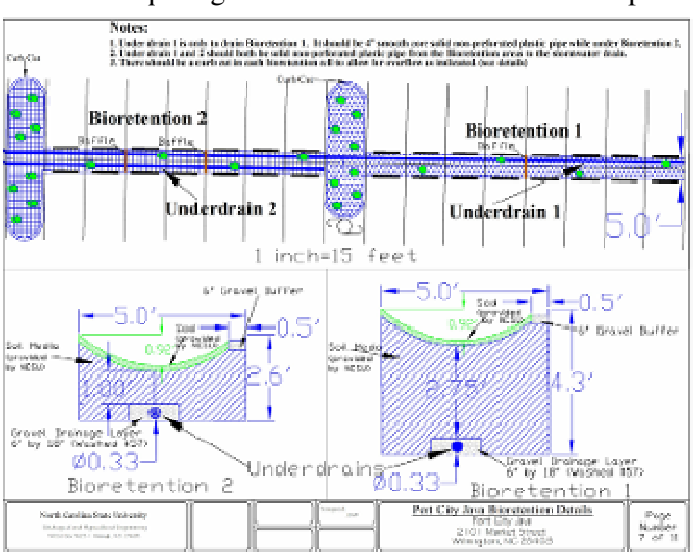

Figure 5 Bioretention Design

Figure 6 Asphalt Removal

than 1.5 m. The existing soil was sandy and was removed and temporarily stored on site to be later used in the bioretention area. Underdrains were installed in the cells at two different depths to collect filtered samples after rain events. The underdrains were installed 84 cm (2.75 ft.) and 30 cm (1 ft) below the surface of the bioretention area in the cells named PCJ Deep and PCJ Shallow, respectively. The underdrains were installed in a gravel layer 15 cm (6 in) deep and 45 cm (18 in) wide and were covered in a soil stabilization fabric (Figure 7). The underdrains were connected to the existing stormwater inlet.The soil removed from the cells was replaced to an elevation within 30 cm (1 ft) of the parking lot. A linear storage zone was formed and zenith zoysia sod was installed. A sodden verge was installed to slow the runoff from the parking lot and allow for pretreatment. Curb stops were installed along the edge of the cells to prevent vehicles from driving into the bioretention areas. The curb stops on the upper side of the bioretention areas were raised 6 mm (1/4 in) to allow runoff to pass beneath them, minimizing concentrated flow that may lead to erosion of the bioretention areas. Curb and gutter surrounded the top of the "T" of the bioretention areas to delineate the cells and prevent vehicles from accidentally driving into the bioretention areas. A curb cut was installed in the curb and gutter to allow for overflow into the existing storm drains when the capacity of the cells was exceeded. Footbridges were also installed across the bioretention cells to allow customers and employees easy access to both sides of the bioretention areas (Figure 8). A dwarf variety of wax myrtle was planted in the cells to provide some woody vegetation for diversity and aesthetic purposes. The dwarf variety was chosen so that the view of the Port City Java building would not be obstructed.

Figure 7 Underdrains

Figure 8 Bioretention Cells

Mary Bridgers Stormwater Wetland (MB)

Site Description

Mary Bridgers Park is an area owned by the City of Wilmington that is classified as open space by the city. A 2.2 ha (5.5 acre) drainage area consisting of single family residential drains through the park before entering Burnt Mill Creek. Because the area was designated by the city as open space, there were no design constraints for the size of the wetland and, therefore, was sized appropriately to treat runoff from the 2.5 cm (1 inch) rain event. The 800 m^2 (8,605 ft^2) stormwater wetland consisted of 22% deep pools, 29% shallow water, and 49% temporary inundation zone (Hunt et al. 2007). The pools were 0.75 m (2.5 ft) deep and the shallow water areas were 10 cm (4 inches) to 15 cm (6 in) deep at normal pool. Burnt Mill Creek has had elevated bacteria levels in the area of Mary Bridgers Park (Mallin et al. 2006); therefore, the shallow water and temporary inundation areas were increased to promote bacteria removal (Figure 9). The level of the water in the wetland was controlled by an adjustable outlet control structure. Weir boards were installed in the outlet structure such that water is ponded to a depth of 30 cm (12 inches) in the wetland following rain events.

Wetland Construction

Construction began at the outlet structure and progressed to the inlet taking precautions to ensure that the equipment did not compact the finished surfaces. The banks and all disturbed areas outside the wetland banks were covered with a straw mat with a biodegradable net and seeded with a Bermuda mix (Figure 10). More than 3,500 plants were planted by volunteers from the surrounding neighborhoods including 4 cypress tress.

Figure 9 MB Stormwater Wetland Design Figure 10 MB Wetland After Construction

Residential Practices

Two residential practices, rain gardens and rain barrels, were installed at residences throughout the bottom area. Home owners interested in installing stormwater practices at their homes were initially identified at a workshop held in the bottom neighborhood. Site visits were conducted by NCSU and Cape Fear River Watch employees to evaluate the site and determine if a rain garden and/or rain barrel were appropriate.

Rain Garden Installation

Rain gardens were installed at eleven homes in the bottom area and at an assisted living home. Site visits were conducted to evaluate the impervious area that could be captured in a rain garden. The rain gardens were then sized and installed by the Cape Fear River Watch and their volunteers. A variety of vegetation was planted in the rain gardens. Rain gardens were installed to collect surface runoff in low spots on the property or roof runoff was routed into the rain garden by connecting the downspout using plastic corrugated pipe. An example of the rain gardens that were installed is presented in Figure 11.

Rain Barrel Installation

Rain barrels can be utilized to collect roof top runoff during rain events and can be used for irrigation between storms. Twenty four 246 L (65 gallon) rain barrels were distributed to home owners throughout the bottom area. Gutters were required for the rain barrels and were not covered by the grant funding. Homeowners had to demonstrate a demand for the water in order to qualify for the rain barrels. The rain barrels were installed by the homeowners at the end of an existing downspout (Figure 12).

Data Collection

Port City Java

Inflow volume was calculated based upon watershed characteristics and rainfall data recorded at the site. An ISCO rain gage was used to measure rainfall and trigger an ISCO 6712 sampler. The sampler was enabled and began taking samples when water was detected and took samples with every 3.8 mm (0.15 in.) of rain. A steel “trough” was constructed to pool a small amount of water at the edge of the parking lot so a sample could be taken. The location of the inlet sample was selected so that an area representative of the watersheds of

Figure 11 Residential Rain Garden

Figure 12 Residential Rain Barrels

both bioretention systems could be intercepted. To monitor outflow from the underdrains, steel weir boxes were constructed and mounted inside the concrete drop inlet, where underdrains daylighted, for both bioretention systems. Effluent flowed over a 30-degree weir plate for measurement.

ISCO 730 bubbler modules were used to measure the depth of flow over the weirs and calculate flow rate. The bubblers triggered ISCO 6712 automatic samplers to take flow-weighted composite samples for the storm. The sampler received pulses from the bubbler each time a pre-defined volume of water passed over the weir and then took a sample. Runoff from storm events up to 25 mm (1 inch) in size was expected to be fully captured by the bioretention cells.

Results and Discussion

Port City Java

Water quality results from the Port City Java Bioretention area are presented in Table 2. The bioretention cells showed some pollutant reduction except for fecal coliforms, Enterococcus, nitrate nitrite (referred to subsequently as nitrate), and ortho phosphorus (OP). The concentrations of OP entering the bioretention area are relatively low, and it is difficult to obtain significant reductions from these concentrations. The increase in nitrate is somewhat

Table 2 Concentrations and Removal Efficiencies for PCJ

Concentration	Median Influent	Median Effluent (Shallow n=7)	Reduction Efficiency	Median Effluent (Deep n=8)	Reduction Efficiency
Fecal (CFU/100mL)	5650	6132	-9%	2737	52%
Entericoccus (MPN)	272	692	-155%	460	-69%
TKN (mg/L)	1.88	0.56	70%	0.42	77%
NO_3&NO_2 (mg/L)	0.17	0.31	-81%	0.47	-176%
TN (mg/L)	2.05	0.87	58%	0.90	56%
NH_3-N (mg/L)	0.10	0.04	59%	0.03	68%
TP (mg/L)	0.28	0.19	34%	0.12	59%
Ortho P (mg/L)	0.03	0.07	-112%	0.02	22%
TSS (mg/L)	157.71	17.69	89%	11.00	93%
PAH (ng)	459	112	76%	39	91%

expected due to the fact that the bioretention is designed to dry and remain in an aerobic state.

The fact that there is an increase in fecal coliform bacteria and Enterococcus indicates that the bioretention area may not be drying out completely as bacteria thrive in damp environments. This is somewhat contradictory to the explanation for the increase in nitrate. The effluent water could also be contaminated by water from Burnt Mill Creek, although there is no data to show that the creek impacts the outlet of the bioretention. The bioretention areas did perform well in the area of TSS removal as expected. There was also a significant reduction of PAH's. Concentrations of PAH's were only detected in the first two storms and were undetectable in the remaining storm events. The parking lot was seal coated immediately prior to the completion of the bioretention project. Any PAH's in the seal coat may have been flushed during the first few events. There were also some differences in the concentration reduction efficiencies between the shallow and deep cells. The deep cells showed greater reduction efficiencies for each pollutant except for nitrate and TN. The greater reduction in fecal bacteria and increase in nitrates indicates that the deeper cell dries out at the surface more often than the shallow cell. Because of the proximity to Burnt Mill Creek it is possible that the water from the creek influenced the outlet of the shallower cell although there are no data to support this theory.

When the effect of the reduction in volume from the shallow bioretention is considered there is a reduction in each pollutant except for Ortho P (Table 3). Similar results were found in the load reductions form PCJ Deep (Table 4). The deeper cell showed a slightly greater volume reduction. This, in conjunction with greater concentration reductions, showed reductions in each pollutant in the bioretention cell.

Table 3 Pollutant Load from PCJ Shallow

Shallow Load (n=10)	Median Influent	Median Effluent	Reduction Efficiency
TKN (g)	15.0	2.8	81%
NO_3&NO_2 (g)	2.6	1.7	34%
TN (g)	17.7	4.5	74%
NH_3-N (g)	0.8	0.2	71%
TP (g)	2.4	1.0	58%
Ortho P (g)	0.2	0.3	-44%
TSS (g)	1551.7	87.3	94%
PAH(mg)	7.6861	0.2323	97%
Water Volume (L)	125248	61250	51%

Residential Practices

The rain garden and rain barrels were offered to home owners in the bottom neighborhood at no cost to them; however, their property had to be suitable for one of the practices, and they had to agree to maintain them after the grant ended. There had to be a defined drainage path where runoff could be intercepted by a rain garden or gutters where a downspout could be routed into the rain garden. Wilmington, being in the coastal plain, is very flat and several of the homes did not initially meet the criteria. Many residents in the bottom made the financial investment ($100 to $300) to install gutters on their homes in order to meet the criteria to receive a rain garden or a rain barrel. Home owners have taken ownership of their rain gardens in a variety of ways including adding decorative borders and supplementing the vegetation that was provided with additional plants from their surrounding landscaping.

Table 4 Pollutant Load from PCJ Deep

Deep Load (n=11)	Median Influent	Median Effluent	Reduction Efficiency
TKN (g)	28.4	5.0	82%
NO3&NO2 (g)	6.5	4.8	26%
TN (g)	34.9	9.8	72%
NH3-N (g)	2.1	0.4	80%
TP (g)	5.0	1.6	69%
Ortho P (g)	0.5	0.3	34%
TSS (g)	2,352.0	134.3	94%
PAH(mg)	19.57	0.6045	97%
Water Volume (L)	313580	138742	56%

A survey conducted by a graduate student in the College of Design Landscape Architecture Department at NC State University found that all of the residents involved in the residential project who responded to the survey were educated about stormwater runoff and water quality as a result of their involvement in the residential project. The survey revealed that the majority of the survey respondents involved in the Bottom Neighborhood Empowerment Association and the project were women above the age of 55 and long time residents of the community. It is important to note that the residential project generally excluded people who did not own their homes (100% of respondents owned their homes). Many of the respondents indicated that they shared what they learned with their neighbors, a significant accomplishment in accordance with the goals of the overall project. The survey also indicated that the residents responded to the emphasis placed on the beautification of their property using rain gardens rather than just stormwater management. According to the survey, word-of-mouth was the most effective tool for informing the residents about the BNEA and the residential program. Many of the homeowners who requested a rain garden or a rain barrel did so after seeing the practice installed at a neighbor's home. Also, visual information, such as fliers, captured people's attention. All of the respondents that participated in the residential program had some affiliation with the BNEA and three of the respondents became involved in the BNEA after they first became involved in the residential stormwater retrofit program (McCoy, 2007)

Conclusion

The Port City Java Bioretention area appears to be performing as expected based on the load reductions. There were higher than expected loads with respect to ortho phosphorus, however, the concentrations where low enough that reduction efficiencies may be difficult. The deeper cell showed greater load reductions indicating that the deeper media is more effective for pollutant removal including TSS, PAH, and pathogens where the pollutant removal generally occurs at the surface. The deeper cell may have greater capacity for infiltration allowing the surface to dry more than the surface of the shallower cell. Moisture probes have been added at the surface of both cells to determine if moisture content at the surface is a factor in pathogen removal.

Each of the stormwater BMPs installed has been well received by each of the land owners. All of the land owners have agreed to maintain the BMPs on their property, and have been provided BMP management guidebooks that were published by the City of Wilmington's Stormwater Services. All of the landowners were aware that stormwater runoff is an issue that must be addressed but were uncertain of how to proceed. The survey that was conducted

revealed the necessity of public education in the community. One of the main goals of the project, public education, was most widely accomplished by focusing on the BNEA. A greater impact on stormwater can be made at a residential scale if an emphasis is placed on stormwater treatment practices that provide beautification rather than just stormwater impacts.

Acknowledgements

The authors would like to thank the Burnt Mill Creek action team for the continued efforts in the Burnt Mill Creek watershed. They would like to thank the USEPA and NC DENR for funding the project. They would also like to thank the City of Wilmington Stormwater Services and Alicia Herrmann for her efforts in data collection and the Cape Fear River Watch and Joseph Abbate for his efforts in coordinating the rain garden and rain barrel installations.

ABSTRACT

Outflow structures for stormwater detention basins can vary widely within a single watershed. The designs are often left to the whim of the local engineer. Why should there be such differences? This research attempts to discern the performance and efficiency of various typical and atypical weir shapes. To accomplish this task, a scale model of a stormwater detention basin was constructed with removable outlet weirs. The physical model was calibrated using typical weir structures (e.g. rectangular, V-notch, submerged orifice, etc.) in which accepted numerical models exist to calculate outflow discharge. Empirical stage-discharge relationships were then calculated for the atypical weir structures (e.g. stepped notch, combinations of typical shapes, etc.). The atypical weirs simulated herein represent the range of outlet structure designs located in the Upper Mantua Creek watershed, Gloucester County, New Jersey. This area of New Jersey has experienced large urban growth in the past 40 years, and many of the existing basins were not designed for the current runoff volumes they experience. Within this 7.3 square mile watershed, there are currently 61 stormwater basins and more than 50 different outlet structure designs. The ability of each stormwater basin to pass or detain a given flow event can now be determined empirically. From these data, appropriate retrofit designs can be implemented.

INTRODUCTION

As urbanization increases within watershed boundaries, the effectiveness of stormwater detention basins to attenuate peak-flow rates also becomes increasingly more important. Common characteristics of the outlet structures within the detention basins include a low-flow orifice near the base of the structure, a weir or orifice opening above that for attenuating normal runoff volumes, and emergency overflow spillway to pass the extreme events. (Akan and Houghtalen 2003). The shape and size of the weir or orifice outlets for the normal runoff events can vary widely within a single watershed. As new outlets are designed and built, or old outlets re-tested for their efficiency at passing the newer, higher runoff volumes, a simple model is needed to accurately assess their capability. This research describes an effort to create a physical scale model of a detention basin with varying weir configurations to analyze the performance of any outflow structure.

The basin outlets modeled in this study are examples of the range of designs found within the Upper Mantua Creek watershed (Fig. 1). There are currently 61

stormwater basins and more than 50 different outlet structure designs within this watershed. Located in southwest New Jersey, Mantua Creek flows northwest towards its junction with the Delaware River. The study area encompasses about 7.3 square miles and is contained within five municipalities: Washington Township, Glassboro Borough, Pitman Borough, Mantua Township, and Monroe Township. The topography of the watershed is relatively flat with a few rolling hills at the headwaters. Prior to the 1970's, the land use was dominated by agriculture. Based upon land use data from the New Jersey Department of Environmental Protection (NJDEP), over the past forty years, urban development has increased from 45% to 67% of the watershed while agriculture has decreased from almost 30% to less than 10%. This decrease in pervious land cover has led to increases in peak runoff volumes in Mantua Creek.

Figure 1. Location of the Upper Mantua Creek Watershed (in black) in New Jersey

RELEVANT THEORY

Most outflow structures in detention basins can be considered as sharp-crested weirs (SCW). For typical SCW configurations, theoretical numeric solutions for discharge relationships exist in the literature (e.g., Ackers, et al. 1978). These discharge relationships are dependent on the depth of ponding above the weir crest. For a rectangular SCW, the outflow discharge is a function of the depth to the 3/2 power (Eq. 1a) and the effective width of the over-fall (Eq. 1b). For a V-notch SCW, the discharge is a function of the depth to the 5/2 and the internal angle (Eq. 2). Flow through a submerged orifice is a function of depth to the 1/2 power and the size of the orifice (Eq. 3).

$$Q = C_d \frac{2}{3} \sqrt{2g} B' H^{3/2} \tag{1a}$$

$$B' = B - 0.1nH \tag{1b}$$

$$Q = C_d \frac{8}{15}\sqrt{2g}\tan\left(\frac{\theta}{2}\right)H^{5/2} \tag{2}$$

$$Q = C_d\sqrt{2gH}\,A \tag{3}$$

Where, Q is the discharge, C_d the discharge coefficient, g the acceleration due to gravity, B' the effective width of the weir, B the channel width, n the number of contracted sides (0, 1, or 2), H the depth of the flow above the weir crest, Θ the internal angle of the V-notch in the weir, and A the cross-sectional area of the orifice.

For all theoretical discharge solutions, a discharge coefficient (C_d) is used to amend the flow calculations. This discharge coefficient can vary with the type of weir structure, and accounts for errors in the theoretical derivations due to assumptions about the pressure distributions, water surface profile, and viscous effects (Chin 2006). For a rectangular SCW, the discharge coefficient is a function of the flow depth and weir height (Eq. 5). For a triangular SCW, the discharge coefficient (Eq. 6a) is a function of the Reynolds Number (Eq. 6b) and the Weber Number (Eq. 6c) (Chin 2006).

$$C_d = 0.611 + 0.075\frac{H}{H_w} \tag{5}$$

$$C_d = 0.583 + \frac{1.19}{(Re\,We)^{1/6}} \tag{6a}$$

$$Re = \frac{g^{1/2}H^{1/2}}{\upsilon} \tag{6b}$$

$$We = \frac{\rho g H^2}{\sigma} \tag{6c}$$

Where, H_w is the height of the weir crest above the channel bottom, Re the Reynolds Number, We the Weber Number, υ the kinematic viscosity of the fluids, ρ the fluid density, and σ the surface tension of the fluid.

For submerged orifices, the discharge coefficient is required because of the vena contracta phenomenon, which is due to the fluid's inability to turn a sharp corner (Munson, et al. 2006). This value is usually assumed to be 0.61 for the type of model outflow structure present in the experimental basin (Mays 2005). Often, discharge equations for weirs may combine the gravitational and numeric constants with the discharge coefficient to create an all-encompassing weir coefficient, C_w. It is this weir coefficient that will be compared and calibrated for the physical model presented herein, and discussed in the following sections.

EXPERIMENTAL METHODOLOGY

Outflow discharges for basin outlet weirs are typically determined using numerical models.

In order to accurately depict the outflow through the weirs in this study, a scale model detention basin was built with replaceable weir configurations (Fig. 2). The walls of the model basin were constructed out of Plexiglas and the weirs from 0.25-in thick aluminum plates. The dimensions of the model basin are 36-in x 36-in x 22-in with a 6-in high weir structure, which provides a basis for varying length scales for comparisons to actual stormwater basins. The comparatively over-sized side walls (22 inches) prevented losses from splashing and spills (Fig. 2).

.

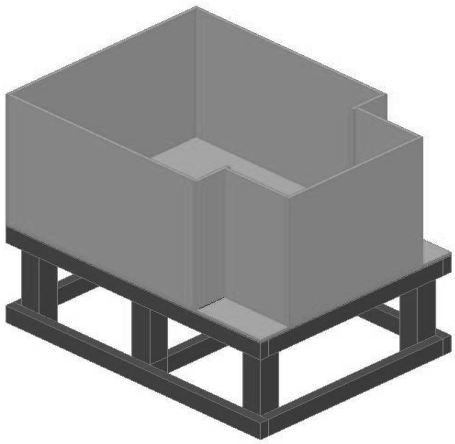

Figure 2a. Computer Rendering of Model Detention Basin.

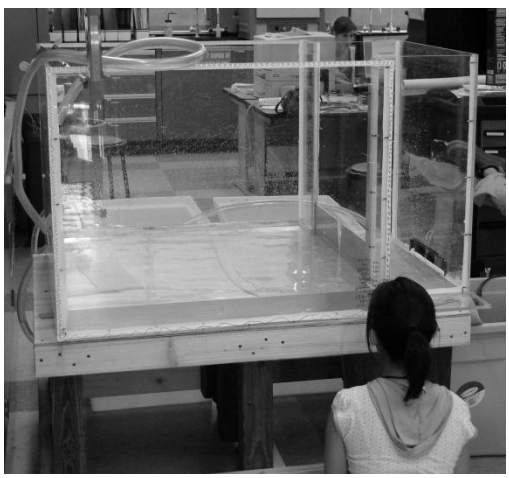

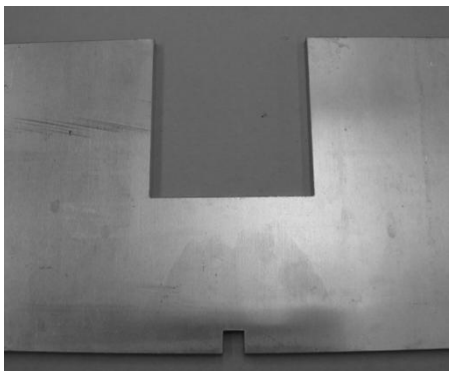

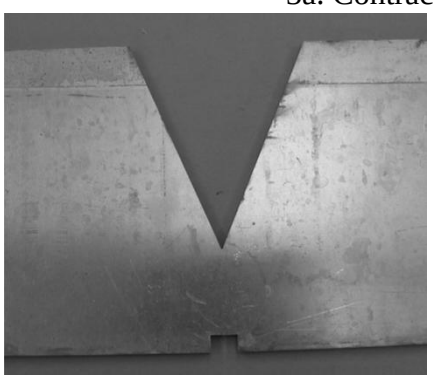

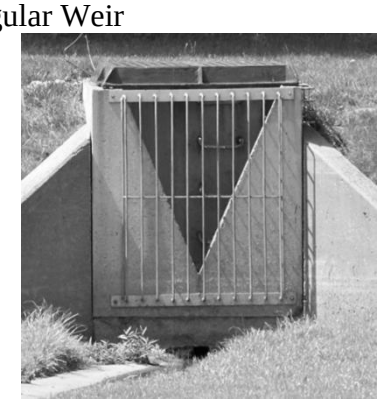

Figure 2b. Measuring Discharges in Model Detention Basin.

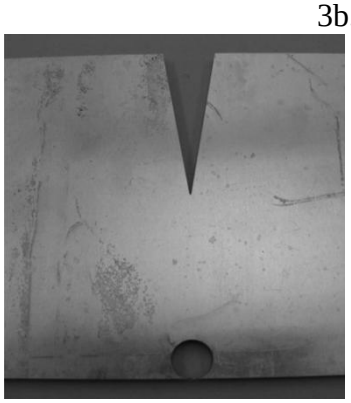
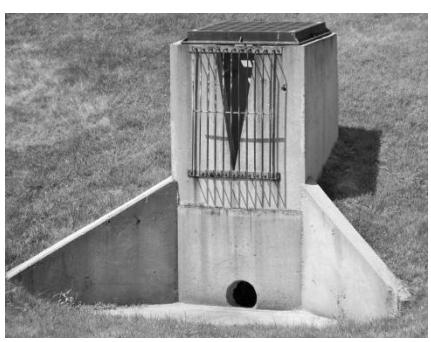
Of the 61 stormwater basin designs in the Upper Mantua Creek, six distinct outflow weir configurations were chosen to be modeled for this study. Some of the weirs chosen represent typical configurations, such as a contracted rectangle, V-notch, and a submerged circular orifice (Fig. 3). These "typical" configurations were chosen to validate the model using accepted numeric equations (Eqs. 1, 2, and 3). The other weir shapes modeled here represent atypical configurations (Fig. 4) that do not have simple numeric solutions.





Most basin outflow weirs are also equipped with low-flow orifices (e.g., Fig 3 a-c). These allow for small runoff events to pass through the basin unabated, while larger events will pond behind the outlets. The theoretical discharge calculations accounted for these low-flow outlets, and thus used a combination of Equation 3 with either Equation 1 or 2.

Figure 1. Typical Outlet Weir Configurations Used in the Scale Model.

4a. Keyhole Combination Weir

4b. Stepped Notch Weir

Figure 4. Atypical Weir Configurations used in the Scale Model

The flowpath through the model includes water being pumped from a reserve reservoir into the model basin, over or through the weir, and out an exit orifice into a catchment basin. To quantify the discharge rate of each weir structure, the incremental changes in storage volume behind the weir were measured visually over time with a depth gauge and a stopwatch (Fig. 2b). Each weir and discharge rate was modeled at least five times to ensure accuracy.

RESULTS & DISCUSSION

To calibrate the physical model, theoretical flows for the typical weir configurations (Fig. 3) were modeled using Equations 1-3. The empirical depth-discharge data measured for each scale model weir was then compared, and was modified with a varying discharge coefficient until the theoretical and experimental data matched. The overall shape of the empirical data fits very well with the theoretical data (Figs. 5 and 6), thus the coefficient modification only resulted in a shift of the data points.

Figure 5 represents the comparison of the theoretical depth-discharge relationship for a contracted rectangular weir (Fig. 3a) to the empirically collected

model data after the sensitivity analysis was performed on the discharge coefficient. Figure 6 represents the comparison for the wide V-notch weir (Fig. 3b).

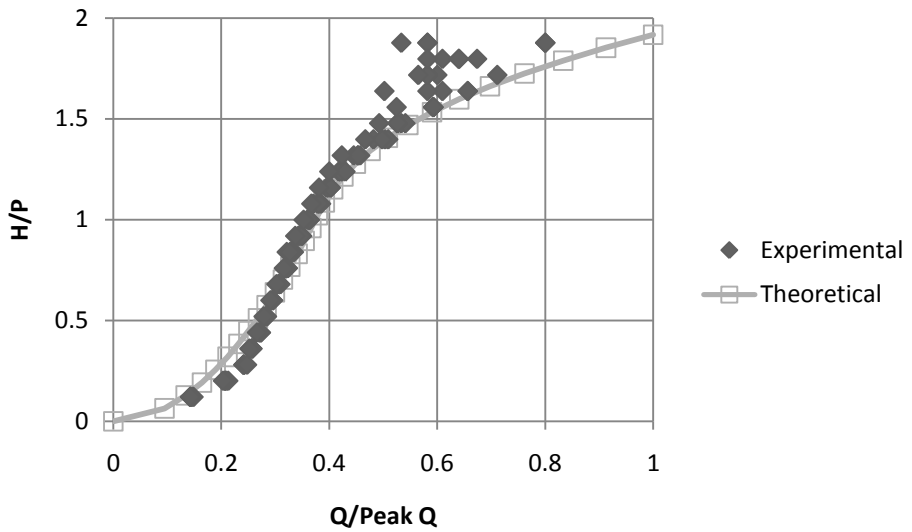

Figure 5. Relationship of Depth (normalized by weir height) to Discharge (normalized by peak discharge) for the Contracted Rectangular Weir (Fig. 3a)

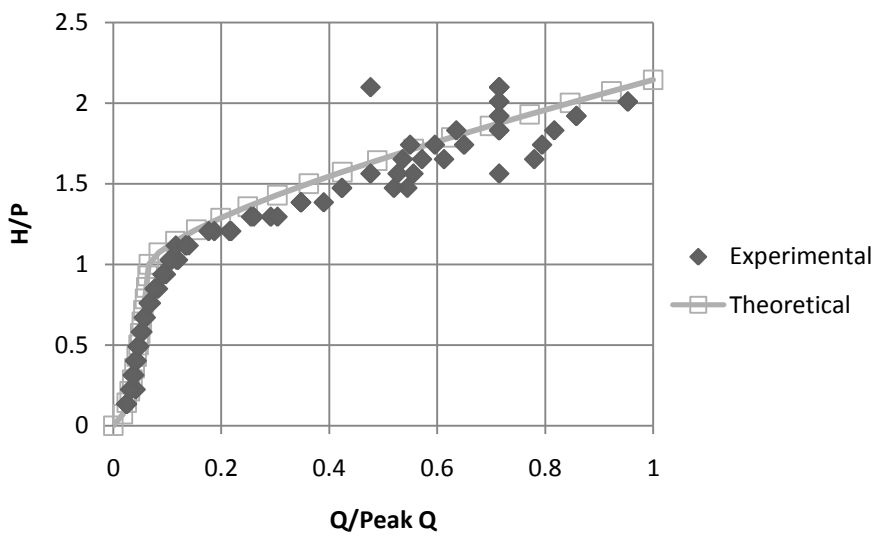

Figure 6. Relationship of Depth (normalized by weir height) to Discharge (normalized by peak discharge) for the Perched V-notch Weir (Fig. 3c)

A sensitivity analysis was performed on each of the typical weir configurations to determine their empirically-derived discharge coefficients (Table 1). The sensitivity analysis included the altering of only the discharge coefficient for the lower orifice of the outflow structure. This was done because the data for the theoretical and experimental outflow in the upper sections of each weir were in relative agreement already.

Table 1. Discharge Coefficients for Lower Orifices after Sensitivity Analysis.

Weir	C_d *Value*
Rectangular	2
Perched V-notch	1
Wide V-notch	2
Circular Orifice	0.61

The empirically-solved discharge coefficients listed in Table 1 are greater than normal expected values, which typically range from 0.5-0.7. Several factors could be the cause for this discrepancy. The first is that the available material constrained the width of the model weir plate to be 0.25 inches and the typical widths of the actual outflow structures are 6 – 8 inches. For the length scale factor based on the weir heights, the model weir width should be about 0.07 inches. It is unclear whether this factor is providing a significant difference in experimentation but will be further researched. Another factor that could potentially be skewing the experimental data is the material used for the model. The aluminum used in the model does not exhibit the equivalent scaled roughness compared to the concrete used in the actual outflow structures. The variable roughness's of these materials could cause some discrepancies and also need to be further researched.

Table 1 at least provides a range of C_d values with which to calculate the depth-discharge relationships for the atypical weir configurations (Fig. 4). Figure 7 represents the empirical data for the keyhole-shaped weir (Fig. 4a). Superimposed onto the data are the original design calculations provided by the local soil conservation district. The methodology for the original design values is unavailable, but the data do correspond fairly well to the empirical model data.

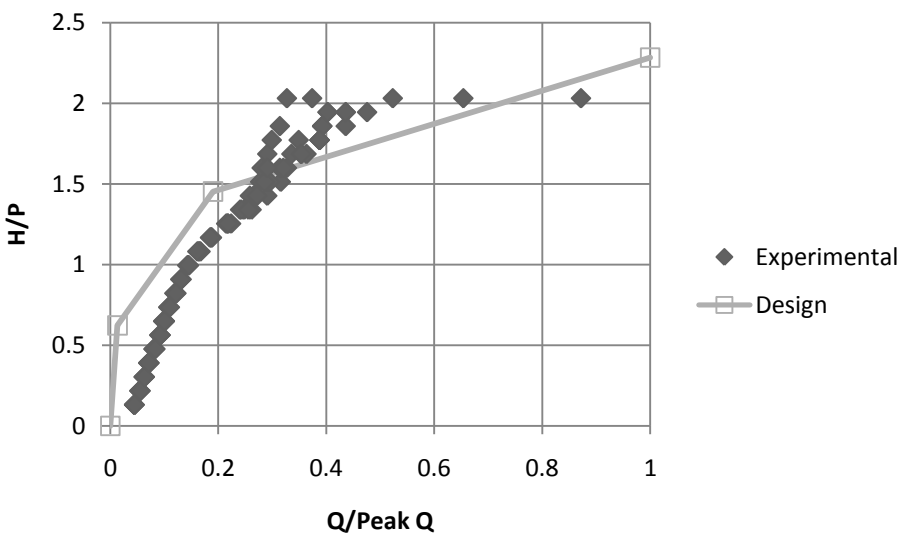

Figure 7. Relationship of Depth (normalized by weir height) to Discharge (normalized by peak discharge) for the Keyhole Weir (Fig. 4a)

Once the data presented in Figure 7 are determined to be accurate enough, a weir coefficient (C_w) for the upper section of the weir can be derived (i.e. the "keyhole" section). To determine this weir coefficient, the general weir equation, $Q = C_w\sqrt{H^3}$, is used. A plot of discharge versus $\sqrt{H^3}$ was created for each of the atypical weir structures. The slope of a linear trendline fitted to the data provides the weir coefficient for the upper section of the weir (Fig. 8). The depth, H, used for these analyses represent only the depth of flow above the upper weir crest, thus the non-zero value for H=0 accounts for the low-flow orifice.

The weir coefficient calculated for the Keyhole weir was determined to be 0.09 (Fig. 8) and for the Stepped Notch it was 0.12. These values may be lower than expected, but they might be offset due to the previously described theoretical discrepancies in the low-flow outlets.

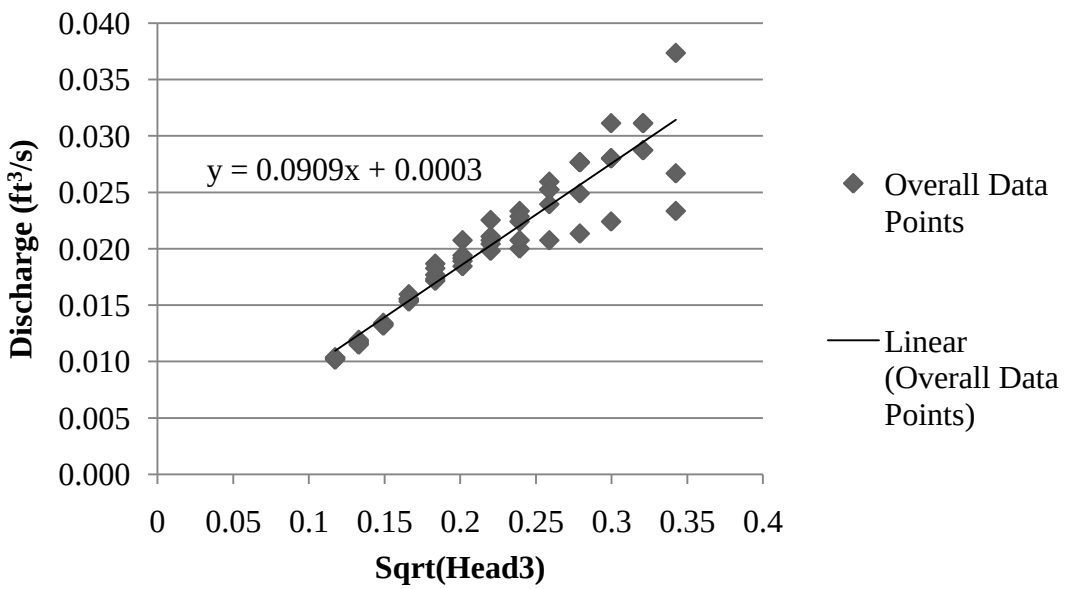

Figure 8. Experimental Data used to determine Discharge Coefficient for the Keyhole Weir.

CONCLUSIONS AND FUTURE WORK

Physically-based models of detention basin outlet structures are rare in hydrology research experiments. However, they could be a quick and effective method to predict their performance, especially if older structures are tasked to handle new and greater runoff inflow volumes. Using a physical model can help determine the efficiency of any new or old structure, and help to determine if any retro-fits are required for older structures.

The model presented herein represents a step forward in physically-based scale models. The calibration and validation of the model may not yet be perfect, but

overall results are in relative agreement, and any model discrepancies will likely be resolved soon.

Because the most common method for modeling detention basin outlets is the use of numerical models such as HEC-HMS (e.g., Emerson et al. 2005), the obvious future for this model study is to compare the physical scale model data to the numerical, computer-derived data. That study is currently underway.

Stormwater Infiltration Retrofits
Experience Gained Through Long Term Monitoring

R. G. Traver

Professor, Dept of Civil & Environmental Engineering, Villanova University, Villanova, 19085; PH (610)519-6754; email: Robert.Traver@Villanova.edu

ABSTRACT

This paper presents an overview of the experience gained through the design, construction and extended monitoring of multiple retrofit stormwater infiltration best management practices (BMP). Common design issues for retrofit infiltration BMPs include utilities, hydraulic inflow and outflow paths, and compacted urban soils. Assuming these constraints are addressed, the resulting project should work at least as well as any newly constructed BMP.

The experience of long term monitoring of multiple BMPs allows the researcher to contrast performance and design features for both individual storms and seasons. Simply building new BMPs in a public setting introduces this concept to the professional community and the public. Findings from a suite of project reports, journal and conference proceedings, and student work is presented.

INTRODUCTION

While information on the design of stormwater infiltration Best Management Practices (BMP) for newly urbanizing sites is becoming available, retrofitting existing sites is still somewhat of a mystery. Compacted soils, limited hydraulic pathways, existing utilities all complicate the design requiring the designer to be innovative, and to understand the opportunities that are available. Additional perspective of the character and performance of these infiltration BMPs has been gained through long term monitoring of the sites through the Commonwealth of Pennsylvania's 319 non point source program (Emerson and Traver 2008, Traver 2008). A major benefit of continual monitoring is the marriage of observation and performance data, and a continuum of research, with each component building upon the past. This paper will first review three individual infiltration BMPs, and conclude with overall conclusions based upon the body of work.

RETROFIT INFILTRATION BMPS

Funding for developing the BMP park concept, as well as for construction of the BMPs was provided by Pennsylvania Department of Environmental Protection through Section 319 Nonpoint Source Pollution Program, Pennsylvania's Growing Greener initiative, and donations from the Villanova Urban Stormwater Partnership (VUSP) corporate partners (Traver 2002a, 202b, 2004, 2005). As of the submittal date of this publication, the park includes a stormwater wetland, two green roofs, an infiltration trench, two bioinfiltration BMPs, three pervious pavement sites, and a

historic seepage pit. Construction is expected in the immediate future on several bioretention / bioinfiltration type BMPS to include a bioswale. Each of these sites with the exception of the historic seepage pit are retrofits, each with its own set of challenges and lessons learned. Information on each project can be found through the VUSP website (http://www.villanova.edu/VUSP).

Bioinfiltration BMP Two Bioinfiltration BMPs are now on campus. The first was constructed in the summer of 2001 from an existing traffic island (Traver 2002b). Funded by the Pennsylvania Growing Greener program, the site has been monitored since 2003. The facility was designed to capture and infiltrate the initial first 2.5 cms of rainfall from the site, but routinely exceeds those performance criteria. A second newer bioinfiltration site has been built as part of a university expansion of the Villanova Pavilion. It was built to meet state requirements for stormwater management, and to partially replace an existing detention basin.

Retrofit lessons learned on this site included hydraulics of how to get the flows into the bowl of the traffic island, outflow, utilities, and compacted soils. First and foremost the existing utilities were located. Utility lines, and lighting, are routinely included in green strips in existing parking areas. These also can be an asset to the project for monitoring (communications / power). The hydraulics of the site was the second challenge. Clearly the capture of flows off the impervious surface is key. This first flush is the most frequent and dominate source of runoff, and capturing it maximizes the capture efficiency of the BMP (Batroney 2007).

For the traffic island site, two methods of ingress were used. First adjacent runoff was directed into the site using curb cuts, located through observation during storm events. As part of this process, an inlet was filled with rock and paved over to capture more surface inflow. A second inlet was located adjacent to the site that carried flows from multiple inlets upstream. By insuring that the bottom of the inlet was lower than the BMP bowl, flow was redirected by cutting through the back of the inlet, installing a culvert into the BMP, and constructing a redirection barrier within the inlet. The barrier also acts as a weir, allowing overflow to be directed through the original site drainage system to a detention basin. Similar concepts were used for the Pavilion site, except an inlet structure was used for overflow, connected by piping to a new underground detention structure. Note that in both cases, the great majority of runoff is infiltrated and never reaches the detention structure.

In both cases, compacted soils were a design consideration. By insuring that the depth of excavation was deeper then the compacted layer, no difficulties were encountered. The excavation needed for the bowl and made soils was well below any compacted layers.

Figure 1 - VU Bioinfiltration BMPs (Traffic Island Left – Pavilion Right)

Infiltration Trench Constructed in August 2004, the project is designed to capture runoff from an elevated parking deck and then infiltrate it through a rock bed into the ground (Traver 2002b). Funded through the state / EPA 319 program, this BMP presents some unique possibilities. It is the only site available with a 100% impervious drainage area, and is purposely undersized to speed aging of the site. The void space in the rock is filled quickly at around 0.5 cms. It is postulated that the bottom of the trench has sealed and all infiltration occurs through the sides (Emerson 2007, Emerson and Traver 2008)

Retrofit lessons learned on this site again included hydraulics of how to get the flows into the bowl of the traffic island, outflow, utilities, and depth to bedrock. In this case depth to bedrock dictated the location. As the site was in between two separate buildings that were constructed at different times, and had legacy utilities, locations of water, power, telephone, sanitary and storm sewer dictated the footprint precisely. An adjacent tree was expected to be damaged, but in the long run benefited from the runoff infiltration. Depth to bedrock also drove the site selection. Core samples at the original site showed rock close to the surface. By moving only 20 feet down slope, the depth to bedrock tripled enabling the project. Compaction was not an issue due to the depth if the infiltration trench.

As the runoff was captured from an elevated parking garage, it was relatively simple to reroute the piping under the parking deck to the infiltration trench, and to create measurement points. Overflow though was more of a challenge. A small pipe was routed close to the surface exiting to an adjacent inlet. Larger storms exit as sheet flow rising through the EP Henry Ecopavers that are the cover of the Infiltration Trench. Note that these pavers are designed to permit infiltration.

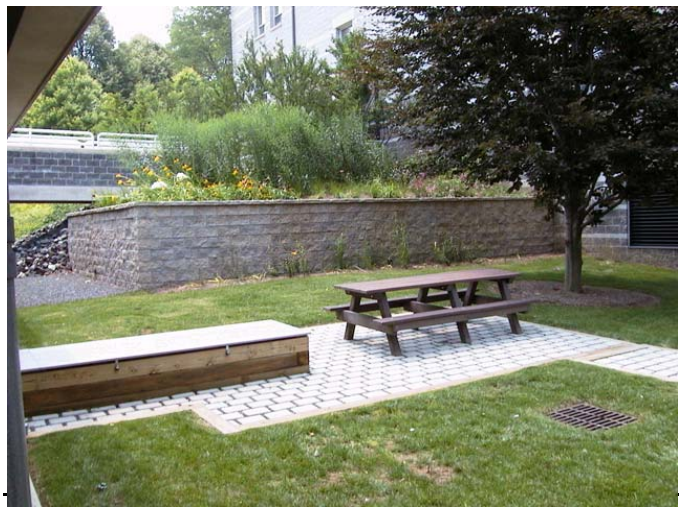

Figure 2 - VU Infiltration Trench BMP

Pervious Pavements

The original Porous Concrete site has been joined by two other pervious pavement sites to include a pervious asphalt site, and a Porous Concrete / Pervious Asphalt. This discussion focuses on the original site constructed through the 319 program in summer 2002 (Traver 2004). Note that due to the size of this project it had to be constructed in the summer as it is a pedestrian mall in the center of the campus. Noise and service interruption are a concern for retrofit projects. The grant was to create a porous concrete infiltration facility in an existing central paved area on the Villanova University campus. The site is much larger than the previous two projects, capturing flows from the roof top and the pervious surface. The retrofit design issues of utilities, compacted soils, and hydraulics was actually much simpler due to the scale of the project. There was much less uncertainty over utilities as in general they were relocated, and the depth of the beds was well below any compacted layer.

The hydraulics of the collection system was again the prime design feature. As the site was surrounded by buildings, runoff was directly connected to the underground rock bed, plus of course the infiltration through the porous surface. Due to the slope of the site, the rock bed was designed as three rock beds each separated by an earthen dike. The design engineer installed a collection system immediately below the surface to prevent overflow which was routed to the existing downstream stormwater collection system. Note that the designer also included an under drain which in hindsight was either not needed, or should have included a valve to restrict flows between beds. Note that there were several surface materials issues at the site that have previously been reported (Traver 2004). Since that time the pervious concrete industry has matured, and our second site had no similar issues.

Figure 3 - VU Pervious Pavement BMPs

PROJECT FINDINGS

When researching the performance of multiple BMPs monitored continuously over multiple years, the resulting findings are greater than the sum of the parts. The ability to contrast observations and results, plus the ability to compare past work provides insight into the mechanisms and characteristics of the BMPs. The below findings from the 319 program are an overview of the results from multiple student and faculty research projects over the last 5 – 7 years. Note: These findings are the author's interpretation of accumulated results from the combined research projects support through the 319 EPA National Monitoring Program, Growing Greener, and CiCEET funding, as presented in journal articles, masters thesis's, and research project reports as listed in the references.

Major Findings

- Proof of Concept: Results from constructing, operating, and monitoring infiltration practices has proven that these devices are an effective Stormwater Management Practice in removing pollutants and volume from the surface stream.

- Effectiveness of Small Storm Capture: The efficiencies of designing for small storms has been proven. Results from the infiltration trench, pervious concrete, and bioinfiltration traffic island have shown that because the majority of the regions rainfall is produced by smaller storms, BMPS designed for smaller storms are extremely effective in reducing runoff volume and capturing surface pollutants. If has also been shown that infiltration occurs throughout the storm event, and should be included when estimating removals.

- Variability of Infiltration Rate: Results from all three sites have shown that while the rate of infiltration is consistent over an individual storm event, it is dependent on season / temperature and thus considerable variation is seen

when looking across a year of events. Several papers have been published that relate at least part of this variation to the change in viscosity of the water. Note that on a yearly basis, this variation has not diminished the BMP's performance, but does impact municipal inspection / monitoring programs.

- Variation in Pollutant Loading Rate / First Flush: One result has been that the runoff from contributing areas has been found to vary considerably in quality. For example, roof top runoff from taller buildings has been found to be remarkably free of TSS, which makes it an ideal candidate for infiltration. The same was found for the Pervious Concrete site which is a pedestrian area. Contrasting the Infiltration Trench has extremely high loading of pollutants.

- Longevity: A study based upon the results of this project has shown that there is no statistical reduction in performance for the BioInfiltration Traffic Island after 7 years, or from the pervious concrete site after 4 years. In fact there is every expectation that these sites will remain effective for a very long time. Longevity is supported through proper design, construction, and location (characteristics of the drainage area). For the bioinfiltration BMP, freeze thaw, and vegetation are aiding in maintaining the infiltration capacity. For the pervious concrete BMP, the lack of suspended sediments in the rooftop runoff, the filtering through the pervious concrete, and the large bottom area support its longevity. Conversely a considerable change in performance has been seen at the infiltration trench due to the theorized clogging of the bottom layer. It should be noted, that it is estimated that when compared to the design recommendations of the Pennsylvania BMP manual, the infiltration trench has experienced a pollutant load closer to over 80 years when compared to the Pennsylvania BMP Manual specifications, and remains extremely effective (Emerson 2008, Emerson and Traver 2008).

Indirect Benefits

Besides the engineering research findings, the construction and research on the performance of BMPs has multiple indirect benefits.

- Introduction to the Profession: These sites have introduced the concept of infiltration BMP's to both the profession and the public across Pennsylvania and beyond. Lessons Learned as to design, maintenance, and expected performance are disseminated through publications, presentations, tours, and the project internet site.

- Catalyst for Advanced Studies: Through the continuing data stream, more advanced studies are using this data. Projects with CICEET sharing data with University of Maryland and NC State are underway, as are funded projects with William Penn working with Temple University.

- Catalyst for Studies by others: The data submitted to the ASCE – EPA BMP National Database is supporting other studies nationwide on BMP Performance.

- Education: The graduate and undergraduate students who are supported on these grants enter the workforce as engineers with advanced understanding of stormwater design to mitigate nonpoint source pollution. In addition, these results are used in undergraduate and graduate engineering classes at Villanova, supporting the advancement of the profession, and aiding in the protection of the water resources of the Commonwealth.

CONCLUSION

Retrofitting infiltration BMPs in the urban environment is clearly possible and is an effective strategy to reduce the impact of past urbanization. While the fundamental engineering design principals are the same as for new construction, the site design may be limited by hydraulic gradients and utilities. This may also be an opportunity as the existing drainage structure can be incorporated as inflow / outflow to the infiltration BMP. Note that in some cases retrofit designs may actually be an easier process, especially compared to new projects with large cuts and fills.

The value of multiple continuously monitored sites is clear. The variability of performance, longevity, effects on the surrounding environs, and issues to include maintenance and longevity can only be addressed with long term records. The multiple sites allow direct comparison of design components.

These results confirm the need to continue studying the operation of these BMPs. The relations between site characteristics, load and volume to BMP design are still poorly understood. As the understanding of the processed involved advance, the VUSP expects that the design methods used for these BMPS will change, to more accurately represent the hydrologic, chemical and biological processes involved.

ABSTRACT

This paper describes the development of a tool that can be used to determine cost effective stormwater management strategies on a watershed scale, using various structural stormwater best management practices (BMPs). The tool is designed for application at the planning level and is simple enough to be used and understand by both technical and non-technical personnel in the stormwater management field. With relatively few required user inputs, the tool estimates the following:

- BMP effectiveness; reported in terms of the reduction of annual pollutant loading to the receiving water
- BMP whole life cycle costs; reported as the net present value of all costs incurred over the economic life of the BMP
- BMP cost effectiveness, reported in terms of cost per mass of pollutant removed from the receiving water

The tool is applied to a theoretical problem where a municipality must reduce pollutant loads from an existing, highly-developed urban setting. Several scenarios that meet the regulatory objectives are determined using different BMP technologies, and the differences in whole life cycle costs for each scenario are presented. The results show how the tool is useful in making better decisions based on the cost effectiveness of BMPs. In addition, the results show the importance of including long-term costs of maintenance and rehabilitation in evaluating cost effectiveness. *NOTE*: *At the time of writing this paper and preparing the example application, the tool was still in "beta" version. The results and methods used here may differ from those presented at the conference and in subsequent versions of the tool. Please contact the authors for the most up-to-date versions of the tool and documentation.*

INTRODUCTION

Structural best management practices (BMP) are constructed facilities that prevent, capture and/or treat stormwater runoff. There are many types of structural BMPs available, each with their own advantages and disadvantages. Over the past 20-30 years, hundreds of thousands (perhaps even millions) of BMPs have been constructed throughout the United States at a considerable cost to the public. In most cases, the decision to select one BMP over another in a given situation was based on site-

specific and/or short-term constraints such as construction costs, land availability and/or the acceptance level of a BMP by the regulating authority (based on "proven" BMP performance). However, the state of the stormwater management planning practice is evolving, and it is becoming better understood that the decisions made to select certain BMPs will have broader, more long-term ramifications that include (1) the effectiveness in the protection of the receiving waters, (2) long-term costs of operating and maintaining the BMPs, and (3) administrative costs that the municipality will need to budget for over the years to make sure that the BMPs deployed within its boundaries continue to function as originally designed.

The primary objective of this tool is to provide professionals and decision makers with facts and fiscal information on what effects their decisions will have on the financial and environmental resources of the owners and/or municipality in which the BMPs are deployed, over the long-term. The tool, developed in Microsoft Excel® specifically for use in communities on the Front Range of Colorado, allows the user to efficiently determine the expected effectiveness and whole life costs (capital plus long-term maintenance/administration) of various BMPs when implemented within a watershed. The user enters watershed data (i.e. land use, contributing area, slope, etc.) into the tool, and then selects what types and sizes of BMPs will be implemented within the watershed. The model generates outputs for: average annual pollutant emissions from the watershed (without BMPs), average annual pollutant loading to receiving waters (with BMPs), average annual runoff volume generated from watershed (without BMPs), average annual runoff volume entering receiving waters (with BMPs), and net present value of all initial and future costs. The user can test different scenarios of BMP application in a watershed to determine which scenario most cost effectively removes pollutants from stormwater discharges on an average annual basis.

The tool can be used to evaluate the cost effectiveness of 12 structural BMPs; constructed wetland basin (CWB), constructed wetland channel (CWC), extended detention basin (EDB), hydrodynamic separator (HS), inlet insert (II), media filter vault (MFV), porous landscape detention (PLD), retention pond (RP), sand filter basin (SFB), sand filter vault (SFV), sediment/oil/grease separator (SOG), vault with capture volume (VCV).

METHODS

The methods used to quantify whole life cycle costs and BMP effectiveness are described in the following sections.

Whole Life Cycle Costs

Whole life cycle costs associated with constructed facilities typically include; 1) capital costs, 2) land costs, 3) annual operation and maintenance (O&M) costs, 4) infrequent rehabilitation/replacement costs, and 5) salvage value. In addition, Urbonas (pers. comm.) recommends that the administrative costs of operating a stormwater management agency also be included as an annual cost.

Capital Costs

Capital costs are the costs of planning, designing and constructing a facility. There have been many studies conducted over the past 20-30 years to identify the construction costs of BMPs. Table 1 summarizes the BMP construction cost estimates used in the tool. The original cost estimates were adjusted to May 2008 costs using the Engineering News Record Construction Cost Index (ENRCCI)[1].

Table 1: BMP construction cost estimates provided in the literature

BMP	Construction Cost ($2008)	Source	Notes
CWB	34,973(A) - 75,893(A)	USEPA, 1999a	
CWC	17,487(A) – 37,946(A)		Assume 50% of CWB costs, no better information available
EDB	$15.94(V)^{0.694}$	Wiegand et al, 1986	
HS	2,200(F) - 18,333(F)	USEPA, 1999b	
II	145(E) - 2,173(E)	USDOT, 2008a	
MFV	$58,231(IA)^{0.882}$	Wossink and Hunt, 2003	Assumed same as sand filter vault.
PLD	$6,178(IA)^{0.796}$	Wossink and Hunt, 2003	
RP	35,592 + 0.45(V)	SEWRPC, 1991	
SFB	30,390 + 0.63(V)	SEWRPC, 1991	
SFV	$58,231(IA)^{0.882}$	Wossink and Hunt, 2003	
SOG	3,266(IA) – 4,899(IA)	APWA, 1992	
VCV	$56.69(V)^{0.681}$	USDOT, 2008b	For concrete structure

Notes:
E - each
F – design flowrate of BMP (cfs)
IA – contributing area to BMP (impervious acres)
SA – surface area of BMP (acres)
V – storage volume of BMP (ft^3)

In addition to the construction costs, other costs associated with planning, designing and unexpected costs (i.e. contingencies) are incurred. Typically, these can be estimated as a percentage of the construction costs. Urbonas (pers. comm.) suggested a 40% increase in construction costs to account for these other costs.

Capital costs are computed using the equation;

$$CapitalCosts = (1 + CEA) * (B + XU^{\alpha})$$

Where,

CEA = percentage to account for contingencies/engineering/administration
B = base cost
X = unit cost

[1] The 20-city averaged ENRCCI value for May 2008 was 8,141.

U = number of units (i.e. size of BMP)
α = economy of scale factor

Land Costs

There are two components to estimating the land costs associated with structural BMPs. One is the cost of the land itself ($/acre) and the second is the area of land (acres) required for the BMP. Land costs can vary considerably from site to site. If a BMP is to be constructed within an area of open space, easement, public park, etc; then that land may be considered "free". But if the land consumed by the BMP could have been developed, then the land cost could be considered equal to the market value of that land (Strecker et al, 2005) or the opportunity costs (future returns) that are foregone from not developing the land (Sample et al, 2003).

Estimates of urban land costs as a function of land use are provided in Strecker et al (2005) and presented in Table 2.

Table 2: Land cost estimates as function of land use

Land Use	Land Cost ($/acre)
Unimproved Land	$25,000 – 50,000
Residential	$75,000 – 200,000
Commercial	$100,000 – 300,000
High Density	$500,000 – 3,000,000

The authors have estimated the area of land consumed by various BMPs, as a factor of the total size of the BMP (LCFCTR) (Table 3).

Table 3: Land consumed by BMPs

BMP	LCFCTR (acres/unit)	Units	Notes
EDB	0.5	acre-feet (storage volume)	
RP	0.5	acre-feet (storage volume)	
SFB	0.33	acre-feet (storage volume)	
VCV	0	-	underground
SFV	0	-	underground
MFV	0	-	underground
CWB	1	acres (surface area)	
PLD	0	-	assume that PLDs are assimilated into existing landscaping
HS	0	-	underground
SOG	0	-	underground
II	0	-	underground
CWC	1	acres (surface area)	

Land costs are computed using the equation

$$LandCosts = UnitCost * BMPSize * LCFCTR$$

O&M Costs

Annual operation and maintenance (O&M) costs were estimated using information collected from several stormwater agencies in the Denver, Colorado region and the RSMeans 2005 Site Work & Landscape Cost Data Guide (RSMeans, 2005). All costs were adjusted to May 2008 dollars using the ENRCCI. Table 4 presents the equations developed to estimate O&M costs as a function of the size of the BMP.

Table 4: Annual O&M cost equations

BMP	O&M Cost Equations ($2008)	Units
EDB	1,420 + 3,502(AF)	AF = acre-feet storage
RP	1,809 + 2,825(AF)	AF = acre-feet storage
SFB	3,948(AF)	AF = acre-feet storage
VCV	0.29(CF)	CF = cubic feet storage
SFV	0.54(CF)	CF = cubic feet storage
MFV	0.55(CF)	CF = cubic feet storage
CWB	3,152(AF)	AF = acre-feet storage
PLD	0.37(CF)	CF = cubic feet storage
HS	493(cfs)	cfs = cubic feet per second flowrate
SOG	1,368(cfs)	cfs = cubic feet per second flowrate
II	561(E)	E = each
CWC	534(A)	A = acres surface area

Rehabilitation/Replacement Costs

These costs represent the costs associated with major rehabilitation and/or replacement activities that occur infrequently during the life of a BMP, such as inlet/outlet and headwall replacements on storage basins or baffle replacement in hydrodynamic separators and sediment/oil/grease separators. Urbonas (pers. comm.) suggested the following costs (as a percentage of initial capital costs) and frequencies of rehabilitation/replacement costs for each BMP included in the tool (Table 5).

Table 5: Rehabilitation/Replacement cost and frequency estimates

BMP	Frequency (years)	Cost (as % of capital costs)
EDB	25	80%
RP	25	80%
CWB	40	80%
CWC	20	20%
SFV	0	0%
MFV	0	0%
SOG	10	50%
PLD	0	0%

VCV	20	50%
HS	25	50%
SFB	25	80%
II	0	0%

Salvage Value

Strecker et al, in a similar work to compute whole life cycle costs of BMPs, suggested that estimating the future salvage value is too difficult and therefore were assumed to be zero (2005). In this tool, salvage value is also assumed to be zero.

Administrative Costs

Administrative costs account of the additional costs of operating a stormwater management program, including the costs of maintenance planning and oversight, regulatory reporting, compliance inspections, etc. Urbonas (pers. comm.) suggested an estimate of administrative costs as 12% of the annual O&M costs. In addition, separate compliance inspection costs were estimated to be approximately $27 per BMP.

Net Present Value Costs

The net present value (NPV) of all costs is computed using the equation (Newnan, 1996);

$$NPV = F(1+ROR)^{-n}$$

Where,

NPV = net present value of cost
F = future cost ($) in year "n"
n = year in which cost/return occurs (i.e., years from present)
ROR = average rate of return (%) over period of analysis

BMP Sizing

The size of a BMP refers to the quantity of its design storage volume (expressed in acre-feet, cubic feet, etc.) or its design flowrate (expressed in cubic feet per second). "Volume-based" BMPs are designed to capture and treat a specified volume of runoff and "flow-based" BMPs are designed to convey and treat a specified peak flowrate of runoff. Table 6 lists the BMPs and their design classification.

Table 6: BMP design classification

Volume-Based BMPs	EDB, RP, SFB, VCV, SFV, CWB, MFV, PLD
Flow-Based BMPs	HS, SOG, II, CWC

Volume-based BMPs are sized to capture and treat the water quality capture volume (WQCV) (approximately 0.43 watershed inches near Denver, CO), based on design criteria published in the Urban Drainage Flood Control District's (UDFCD) Urban Storm Drainage Criteria Manual (UDFCD, 2004). **Note**: The design volume computed for each BMP does not account for additional storage required for larger storms or flood control.

Flow-based BMPs are sized to convey the 2-peak flow rate. The peak flow rate is computed using the Rational Method, using UDFCD methods for estimating time of concentration and design rainfall intensity.

BMP Effectiveness

BMP "effectiveness" is defined as a "measure of how well a BMP system meets its goals in relation to all stormwater flows" and a "BMP system" is defined as "a BMP and any related bypass or overflow" (Geosyntec and ASCE, 2002). Therefore, BMP effectiveness accounts not only for how well a BMP removes pollutants from runoff that is captured, but also for how much runoff is not captured (i.e. bypassed) and what pollutant quantity is in the bypassed runoff. It is recommended that BMP effectiveness be assessed by determining the following (Strecker et al, 2001);

1. How much stormwater runoff is prevented by evapotranspiration, infiltration, source controls, etc.
2. How much stormwater runoff is treated by the BMP and how much bypasses?
3. What is the effluent quality leaving the BMP?

In this tool, BMP effectiveness is reported in terms of reduced annual pollutant loading to the receiving water. The tool estimates annual pollutant loads with and without BMPs implemented in the watershed. When BMPs are implemented, it is assumed that 85% of annual runoff is effectively "treated" by the BMP and 15% "bypasses" the BMP.

Annual Pollutant Load without BMPs

$$AnnLoad_{WO} = LUEMC * Runoff$$

Where,

$AnnLoad_{WO}$ = average annual pollutant loading (mass/year) without BMPs
LUEMC = "land use" event mean concentration (concentration)
Runoff = average annual runoff (volume)

The "land use" event mean concentrations are provided in the appendix.

Runoff volume is computed by The Simple Method (Schueler, 1987);

$$V = P \bullet Pj \bullet RC$$

Where,

V = annual runoff (volume)
P = annual precipitation (depth)
Pj = percentage of annual storms producing runoff (0.9)
RC = runoff coefficient

Annual Pollutant Load with BMPs

$$AnnLoad_{W} = (EffEMC * Discharge) + (LUEMC * Runoff * 0.15)$$

Where,

$AnnLoad_{W}$ = average annual pollutant loading (mass/year) with BMPs
EffEMC = "effluent" event mean concentration (concentration)

Discharge = average annual discharge from BMP (volume)

The "effluent" event mean concentrations are provided in the appendix.

Discharge is computed by;

$$Discharge = (Runoff * 0.85 - \Delta S)Z$$

Where,

Discharge = volume of effluent
ΔS = change in storage (assumed to be zero)
Z = ratio of measured outflow/measured inflow (Table 7)

Table 7: Ratio of measured outflow/measured inflow for various BMPs

BMP Type	Outflow/Inflow
Detention Basins	0.70
Biofilters	0.62
Media Filters	1.00
Hydrodynamic Separators	1.00
Wetland Basins	0.95
Retention Ponds	0.93
Wetland Channels	1.00

Source: Strecker et al (2004)

The difference between the two loads is the annual mass of pollutant removed from the receiving water.

$$\Delta AnnLoad = AnnLoad_{WO} - AnnLoad_{W}$$

BMP Cost Effectiveness

The cost effectiveness of a structural BMP (reported in terms of the total cost to remove a unit of pollutant) is computed using the following equation;

$$CostEff = \frac{NPV}{\Delta AnnLoad}$$

Where,

CostEff = cost per unit of pollutant removed ($/mass)

APPLICATION

This application demonstrates how the tool can be used to quickly evaluate multiple different scenarios for an urban BMP retrofit project.

Watershed Information

Assume the area is already developed with no BMPs currently in place. The stormwater agency must reduce TSS loading to the receiving water by 60%, however because the area is already developed, there is very little land available for BMPs. The following information is available to the user.

- The 55 acre area has a land use density similar to "commercial" land uses and has average slope <1%.
- The agency has determined that some portions of existing right-of-ways (roadways, sidewalks, alleyways) could be used for long, narrow-type BMPs, such as porous landscape detention or sand filter vaults. There would be no land costs associated with these areas (the city already owns them).
- For other BMPs that consume land area, the land and demolition costs of $300,000 per acre.
- Soils in the area are NRCS Type D and are NOT adequate for infiltration-type BMPs.
- The economic life of the BMPs is assumed to be 50 years (i.e. whole life cycle costs are computed for 50 years)

Although the watershed can be considered homogeneous, in some scenarios it was subdivided to allow for applying BMPs to some areas and leaving other areas "untreated".

BMP Scenario 1
For this scenario, the use of hydrodynamic separators will be evaluated. Typically, the contributing area to each device should not exceed 5 impervious acres. It was found that implementing 10 hydrodynamic separators with treatment capacity of 1.5 cfs, each treating 5 acres, would reduce TSS loading approximately 60%. The 50-year NPV of all costs for this scenario is $1,420,000. These are underground structures; therefore no land costs are incurred by these projects.

BMP Scenario 2
For this scenario, the use of porous landscape detention will be evaluated. It was found that approximately 8 PLDs, each capturing runoff from 5 impervious acres, would reduce TSS loading by approximately 60%. The 50-year NPV of all costs for this scenario is $1,578,000. These costs neglect land costs, as it is assumed that the PLDs could be constructed within the right-of-ways as discussed in the problem statement.

BMP Scenario 3
For this scenario, underground sand filter vaults will be evaluated. To reduce TSS loading by 60%, 8 SFVs capturing runoff from 5 impervious acres and 1 SFV capturing runoff from 2 impervious acres would be required. The 50-year NPV of all costs for this scenario is $6,442,000. These costs neglect land costs, as it is assumed that the SFVs could be constructed within the right-of-ways as discussed in the problem statement.

BMP Scenario 4
The cost effectiveness of constructing a single, extended detention basin is evaluated in this scenario. It was found that a single EDB treating 43 impervious acres would

reduce TSS loading by 60%. The 50-year NPV of all costs for this scenario is $1,481,000.

BMP Scenario 5

This scenario will evaluate the use of a single, constructed wetland basin. It was found that a single CWB treating 43 impervious acres would reduce TSS loading by approximately 60%. The 50-year NPV of all costs for this scenario is $1,326,000.

RESULTS AND DISCUSSION

Table 8 summarizes the results of each of the 5 scenarios evaluated. Each scenario was optimized to reduce TSS loading by approximately 60% (9000 kg).

Table 8: Summary table of results for Application #2

	Scenario				
	1	**2**	**3**	**4**	**5**
BMP	HS	PLD	SFV	EDB	CWB
Treated Area (acres)	50	40	42	43	43
NPV Costs	$1,420,000	$1,578,000	$6,442,000	$1,481,000	$1,326,000
Capital Costs	$1,043,000	$529,000	$3,477,000	$1,047,000	$1,081,000
O&M Costs	$325,000	$927,000	$2,638,000	$387,000	$218,000
Admin. Costs	$51,000	$121,000	$327,000	$48,000	$27,000
Cost/Kg TSS Removed	$158	$175	$716	$165	$147

CONCLUSIONS

Several important conclusions can be made from the results of this application. First, it shows how the tool can be used to develop a cost-effective plan for achieving reductions in pollutant loadings to receiving waters. Second, it shows the importance of including maintenance and administrative costs in evaluating the cost effectiveness of a BMP plan. One can see that if BMPs were planned solely based on capital costs alone that PLDs would have been found to be considerably more cost effective. Lastly, this evaluation took only 1 hour for an experienced user to conduct, which shows how the tool will enable effective decisions to be made in an efficient manner.

ACKNOWLEDGEMENTS

This project was funded by Urban Drainage and Flood Control District, the Colorado Stormwater Council, the Urban Watersheds Research Institute and the member agencies that support each of those entities. The authors appreciate the cooperation of many agencies in the Denver metropolitan region that provided cost information for this project.

ABSTRACT
The objective of this research is to examine the removal capacities of a recently developed stormwater filtration device, in part developed by engineers at the University of Alabama through a Small Business Innovative Research (SBIR) grant from the U.S. Environmental Protection Agency. The UpFlo™ Filter is an efficient high-rate stormwater filtration technology designed for the removal of trash, sediments, nutrients, metals and hydrocarbons from stormwater runoff. Compared with the traditional downflow filtration treatment, the upflow filtration method reduces clogging and was developed to remove a broad range of stormwater pollutants, especially those associated with particulates. The high flow rate capacities of the upflow filter are accomplished through controlled fluidization of the filtration media, while still capturing very small particulates through a flexible, but constraining, media container. The upflow filter also drains down between rain events which minimizes anaerobic conditions in the media and which also partially flushes captured particulates from the media to the storage sump, decreasing clogging and increasing run times between maintenance. Gross floatables are captured through the use of an angled screen before the media and a hood on the overflow siphon, while the sump captures bed load particulates.

INTRODUCTION
Many types of stormwater controls are available, but most are relatively large or insufficient in their treatment capacity. Adequate treatment of runoff requires the removal of many types of pollutants as well as large amounts of debris and floatable materials, over a wide range of flows. Traditional downflow filters, which can provide high levels of treatment, can quickly clog, reducing their treatment flow rate and overall treatment capacity. They also usually operate at a low treatment flow rate requiring a large area to treat substantial portions of the runoff from a site. The UpFlo filter is designed to treat stormwater runoff from critical source areas that discharge especially high levels of pollutants. The commercialized UpFlo filter minimizes clogging and was developed to remove a broad range of stormwater pollutants at a relatively high rate, and can be retrofitted into existing stormwater drainage. This presentation will present the results from a controlled full-scale field evaluation located at a parking lot in Tuscaloosa, AL. Treatment flow rates, particle size controls, and SSC reductions will be stressed in this presentation.

LOCATION AND SIZE OF FILTER

A 7-foot tall 4-foot diameter standard inlet containing a six module UpFlo™ Filter has been installed at the Riverwalk parking lot near the Bama Belle on the Black Warrior River in Tuscaloosa, Alabama. The chamber is a conventional concrete manhole with a sump, with the UpFlo™ filter components installed. The filter receives surface runoff from a parking lot, road, sidewalks, and a small landscaped area, as shown in Table 1. The total drainage area tributary to the device is approximately 0.9 acres. Figure 1 shows the drainage area and the location of the test site.

Table 1. Drainage Area Land Use

Land Use	Area (ft^2)	Area (acre)	% of Land Use
Parking Area	11,800	0.27	30.5
Other Paved	1,300	0.03	3.4
Side Walks	2,100	0.05	5.4
Entrance Road	10,990	0.25	28. 5
Green Space	12,400	0.29	32.2
Total	**38,610**	**0.89**	**100.0**

Figure 1. Site map and drainage area.

DESCRIPTION OF FILTER

The full-scale filter system (having a full complement of 6 filter modules) was installed and is being tested to confirm laboratory and the initial pilot-scale test results under actual rain conditions. Hydraulic capacity and pollutant removal capabilities in the full-scale field installation are being monitored under both controlled and actual runoff conditions. Figure 2 shows the main features of the UpFlo™ filter, while Figure 3 shows the installation of the full-scale test filter at Tuscaloosa. Depending on the selected media, the filtration treatment flow rate varies from 15 to 25 gal/min/ft^2. With 6 modules, each having about 1ft^2 of filter surface,

the total treatment flow rate for this installation is expected to be at least 100 gallons/minute.

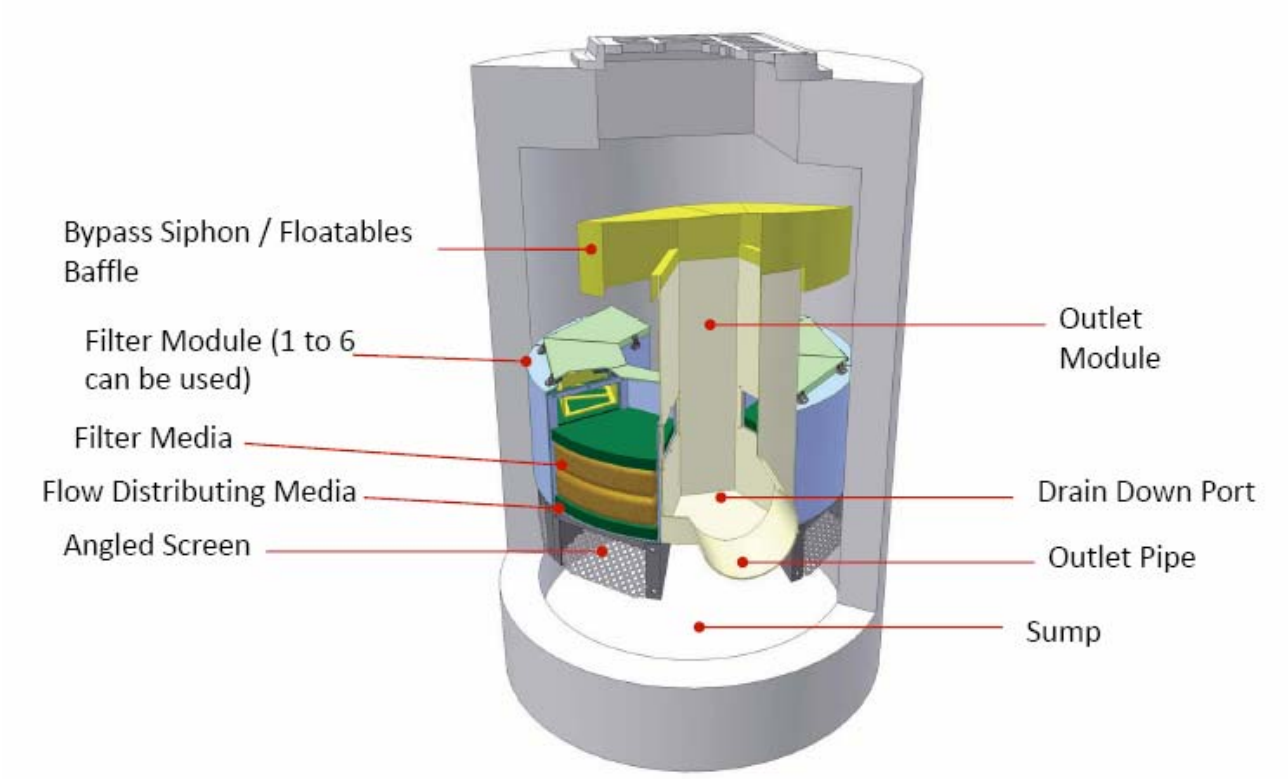

Figure 2. UpFlo™ Filter components.

Figure 3. Installation of Tuscaloosa UpFlo™ filter.

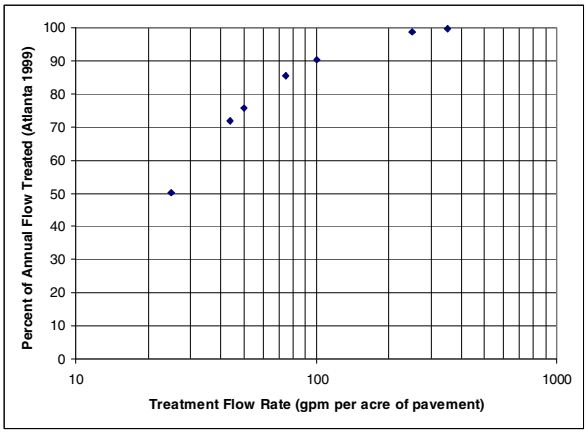

Figure 4. Treatment flow rate requirements for southeast US paved conditions (Example shown for continuous simulation results for Atlanta, GA).

Figure 4 shows the treatment flow rate requirements for typical southeastern US conditions, based on continuous simulations (Pitt and Khambhammettu 2006). The 100 gal/min for the test site is expected to treat about 90 percent of the annual flow for a typical rain year, with about 10 percent of the annual flow bypassing filtration.

CONTROLLED FLOW TEST & CONTROLLED PARTICLE CAPTURE TEST

This paper describes the initial controlled performance monitoring that is being conducted at the Riverwalk parking lot near the Bama Belle in Tuscaloosa, Alabama. The first flow test was conducted for the purpose of determining the hydraulic capacity and the pollutant removal capabilities in a full-scale field installation under controlled conditions. In the test, the filtration rate of the CPZ Mix™ filter media, a proprietary mixture of bone char activated carbon, peat moss, and manganese coated zeolite was evaluated. Based on results of prior lab scale testing, the mixed media is expected to have high pollutant removal at relatively high filtration rates. The UpFlo™ Filter was fitted with two media bags in each of the 6 chambers, for a total of 12 bags, as well as the flow distribution material placed above and below the media bags.

METHODOLOGY FOR THE EVALUATION OF FILTRATION RATE

Flow tests were conducted in the field with the cooperation of the Tuscaloosa Department of Transportation by using a pump to deliver river water to a flow splitter/flow controlling barrel. The water flow rate was measured by measuring the time needed to fill a measured volume (Figure 5). When the rate was established, the volume tray was removed, directing the known and steady flow to the gutter immediately above the Up-Flo intake. For each flow rate, measurements were taken of the steady-stage water depth in the filter and the reported flow rate from the area-velocity sensor that will be used to monitor the flow during rain events. The measurements were repeated 5 times for each flow to reduce the errors. Figure 6 shows an example flow vs. head graph developed during these tests.

Figure 5. Pumped River water is discharged from splitter barrel to the 11 gallon plastic tray.

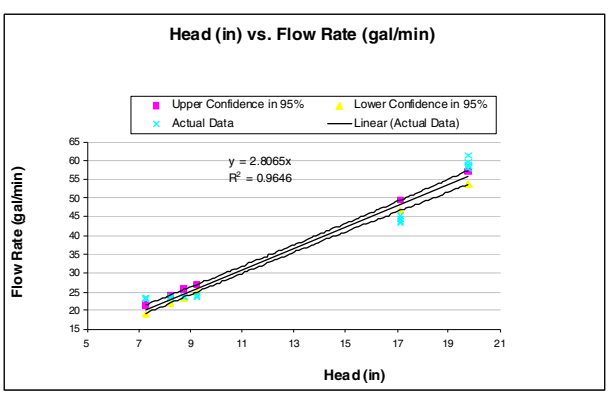

Figure 6. Example flow vs. head graph for mixed media, showing highly repeatable measurements.

PARTICLE SIZE DISTRIBUTION OF TESTED MEDIA AND TEST SEDIMENT

The test sediment in the stormwater stimulant used a mixture Sil-Co-Sil 250, Sil-Co-Sil 106 (both from U.S. Silica Co.), and coarse and fine concrete sands. The mixture was made by mixing the four components with different ratios to obtain a relatively even particle size distribution representing the complete range from about 20 to 2,000µm. This mixture was not intended to represent actual stormwater (which usually has a smaller median size), but to ensure sufficient amounts of large particles so they could be accurately monitored to quantify their removal. As shown later, all of the results of these controlled tests were presented based on many narrow particle size ranges so they could be applied to any expected particle size distribution of the flowing water. Since the samples were all analyzed using sieves and a Coulter Counter, the results are much more useful than if individual SSC analyses were conducted representing all sizes combined. If a single analysis was conducted, then the psd of the challenge water would have to match the stormwater psd, a difficult objective given the highly variable particle size characteristics of stormwater. Figure 7 shows the particle size distributions of two test mixtures that were used during the tests.

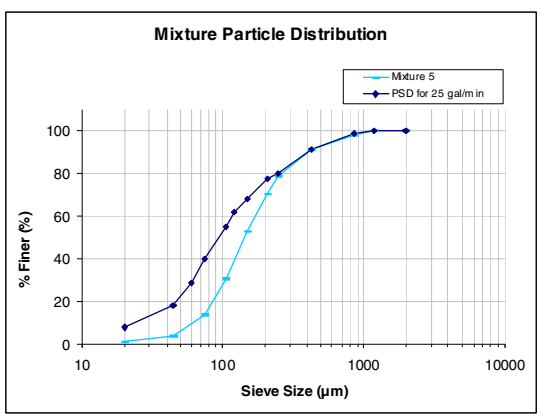

Figure 7. Particle size distribution of mixture used for the flow test.

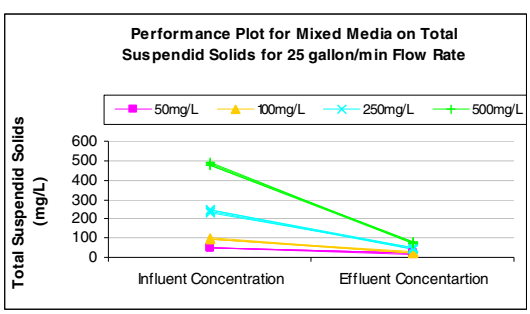
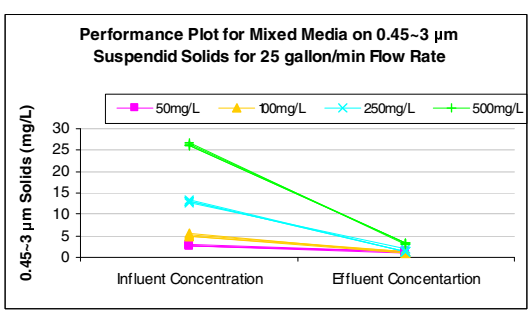
Figure 8. Sediment mixture was manually and consistently added to the influent water over the 30 minute test period.

TEST METHODOLOGY FOR CONTROLLED SEDIMENT CAPTURE TESTS



The test described below used several known concentrations of particulate solids over a wide range of particle sizes and an influent flow rate that averaged 24 gallon per minute (having a standard deviation of 0.3 gpm). Each experiment was conducted for 30 minutes, during which time measured aliquots of the dry sediment were constantly poured into the pumped influent "river flow" from the Black Warrior River. River water was also collected before any sediment was added to measure the background solids in the test water to determine the background conditions. Effluent samples were collected using a dipper grab sampler every 1 minutes and composited in a churn sample splitter during the 30 minutes test period. The effluent was sampled at a completely mixed cascading flow exiting the filter in a specially constructed sampling chamber. Using the churn splitter, two samples of 1000 mL each were placed in sample bottles for duplicate laboratory analyses for each test.



In preparation for the tests, test sediment portions were pre-weighted in many 50 mL polyethylene bottles. The sediment was manually feed into the influent water over the whole period of each experiment, according to the desired particulate solids concentration for the specific flow rate for each test (Figure 8). This method ensured that all of the sediment and all particle sizes entered the test chamber. Depth readings of the water levels were also taken during each experiment to determine the head loss during the Up-Flo^{TM} Filter operation. Also, after completion of each experiment, additional multiple flow and depth readings were taken to determine the final flow rate and available head to detect any change in filtration rate during the test.

During these tests, four different influent sediment concentrations were tested: 50mg/L, 100mg/L, 250mg/L, and 500mg/L.

INITIAL CONTROLLED TEST RESULT OF FILTER

Controlled tests can measure the filter behavior under known conditions. Mixtures of ground silica available from U.S.Silica Co. were used for these initial tests, reflecting filter performance for a variety of particle sizes. Figure 9 shows the influent and effluent concentrations during tests using 50 to 500 mg/L influent conditions. Further controlled tests are being conducted, along with measurements conducted during actual rain conditions.

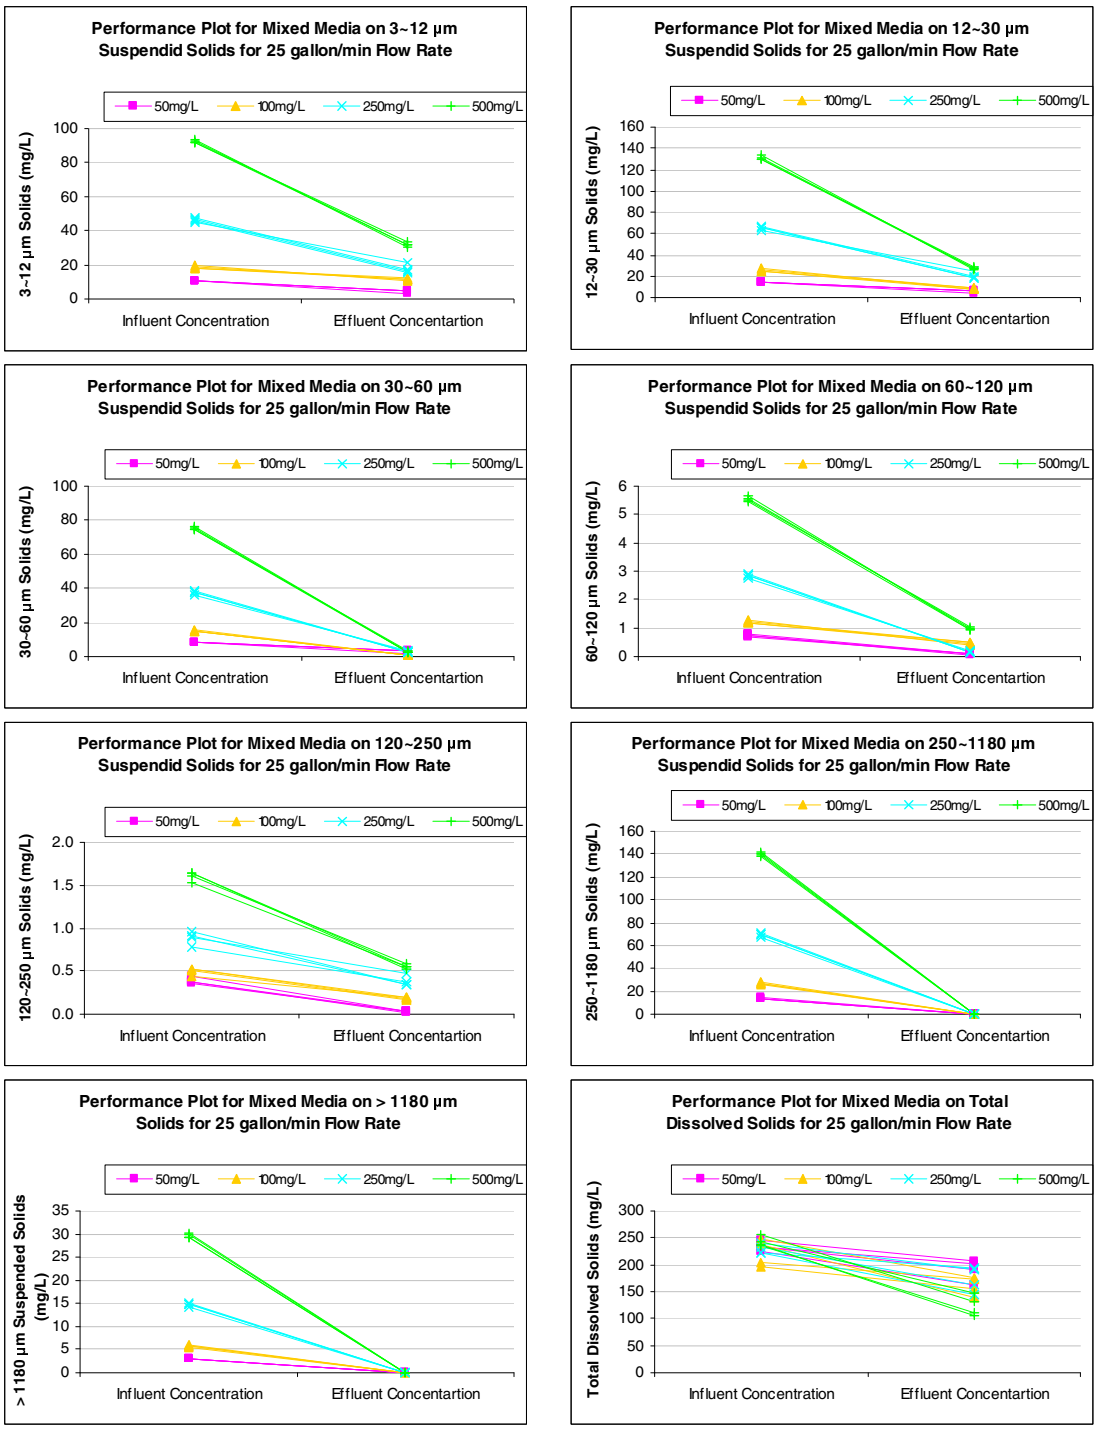


Figure 9. Controlled test results for different particle sizes.

Table 2 summarizes the average influent and effluent concentrations, along with the percentage reductions for 100 and 500 mg/L influent conditions (including river water additions). Table 3 shows the average influent and effluent concentration of TDS concentrations.

ABSTRACT

This research presents a case study of the impacts of stormwater infiltration on a shallow unconfined aquifer at a bioinfiltration BMP on the campus of Villanova University. The study site is a vegetated basin that with a 0.53 hectares drainage area consisting of parking areas and recreational fields with 35% directly connected impervious area. The study utilizes continuous monitoring of groundwater elevation, temperature and conductivity in conjunction with surface water hydrologic monitoring to assess the transport of conductivity and to examine the extent of groundwater mounding. Results indicate a direct impact on groundwater conductivity near the BMP, but also show significant attenuation compared to influent surface water. Following storms less than approximately 1.9 cm the upgradient control well presents larger increases in groundwater elevation, but for larger storms the well adjacent to the site displays increased mounding. Groundwater elevation monitoring indicates that the extent of groundwater mounding is related to infiltration rate and groundwater temperature. This study demonstrates the utility of groundwater monitoring for the purpose of BMP performance assessment. It is suggested that groundwater monitoring be considered for site monitoring plans and as a tool for BMP site selection.

INTRODUCTION:

Infiltration BMP have become essential tools of urban stormwater management (Mikkelsen *et al.* 1996; USEPA 2000; Hsieh and Davis 2005; Schuster *et al.* 2007). Research has examined many parameters related to the design, construction and evaluation of infiltration BMP, but less emphasis has been placed on the impact to groundwater and subsurface contaminant transport (Mikkelsen *et al.* 1997; Strecker *et al.* 2001; Akan 2002; Winogradoff 2002; Fischer *et al.* 2003; Birch *et al.* 2005; Dietz and Clausen 2005; M. Clar *et al.* 2007). On an annual basis, baseflow, which is derived from groundwater, typically comprises a major component of total stream flow (Leopold 1974; Bouwer 1978; Viessman and Lewis 2003). Since groundwater flow is the link between infiltration and base-flow; it is essential to consider the fate of water at infiltration BMP to ensure the protection of streams and water resources (Winter *et al.* 1998; Barraud *et al.* 1999; Pitt *et al.* 1999).

The primary concerns of stormwater infiltration related to groundwater include the contamination of soil and groundwater and the subsurface impacts of

groundwater mounding. Infiltration BMP are primarily designed to provide volume and contaminant reduction to protect surface water. Infiltration BMP typically have little or no pretreatment devices, therefore contaminants in stormwater are conveyed directly to the BMP and the potential exists for subsurface contamination. BMP rely on the physical and biological processes involved with infiltration to remove contaminants from influent water (Muthukrishnan *et al.* 2004; PADEP 2006; Mikula *et al.* 2007). Concerning groundwater mounding, the potential exists for subsurface damage to utilities, basements and building structures. Groundwater mounding may also result in detrimental changes in the groundwater flow regime, therefore it is important to understand the impacts of mounding (Rai *et al.* 1998; Guo 2001; Park *et al.* 2006; Schreffler *et al.* 2006).

To assess the impacts of stormwater infiltration on groundwater, this study examines the following questions:

- What is the extent of groundwater mounding that occurs in response to focused recharge?
- Do the physical, chemical and biological processes involved with infiltration and groundwater flow attenuate the impacts related to total dissolved solids as measured by conductivity?
- What pertinent information can be gathered from groundwater monitoring of infiltration BMP?

Specifically, the study focuses on groundwater mounding, temperature and the transport of conductivity through a bioinfiltration basin. Continuous groundwater monitoring is coupled with hydrologic modeling and storm sampling to assess the hydrologic and chemical impact of infiltration on the shallow aquifer.

SITE DESCRIPTION

Research for this study was conducted at the Villanova Bio-Infiltration Traffic Island. The site is on the campus of Villanova University in Southeastern Pennsylvania; a suburban area about 17.7 km miles west of center-city Philadelphia. The site is located in a parking area with a total drainage area of approximately 0.53 hectares including 35% directly connected impervious area (Emerson 2008). Villanova is located in PADOT region 5 precipitation area and receives an average annual precipitation of 114 cm (Aron et al. 1986). Furthermore, between 80 to 90% of the average annual precipitation occurs in storms with less than 2.5 cm of precipitation (Traver 2002).

The BMP was constructed as a retrofit of an existing parking lot traffic island and was designed to retain and infiltrate the runoff produced by a 2.5 cm storm. The BMP was constructed by excavating the existing traffic island to a depth of approximately 1.8 meters. The excavated soil was mixed with sand at a 1:1 ratio and replaced into the excavation to a depth of 1.2 meters. The area was then formed into a basin, mulched and planted with appropriate vegetation. The site is equipped with a variety of hydrologic monitoring equipment and has is used as a research and demonstration site. Additional information pertaining to site history, performance,

construction and research is presented by Prokop (2003), Ermilio (2005), Heasom et al. (2006), Traver (2002), Traver et al. (2007), and Emerson (2008).

METHODOLOGY

This study consists of continuous monitoring conducted between November 2007 and August 2008. Four monitor wells are located around the site; MW1 is located upgradient, MW3 is located downgradient and both MW2 and MW4 are located adjacent to the site. Wells MW1, MW2 and MW3 are equipped with In-Situ Aqua Troll 200 multi-meters that are programmed to measure and record groundwater elevation, temperature and conductivity. MW4 is equipped with an Instrumentation Northwest (INW) PT2X pressure transducer that logs groundwater elevation. Precipitation at the site is measured with a Sigma tipping bucket rain gauge. Basin water level is measured by a Sigma ultra-sonic sensor and outflow from the basin is measured by an INW PT2X located behind a v-notch weir near the outlet structure. Data from these gauges are logged by a Sigma 950 flow meter. The site hydrology, including total runoff and hydrologic timing is estimated using rainfall and basin water level data in conjunction with the HEC-HMS model developed for the site by Heasom et al (2006). The predicted inflow volume is compared to the resulting changes in groundwater elevation and is used to examine the hydrologic impacts of stormwater infiltration on groundwater. Continuous

RESULTS

Approximately 79.2 centimeters of precipitation was recorded during the study period. The majority of this precipitation occurred in storms less than 2.5 centimeters and the great majority of the runoff was infiltrated by the site. Significant fluctuations in groundwater elevation were observed at each well. The groundwater elevation at MW1 responds to precipitation within about two hours, whereas MW2 and MW4 generally required over 30 hours and MW3 typically required over 35 hours. The range between the maximum and minimum water level was 1.32 m at MW1, 2.22 m at MW2, 1.08 m at MW3 and 1.76 m at MW4. The largest fluctuation in groundwater elevation occurred after the storms on 3/4/08 and 3/7/08, which produced a total rainfall of 7.8 centimeters and an estimated inflow volume of 185.6 m^3. During this period, the groundwater elevation at MW1 rose 0.56m, 1.04m at MW2, 0.28 m at MW3 and 0.87 m at MW4.

In general the groundwater elevation was highest at MW4 followed by MW1 then MW2. At times MW1 had the highest elevation and for several brief periods the elevation at MW2 exceeds MW1. Groundwater elevation at MW3 remained the lowest over the entire period and in general showed only gradual longer-term fluctuations. The resulting hydraulic gradient is relatively flat in the vicinity of the MW1, 2 and 4, with a fairly steep gradient towards MW3. Over the study period, the water table was highest from mid-January to mid-May and lowest towards the end of summer and beginning of winter. Figure 1, below presents the groundwater elevation during the study period.

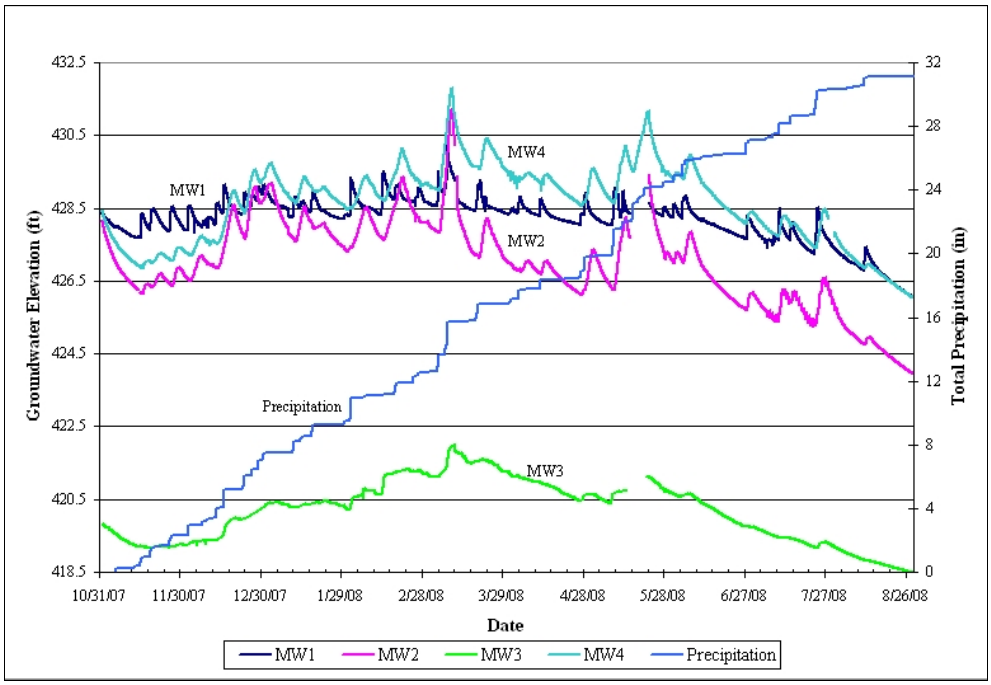

Figure 1. Groundwater Elevation

During the study period, MW2 displayed a wide range in conductivity, while MW3 displayed a narrower range and MW1 had a moderate range. The minimum and maximum values were 68 to 465 µS/cm at MW1, 90 to 815 µS/cm at MW2 and 291 to 353 µS/cm at MW3. The conductivity at MW1 was generally stable except after large storm events when the conductivity displays a rapid decline followed by a rapid return to previous conditions. The conductivity at MW2 fluctuated between 75 and 275 µS/cm for most of the period, except for an extended period in the early spring following the storm events in early March 2008. During this period the conductivity generally remained above 675 µS/cm. The conductivity at MW3 remained within a narrow range during the study period, but was observed to display a general decline between November 2007 and April 2008, after which the conductivity followed a general incline. Overall, MW2 displayed the widest range, with the highest and lowest values, while MW1 and MW3 followed similar trends with MW1 typically higher than MW3. Figure 2, below presents the groundwater conductivity and temperature during the study period. It should be noted that the monitoring record was interrupted for a brief period in May 2008.

The groundwater temperature at MW1 and MW3 remained very stable and followed a similar gradual trend with an average temperature difference of about 0.2 ^{o}C over the study period. In contrast, MW2 had a highly variable temperature and followed a very different trend. While MW1 and MW3 had a range of less than 1 ^{o}C, MW2 had a range of over 6.2 ^{o}C. The temperature curves at MW1 and MW3 were smooth and gradual, while MW2 had a variable curve with many fluctuations. In November 2007, MW1 and MW3 had temperatures of 13.35 and 13.16 ^{o}C, respectively. The temperatures rose gradually to 13.76 and 13.56 ^{o}C, respectively, by early March and then proceeded to gradually decline to 13.20 and 12.98 ^{o}C by August 2008. MW1 had two large temperature decreases in March 2008, both occurring

immediately after large storm events. In November 2007, MW2 had a temperature of 14.41 °C and increased to 15.05 °C by the end of December 2007. From January 2008 until late May 2008, the temperature at MW2 decreased from 15.05 °C to 8.77 °C and then from 5/22/08 until the end of the study period in 8/28/08, the temperature rose steadily to 11.68 °C with only minor variations.

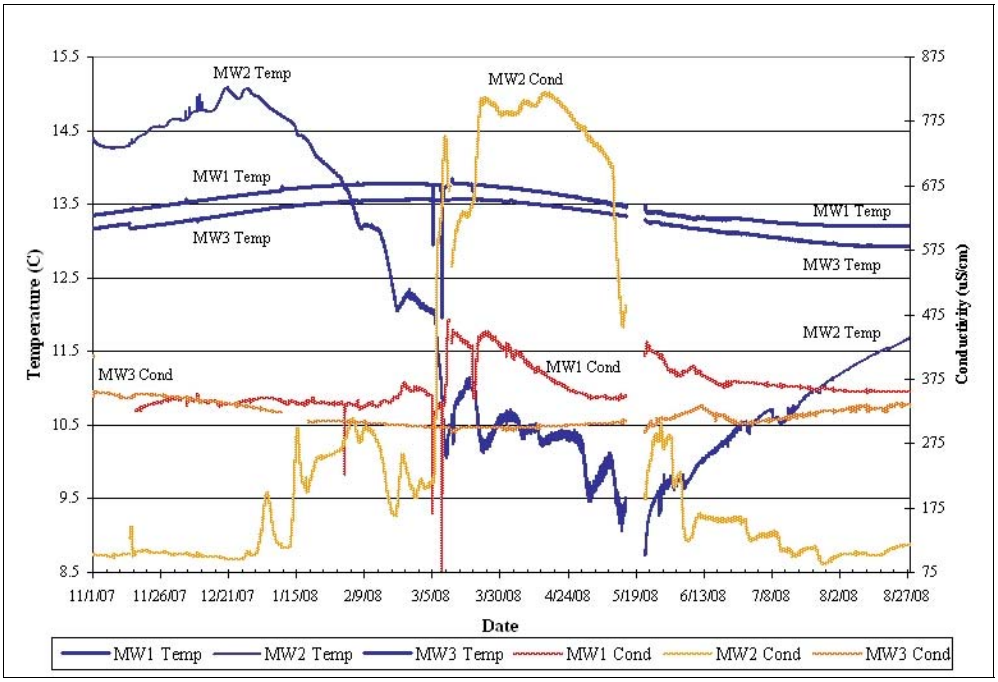

Figure 2. Groundwater Conductivity and Temperature

DISCUSSION

Groundwater Mounding

Infiltration of water to an unconfined aquifer naturally causes the groundwater elevation to rise, thus the fluctuations observed at the monitor wells are to be expected. Infiltration BMP focus recharge in a specific area rather allowing rainfall to infiltrate over a dispersed area. The question thus arises, how does focused recharge effect the change in groundwater elevation? Groundwater monitoring for this study shows that for storms smaller than approximately 1.9 centimeters the upgradient well (MW1) exhibits a larger change in groundwater elevation than the wells closer to the site (MW2 and MW4). For storms greater than 1.9 centimeters the reverse is generally observed. However, for larger storms, the groundwater elevation at MW3 demonstrates that the increased mounding observed at MW2 is attenuated before reaching MW3. These findings are illustrated in Figure 3, below which plots the change in groundwater elevation versus the total rainfall.

An interesting observation regarding groundwater fluctuations is that the observed rise in groundwater elevation does not correlate well to the amount of precipitation received. Figure 4, presents the R^2 value for the trend-line correlating

the volume of precipitation to the associated rise in groundwater elevation. MW1 has the highest R^2 value and correlation coefficient of 0.863 and 0.929, while MW4 has the lowest values of 0.818 and 0.904. These statistics indicate that the parameters are related, but that there is not a strict correlation. This implies that other factors, such as rainfall intensity, temperature, antecedent moisture content and evapotranspiration play a significant role in the magnitude of groundwater mounding. Along these lines it should be noted that in general, it was observed that for events with similar rainfall, MW2 displayed larger increases in groundwater elevation when the groundwater temperature was lower.

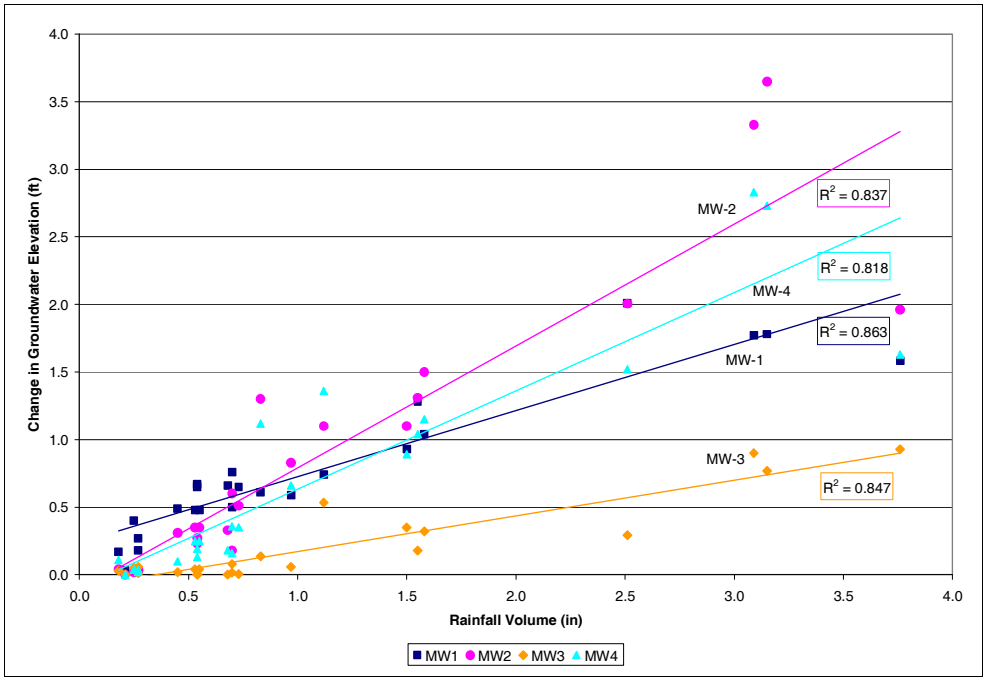

Figure 3 Comparison of Groundwater Mounding and Total Precipitation

Based on the results it is observed that infiltration rate, which is temperature dependent, is a primary factor affecting the extent of groundwater mounding. As an analogy, it is hypothesized that the subsurface below the site is similar to a retention basin and that the infiltration rate is equivalent to an outlet control structure. Expanding upon this analogy, it is observed that the infiltration rate at MW1 is quicker than at MW2 and MW4 as can be seen by the rapid rise in groundwater elevation after a storm. For a given storm less than 1.0 cm centimeters, rain rapidly infiltrates near MW1 causing a quick increase in groundwater level. At MW2, a slower infiltration rate requires a longer duration for water to reach the groundwater. Thus in a given time period, less volume of water is delivered, resulting in a lower rise in groundwater elevation. However, more total volume of water is infiltrated near MW2, because of the basin and this larger volume is conveyed to the groundwater over a longer period of time. Therefore the hydrograph at MW2 has slow gradual changes in elevation that are sustained for a longer duration. Returning to the retention basin analogy, just as a retention basin stores a volume of water and releases it at constant rate, the infiltration rate slowly releases water to the groundwater at a

low rate for a long duration. It appears that for storms smaller than 1.9 cm centimeters the infiltration rate is sufficiently low to allow the water to be stored in the vadose zone without causing a large increase in groundwater elevation. However, for larger storms, infiltration occurs for a sufficient duration to cause larger increases in groundwater elevation. Also for larger more intense storms the basin is maintained at capacity for longer durations and the surface soil of the drainage area may become saturated so that rainfall produces runoff rather than infiltration and this runoff flows into the basin rather than the groundwater near MW1.

Although larger storms lead to a larger groundwater mound at MW2 and MW4, the hydrographs from MW3 indicate that the mounding does not extend very far laterally. In addition, the mounding near the site remains at a significant depth below the site. The maximum elevation observed at MW2 occurred on 3/10/08 in response to 7.8 centimeters and was still 3.66 m below the bottom of the basin. Thus substantial storage space exists in the vadose zone to accommodate larger volumes.

Conductivity

The conductivity at MW2 was observed to be significantly effected by stormwater infiltration. During warm periods when no de-icing salts are applied, the groundwater has low conductivity, but in winter and early spring when road salts are applied the conductivity rises. Precipitation naturally has low conductivity due to the lack of dissolved solids, but as the rainfall travels across the land it picks up dissolved solids and ions, such as the chloride ions derived from de-icing salts. Thus it is intuitive that the conductivity at MW2 is low during warm periods and higher during colder periods, when de-icing salts are applied. Furthermore it follows that the low conductivity water that infiltrates the site will dilute the ambient conductivity level of the groundwater near the basin and down gradient. Although the groundwater at MW2 varies between high and low conductivity, it appears that this fluctuation is sufficiently attenuated by the time it reaches MW3. However, the conductivity at MW3 is generally lower than at MW1 and this may be due to dilution caused by infiltration at the site. Still the difference in conductivity between MW1 and MW3 is relatively small and likely represents an inconsequential impact, if any.

CONCLUSIONS

While the formation of a groundwater mound is a natural occurrence associated recharge to an unconfined aquifer, increased groundwater mounding was observed to occur at the site in response to storms greater than 1.9 centimeters. However the extent of mounding appears to be confined to the area adjacent to the site. This is indicated by a steep gradient between MW2 and MW3 and the minimal groundwater elevation increases observed at MW3. The rate of infiltration was observed to be a primary factor affecting groundwater mounding; additionally temperature was observed to affect the infiltration rate and resulting mound. Despite the observed mounding, the depth of groundwater remained a sufficient depth below the site (12 ft). Given the maximum extent of groundwater mounding, it is believed

the sufficient storage capacity exists in the vadose zone to accommodate larger storms without adversely affecting the local subsurface.

Continuous monitoring of the groundwater temperature and conductivity, indicate that the bioinfiltration best management practice causes significant fluctuations near the site but that these fluctuations are attenuated downgradient. The temperature and conductivity of wells MW1 and MW3 were observed to be similar, indicating that infiltration by the site does not significantly impact the downgradient water. However, at MW2 stormwater infiltration was observed to significantly alter the groundwater temperature for prolonged periods. Decreases in temperature were observed to be related to increased groundwater mounding, thus while the downgradient temperature may not be effected variations in temperature effect the performance of the system.

RECOMMMENDATIONS

A surprising observation of this study is that the upgradient well, MW1 displayed rapid responses to precipitation indicating a rapid infiltration rate. This observation underscores the importance of minimizing site disturbance during construction and further the capability of un-compacted turf areas to infiltrate water. Thus it is recommended that site design seek to minimize site disturbance and maximize pervious surfaces.

Another interesting observation was the prolonged decrease in temperature observed at MW2. While the effects were observed to be very localized, the decreased temperatures also lead to slower infiltration rates, even after surface temperatures may have increased. Thus, it is important to consider the variation in infiltration rate due to temperature during the selection and design of infiltration BMP. Further it is suggested that groundwater monitoring may be a useful tool for BMP design. For instance, continuous monitoring data would provide accurate estimation of infiltration rates and expected mounding, in addition to establishing the groundwater elevation at a site.

Lastly, the effectiveness of infiltration BMP for smaller storms should be noted. As observed in the study, for smaller storms the BMP did not lead to excessive mounding. Additionally it was observed that downgradient conductivity, temperature and groundwater elevation were not significantly effected by the BMP. Therefore it is suggested that similar infiltration BMP be considered to treat similar water quality issues for smaller storms.

ABSTRACT: Stormwater experts agree that the currently used percent removal methodology metric has many flaws, and some have suggested utilizing a BMP effluent concentration metric. This paper examines a new method that establishes effluent target concentrations for BMPs based on the health of macro-invertebrates in the receiving water. 193 ambient water quality monitoring stations in North Carolina were paired with benthic macro-invertebrate health ratings collected in very close proximity. Water quality for the sites ranged from Excellent to Poor and was divided into three distinct eco-regions. Median NO_3 + NO_2, TKN, TN, and TP concentrations all increased with poorer benthic ratings; however, there was no such trend with respect to DO, TSS, and Fecal Coliforms. Overall, the new method was most effective in the Piedmont and Coastal eco-regions; however with more data collection, the Mountain eco-region may also benefit. For example, if regulators were to require "Good" water quality in the Piedmont eco-region, designers would have to limit effluent concentrations of TN and TP would be 0.99 mg/L and 0.11 mg/L, respectively, per the method presented herein.

INTRODUCTION

The USEPA requires that all stormwater pollution is controlled to the maximum extent practicable (MEP) through the use of best management practices (BMPs). Local and state stormwater manuals and handbooks provide guidance on BMP designs, including the assignment of load reductions and/or percent removals of pollutants. For example, The North Carolina Department of Environment and Natural Resources (NCDENR) utilizes a post-development standard of 0.45 kg/ha/yr (0.4 lb/ac/yr) and 4.5 kg/ha/yr (4.0 lb/ac/yr) for total phosphorus (TP) and total nitrogen (TN), respectively, in the Tar-Pamlico River Basin (NCDENR, 2007). BMPs are implemented to meet post-development regulatory standards and are given credit based on percent nutrient removal for that BMP type. For instance, a stormwater wetland is credited with a 35% and 40% pollutant reduction of TP and TN, respectively, in North Carolina (Table 1). The load reduction and percent removal methods do not typically account for variations in BMP designs, eco-region, or background contaminant levels in receiving waters.

As stated by the Center for Watershed Protection, "Stormwater management criteria commonly assign the median removal efficiency, but this often masks the role of certain design factors in reducing or enhancing performance" (Winer, 2007). Other studies show that changes in design, including media composition and depth, ratio of watershed area to BMP surface area, and/or ponding and retention times, heavily influence BMP efficiency (Dietz and Clausen, 2006; Li et al, 2009; Clary et al., 2002; Hunt et al, 2006; Urbonas, 1995; Scholes et al., 2008). Similarly, local hydrology, climate and system age impact BMP performance (Scholes et al., 2008; Urbonas, 1995; Line et al., 2008), creating variations in reported removal rates (Table 1).

Table 1. Assigned total nitrogen (TN) and total phosphorus (TP) BMP removal efficiencies by state.

	BMP type							
	Bioretention		Wetpond		Wetland		Sand Filter	
State	TN	TP	TN	TP	TN	TP	TN	TP
New Jersey [1]	30%	60%	30%	50%	30%	50%	35%	50%
North Carolina [2]	35%	45%	25%	40%	40%	35%	35%	45%
Virginia [3]	46%	5%	31%	52%	24%	48%	32%	59%*

[3] VDCR (1999.)

The documentation of physical, chemical, climatic, geological, biological, and meteorological parameters are often not required in BMP monitoring (Urbonas, 1995), yet are essential in correlating design characteristics with performance (Clary et al., 2002; Urbonas, 1995). Percent removals and load reductions, as a performance indication, can be misleading. Such metrics do not necessarily coincide with water quality. For example, Lenhart and Hunt (2009) show that influent TN concentrations at a wetland in River Bend, North Carolina, appear to approach irreducible levels.

The wetland demonstrated poor performance, when evaluated through the percent removal metric, even though influent and effluent nutrient concentrations were lower than BMP effluent concentrations measured in other nearby studies (Line et al., 2008). Conversely, (Schaafsma et al., 1998) showed that for a wastewater wetland, even when TN, TP, and total suspended solids (TSS) influent loads were reduced by more than 90%, effluent concentrations remained above regulatory levels.

In some situations, a BMP may produce higher effluent concentrations due to surrounding environmental conditions. For example, a bioretention cell receiving runoff from a well-fertilized area tends to have higher inflow nutrient concentrations than a cell receiving runoff from a lightly used parking lot (Passeport and Hunt, 2009; Sharkey, 2006). Similarly, Emilsson et al. (2007) showed that runoff nutrient concentrations increase when vegetative roof systems are conventionally fertilized, when compared to roofs that receive controlled release fertilizers. Finally, runoff from greyfield developments, brownfield developments, and reclaimed lands are expected to show higher pollutant loads than runoff from greenfield developments (Stehouwer et al., 2006). Hence, background and inflow concentrations impact nutrient removal performance and should be considered when setting regulatory standards.

The ultimate goal of stormwater management is to protect water quality and promote healthy aquatic ecosystems. The percent removal and load reduction methods do not take into account aquatic health when assessing BMPs and do not ensure high quality, healthy waters. The following study introduces a novel methodology of assessing BMPs by relating aquatic health to ambient water quality data, and then selecting BMPs able to meet this ambient water quality.

POSSIBLE SOLUTION: ASSESSING WATER QUALITY USING BENTHIC MACRO-INVERTEBRATES. Biotic indicator species, such as benthic macro-invertebrates (benthos), periphyton, and certain fish populations, are used to assess water quality of streams and rivers across the world (Skoulikidis et al., 2004; Van Duinen, 2006; Gray, 2008). The organisms predict the degree of impairments in streams and can be an evaluation metric to determine the effectiveness of best management practices (Barbour et al., 1999). Forty-three states use biotic protocols in water resource management (NCDENR, 2008) with benthos being the most commonly used indicator species by state agencies in the United States (Southerland and Stribling, 1995). Benthos reside in rivers, streams, and estuaries in the following 5 habitats: cobble (hard substrates common in the mountain and piedmont regions), snags (woody debris including sticks and branches), vegetated banks (submerged lower banks with the presence of plants and roots), submerged macrophytes (seasonal aquatic plants rooted to the stream bottom), and sand/fine sediment (Barbour et al., 1999). A different collection technique is recommended for each habitat (Barbour et al., 1999). Different benthos are used in monitoring, corresponding to the native species of the particular eco-region of interest. For example, common freshwater benthos include mussels (class bivalvia), crayfish (order decpoda), worms (order oligochaeta), and stoneflies (order plecoptera). Benthos range in tolerance and therefore may be predicative of varying water qualities (Table 2).

After collection, the benthos are preserved and identified by family and genus/species type. Depending on the abundance and diversity of benthos collected, a stream health rating is assigned, including: Excellent, (E), Good, (G), Good-Fair, (GF), Fair, (F,) and Poor, (P) (Barbour et al., 1995). Similar ratings and modified collection and assessment techniques are used in other regions of the world (Buffagni et al., 2004; Simboura and Reizopoulou, 2008).

Table 2. Tolerance of Benthos in terms of Water Quality (Barbour et al., 1995)

Rating	Description of Benthos	Sample Organisms by Scientific Name
Excellent	Very sensitive	Ephemera Guttulata (mayfly), Litobrancha recurvata (mayfly)
Good	Sensitive	Drunella allegheniensis (mayfly), Rhyacophila fuscula (caddisfly)
Good-Fair	Semi-tolerant	Amnicola (snail), Elliptio complanata (mussel)
Fair	Tolerant	Cambarus (crayfish), Crangonyx (crustacean)
Poor	Very tolerant	Enchytraeidae (worm), Limnodrilus cervix (worm)

Benthic macro invertebrate health ratings (BMR) are commonly used in European countries to assess water quality, as shown by the **A**ssessment System for the Ecological **Q**uality of Streams and Rivers throughout **E**urope using Benthic **M**acroinvertebrates (AQEM) project. The program uses BMRs to assign a stream health rating from 5 (best) to 1 (worst) and, furthermore, aspires for all rivers and streams across 8 countries in Europe to reach at least a "good" or "4" quality rating by 2015 (Skoulikidis, 2004) .

Trends toward regional specificity have increasingly emerged with regards to BMR collection techniques and analysis. Using BMRs, Skoulikidis (2004) examined the difference in water quality among three eco-regions in Greece with varying geographical and climatic features. A nutrient metric, reflecting ambient water quality (AWQ), exhibited satisfactory correlation with the biotic metric (BMR). Another study expands on the collection techniques of Barbour et al. (1999) by assessing benthos from 53 streams in Illinois. The study determined that high nutrient levels in streams corresponded to degraded aquatic habitat (Heatherly and Whiles, 2007). Contrasting Skoulikidis (2004), Heatherly and Whiles (2007), caution against using an eco-regional approach to stream classification. The study suggests that a certain eco-region may not exhibit the same benthos throughout. However, like Skoulikidis (2004), the study shows an overall correspondence between elevated nutrient levels and degraded habitats of benthos (Heatherly and Whiles, 2007). In addition to regional studies, notable efforts are being made to localize collection techniques. The Mid Atlantic Coastal Streams (MACS) workgroup (including North Carolina) and the Florida Department of Environmental Protection (FLDEP) have developed a scientifically validated sampling procedure for low-gradient coastal streams (Barbour et al., 1999).

Previous North Carolina studies have not yet directly compared ambient water quality nutrient concentrations to BMRs, yet plentiful data collected by NCDENR provides potential to do so. The ambient water quality (AWQ) at 339 stream and river sites throughout North Carolina has been monitored for the past 30 years, including monthly visits and five-year basin wide assessment reports (NCDWQ, 2008). AWQ data include concentrations of dissolved oxygen (DO), total suspended

solids (TSS), nitrogen-ammonia (NH3), Nitrate-Nitrite (NO3 + NO2), Total Kjeldahl Nitrogen, (TKN), TP, and Fecal Coliforms. Simultaneously, the water quality of approximately 200 North Carolina streams has been rated using benthos or fish (NCDWQ, 2008).

PROPOSING THE WQABI METHOD. Similar to the study by Skoulikidis (2004), the following method evaluates regional impact on ambient water quality. This study is different from others because all data are specific to North Carolina, including: BMRs, AWQ data, BMP efficiencies and effluents, and pollutant regulations. Relating pollutant concentrations associated with healthy streams and estuaries to BMP effluent concentrations provides an innovative method for BMP performance evaluation. While these particular findings are regionally specific, the methodology presented has wide application.

To properly design BMPs for a given watershed, target pollutant effluent concentrations need to be established. While excellent water quality conditions are encouraged, it is understood that background local ambient water quality may create exceptions. For example, most greenfield developments have cleaner background water quality, so perhaps they should be held to more stringent ratings such as E or G. A greyfield or infill development, with degraded background water quality, however, may have lower standards such as GF. It is expected that DO concentrations will increase with higher BMRs, while concentrations of TSS, NH3, NO3 + NO2, TKN, TP, and Fecal Coliforms will increase with lower ratings. Additionally, it is hypothesized that some pollutants will show a higher correlation in one eco-region than in another, therefore it is expected that the WQABI method may be better able to be used in one eco-region over another.

This study evaluates a method of assessing BMP performance using water quality assessed by benthic macro-invertebrate health ratings (WQABI), specific to one of three eco-regions. Specifically, in North Carolina, do the mountain, piedmont, and coastal regions require different regulatory standards? This concept is important in determining criteria for development and whether or not a developed land can meet pre-developed, or target, water quality conditions.

METHODS

AWQ, benthos, and fish sampling locations were obtained from the North Carolina Division of Water Quality (NCDWQ) and imported into ArcGIS, version 9.2. (NCDENR, 2008). Each BMR or fish sampling location was located in one of three eco-regions: mountain, piedmont, or coastal.

The mountain eco-region is the smallest of the three and is separated from the piedmont region by the Blue Ridge Mountain range. The piedmont eco-region is located between the mountain region and the coastal region. It consists of a wide variety of streams, with higher levels of urbanization. Lastly, the coastal region is located in eastern North Carolina, and consists of coastal wetlands, sand hills, and swamps (NCDENR, 2008). Numerous states have accepted the eco-region approach in benthos assessment (e.g. Iowa (IADNR, 2008), North Carolina (NCDENR, 2008), and Virginia (VDEQ, 2008)).

AWQ monitoring sites were then paired with BMR and fish collection sites within a 402 m (¼-mile) range. All paired monitoring locations (AWQ with BMR, or AWQ with fish monitoring sites) were located in the same river or estuary. Also, if the monitoring date ranges of AWQ and BMR/fish population data collection did not fall within two years of each other, the pair was omitted from the study due to possible temporal changes in water quality. If multiple benthic ratings were given within the time range of AWQ collection, the lowest rating documented was used. Additionally, if both fish community and BMRs were available, the BMR was used, as the majority of water quality ratings from NCDENR are based on BMR data. Ultimately, each match included one of 5 ratings and one of three eco-regions, yielding a total of 15 possible combinations. Lastly, the significance between BMR and AMS data was analyzed using SAS statistical software package (2004).

RESULTS AND DISCUSSION

There were 193 DWQ stations in which both AWQ data were collected and BMRs were assigned. For accuracy, if a pair contained a station where collected AWQ data were limited (a sample size of 10 or less), the pair was excluded. Also, if the number of pairs in a given eco-region was less than 8 that rating was excluded from the study. Namely, Fair (F) and Poor (P) ratings from both the mountain and coastal eco-regions were omitted (Table 3).

Table 3: The number of paired AWQ and BMR collection sites for each eco-region

Number of Location Matches			
	Eco-Region		
BMR Rating*	Mountain	Piedmont	Coastal
E	8	8 (1)	10
G	19	20	14
GF	10 (1**)	31 (2)	16
F	4	39 (3)	3
P	1	8 (1)	2

* E = excellent, G = good, GF= good-fair, F = fair, and P = poor ratings

** Values in parentheses represent DWQ stations in which both AWQ and fish populations were monitored. The values outside of parenthesis represent stations in which BMR and AWQ were monitored.

The Piedmont region had the most stations in which both AWQ and BMRs were monitored (106), followed by the Coastal (45), and the Mountain (42) (Table 3).

Median pollutant concentrations for the Piedmont eco-region exhibited the most apparent trend with BMR. As expected, median $NO_3 + NO_2$, TKN, TN, and TP concentrations all increased with decreased BMR (Table 4). NH_3 concentrations typically increased with decreased BMR. Median DO concentrations decreased with increased BMR, yet median concentrations of TSS and fecal coliforms did not exhibit a noticeable relationship with BMR.

Table 4. Median Concentrations of Pollutants in the Piedmont Eco-region

	PIEDMONT							
	Constituent concentration (mg/L)							
Rating	DO	TSS	NH3	NO2 + NO3	TKN	TN	TP	Fecal (#/100mL)
E	9.25	4.00	0.02	0.39	0.30	0.69	0.06	229.0
G	8.80	6.40	0.04	0.59	0.40	0.99	0.11	103.1
GF	8.40	5.00	0.06	0.67	0.50	1.17	0.13	93.0
F	7.70	7.00	0.06	1.60	0.56	2.16	0.22	169.2
P	6.80	5.00	0.13	6.34	1.25	7.59	0.63	316.4

The coastal eco-region exhibited similar results (not shown): however, the mountain eco-region did not show an obvious relationship between AMS data and BMRs (not-shown). It is suggested that more data be collected in the fair and poor water-quality classes of both the mountain and coastal eco-regions, to more accurately define the relationship between BMR and AMS data. As of now, the WQABI method could only apply to the Piedmont eco-region *with confidence*.

Stormwater regulators could use the data presented for the Piedmont eco-region to establish target BMP effluent concentrations. For example, suppose a green field development were to take place. Regulators could require that practices be used such that the composite water quality from the development met "Good" water quality standards of 0.99 mg/L and 0.11 mg/L for TN and TP, respectively (Table 4). Perhaps a grey field development could have more relaxed standards placed on it ("Good-Fair").

Overall, macro-invertebrate tolerance to "dirtier" ambient conditions appears to increase with eco-region as follows: mountain, coastal, and piedmont. This suggests that it is more difficult to design a treatment system to achieve comparable benthos protection in the mountain than in the piedmont. Of the three eco-regions, the piedmont exhibited the most apparent trend between AWQ data and BMRs and would therefore benefit most from using the WQABI method. WQABI does not work for all constituents, but it does appear reasonable for some. NH_3, NO_2, TN and TP exhibited significant BMR effects, as they increased with decreased BMR. The mountain eco-region typically exhibited lower median nutrient concentrations than either the coastal or piedmont eco-regions, however there was little to no correlation between BMR and AMS data, and therefore use of WQABI in this eco-region is not recommended without further research.

FUTURE DIRECTIONS OF WQABI. Numerous flaws have been documented in using load reduction and percent removals for assessing BMPs (Lenhart and Hunt, 2009; Schaafsma et al, 1998; Jones et al., 2008), including the false notion that high concentration and load percent removals directly correspond to excellent BMP performance. The WQABI method accounts for errors associated with the conventional BMP assessment methods by relating performance to target ambient water quality concentrations. The purpose of this paper was to introduce this concept; however, many questions about using WQABI persist. For example, do the various types of indicator species (benthos, fish, periphyton) give equivalent water quality

ratings? How much variation lies among species collection techniques? What is the appropriate course of action when no BMP can meet desired water quality effluent concentrations? Further studies are encouraged to ensure consistency in the measurement of biotic health ratings. Likewise, detailed reporting of BMP design parameters, such as those required by the International BMP database (Clary et al., 2005), is encouraged to determine optimal BMP design criterion.

All three eco-regions exhibited a similar tendency: differentiation among AWQ data begins to blur as BMRs improve. For instance, there is a noticeable difference in AWQ data between GF, F, and P, but not much variation among E, G, and GF. It appears there are two distinct categories of AWQ data: those associated with cleaner water and those associated with poorer water quality. It is recommended that this ambiguity between BMRs be studied further by considering the tolerance of different biotic indicators, fish versus benthos for example.

Furthermore, it is important to recognize that the WQABI method only considers water quality and not quantity. Total Maximum Daily Loads (TMDLs) may be surpassed when runoff volume increases with large storm events, negating potential benefits of cleaner effluent concentrations. Volume control must be considered in addition to the WQABI method to prevent flooding, maintain stable stream morphology, and meet target or pre-development hydrology. While the WQABI method can be completed independent of hydrologic data, it is strongly recommended that hydrologic design guidance be provided in addition to the WQABI method. Also, WQABI works when substantial BMP studies reporting effluent concentrations from the region exists or if a reliable, deterministic way of predicting effluent concentrations is employed. It is recognized that for some practices in some parts of the U.S.A, a deficiency exists in data collection and BMP performance prediction.

CONCLUSIONS

Several conclusions were drawn from this study:

(1) AWQ data and BMRs can be combined to set target nutrient concentrations that protect high quality waters. Target concentrations can be used as a baseline for BMP assessment. This study examined NC-specific data, but similar analyses could be conducted elsewhere.
(2) Unlike the percent removal method, the WQABI method accounts for irreducible and background concentrations.
(3) Different eco-regions require different regulatory standards. This study showed that the streams in the mountain eco-region of North Carolina held lower median nutrient levels across all BMRs when compared to streams in the piedmont and coastal eco-regions. The higher background water quality implies a need for more stringent regulations on development. Perhaps development in some pristine parts of the mountain eco-region should be prevented altogether if excellent water quality is to be maintained. A similar trend is evident in the coastal eco-region, where stream nutrient concentrations are generally lower than those in the piedmont eco-region.

(4) The WQABI method allows different target conditions/standards to be chosen depending upon existing in-ground conditions. For example, a greenfield development could be held to a more rigorous standard (an E or G BMRs) than a greyfield, infill development (perhaps a GF BMR).
(5) Some eco-regions respond better to the WQABI method than other eco-regions. This study showed that the piedmont eco-region exhibited the most obvious trend between AWQ-data and BMRs; however, more AQW data and BMRs were monitored in the piedmont compared to the mountain and coastal regions. More paired data (AWQ and BMRs) from the mountain and coastal eco-regions are recommended for further analysis.
(6) Some pollutants responded better to the WQABI method. For example, NH_3, NO_2, TN and TP concentrations exhibited significant BMR effects; whereas, TSS, DO, and fecal coliform concentrations showed little or no relation to BMR.
(7) The WQABI method needs further refinement. Efforts are needed to synchronize benthos collection and identification techniques and more data are needed to differentiate water quality among the five BMRs, particularly among the better water quality ratings. Additionally, hydrologic function, especially reductions in outflow volume should be considered and combined with the WQABI method in order to ensure optimal BMP effectiveness.

ACKNOWLEDGEMENTS

Abstract

This work is part of a long term project which aims to simulate (1) the hydrology, (2) street flows, (3) flow interception at inlets and (4) storm-sewer flows in urban areas. The present work describes the application of the model using only the first two modules. The hydrologic model (first module) transforms rainfall to runoff using the kinematic wave approximation and simulating the infiltration process with the Green-Ampt method. The street model (second module) is based on a finite volume-shock capturing scheme that solves the full conservative Saint-Venant equations and can be used to simulate subcritical and supercritical flows. The formulation of boundary conditions at the street crossings in the street model is general and can be used for any number of streets, any combination of inflowing and outflowing streets, and any flow type (e.g., supercritical flows). The model using the first two modules is fast and robust and it has several potential applications. Perhaps the most important one is that it can be used in new urban developments to identify critical zones of urban flooding (e.g., zones with high water depths and flow velocities) in order to take appropriate measures of drainage control (e.g., to increase capacity of inlets). This model can also be used in developed urban areas to locate the critical areas in case of inlet clogging. In order to illustrate the capabilities of the model (first two modules) it was applied to an urban catchment in the village of Dolton, a southern suburb of Chicago. The watershed of this village drains to the dropshaft CDS-51 in the Calumet TARP (Tunel and Reservoir Plan) system which is operated by the Metropolitan Water Reclamation District of Greater Chicago. The fact that this model is fast makes suitable its application to large urban areas.

Introduction

Urban catchments in rainy climates commonly are exposed to flood threats. In upland areas urban flooding is often associated with an inadequate drainage system, in most cases due to inadequate inlet capacity. Urban flooding may cause material losses in the form of public and private property damage. Furthermore, street flooding may interfere with traffic and in some cases, may jeopardize pedestrian safety. To identify the critical zones of urban flooding (e.g., zones with high water depths and flow velocities) so that appropriate

measures of control (e.g., to add inlet grates) can be taken, hydrologic/hydraulic modeling of a large urban catchment is required, especially in flat urban areas. For a flood modeling tool to be practical, the flooding analysis needs to be done in a relatively short time frame.

Street runoff is frequent in cities which have either direct surface or combined or separated storm/sanitary sewer systems. Nanía (1999) presented a model for simulating street runoff in steep urban areas using a finite difference scheme. This model was later improved using laboratory results (Nanía et al. 2004) for a better representation of the flow distribution at the crossings (supercritical flow). In flat urban areas such as in the city of Chicago, most of the street flows are in subcritical regime for which the model of Nanía (1999) can not be used.

As part of a long term project, a new street model that can be used for simulating subcritical and supercritical flows was developed based on previous works of the authors for pipe transient flows (León et al. 2006, León et al. 2009). In the new model, the formulation of boundary conditions at the street crossings are general and can be used for any number of streets, any combination of inflowing and outflowing streets and any flow type.

Model description

This work is part of a long term project which aims to develop an integrated model to simulate the hydrology and hydraulics of urban drainage systems. This integrated model has four modules. The first module is a hydrologic model, which transforms rainfall into effective runoff depending on surface characteristics (e.g., slope, roughness, paved/unpaved surface area). The resulting runoff of each block is distributed over the respective street and it is used as input for the hydraulic street model (second module). The street model routes the flow over the streets. The third module estimates flow interception at inlets, which lead street runoff into the underground storm-sewer system. The intercepted runoff is used as input for the storm-sewer model. For modeling storm-sewers the Illinois Transient Model (ITM) developed by the first author of this paper was adopted. As mentioned before the present work describes the application of our model using only the first two modules. The application of the integrated model (four modules) will be presented in the near future. Following a brief overview of these modules is presented.

First module: hydrologic model

The hydrologic model transforms rainfall to runoff considering both impervious and pervious surfaces and simulating the infiltration process with the Green-Ampt method (Green and Ampt, 1911; Chow et al, 1988). The depression storage (initial abstraction) is also considered to obtain an effective rainfall. The transformation from effective rainfall to runoff is made considering overland flow on two independent equal-length sloping planes, one pervious and one impervious, and using the kinematic wave approximation of the Saint Venant equations.

Second module: street flow routing

The street model solves the one-dimensional open channel flow continuity and momentum equation that for non prismatic channels or rivers may be written in its vector conservative form as follows (e.g., Chaudhry 1987, León et al. 2006):

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} = \mathbf{S} \tag{1}$$

where the vector variable **U**, the flux vector **F** and the source term vector **S** are given respectively by:

$$\mathbf{U} = \begin{bmatrix} A \\ Q \end{bmatrix}, \ \mathbf{F} = \begin{bmatrix} Q \\ \frac{Q^2}{A} + \frac{A\overline{p}}{\rho} \end{bmatrix} \text{ and } \mathbf{S} = \begin{bmatrix} q \\ F_w + (S_0 - S_f)gA \end{bmatrix} \tag{2}$$

where A = cross-sectional area of the channel; Q = flow discharge; $\overline{p}$ = average pressure of the water column over the cross sectional area; ρ = liquid density; g = gravitational acceleration; S_o = slope of the bottom channel; S_f = slope of the energy line, which may be estimated using an empirical formula such as the Manning's equation; q = lateral flow discharge per unit width, and F_w = momentum term arising from the longitudinal variation of the channel width.

The governing equations [Eq. (1)] are solved using a Finite Volume (FV) shock-capturing scheme in an identical way to that presented in León et al. (2006). The FV scheme used is the second-order MUSCL-Hancock method with the MINMOD Total Variation Diminishing (TVD) pre-processing slope limiter. The FV-shock capturing scheme used ensures that mass and momentum are conserved. For the boundary conditions at the street crossings an identical approach to that presented in León et al. (2009) was used. The formulation of boundary conditions presented in León et al. (2009) is general and can be used for any number of streets, any combination of inflowing and outflowing streets, and any flow type (e.g., supercritical flow).

Third and fourth modules: inlets and sewer system

The third module comprises a model for estimating flow interception at inlets. Inlets lead street runoff into the underground storm-sewer system. The inlet module was implemented according to manual HEC-22 (Federal Highway Administration, 2001).

The fourth module is the Illinois Transient Model (ITM) developed by the first author of this paper. In the ITM model, the free surface region is simulated using the 1D Saint-Venant equations, the pressurized region is modeled using the 1D compressible waterhammer equations and open channel-pressurized flow interfaces are modeled by enforcing mass, momentum and energy relations across the interfaces. The ITM model is a finite volume-shock capturing scheme that can simulate transient free surface flows, transient pressurized flows and the simultaneous occurrence of free surface and pressurized flows (mixed flows) in complex pipe networks.

Evaluation of the model

The primary objective of this section is to illustrate potential applications of the model (first two modules). For instance the model can be used to identify critical zones that need more attention in terms of inlet capacity and maintenance when most of the inlets in the urban watershed are clogged.
In this section the first two modules of the model are applied to an urban catchment in the village of Dolton, a southern suburb of Chicago.

Project storm

In the current application the triangular storm proposed by Chow and Yen was used (Chow and Yen, 1976). The storm which is depicted in Figure 1 has a duration of 80 minutes and a maximum intensity of 45.72 mm/h at 30 minutes and it is a simplification of the storm that occurred in Chicago on July 2nd, 1960.

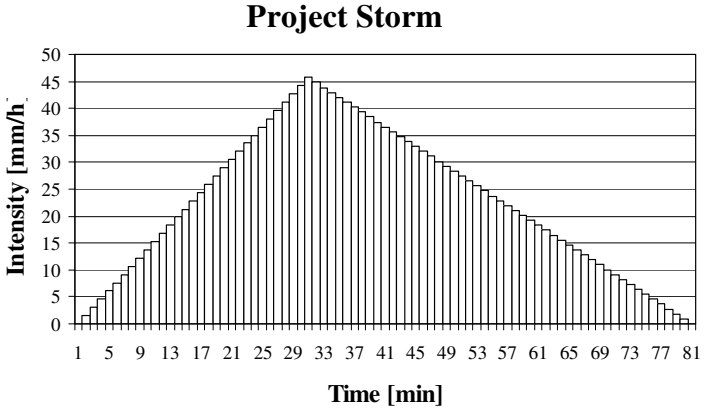

Figure 1: Simplified rainfall hyetograph for Chicago on July 2nd, 1960 (Chow and Yen, 1976).

Characteristics of the watershed

CDS-51 is the name given to the dropshaft that captures the pluvial waters from the sewer system of the village of Dolton. The characteristics of the 3.55 km^2 CDS-51 watershed are presented in the following table:

	Pervious area	Impervious area
Percentage of total area	42.6	57.4
Average slope m/m	0.0133	0.0133
Manning coefficient	0.2	0.015
Depression storage [mm]	1.27	
Hydraulic conductivity [mm/h]	10.7	
Effective saturation	0.418	
Effective porosity	0.412

The street network which is depicted in Fig. 2 is composed by 267 blocks (or fraction of blocks), 454 nodes (street crossings) and 637 streets, being the total area modeled of 3.55 km^2 (aprox. 2.22 sq. miles). For the street flow routing the street cross-section shown in Fig. 3 (Nania 1999) was used.

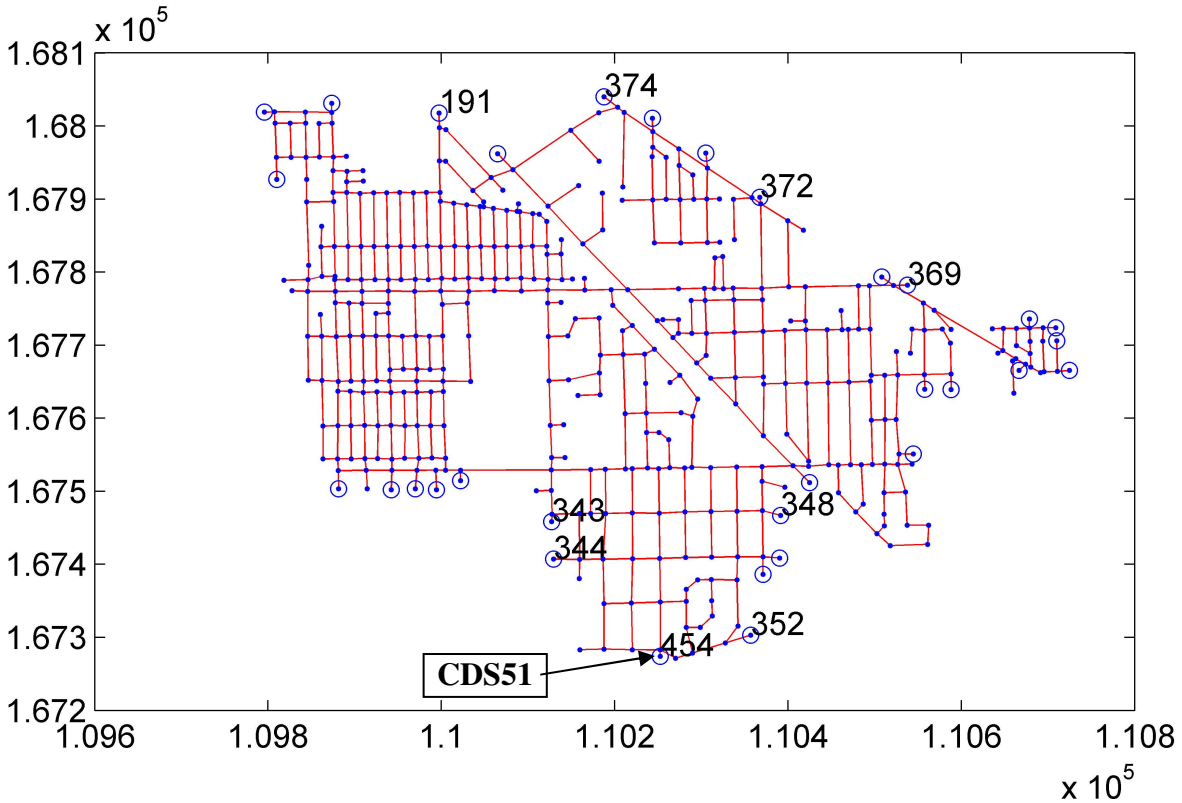

Figure 2: Street network showing the nodes with the largest outflow discharges (*x* and *y* axes on this figure show distances in feet).

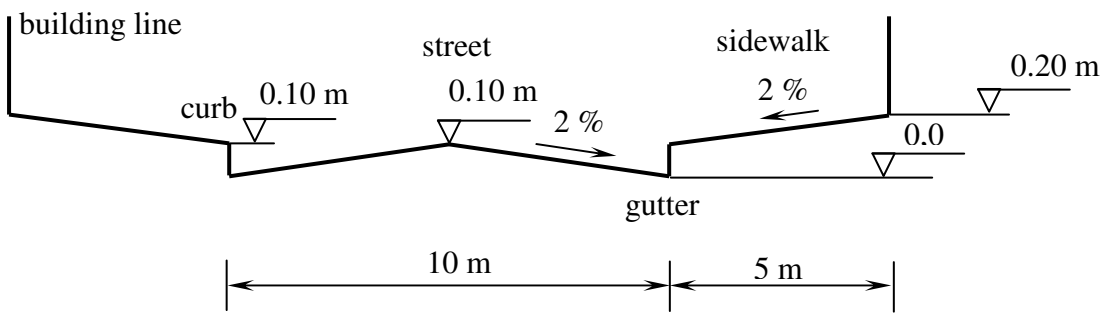

Figure 3: Typical street cross-section (Nania 1999)

Outflow discharge hydrographs

The CDS-51watershed has 32 outflowing streets at the boundaries of the watershed which are represented by blue circles in Figure 2. A street is denoted outflowing if draws water

from the node (street crossing) in normal conditions (e.g., uniform flow) and inflowing otherwise. If the street has zero slope, the street can be treated as either inflowing or outflowing. The numbered outflowing streets presented in Figure 2 (e.g., 454) represent those streets having the largest outflow (flow out of the watershed) discharges. The sum of the hydrographs at these nodes (numbered) represent 90% of the total outflow. The outflow of node 454 coincides with dropshaft CDS-51 and it has the largest outflow of the watershed (23% of total outflow). The outflows from nodes 343, 344 and 348 represent 52% of the total (20, 14 and 18%, respectively). The total outflow hydrograph which is the sum of the hydrographs at the nodes marked by blue circles in Figure 2 is presented in Figure 5 along with the rainfall hyetograph. The reader must notice that the inlets module (module 3, flow interception) is not considered so that the only way the flow can be drained from the watershed is through outflowing streets at the boundary of the watershed.

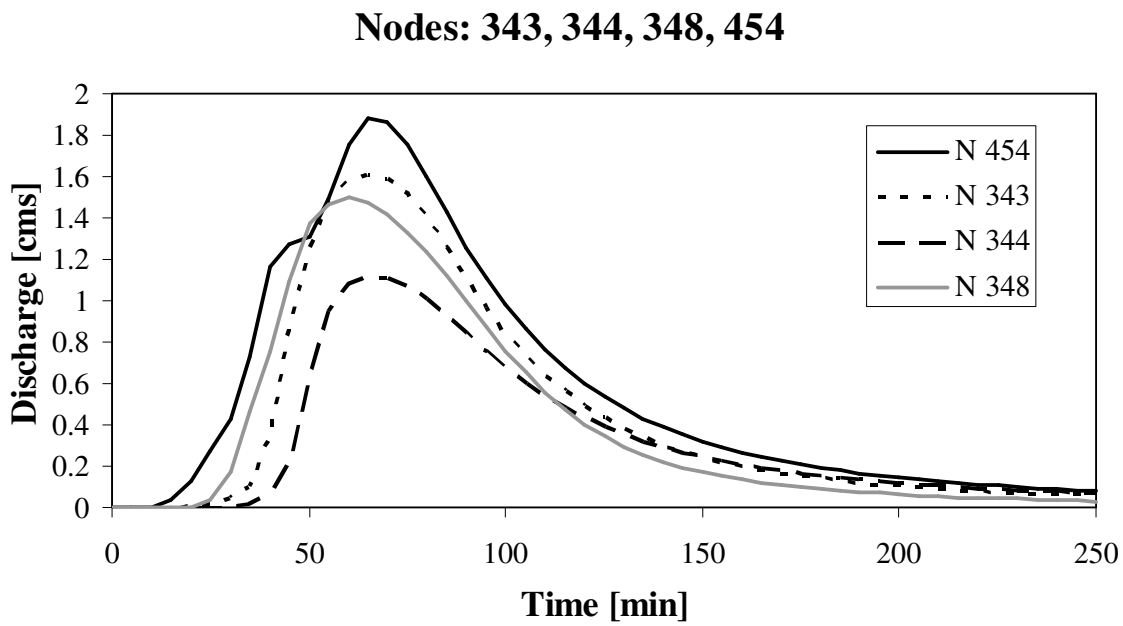

Figure 4: Hydrographs for the four largest outflow discharges in the watershed. The sum of these outflows represent 75% of the total outflow.

Danger analysis of street flows

The water depths and flow velocities in the street network can be used for a danger analysis using some criteria of the literature such as those presented by Nanía et al. (2006 and 2007). These authors suggest a threshold value for maximum flow depth, maximum flow velocity, maximum product between depth and velocity and maximum product between depth and squared velocity. As an example of danger analysis, a map of water depths obtained 65 minutes after the beginning of the storm is presented in Figure 6. As can be observed in this figure, water depths between 10 to 30 cm are the most common in the street network. An area can be denoted as critical when the water depth exceeds for instance a depth of 30 cm. The most critical areas (water depths up to 1.2 m) in Fig. 6 are marked with red circles. Evidently these critical areas are the zones that need more attention in terms of inlet capacity and maintenance. It should be noted that for the

simulations, the curb edge was assumed to be extended vertically, confining the flow to the streets. Figure 7 shows a map of water depths at the end of the simulations (250 minutes). As can be observed in this figure, the water depths in most streets have been depleted except in the critical zones (red circles), where the water is trapped. The latter is expected since the inlet module (flow interception) was not considered in the simulations.

Conclusions

This work is part of a long term project which aims to simulate (1) the hydrology, (2) street flows, (3) flow interception at inlets and (4) storm-sewer flows in urban areas. The present work describes the application of the model using only the first two modules. The hydrologic model (first module) transforms rainfall to runoff using the kinematic wave approximation and simulating the infiltration process with the Green-Ampt method. The street model (second module) is based on a finite volume-shock capturing scheme that solves the full conservative Saint-Venant equations and can be used to simulate subcritical and supercritical flows. The formulation of boundary conditions at the street crossings in the street model is general and can be used for any number of streets, any combination of inflowing and outflowing streets, and any flow type (e.g., supercritical flows). In order to illustrate the capabilities of the model (first two modules) it was applied to an urban catchment in the village of Dolton, a southern suburb of Chicago. The watershed of this village drains to the dropshaft CDS-51 in the Calumet TARP (Tunel and Reservoir Plan) system which is operated by the Metropolitan Water Reclamation District of Greater Chicago.

The aforementioned application of the model (two first modules) identified two critical zones (maximum water depths) in the CDS-51 watershed. The first zone is located on the

center of the watershed and the second on the SE border. Evidently these critical areas are the zones that need more attention in terms of inlet capacity and maintenance. The results also show that when no inlets are considered (e.g., clogged inlets), most of the total flow generated in the watershed are drained out of the watershed through outflowing streets at the watershed boundary and only 23% of the total flow will reach dropshaft CDS-51.

The CPU time of the model (first two modules) for the present application (~ 600 streets) was about one hour which makes suitable its application to large urban areas.

Evaluating the Mixing Mechanism of Outfall Discharges from Municipal Separate Storm Sewer Systems

MICHAEL H. WOO, Ph.D., P.E.[1]

[1]Department of Civil and Environmental Engineering, THE CITADEL, 171 Moultrie St., Charleston, SC 29409; PH (843) 953-7679; FAX (843) 953-6328; email: Michael.woo@citadel.edu

Abstract: Under the National Pollutant Discharge Elimination System (NPDES) stormwater program, operators of large, medium, and regulated small municipal separate storm sewer systems (MS4s) require authorization to discharge pollutants under an NPDES permit. MS4s can be linear or complex, open, piped, manmade, natural, or a combination of all of the above. Some carry groundwater or piped streams, are tidally influenced, or have some other constant source of non-stormwater discharge. An MS4 is not always just a system of underground pipes-it can include roads with drainage systems, gutters, and ditches. Typically, an outfall from a MS4 discharges into a creek system and ultimately into a larger receiving water body which might or might not be tidally influenced. In order to evaluate the existing and expected water quality of the ultimate receiving water body, mathematical models are used to conduct flushing modeling and water quality modeling of the ambient waters. A hydrodynamic mixing zone model will be used to simulate steady or unsteady discharge from a single open channel outfall or a system of outfalls from municipal separate storm sewer systems (MS4s). This model is applicable for a wide range of hydrologic situations wherein flow and transport are governed by time-dependent forcing functions. Permit requirements will consist of a Water Quality Monitoring Program to be implemented and samples collected according to permitting agencies' procedures for collection, control and preservation.

INTRODUCTION

The treated effluent from the City of Gainesville, Georgia Linwood Wastewater Treatment Facility is currently discharged through a submerged outfall into Lake Lanier. The effluent is first chlorinated and then dechlorinated before being discharged. The outfall is located just offshore from the City of Gainesville at approximately one mile downstream from the Thompson Bridge. Figure 1 shows the aerial view of the facility. The original outfall is a three-port diffuser. However, according to the report entitled "Development of Linked Watershed and Water Quality Models for Lake Lanier", two of three ports are silted over (Limno-Tech, Inc.). The remaining functional port is a 24-inch diameter pipe and is located at approximately 120 to130 meters (m) (394 to 427 feet (ft)) from the bank. The effluent is discharged vertically from this port. The water depth at the discharge location is about 30 m (98 ft) and the discharge port is approximately 0.5 m (1.64 ft) above the lake bottom. Future improvement plans call for the Linwood Wastewater Treatment Facility be upgraded in stages and expanded to increase the future ultimate peak day treatment capacity.

Figure 1. City of Gainesville, GA Linwood Wastewater Treatment Facility

IMPACT OF STORMWATER DISCHARGE STUDY

The CORMIX 2 model (Gerhard H. Jirka et. al. 1996) is applied to a range of discharge rates to study the impact of stormwater temperature on the ambient water temperature adjacent to the Linwood Wastewater Treatment Facility. This paper documents the results and final recommendation from a CORMIX 2 evaluation of the effect of the higher water temperature of the effluent on the ambient water temperature of the lake.

DESIGN CRITERIA

The Environmental Protection Division (EPD) of the Georgia Department of Natural Resources stipulates that "at a sampling point 3 m (9.8 ft) from the outfall diffuser, the temperature shall not exceed 90 degrees Fahrenheit (F) nor increase the lake ambient temperature more than 5 degrees Fahrenheit." This study was conducted to establish the new outfall discharge location and optimum outfall diffuser configuration to achieve the above stated EPD requirement.

Instead of applying a mixing zone to regulate a point source wastewater discharge to a natural water body, the State of Georgia establishes that any point source effluent parameter must be diluted by a factor of at least two (2.0) at a sampling point 3 m (9.8 ft) from the outfall diffuser. The model will evaluate the dilution level at this location.

Ambient (Lake Lanier) Condition and Modeling Assumption

Ambient conditions were assumed primarily based on the assumptions used in a previous study. The CORMIX 2 model input parameters are listed below.

- The ambient winter water temperature range is between 42.8°F to 46.4°F (6°C to 8°C) and the temperature does not vary over the water depth. An ambient winter water temperature of 42.8°F is used in the model.
- The ambient summer water temperature varies with depth, with a pycnocline at approximately 20 to 60 ft below the water surface. The upper layer temperature varies from 82.4°F to 87.8°F; while the lower layer temperature is about 46.4°F to 50°F**.** An ambient lower layer summer water temperature of 46.4°F is used in the model with a pycnocline height of 30 ft.
- The stormwater discharge temperature is assumed to be 82.4°F.
- The model tested the impact of various discharge rates of 22.6 cubic feet/second (ft^3/s), 33.6 ft^3/s, and 51.7 ft^3/s.
- The ambient current velocity is estimated to be 0.13 ft/s (0.04 m/s).
- The Manning's n for the lake bottom is assumed to be 0.02 (smooth, earth channel, no weeds).
- The wind speed at the water surface is assumed to be 6.6 ft/s (2 m/s) (a breeze condition). CORMIX 2 defines a breeze as a wind speed from 0 ft/s to 9.8 ft/s.

MODEL EVALUATION AND RESULTS

The critical parameter that is evaluated for all the results is the water temperature at a sampling location of 3 m (9.8 ft) from the diffuser port. This study used the CORMIX 2 model to analyze numerous combinations of the following outfall diffuser location and diffuser configuration. Based on the results, the recommended design configuration is detailed in the Table 1 and shown in Figure 2.

- Outfall discharge depth.
- Number of diffuser ports.
- Distance of the diffuser from the shoreline.
- Size of each diffuser port.
- Effluent discharge direction – Against or perpendicular or in the same direction as ambient current direction.
- Orientation of the diffuser to the ambient current direction (Beta angle). Refer to Figure 3.
- Discharge vertical angle (Theta angle). Refer to Figure 3.
- Height of each diffuser port above the lake bottom.

Table 1. Final Design Configuration

(1) Outfall discharge depth	88 ft
(2) Number of diffuser ports	30; spaced evenly at 5 ft apart.
(3a) Distance of the closest diffuser port from the shoreline	500 ft
(3b) Distance of the furthest diffuser port from the shoreline	650 ft
(4) Size of each diffuser port	4-inch diameter
(5) The orientation of the diffuser to the ambient current direction (Beta angle)	90°
(6) Discharge vertical angle (Theta angle)	65°

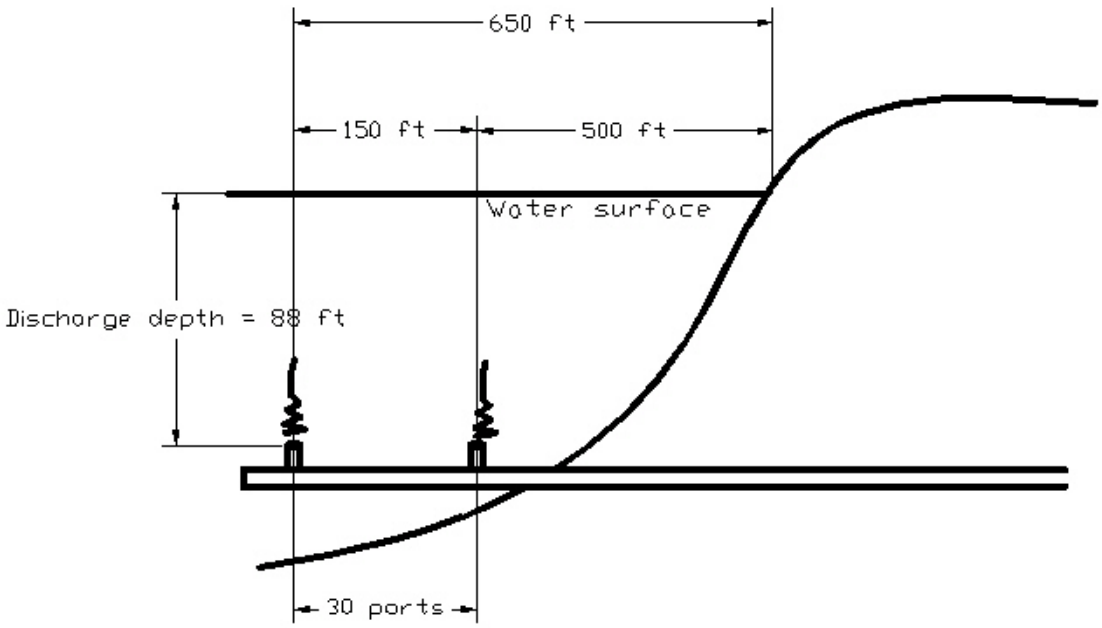

Figure 2. Diffuser Port Design Configuration

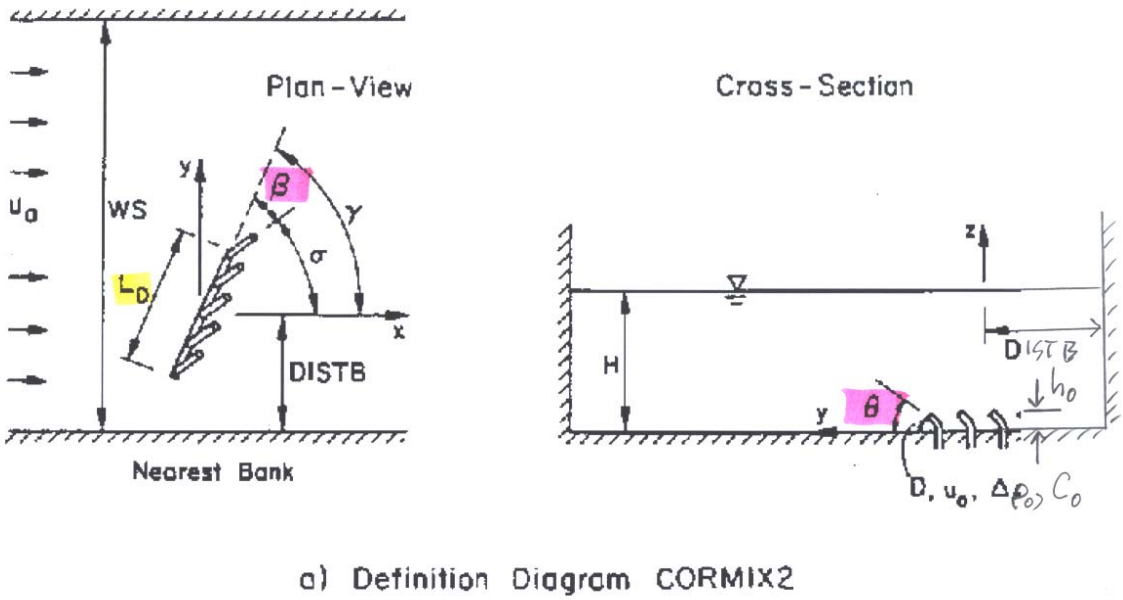

Figure 3. Discharge Vertical Angle (Gerhard H. Jirka et. al. 1996)

Using the recommended outfall diffuser location and diffuser configuration as given in Table 1, the CORMIX 2 results are shown in Table 2. It tabulates the water temperatures at EPD's regulatory critical location of 3 m (9.8 ft) from the discharge port under the various discharge rate scenarios.

Table 2. Ambient Temperature at 3 meters (9.8 feet) from Each Diffuser Port

		Increase in Ambient Temperature and Actual Temperature			
Discharge	Discharge Depth	Temperature Increase	Actual Temperature	Temperature Increase	Actual Temperature
(ft^3/s)	(Ft)	(°F)	(°F)	(°C)	(°C)
		Winter Ambient Temperature is 42.8°F or 6°C			
22.6	88	1.59	44.39	0.881	6.88
33.6	88	2.07	44.87	1.15	7.15
51.7	88	2.57	45.37	1.43	7.43
		Summer Ambient Temperature is 46.4°F or 8°C			
22.6	88	2.38	48.78	1.32	9.32
33.6	88	2.97	49.37	1.65	9.65
51.7	88	3.55	49.95	1.97	9.97

CONCLUSION

As shown in Table 2, none of the evaluated discharge rates cause any increase in the ambient temperature above EPD's regulatory requirement of no greater than 5°F at a sample location of 3 m (9.8 ft) from the discharge point. This holds true for both the winter period as well as the critical summer period. As such, as long as the diffuser configuration and discharge location as established in Table 1 are implemented, the EPD regulation on temperature increase will be met.

ABSTRACT

A significant concern in the design of large, underground conduits for storm or combined sewer systems is the avoidance of geyser formation, a phenomenon which involves the explosive release of water through vertical shafts. Current practice for transient analyses of these systems involves application of numerical models to simulate the rapid filling processes. Since these models do not consider interactions between the inflows and air being displaced during the filling process, it is felt that these models cannot predict geyser formation.

Data from a large diameter stormwater tunnel in Minneapolis, Minnesota has been analyzed to determine the events that led to a series of observed geyser events. Data include pressure and velocity measurements within the tunnel that can be correlated with a videotape of the geyser events themselves. The pressure records are inconsistent with hydrostatic pressure lifting water to the ground surface. Features of the pressure records can be interpreted to indicate the release of large air pockets through the dropshaft. A qualitative comparison of these results with smaller scale laboratory experiments indicates similarities in the pressure responses. These results suggest that the entrapment of large air pockets is an important component to the geysering process and that tunnel design procedures need to properly account for these effects.

INTRODUCTION

The phenomenon commonly referred to as "geysering" that occurs in below grade sewer systems is manifest as an explosive release of water through vertical ventilation shafts or manholes. Figure 1 presents images of two such events, one in Novosibirsk, Siberia and the other in Minneapolis, Minnesota. These clips are parts of larger images and based on other features such as nearby buildings, the geyser rises at least 20 m above the land surface. Such occurrences following the construction of the Chicago Tunnel and Reservoir Project (TARP) in the early 1980s initiated interest in development of analysis methods so that geyser formation

a.) Novosibirsk, Siberia b.) Minneapolis, Minnesota

Figure 1. Images of geysers formed in underground sewer systems.

could be predicted during design and modifications implemented to avoid such problems. Numerical models of transient mixed flow where both free surface and pressurized flow can occur simultaneously in nearly horizontal conduits were developed for this purpose with the model by Cardle and Song (1988) being a notable early contribution to the literature on the topic. Additional investigations in more recent years include Capart, et al (1997), Politano, et al (2007), and Vasconcelos, et al (2006). These represent various approaches to the problem of predicting the simultaneous occurrence of both free surface and pressurized flow with sufficient numerical accuracy to predict the hydraulic bores that may form in a rapidly filling conduit.

In spite of the numerical sophistication associated with the implementation of these models, it is not clear that any of them are relevant to the issue of geyser formation. To date, there is very little discussion in the literature on the physical processes involved in geyser formation. The geyser images in Figure 1 could be interpreted as a mixture of air and water, raising the possibility of air-water interactions. Small scale laboratory experiments reported in Vasconcelos (2005) indicated that the most likely explanation for geyser formation was the escape of discrete air pockets through vertical shafts that were in a pressurized state at the time of air arrival such that water was forced upwards ahead of the rising air pocket. Vasconcelos and Wright (2006) describe a number of different ways in which trapped air pockets can form in a rapidly filling pipeline, even with very simple geometries. Wright, et al (2008) suggest that a common situation for trapping large air pockets involves the reflection of a free surface bore at a conduit transition that results in the filling of the pipe at the transition with air behind the bore becoming pressurized. However, the small scale of the experiments from which these observations were made does not permit generalization to the much larger prototype

scale of large natural systems. Other studies that discuss the phenomenon of geysering are curiously quiet on this issue. For example, Guo (1989) and Guo and Song (1990) discuss geyser formation but then present simple hydraulic analyses that don't consider air interactions. In Guo and Song (1991), the following discussion is presented "…If the water level rises above ground surface, the geyser occurs. It has been ascertained that if the dropshaft is ventilated, as most are, the cover could not be blown off by air pressure alone. That is, most blowoffs are caused by the impact force of the rising water. Therefore, it is sufficient to study the hydrodynamics alone." Although it is true that adequate ventilation will prevent buildup of air pressures sufficient to displace manhole covers, a simple calculation will show that air pressures as small as 3 kPa can be sufficient to lift a typical manhole cover on the order of 0.8 m diameter. The first writer was involved in an application where providing additional ventilation at an appropriate location eliminated a recurring problem with manhole cover displacements in a 1.8 m diameter combined sewer system. However, the above statement does not address the fundamental question of whether geyser formation involves an air-water interaction. This question is of critical importance to design issues since a numerical model that requires the hydraulic grade line to rise to the ground surface in order for a geyser to occur would entirely miss an occurrence that is associated with an air-water interaction. Fortunately, data has been collected on one large scale system that allows this issue to be addressed.

SYSTEM DESCRIPTION

The image of the Minneapolis geyser depicted in Figure 1b was extracted from a video recorded as part of a data collection effort due to a recurrence of geyser formation at two dropshafts in a stormwater collection system that flowed beneath the median of Interstate 35W in Minneapolis, Minnesota. The video recorder was installed at a dropshaft near the 35th Street overpass and was accompanied by the installation of velocity and pressure transducers. Records spanned the time from at least 1997 through 2005 with 13 events captured between 1999 and 2005 (and additional ones prior to 1999). Individual events often involved more than one discrete geyser event. Data is presented below for a rainfall event that occurred on the morning of July 11, 2004 and involved nine individual geyser events that formed and subsided at intervals of approximately two minutes. A video record of two geyser events is provided on the Minneapolis Star Tribune website at www.startribune.com/video/15509842.html/. It is noted that the writers possess other video records from this same installation that depict even stronger geysers.

The general details of the system are as follows:

- Stormwater tunnel diameter of 3.66 m;
- Dropshaft diameter of 2.44 m;
- Tunnel invert located 28.6 m below grade;
- Pressure transducers installed at 0.47 and 2.88 m above the local tunnel invert. The data acquisition system was programmed to record pressures only when

water depths in the tunnel exceeded 1.46 m. Data was collected every five seconds for water depths (as determined by the velocity meter) between 1.46 and 2.93 m and every second for indicated depths greater than 2.93 m;

- Velocities were recorded at five minute intervals with an American Sigma area-velocity meter.

RESULTS

The particular data presented below were collected on July 11, 2004 at approximately 5:30 AM. Nine independent geysers were observed in the video record of the event; there is some variability in strength as some of the geysers were not explosive, each geyser lasted for about 10-25 seconds with about 75-90 seconds between separating the onset of each one. The velocity record indicates that the velocity was relatively constant at about one meter per second between about 5:30 and 8:50 AM with no indication of fluctuations that might be indicative of inertial oscillations in the pipeline. Figures 2 and 3 present the pressure and velocity records, respectively, for a time period spanning the occurrence of the geyser events. The pressure record is from the lower pressure transducer and converted to a pressure head relative to the tunnel invert. Superimposed on the figures are the visual observations of the geyser occurrences indicated in the video record. This is indicated by the vertical rise and fall in the line; the height of the line has no relationship to the pressures indicated on the vertical axis.

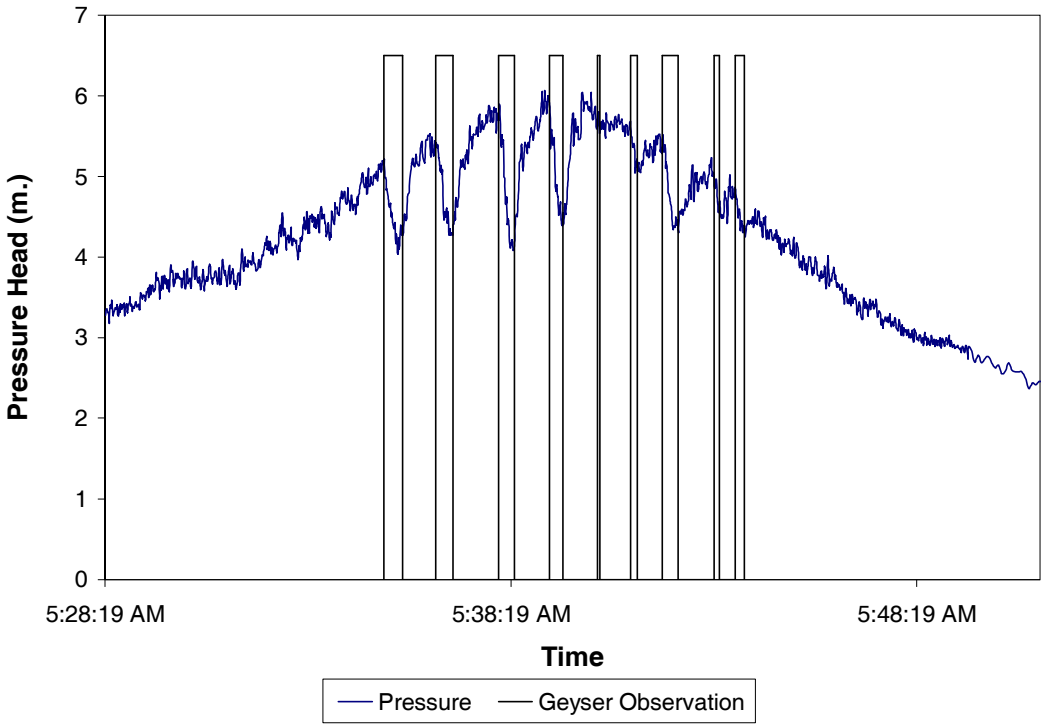

Figure 2. Pressure head relative to tunnel invert in tunnel recorded during geyser events.

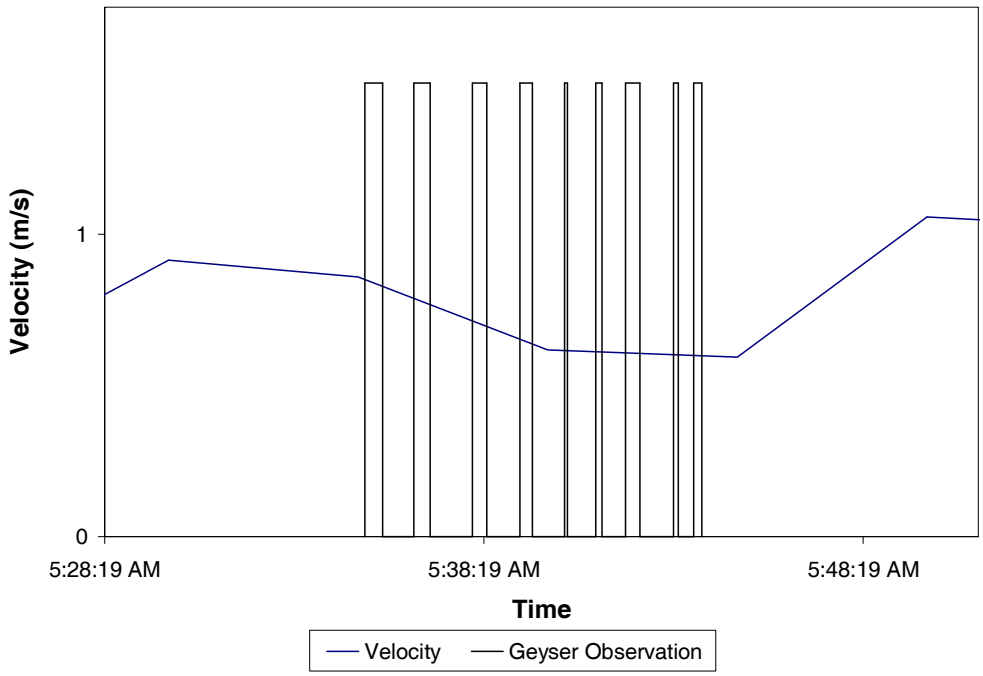

Figure 3 Velocity recorded during geyser events.

A number of observations can be made from the results presented in Figures 2 and 3. First of all, the pressure head never went above about 6 m during the entire event which is only nominally greater than the tunnel diameter of 3.66 m. Since the tunnel invert is 28.6 m below grade, the discussion in Guo and Song (1991) discussed in the Introduction would exclude the possibility of geyser formation as the hydraulic grade line never approaches the land surface. This clearly indicates that some other mechanism must be invoked to explain the observed geysers. Another interesting observation is related to the observed geyser height. If it is assumed that the geyser height is approximately 20 m from the video record, the exit velocity of a water jet can be estimated by the simple conversion of velocity to elevation head as $V^2/(2g) = h$ with h the rise height of the water jet. Using h = 20 m would result in an exit velocity of 19.8 m/s, suggesting an upward discharge in the dropshaft of 93 m^3/s. This compares to a tunnel discharge of approximately 9 m^3/s during the geyser events according to the velocities presented in Figure 3. Thus, there is an insufficient source of water to produce a water jet rising that high in the air. Finally neither the pressure nor the velocity records in Figures 2 or 3 suggest any indication of inertial oscillations that would be necessary to produce the discrete geyser events according to the explanation suggested by Guo and Song (1990). Although there does appear to be a velocity oscillation in Figure 3 during the time that the geyser events occur, a careful inspection of the timing indicates that the velocity is continuously declining during the geysering interval and then increases again once the events cease. This is more indicative of additional flow resistance during that time period such as partial flow blockage due to air pocket

migration upstream against the water flow. Therefore, there is a total lack of evidence to support the concept that geysers are created by water column rise in a vertical shaft to above grade. A different explanation must be invoked to explain the geyser formation in these particular events. While the data is only applicable to the particular physical setting and the particular event, it is felt that the observations can be more generally applied to understand geyser formation.

A more careful inspection of the pressure records provides additional insight. Assuming that the tunnel becomes pressurized when the pressure height exceeds the diameter, this occurs about six minutes prior to the commencement of the first geyser event. The last geyser event finished about two minutes before the system transferred back to a free surface state. Figure 4 is an expansion of the pressure record to examine the pressure variation during the sequence of geyser events. It is seen that each geyser lasted for about 10-25 seconds with about 75-90 seconds separating the onset of the next one. The pressure tends to rise gradually between geyser events and then drop abruptly at the onset of the geyser. This behavior is inconsistent with a "hydraulic" or water flow only explanation of geyser formation but would be consistent with the arrival of discrete air pockets at the dropshaft with a pressure drop as the air releases into the vertical shaft. Although this is not conclusive proof, the data are far more consistent with an air-water interaction, specifically with the expulsion of discrete air pockets through vertical shafts than other explanations considered. It is also noted that the apparent regularity of the geyser events displayed in Figure 4 is not necessarily consistent with observations during other events and the time intervals between individual occurrences is also inconsistent between events. The writers believe that the geometry of the particular system results in the propagation of discrete air pockets from the downstream direction, but are awaiting further investigation to confirm this hypothesis.

LABORATORY OBSERVATIONS

An adaptation of the experimental setup described by Vasconcelos (2005) was used to measure pressures during laboratory events that were interpreted as geysers. Figure 5 indicates the experimental setup. A 0.038 m diameter, 2.5 m tall ventilation shaft was installed on the top of the horizontal pipeline at about its midpoint. Experiments were performed with the pipe initially partially full of stagnant water. The two-way valve indicated in Figure 5 was opened in two steps. The first step produced a free surface hydraulic bore that propagated to the downstream end and reflected off the closed end of the pipe, with a higher free surface bore propagating back towards the inlet. An additional partial valve opening increased the upstream flow rate and produced a pressurized condition with a significant amount of air trapped between the two fronts. The timing of the second inflow increase was selected to result in the two bores interacting near the ventilation shaft so that water rose a few cm into the shaft prior to the arrival of the discrete entrapped air pockets. The flow was switched off once the water level began to rise in the inflow shaft so that the pressure head within the pipeline never exceeded about 1.2 m. Regardless of this, water was expelled out the top of the 2.5 m high ventilation shaft at a height far above the hydrostatic pressure level. Each arriving air pocket lifted the water successively higher in the shaft. Although there

was no attempt to reproduce the unknown inflow conditions associated with the field event described above, the height of the laboratory ventilation shaft, when scaled by the pipe diameter, is greater than the 28.6 m for the Minneapolis stormwater tunnel and it appears reasonable to conclude that air can indeed lift water to the heights observed in the video.

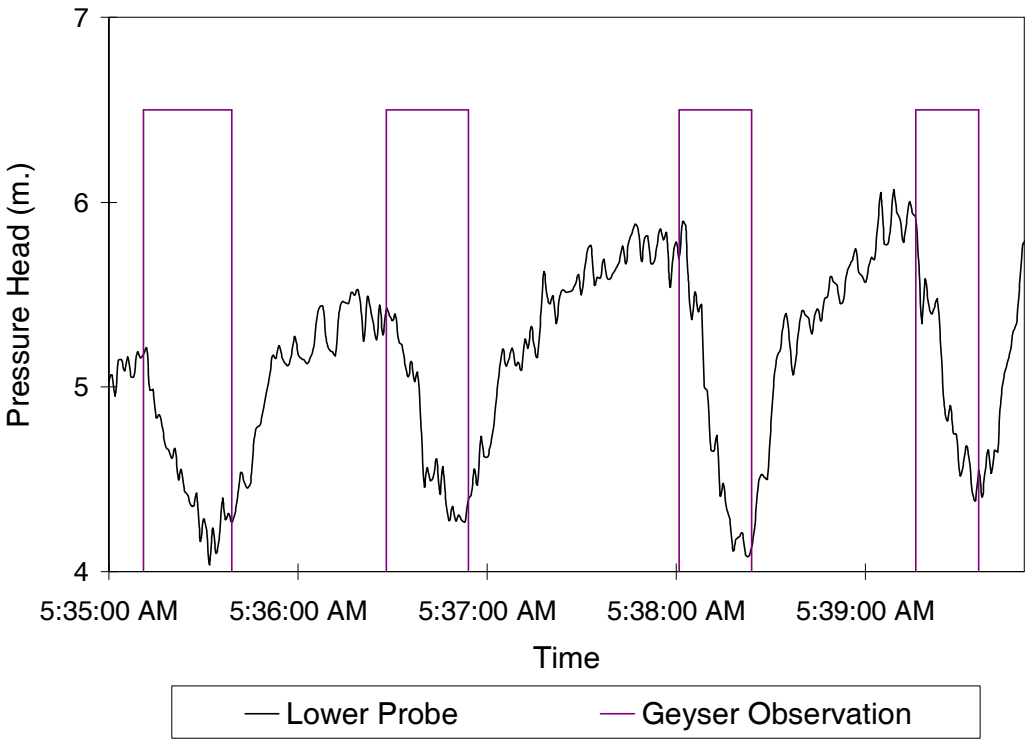

Figure 4. Output from lower pressure probe during geyser events.

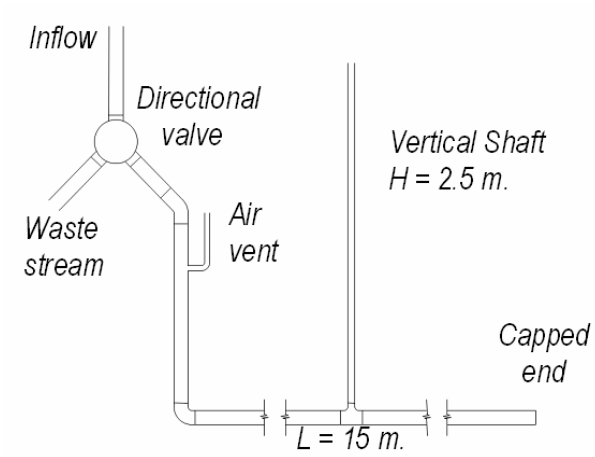

Figure 5. Schematic of laboratory apparatus.

Two piezo-resistive pressure transducers (Endevco model 8510B-1) were connected at the bottom of the pipe at distances of 6.45 m and 11.70 m downstream of the center of the inflow pipe. Outputs from these transducers were sent to a data acquisition system (National Instruments DAQPad MIO-16XE-50) at a frequency of 10 Hz. A typical pressure record from the transducer located upstream of the ventilation shaft is presented in Figure 6. The effect of the air pockets rising in the shaft is seen as sudden drops in the overall trend of the pressure variation. This feature is similar to the behavior indicated in Figure 4.

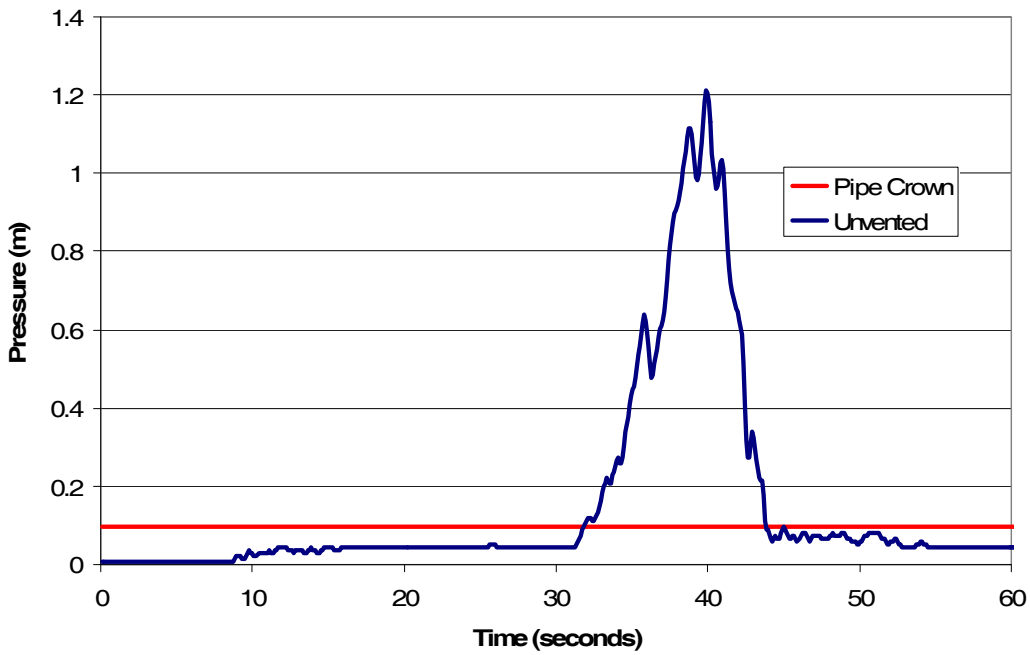

Figure 6. Pressure in pipeline upstream from ventilation shaft during expulsion of entrapped air pockets.

DISCUSSION AND CONCLUSIONS

The field measurements collected during a rainfall event in Minneapolis, Minnesota in 2004 included visual observations of the dropshaft at the ground level along with velocity and pressure measurements within the stormwater tunnel immediately upstream from the dropshaft. The most plausible explanation for the observed geyser formation is the interaction of trapped air with water initially standing in the drop shaft due to the existence of surcharge conditions. The measured pressures within the pipeline were incapable of lifting that water even close to the ground surface, let alone eject it 20 m into the air. Converting the estimated rise height of the geyser into a vertical velocity in the dropshaft requires a discharge an order of magnitude than actually measured to be flowing within the tunnel at the time of geyser formation. Furthermore, the measured pressures and

velocities do not support the presence of large scale inertial oscillations within the tunnel such as might be required to lift the water to the ground surface in a series of short duration events. The patterns of water pressure drop during air expulsion through the ventilation shaft are similar in the field and laboratory measurements, suggesting that in spite of possible limitations due to the small laboratory scale, there are similarities between the mechanisms for water rise in the vertical shaft in both situations.

There are several implications associated with these findings. The process of geyser formation is apparently not directly connected with surging in the tunnel system as suggested by the previous literature on the subject. Numerical models that are currently applied to simulate transients in rapidly filling tunnel systems do not account for the air phase. The predicted results of these models should be interpreted with caution with respect to the issue of geyser formation. Predictions that transient hydraulic grade lines remain below grade should not be interpreted to suggest that geyser formation will not occur. Model capability to predict the location of air entrapment within a system is useful, even if the subsequent motion of the air cannot be predicted with a single phase flow model. This information can be used judiciously to make design decisions about the location and capacity of air ventilation required in a system.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the cooperation of Dr. Christopher Ellis (originally with the St. Anthony Falls Hydraulics Laboratory) and Bruce Irish of the Minnesota Department of Transportation in providing the field data used in this manuscript.

ABSTRACT

In February 2006, as part of its Phase II Stormwater Quality Management Program, the Metropolitan St. Louis Sewer District (MSD) implemented rules that require post-construction stormwater best management practices (BMPs) at development and redevelopment sites. MSD references the Maryland Department of the Environment's *Stormwater Design Manual* as a BMP design guide. However, this document does not specifically address proprietary BMP devices and currently there is not a national or Missouri state standard by which to evaluate them.

For a proprietary BMP to be approved for use within MSD boundaries, the device's manufacturer must present it to MSD and request approval for one or more use levels. Possible use levels include General Use Level, Redevelopment Use Level, Highway Use Level, and/or Provisional Use Level. Submittal requirements and use level descriptions are provided in *Proprietary Water Quality Products and the MSD's Stormwater Management Program* (rev. Jan 2009), which can be downloaded from the MSD web site (www.stlmsd.com). Devices are approved for a particular use level based on (1) the treatment performance requirement for that use level and (2) the certified performance of the device. Performance certification testing must comply with the Technology Acceptance and Reciprocity Protocol (TARP) or the Technology Assessment Protocol-Ecology (TAPE). When approved for use by MSD, each device is issued an approval letter that is posted on the MSD web site. Advantages of the process include (1) MSD recognition that the device is effective for its use, (2) manufacturers quickly ascertain whether their product can be approved, and (3) BMPs that meet requirements are approved in a reasonable time period.

INTRODUCTION

History of MSD. The St. Louis Metropolitan Statistical Area covers 16,555 square kilometers, and has a population of 2,603,607. This area includes the City of St. Louis, St. Louis County and ten (10) other surrounding counties located in both Missouri and Illinois. The bulk of the metropolitan area's population and infrastructure lies within the City of St. Louis and St. Louis County, with the outlying counties being developed at a much lower density. St. Louis County and the City of

St. Louis are two distinct entities, with the City of St. Louis being a county unto itself. St. Louis County includes not only its own incorporated areas but also 91 separate municipalities (East West Gateway, 2002).

As shown in Figure 1, St. Louis stormwater drains into three major watersheds: the Mississippi River, Meramec River and Missouri River. All stormwater runoff ultimately enters the Mississippi River. All three rivers serve as sources for public drinking water, while both the Mississippi and Missouri serve as a commercial barge transportation corridor. The Meramec is a major recreational asset for the region.

Figure 1. Major Watersheds and Municipalities within MSD [source: MSD]

Prior to the formation of MSD the City of St. Louis, St. Louis County, and the various municipalities handled sanitary and stormwater drainage issues independently. This fragmented approach was complicated by the fact that the area is drained by the Mississippi, Missouri, Meramec Rivers, contains many sinkholes and floodplains, and

the City of St. Louis is drained by combined sewers. In 1954 increasing frustration with the status quo, ongoing problems, and an increased appreciation for water quality issues in general lead to the formation of Metropolitan St. Louis Sewer District (MSD) by state constitutional amendment (Moore, 2003). Today, MSD is the fourth largest sewer district (based on miles of pipe) in the U.S., and roughly forty percent of the regulated MS4s in Missouri are located within its boundaries.

The St. Louis region's form continues to change as the population sprawls outward from the urban core. The vast majority of MSD has been developed; only outer portions of west and north St. Louis County remain undeveloped. It is anticipated that much of the future construction activity within MSD boundaries will be redevelopment.

Stormwater Quality Regulations. With the passage of the Water Quality Act of 1987 and the establishment of the national stormwater program, most large metropolitan areas were forced to address stormwater quality issues under the 1990 Phase I regulations. However, given that combined sewers serve the City of St. Louis, and St. Louis County is made up of a patchwork of small municipalities, each less than 100,000 in population, the St. Louis region escaped regulation under the Phase I requirements. The St. Louis area may have been the largest "donut hole" (exempted area) under Phase I of the National Pollutant Discharge Elimination System (NPDES) storm water program.

The 1999 Phase II regulations specifically required many of the political subdivisions within St. Louis County to obtain a Phase II NPDES permit. Given that MSD has been given authority for providing adequate sewer and drainage facilities within its boundaries, it was the obvious choice to coordinate compliance activities associated with Phase II. Sixty additional co-permittees were also named under the small MS4 permit. While MSD is the coordinating authority and regulates post-construction stormwater management, either the individual municipalities or St. Louis County are responsible for construction site stormwater control.

MSD PROPRIETARY BMP APPROVAL PROCESS

MSD Regulations. MSD has adopted regulations (*Rules and Regulations and Engineering Design Requirements for Sanitary Sewer and Stormwater Drainage Facilities*, February 2006) that represent a more comprehensive approach to stormwater management, and include water quality standards that must be met at development and redevelopment sites. These standards apply to any construction activity disturbing, individually or in aggregate, one (1) acre or more. While providing incentives and preference for nonstructural practices, these standards also address the design of structural BMP's to mitigate water quality and channel stability impacts.

For specific guidance regarding the design of structural BMPs, MSD references the Maryland Department of the Environment's (MDE), April 2000, *Stormwater Design*

Manual, Vol. I and Vol. II (herein referred to as the Maryland Manual). The Maryland Manual outlines the selection, design and construction of various "generic" structural BMPs (ponds, wetlands, infiltration basins/trenches, filtering systems, and open channel systems), but the Maryland Manual does not address proprietary BMPs. This was a problem because, in some redevelopment and/or highway projects, space availability and utility conflicts make construction of generic BMPs impractical. Also, experience indicates generic BMPs are not cost effective on some 1-2 acre redevelopment projects (i.e., a gas station or drugstore redevelopment).

Proprietary BMPs were proposed as potential solutions for redevelopment and highway projects. A proprietary BMP (also referred to as mechanical BMPs or manufactured BMPs) is a pre-fabricated stormwater treatment structure utilizing settling, filtration, absorptive/adsorptive materials, vortex separation, vegetative components, and/or other appropriate technology to remove pollutants from storm runoff. Proprietary BMPs are intended to capture sediments, metals, hydrocarbons, floatables, and/or other pollutants in stormwater runoff before being conveyed to a storm sewer system, or water body.

Different types of sites produce different pollutant and runoff characteristics, and it is reasonable that different sites may necessitate the use of different types of BMPs and that what is suited for one site may not be suited for another. MSD researched the literature for the types and particle sizes of contaminants in runoff from small drainage areas with a predominance of impervious cover (e.g., small parking lots, gas stations, and roadways), and compared this information with available testing data on proprietary devices (such as hydrodynamic separator devices). Based on this comparison, it appears that some proprietary BMPs provide effective treatment at these sites. The challenge is to develop a regulatory framework for (1) focusing these devices on the types of sites where they can be effective and (2) approving BMPs that have been appropriately tested.

Use Level Designations. All MSD approved proprietary BMPs are given a Use Level Designation that describes the types of site where a proprietary BMP can be applied. The four Use Level Designations that MSD considers are provided in Table 1.

Table 1: Proprietary BMP Use Level Designations

USE LEVEL DESIGNATIONS	DEFINITION / USES
General Use Level (GUL)	BMPs approved at this level may be used at all types of sites.
Redevelopment Use Level (RUL)	BMPs approved at this level may be used at non-residential redevelopment sites (i.e., total property area) less than five (5) acres in size.
Highway Use Level (HUL)	BMPs approved at this level may be used on public highway and public road projects.
Provisional Use Level (PUL)	BMPs approved at this level may be used only according to specific "provisions" outlined in the approval. This designation is intended only for use in certain and specific instances.

Additionally, underground BMPs are not allowed on residential projects. A site (i.e., total property area) is considered a redevelopment site if at least 20% of the existing site was impervious coverage as of January 15, 2000.

Performance Certification. New stormwater BMP products keep appearing in the marketplace, yet the availability of good testing data and standards on some of these technologies is scarce. To address this problem, MSD requires specific performance for each Use Level Designation and certification of that performance claim. Performance requirements and certifications required are outlined on the next page in Table 2.

A cornerstone of the MSD program is that all performance claims must be supported by test data and third party certification. The performance certification may be provided by the New Jersey Department of Environmental Protection (NJDEP) or by the Washington State Department of Ecology. (While neither agency has authority in Missouri, these protocols are largely consistent with MSD's goals, and their certification programs are the most thorough ones available.) The NJDEP certification utilizes the New Jersey Center for Advanced Technology (NJCAT) verification as conducted according to the Technology Acceptance and Reciprocity Partnership (TARP) Protocol. Washington State Department of Ecology utilizes the Technology Assessment Protocol - Ecology (TAPE).

In January 2009, MSD began to allow use of some RUL approved BMPs at redevelopment sites larger than five (5) acres, and these BMPs would be provided the PUL designation in addition to the RUL designation. The additional PUL designation is limited to proprietary devices, such as proprietary filters, that have conditional interim certification of proprietary BMP performance claims by the NJDEP in accordance with NJCAT performance verification program. These devices must also be actively pursuing field testing in accordance with NJCAT Tier II protocol and final certification by the NJDEP.

Table 2: Proprietary BMP Performance Requirements and Certifications

USE LEVEL DESIGNATION	PERFORMANCE REQUIREMENT	CERTIFICATION REQUIREMENT
General Use Level (GUL)	The BMP must be able to achieve a removal rate of 80% Total Suspended Solids (TSS) from stormwater runoff generated by the stormwater quality design storm.	Final certification of proprietary BMP performance claims by the NJDEP in accordance with TARP Tier II protocol, or General Use Level Designation for Basic Treatment by the Washington Department of Ecology.
Redevelopment Use Level (RUL)	BMP must sequester all non-aqueous phase hydrocarbon, scum, and floating debris and achieve an instantaneous removal rate of 80% TSS for the storm water quality design storm. TSS removal efficiency shall be based on an influent concentration of <300 mg/L and OK-110 particle size distribution.	Interim certification of proprietary BMP performance claims by the NJDEP in accordance with a NJCAT technology performance verification, or General Use Level Designation for Pretreatment by the Washington Department of Ecology.
Highway Use Level (HUL)	BMP must sequester all non-aqueous phase hydrocarbon, scum, and floating debris and achieve an instantaneous removal rate of 80% TSS for the storm water quality design storm. TSS removal efficiency shall be based on an influent concentration of <450 mg/L and OK-110 particle size distribution.	Interim certification of proprietary BMP performance claims by the NJDEP in accordance with a NJCAT technology performance verification, or General Use Level Designation for Pretreatment by the Washington Department of Ecology.
Provisional Use Level (PUL)	A specific Total Suspended Solids (TSS) removal rate applicable to the use requested is required.	Third party documentation from a public agency or testing agency confirming removal efficiency is required.

Key provisions of the PUL approval include a firm due date for obtaining the final certification and some form of annual reporting during the testing period. The manufacturer sets the due date, but in no case is the PUL due date allowed to extend beyond the expiration date of the region's current MS4 permit (June 2013). Annual reporting includes results from the TARP monitoring or a letter from NJCAT/NJDEP stating the results of the quarterly performance monitoring reports. Annual reporting allows the manufacturer and MSD to identify any performance or operational issues during TARP testing. Also, given the uncertainty of design flow rates tested in the laboratory versus actual flow rates encountered in the field, MSD may require for devices not holding Tier II certification a reduced allowable flow rate in the design of the BMP.

For larger site development projects, MSD does not believe the sole use of a BMP filter device is sufficient to addresses a site's obligation to manage site stormwater to the maximum extent practicable (MEP). These devices do not minimize stormwater pollutant loading at the point of generation nor do they mimic a site's natural runoff condition (i.e., these devices accept whatever loading and pollutants are created). For these larger sites, the overall stormwater management plan should also include practices that minimize directly connected impervious areas, stormwater pollution, and stormwater runoff. While MEP is not a required percentage or amount, the goal is that proprietary devices will be treated as a supplementary (rather than a primary) means of meeting the region's MS4 permit.

Proprietary BMP Application. Each BMP manufacturer submits an application packet and provides a presentation on their product to the MSD Proprietary BMP Committee. The Proprietary BMP committee is composed of MSD development review engineers and an outside consultant. The committee typically meets monthly or bi-monthly, depending on the number of applications under consideration.

The application packet and presentation discuss many topics, but are primarily focused on:

- A detailed description of the operation of the device, including a depiction of the flow path of water through the BMP.
- Construction specifications or installation instructions, engineering drawings or catalog sheets, and details on how BMP construction should be phased during site development.
- Product performance claim and certification, including data that support the manufacturer's claim of TSS removal, the appropriate verification/certification documents, and a summary table of BMP models and their peak water quality volume or flowrate (appropriate for the use level's performance requirement).
- Product design criteria, including sample proprietary BMP sizing calculations that indicate how to size and select the device as well as how to size and select any special components. A sample site layout plan (including pretreatment methods) for a typical site should also be included.
- Device, installation, and shipping costs, as well typical annual maintenance costs.
- One of advantages of proprietary BMPs is that the maintenance activities may be uniform from site to site. Manufacturers are required to provide a generic maintenance plan that includes a description of specific preventative and corrective maintenance tasks, a schedule of regular inspections and tasks, tools and supplies necessary to perform the maintenance tasks, and maintenance and replacement instructions for special components.

Approval Letter. Each approved device is issued an approval letter that specifies the device's use level designation; treatment rates, volumes, special equipment, and/or dimensions; and what reporting requirements apply. A hard copy of the approval

letter is provided to the applicant, and an electronic copy is posted on the MSD website. Posting the approval letters to the web works well because it allows vendors, designers, and developers convenient access to this information.

CONCLUSION

As of January 15, 2009, fourteen proprietary BMP devices have been approved for some level of use by MSD. The majority of manufacturers have requested RUL and/or or HUL approval. MSD has only approved one proprietary device for GUL. However, where space is available and utility conflicts are manageable, most designers prefer the generic BMP because these typically cost less to construct. The number of sites implementing generic BMPs is greater than the number using proprietary BMPs. Proprietary devices are mostly filling a niche for smaller redevelopment and public highway projects.

Feedback from manufacturers is that the approval process is "straight-forward" – manufacturers know where they stand when their application is submitted, and applications are typically processed within a few weeks. Some manufacturers have voiced concern about a lack of product competition at GUL eligible sites because at present only one device has met the GUL performance verification requirements (specifically, the field testing component). However, to efficiently and knowledgeably evaluate these BMPs, MSD feels third party field verification is very important. The TARP Tier II and TAPE verification protocols are compatible with our program. When available, consideration will be made for the protocol and certification recommendations of the ASCE/EWRI Task Committee on Guidelines for Certification of Manufactured BMPs.

In June 2008, the Missouri Department of Natural Resources renewed the regions MS4 permit. The permit has new language that states "*The permittee's program shall ensure that controls are in place that have been designed and implemented to prevent or minimize water quality impacts by reasonably mimicking pre-construction runoff conditions on all affected new development property and by effectively utilizing water quality strategies and technologies on all affected redevelopment projects, to the maximum extent practicable*" (emphasis added). This statement is significant because, inherently, the agency is expressing preference for low-impact development (LID), as opposed to structural techniques. Regulatory trends nationwide indicate a greater emphasis on LID techniques is coming. If requirements for mimicking a site's natural hydrology are applied to redevelopment projects, then MSD's proprietary BMP program will likely be revised and proprietary BMP use further restricted.

Also in 2008, several urban streams within the MSD were proposed for addition to Missouri's 303(d) list of impaired waters. Pollutants include bacteria, heavy metals, mercury, and chloride. The agency is attributing these pollutants to urban non-point sources. How this is addressed remains to be seen, but BMP design could be affected.

As such, the MSD proprietary BMP approval program will be somewhat fluid in the near term as the regulations, science, accepted standards, and industry mature.

ABSTRACT

A primary responsibility of water utilities is the protection of their water and wastewater infrastructure from significant threats created by natural disasters, malicious actions, and accidents. Following the events of September 11, 2001, water utilities placed additional emphasis on protecting their infrastructure from malicious threats, and security standards and guidelines were developed by various organizations across the world. A noteworthy set of guidelines was developed through the U.S. Environmental Protection Agency's (USEPA's) Water Infrastructure Security Enhancements (WISE) project, which was cooperatively executed by the American Society of Civil Engineers (ASCE), the American Water Works Association (AWWA), and the Water Environment Federation (WEF). In this project, both guidance documents that cover all aspects of water security (design, management, operations) and voluntary standards that cover physical security were developed. During the execution of this project a very thorough review of national and international guidances and standards was conducted. It was found that efforts by various organizations were at different stages of development and few, if any, had reached the stage of the WISE documents.

The International Organization for Standardization (ISO) has recently published a limited consensus document, the International Workshop Agreement (IWA) 6, for managing drinking water supplies during crisis conditions, and related efforts are currently being undertaken by ISO Technical Committee 224, Working Group 7 convened jointly by Germany and Israel (ISO TC 224/WG7) to develop a guideline standard for water and wastewater utilities to design, implement, operate, maintain, and improve a crisis management system to protect a utility's infrastructure from all threats. Similarly, the European Committee for Standardization or "Comite European de Normalisation" (CEN) has also started the preparation of a water security document.

It is important to note that water security is a sensitive issue among many countries due to significant differences of opinion on what constitutes threats. Some countries are reluctant to implement advanced security technologies and methods that may cause unease among their populations as well as controversy at the political level. Recognizing the sensitivity of security approaches to individuals and organizations, neither the WISE documents nor the ISO documents were developed to serve as regulatory requirements. Rather they were developed to provide best practice guidance to utility managers and policy makers.

INTRODUCTION

Protection of water and wastewater infrastructure from natural disasters and man-made accidents has been and continues to be a key focus for water and wastewater utilities (hereinafter referred to as water utilities) as part of their overall missions to protect the public health and provide affordable and reliable service to its customers. Following the terrorist attacks of September 11, 2001 in the United States (US) and similar incidents throughout the world, water utilities have significantly increased efforts to protect their infrastructure from malicious actions.

In the international arena, water system security has a slightly different connotation than in the US. Internationally it usually refers to the sustainable use of water and sustainable development of water resources, the protection of systems from drought and floods, and the safeguarding of access to water utility services. As a result, international efforts in the development of water security guidances and standards have covered a wider range of topics than in the US. International efforts that resemble the US definition of water security have thus focused on "crises management" which is equivalent to emergency response, remediation, and recovery (or consequence management).

Guidance documents and standards have been prepared in the US to assist utilities in the development and implementation of effective security systems. Notable guidance documents among these have been prepared under the USEPA's WISE project. The first water security focused document backed by international consensus was recently released by the International Standards Organization (ISO). Similarly, the European Committee for Standardization or "Comite European de Normalisation" (CEN) has also started the preparation of a water security document. Most of the ISO and CEN standards and other approved documents are drawn up in Technical Committees (TC). If a faster track of document development is required, then workshops are convened to deliver formal documents. Highlights of the documents prepared, including key aspects of emergency response planning, and each organization's objectives and structural make-up are presented below.

UNITED STATES WISE DOCUMENTS

A cooperative effort of the ASCE, AWWA, and WEF under the general direction WISE Standards Committee was funded by the USEPA to prepare a set of consensus documents. The majority of the documents were prepared by CH2M HILL under the guidance of the appropriate WISE Subcommittees: i.e. Water Supply, Wastewater/Stormwater, and Methodology and Characteristics, and reviewed by members of the WISE Standards Committee, members of various technical and standards committees from the three professional organizations, representatives from the USEPA, and other stakeholders who volunteered to provide input.

Under the WISE project, six guidance documents were prepared to assist water utilities in implementing infrastructure security systems and approaches. The first three documents were Interim Voluntary Security Guidance documents (ASCE 2004, AWWA 2004, and WEF 2004) prepared as Phase 1 of the project. These documents provided a centralized starting point for utilities to integrate modern security practices into the management, operation, and construction/retrofit of their infrastructure systems. The documents also provided guidance on integrating security related activities in a utility's emergency response plans. Training materials on these documents were developed as Phase 2 of the project to facilitate dissemination of the guidance information to US utilities.

Phase 3 documents (ASCE 2006a and ASCE 2006b) focused only on the physical security of water utility infrastructure and presented best engineering guidelines for physical protection approaches and measures of individual facilities or assets.

The Recovery Practices Primer for Natural Disasters (ASCE 2008) was also prepared under the WISE project. Its focus is to document recent successful actions and responses by utilities to mitigate natural disaster impacts and quickly restore service operations. The document is intended to be used by utilities to improve their emergency response plans and supplement existing guidance on emergency preparedness planning and response.

In addition to the above documents and to support the WISE overview and awareness initiative, three webcasts were presented in 2007 on the importance of security, security design considerations, and operational and maintenance changes to improve security. Two supporting videos were produced in 2008, one for public officials on the importance of water utility security and one for utility managers and operators on the principles of water security.

The primary purpose of the WISE documents is to provide water utilities guidance on the design of new facilities or the retrofit of existing facilities to reduce the risks posed by malevolent threats. Management and operational practices that can reduce risk are presented along with guidance on the development of emergency response plans that include malevolent threats as well as natural disasters and accidents.

Two of the WISE Phase 1 documents, "Interim Voluntary Security Guidance for Water Utilities" (AWWA 2004) and "Interim Voluntary Security Guidance for Wastewater/Stormwater Utilities" (WEF 2004) present concepts for effective emergency response planning for water and wastewater utilities, respectively. The purpose of an Emergency Response Plan (ERP) is to provide a utility with a standardized response and recovery protocol to prevent, minimize, and mitigate injury and damage resulting from emergencies or disasters of human-caused or natural origin. Emergency response is divided into four types of actions: planning, response, recovery, and termination.

The WISE Phase 3 documents, *Guidelines for the Physical Security of Water Utilities (2006) and Guidelines for the Physical Security of Wastewater/Stormwater Utilities* only focused on the physical security of utilities. These two documents covered physical security measures for perimeter, site, facility, water quality, SCADA security, etc. for various design basis threats (vandal, criminal, saboteur, etc).

ISO DOCUMENTS

ISO is a network of the national standards institutes and similar organizations from 160 countries and its technical work is normally carried out through ISO technical committees in which each ISO member has the right to be represented. For urgent market requirements, ISO has established a procedure to prepare documents through a workshop mechanism, external to the normal committee processes. These documents are published by ISO as International Workshop Agreements (IWAs).

The Standards Institution of Israel (SII) identified water security as critical and crucial for communities, countries, and society in general and proposed to develop an IWA on water security. Thus, the first international consensus document on water security was prepared by under the leadership of SII through the ISO process as the IWA 6 "Guidelines for the management of drinking water utilities under crisis conditions" (ISO 2008). IWA 6 was drafted at a workshop held in Tel Aviv, Israel in October 2007 and sponsored jointly by Israel's Water Authority and the SII.

This document provides a framework for management of a water crisis using an approach similar to emergency response plans, and was developed to be consistent with three established ISO standards on management of water and wastewater utilities (ISO 24510, ISO 24511, and ISO 24512). Unlike the WISE documents that focus primarily on malicious

incidents by individuals intending to damage or destroy the utility infrastructure or threaten the health of customers, IWA 6 focuses equally on all potential threats, whether natural or man-made, intentional or non-intentional. The document summarizes the framework for effective crisis management in Figure 1. This is similar to the framework presented in the WISE documents.

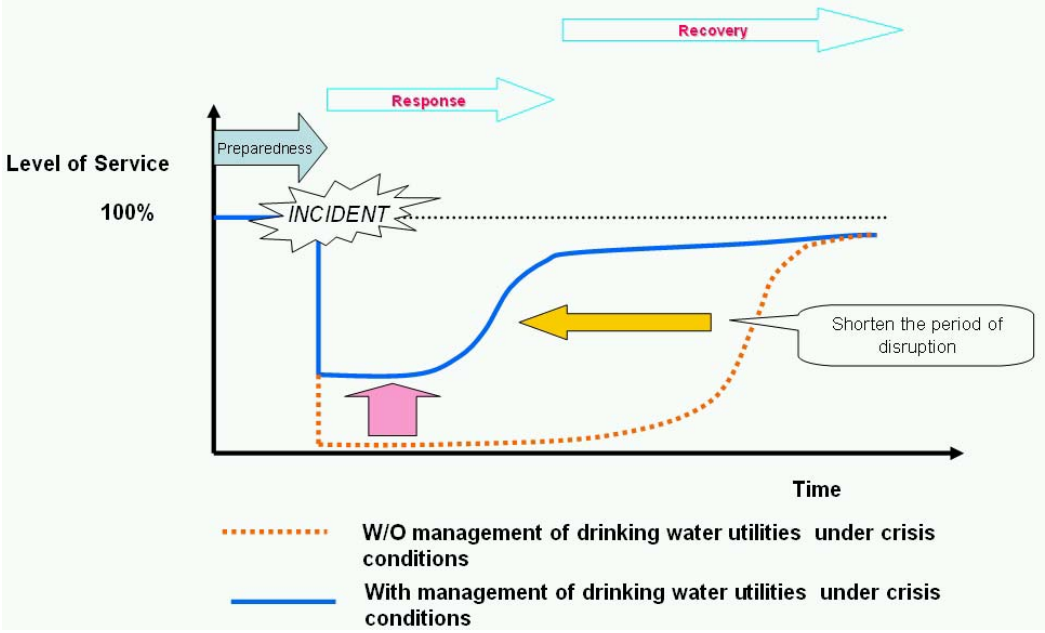

Figure 1. Effectiveness of crisis management (*Source – ISO/TC 223 - ISO/PAS 22399*)

The IWA 6 document identifies four stages for responding to a water crisis that parallel the four actions presented in the WISE documents: preparedness, response, recovery, and lessons learned. These stages are based on the Plan-Do-Check-Act (PDCA) model, which is also referred to as the Assess-Protect-Confirm-Improve (APCI) model. Figure 2 adapts the PDCA model to water security. The IWA 6's crisis management elements are similar to the ones identified in the WISE documents with the exception of an Incident Command System. Furthermore, the WISE documents provided significantly more information on each element.

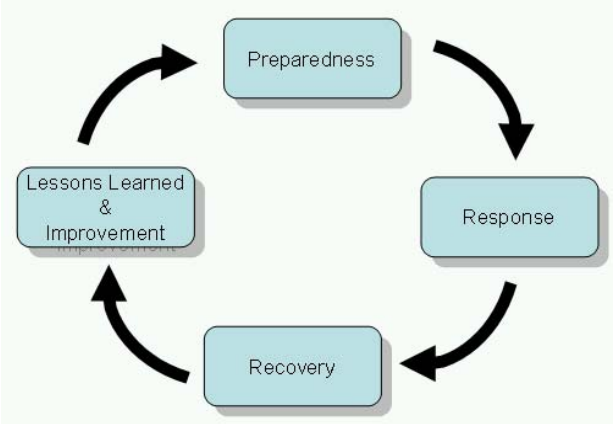

Figure 2. The water crisis management cycle (*Source – ISO/TC 223 - ISO/PAS 22399*)

The document also recommends a number of areas for the development of ISO standards including crisis management, on-line monitoring instrumentation, and hydraulic

network models to identify the locations and number of monitoring instruments and to predict the area of contamination. This recommendation covered many elements included in the WISE online contaminant monitoring systems (ASCE 2004) guidance. To assist in the development and installation of these warning systems, IWA 6 recommended the development of future standards for on-line monitoring instrumentation, models for establishing the number and location of monitoring instruments, models for defining the contaminated area within a water distribution system, and distribution system hydraulic models. The online monitoring systems were identified as a secondary tier of the security tier. Development of standards for the primary security tier, physical protection approaches, was also recommended.

Based on a proposal by SII to TC 224, a separate ISO/TC 224 working group (WG7) under the joint leadership of Israel and Germany was created to prepare a guideline standard for "crisis management in water utilities" that will include both water and wastewater utilities. The guideline, which currently is in a draft stage, will focus on establishing an incident preparedness and operational continuity management system for water utilities, similar to the emergency response plans used in the United States. Current plans are to complete a draft document by the end of 2010 and initiate the ISO process for achieving international consensus of the standard.

EUROPEAN DOCUMENTS

The European Committee for Standardization (CEN) develops European Standards and other technical specifications for its 30 nation members. These standards also constitute the national standards for each of its 30 member countries. With one common standard in all these countries, and every conflicting national standard withdrawn, a product can reach a far wider market with much lower development and testing costs. The European standards are developed by Technical Committees, approved by the CEN members and go through a public comment period. On the other hand, CEN Workshop Agreements (CWAs) are standardization documents open to the direct participation of any interested party. CWAs are fast and flexible, usually completed in 12-18 months. There is no requirement to adopt them as national standards in the CEN member countries, but they can be used as an alternative route towards a formal voluntary standard or taken up at international level within ISO.

One relevant guideline is *Security of Drinking Water Supply - Guidelines for risk and crisis management,* currently being prepared by the Working Group 15 "Security of Drinking Water" of the CEN/TC 164 "Water Supply". This guideline describes the fundamentals of crisis management, including relevant recommendations for water utilities, and offers abundant examples about the disaster and crisis management organization of the relevant national authorities. The objective of this Guideline is to enable the water supplier to take action in the event of a crisis in order to ensure the continued supply of water to the greatest possible extent and to restore normal operating conditions as quickly as possible.

SUMMARY

A survey of the international standards on water and wastewater system security shows that most of the available documentation in use has been prepared under the WISE project. These documents have covered the design, operational and management aspects of utility security, including emergency response, remediation and recovery (or crisis management). Other standardization efforts include those by ISO and CEN, but to date their efforts have focused primarily on crisis management. Efforts on other aspects of water security have also commenced.

ABSTRACT

The City of Glendale, Arizona has been developing and implementing the various elements of a Contamination Warning System (CWS) since 2005. The purpose of the CWS is to provide multiple benefits to the utility through early identification of unusual water quality events, including those due to operational changes, occurring in the distribution system.

The key to a successful CWS is the rapid analysis and evaluation of data from multiple sources to extract the relatively small amount of information related to the unusual occurrences in the distribution system. To effectively accomplish this, Event Detection System (EDS) software needs to have robust processes in place for both data validation and data analysis to enable accurate event detection.

s::can and CH2M HILL are developing an EDS for the City of Glendale with the following attributes:

- Unique sensor station management system that captures sensor failure, maintenance, and repair activities
- Enhanced Data Validation: Minimum/maximum boundaries, drift analysis, step change analysis, and outlier analysis
- Data Analysis: Capability of evaluating both single and multi-dimensional data
- Advanced Event Detection: Both single-point and spatial recognition within the distribution system

This paper provides an overview of the Glendale EDS and its capabilities for data validation and event detection.

Background

The City of Glendale has partnered with CH2M HILL to create a state-of-the-art Contamination Warning System (CWS) to detect, assess, and respond to potential water contamination events through the use of strategically placed water quality monitoring (WQM) stations. The monitoring stations constantly feed water quality data into a data warehousing application that analyzes this data and other critical data streams (e.g., customer complaint information and field operations activities) that can indicate possible contamination in the system. CH2M HILL and s::can have collaboratively developed an event detection system (EDS) for the Glendale CWS to streamline the collection of data from several sources, enable rapid understanding of water quality events in the distribution system, quickly identify areas for operational improvement, and enhance response capabilities to reduce the potential for public health/aesthetic impacts. Glendale is one of just two cities in the nation to implement a full-scale CWS program, which takes a cutting-edge, holistic approach to safeguarding public water systems from terrorist attacks, accidental events, and operational malfunctions. The EDS utilized by Glendale's CWS is the first of its kind to be implemented in the United States.

The main objective of the Glendale CWS is to enhance the ability to detect, assess, and respond to water quality changes in the water distribution system, thus minimizing the potential impact on public health, economic loss to business customers and the City, liability to the City, and loss of confidence by the public. To meet these objectives, the CWS monitoring stations are designed to continuously monitor traditional water quality parameters, including pH, conductivity, residual chlorine, turbidity, total organic carbon (TOC), dissolved organic compounds (DOC), and nitrate (NO_3), as well as spectral fingerprinting. Different water quality monitoring technologies are deployed at the water quality monitoring stations within Glendale's system, including instrumentation from Hach, ATI, and s::can, and Sandia's unattended water sensor (UWS) prototype. The water quality monitoring instruments, along with EDS equipment, are deployed locally at eight CWS monitoring stations. These stations are all linked to the central CWS.

The central part of the CWS, the EDS integrates all of the data sources, analyzes the data, identifies water quality trends, and develops contamination event alarms, essentially tying together the individual pieces of the CWS. Without a properly functioning EDS, the data and databases would be of limited usefulness because the system would generate a high number of false alarms, resulting in an unreliable contamination warning system.

Online water quality monitoring data are an integral part of the system, but are not the only data utilized to identify a potential contamination event. Several other sources of data and databases, as depicted in Figure 1, have been considered in the implementation of this system-wide CWS, including customer complaints, health care information, laboratory and field data, security alarms, and operations and maintenance information.

Local Data Validation, Storage, and Event Detection

The s::can - CH2M HILL EDS comprises both local components (installed at the WQM stations) and centralized components. The individual WQM stations are interfaced via diverse protocols to a central database. Though this interfacing structure of the EDS is not absolutely necessary, it greatly enhances the system security and multi-station management. More importantly, performance is improved because additional information may be obtained by comparing station data and adding in supervisory control and data acquisition (SCADA) information (pressure and flow), thus allowing additional events to be generated based on the aggregated data.

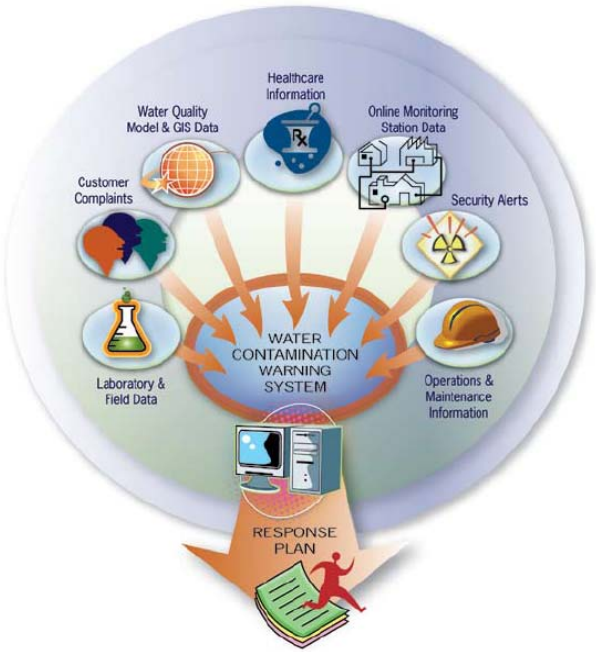

Figure 1: Data from numerous sources are captured in one central data warehouse

In addition, an EDS without prior state-of-the-art sensor/station management and real-time data validation has been shown to yield countless false alarms. Such a system will, under real-world conditions, fail to meet desired system-level performance and lead to low operator acceptance and confidence in the long term.

The station-level EDS software package minimizes the generation of non-interpretable data by combining local station management with an enhanced data validation component to keep full control of sensors and parameters. Figure 2 is a picture of an industrial PC, which is used as part of the local EDS, installed at a local WQM station. The local station software package consists of three tools:

- (Sensor/Station) Control and Management Tool (moni::tool)
- Data Validation Tool (vali::tool)
- Event Detection Tool (ana::tool)

The **(Sensor/Station) Control and Management Tool (moni::tool)** provides a web-based graphical user interface for easy and transparent station and sensor configuration. All configuration data are stored in a local database which is synchronized with the central database. The database not only stores the current configuration, but also stores previous configuration information as a timeline, allowing proper metadata information to be presented with the results. The moni::tool also monitors the “health” of instruments by querying instrument diagnostics.

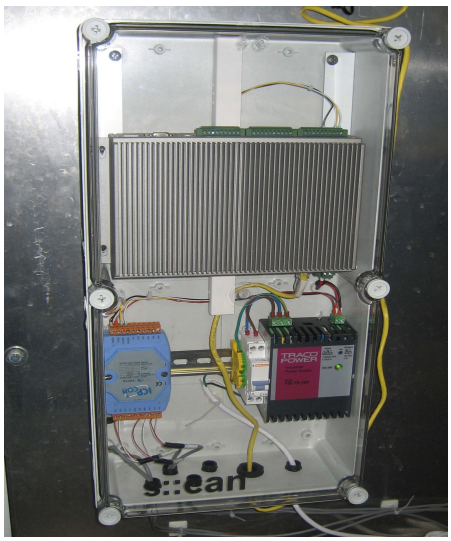

Figure 2: Industrial PC provides local event detection

Clear and transparent management of all sensors and stations by dedicated software is the indispensable backbone of any complex monitoring system. When systems exceed a certain level of complexity and are used for critical applications and real-time control (i.e., for alarm and protection purposes), traditional data management and SCADA software is no longer adequate for system management. The moni::tool provides unique sensor identification management and tracks any *activities* and *status information updates* (e.g., any changes in inputs, configurations, settings, exchange of sensors or components, calibration or service activities), in addition to all other sensor messages or functional checks. All of this information is locally communicated, collected, managed, utilized, and documented, then synchronized with the central database. This station metadata is essential for the later qualification and interpretation of any generated data. This management information also allows statistical evaluation of operational parameters such as "operational availability of sensor X," and "total service time/yr." All of these parameters are important in defining proper maintenance procedures and ensuring that the WQM stations are providing the best data possible.

The **Data Validation Tool (vali::tool)** provides dynamic analysis of incoming data from any sensor or analyzer. By comparing the incoming data to locally stored historical data and reference values, the system can determine if values are:

- Within expected ranges
- Outliers
- Exhibiting noise or scatter
- Drifting
- Exhibiting step jumps
- Non-plausible (as compared to other related parameters)

Incoming data, regardless of the source (SCADA, monitoring stations, or single sensors) or the interface by which the data are communicated, are validated in real-time by comparing them to their reference data sets, considering statistical parameters and time-dependent behavior. Data validation is performed using innovative statistical tools in a fully automated fashion. Once adjusted during system initialization to account for the dynamic behavior of the system, the only parameter that needs to be adjusted afterwards is "sensitivity." Automatic data validation ensures that only unmarked, "clean" data are used for further analysis, training, and alarms. Any non-event related, deviating data are identified and marked before being fed into the EDS module to avoid the system being trained on invalidated data.

The **Event Detection Tool (ana::tool)** allows the EDS to integrate the output of the spectral ana::larm too, and combinesit with all other collected parameters into a single stationlevel EDS. It typically runs on the local station level, but also can be integrated into the central database. The proven spectral EDS ana::larm software is a standard package used by many water utilities worldwide. It "learns" the shape and features of the "normal" spectrum of the water body within a defined range. The initial definition of the reference (i.e., baseline) spectra for later identification of extraordinary composition is done automatically, and can be continuously improved and re-trained. The spectral baseline training is simple and reliable and has adjustable false alarm levels.

The spectral alarms also detect a high percentage of "organic" events. A key advantage with this algorithm is that ana::larm is able to distinguish between changes of background/natural organics and "abnormal" organics. Thus the system will not react to normal changes of TOC and DOC, but will distinctively react to any organics in the water that are not part of the natural composition.

The spectral absorption values provide an extremely rich source of data to perform event detection. This data provides more complete EDS functionality than would be found by relying on just the traditional surrogates of conductivity, pH, chlorine, turbidity, and so on. All collected and validated parameters from all provided sensors and tools are fed into a module for baseline definition and event detection. A baseline of normality versus the typical pattern for all parameters relative to each other is established during a training period.

Central EDS Database

The EDS is applied both on a local (monitoring station) level and at a central database. The same local data validation and algorithms are applied to all data entering the central database (i.e., from the SCADA system and multiple WQM stations). Spatially and hydraulically resolved data analysis in the central database allows for additional information to be generated from spatial differences between sampling points in the distribution network. This unique method allows for the nearly complete elimination of any baseline noise of "normal" water composition, and with this method, the lowest limits for detection of events can be achieved. By performing spectral data differencing on time-shifted spectrum from upstream and downstream sampling points, additional events can be resolved. This spatial differencing also yields potential contamination locations and provides more insight on the possible contaminant.

Advantages of Glendale's EDS Approach

The station and sensor management tool eliminates the risk of sensor misuse, malfunction, or mismanagement, and allows sensors and stations to be operated by non-expert, entry-level staff. The data validation step before event detection eliminates non-interpretable data and thus reduces false alarms dramatically. The s::can - CH2M HILL approach used by the City of Glendale provides an EDS with high sensitivity: the sensors and algorithms offer the lowest detection limits for most contaminants (organic and inorganic), lower than any system on the market (e.g., as low as a part-per-billion (ppb) level for some solvents and pesticides). The Glendale

EDS approach also provides high selectivity; the EDS can distinguish between changes of organic background matrix (i.e., natural organics) and organic contaminants, thus greatly reducing false alarms.

Implementing a Contamination Warning System at a Department of Defense Facility: Case Study – Port Hueneme, California

Abstract

The Naval Facilities Engineering Command, Engineering Service Center (NAVFAC ESC) in Port Hueneme, California is in the final stage of the development and implementation of a Contamination Warning System (CWS) Pilot Program, culminating a 3-year effort. The purpose of the pilot program is to demonstrate the multiple benefits associated with a CWS, and it will serve as a model for other Department of Defense facilities.

The CWS will include real-time online water quality monitoring (OWQM) stations at multiple locations in the water distribution system. The OWQM stations will provide continuous data for pH, chlorine residual, turbidity, conductivity, total organic carbon, dissolved organic carbon, and ultraviolet/visual spectral imagery (200 to 700 nm). OWQM technologies that will be evaluated as part of the pilot program include the s::can spectro::lyzer™, s::can ammo::lyzer™, the Analytical Technologies (ATI) Water Quality Panel (for pH, free chlorine residual, conductivity, and turbidity), ATI mono-chloramine analyzer, the Hach Q45WQ Water Quality Panel (also for pH, free chlorine residual, conductivity, and turbidity), and the Intelletect Intellisonde™ (pH, free chlorine, mono chlorine, turbidity, conductivity, color, pressure, temperature, and flow).

The event detection system (EDS) being developed by s::can and CH2M HILL for the Port Hueneme will have the attributes listed below:

- Enhanced Data Validation: Minimum/maximum boundaries, drift analysis, step change analysis, and outlier analysis
- Data Analysis: Capability of evaluating both single- and multi-dimensional data
- Advanced Event Detection: Both single-point and spatial recognition within the distribution system

Introduction

Naval Base Ventura County (NBVC) is a major aviation shore command, and its Port Hueneme (PH), California facility provides logistical support to construction battalions worldwide. The NAVFAC ESC executes this demonstration project funded by the Navy's Environmental Sustainability Development to Integration (NESDI) program. The project is in the design and construction stage of the development and implementation of a Contamination Warning System (CWS) Pilot Program. The purpose of the pilot program is to demonstrate the multiple benefits associated with a CWS (which are contamination warning, regulatory compliance, and operational support) and to serve as a model for other Department of Defense (DoD) facilities.

Overall, this project has three primary tasks:

1. Design of the CWS
2. Installation and testing of the CWS
3. CWS data analysis and lessons learned

This paper presents the basic structure of the CWS design process used at a Department of Defense Naval base. While the information to consider when making the design decisions was essentially the same as that used for municipal water distribution systems, the system characteristics of size, water usage, and monitoring station location at Port Hueneme makes the ultimate design more applicable to water distribution systems at other military bases and very small systems instead of typical municipal systems.

System Design

To successfully design a CWS, information about a number of elements is required:

- Utility characteristics
- CWS characteristics
- Available online monitoring technologies
- Data handling and transfer options

Utility Characteristics

When designing a CWS for either a DoD or municipal system, it is critical that the infrastructure, water quality, and operations and maintenance (O&M) practices of the utility are clearly understood prior to the start of the project.

Infrastructure

Water distributed to the more than 10,000 residents at Port Hueneme comes primarily from a single source, the Port Hueneme Water Agency. Two secondary sources exist, but are rarely used. The daily quantity provided by Port Hueneme Water Agency averages 768,000 gallons.

The water distribution system infrastructure includes typical facilities such as turnouts (some with chlorine booster stations), a source well, a small treatment plant, storage

tanks, pump stations, pressure-reducing valves, piping, and appurtenances. Detailed information about the facilities and their characteristics and locations was gathered.

The water system was originally designed for firefighting and warehouse use, thus an extensive system comprising large pipes was put in place. Today, the system is used primarily to supply potable water to Base housing and the Engineering Center. The demand and usage patterns from these geographically separated areas is too low for the size of the system, resulting in non-moving water.

Water Quality

Water quality at Port Hueneme is monitored through samples collected to meet regulatory requirements and for operational reasons. Data regarding existing sample stations (such as age, location, and types of parameters monitored), sample collection, regulatory and operational sampling parameters, and laboratory analysis were compiled to create a complete picture of existing water quality. Regulatory and operational sampling parameters included total and fecal coliform, heterotrophic plate counts (HPC), and Total Trihalomethanes (TTHMs)/Haloacetic Acids (HAA5), total and free chlorine residual, total and free ammonia, pH, temperature, and nitrite.

The primary water quality issues at the base were determined to be nitrification and low residual chlorine. These system operations problems were used as part of the criteria for selecting a suite of water quality monitoring technologies (ammonia, nitrate, free chlorine and mono-chloramines).

Operations and Maintenance

Use of chloramines as a disinfectant creates nitrification issues for Port Hueneme. The ratio of chlorine to ammonia-N in the system is lower than what would be required to prevent the formation of nitrites. Short- and long-term prevention strategies to maintain an acceptable chlorine residual throughout the distribution system while preventing the formation of nitrites are employed. Short-term strategies include flushing, an annual period of free chlorine use, creation of additional demand and closing of redundant mains to decrease detention times, and increased monitoring at turnouts. Long-term strategies include the construction of an additional turnout to reduce detention time and investigation of other potential disinfectants.

The CWS demonstration project will collect real-time water quality data that can be directly related to retail water quality entering into the water system and the effectiveness of operational activities in the distribution system.

Contamination Warning System Characteristics

To develop a CWS for a distribution system, detailed information about the following elements needs to be collected and considered:

- Contaminant classes to be monitored
- Water quality instruments and analyzers that respond to the selected contaminant classes
- Contaminant fate and transport models that are applicable under the utility's existing hydraulic and water chemistry conditions

- Potential monitoring locations
- Communications links and protocols for collection, transfer, and analysis of data
- Integration with the existing supervisory control and data acquisition (SCADA) system
- Tools and guidance for data interpretation

The CWS must also include the features specified by the U.S. Environmental Protection Agency (USEPA) in its draft documents, *WaterSentinel System Architecture*:

- **Capability** to sense changes to water quality parameters that can indicate potential contamination
- **Contaminant coverage** that has a high-to-medium detection potential for most classes of contaminants evaluated by USEPA
- **Spatial coverage** that provides adequate detection capability, including location, number, and density of monitoring stations
- **Timeliness** of detection, including hydraulic travel time from the contamination source and the concentration of the contaminant
- **Reliability,** including the expected rate of false positive and negative results
- **Sustainability** to provide a better understanding of water quality variability throughout the distribution system

Information about contaminants that may potentially be found within the distribution system and the surrogate parameters that can indicate the presence of these contaminants is also essential to the design of a CWS. This information is relevant to instrument selection and the understanding of the dynamic nature of distribution systems, which can be affected by operational changes or source water blending.

All of the CWS characteristics identified above were evaluated to determine how they should be applied to Port Hueneme and its specific requirements. For example, the CWS must assist in the monitoring and prevention of nitrites in the distribution system. As a result of the Port Hueneme-specific evaluation, the following parameters were selected for monitoring by the CWS:

- Chlorine residual
- Conductivity
- Turbidity
- pH
- Total organic carbon
- Nitrate
- Dissolved organic compounds
- Temperature
- Pressure
- Ammonia
- Continuous spectral data

The next consideration was the location of the monitoring stations. Because of the extent of water distribution systems and the large number of potential contaminant insertion points, a large number of monitoring stations may be recommended. The costs associated with monitoring stations can be substantial, so the number and location of the stations must be optimized to be both financially and functionally effective. Criteria to be considered when locating monitoring stations include the following:

- Pressure zones
- Employee access
- Available utilities (sewer, power, communications)
- Physical security
- Turbulent hydraulic conditions
- Existing sampling sites
- Potential entry for contamination
- Vulnerable populations
- Instrument performance in the installed conditions

Two monitoring station locations were ultimately selected. The criteria that most affected the selection process were available utilities, physical security, and existing sampling sites. In addition, because this is a pilot program, the minimum number of stations was used.

Available Online Monitoring Technologies

Prior to the start of this pilot project, NAVFAC ESC performed an extensive evaluation of the wide range of instruments currently available. Based on experience, parameters to be monitored, and site constraints, the following instruments were selected:

- HACH Water Distribution Monitoring Panel sc (purchased prior to project)
- ATI Q45WQ Water Quality Panel
- s::can spectro::lyser™
- s::can ammo::lyser™

The Intelletect Intellisonde™ (a multi-parameter probe for pH, free chlorine, mono chlorine, turbidity, conductivity, color, pressure, temperature, and flow) will be tested at Port Hueneme.

The selection of technology was driven by the triple bottom line of sustainability at Port Hueneme:

- Economics
  - Capital costs
  - Operations costs
    - Labor
    - Expendables
    - Replacement costs

- Societal
  - Security
  - Regulatory
  - Consumer aesthetics
- Environmental
  - Landfill impacts
  - Water quality discharge impacts (reagents)
  - Air impacts (greenhouse gases)

Data Handling and Transfer Options

When identifying data handling and transfer options, the following items are typically considered:

- Data collection
- Sample collection
- Operator interaction
- Centralized SCADA system data archiving
- Sensor monitoring
- Data storage
- Monitoring station and sensor definition
- Data analysis
- Data communication protocols
- Digital communication

Port Hueneme will use secure/encrypted communication over a cellular link to relay the water quality data to a centralized database. Local data validation and event detection is provided by an industrial personal computer prior to the data being transferred to the central database using the Transducer Markup Language (TML), a standards-based data transfer method for communicating real-time sensor data. This methodology avoided the complexities of setting up radio telemetry on an operating base and the time delay of obtaining a Certificate To Operate (CTO). Communication will be provisioned in a matter of minutes instead of months. In addition, this choice allows the project team to have direct access to the data to provide real-time assistance in data evaluation and management.

Data Analysis

The event detection system (EDS) being developed by s::can and CH2M HILL for the Port Hueneme will have the attributes listed below:

- Enhanced Data Validation: Minimum/maximum boundaries, drift analysis, step change analysis, and outlier analysis
- Data Analysis: Capability of evaluating both single- and multi-dimensional data
- Advanced Event Detection: Both single-point and spatial recognition within the distribution system

Current Status

With the information gathered, CH2M HILL is providing NAVFAC ESC with strategies to identify potential water quality monitoring station locations, a conceptual system design for the monitoring stations, development of an operational test plan for the installed systems, and technical support to collect and analyze data collected from the system.

Conclusion

The information considered when making the CWS design decisions was essentially the same as that used for municipal water distribution systems. However, the system characteristics of size, water usage, and monitoring station location at Port Hueneme makes the ultimate design more applicable to water distribution systems at other military bases and very small systems instead of typical municipal systems.

Concentrate Management and Disposal Practices in Australia

James H Jensen, PG

Member, Zero Liquid Discharge Concentrate Disposal Systems Subcommittee,
Committee on Concentrate Management in Desalination, EWRI of ASCE
Parsons Brinckerhoff Australia Pty Ltd. GPO 398, Adelaide SA 5001, Australia;
email: Jensen@pbworld.com

Potable water supplies are a limited resource in an arid continent like Australia where many areas have experienced extended droughts further limiting available water supplies. However, Australia has built comparatively few desalination plants until recently. Isolated mining towns and small communities as well as industrial processes such as power stations that require high quality water have been the main users of desalination technologies in Australia. Now, a number of the coastal located capital cities like Sydney, Brisbane, Melbourne, Adelaide and Perth are among cities that are either investigating or developing seawater desalination facilities as a means to ensure that water demands can be met successfully and supplies are sustainable.

This paper summarises the concentrate management and disposal methods currently used and proposed in studies in Australia based on publically available information. Concentrate disposal considerations for desalination facilities in Australia include the potential environmental impacts and regulatory permitting requirements, including concentrate water quality, receiving water quality, stakeholder perception and issues, costs of the disposal system and other site specific issues. The operating 143,000 m^3/day Perth seawater desalination facility and the coastal facilities under development use ocean outfalls with diffuser systems for mixing the concentrate with the receiving waters for disposal. However, the inland desalination plants have limited options for concentrate disposal. The disposal methods are often further limited by locally endangered and/or fragile habitat. The most common methods of concentrate disposal for inland facilities include surface water discharge, mixing with process or wastewater and concentration/evaporation. There may be other disposal methods that are unique to a particular facility and situation.

Although Australia is depending for the most part on research being conducted elsewhere concerning the disposal options for desalination concentrate, the Commonwealth Scientific and Industrial Research Organisation (CSIRO) is assessing brine chemical composition as a source for mineral recovery and salt extraction.

BACKGROUND

Australia is often described as the driest inhabited continent. In an arid continent like Australia, potable water supplies are a limited in many areas. Recent studies have

indicated further decline in the quality of water supplies over the next fifty years arising from the impacts of salinity on groundwater and surface water resources.

Australia has had comparatively few desalination plants until recently. Isolated mining towns and small communities as well as industrial processes such as power stations that require high quality water have been the main users of desalination technologies in Australia (AFF 2002). Desalination is now being evaluated or developed as potable water supplies in a number of both small and large communities in Australia to supplement other water sources so that current and future demands can be met and are sustainable.

The coastal seawater desalination facilities in Australia use ocean outfalls with diffuser systems for mixing the concentrate with the receiving waters as the disposal method. However, the inland desalination plants have limited options for concentrate disposal. The disposal methods are often further limited by endangered and/or fragile habitat in the area. The most common methods of concentrate disposal for inland facilities include surface water discharge, mixing with process or wastewater and concentration/evaporation. The following sections cover concentrate management and disposal practices of representative desalination facilities in Australia based on publically available information. The facilities were selected in part because of the level and perceived reliability of the information. However, the projects underwent rigorous environmental and design studies over a period of several years and any changes overlooked should not take away from the overall value of the review.

ENVIRONMENTAL PROTECTION

The National Environment Protection Council (NEPC) which is comprised of the environment ministers from the Australian Government, each state and territory is tasked with ensuring that major environment protection initiatives are established and are similar in each member government. The NEPC establishes National Environment Protection Measures (NEPMs) which are broad framework-setting statutory instruments that outline agreed national objectives for protecting or managing particular aspects of the environment. NEPMs are similar to environmental protection policies. (AGDEWHA, 2008)

Each member government has established an independent Environmental Protection Agency or similar named entity which is in charge of environmental matters including protecting air, water and soil quality, managing waste, preventing or controlling pollution, managing the state's coastline, and promoting environmentally sustainable industry. There are stringent requirements for project development including environmental assessment and documentation, compliance monitoring and mitigation measures. The responsibilities for managing the assessment procedures, monitoring compliance and the enforcement of environmental matters vary among the member governments.

The environmental assessment, permitting and compliance requirements for desalination projects in Australia are similar to those in the United States. Environmental considerations for desalination facilities in Australia include the potential environmental impacts of the concentrate effluent (temperature and quality), receiving water quality and site specific issues. The major environmental concern for concentrate discharge relate to the effectiveness of concentrate plume dispersion in the mixing zone.

PERTH KWINANA SWRO PLANT

The greatest amount public information is available for the Perth Seawater Desalination Plant, the first large capacity seawater desalination plant in Australia. The facility is located at Kwinana, south of Perth, Western Australia. The Perth Desalination Plant commenced delivering up to 144 ML/day of much needed drinking water in November 2006.

Intake screening at the intake structure for the Kwinana facility consists of course barred screens offshore and automatically cleaned travelling band screens onshore. Ferric sulphate and an organic coagulant are added to the seawater influent to the multimedia pressure filters to coagulate particulate and colloidal material. The backwash materials (solids) from the pretreatment system are disposed to landfill due concerns about possible discolouration of the white sandy beaches if the backwash was discharged at sea (Crisp, 2008).

The partial two pass RO system produces a permeate of less than 100 mg/L Total Dissolved Solids (TDS) from a feedwater salinity of ~37,500 mg/L. The facility incorporates isobaric energy recovery devices (PX) from ®ERI resulting in a specific energy consumption of less than 3.9 kWh/m3. At a 43% recovery, the facility discharges up to 200 ML/d of concentrate at an average TDS of 66,000 mg/l (Crisp 2008, Ludetina and Christie, 2008).

During the environmental approval process, disposal of the concentrate in Cockburn Sound was raised as an area of concern by the Department of Environment and Conservation (DEC). The hypothesis was that it could exacerbate the naturally occurring stratification, particularly during the autumn when long periods of calm occur, and cause oxygen depletion in the deep basin of the Sound (Ludetina and Christie, 2008).

To ensure that the environment is protected, a series of marine monitoring studies were commissioned prior to and as part of the environmental approvals, including in the discharge area. These studies included Whole Effluent Toxicity testing on simulated brine and actual seawater concentrate at commissioning and 12 months later, sediment oxygen demand tests, international literature review of dissolved oxygen levels, ecological investigations, cause effect models, and an intensive baseline investigation commissioned to document water quality and macrobenthic fauna present prior to operations (Crisp, 2008).

Western Australia's Environmental Protection Authority (EPA) set strict criteria for the concentrate discharge, requiring the salinity within 50 meters of the discharge point to be within 1.2 ppt of background levels and at one kilometre offshore within 0.8 ppt of background levels. Computer modelling of the diffuser system, a scale physical model testing study and a rhodamine die dispersion test indicate that the seawater concentrate is effectively mixed within the mixing zone of less than 2.5 hectares (Crisp, 2008).

The concentrate is fully oxygenated by a drop structure before being discharged. The seawater concentrate is delivered via an underground 1.6 m diameter pipeline to the eastern shelf of Cockburn Sound in a depth of about 10 m of water (Craig 2005). The pipeline terminates about 270 metres offshore in Cockburn Sound at a 200 metre long diffuser system with the 40 discharge nozzles about 0.5 m from the seabed surface at a 60 degree angle and spaced at five metre intervals. The diffuser system is designed to ensure 45 times dilution of the effluent within 50 m on each side of the diffuser system. A real time monitoring system within Cockburn Sound feeds water quality data back to the plant to confirm the effectiveness of the diffuser system. Temperature and conductivity is recorded at 1-2 m intervals through the water column, and dissolved oxygen is recorded at the bottom of each monitoring buoy and at mid-depth (Crisp, 2008).

After a year of operation, the diffusers were found to be heavily populated by marine growth, mussels and surrounded by feeding fish. Nevertheless, in its first year of operation the plant was shutdown or capacity reduced by the DEC as a precautionary basis for two, two-week periods during extended calm periods in the autumn (Luketina and Christie, 2008).

GOLD COAST SWRO FACILITY

In order to meet the tight deadline to complete the Gold Coast project before the end of 2008, construction had to get underway whilst the approvals process was still in progress. This meant that the design team had to be able to amend the design of systems, if required, to achieve improved environmental outcomes (SKM, 2008)

The process consists of initial coarse screening followed by pretreatment by coagulation and gravity sand filtration, cartridge filtration and desalination by a two-pass reverse osmosis system to ensure that treated water meets the required water quality limits. A dedicated filter backwash water treatment system is being constructed. Backwash solids will be transported off site (SKM, 2008).

Concentrate effluent from the RO process is discharged back to the ocean via the discharge tunnel and a seabed diffuser system. The plant will initially discharge up to 125 ML/day of effluent. The effluent will be 1.8-1.9 times the salinity of the intake seawater, an elevated temperature of 1-2º C and may possess a reduced concentration of dissolved oxygen (1.5-2.0 mg/L) (Tripodi and Ramsay, 2008).

Intake and outfall concrete-lined tunnels were constructed about 70 m below the surface extending about 1.5 km offshore (water depth about 20 m) to riser shafts for the intake and outfall systems. (SKM, 2008). Extensive computer modelling, supported by physical modelling, was used to design the diffuser system. The diffuser design was modified during the design period to 397 m in length with a 20-port diffuser based on the State Government desire to facilitate increased clear water production without changes to the diffuser if the effluent discharge is increased to a maximum of 170 ML/day (Tripodi and Ramsay, 2008).

The investigations indicate that under worst case mixing conditions, defined as the highest salinity concentration (100% plant duty) and lowest observed receiving water oceanic currents, a 40-fold dilution is predicted at the edge of the near-field mixing zone (bounded at 60 m from any point of the diffuser – total area 120 m x 404 m) and a 25-fold dilution at the point where the brine plume impacts with the sediment (16 m from the diffuser). These dilution figures and supporting evidence from concentrate dispersion at the Perth Desalination Plant indicate that minimal adverse environmental impact is expected from elevated salinity concentration in the near-field mixing zone. These model-predicted dilution values will be validated in the field during plant operations through a Diffuser Performance Monitoring Plan (DPMP) (Tripodi and Ramsay, 2008).

BURRUP MVC DESALINATION FACILITY

In the Burrup Peninsula in Western Australia, the capacity of the potable water supply was determined to be insufficient to meet requirements of industrial development in the region (EPA, 2001). As a result, Water Corporation built the Burrup Desalination Plant as part of the Burrup Peninsula Industrial Water Supply Project. The pipeline supplies up to 380 ML/day of seawater including 3.6 ML/day of desalinated water. The desalination plant is now operational and supplying water to their first customer, Burrup Fertilisers, the world's largest Ammonia plant. (Water Corp, 2006)

The 3.6 ML/day of desalinated water is produced by three mechanical vapour compression (MVC) units. A cooling tower was installed designed to cool the concentrate from the thermal desalination process. The concentrate is returned to the Indian Ocean via a control tank, a four-kilometre pipeline and a 1.3 km ocean outfall (GWA, 2003).

The seawater temperature in the vicinity of the proposed outfall was found to vary due to natural causes by as much as 2° C over a tidal cycle and by up to 5° C in a month. The temperature variation is caused by the large area of shallow water in King Bay and the large tides in the region. Near-field modelling (CORMIX v.3.2) of the saline plume (approximately 55,000 mg/L) predicted that the environmental quality criteria for increase in salinity (<5% variation) would be met, apart from within a 40 m mixing zone at the outfall. Near-field modelling for thermal dispersion

was based on a high, worst case discharge temperature of 5° C above ambient seawater temperature. The model predicted that within distances of 7 m and 110 m of the outfall the temperature elevation would be less than 2° C and 0.25° C above ambient, respectively. Far field modelling predicted the temperature increase to be less than 0.1° C above ambient within a few hundred metres of the discharge. The EPA considers the predicted temperature increase to be acceptable, given that the nearest coral communities are approximately 500 m away. Operations will be managed to ensure that the effluent discharge (end of pipe) temperature is less than 2° C above ambient seawater temperature for 80% of the time; and does not exceed 5° C above ambient seawater temperature. (EPA 2001)

OTHER DESALINATION PROJECTS

A number of other coastal located capital cities are among cities that are either investigating or developing seawater desalination facilities as a means to ensure that water demands can be met successfully and supplies are sustainable. Each facility has undergone or is undergoing a number of specified environmental assessment studies and the process of establishing operating conditions and compliance monitoring.

Southern Seawater Desalination Plant. The Water Corporation has selected a consortium to build by 2011 a new seawater desalination plant at a coastal site near Binningup, south of Perth. The plant, powered by renewable energy, will have a production capacity of 140 ML/day in Phase I, with a possible extension up to 280 ML/day in Phase 2. The approximately 42 hectare site owned by Water Corporation is located within the coastal dunes. The site includes a small wastewater treatment plant (Worley Parsons, 2007).

To minimise both dune disturbance and beach closure, tunnelling will be used to construct 2, 2.4m diameter intake pipes and a 2 metre diameter outlet pipe. The intake structures will be about 500 m offshore. A dredged trench will be used from the end of the outfall pipe to the end of diffuser at 950 m offshore in ~12 m of water. The bathymetry of the site slopes relatively uniformly down to the west, with little north-south variation (Water Corp, 2008).

The site is located in a high energy environment, exposed to ocean swell and wind. To evaluate concentrate dispersion, a Rhodamine WT dye plume study was conducted over four hours by keeping track of the same parcel of water using a combination of drogues, dye measurements and vertical profiling. Analysis of the measurements indicates horizontal mixing is dominated by the prevailing wind, with shear dispersion dominating over horizontal diffusion.

Adelaide Desalination Project. SA Water is currently in the process of selecting a consortium to build and operate a 150 ML/day SWRO project. The SWRO facility will be located at Port Stanvac, south of Adelaide. Pilot plant testing is underway to

monitor seawater quality and assess the pre-treatment process and at a later stage reverse osmosis membrane testing will be conducted.

Siting investigations identified that seawater depth significantly decreases north of Port Stanvac along the Gulf St Vincent, which has ramifications for concentrate dispersion. A nominal water depth of at least 10 m was identified as preferred for seawater concentrate dispersion. The sensitivity of marine habitats and water quality considerations were also identified as additional constraints for sites further north of Port Stanvac due to their proximity to seagrass meadows and sensitive marine nursery areas (SA Water, 2008a).

Marine investigations and modelling work for the project include sea dispersion patterns, seawater quality, seasonal effects, diffuser options/locations and methods, and potential impact on marine organisms. At the outfall, a minimum initial dilution of 50:1, sufficient to avoid any effects on marine species has been specified (SA Water, 2008b).

Sydney Desalination Plant. Sydney Water is building a desalination plant to be completed in late 2009 in the Kurnell industrial estate area, in Sydney's southern suburbs. The plant will be able to generate 250 ML/day of potable water, with the possibility of scaling up to 500 ML/day in the future if needed. Both the intake and outfall tunnels and the pipeline to the water supply will be built to the ultimate capacity of 500 ML/day (Wikipedia, 2008).

The seawater intake and discharge outlet will be tunnelled at a depth of 50 to 70 m under the Kurnell Headland and approximately 30 m under the seabed. There are four drill shafts connecting each of the tunnels to the intake and outfall systems. The Four intake and four outlet structures are being built on the seabed about 300 m offshore in the Tasman Sea in water approximately 20 to 25 m deep. The diffuser system is designed disperse the 65,000 mg/l salinity and temperature of the seawater concentrate return to the background level of 34-36,000 mg/l within 50-75 m from the discharge point (GHD Fichtner, 2008).

Agnes Water Desalination Plant. The desalination plant will be located on the coast north of Brisbane between Bundaberg and Gladstone immediately adjacent to the existing Spring Road water treatment plant. The plant will supply 12 ML/day of potable water by 2026; with first-stage output estimated at 1.5 ML/day.

The offshore seawater intake is planned at a depth of some 8m to 10m sea level by constructing an intake pipeline some 600 m from shore. From an underground break tank, concentrate can discharge under gravity to the pipeline diffuser. Directional drilling is proposed for construction of the ~280 mm diameter concentrate discharge pipeline to terminate about 800 m off shore with a diffuser system (Cardno 2006).

Lake Beach Desalination Plant. The Wyong Shire Council in New South Wales is planning the construction and operation of a 20 ML/day SWRO plant adjacent to the

Toukley sewage treatment plant. Saline concentrate water will be discharge through the existing Norah Head Outfall after mixing with effluent from the Tourley Sewage treatment Plant.

Dalby Coal Seam Methane Water (CSM) Reverse Osmosis Plant. Dalby Town Council is designing a .3.75ML/day RO plant to augment drinking water supplies to the Dalby water distribution system. The new RO plant is to be constructed at the same facility as a conventional water filtration plant and brackish water RO plant.

The new desalination plant will be supplied by CSM sourced water from approximately extraction 100 bores with an approximately TDS of about 6,000 mg/l. The CSM sourced water will be blended with a varying proportion of water from other groundwater sources

The CSM-sourced groundwater is to be treated through two parallel treatment trains of equal capacity. The water treatment process will be comprised of pre-treatment including membrane filtration, two-stage reverse osmosis, aeration, and post-treatment. The overall recovery goal for the CSM-sourced water is approximately 72%. The particulate matter removed during the pretreatment stage will be blended with the brine from the RO units and transferred to existing evaporation ponds.

RESEARCH ON CONCENTRATE DISPOSAL IN AUSTRALIA

Although Australia is dependent for the most part on research being conducted elsewhere for disposal options for desalination concentrate, the Commonwealth Scientific and Industrial Research Organisation (CSIRO) may play a significant role including in the characterisation of water quality proposed for desalination, concentrate disposal issues and options and in salinity management projects.

CISRO is involved in the identification of the areas where desalination may contribute to the salinity management program as a part of salinity control measures. In particular, the salt interception works coordinated through the Murray-Darling Basin Commission have been implemented to control salinity levels in the River Murray through disposal of saline waters in specifically designed basins or lakes. Some of these basins have been constructed as controlled leakage basins permitting ultimate disposal to the deep aquifers whilst others are constructed to minimise leakage and rely solely on evaporation to dispose of water drawn from the salt interception works. A major programme emphasis has been given to improving solar evaporation techniques (Barron, 2006).

There is limited data available on the ionic composition of the waters in the disposal basins and therefore the nature of the salts, besides sodium chloride, that may be recovered. It can be expected that solar evaporation of waters in the disposal basins will yield halite, probably gypsum, and magnesium salts (sulphate and chloride) (Barron, 2006).

Initially it was thought that some commercial use could be found for the salt components of the concentrate, for example, chemical feedstock, which might cover the costs of dewatering. However, the composition of the salts present and the contamination with soluble organics mean that the salt is of limited commercial value. It is recognised that there still may be some value in the salt for remediation or other purposes and that this could become the ultimate disposal route for the dry product. The beneficial reuse avoids the estimated $500/t cost for ultimate disposal to landfill (ACTEW Corp Ltd, 2007).

Desalination of Brackish Groundwater and Deep Well Injection of Concentrate in El Paso, Texas

William R. Hutchison, Ph.D., P.E., P.G.[1]

[1]Water Resources Manager, El Paso Water Utilities, 1154 Hawkins Blvd., El Paso, TX 79925, 915-594-5516, bhutchison@epwu.org

ABSTRACT

El Paso has relied on the Hueco Bolson as a major water supply source since 1903. As a result of high pumping, groundwater levels in the Hueco have declined and brackish groundwater has intruded into areas that historically yielded fresh groundwater. El Paso Water Utilities (EPWU) began reducing its Hueco pumping in 1989 as a result of a variety of water management initiatives. The reduction in pumping resulted in stabilized groundwater levels in many areas. However, brackish groundwater intrusion remains an issue. A 27.5 mgd desalination plant has recently been completed that will result in reductions in brackish groundwater intrusion, and allow EPWU to better utilize its fresh groundwater wells during droughts. The location of the pumping wells will provide an opportunity to intercept the brackish groundwater before it intrudes into historically fresh groundwater areas. This approach is a component of EPWU's overall groundwater management of the Hueco Bolson.

OVERVIEW OF DESALINATION PROJECT

Since 1903, fresh groundwater from the Hueco Bolson has constituted a significant portion of the water supply for the greater El Paso area (Figure 1). Prior to 1989, pumping from the Hueco Bolson to supply El Paso Water Utilities (EPWU) customers was increasing each year. Since 1989, EPWU pumping from the Hueco Bolson has been decreasing due to concerns regarding decreasing groundwater levels and brackish groundwater intrusion. Increases in surface water diversions, aggressive and innovative water conservation programs, and increased reclaimed water use have allowed EPWU to reduce pumping in the Hueco Bolson. As a result of the decreased pumping in the Hueco Bolson, groundwater levels have stabilized in many areas.

The Hueco Bolson has a large volume of brackish groundwater that can be used as a potable supply after desalination. Brackish groundwater lies to the east and beneath a relatively small lens of fresh groundwater. Groundwater pumping of the fresh groundwater has caused brackish groundwater to intrude into areas where wells had historically pumped fresh groundwater. Figure 2 shows a simplified representation of where fresh groundwater and brackish groundwater occur at depths normally associated with production wells in El Paso. The interface has been moving east to west and northeast to southwest in response to cones of depression caused by pumping in El Paso and Ciudad Juarez.

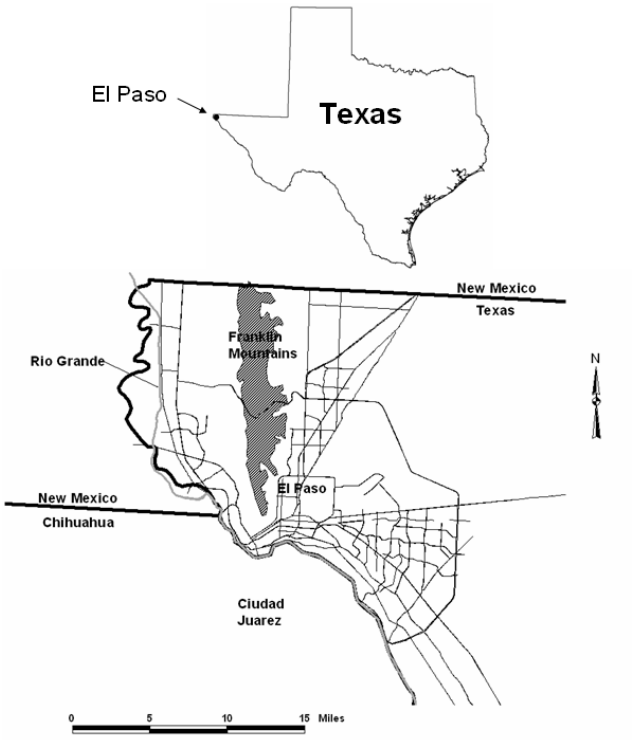

Figure 1. Location of El Paso, Texas

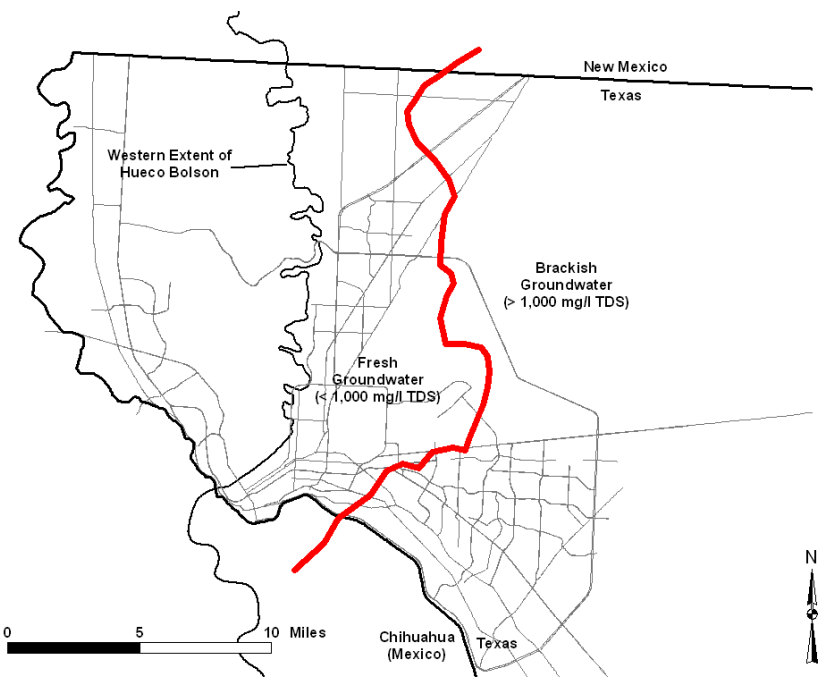

Figure 2. Location of Approximate Interface between Fresh Groundwater and Brackish Groundwater

Technological advances in the last decade have made desalination a more economically viable water source. Integrating desalinated brackish groundwater resources into the overall EPWU water supply portfolio presents certain opportunities to manage the brackish groundwater intrusion, which has caused wells that had historically pumped fresh groundwater to exceed secondary water quality standards for chloride and total dissolved solids.

A critical issue in the development and treatment of brackish groundwater is the disposal of the concentrate that is produced by the desalination process. After completion of various studies and a test drilling program, EPWU selected deep well disposal of the concentrate in the northeast corner of the South Training Area of Ft Bliss (Figure 3). Also shown on Figure 3 are the locations of existing and new EPWU wells in the Hueco Bolson that supply the desalination plant.

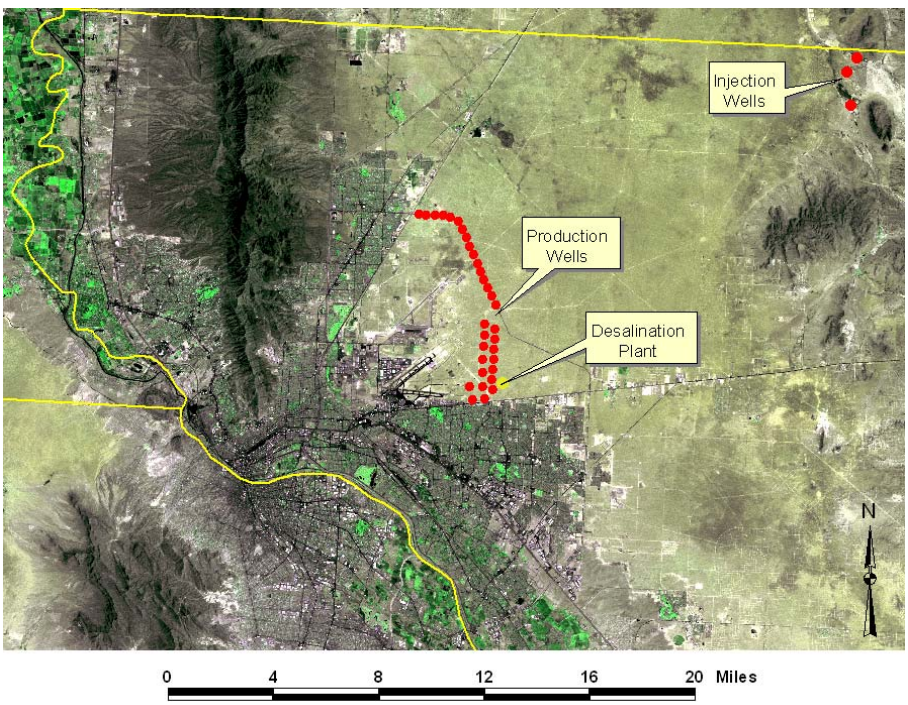

Figure 3. Location of Desalination Plant, Production Wells, and Injection Wells

Figure 4 presents a schematic of the desalination plant project at design capacity. 30.5 mgd of brackish groundwater from the Hueco Bolson is pumped. 18.5 mgd of this brackish water is processed in the plant, which yields 15.5 mgd of permeate and 3 mgd of concentrate. The remaining 12 mgd of brackish groundwater is blended with the 15.5 mgd of permeate to yield 27.5 mgd of finished water with a TDS of between 600 and 700 mg/l. The concentrate is sent 22 miles to the injection wells for disposal.

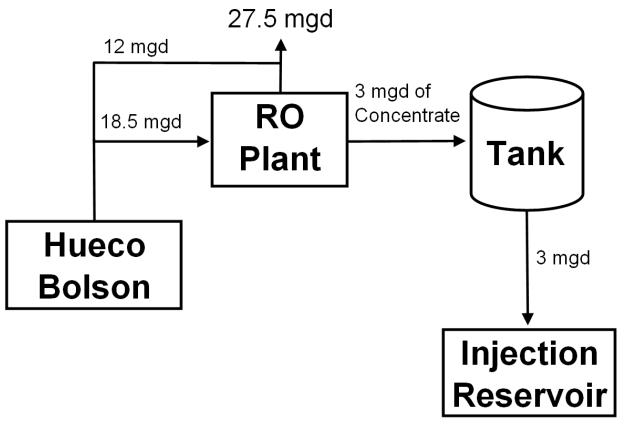

Figure 4. Schematic of Desalination Plant Process

COMPONENTS OF DESALINATION PROJECT

The major components of the desalination project are:

- Production wells and collector lines
- Reverse osmosis and near-plant pipelines
- Concentrate disposal wells and pipeline

As shown previously in Figure 3, there are 36 production wells that are connected to the desalination plant. These wells are a combination of existing wells (4), rehabilitated wells (3), and new wells (29), and are connected to the plant by 88,700 ft of new collector lines. The location of the wells is designed to intercept brackish groundwater. The drawdown trough that will be created will prevent further migration of brackish groundwater into areas that have historically pumped fresh groundwater. The production wells and collector lines were constructed under 12 separate contracts from March 2005 to June 2007.

The reverse osmosis plant has five skids of membranes manufactured by Hydranautics. Each skid is capable of flow rates between 1.70 and 3.64 mgd. Expected water recovery is between 70% and 82.5%, and expected salt rejection is up to 93%. The plant inflow is pre-treated with an antiscalant to control mineral precipitation (notably silica) and hydrochloric acid to adjust pH. The finished water is treated with caustic soda to raise the pH, a corrosion inhibitor, and disinfected with sodium hypochlorite. The concentrate can be treated with hydrochloric acid to adjust the pH prior to disposal, if needed. The near-plant pipelines include the completion of the two well collector lines, the initial part of the concentrate disposal line, and the finished water pipeline. The plant and pipe projects were constructed under two separate contracts (one for the plant and one for the pipe) from July 2005 to June 2007.

The concentrate disposal portion of the project consists of the remainder of the concentrate pipeline, three injection wells, and above-ground facilities associated with the injection wells (Surface Injection Facilities). The three injection wells are between 3,700 and 4,000 ft deep, and are completed in the Silurian Fusselman Formation, a fractured dolomite, and the underlying Montoya Formation, a fractured limestone. The Surface Injection Facilities consist of yard piping, a 300,000 gallon storage tank at each site, a solar power system (with generator backup), and various instrumentation and controls to manage the injection and collect performance data. The work associated with concentrate disposal was completed under seven separate contracts, including a test-hole contract by the US Army Corps of Engineers that represented the initial characterization of the area. The work was completed from April 2003 to June 2007.

CONCENTRATE DISPOSAL VIA DEEP WELL INJECTION

The investigations and analyses that culminated in the construction and operation of the three injection wells began in 2001. Initially, three methods of concentrate disposal were considered: passive evaporation, enhanced evaporation and deep well injection. Passive evaporation for 3 mgd of concentrate would have required a 700-acre double-lined pond. Enhanced evaporation would have required a smaller pond and mechanical sprayers to enhance the evaporation rate. An economic analysis of the three alternatives completed in 2002 showed that deep well injection would be significantly less expensive than either of the evaporation alternatives, if a suitable site was located. Because of the attractive costs, a detailed investigation of the deep well disposal option was completed from 2002 to 2004, and consisted of geologic investigations, test drilling, geophysical studies, preliminary modeling, and culminated in the construction and testing of a pilot well in 2004.

The results of the studies and the testing of the pilot well were used in 2004 and 2005 to prepare an application to the Texas Commission on Environmental Quality (TCEQ) for a Class V Authorization to inject concentrate into the Fusselman and Montoya formations of Silurian and Ordovician age. The authorization was obtained on July 13, 2005, and included a provision that the injectate had to meet primary drinking water standards.

During the development of the TCEQ application and after the authorization was obtained, several studies were completed related to the potential for mineral precipitation in the well and formation. Of notable concern were calcite, barite and silica. Mitigation strategies were identified (e.g. lowering the pH of the concentrate), and a plan for initial operation was developed to further test the potential for mineral precipitation during initial operation.

The second and third injection wells were constructed in 2006 and the beginning of 2007. These wells were also completed to Class I standards. The wells are completed with open holes in the injection zone (below 2,900 ft). A key aspect of the

injection wells is that no pumps are needed. The wells are capable of accepting water by gravity at rates that approach 2,000 gpm.

Initial testing of the wells began in May 2007 and initially involved injecting fresh water in order to develop well performance data without concern of mineral precipitation. At the beginning of plant operations, the concentrate was diluted, thus continuing baseline data collection. After sufficient baseline data were collected, the dilution of the concentrate was reduced and finally eliminated, with no observable change in well performance (i.e. injection rate and groundwater level build-up).

INITIAL OPERATION OF INJECTION WELLS

As of the submission of this paper (late January 2009) data have been collected from the beginning of operation of the plant after initial testing (September 2007) through the end of December 2008. A summary of operations is presented in Table 1.

Table 1. Summary of Operations – September 2007 to December 2008

Component	***Total Flow***
Airport Well Pumping	5,100 AF
Ft. Bliss Well Pumping	1,000 AF
Total Pumping	6,100 AF
Finished Water to Distribution System	5,100 AF
Concentrate from Reverse Osmosis Units	1,000 AF
Dilution Water from Ft Bliss Wells	1,400 AF
Total Concentrate Flow to Injection Wells	2,400 AF

Note that dilution water from Ft Bliss wells has been added to the concentrate from the reverse osmosis units in an attempt to comply with the requirement that the injectate meet primary drinking water standards. Several of the monthly samples of the concentrate, however, slightly exceed the primary standard for arsenic and selenium despite using different combinations of wells for dilution. TDS of the injectate during this initial operating period ranges from 2,500 mg/l to about 5,100 mg/l, which is considerably below the receiving formation TDS of about 8,800 mg/l.

In response to the difficulties in meeting the primary standard requirement, EPWU initiated discussions with Texas Commission on Environmental quality (TCEQ) and EPA in December 2007 to obtain an aquifer exemption status under 40 CFR Parts 144-146 and 30 TAC Chapter 331 for the injection zone. Because the receiving formation has a TDS below 10,000 mg/l, it is considered an Underground Source of Drinking Water (USDW). Under the regulations, exemptions can be sought if:

- The aquifer does not currently serve as a source of drinking water
- The aquifer cannot now and will not in the future serve as a source of drinking water based on certain criteria
- The TDS of the ground water is more than 3,000 and less than 10,000 mg/L and it is not reasonably expected to supply a public water system

An Aquifer Exemption application was submitted to TCEQ in August of 2008. It was also submitted to the New Mexico Environment Department (NMED) because the plume of injectate will eventually extend slightly north into New Mexico. If approved by TCEQ and NMED, it will then be submitted to EPA for concurrence and final action. Highlights of the application include:

- The wells are located in a remote area with no other production or injection wells
- The receiving formation meets TDS guidelines of the regulations (less than 10,000 mg/l and more than 3,000 mg/l)
- The receiving formation water does not meet primary drinking water standards
- Treatment would be required to meet primary drinking water standards and reduce TDS
- Introduction of the injectate would not necessitate further or more expensive treatment

Well performance during the initial operating period is summarized in Figures 5, 6 and 7, which show the minimum and maximum depth to water from September 2007 to December 2009 for each of the three wells. Note that the maximum depth to water each month is coincident with the highest injection rate, and the minimum is coincident with periods of non-operation.

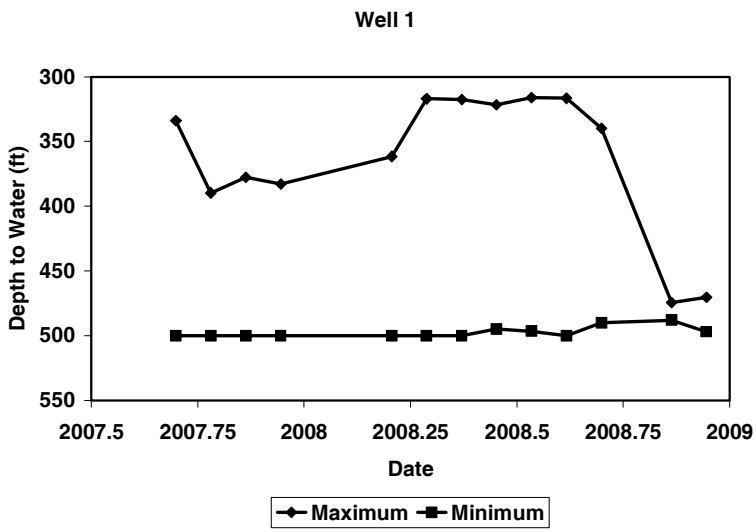

Figure 5. Monthly Minimum and Maximum Depth to Water in Injection Well 1

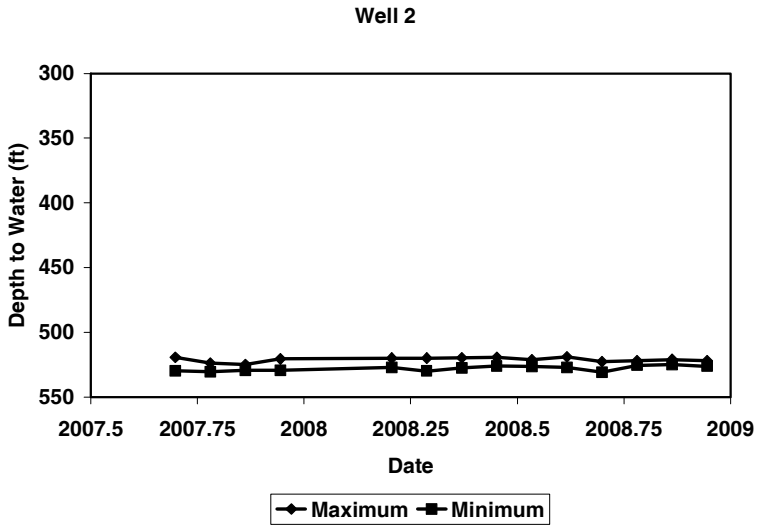

Figure 6. Monthly Minimum and Maximum Depth to Water in Injection Well 2

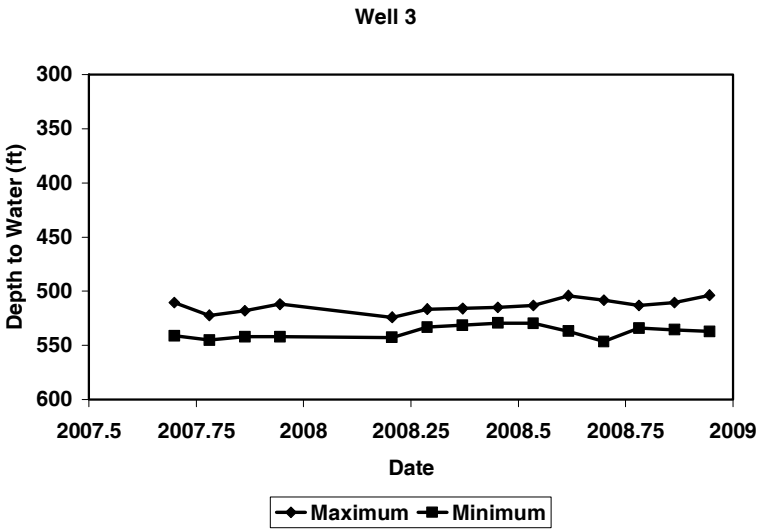

Figure 7. Monthly Minimum and Maximum Depth to Water in Injection Well 3

Note that during operation of Well 1, depth to water rises from a static level of about 500 ft below ground surface to as high as about 320 ft below ground surface (rise of about 180 feet). Injection rates have been as high as about 1,800 gallons per minute (gpm).

Well 2 is not operational due to issues with the annular space monitoring system. The depth to water ranges from about 520 feet below ground surface to about 530

feet below ground surface. Response to the injection in Wells 1 and 3 has been about 4 or 5 feet.
The injection rate in Well 3 has been as high as approximately 1,800 gpm, and depth to groundwater has risen 25 to 30 ft in response to the injection. Minimum depth to water (during non-operation) is about 530 ft below ground surface, and maximum depth to water during injection has been as high as about 500 feet below ground surface.

It is also important to note that all three wells exhibit no upward trend in minimum depth to water during the initial 16-month operational period. An upward trend would suggest limitations to the injection reservoir. Based on this initial operational period, well performance is considered acceptable, and monitoring continues.

PROJECT COSTS

Total capital cost of the project was about $91 million as follows:

- Production wells and collector lines: $32 million
- Plant and near-plant pipelines: $40 million
- Concentrate disposal: $19 million

Funding for the capital costs was as follows:

- Congressional appropriations: $26.0 million
- Texas Water Development Board interest-free loan: $1.0 million
- EPWU Bonds and cash: $60.7 million
- US Army contribution: $3.3 million

Annual operating costs (assuming a electrical cost of $0.07/kwh and 80% operation) are estimated to be $4.8 million. Amortized capital and operations costs (assuming a 5% discount rate) are estimated to be about $534/AF. The cost of the project (in terms of $/AF) are reasonable when compared to other EPWU sources ($163/AF for groundwater, $300/AF for surface water, and $706/AF for reclaimed water), and are far more attractive than importation from other parts of Far West Texas ($1,400/AF).

Membrane Treatment of Rio Grande Water for Municipal Water Production During the Non-Irrigation Season

ABSTRACT

Using impaired waters to meet increasing municipal demands has become nearly mandatory in many locations. This pilot scale project was undertaken to determine the feasibility of using brackish irrigation return flows (that also contain a small percentage of treated wastewater) to satisfy part of El Paso's municipal water demand during the non-irrigation season.

The first step was to determine if a sufficient quantity of water is available during the non-irrigation season to provide 10 MGD of potable water. Historical data obtained from the United States Geological Survey for the years 1936 through 2004 revealed that a flow of at least 20 MGD is available 89% of the time.

A simple microfiltration system (MF) was installed ahead of the reverse osmosis (RO) and nanofiltration (NF) membranes for suspended solids removal. The desalting results showed that both the RO and NF systems performed very well, with salt rejections in the 98% range. The lowest cost blended water was $0.76 per thousand gallons, produced in the NF unit when operating at 170 psi with a flux of 25 gallons per square foot per day. This cost includes disposal of concentrate through re-blending with available irrigation return flows for possible irrigation of onions, the major winter crop in El Paso County, Texas.

INTRODUCTION

The El Paso Water Utilities (EWPU) receives as much as 85% of its potable water supply from the Rio Grande during the irrigation season of the U. S. Bureau of Reclamation's Rio Grande Project. The irrigation season normally runs from March through September during a typical water supply year. The raw water quality is acceptable for treatment to potable water standards using conventional treatment methods during this period. However, when raw water releases from Elephant Butte and Caballo Reservoirs are curtailed at the end of the regular, irrigated growing season, the river water consists primarily of return flows from agricultural drains. These simple, incised drains were excavated to remove water from the root zone, thereby relieving the soil of excess water and improving crop production.

EPWU must curtail diversions from the river during the non-irrigation season (approximately October through February) because the total dissolved solids (TDS) content of Rio Grande water during that time generally exceeds 1000 mg/L. This represents a considerable portion of the year during which surface water is essentially unusable as a potable supply due to high TDS. This project was undertaken to determine the feasibility of treating river water after

the irrigation season ends (i.e. irrigation return flows) to meet potable water quality standards using membrane technology, thereby utilizing an available water resource that is currently not put to full beneficial use.

METHODOLOGY

The first step in the project involved assessing the availability, reliability, and quantity of winter return flows in the Rio Grande. If the water available during the non-irrigation season is insufficient from a quantitative standpoint, any qualitative evaluation would be irrelevant. Therefore, historical data were obtained from the United States Geological Survey (USGS) for the years 1936 through 2004 at the Courchesne Bridge and analyzed for average, median, and low flows during the non-irrigation season. Once the quantity of water available was determined to be adequate, the same database was used to obtain water quality parameters as a function of flow. Treatability studies were then conducted using pilot plants containing different types of membranes as discussed below. This part of the study also generated design and cost information for possible full-scale implementation of the project.

Three different pilot units were set up at EPWU's Canal Street surface water treatment plant site to collect data for this study. The MF unit, which was used for suspended solids removal, consisted of four, 4-inch (10 cm) diameter microfiltration membrane housings 40" (100 cm) long connected in parallel and mounted horizontally on a stand, one above the other. The other two pilot units were single-membrane GE-Osmonics units, one equipped with a nanofiltration membrane and the other with an RO desal membrane. Ball valves at the end of each housing allowed for any of the membranes to be isolated for cleaning or other servicing. The antiscalant Pretreat Plus Y2K from King Lee Technologies was added at 2 ppm during all testing.

In addition to the treatment units themselves, there were two storage tanks included in the treatment system. All pilot equipment (i.e. everything except the two storage tanks) was housed in a 12'x 24' (3.7 x 7.3 m) building located close to the American Canal. A schematic of the pilot treatment system is shown in Figure 1. For a full-production scale plant, permeate water would be blended back with river return flows treated in the conventional treatment plant and pumped into the potable water distribution system.

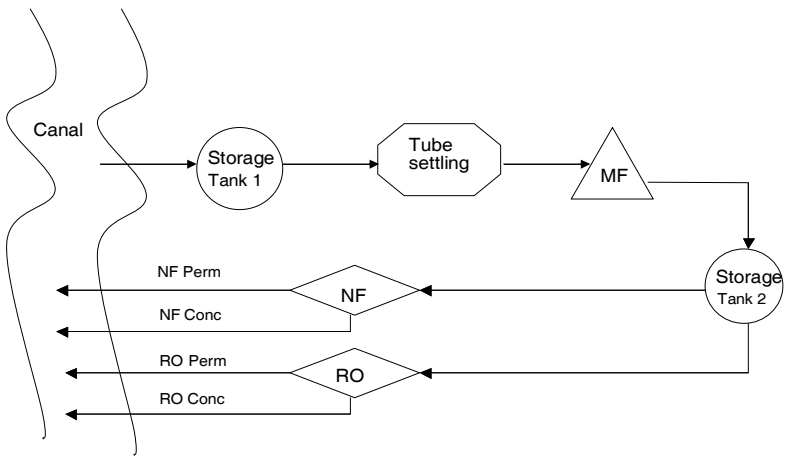

Figure 1. Pilot Plant Schematic

DATA COLLECTION PROCEDURES

Data collection activities for this project spanned parts of the 2006 thru 2008 irrigation and non-irrigation seasons. The pilot plants were operated on an intermittent basis, ranging from a few hours at a time to several weeks continuously, depending on the task at hand. The water quality parameters that were measured also varied according to what was being investigated at the time. Some of the water quality parameters were measured at the site, but most were measured in the lab. Besides the operating parameters that obviously had to be recorded at the site (such as temperatures, pressures, flows, etc.), some of the conductivity, pH, and turbidity readings were also made at the site. Conductivity and temperature readings were made with an Oakton model Con 110 combination pH, conductivity, TDS meter. Turbidity readings were made with a HACH model 2100N Turbidimeter. The more routine analyses such as alkalinity, chlorides, hardness, etc. were done at The University of Texas at El Paso using HACH standard procedures. The more robust sample analyses were done at the International Water Quality Laboratory of EPWU, including analyses for anions and cations, total organic carbon, silica, etc.

QUANTITY AND QUALITY OF IRRIGATION RETURN FLOWS

As stated previously, USGS data spanning a 65-year period were used for determining the quantity and quality of the river water during the non-irrigation season. The summarized flows for October thru February are shown in Table 1, and the data show that the lowest average and median monthly values occur during January, at 91.5 MGD and 63.7 MGD, respectively.

Table 1. Average and Median Flows

	Years of Record	Avg, MGD	Median, MGD
Oct	68	197.1	184.8
Nov	68	111	96
Dec	68	105.6	76.2
Jan	68	91.5	63.7
Feb	68	119	84.1

Source: Riley, R. T., “Treatment of Non-Irrigation Water at the Canal Street Water Treatment Plant”, Master of Science Thesis, Department of Civil Engineering, August 2005, University of Texas at El Paso.

The October median flow at 185 MGD is almost three times greater than the January median, showing that the flows decrease considerably in a fairly short period of time. On the other hand, these results also show that relatively large volumes of water are available in the non-irrigation season winter months.

Table 2 shows that flows below 40 MGD occur about 20% of the time, and flows below 20 MGD occur about 11% of the time. Review of Table 2 also indicates that a plant designed to treat 10 MGD would be able to operate at full capacity 92% of the time, based on flow. If the plant were operated only when the river flow exceeded 20 MGD, it would be able to provide water during the non-irrigation season 89% of the time.

Table 2. Winter Flows in the 10 – 40 MGD Range

Month	Years of Record	No. Flows > 40	% Flows > 40	No. Flows > 20	% Flows > 20	No. Flows > 10	% Flows > 10
Oct	68	59	87%	64	94%	66	97%
Nov	68	56	82%	60	88%	62	91%
Dec	68	54	79%	59	87%	61	90%
Jan	68	53	78%	60	88%	62	91%
Feb	68	49	72%	58	85%	61	90%
		Avg =	**80%**		**89%**		**92%**

Given that the *quantity* of water available is adequate for winter operation, the next most important consideration is water quality, since that determines the type of treatment system that will be required. The primary parameters of interest for this project were total dissolved solids (TDS), sulfates, and chlorides, since one or more of them is usually what dictates when the Canal Street plants terminate their normal seasonal operations. Figure 2 is a plot of TDS, sulfates and chlorides for flows less than 100 MGD and, as the figure shows, all concentrations increase significantly as the flow decreases to less than 20 MGD.

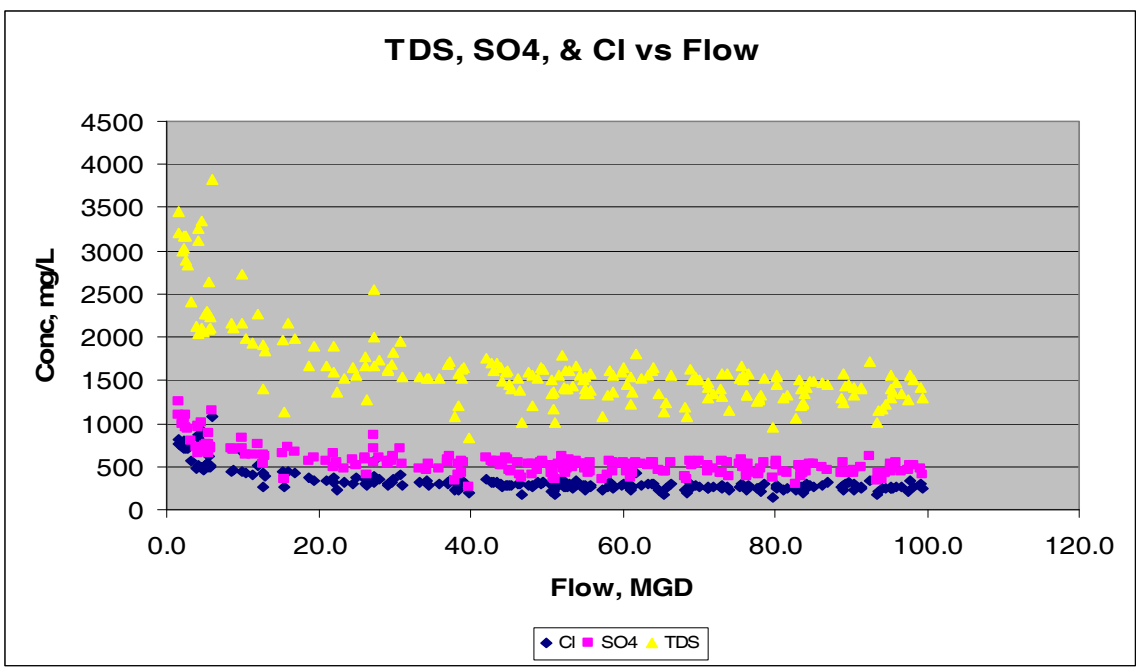

Figure 2. TDS, Sulfate, and Chloride Concentrations for Flows Below 100 MGD

The approximate concentrations associated with each parameter at flows of 10, 20, and 40 MGD are shown in Table 3. These data show the significant deterioration in water quality that occurs at flows below 20 MGD.

Table 3. TDS, Sulfate, and Chloride Concentrations vs. Flow

	10 MGD	20 MGD	40 MGD
Cl	512	335	287
SO4	726	586	453
TDS	2292	1780	1407

PERFORMANCE OF RO AND NANO MEMBRANES

The RO membrane was a GE - RO desal membrane and the nano membrane was a Filmtec nano NF90-4040 membrane. Table 4 shows some of the chemical parameters for the permeate and concentrate from each membrane. As the data show, both membranes performed very well from the standpoint of salt rejection, with the nano membrane performing as well as the RO membrane. (There is a wide spectrum of the performance in nanofiltration membranes).

Table 4. Permeate & Concentrate Quality from RO and Nano Membranes

Parameter	Tank 2 (Feed)	RO Perm	RO Conc	Nano Perm	NanoConc
Calcium	95.1	<10	364	<10	380
Magnesium	25.8	<0.5	97	<0.5	102
Potassium	12.3	<2	44.1	<2	46.5
Sodium	396	25.9	1480	16.1	1560
Bromide	<0.05	<0.05	<0.50	<0.05	<0.50
Chloride	341	30.7	1250	16.89	1360
Fluoride	0.76	<0.1	2.33	<0.1	2.43
Nitrate-N	2.68	0.97	6.16	0.66	6.94
Nitrite-N	0.25	0.07	0.56	<0.05	0.62
Ortho-P	0.3	<0.05	0.82	<0.05	0.94
Sulfate	427	4.8	1640	1.26	1760
Alkalinity	226.8	11.7	771	<5	880.3
Conductivity	2360	150	7500	79.5	8000
TDS	1450	62	5410	58	5790
pH	8.2	7.1	8.2	6.9	8.2
Silica	20.3	<5.0	77.4	<5.0	83.9

Note: All units mg/L except Cond (µS/cm) and pH

Source: Data from "Membrane Treatment of Impaired Irrigation Return and Other Flows for Creating New Sources of High Quality Water." Copyright 2008. Awwa Research Foundation. ALL RIGHTS RESERVED.

The flux in the RO unit was 12.7 gallons per square foot per day (gfd) at a recovery rate of 73%, with the values in the nano unit at 23.5 gfd and 75%, respectively. The results are for treatment that occurred in the month of February during a period of prolonged, multiple-year, regional drought. The raw water conductivity of 2440 µS/cm is approximately the 93rd percentile of non-irrigation season conductivities, so these results can be considered as nearly worst-case conditions. Even so, the TDS of both permeates is so low that a considerable amount of blending can be done. The silica concentration of 84 mg/L in the nano concentrate is well below the concentration that would be of concern with respect to membrane fouling, even if an antiscalant weren't used. Thus, in general, these results appear to be very favorable from the standpoint of system performance.

FINANCIAL ANALYSIS

Since both the RO and nano systems performed well from the standpoint of salt rejection, an economic analysis was conducted to determine the optimum operating conditions for each system based on the cost of the produced water. Data were collected over a full range of permeate flows and pressures for both systems by changing the variable frequency drive (VFD) settings from 25% to 75% and adjusting the recoveries from 35% to 90%. The data were collected in three different time periods: November, 2006, and January and February of 2007. These data were then used to project the capital and operating costs of a full scale system so that the unit cost of water could be determined for each condition.

The values used in the cost calculations are shown in Table 5. Note that the costs are based on a permeate water volume of 5 MGD and a final product water quality of 750 mg/L TDS. Blending would be approximately 1:1, using pretreated river water, so the total net river water removal volume would be about 10 MGD. Membrane concentrate is assumed to be discharged back into the raw water canal for winter crop irrigation, or for eventual return to the river. Personnel costs for the 5-month operating season are estimated at $100,000. Contingency costs of $100,000 per season are also included in the calculations. The unit costs are plotted as a function of pressure in Figures 3 and 4 for the RO and nanofiltration units, respectively.

Table 5. Values Used in Financial Calculations

Item	Value
Permeate volume, MGD	5
River TDS, mg/L	1400
Final product water TDS	750
Raw water cost, $/acre-ft	$16.00
Pretreatment cost (Canal plant), $/1000 gal	$0.15
Interest rate, %	5%
Equipment life, yrs	20
Recovery of pretreated water,%	96%
RO capital cost, $/ft^2 membrane	$8.64
Power cost, $/kw-hr	$0.07
Pump & Motor efficiency, %	75%
Building Cost, $	$500,000
Building Life, yrs	30
Membrane cost, $/80 sq ft	$300
Membrane life , yrs	3
Antiscalant, $/9 lb gal	$11.00
Antiscalant dosage, mg/L	2.0
Personnel, $/yr	$100,000
Contingencies, $/yr	$100,000

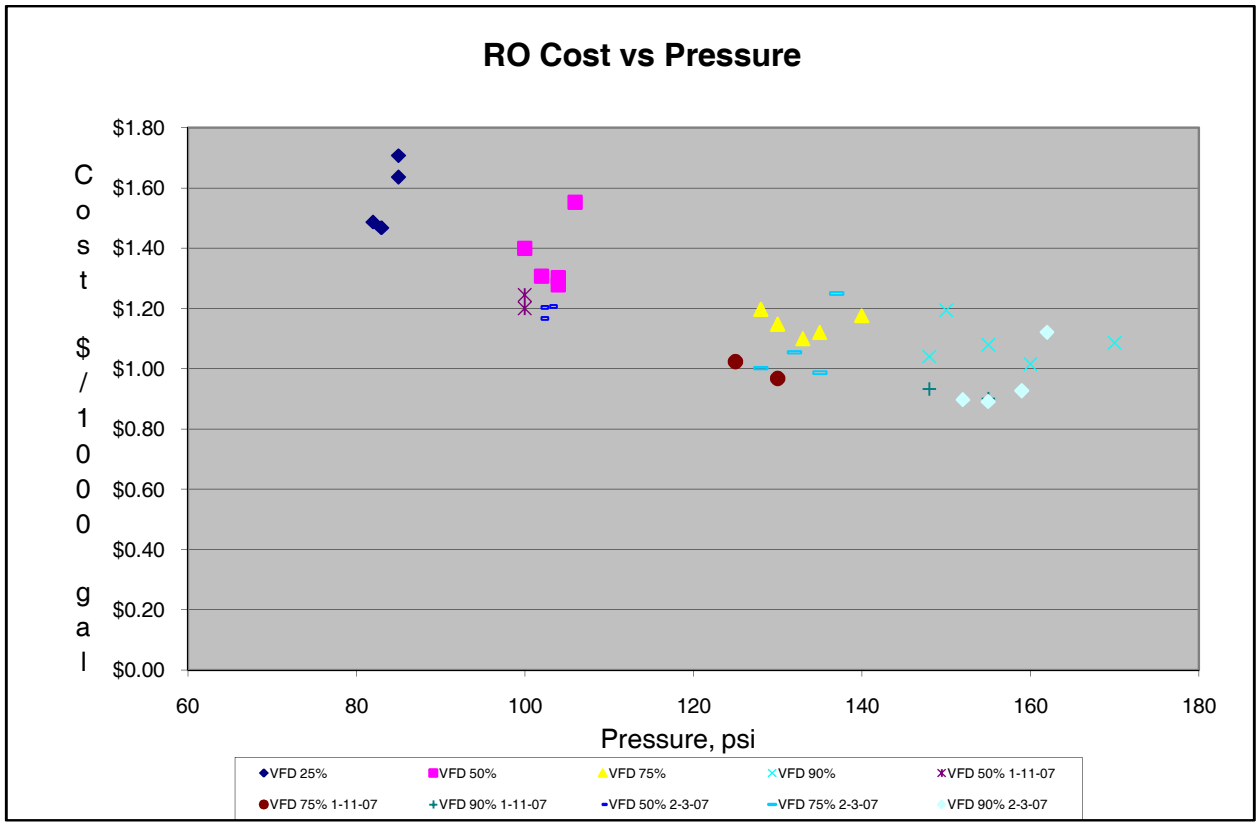

Figure 3. RO Unit Water Costs versus Pressure

Source: Data from "Membrane Treatment of Impaired Irrigation Return and Other Flows for Creating New Sources of High Quality Water." Copyright 2008. Awwa Research Foundation. ALL RIGHTS RESERVED.

The results show that the unit cost of the final product water (i.e. blended water) generally decreases as the pressure and recovery increase in both the RO and nano units. The pressure effect is more pronounced for the RO unit than for the nano. For the RO unit, the lowest costs are generally associated with recoveries around 75% and pressures in area of 150 psi. The lowest costs are in the $0.89 to $0.96 per thousand gallon range for the 2007 data, which were collected under conditions that were more normal than in 2006. The 2006 data gave higher unit costs because the water was a little saltier at that time. Even so, the cost for desalting Rio Grande irrigation return flows in a reverse osmosis system would still be about the same as water produced in the conventional surface water treatment plants during the normal irrigation season (because of the much lower cost of the raw water).

For the nano unit, the costs are lower than for RO over a rather broad pressure range, but the lowest unit costs are generally associated with pressures above 170 psi and recoveries in the 60% to 80% range. Since the fluxes above 200 psi tended to exceed 30 gfd, a pressure of around 170 psi would probably be preferable for the final design. The unit water costs are in the $0.70 - $0.80 range for the 2007 data.

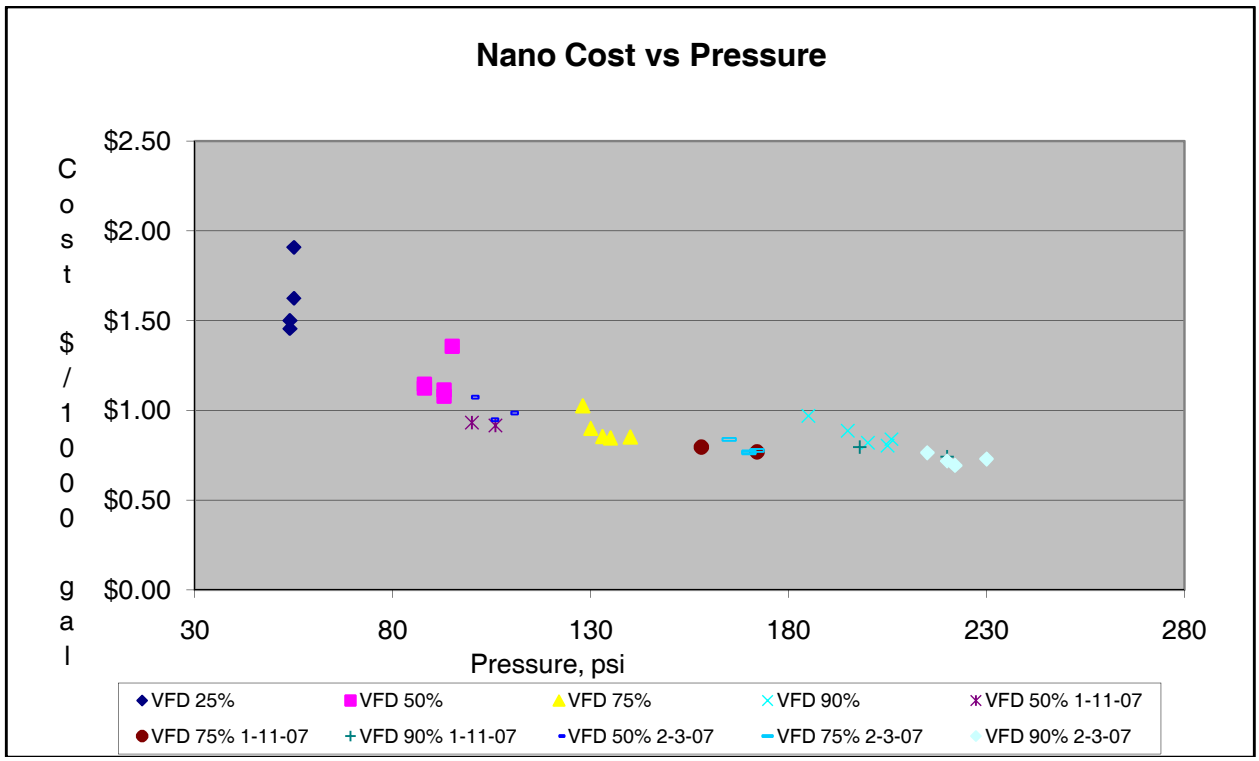

Figure 4. Nano Unit Water Costs versus Pressure

Source: Data from "Membrane Treatment of Impaired Irrigation Return and Other Flows for Creating New Sources of High Quality Water." Copyright 2008. Awwa Research Foundation. ALL RIGHTS RESERVED.

Research nursery testing of the RO and Nano concentrates for irrigation of commercial onions indicates that the concentrate may be successfully blended back with raw winter return flow waters and used for irrigation. Since the concentrate can easily be discharged back into the raw water source canal at this plant location, and thereby blended back with additional raw winter return flow waters for downstream winter irrigation, there should theoretically be no additional cost for concentrate disposal.

CONCLUSIONS

Based on the results of this investigation, the following conclusions can be made with reasonable certainty:

1. From a technical point of view, desalting of Rio Grande irrigation return flows during the non-irrigation season appears to be quite feasible for producing at least 10 MGD of drinking water for EPWU customers.

2. A nanofiltration system using a Filmtec nano NF90-4040 nanofiltration membrane will produce drinking water having a slightly lower cost than a reverse osmosis system. The unit cost of water produced in such a system is projected to be about $0.76 per thousand gallons.

3. Several nanofiltration full-scale system designs would produce water in the $0.76 - $0.79 per thousand gallon range. The one that would seem to produce the least amount of stress in the system would operate at 170 psi with a recovery of about 75% and a flux of 25 gfd.

4. Both of the membranes tested in this study (RO and nano) produced very high quality water (TDS concentrations generally less than 100 mg/L). This will allow for a high blend ratio of 1:1, which results in low-cost product water, rendering the project very attractive from an economic point of view.

5. Winter irrigation of commercial onion crops is possible using RO or Nano concentrate during periods when an adequate supply of raw winter return flows is available for blending prior to application. Careful management would be required for germination and crop establishment.

Carollo Engineers, 401 N. Cattlemen Road, Suite 306, Sarasota, FL 34232; PH. 941-371-9832; FAX 941-371-9873; email: ssethi@carollo.com

ABSTRACT

The National Academies' National Research Council (NRC) formed a committee on desalination that was tasked with performing a critical analysis of the desalination technology, barriers to its widespread implementation, and the development of a national strategic research agenda. A synopsis of the final committee report including the major conclusions and recommendations are presented in this paper.

Desalination is an established technology and has advanced significantly over the past five decades, making it a realistic option for increasing water supplies in some parts of the U.S. Desalination, using both brackish and seawater sources is likely to have a niche in the nation's future water management portfolio. However, while the required source water resources and inherent technology capabilities are themselves not constraining, the potential of desalination is somewhat constrained by associated financial, social, and environmental factors. Potential environmental impacts of desalination are characterized with uncertainty, which leads to costly delays in permitting.

The committee concluded that resolving these uncertainties and developing methods to mitigate the impacts is the highest priority for future research. Other priorities include research and development to continue current trends in reducing the process costs of desalination and developing cost-effective, environmentally sustainable approaches for concentrate management. The committee recommended that a coordinated, strategic research effort with steady funding is needed to better understand and minimize desalination's environmental impacts and to find ways to further lower its costs and energy use. Thus, implementing the proposed research agenda will require federal leadership and a coordinated, strategic plan among multiple agencies, with successful implementation depending on participation by federal, state, local agencies, nongovernmental entities, and the private sector.

INTRODUCTION

The National Academies' National Research Council (NRC) formed a Committee on Advancing Desalination Technology in 2006, with the support of the U.S Bureau of Reclamation and the U.S Environmental Protection Agency. The committee was tasked with performing a critical analysis of current desalination technologies and the barriers to widespread implementation, as well as addressing the development of a national strategic research agenda for desalination. The project's findings and analysis were recently published in the report entitled "Desalination: A National Perspective." (NRC, 2008). A synopsis of the report, focusing on the major topics and findings, as well as key aspects of the research agenda, is presented and discussed in this paper. This report builds on a 2004 NRC report (NRC, 2004) that provided a scientific assessment of the Bureau of Reclamation's and Sandia National Laboratories' Desalination and Water

Purification Technology Roadmap, which was intended to serve as a strategic pathway for future desalination and water purification research (USBR and Sandia National Laboratories, 2003).

The author of this paper served as a member of the committee, and the complete list of team and committee members who contributed to the report is acknowledged at the end of this paper.

BACKGROUND

Only 2.5 percent of the water on earth is freshwater and much of even that small percentage is bound up in glaciers and snowpack, leaving only a small fraction available to meet the world's freshwater demands. Climate change, population growth, and local water scarcity are driving factors for desalination of brackish water and seawater. Desalination can provide a safe, reliable, and sustainable water supply to communities. However, while the required source water resources and inherent technology capabilities are themselves not constraining, the potential of desalination is somewhat constrained by associated financial, social, and environmental factors. Potential environmental impacts of desalination are characterized with uncertainty, which leads to costly delays in permitting.

Since the 1960, desalination capacity has seen an exponential increase both globally and nationally. This increase was fueled in part by the growing concern for local water scarcity and was made possible to a great extent by a major federal investment for desalination research and development in the late 1950s to the early 1980s. Desalination technology offers the potential to substantially reduce water scarcity by converting the almost inexhaustible supply of seawater and the apparently vast quantities of brackish groundwater into new sources of freshwater. Although total water use in the United States has remained steady over recent decades, interest in brackish water and seawater desalination will likely continue, particularly in water-scarce regions, in localities experiencing rapid population growth, or where users are able and willing to pay for a high-quality, reliable new supply.

Recent advances in technology, especially improvements in membranes, have made desalination a realistic water supply option. The cost of desalinating seawater in the United States is now competitive with other alternatives in some locations and for some high-valued uses, and there is considerable interest in hastening the time when costs of desalination are routinely competitive with the costs of alternatives. Through this NRC project, priority research areas and goals were identified to help make desalination a competitive option among water supply alternatives.

STATUS-QUO OF INVESTMENT IN DESALINATION R&D

The committee performed a survey of investment in desalination research and development. This included gathering data on federal investments and estimates of state, nongovernmental organizations, and private-sector funding. Based on the survey data and corresponding analysis, the committee reached the following conclusions that emphasize the need for the development of a national strategic research agenda for desalination:

- There is no integrated and strategic direction to the federal desalination research and development efforts.

- Some states, especially California, have also made sizeable recent investments in desalination research and development.

- The private sector appears to fund the majority of desalination research, with total annual spending estimated to be more than twice that of all other surveyed sources of such funding.

STATE-OF-SCIENCE OF DESALINATION TECHNOLOGY

The committee assessed the state-of-science of desalination technology for its five major components including intakes, pretreatment, desalination processes, post-treatment, and concentrate management. Significant improvements have been made in the reduction of energy use for RO with the improvements in membrane technology and commercialization of high-efficiency energy recovery devices. Although RO and thermal desalination technologies are relatively mature, there are opportunities to further reduce energy and costs. For RO, and current energy use is within a factor of 2 of the theoretical thermodynamic minimum value for separating solutes from water; practical constraints are likely to limit the further decrease in energy use to approximately 15 percent. Thus, the committee concluded that opportunities exist to further reduce cost and energy use of current technologies by small but economically significant amounts:

- In RO desalination, the costs and energy requirements of water production can be further reduced by mitigating fouling through pretreatment; developing high-permeability, fouling-resistant, high-rejection, oxidant-resistant membranes; and optimizing membrane module and membrane system design.

- Seawater desalination using thermal processes can be cost effective when waste heat is utilized effectively.

- Few, if any, cost-effective environmentally sustainable concentrate management options exist for inland desalination facilities.

MITIGATION OF POTENTIAL ENVIRONMENTAL IMPACTS

Desalination has been used worldwide for municipal applications for several decades, however, since the potential environmental impacts have not been fully quantified, it is considered a “new” water supply option by many entities. In order to change this, it is essential to systematically assemble knowledge of the potential environmental impacts of desalination processes so that is easily available to water supply planners for consideration of desalination as an alternative water supply. The key environmental considerations can be categorized as:

- Impacts from the acquisition of source water.

- Impacts from the management of concentrate and other waste products (e.g. cleaning chemicals) from the desalination process.

- Impacts of greenhouse gas emissions due to energy intensive nature of desalination processes.

- Considerations with product water quality in terms of specific challenges (e.g. boron rejection).

Ideally, these considerations should be compared against equally rigorous environmental impact analyses of water supply alternatives, so that decisions can be made based on comparisons of the full economic costs and benefits, including environmental and social costs and benefits, among the various water supply alternatives.

The committee concluded that there is a considerable amount of uncertainty about the environmental impacts of desalination and, consequently, concern over its potential effects. However, desalination efforts do not need to be halted until this research is done and uncertainties are removed, but research investments should be made to help reduce potential risks. Therefore, the following research is recommended:

- Site-specific assessments of the impacts of source water withdrawals and concentrate management should be conducted and the results synthesized in a national assessment of potential impacts.

- Monitoring and assessment protocols should be developed for evaluating the potential ecological impacts of surface water concentrate discharge.

- Longer-term, laboratory-based assays on the sublethal effects of concentrate discharge should be conducted to understand the range of environmental impacts from desalination plants.

- Water quality guidance, based on an analysis of the human health effects of boron in drinking water and considering other sources of exposure, is needed to support decisions for desalination process design.

- Further research and applications of technology should be carried out on how to mitigate environmental impacts of desalination and reduce potential risks relative to other water supply alternatives.

COSTS AND BENEFITS OF DESALINATION

In the past, the relatively high financial costs of desalination has limited the application of desalination technologies in most areas. However, the costs and relative economic scenario of desalination application are both changing in a number of important ways, largely due to the following key factors:

- Improved membrane technologies are less expensive.
- The desalination process is becoming more energy efficient.

- Cost of desalination is becoming relatively more competitive due to increasing costs of alternatives for augmenting water supplies.

When two of the noteworthy benefits of desalination, including provision of a drought resistant supply and a means to diversify a community's water supply portfolio are considered in the analysis, the current costs of desalination costs can generally be low enough to make it an attractive option for some communities. However, this is subject to several key factors that can play an important role in determining the costs of desalination. First, like the costs of other water supply alternatives, the costs of desalination are locally variable and are influenced by factors such as site conditions. Secondly, the availability and final selection of the concentrate disposal options can influence the overall costs of desalination in a significant fashion. Thirdly, the increasing awareness of potential environmental impacts is raising the costs of permitting and intake and out fall configurations in the United States. Finally, the future costs of energy are uncertain. Conservation and water transfers will usually be less costly than desalination, and conservation of water often comes with associated benefits, such as reduced energy costs.

The committee made the following key conclusions with respect to the cost and benefits of desalination:

- Substantial reductions in the financial cost of producing desalinated water will require substantial reductions in either energy costs or capital costs.

- For brackish water desalination, the costs of concentrate management can vary enormously from project to project and may rival energy and capital costs as the largest single component of cost.

- Conservation and transfers from low- to high-valued uses will usually be less costly than supply augmentation schemes, including desalination.

- There are small but significant efficiencies that can be made in membrane technologies that will reduce the energy needed to desalinate water and, therefore, offer potentially important process cost reductions.

- To make the true costs of desalination transparent, the economic costs should be accounted for and reported accurately.

STRATEGIC AGENDA FOR FUTURE DESALINATION R&D

Although desalination technology has advanced significantly over the past five decades, concerns remain about its potential environmental impacts and costs. The committee identified two overarching long-term research goals that need to be met for desalination to become a more attractive option for municipal application.

1. Understand the environmental impacts of desalination and develop approaches to minimize these impacts relative to other water supply alternatives, and

2. Develop approaches to lower the financial costs of desalination so that it is an attractive option relative to other alternatives in locations where traditional sources of water are inadequate.

The committee concluded that a coordinated, strategic research effort with steady funding is needed to better understand and minimize desalination's environmental impacts - and to find ways to further lower its costs and energy use. Thus, the committee also developed a strategic research agenda in support of these two overarching goals. Broad based objectives are identified as part of the research agenda that can be funded and conducted in either the public or the private sector. Several recommendations for implementing the proposed research agenda follow:

- A coordinated, strategic plan should be developed to ensure that future federal investments in desalination are integrated and prioritized and address the two major goals identified above.

- Environmental research should be emphasized up front when implementing the research agenda.

- Research funding in support of reducing the costs of desalination should be directed strategically toward research topics that are likely to make improvements against benchmarks set by the best current technologies for desalination.

Besides research, other practical implementation issues also require consideration to address the barriers to increased application of desalination technology. Some issues identified in the report include building trust and educating the public on desalination project planning, anticipating the sometimes cumbersome regulatory and permitting process, and utilizing pilot testing to optimize the process design.

The committee identified priority research areas to help make desalination a competitive option among water supply alternatives for communities facing water shortages. Some of this research may be most appropriately supported by the private sector. The research topics for which the federal government should have an interest - where the benefits are widespread and where no private-sector entities are willing to make the investments and assume the risk - are marked with asterisks.

Priority Research Areas:

GOAL 1. Understand the environmental impacts of desalination and develop approaches to minimize these impacts relative to other water supply alternatives.

1. Assess environmental impacts of desalination intake and concentrate management approaches**
   a. Conduct field studies to assess environmental impacts of seawater intakes**
   b. Conduct field studies to assess environmental impacts of brackish groundwater development**

c. Develop protocols and conduct field studies to assess the impacts of concentrate management approaches in inland and coastal settings**
d. Develop laboratory protocols for long-term toxicity testing of whole effluent to assess long-term impacts of concentrate on aquatic life**
e. Assess the environmental fate and bioaccumulation potential of desalination-related contaminants**

2. Develop improved intake methods at coastal facilities to minimize impingement of larger organisms and entrainment of smaller ones**

3. Assess the quantity and distribution of brackish water resources nationwide**

4. Analyze the human health impacts of boron, considering other sources of boron exposure, to expedite water-quality guidance for desalination process design**

GOAL 2. Develop approaches to lower the financial costs of desalination so that it is an attractive option relative to other alternatives in locations where traditional sources of water are inadequate.

5. Improve pretreatment for membrane desalination
   a. Develop more robust, cost-effective pretreatment processes
   b. Reduce chemical requirements for pretreatment

6. Improve membrane system performance
   a. Develop high-permeability, fouling-resistant, high-rejection, oxidant-resistant membranes
   b. Optimize membrane system design
   c. Develop lower-cost, corrosion-resistant materials of construction
   d. Develop ion-selective processes for brackish water
   e. Develop hybrid desalination processes to increase recovery

7. Improve existing desalination approaches to reduce primary energy use
   a. Develop improved energy recovery technologies and techniques for desalination
   b. Research configurations and applications for desalination to utilize waste heat**
   c. Understand the impact of energy pricing on desalination technology over time**
   d. Investigate approaches for integrating renewable energy with desalination**

8. Develop novel approaches and/or processes to desalinate water in a way that reduces primary energy use**

GOAL 1 and 2 Cross Cuts.

9. Develop cost-effective approaches for concentrate management that minimize potential environmental impacts**

Abstract

Design improvements, operational simplicity, advancements in new membrane materials, and competition in membrane industry have reduced both capital and operating costs of nano filtration (NF) and reverse osmosis (RO) systems for drinking water treatment applications. In Florida, the use of membrane technologies has increased to about 200 MGD today in comparison to 60 MGD in 1994. Currently, there are 125 membrane treatment systems in Florida with design capacities ranging from 800 gallons per day (gpd) to 25 MGD. A survey of economics of membrane treatment (NF and RO) facilities for drinking water treatment and concentrate management options were conducted for facilities located in Florida. Cost comparisons were based on data from different planning documents and plant surveys (Bergman, 1995; LEC, 2000; and budget data provided by the facilities). Since the capital costs depend on land cost, loan interests, consulting fees, design cost, pilot tests, costs of permits and other site specific factors; for accuracy of comparison, only the construction costs were considered for capital costs.

Introduction

Once considered as an expensive technology to be economically attractive in comparison to conventional water treatment processes; membrane technology has become a widely used water treatment process option. In the US, the installed desalination capacity using membrane technologies has increased to over 3.8 million cubic meters (one billion gallons) per day, accounting for about 91 percent of desalination capacity (RosTek Associates, Inc., 2003). Only in Florida, the use of membrane technologies has increased to about 200 MGD today in comparison to 60 MGD in 1994. Currently, there are 125 membrane treatment systems in Florida with design capacities ranging from 800 gallons per day (gpd) to 25 MGD. A survey of economics of membrane treatment (NF and RO) facilities for drinking water treatment and concentrate management options were conducted for facilities located in Florida.

Construction Costs

The construction cost data for membrane treatment facilities were obtained from planning documents and plant surveys (Bergman, 2005; LEC 2000, facility budget data). These costs include all facilities including installed membrane process equipment, buildings, degasifiers, clearwells, and transfer pumps (if applicable), ground storage and high-service pumping, bulk chemical storage, emergency power, yard piping, and site development. Supply wells and raw water piping are not included. However, where applicable, concentrate treatment and disposal facilities are included. Table 1 lists the plants and their capacities that are included in this study. Figure 1 presents the construction costs for membrane treatment plants in Florida. As shown in Figure 2, the constructions costs in terms of product water quantity vary from about $3/gpd for 1 MGD facilities to $1.2 to $1.8/gpd for 20 MGD plants.

Table 1. Construction costs of some of membrane treatment (NF, RO) plants in Florida.

Plant name	Capacity (MGD)	Construction cost (million $)(a)
Plantation	12.0	16.23
Ft. Myers (Bergman,1995)	12.0	18.89 (b)
Collier Co.(Bergman,1995)	12.0	22.34
Indian River Co. (Bergman, 1995)	6.0	15.16 (b)
Dunedin (Bergman, 1995)	4.8	13.97 (b)
Boynton Beach (Bergman, 1995)	4.0	16.23
Village Palm Beach (Bergman, 1995)	1.5	5.05 (b)
St. Lucie West Dev.(Bergman, 1995)	1.0	9.31 (b)
Hollywood	14.0	23.14 (b)
Miramar	4.5	16.36
North Miami Beach	15.0	29.9 (d)
South Miami Heights	25.0	39.0 (d)

(a) Does not include raw water supply.
(b) Does not include concentrate disposal well costs.
(c) Actual budgeted O&M costs, the other data are estimates are based on 1994 costs.
(d) In construction

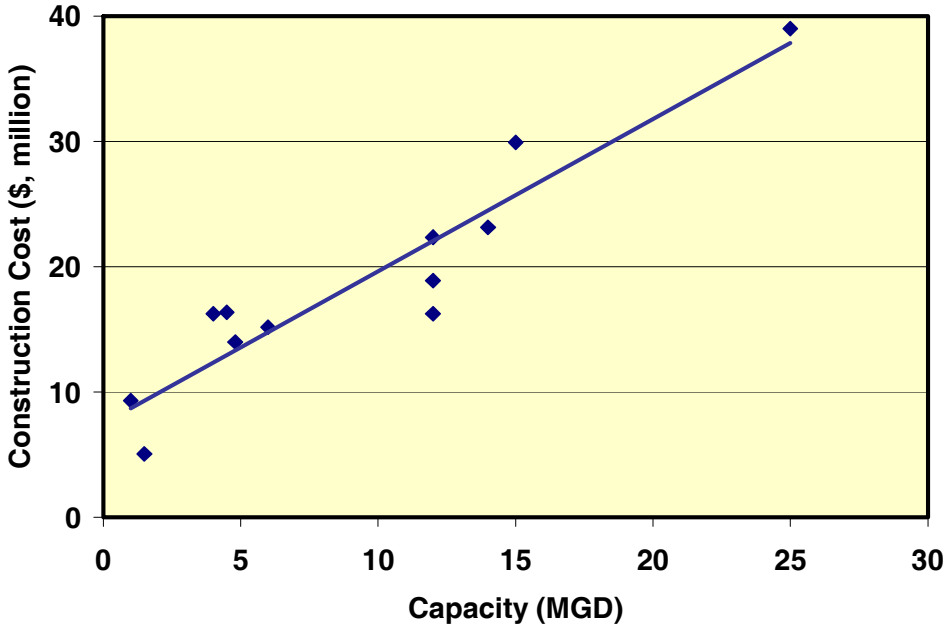

Figure 1. Construction costs of membrane treatment plants in Florida.

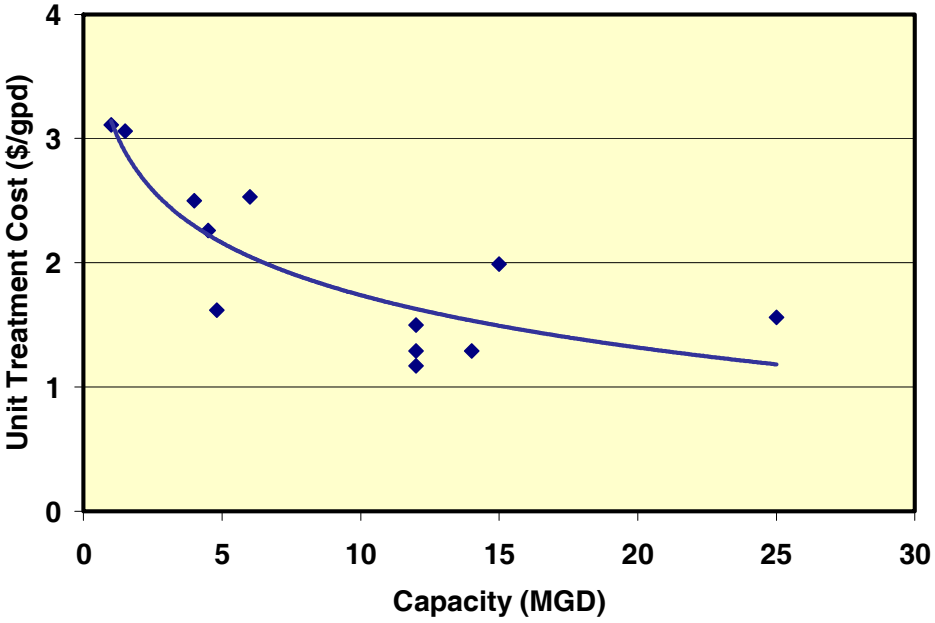

Figure 2. Constructions costs expressed as unit product water treatment cost of membrane treatment plants in Florida.

O&M Costs

Membrane replacement has become a less significant cost concern in the recent years as the average membrane life has increased from about 5 years to 10 or more years. When estimating the construction, operating and maintenance (O&M), and unit costs for treated water, membrane bypass/blending and plant operating factor must be considered. In O&M cost calculations, costs are usually lowered in proportion to the amount of water that is bypassed around the membrane system. The water flow rate that is bypassed the membranes and blended with permeate to produce the overall finished water is controlled by the membrane feed and permeate water qualities and the product water goals. At most plant, all of the water must be treated by the membranes (i.e. no bypass/blend is acceptable). However, in seawater or high brackish water supply systems this may be an option. For low brackish or softening applications, there is also an option that involve treating the raw water to a high level of purity, enabling blending of permeate with raw water to reduce the quantity of water that must be treated by the membrane system. Blending the filtered water with raw water is an effective way to provide alkalinity and pH control, thus reducing the amount of post-treatment chemicals. This scenario is projected for North Miami Beach membrane treatment plant which is in construction. There are advantages and disadvantages to each approach and a cost analysis should be performed to weigh the cost impacts. The amount of chemicals required can vary site-specifically. Typically a high level RO treatment process will require higher pre-treatment chemical dosages as a result of rejecting more ions and producing a more scale-forming concentrate.

O&M costs include labor salaries, fringe benefits, chemicals, power, membrane replacements, repair and maintenance. The ratio of actual production to plant capacity is called the plant utilization factor. Because all the plants have different utilization factor, a utilization factor of 0.9 was used for calculation of O&M costs per 1,000 gallons of permeate.

The average breakdown of O&M costs is as follows:

Labor costs (salaries and fringe benefits)	30%
Power	30%
Chemicals	15%
Membrane replacement	10%
Other (filter replacement, repairs and maintenance)	15%

About 5% up to 10% of the time operational time is generally adequate for membrane cleaning and other facility maintenance requiring full or partial plant shutdown. As shown in the Figure 3, the average annual O&M costs vary from $2.7 per 1,000 gallons for 1 MGD plant to about $0.5 to $0.7 per 1,000 gallons for 20 MGD facilities.

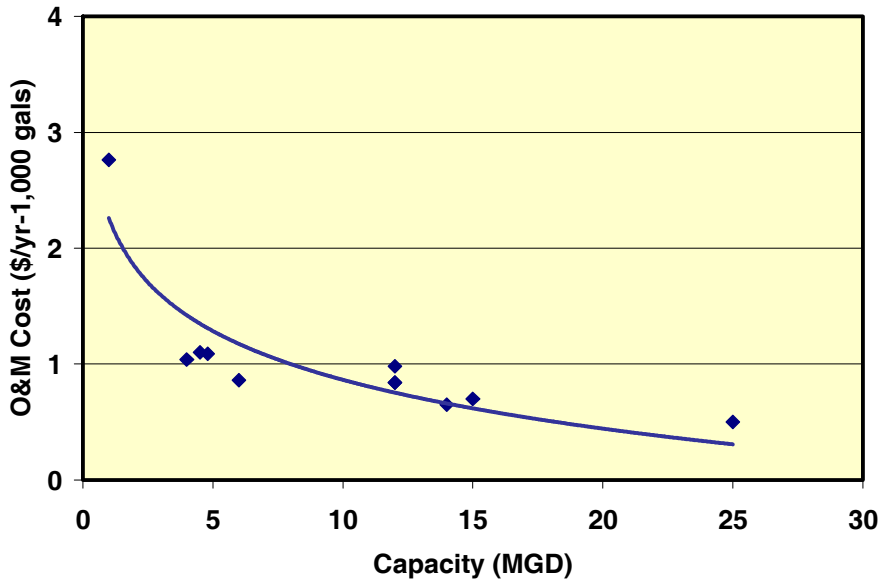

Figure 3. Annual O&M costs of membrane treatment plants in Florida.

Concentrate Management Options

Membrane filtration systems may generate different types of waste streams such as the effluent from backwash and chemical cleaning as well as the concentrate stream. The term "concentrate" is usually associated with the continuous waste stream of concentrated dissolved solids produced by NF and RO processes. Concentrate is typically 4 to 10 times more concentrated than the feed with respect to suspended and dissolved constituents and represents about 15 to 25 percent of the total feed flow. As a result, concentrate management is a significant operational and regulatory concern for utilities and is often a critical factor in the planning and design of NF or RO facilities. There are a variety of chemicals that may be used for membrane cleaning to minimize rate of fouling as shown Table 2. Chemical cleaning residuals are generally treated on-site and discharged to either a suitable surface water body or sanitary sewer, subject to state and/or local regulations. Some pretreatment may be necessary (i.e., quenching for for oxidants such as chlorine, and neutralization for acids and bases). The rinse water used the cleaning process also represents a chemical waste and must be treated prior to discharge.

Typical concentrate management options include:

- Surface water discharge
- Sanitary sewer discharge
- Land application / irrigation
- Deep well injection
- Evaporation

Because there are site specific factors associated with each of these options, no single option is ideal for every application. In the U.S., about 55% of the facilities use surface discharge, 25% discharge to sanitary sewer, 18% deep well injection, and 1% other methods for concentrate management (Mickley, 2001). Zero liquid discharge which involves sufficiently concentrating the residual stream through the use of such technologies as crystallizers and evaporators to allow remaining solids to be landfilled. In many cases surface water discharge is the least expensive option, although the permitting process may be difficult, since there are potential environmental impacts if the salinity of the concentrate is significantly higher than that of the receiving body. Discharge to the sanitary sewer may have similar issues, since the wastewater treatment process does not typically affect dissolved solids concentrations, and the treatment plant effluent may ultimately be discharged to surface water receiving body.

Table 2. Chemical used to reduce membrane fouling.

Chemical type	Chemical	Control Target
Acid	Citric acid Hydrochloric acid Sulfuric acid	Inorganic scale
Base	Caustic	Organics
Disinfectant	Sodium hypochlorite Chlorine gas Hydrogen peroxide	Biofilm
Surfactant	Various	Organics Inorganics Inert

Table 3 presents examples of the concentrate disposal practices for the water treatment plants in Florida. Only the State of Florida practices deep well injection for concentrate disposal (RosTek Associates, Inc., 2003). Deep disposal wells are defined as wells that inject fluids beneath the lowest geologic formation. The wells must be at least 0.4 kilometer (km) (0.25 mile) from an underground drinking water source. Many States do not permit deep well injection at all. Feasibility of deep well injection is highly dependent on regional geology. Evaporation ponds are extremely land intensive and are, therefore, only applicable in areas with low land value. Ponds are most appropriate for smaller desalination facilities located in arid climates such as the Southwestern U.S.

Table 3. Examples of concentrate disposal methods at some of Florida's membrane treatment facilities.

Plant	Concentrate management practice
Miramar	injection wells
Plantation Central	injection wells
Plantation East	injection wells
Jupiter	injection wells

ABSTRACT

Sea and ocean Reverse Osmosis (RO) desalination plants are often designed to remove more than 90% of dissolved ingredients (organic and inorganic) from feed water, thus creating a permeate water that is potable. Typically 40-60% of the feed water is recovered as permeate water. The water not recovered as permeate becomes concentrated into a stream of RO concentrate (brine) because the salts rejected by RO remain in the unrecovered water. The RO concentrate is usually about 1.67 to 2.5 times the salt concentration of the source water, but can be as high as four times.

RO concentrate discharged into a source water body is a major environmental consideration during the planning and design of bay or ocean desalination plants. Co-location of desalination plants with wastewater treatment plants or power plants allows using a shared outfall to dilute the high salt concentration of RO concentrate. Diluting the RO concentrate in a shared effluent outfall mitigates the issue of high salinity around the outfall.

This paper compares side by side two main classes of water bodies that receive concentrated brine discharge from Reverse Osmosis (RO) Desalination Plants: oceans (or open seas) and estuarine bays (under the influence of fresh water). These two classes of water bodies have inherent properties which drive not only the operation of RO plants, but also the physical and chemical reactions of outfall discharge. Major differences between oceans and estuarine bays are evident when comparing salinity levels, variability of salinity, and variability of the overall water quality. Furthermore, there are differences in terms of flora and fauna. Using a nuanced approach of comparing and contrasting oceans and estuarine bays as receiving waters for desalination plant concentrate, this paper brings to light the natural processes occurring offshore of potential desalination plant sites, and distinguishes what natural processes may be affected by brine entering the ecosystem.

Indeed the receiving waters for different regional RO desalination plants will be unique in many ways. The prevailing currents, type of aquatic habitat, water quality, and seasonal weather patterns must be evaluated for each individual site in order to accurately model the effects that RO plant outfall plumes will have on the environment. Yet, understanding the differences between ocean outfalls and estuarine bay outfalls brings to light many factors that should be addressed in planning and design.

INTRODUCTION

The major commercial seawater desalination technologies are: Thermal Desalination, and Membrane Desalination. Membrane desalination will be the focus of this paper because this technology has gained more attention and popularity lately due to lower costs, lower energy demand and flexibility of operation. All desalination processes separate the feed water into two major streams:

- product water (i.e. permeate), and
- concentrate (i.e. brine).

One of the reasons Desalination Plants are becoming more attractive is that, in certain geographical locations, human, industrial and agricultural consumptive use of fresh water is growing past the point where natural surface water flows necessary for a healthy environment can concurrently be maintained. The dramatic drop in salmon populations along the North Pacific coast of the U.S. exemplifies how fresh water ecosystems are impacted when natural flows are pumped and diverted. Desalination of the vast water resources in ocean and brackish waters can directly address the growing water imbalance between fresh water ecosystems and human consumptive use. By moving from strictly fresh water sources to a combination of water sources, which includes brackish and salt water sources, some of the burden that now falls heavily on fresh water ecosystems can be shared by oceans and bays.

In shifting some of the demand for potable water from fresh water sources to salt water sources it must be clear that increasing the number of desalination plants in the U.S. does not necessarily result in environmental or other consequences. To understand potential environmental impacts of desalination plant concentrate on the receiving waters of oceans and bays several key factors need to be discussed:

- Desalination Plant – Seawater Reverse Osmosis (SWRO) Operation (Bays vs. Oceans)
- Salinity and Water Quality Variations (Bays vs. Oceans)
- Desalination Plant (SWRO) Power Requirements (Bays vs. Oceans)
- Temperature (Bays vs. Oceans)
- The Salt Wedge (Estuarine Bays)
- Discharge Plume Dispersion/Mixing (Bays vs. Oceans)
- Ecology (Bays vs. Oceans)
- Co-Location and Shared Outfalls (Bays vs. Oceans)

Estuarine Bays in Brief

In general, estuarine bays on the Pacific Ocean under the influence of fresh water have lower salinity levels ranging from 0.5-32 psu (500-32,000 mg/l), because of the influence of fresh water from rivers, run-off, and municipal and industrial discharges. Due to seasonal variations in flows from rivers, estuarine bays have seasonal fluctuations in water quality and salinity. Tidal activities can contribute to

daily fluctuations of water quality, and tidal influences are major drivers of mixing in bays. The introduction of autochthonous (organic detritus) material from a river into a bay brings nutrients into the bay water. The most nutrient rich part of estuarine bays is in the zone where salty ocean water mixes with fresh water, causing nutrients that were suspended to drop out due to the difference in density between salt and fresh water. The high nutrients in estuarine bays and the shallower waters make estuarine bays "nurseries" for many aquatic species.

Oceans in Brief

In general, the Pacific Ocean has salinity averaging 35 psu (35,000 mg/l) which is higher than the salinity of bays. The water quality and salinity of ocean water fluctuate fractionally compared to that of estuarine bay water. In other words, ocean water quality and salinity is relatively unchanging on a daily basis and does not change drastically over the year. Currents and upwelling in the ocean dominate mixing. Nutrients in the ocean are much less concentrated and thus productivity (per unit area) in oceans is less than in bays. Although ocean species are much more diverse than in estuaries, the species are also generally more spread out and less concentrated compared to estuarine bays.

DISCUSSION

Desalination Plant (SWRO) Operation (Bays vs. Ocean)

Osmosis is the natural phenomenon that occurs when two solutions with different concentrations exist side by side, separated by a semi-permeable barrier (membrane). The solution of lesser concentration will flow through the membrane into the solution of greater concentration until equilibrium is reached. Osmotic pressure is the static pressure when the system is balanced and no flow occurs. The pressure required to desalinate water through a reverse osmosis desalination membrane is equal to the osmotic pressure plus hydraulic head loss across the membranes. The pressure required to desalinate salt water is exponentially proportional to the salinity due to the increase of the concentration gradient between two solutions. The pumping pressure required to desalinate estuarine bay water can often be around 300 psi or higher depending on the water salinity, system recovery, and temperature while the pressure required to desalinate ocean water reaches 900 psi and greater depending on the same major parameters. The exact pressure required, however, is a function of the salinity, the percentage of permeate water that is produced from the feed (system recovery), water temperature, type of membranes, system configuration, and other factors.

Bay and ocean SWRO desalination plants are often designed to remove more than 90% of dissolved ingredients (organic and inorganic) from feed water, thus creating a permeate water that is potable. Typically 40-60% of the feed water is recovered as permeate water by SWRO desalination plants. The water that is not recovered as permeate becomes concentrated into a stream of SWRO concentrate (brine), because the salts rejected by SWRO remain in the unrecovered water.

The percent of water that is recovered is an operational consideration which can affect the concentration of brine discharge. At 40% recovery the concentration of the brine is about 1.7 times that of the source water. At 60% recovery the concentration of the brine is about 2.5 times that of the source water. For salinity less than about 7 psu (7,000 mg/l) the recovery can be increased to the high end of 75%. ***Operating at 75% recovery results in a concentrated brine with close to 4 times the salinity of the source water.*** In order to optimize the efficiency of a particular plant, adjustments must be made to the percentage of recovery in a RO desalination facility. For instance, increasing the percentage of recovery results in lower costs for intake pumping power and pretreatment, but increases the cost for pumping at higher pressure through the RO membranes, and also increases maintenance intervals on RO membranes. Higher recovery would be feasible at facilities with higher intake pumping costs as it would reduce volume of the pumped water and cost accordingly. At higher recovery the product quality suffers because more leakage through the membranes is achieved. The inverse of this is true for plants operating at a lower percentage of recovery.

Ocean SWRO plants usually run at a lower percentage of recovery than do estuarine bay SWRO plants due to higher salinity levels in ocean water. Ocean and sea water around the globe ranges from as low as TDS 18 psu (18,000 mg/l) in the Baltic Sea up to 50 psu (50,000 mg/l) in the Red Sea and higher in the Middle East regions. While these mentioned ocean and sea salinities are varied between geographic regions they remain relatively consistent locally. In the Pacific Ocean along the California coast, water salinity ranges from 32 psu (32,000 mg/l) up to 37 psu (37,000 mg/l). This high salinity (32 and 37 psu) requires pressure for SWRO treatment in the range of 900 psi up to 1,200 psi, depending on the major design and operational factors described above. Maintaining lower energy requirements is the driving force for optimizing the percentage of recovery for ocean RO desalination.

Flows coming from rivers into bays fluctuate seasonally and even daily. This directly affects the salinity of the water because the mixture of fresh water and salt water varies with river flows. Snow melts, rainy seasons and droughts all influence the amount of fresh water flowing into an estuarine bay.

The lower salinities of water in estuarine bays directly correlates to lower power costs required for the operation of SWRO desalination equipment compared to ocean water desalination. This translates into an overall lower demand for power, reducing the associated effects of power generation on the environment. The reduced energy requirements for the SWRO treatment of estuarine bay water allows a higher percentage of recovery. Therefore, for higher recovery discharges in estuarine bays, there is a resulting greater difference in the salinity of the concentrated brine discharge relative to the source.

Salinity and Water Quality Variations (Bays vs. Oceans)

While salinity in the Pacific Ocean is relatively consistent, averaging 35 psu (35,000 mg/l), estuarine bays vary widely depending on the geography. San Francisco Bay can range from 5 psu – 30 psu (5,000 mg/l – 30,000 mg/l) because fresh water influences can be high during the wet weather season. San Diego Bay, on the other hand, does not have a wide salinity range because there is less influence of fresh water than in the San Francisco Bay.

Turbidity fluctuations are more drastic in bays than oceans because of the shallower water and silty benthos. Oceans do see fluctuations in turbidity; however, this occurs nearer to shore and depends on how shallow the water is and on proximity to rivers and creeks. Site specific pollutant point sources can be of equal concern for both oceans and bays. Algal blooms (red tides) are also of concern for SWRO desalination and can occur in both ocean waters and bay waters, while historically red tides are more intensive in ocean waters.

For example, Figure 1 shows data from the San Francisco Bay which illustrates the seasonal variations of salinity (measured as conductivity), as well as turbidity and TOC that can occur in estuarine bays. Turbidity was higher in December through April, when storms and winds were prevalent, making the shallow waters turn up the settled benthos material into a suspended state. The increase in turbidity during these months increases the stress placed on the SWRO pretreatment equipment.

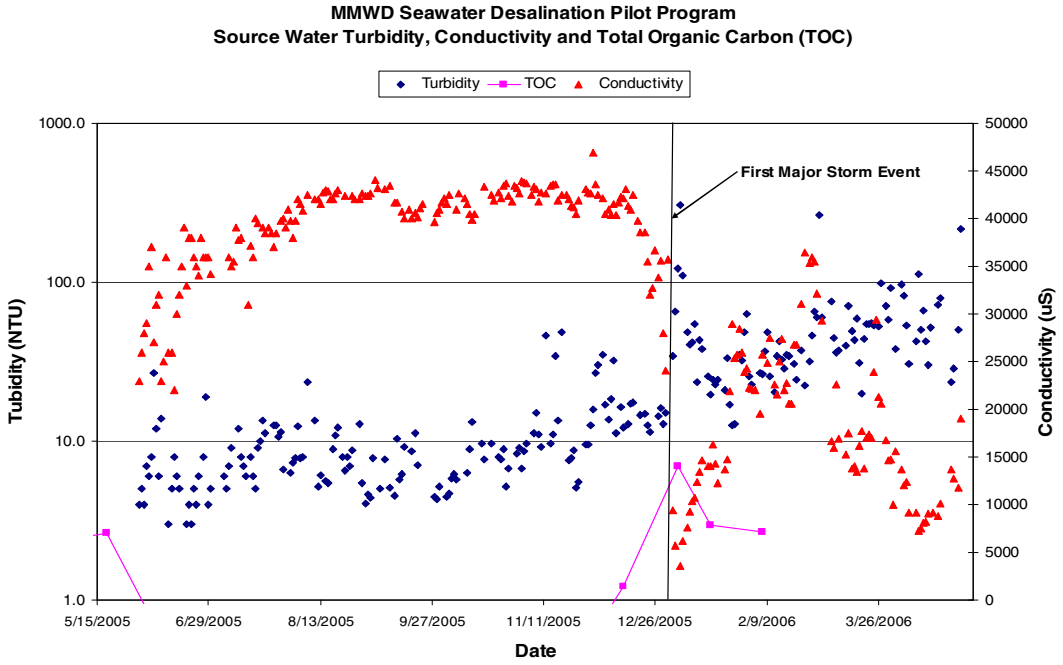

Figure 1. Source Water Conductivity (Salinity) and Turbidity in San Francisco Bay. (Frenkel et al, 2007)

Desalination Plant (SWRO) Power Requirements (Bays vs. Oceans)

Although this discussion is primarily about concentrate discharge, it is important to recognize that the power requirements for SWRO equipment can contribute to the overall environmental impacts of a desalination facility. Simply stated, the lower salinity of estuarine bays can result in much lower power requirements for SWRO treatment than for ocean SWRO.

Temperature (Bays vs. Ocean)

The temperature of water being treated by SWRO membranes affects the pressure required for desalting. Lower temperature water requires higher pressure for SWRO and more energy as a result. Source water temperatures can vary seasonally with shallower estuarine waters showing greater fluctuations in seasonal temperatures than oceans. In addition to fluctuations in source water temperature, an outfall plume can have a temperature that is slightly higher than the ambient temperature, because of heat transferred to the water during pumping. Generally, the heat transferred from pumping equipment into the process water is about 1^{o} to 2^{o} Celsius for desalination plants.

The Salt Wedge (Estuarine Bays)

At the interface between a fresh water river and a bay there is an area called the salt wedge. The salt wedge occurs as a result of the difference in density between salt water and fresh water. Salt water is denser than fresh water and, therefore, can form a salt water wedge underneath the advancing fresh water flow at the interface between fresh water and salt water. Flocculation of nutrients transported within the river system occurs at this interface. Autochthonous material, silts, dissolved organic matter and organic compounds such as phosphates can flocculate and fall out of suspension in the salt wedge. The nutrients that fall to the bay floor provide food for young larvae, such as crabs and oysters that are carried upstream by the salt water counter flow.

The density-salinity variation in the salt wedge illustrates how concentrated brine interacts with receiving waters as it is discharged. The denser concentrated brine discharge will tend to stay lower in the water column and thus can slow vertical mixing. It is not a surprise, then, that mixing and plume dispersion will be primarily driven horizontally by currents and tidal action.

Discharge Plume Dispersion/Mixing (Bays vs. Oceans)

Plume dispersion and mixing are driven primarily by changing tides and by prevailing currents. In general, bays are influenced more significantly by bi-modal tidal mixing currents than are ocean locations. Ocean outfall locations are more subject to prevailing currents that are caused by weather patterns over the ocean.

Currents are not the only factor that affects brine plume dispersion. As discussed previously, there is a bigger difference in salinity between brine and receiving water in estuarine bays because these plants can run at a higher recovery. The more pronounced difference in salinity reduces mixing because of the salinity-density effect. The density difference inhibits vertical mixing. Mixing can also be inhibited in bays because they are often shallower than offshore ocean outfall locations.

Because bay SWRO plants are usually designed with higher recovery than ocean SWRO plants, the difference in the feed water and concentrate is higher for bay SWRO plants than for ocean SWRO plants. At lower source water salinity levels, the recovery can be run at 75% to increase efficiency. ***At 75% recovery the brine concentration will be almost 4 times that of the source water. This drives the requirements to design much more intensive and sophisticated brine mixing for bay projects than for ocean projects.***

Ecology (Bays vs. Ocean)

The ecology of bays differs greatly from the ecology of oceans. Benthic species live in the sediment of bay floors and are the basis of the food chain in estuarine bays. The nutrient rich benthos of estuarine bays is what makes them such thriving environments. Interestingly, while the amount of biological production is high in estuarine bays, the species diversity is low when compared to that of the ocean. The species that do exist in estuarine bays are either salt water (marine) species or euryhaline species, such as salmon or eels, which can live in fresh water and salt water environments. Marine species that migrate to estuaries can tolerate lower salinities, but have been shown to sometimes prefer salinities that are closer to ocean levels. A study conducted by the Marin Municipal Water District and Weston Solutions, Inc (Bodensteiner et al, 2008) tested the impacts of desalination brine mixed with treated wastewater effluent and found that "the sublethal effects observed on kelp spore growth and bivalve embryo development were substantially less significant among organisms exposed to High Brine blend than those observed with Average Brine blend exposures."

Co-Location and Shared Outfalls (Bays vs. Oceans)

Power plants and wastewater plants are both attractive options when it comes to co-locating potential RO desalination plant sites. Co-locating RO desalination facilities with power or wastewater treatment plants allows for outfall blending which can reduce the concentration of the brine discharge to levels that are more similar to the receiving water. For instance, if the % recovery of a RO facility is 50% and the brine is mixed 50/50 with outfall water from a power plant or wastewater plant, the result is a salt concentration that is similar to that of the receiving water.

Power plants are located on many ocean shores and can prove to be beneficial because the proximity of a power plant to a RO desalination plant with high electricity demands can reduce the actual power generation requirements as

transmission inefficiencies are reduced. Furthermore, desalinating the power plant cooling water (which carries higher temperatures and needs less energy for the RO process) can be beneficial. On the other hand, higher temperature water can have higher biological productivity and therefore a greater potential for RO membrane bio-fouling.

Wastewater treatment plant outfalls can also be used for blending brine discharge. However, in certain cases there can be precipitation of solids in the outfall pipe when wastewater is mixed with concentrated brine. This can be mitigated by periodic cleaning of the outfall pipe.

SUMMARY

Table 1 summarizes the factors that are useful for consideration in assessing possible environmental impacts for new desalination plants for either estuarine bays or the open ocean. At this time the environmental impacts of desalination to marine life can be mitigated through proper diffusion design and mixing analysis. The environmental impact of energy generation remains a concern for the future of desalination. However, with a coordinated effort to reduce power usage by residential, commercial and industrial buildings and processes, the power required for desalination can be completely offset.

Table 1. Outfall Considerations: Estuarine Bays vs. Oceans

Outfall Considerations	In Estuarine Bays	In Oceans
% Recovery	• Recovery generally higher than in oceans • Seasonal changes in salinity require adjustments be made to maintain optimization	• Recovery generally lower than in bays • Operating parameters are relatively constant
Salinity	• For bays on Pacific Ocean waters, salinity has very wide variations ranging from 5 psu to 32 psu (5,000 mg/l up to 32,000 mg/l)	• Salinity is relatively stable from 32 psu to 37 psu (32,000 mg/l – 37,000 mg/l) with insignificant variation affecting control operation of the SWRO
Water Quality	• Turbidity can be quite high during wet and windy weather due to shallow water and silty benthos	• Water quality is relatively stable with some wet weather related increases in turbidity due to runoff • Depends on proximity to the shore and depths of the water

Outfall Considerations	In Estuarine Bays	In Oceans
Power Requirements	• In general, lower salinities equate to lower power costs for desalination	• In general, higher salinities equate to higher power costs for desalination
Salt Wedge	• Nutrient rich flocculation area at the salt wedge	• Very little salt wedge; driven by thermocline
Temperature	• Seasonal temperature changes are site specific and variations can be relatively high	• Seasonal temperature changes are site specific and variations are relatively low
Mixing	• Stronger bimodal currents created by tidal influences • Mixing reduced by shallower water depth • Bigger difference in salinity between brine and receiving water reduces mixing because of salinity-density effect	• Some weaker bimodal currents • Generally deeper water • Smaller difference in salinity between brine and receiving water
Ecology	• Benthic micro-algae dominate	• Planktonic processes dominate
Production	• High organic production	• Lower organic production than in estuaries
Types of Species	• Low species diversity • Mostly marine and euryhaline species (i.e. not freshwater species)	• High diversity among marine species
Co-location Options	• Generally more wastewater plants, some power plants	• Generally a wide range of choices of wastewater and power plants
Co-location and Shared Outfalls (*Wastewater Treatment Plants vs. Power Plants*)	***Wastewater Treatment Plants*:** • Blending SWRO brine in a shared outfall with wastewater treatment effluent mitigates high brine concentration • Precipitation of solids in wastewater may occur in outfall	***Power Plants:*** • Benefit of blending brine in shared outfall. • Added benefit to power transmission efficiency • Can reduce energy costs by desalinating higher temperature cooling water • Less precipitates in outfall

ABSTRACT

Desalination - processes that remove excess salt and other minerals from water - is a critical technology in today's age of shrinking freshwater supplies. Currently Reverse Osmosis (RO) and thermal technologies, such as Multi-Effect Distillation (MED) and Multi-Stage Flash (MSF), dominate the desalination market. However, rising energy costs and government regulations on carbon emissions are likely to change the future of desalinating water.

Seeking to identify and validate market attractiveness of emerging technologies to power and treat non-freshwater sources, the authors evaluated whether the cutting-edge membrane technology known as Forward Osmosis (FO) was a viable desalination method. Forward Osmosis (FO) uses highly concentrated carbon dioxide (CO_2) and ammonia (NH_3) to separate the freshwater from the brine. A thermal process is used to remove the CO_2 and NH_3 from the freshwater; the CO_2 and NH_3 are then recycled to be used again.

The study concluded that even with its increased efficiency, FO alone will not resolve all of the world's desalination challenges. The study concluded that with its increased efficiency, FO can be successful under the proper circumstances.

FORWARD OSMOSIS: THE TECHNOLOGY OF THE FUTURE

Forward Osmosis is a cutting-edge membrane technology using age-old principles to solve a modern day problem. Unlike Reverse Osmosis (RO), which uses high pressure pumping, Forward Osmosis (FO) uses natural osmotic pressure to separate seawater into freshwater and brine. It does so by using a draw solution of highly concentrated carbon dioxide (CO_2) and ammonia (NH_3) to pull freshwater across a membrane. See Figure 1 for schematic representation. The residual of the FO process is the salt, which dilutes the draw solution.

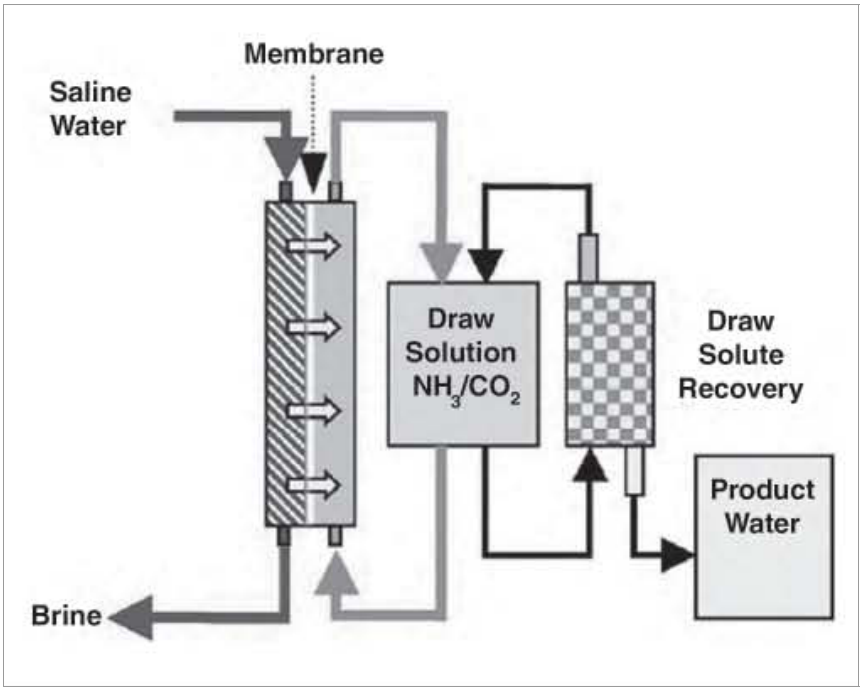

Figure 1. Schematic of Forward Osmosis Desalination Process

Once freshwater has been pulled across the membrane, a thermal process is used to remove the CO_2 and NH_3 from the freshwater. The CO_2 and NH_3 are then recycled to be used in the draw solution once again. The energy required for the chemical removal process is much less than would be used for a complete thermal desalination processes such as Multi-Effect Distillation (MED) and Multi-Stage Flash (MSF). As indicated in Figure 2, a comparison of desalination technologies based on equivalent work shows that FO requires significantly less (one-sixth) energy use. (McGinnis, 2007).

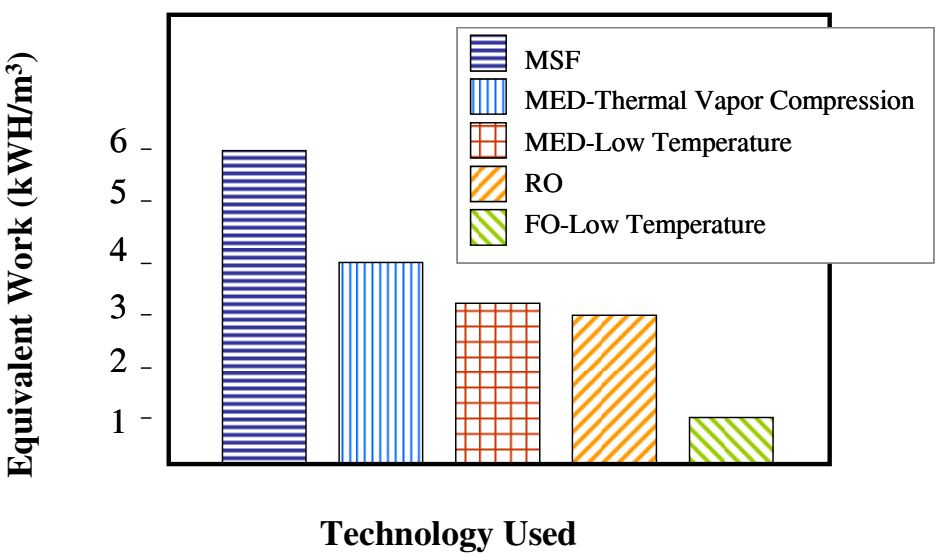

Figure 2. Power Consumption of Desalination Technologies

FO exhibits many sustainability principles not present in any other current desalination technology. First, the energy savings translates into environmental and economic benefits. Another benefit is FO's ability to recover more fresh water (up to 85 percent) than RO, which typically runs at 50 to 80 percent. Over the years, RO membranes have improved greatly, but they now are reaching their theoretical limit of efficiency. Once this occurs the next logical solution may be the FO technology.

CO-LOCATION OF DESALINATION AND POWER GENERATION FACILITIES

Even with its increased efficiency, FO alone is not the solution to all of the world's desalination challenges. Utilizing alternative sources of power can help make the desalination processes more environmentally and economically friendly. For example, currently steam emitted following the end of the power generation process is wasted. By using that steam from the power plant in the desalination facility, it would thereby use less electrical power than is currently being pulled off the grid. In addition, use of currently existing – or shared – ocean intakes and outfalls in the form of simplifying permitting and construction, helps make a case for coupling the desalination and power facilities.

Currently existing desalination processes could benefit from utilizing waste heat from power generation. For RO, heat will increase the efficiency of the process, and for thermal processes this waste heat can be used for a portion of the heating needed. For FO, however, these benefits are much greater, as removing the chemicals from the draw solution requires heat of about 60 degrees Celsius, whereas the waste steam from a low pressure turbine is usually 48 to 60 degrees Celsius. Professor Menachem Elimelech and Robert McGinnis demonstrated (see Figure 3) this theory in their study of energy requirements of ammonia-carbon dioxide forward osmosis (Elimelech, 2007).

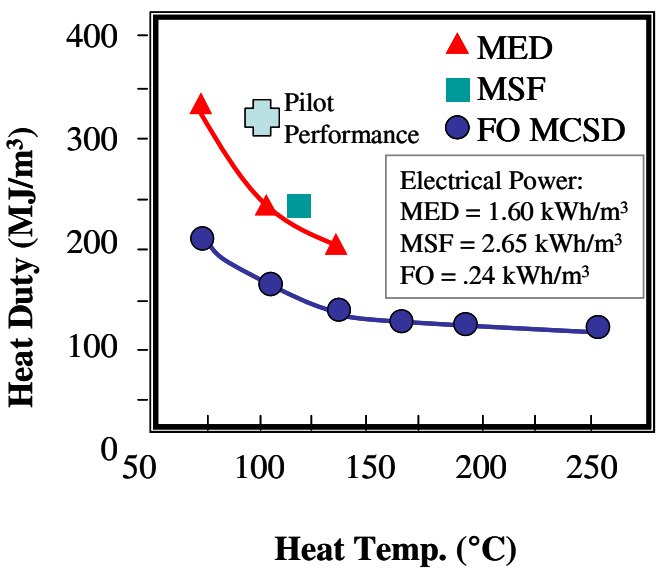

Figure 3. Heat Duty versus Temperature of Heat

Most desalination plants today use electricity derived from fossil fuels. In addition to being costly, this is also less environmentally friendly than a renewable resource. One option that has been tried largely in Kazakhstan, India and Japan is the integration of a nuclear power generator with a desalination plant (WNA, 2008). The general schematic of how it would be configured is shown in Figure 4.

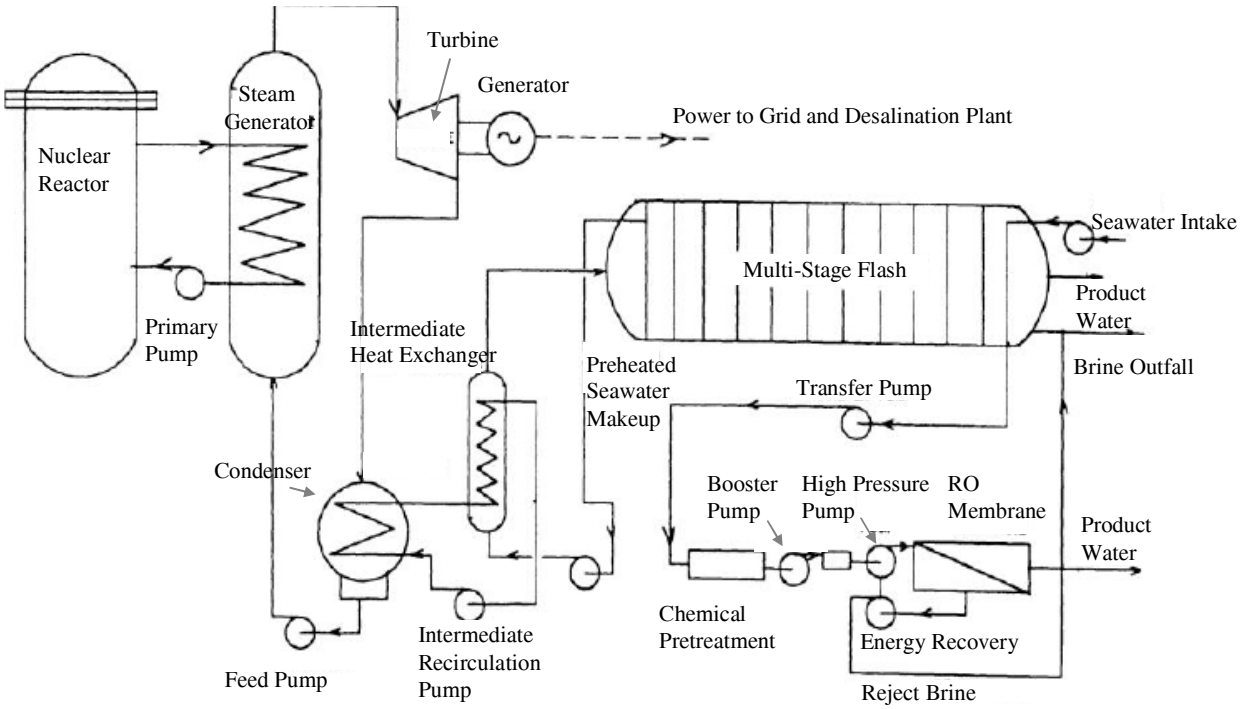

Figure 4. Schematic diagram of nuclear reactor coupled with an MSF-RO plant.

Powering desalination through nuclear power would provide freshwater in a way that emits less carbon dioxide compared to relying on power generated with fossil fuels. Nuclear power is economically compatible with current desalination techniques. For example, Figure 5 (NEI) provides an economic comparison of costs per kilowatt-hour for electricity generated by various methods. Also, Figure 6 (Churchman, 2005) illustrates the comparison of carbon dioxide emissions for a variety of power options.

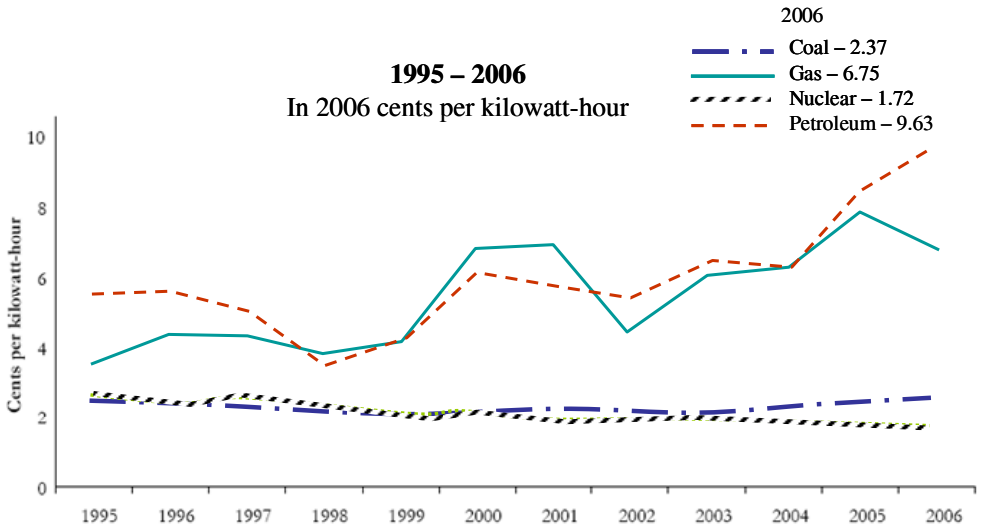

Figure 5. Economic Cost (in 2006 dollars) Comparison of Power Options

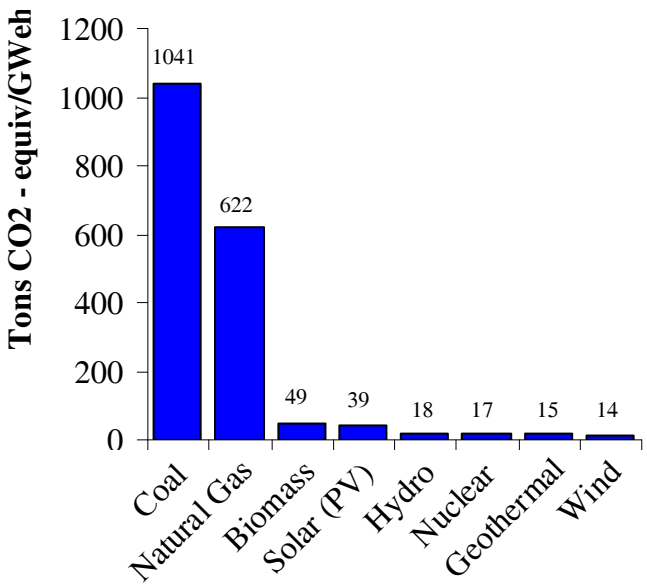

Figure 6. Comparison of Carbon Dioxide Emissions

CONCLUSIONS

Forward Osmosis, because it operates at low or no hydraulic pressure, is very simple to use and requires less energy to operate. FO also has the benefit of needing lower temperature water (60 degrees C), which can be readily supplied through the recycling of power plants' waste steam. This synergy between power plants and desalination is a natural coupling and does not depend on whether this energy source is a fossil fuel or renewable resource such as nuclear. Large-scale deployment of nuclear desalination on a commercial basis would depend primarily on economic factors. The authors believe that neither FO nor a reemergence of reliance on nuclear power alone will be sufficient to solve the emerging problem of drinking water scarcity. They conclude, however, that future testing for FO is warranted to determine its long term viability as an energy efficient desalination solution.

New Strategies for Managing Desalination Concentrate with Zero Liquid Discharge from Two WRF Research Projects

Rick Bond and Srinivas Veerapaneni
Black & Veatch

ABSTRACT

The need for affordable inland desalination in the U.S. is urgent. Many utilities are struggling to meet growing water demands and manage increasing salinity levels in their fresh water sources. The greatest challenge faced by utilities wishing to desalinate inland water sources is concentrate management. Discharge of concentrate to surface waters or deep well injection raise environmental concerns and these alternatives are increasingly difficult to permit. Discharge to a wastewater treatment plant simply recycles salinity or passes it on to a downstream user. The alternative is zero liquid discharge (ZLD) treatment. In ZLD, concentrate is treated so that the water is recovered for beneficial use and there is no discharge of liquid waste from treatment.

Desalination with zero liquid discharge is the subject of two recent AwwaRF research projects. The technical approach in both projects involves treating RO concentrate to reduce its membrane fouling potential prior to a second desalination step. The report for the first project, *Zero Liquid Discharge for Inland Desalination,* was published in 2007. The research involved computer modeling, bench-scale testing and pilot-scale testing. The research results were used to estimate cost and energy requirements for the proposed approach and compare them to those for the established ZLD approach using thermal desalination and evaporation ponds. It was estimated that treatment costs and energy consumption could be reduced by 50 to 70 percent with the proposed treatment approach.

The second project, *Zero Liquid Discharge Desalination for Waters with High Organic Content*, is underway. The focus of this research is the unique challenge posed by water sources that have high concentrations of natural organic matter (NOM) in addition to salinity. NOM inhibits chemical precipitation by the same mechanism as the antiscalants that are added in RO pretreatment for this purpose. Inhibition of chemical precipitation by NOM may have a significant impact on the processes selected for removal of calcium and barium during concentrate treatment. NOM also causes organic fouling of RO membranes, and interactions between NOM and calcium have been shown to increase the potential and severity of organic fouling. Consequently, concentrate treatment in this project will address NOM removal to prevent organic membrane fouling as well as calcium, barium, and silica removal to prevent inorganic membrane fouling.

INTRODUCTION

Increasing population, changing weather patterns, and pollution of renewable water resources have exerted unprecedented demands on water supplies around the world. In 2008, the two largest manmade reservoirs in the US, Lakes Powell and Mead on the Colorado River, were at their lowest levels ever. In Florida, Lake Okeechobee was

at its lowest recorded level, and significant portions of the state were classified as priority water resource caution areas, defined as areas where existing and reasonably expected sources of water and water conservation are not expected to be adequate to meet future needs.

Whether caused by natural or human induced climate change, or some combination of these factors, the current drought has illuminated an urgent need for development of drought proof water supplies. There is consensus in the water industry that increased use of desalination will be needed to meet the world's need for drinking water. The greatest challenge for implementing inland desalination is concentrate management. The options for handling concentrate are as follows:

- Direct discharge.
- Deep well injection.
- Discharge to POTW.
- Zero liquid discharge.

The need to protect receiving streams and groundwater sources from increased salinity may preclude concentrate disposal by the first three methods. The alternative is zero liquid discharge (ZLD). In ZLD, concentrate is treated to produce desalinated water and essentially dry salts. Hence, there is no discharge of liquid waste from the process.

Most ZLD applications in operation today treat industrial waste streams using thermal desalination, evaporation ponds, or both. Thermal desalination is a mature technology that has been practiced for over 30 years, particularly in the Middle East, but it is energy-intensive and expensive. Evaporation ponds require large land areas, even in arid climates, and they are expensive to construct due to the lining and laek protection systems typically required.

New ZLD approaches are being investigated that involve treatment of RO concentrate to reduce its precipitation potential followed by a second application of RO to recover more water and reduce concentrate volume. Secondary desalination can reduce the volume of concentrate sent to evaporation ponds or thermal desalination by two to five times, significantly reducing cost and energy requirements for ZLD.

This ZLD approach is the subject of two recent AwwaRF research projects. The first, *Zero Liquid Discharge for Inland Desalination*, focused on treatment of concentrate in which the precipitation of inorganic salts was the primary concern. This report was published in 2007. The second project, *Zero Liquid Discharge of Waters with High Organic Content*, is ongoing, and its focus is examination of this ZLD approach for brackish waters with high concentrations of natural organic matter (NOM).

PROCESS DESCRIPTION

A general version of this ZLD approach is illustrated by the process schematic in Figure 1. The schematic shows a primary RO system followed by an intermediate concentrate treatment step, secondary RO system, brine concentrator, and evaporation pond. The key step is treatment of primary RO concentrate to reduce its membrane fouling potential in preparation for desalination in the secondary RO system.

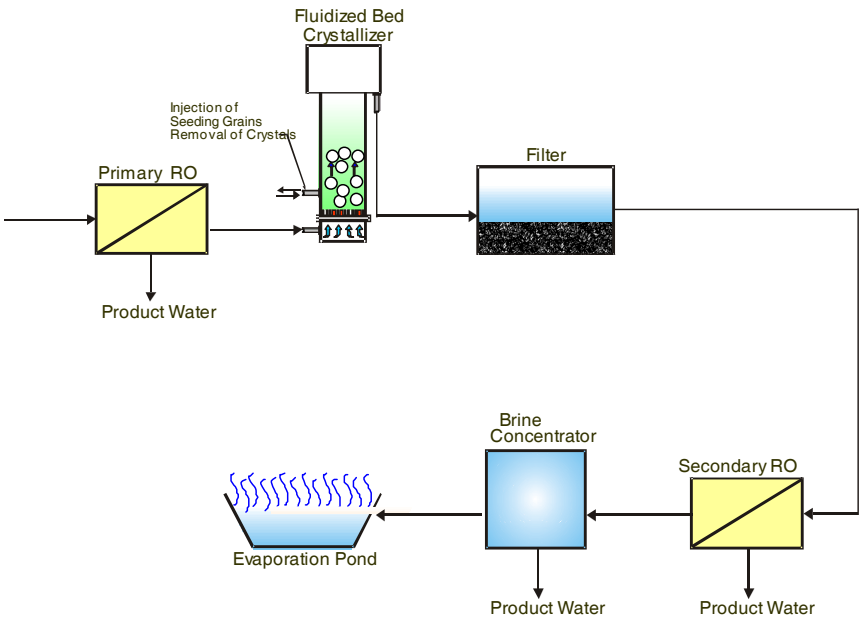

Figure 1 – ZLD Process Schematic

After recovery of as much of the concentrate as possible in the secondary RO, a small percentage of the feed water is discharged as concentrate from the secondary RO to the brine concentrator, a thermal desalination process. Brine concentrators typically recover about 95 percent of RO concentrate from brackish water desalination as a distillate with very low TDS. The remaining volume of concentrate not recovered by the brine concentrator is discharged to an evaporation pond. Consequently, no liquid waste is discharged from the site.

INORGANIC FOULING

RO membranes are designed to reject a high percentage of dissolved salts while allowing water to pass through the membrane. Water that passes through the membrane is recovered as product water, and the ratio of product water flow to feed flow is defined as RO recovery. As RO recovery is pushed to its sustainable limit, water on the feed side of the membrane becomes increasingly concentrated and supersaturated with respect to sparingly soluble salts such as calcium carbonate ($CaCO_3$), calcium sulfate ($CaSO_4$), and barium sulfate ($BaSO_4$). If the feed solution becomes sufficiently supersaturated, these salts precipitate and deposit on the membrane surface. Deposition of inorganic precipitates on the membrane surface, reduces the permeability of the membrane, and

consequently, recovery in RO systems is limited by the precipitation potential of sparingly soluble salts.

RESULTS FROM "ZERO LIQUID DISCHARGE FOR INLAND DESALINATION"

Bench-scale and pilot-scale tests were conducted to evaluate treatment of concentrate to reduce the inorganic membrane fouling potential of RO concentrate. Tests were conducted with five source waters in the Southwestern United States. The test waters included three groundwaters, one surface water, and one reclaimed water.

An understanding of how, when, and why precipitation occurs was essential to this ZLD approach. Precipitation of salts from solution occurs in the following sequential steps, however, in a supersaturated solution containing crystalline solids of the precipitate, precipitation can occur directly by crystal growth:

1. Solution supersaturation
2. Nucleation
3. Crystal growth

RO systems are operated to avoid precipitation of sparingly soluble salts that would foul the membranes, and chemicals designed to inhibit precipitation, commonly referred to as antiscalants, are applied to the feed stream of the RO system. Antiscalants act to retard crystal growth, an integral step in the precipitation. Conversely, a goal of concentrate treatment is to precipitate the salts antiscalants are designed to keep in solution.

The key to this ZLD approach was discovery of a concentrate treatment process that maximizes efficiency of the precipitation process, is not adversely affected by the antiscalant used in RO pretreatment, minimizes the volume of solids generated, and generates solids that are managed easily.

The potential for precipitation exists when a solution is supersaturated, but precipitation is influenced by kinetics, hydrodynamics, and the presence of impurities. Hence, two waters with the same supersaturation ratio can exhibit different propensities for scaling. The time required for precipitation to begin is referred to as induction time, which is defined as the period from start of supersaturation until the appearance of a new crystalline phase. As crystals form and grow, they precipitate from solution, and dissolved concentrations of the constituent ions of the precipitate decrease. Induction time is inversely related to rate of nucleation, and the nucleation rate is dependent on a number of factors including supersaturation, temperature, water chemistry, and the presence of foreign particles.

Foreign particles can reduce induction time by making precipitation more energetically favorable. Induction time decreases as the fit between the foreign particle and the crystal to be formed increases. The best fit between the two solid phases occurs when the particle is a seed crystal of the same salt. A fluidized bed crystallizer was tested in this research to take advantage of the effect of crystals to enhance the rate of precipitation. The fluidized bed crystallizer contains a bed of calcium carbonate pellets, and calcium and carbonate are removed from solution by crystal growth of the pellets.

A preliminary process analysis was conducted to evaluate the salts with the greatest precipitation potential. This analysis indicated that for each water source secondary RO recovery would be limited by the scaling potential of silica (SiO_2), calcium sulfate ($CaSO_4$), and barium sulfate ($BaSO_4$), and in each case, two or all three of these salts would limit recovery. Consequently, calcium, barium, and silica were identified as the treatment targets for the concentrate treatment step.

Figure 2 shows an example of bench-scale test results that were conducted to evaluate presence of calcium carbonate pellets on precipitation of calcium, barium, and silica. Two sets of jars were dosed with sodium hydroxide. One set of jars contained calcium carbonate pellets to simulate fluidized bed crystallization and the other did not to simulate chemical precipitation. Calcium and barium remaining are plotted against pH. The results show that comparable removals of calcium and barium occurred at lower pH in the presence of calcium carbonate crystals. This means calcium and barium can be removed with smaller doses of caustic or lime to increase pH and lower doses of post-treatment acid to bring pH back down.

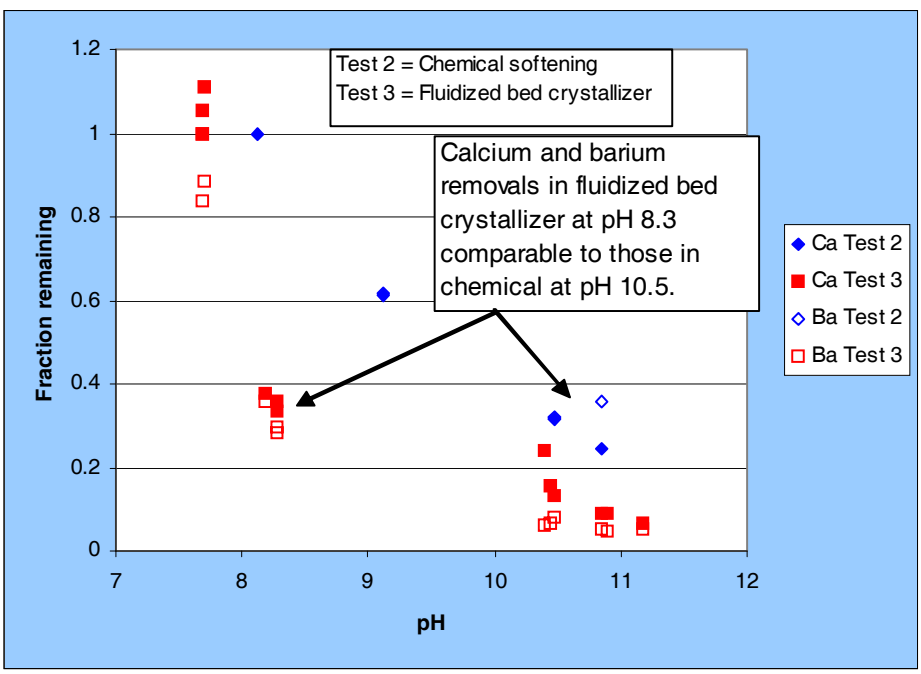

Figure 2 – Removal of calcium and barium by fluidized bed crystallization and chemical precipitation

As illustrated by Figure 3, it was found that barium removal was proportional to calcium removal. This likely occurs due to substitution of barium ions for calcium ions in the calcium carbonate lattice structure. This result was consistent in all tests of fluidized bed crystallization and chemical precipitation. This result indicates that one process, fluidized bed crystallization or chemical precipitation, can be used to remove calcium and barium.

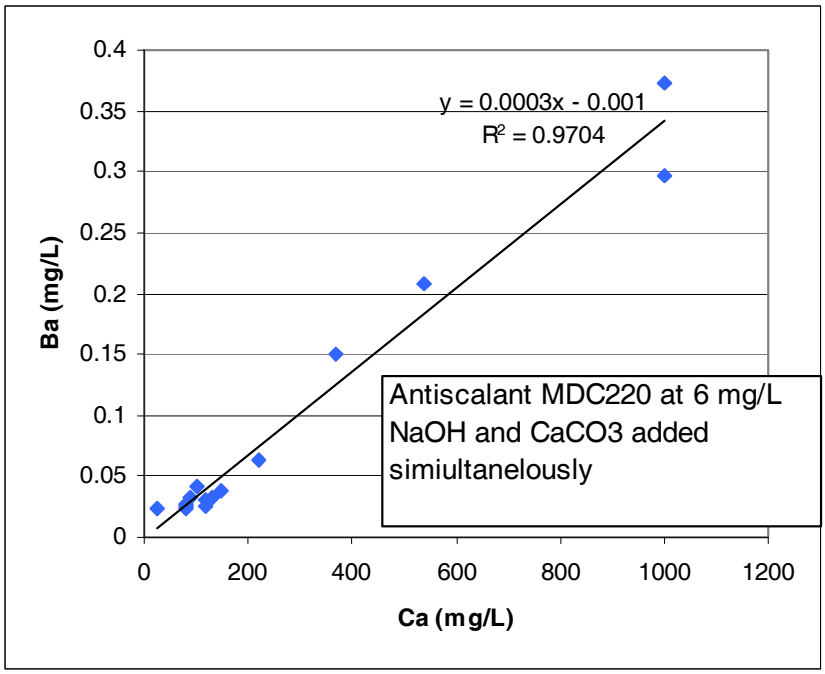

Figure 3 – Correlation between calcium and barium removal in jar tests of fluidized bed crystallization

Silica, however, was not effectively removed below pH 10 as illustrated by Figure 4. Silica concentrations remained relatively unchanged until pH exceeded 10 for fluidized bed crystallization and chemical precipitation tests of all water sources. Calcium carbonate precipitates are not a particularly good adsorbent media for silica but magnesium hydroxide is. Magnesium hydroxide precipitation is pH dependent and typically occurs above pH 10.

Figure 5 shows the silica and magnesium concentrations remaining from one of the fluidized bed crystallization tests. Silica concentration decreased in proportion to the decrease in magnesium concentration, indicating silica removal occurred by sorption to magnesium hydroxide precipitates. Alum and sodium aluminate were tested for silica removal in the fluidized bed crystallization tests, and the aluminum salts were effective for removing silica at pH 8 and higher.

Treatment costs and energy requirements for the ZLD process were compared to traditional ZLD treatment with thermal desalination followed by an evaporation pond. Treatment costs were projected to be reduced by 50 to 70 percent less and energy requirements by 60 to 70 percent compared to the traditional ZLD approach.

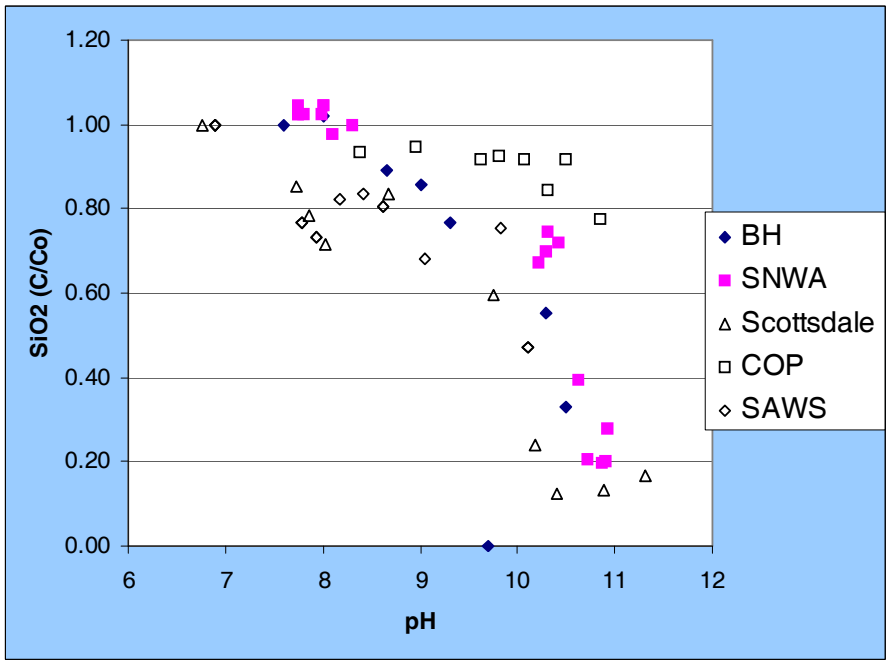

Figure 4 – Silica removal in fluidized bed crystallization tests was not effective below pH 10

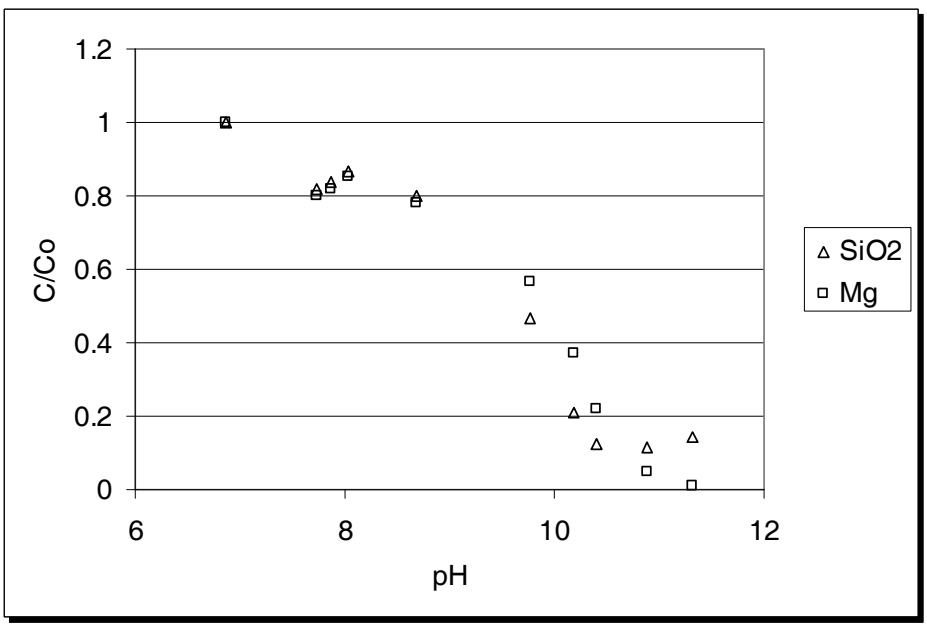

Figure 5 – Silica and magnesium fractions remaining in fluidized bed crystallization test

ORGANIC FOULING

NOM can have a detrimental effect on the ZLD process during: 1) membrane desalination using RO or nanofiltration (NF) membranes, and 2) treatment of concentrate to allow further recovery with membrane desalination. The major fraction of NOM in natural waters is composed of humic substances that are negatively charged in the pH range of natural aquatic systems (Aiken *et al.* 1985). Consequently, NOM molecules readily react with divalent metal cations such as calcium and magnesium (Stumm and Morgan 1996). These reactions produce negative effects on the precipitation processes (chemical precipitation with lime, NaOH, alum, or sodium aluminate and fluidized bed crystallization. Low concentrations of NOM are known to inhibit the kinetics of precipitation and the morphology of crystals formed in precipitation (Stumm and Morgan 1996, Boerlage *et al*. 2000). Conventional theory is that NOM molecules are adsorbed to the surface of precipitate nuclei and block the integration of lattice ions. Adsorption of NOM disrupts crystal growth and changes the shape of the highly ordered crystal lattice structure.

NOM is also the cause of an important type of membrane fouling referred to as organic fouling. Organic fouling of membranes is influenced by the characteristics of the NOM and membrane, the chemical composition of the feed water, and hydrodynamic conditions in the membrane system (Hong and Elimelech 1997). The potential for and severity of organic fouling increases significantly in the presence of calcium (Li and Elimelech 2004), which makes NOM in concentrate an even greater membrane fouling threat.

Jucker and Clark (1994) compared the adsorbability of fulvic and humic acids onto ultrafiltration membranes. The membranes tested had less adsorption capacity for fulvic than for humic acid. The influences of inorganic water chemistry and of membrane charge on NOM adsorption were also studied. Adsorption increased with high calcium concentrations, low pH, and high membrane pore zeta potential. Nilson and DiGiano (1996) also examined the influence of NOM composition on fouling of nanofiltration membranes. The hydrophobic NOM fraction was rejected to a greater extent than the hydrophilic fraction and was responsible for membrane fouling. Hong and Elimelech (1997) examined the chemical and physical interactions that affected NOM fouling of NF membranes. Using three humic acids, they found membrane fouling increased with increased solution ionic strength, decreased pH, and increased divalent cation concentration. Of these factors, the greatest fouling effect was caused by divalent cations.

Li and Elimelech (2004) examined the mechanisms of organic fouling under different solution conditions of pH, total ionic strength, and divalent cation concentration by measuring the attraction and adhesion forces between an organic foulant and the membrane surface. Bench-scale fouling experiments were conducted to evaluate the effect of divalent cations on organic fouling. The test solution had a humic acid concentration of 20 mg/L and a total ionic strength of 10 mM. Three samples were tested, one with Na^+ as the only cation, one with 1 mM of Ca^{2+}, and one with 1 mM of Mg^{2+}. Over a period of 300 minutes, flux declined 11 percent for the solution without cations, 16 percent for the solution with Mg^{2+}, and 49 percent in the solution with Ca^{2+}. Hence, organic fouling was more severe for the solution with calcium than for the solutions with magnesium or sodium ions. These researchers found that attraction forces between the

clean membrane surface and humic acid were comparable for the three solutions, but there were significant differences in adhesion forces. There was no adhesion force for the monovalent solution, slight adhesion for the Mg^{2+} solution, and a significantly greater adhesion force for the solution with Ca^{2+}. This result indicated a much stronger interaction between humic acid and the clean membrane surface when calcium was present. The test was repeated with a fouled membrane with the same result. There was a much stronger interaction between humic acid and the fouled membrane surface in the presence of calcium.

It was concluded that organic fouling was not observed with the monovalent solution because electrostatic repulsion between the negatively charged membrane surface and the negatively charged humic acid prevented deposition of humic acid on the membrane. In contrast, divalent cations form complexes with humic acids, thereby reducing the charge of humic acid and reducing the electrostatic repulsion between it and the membrane surface. The researchers concluded that calcium caused more severe fouling than magnesium because the adhesion force between calcium and the membrane surface was significantly stronger.

NEW CHALLENGES IN "ZERO LIQUID DISCHARGE DESALINATION OF WATERS WITH HIGH ORGANIC CONTENT"

A similar ZLD concept will be applied to the new AwwaRF research project, but the waters tested will pose new challenges as illustrated in Figure 6. High NOM concentrations can affect precipitation kinetics in the concentrate treatment step and the performance of RO membranes. Furthermore, the risk of organic membrane fouling increases in the presence of calcium. The primary RO concentrate in this research will contain high concentrations of ions (including calcium) that can cause inorganic fouling as well as high concentrations of NOM. Consequently, the concentrate treatment step must address the potential for inorganic and organic fouling.

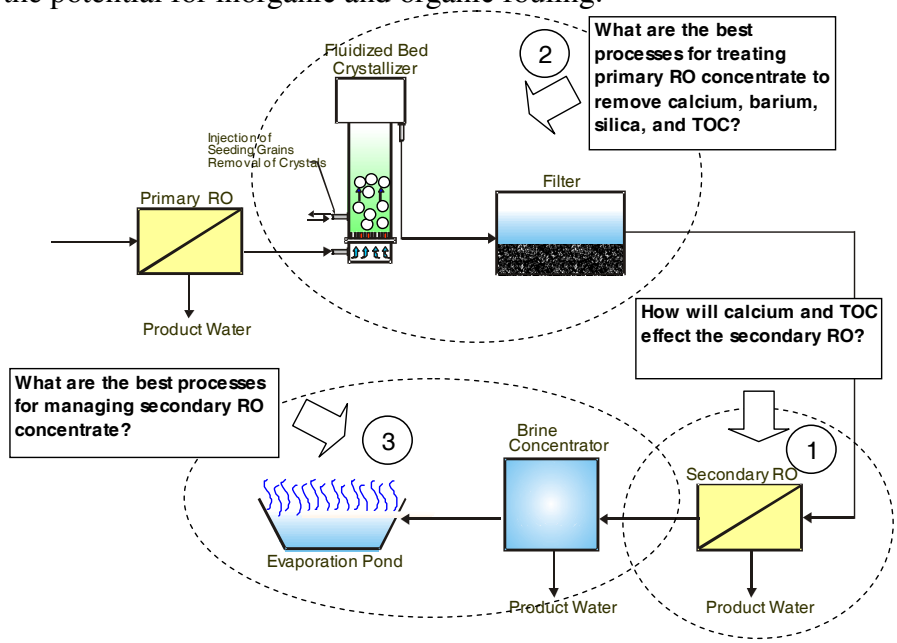

Figure 6 – New challenges posed by waters with high NOM concentrations

The test waters will come from the state of Florida. A second major challenge will be posed by Florida's wet climate. Evaporation ponds will not be an option for concentrate management because average rainfall exceeds the rate of evaporation. Consequently, new technologies will be needed to manage concentrate from the secondary RO.

The high concentrations of NOM and ineffectiveness of evaporation ponds lead to the following three new test objectives:

1. Identify the levels of calcium and NOM removal required in the concentrate treatment step to prevent organic fouling in the secondary RO.
2. Identify the most efficient processes for the concentrate treatment step that meet all treatment goals for reducing the inorganic and organic fouling potential of the concentrate.
3. Identify processes for managing the concentrate from the secondary RO.

The goals for the concentrate treatment step will include removal of calcium, silica, barium, and NOM. Processes that will be considered for evaluation, either individually or in combination, include:

- Chemical precipitation
- Fluidized bed crystallization
- Ion exchange processes such as magnetic ion exchange (MIEX)
- Adsorption processes such as activated alumina and GAC
- Electrodialysis with ion selective membranes

To increase the mobility and wellbeing of U.S. Army units a relatively light-weight, portable source of clean drinking water is needed to replace current practices of obtaining potable water. In addition to the need expressed by the Army, it has become apparent that delivering a reliable source of clean drinking water to municipalities during the aftermath of natural disasters such as Hurricane's Katrina and Ike is essential. Water supply and the associated transportation of potable water is a considerable burden on recovery efforts following a natural disaster. A low cost trailer mounted system, which uses an ultraviolet (UV) disinfection unit in conjunction with cartridge filters, can provide potable water from local surface water bodies until the infrastructure is renewed. The system is powered by a hybrid photovoltaic array and wind turbine system, which allows for the capability to pump and treat surface water when grid power is unavailable. In an effort to maintain low maintenance and increased storability associated with the system, relatively high-maintenance lead acid batteries have been eliminated, which also helps to reduce the system weight. Tests have been conducted to assess the ease of use, effectiveness and feasibility of the system.

INTRODUCTION

Drinking water infrastructure may be damaged or destroyed during natural or man-made disasters. Even if a water treatment plant is not directly damaged, related systems such as the power supply or water distribution system may be disrupted. The transportation of bottled water from unaffected areas may not be desirable because roads and highways may be damaged, the time required for shipment may be unacceptably long, the shipping costs may be too high and/or the shipment of water may displace the shipment of other critical supplies.

The primary objective of this project is the development of a prototype mobile water disinfection system that can provide drinking water to human populations in

areas where the infrastructure has been damaged due to natural or man-made disasters or for deploying troops in areas where a safe water supply does not exist. However, this is a broad and generalized objective and more specific objectives were developed for the system and include:

- Is mobile and which can be relocated to water sources such as surface water bodies
- Is self powered using a hybrid wind turbine/solar cell energy source
- Can be powered through a supplemental power source such as a gasoline generator
- Is relatively lightweight and trailer mounted, so it can be towed by a standard pickup truck
- Can be deployed with small individual military units, set up and functioning with nominal training
- Can be placed in storage for extended periods of time without degradation, without requiring special materials storage, or without requiring periodic maintenance
- Is relatively low-maintenance while in operation and does not require significant consumable supplies
- Has the potential to be produced at a cost that would be affordable for municipal and regional civic entities that are tasked with addressing civil emergencies
- Has on-board test equipment to validate sterilization function

The primary components of the system included an array of photovoltaic panels and a wind turbine to generate energy, an ultracapacitor (UCAP) to provide energy storage, an ultraviolet light system to provide disinfection, and an inverter to manage generated power.

SYSTEM COMPONENTS

To generate the energy needed to operate the system, a hybrid renewable energy system of a photovoltaic array and wind turbine was used. The array of photovoltaic panels was composed of eight Sharp ND216U2 PV panels, with each panel having a maximum power output of 216 W. The array was mounted to the side of the trailer in a fixed position using six 1 inch steel tubes with a piece of angle iron welded at a 53^{o} angle. A piece of UniRac Solar Mount was then bolted to this angle iron to allow for the PV panels to be positioned at 37^{o} to the horizontal. However, due to the size of the solar panels and trailer, this rack only accommodated five PV panels. For the remaining three panels wooden ground racks were constructed, also allowing for the panels to be positioned at 37^{o}.

The wind turbine selected for the project was a Skystream 3.7 manufactured by Southwest Windpower, Inc. with a maximum rated output of 2.4 kW at a wind speed of 13 m/s. The turbine was mounted on a 30 ft guyed tower composed of two 15 ft sections of 5 in Schedule 40 steel pipe. The two tower sections were connected using a coupler composed of three 20.5 in steel sections connected with 9 bolts on each side. Note that the standard 30 ft Skystream tower is composed of one 21 ft section and one 9 ft section. The 21 ft section was too long to be carried on the trailer

and was too heavy to be carried by 3 or 4 people on a routine basis such as would be expected with a mobile system. To raise the turbine tower a third 15 ft section of pipe was used as a gin pole. The tower was anchored into the ground through guy wires composed of 7/16 in wire rope tied into dual anchors. Included with each guy wire was a turnbuckle to allow for adjustments to bring the tower plumb. The anchors used were 30 in dual helix mobile home anchors, with a stabilizer plate to inhibit lateral movement.

To store the energy generated from the renewable energy systems a 48 VDC (nominal) UCAP was used. The use of the UCAP, which replaced a bank of batteries, allowed for a significant reduction in weight of the total system, in addition to an increased robustness of the energy storage system. In addition to the weight reduction achieved by using a UCAP, other benefits over the use of a bank of batteries are attained. A UCAP is a double-layer capacitor incorporating a metal/carbon electrode and a non-aqueous electrolyte solution. Unlike a battery, there are no chemical bonds made or broken in the process. The maximum voltage of the UCAP is not temperature dependent and the UCAP can be fully discharged up to a million times. Due to the low equivalent series resistance, the UCAP can obtain much higher power density than similarly rated lead-acid batteries. Due to its long shelf life and low maintenance, the UCAP provides a simple, reliable solution to buffer short-term mismatches between the power available and the power required by the pump and disinfection system.

In order to convert the alternating current generated by the wind turbine to direct current that could be used to charge the UCAP an Outback inverter was used. The inverter also converted direct current generated by the PV array to alternating current in order to power the disinfection unit. An Outback charge controller managed the direct current charging of the UCAP from either of the renewable energy systems. In addition to these systems a DC/DC converter was used to provide the appropriate level of direct current voltage necessary to power the pumping system.

A pumping and water storage system was also included in the prototype. This was comprised of a 12 VDC submersible pump which delivered water into an elevated 55 gallon HDPE tank. The tank housed level switches which controlled the operation of the pump. The level controls were programmed and operated through a Campbell Scientific CR1000 datalogger. The control logic is described below:

- If both low and high switches are closed, pump will turn on
- Pump will remain on until high switch is open
- Once high switch is open, pump will turn off
- Pump will remain off when the high switch is closed until low switch is closed

A secondary 55 gallon HDPE tank was used to store water post-disinfection.

Disinfection of water was achieved through the use of an ultraviolet disinfection unit. The disinfection unit used was a TrojanUVMax Pro10, which is rated to 10 gallons per minute. The TrojanUVMax unit is certified according to the National Sanitation Foundation (NSF)/American National Standards Institute (ANSI) Standard 55-2007 for Ultraviolet Microbiological Water Treatment Units for Class A systems designed to disinfect and/or remove microorganisms from contaminated

water, including bacteria and viruses, to a safe level using a UV dose of at least 40,000 uw-sec/cm^2 (NSF/ANSI, 2007). The unit is also Underwriter Laboratory (UL) certified. The unit included a solenoid valve which controlled the flow of water through the system based on the UV dosage received by a sensor in the unit's reactor. UV disinfection is a physical process which eliminates the need to generate, handle, transport, or store hazardous, toxic, or corrosive chemicals (USEPA, 1999). With this lack of chemical storage, the UV system enhances the storability and decreases the maintenance associated with the system.

The U.S Environmental Protection Agency promulgated the Surface Water Treatment Rule (SWTR) in 1989 for public water systems using surface water or ground water under the direct influence of surface water. Although the emergency water supply system developed in this project is not technically classified as a public water supply, the SWTR provides appropriate water treatment goals for the project. An important aspect of the SWTR is that solids which naturally occur in surface water must be reduced to concentrations which typically do not interfere with disinfection (USEPA, 2006). To achieve this reduction in solids, a pre-filter system was incorporated into the prototype. This pre-filter system was composed of a dual header system which housed pleated paper filters and activated carbon filters, which removed sediment and discoloration in the water making the water more aesthetically acceptable. A secondary pumping system using a 12 VDC UCAP was also developed and analyzed for the pre-filter system. Detailed information about the water disinfection components can be seen in Table 1.

The prototype system was mounted on a 16 ft tandem axle utility trailer, which was modified to accommodate the needs of raising the wind turbine and mounting of the solar panels. The modifications included; the addition of four mechanical jacks to support and level the trailer, mounting a 4 ft x 3 ft steel plate to

act as a base for and distribute the load of the wind turbine more evenly across the trailer, and the alteration of the front rail to accommodate the gin pole for raising the wind turbine.

PERFORMANCE CHARACTERIZATION

The majority of the prototype testing was conducted in the field, however prior to completion of the prototype, small field and laboratory tests were conducted to characterize the energy generation and consumption of the various components. The prototype system was deployed in the field at Fort Leonard Wood in Missouri for testing. Field testing occurred between the months of August to November 2007 and included; operation of the system under varying weather conditions and periods of time, as well as water sampling and analysis.

During system operation voltage sensors manufactured by Ohio Semitronics, Inc. were used to monitor and log energy generated and consumed of major components including; the wind turbine, the PV array, the UCAP, the UV disinfection unit and the 12 VDC pump. Detailed information about these sensors can be seen in Table 2.

Water sampling and analysis was conducted in four separate events. The water samples came from various surface water bodies located near the field deployment site on Fort Leonard Wood, these included a pond and a lake that were each sampled once, as well as a river that was sampled twice. A small amount of activated sludge from a wastewater treatment plant was added to the second river sample in order to increase the number of coliform bacteria present in the sample prior to disinfection. All water samples were processed in the field or in a lab at Missouri S&T, and were not sent to off-site laboratories.

Water disinfection was characterized by analyzing water samples for the presence of coliforms, including E. coli, which are organisms that indicate the

presence of or potential for fecal pathogen contamination. The U.S Environmental; Protection Agency Total Coliform Rule (TCR) provides a quantitative means for measuring disinfection effectiveness (USEPA, 2001). As with the SWTR, the TCR is only applicable to public water systems. However, by following the TCR during this project, the resulting emergency water supply will provide a safe product to the consumers.

Two methods were used during the project to evaluate the presence of coliforms; IDEXX Colilert and Micrology Labs Coliscan MF (membrane filtration). The Coliscan MF kits were used to quantify total coliform and E. coli concentrations, while the Colilert kits indicate a presence/absence of coliforms. Although removal of coliform bacteria was the primary goal for the disinfection unit, several other water quality parameters were monitored during testing. These include pH, TDS, Turbidity, Phosphate, Dissolved Oxygen and Nitrate. Detailed information about the equipment used for water quality testing is shown in Table 3.

RESULTS AND DISCUSSION

The prototype successfully pumped and disinfected water using the UV system powered by renewable energy. The use of the UCAP instead of batteries was successful, and the PV array supplied sufficient power for system operation. The wind turbine was redundant and was not used to a significant extent to generate power for the system.

The water quality testing results can be seen in Table 4. Throughout each sampling event samples were taken in triplicates of pre- and post-treated water. The membrane filtration tests were not conducted to quantify total coliforms during the pond sampling event. The numbers of total coliform colonies were too great to count in every pre-treatment sample so only E. coli counts are reported in Table 4. The membrane filtration testing indicated that there were no coliform (including E. coli) colonies present in the post-treatment samples. The Colilert testing did not provide colony counts, but the presence/absence results were consistent with the membrane filtration testing. The remaining water quality parameters tested were all in acceptable ranges as outlined by the Code of Federal Regulations Title 40 Part 141

National Primary Drinking Water Regulations and Part 143 National Secondary Drinking Water Regulations.

During testing of the prototype it became apparent that the wind turbine was unnecessary and proved to be problematic. The alteration of the tower from a 21 ft and 9 ft sections to two 15 sections, as well as the trailer-mounted base made keeping the tower plumb difficult. The increased moment created by the upper 15 ft section used in place of the 9 ft section could not be adequately controlled by the relatively small coupler used, which caused a slight deflection from vertical affecting the turbine's ability to rotate downwind. In addition to the problems created by the tower alteration, the erection of the turbine was labor and time intensive, as well as inherently dangerous to personnel and other system components during erection. The wind turbine was primarily designed to operate in grid inter-tie mode and the manufacturer-supplied control modification hardware and software necessary to

operate the wind turbine system in off-grid (UCAP charging) mode did not function well.

The limiting factor of the system was the water treatment capacity. This factor was limited by the hydraulic capacity of the elevated holding tank and tubing carrying the water, as well as the energy consumption of the pump. To characterize the system's ability to operate without energy being generated, the renewable energy system was disabled and energy consumption of the disinfection unit and pumping system were monitored. The disinfection unit operated for 19 minutes beginning on a full 48 VDC UCAP charge and continuing until the UCAP reached 36 VDC at which point the inverter automatically shuts itself off, which allowed for the treatment of 45 gallons of water. If the solar panels were charging the UCAP, the disinfection unit would operate as long as there was sufficient water supply. The typical flow through the disinfection unit was 2.4 gpm. If the flow through the system were increased to the UV system's operational maximum of 10 gpm, approximately 200 gallons of water could be treated on a single UCAP charge. One hour of continuous operation would result in the disinfection of 600 gallons of water. Assuming an average daily per capita drinking water consumption of 2.0 L (0.53 gal), a single UCAP charge has the potential to treat enough drinking water for 360 people for one day, while 1 hr of continuous operation would provide enough drinking water for more than 1,100 people.

The water pump operated at a flow rate of 3.6 gpm for four minutes on a full UCAP charge. This short pumping time only allows for 14 gallons of water to be pumped into the holding tank. It can be seen that the water pump operation was a significant limiting factor in the quantity of water to be treated. If the solar panels were charging the UCAP, the pumping system consumed energy at a faster rate than energy was generated resulting in varying inverter shutdown times dependent upon the available solar radiation. The typical recharge time for the UCAP ranged between 2 and 16 min depending on the available solar radiation. Therefore, an estimated 340 gallons of water could be pumped in a typical day (assuming 3 cycles/hr) if not other loads were imposed on the system.

The water treatment capacity time constraints presented previously provides the primary findings regarding the impact of the energy balance. Therefore, the utility of the actual energy balance using data collected from the OSI voltage sensors is of somewhat diminished importance. Typical data received from the voltage sensors is shown in Table 5. It can be seen in the data that there is some variability in the energy generated by the PV array which reflects the varying amount of available solar radiation, the wind turbine energy generated remains essentially constant because the wind turbine was not in operation, the UCAP data show variability as the voltage varies with PV input from the charge controller, and the pump and UV system loads remain essentially constant over the operational period.

Table 5 Typical Voltage Sensor Data

Time	Sensor Output (mV)				
	PV Array (Generate)	Wind Turbine (Generate)	UCAP (Store)	Pump (Consume)	UV System (Consume)
2:00:00 PM	19.64	8.81	31.84	37.94	14.23
3:00:00 PM	14.9	8.8	0.677	37.93	13.55
4:00:00 PM	16.26	8.13	10.84	38.6	13.55
5:00:00 PM	9.49	8.13	9.49	38.62	14.23
6:00:00 PM	5.42	8.81	32.52	36.59	2.71

CONCLUSIONS AND RECOMMENDATIONS

The prototype system met or exceeded all objectives outlined in the scope of the project and demonstrated the proof of the concept that renewable energy systems could be used to operate the UV disinfection unit. However, several technical recommendations became apparent during testing of the prototype system. These recommendations include; abandoning the wind turbine, increasing the quantity of water treated, and an evaluation of issues specific to potential use by the military.

By abandoning the wind turbine, the potential for energy generation is decreased, however it could be seen during testing that the system did not require the increased energy generation potential provided by the wind turbine. If the need for increased energy generation is required it could be achieved through an increased number of panels in the PV array. In addition to the diminished need for the wind turbine to generate energy, other benefits achieved through its removal include; complexity of the system will decrease, overall system weight will decrease, visibility of the system will decrease, overall cost of the system will decrease, potential for lightning damage is decreased, mobility and ease of set-up of the system will be increased, and the area of deployment for the system will increase because wind obstructions and acceptable soil conditions required for anchoring the turbine will not be siting factors.

An increase in the quantity of water treated could be achieved through the alteration of the water storage and piping system and by identifying an inverter that functions throughout a wider voltage range. To achieve the rated 10 gpm of the disinfection unit, the system would need to be replumbed with larger piping and/or an increased elevation of the holding tank. Identifying an inverter that will function at lower DC voltages would take advantage of the UCAP's ability to be discharged to lower levels without damage relative to a battery, allowing the disinfection unit to run longer than 19 min on a single UCAP charge.

Further recommendations for evaluating issues specific to military use are focused on making the unit more troop friendly and increasing the ease of deployment by creating a system housed in a container more readily handled by military equipment.

ACKNOWLEDGEMENTS

The project described was funded by a grant from the Leonard Wood Institute (LWI). Additional support was provided by Filter-Tek Inc. of Rolla, Missouri and Missouri University of Science and Technology.

Keywords: sanitary sewer, rehabilitation, asset management

Abstract

Sanitary sewer rehabilitation programs are generally triggered by the need for reducing infiltration and inflow and restoring structural integrity of a collection system. On the other hand, improving the condition of the components (essentially pipes and manholes) of a wastewater collection system may turn sanitary sewer rehabilitation into a financially beneficial practice in addition to maintaining desired level of service and regulatory compliance. This study discusses a sanitary sewer rehabilitation program being applied on Marco Island, Florida as a case study of proactive wastewater collection system management. The existing system was evaluated using closed-circuit-TV inspection of pipelines and visual inspection of manholes. Accordingly, a rehabilitation program was developed which is based on using trenchless technologies to maximum extent. Depreciation of the system was analyzed for the next 70 years without rehabilitation to estimate the rate of return of rehabilitation. The results indicated the rehabilitation cost is approximately 16 percent of the depreciation that would occur in 70 years in today's dollars.

Introduction

Wastewater collection systems are valuable capital assets of municipalities, which turns operation and maintenance of these assets into an important matter. The majority of the underground infrastructure in the developed nations were built in the nineteenth or early twentieth century, and have reached far beyond their design life. Wastewater collection systems are comprised of pipelines (main lines, force mains, and service laterals), manholes, and lift stations, where main pipes comprise the highest portion of the cost (approximately 70 percent). Like any structure, sewer systems are subject to degradation over time. Nature and extent of damage to sewer systems is dependent on site conditions, which include loads on the pipelines, groundwater table, wastewater characteristics, materials used for the pipes and other components, and installation quality. To date, there have been several studies on sanitary sewer asset management, with various aspects in defining wastewater collection system needs and how to address them. A formal definition is provided in

the International Infrastructure Management Manual (INGENIUM, 2002): "The combination of management, financial, economic, and engineering practices applied to physical assets with the objective of providing required level of service in the most cost-effective manner."

La Gauffre et al. developed a comprehensive study on identifying sewer system defects, their consequences, and impacts on the overall system. In other terms, discrete (along a pipe segment or particular point) defects were combined into an impact function, which was then used as a tool for a decision matrix to determine whether a particular defect should be addressed by spot repairs, rehabilitation (lining, chemical grouting, etc.) or replacement. The methodology is composed of six principles, which includes system inspection and evaluation criteria, defect identification/classification, a nomenclature to define system discrepancies and actual/potential effects, decision criteria on whether to employ spot repairs, rehabilitate or replace a pipe segment, and a numerical method to make a decision on rehabilitation strategy, into which the decision criteria are incorporated. This study identifies performance indicators in three levels as defects, dysfunctions, and impacts. Where, defect is a deviation from design/initial conditions such as cracks on pipes; dysfunctions are the consequences of defect; e.g., infiltration due to a crack, and impacts are the negative effects of these consequences to the environment, operation conditions and costs.

A similar approach for decision making on rehabilitation of an infrastructure asset was discussed in Guide to Water and Wastewater Asset Management (Underground Infrastructure Management, 2008). A wastewater collection system may be functioning in compliance with the regulations in action, despite of apparent defect that may impact the operation. For instance, a cracked pipe, unless causing significant exfiltration, will not be a problem from regulatory standpoint; however, depending on location, soil conditions, and severity of the cracking, this defect may lead to a structural failure of that pipe segment, which will in return interrupt operation, result in soil or groundwater contamination and social costs due to road closures associated with excavation for fixing it or possible damage to the road. The UIM publication outlines a cost comparison between fixing a problem or leaving it as is. For the cracked pipe example, the cost of not fixing it is the cost of failure, possibility of which can be predicted versus time; i.e., if the failure appears to be imminent in 15 years, then the cost of leaving as is will be at minimum the cost of replacement and social cost per year. On the other hand, the proactive approach would be rehabilitating the crack (e.g., by inserting a liner into the pipe). The capital cost of rehabilitation (note the social cost is trivial with rehabilitation, since it is applied trenchless) can be calculated as annual cost over 15 years so that it can be compared to the annual cost of replacement and social cost as the other option. If the annualized rehabilitation cost per year is less than replacement after failure, then it is justified. This analysis should take the life cycle of each option as well. There will be a design life for the rehabilitated pipe to be compared to the remaining life of the cracked pipe, which is predicted as 15 years.

In their overview of asset management practices of underground infrastructure in the USA, UK, and Australia, Aikman and Doherty (2006) listed the following as the components of asset management programs in the USA: Desired level of service,

performance goals, information systems, asset identification and valuation, consequences of failure analysis and risk management planning, condition assessment, capacity analysis and assurance, maintenance analysis and planning, financial management, and capital improvements and expansion of system. The need for asset management is primarily driven by Government Accounting Standards Board (GASB) Statement 34 (GASB-34), which requires governmental entities to provide an inventory of their long-term assets such as underground infrastructure (water and wastewater pipelines, pump stations and other components of collection and distribution systems) and EPA's Capacity, Management, Operation and Maintenance (CMOM) initiative.

This study discusses the sanitary sewer rehabilitation program being applied on Marco, Island, Florida as an example of proactive wastewater collection system management. The program consists of three phases: Condition assessment, rehabilitation design, and implementation. Based on the condition assessment, depreciation of the existing sanitary sewer system was predicted in long-term. This analysis was used to determine the financial benefits of sanitary sewer rehabilitation in addition to preventing failures, reducing infiltration and inflow (I&I); thereby maintaining the desired level of service.

City of Marco Island, Existing Sewers Assessment and Rehabilitation

Scope of Work: Marco Island, Florida Sanitary Sewer Rehabilitation Project was analyzed as an example of proactive asset management practice. The City of Marco Island purchased the water and wastewater utility from a private company in November of 2003 and was named Marco Island Utilities. As the management became familiar with the utility's capital needs, the projects were prioritized from the most critical to the least critical. At the beginning of the fourth year of ownership, the Utility Director set aside funds to begin an assessment of the wastewater gravity system that was built between early and late 1960s. The existing central wastewater collection system consists of vitrified clay (VCP), built in early 60s, and polyvinyl chloride (PVC) pipes, built in late 60s clay. Only 40 percent of the Island was served by centralized wastewater collection system at the time.

In coordination with BOYLE | AECOM the City started an assessment / rehabilitation program for its sanitary sewers. The goals of this program were to assess the structural integrity of the pipelines; identify sources of infiltration and inflow into the system, and develop a capital improvement plan to prioritize and correct defects that are discovered. Methods used for inspecting the existing system are cleaning the pipelines using a water jet, surveying pipe condition using closed-circuit television (CCTV), and smoke testing of lateral sewers and selected manholes. Defects noted during the CCTV inspection were identified using the Pipeline Assessment and Certification Program (PACP) coding system. The video records were reviewed by BOYLE | AECOM to verify and evaluate the reported defects.

Existing System Inventory: Sanitary sewers on Marco Island consist of polyvinyl chloride (PVC) and vitrified clay pipe (VCP), with clay pipes being older than the PVC pipes. PVC pipes did not demonstrate any notable damage except a few discrete holes and cracks due to rock or miscellaneous object penetration. The

majority of the inspected VCP is in sound or moderate condition requiring spot repairs or no repair at all in the foreseeable future. Approximately 16 percent of the existing clay pipes demonstrated extensive damage such as cracks, fractures, and loose/offset joints. These defects require complete rehabilitation using a structural liner such as cured-in-place-pipe (CIPP).

Approximately 40 percent of the existing pipes are made of clay and the remaining 60 percent are PVC pipes. Vitrified clay is known for its inertness against chemical attack. However, it is more brittle than PVC and tends to generate longitudinal or circumferential cracks due to external loads. In addition, VCP is less flexible than PVC and tends to separate at joints. Marco Island is a barrier island located on the eastern section of the Gulf of Mexico in southwest Florida. Marco Island's groundwater table is on the average of 3 ft (0.9 m) to 3.5 ft (1.1 m) below the surface and is affected by tidal action. Because of the fluctuating water table and the constant movement of the sandy soil the nonflexible clays pipes have sustained most of the damage. Additionally, traffic loads and installation deficiencies (e.g., poor bedding and backfill) may have played a significant role on service life of sanitary sewer pipes.

Extensive defects such as cracks, fractures, holes, loose joints on the pipelines and manholes will potentially allow I&I. Infiltration and inflow will increase the total flow rate and cost of wastewater treatment. In addition, I&I may cause overburdening of the WWTP, which could negatively affect the treatment processes and risk the quality of the effluent. Moreover, infiltration is a result of defects in the pipelines as well as manholes, which may be indicative of premature failure of the sewer lines that may have costly consequences such as sanitary sewer backups and damage to the road above the collapsed pipe segment. Sanitary sewer failures also pose environmental hazard by wastewater leaks out of the pipeline (exfiltration).

The cleaning and televising program included the existing sewers, which are distributed over the Island on the northeast, northwest, and southwest. These areas were divided into phases to prioritize and coordinate the project. The overall project included approximately 190,000 linear ft (58,000 linear m) of sanitary sewer pipes ranging from 8-inch (200 mm) to 12-inch (300 mm) in diameter and 833 manhole, which serves the 34 percent of the island. Approximately 6 percent of the existing sewers were excluded from the rehabilitation program due to pipes/manholes being new or recent rehabilitation.

Sanitary Sewer Pipes

Based on the review of the CCTV records BOYLE | AECOM evaluated condition of the pipelines, which was indicated using color coded plans (Figure 2). Three levels of deterioration; i.e., sound, moderate, and poor, were indicated by green, yellow, and red, as defined below.

Green: Pipe segments that have few or no observed damage. No rehabilitation is recommended for green pipes.

Yellow: pipe segments that have moderate amount of defects such as fractures and cracks. While the yellow pipes, in general, appear to be sound, immediate rehabilitation of some of them may be advisable due to localized severe damages (e.g., a hole or a broken pipe).

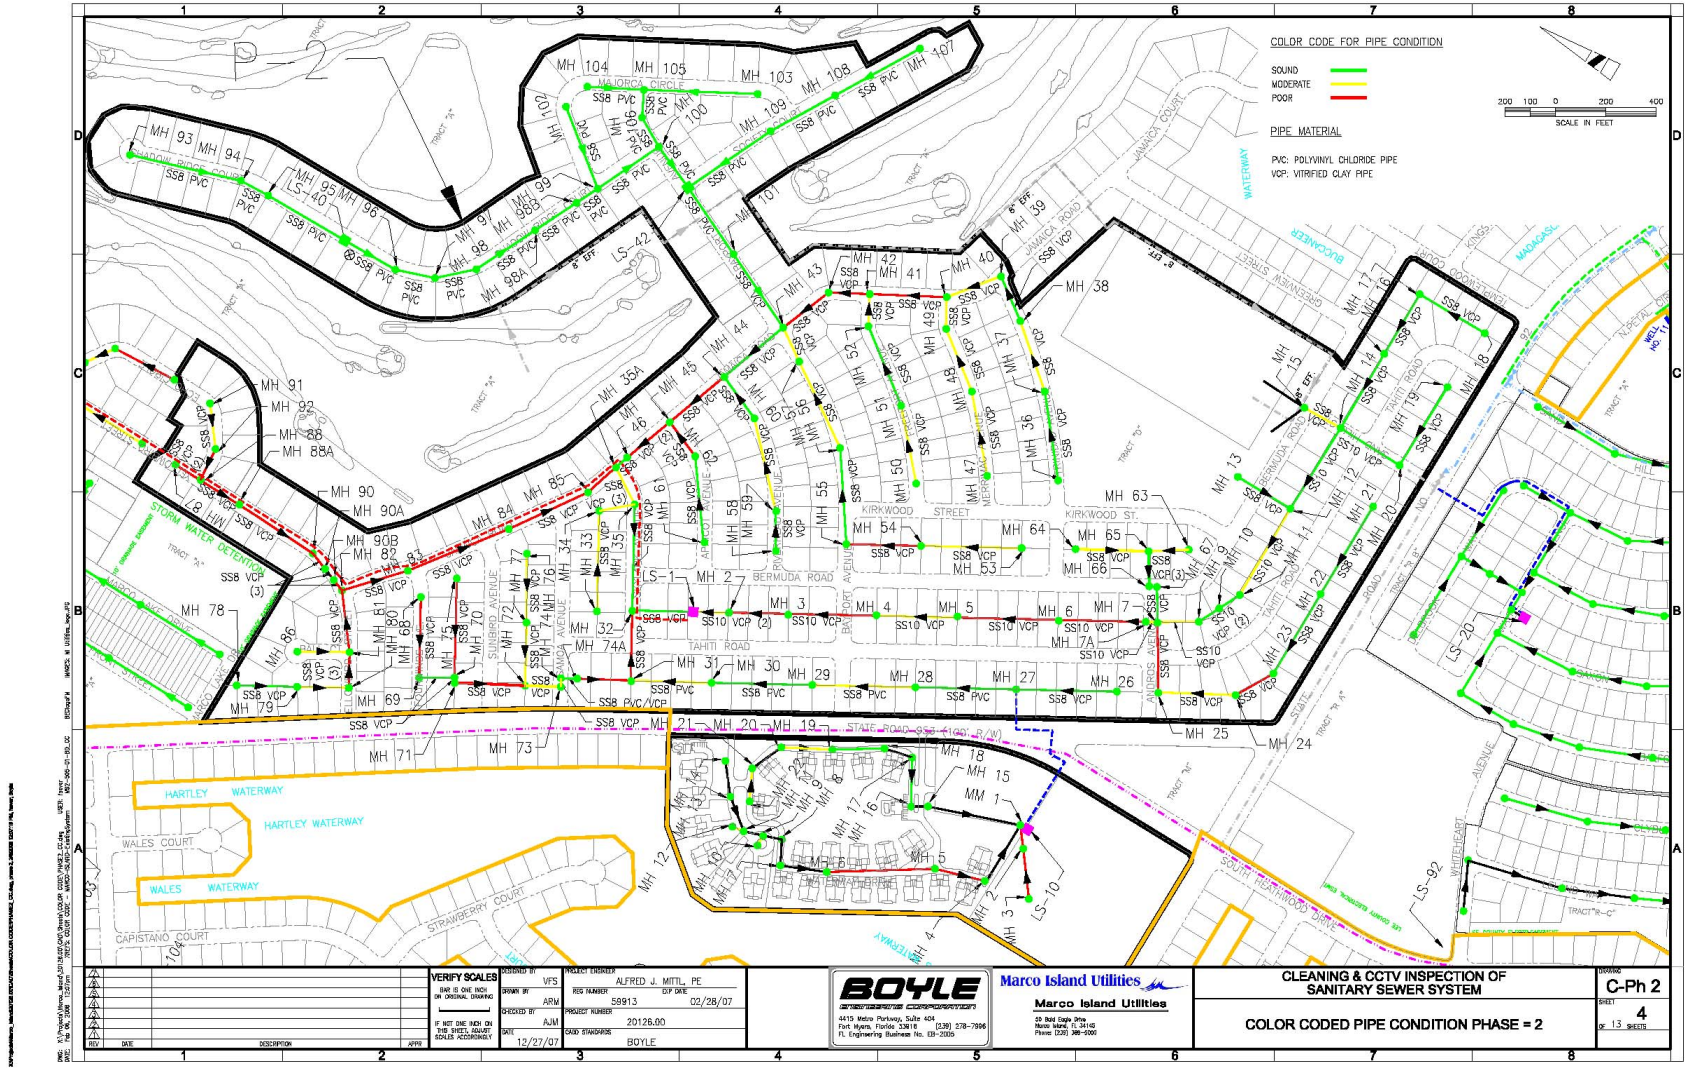

Figure 1. A sample color coded map indicating condition of the inspected pipes in one lift station area.

Red : Pipe segments with frequent cracks and fractures were coded red. Red pipes are not structurally sound; they are prone to failure and source of infiltration. Figure 2 shows a breakdown of inspected sanitary sewer pipes based on their condition.

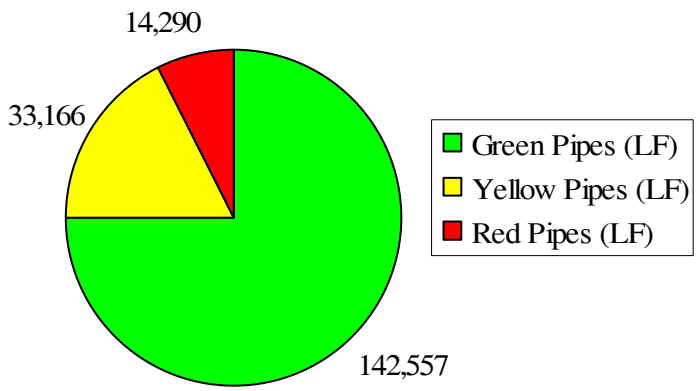

Figure 2. Quantities of inspected of sanitary sewers with respect to their condition indicated by color code.

The condition of the pipelines was highly dependent on the location and material. Accordingly, minor or no damage was noted to the PVC sewers; whereas, the magnitude of damage to the VCP sewers ranged from no damage to extensive (Figure 3). The most common types of defect were cracking, fracture, and root intrusion (at joints) in VCP and sagging in PVC pipes. Pipe segments that have frequent fractures and cracks will allow infiltration or exfiltration depending on the water table and the location of the pipe. In addition, structurally unsound pipe segments are prone to a collapse, which may cause sanitary sewer backups and damage to the road above the pipeline.

Figure 3. A view from a fractured clay pipe.

Based on the condition of the pipelines and flow rates into the system, upsizing any pipe segments was not deemed necessary by the project team; and therefore, pipe replacement was not one of the methods included in the project. Available relining methods include cured-in-place-pipe (CIPP) liner and sliplining (fold and form or deform/reform). CIPP is the method chosen for relining, which is an established method of structural pipeline rehabilitation in North America (ASCE, 1994). A well installed CIPP with adequate resin will minimize, if not eliminate, the annular space between the host pipe and liner (Bakeer and Sever, 2008); thus the risk of annular flow that may enter into the system through service lateral connections (after the liner is cut out at service laterals) and crack/holes on the host pipe.

CCTV records indicated non-structural, localized damages and leaks in some of the sanitary sewers that are otherwise in sound condition. A complete relining of these pipe segments would not be economical; therefore the suggested method for fixing loose joints and circumferential cracks in the pipe segments that are otherwise in sound condition was chemical grout (acryl amide) injection.

Manholes

CCTV inspection survey records did not provide a clear view of the manholes; and therefore, manholes were visually inspected by the project team. Forty six percent of the manholes included in the assessment program were included in the inspection (386 of 833). This selection was based on age and location as manholes in low lying areas (i.e. swales and areas at low elevations). Wet weather flow rates to the Marco Island Wastewater Treatment Plant are significantly higher than dry weather; whereas, based on the CCTV records review, it was understood that infiltration into the collection system is not substantial. Hence, manhole inspection and assessment was aimed at reducing inflow through manholes and enhancing structural integrity of the deteriorated ones. Inspection was conducted using a standard form developed by the project team.

Majority of the manholes had defects on the upper section; i.e., cover, frame, and chimney; whereas, some of them underwent corrosion due to hydrogen sulfide release, which damaged cone and wall. Damage to the bench or trough was observed in only a few manholes, and this was mainly due to root intrusion. Like the sanitary sewer pipes, condition of each manhole is depicted using a color code. Color coding identifies a manhole's condition at three levels as sound (green), moderate (yellow), and poor (red).

Green Manholes are the ones with minimal or no apparent corrosion on the interior or top (frame and lid). Green manholes do not require any rehabilitation or frame/lid replacement. However, some of them require lid sealing to prevent inflow.

Yellow Manholes are the ones with moderate damage. They are structurally sound; i.e., minor or no corrosion to the bench, wall, and cone. Yellow manholes typically require replacement of the frame and sealing of the lid, and partial lining (chimney and/or joints) or grouting.

Red Manholes are the ones with extensive corrosion throughout the interior and significant inflow (and infiltration for some). Lining the interior of red manholes would prevent further corrosion thus a failure or extensive I&I. Red manholes

comprise only 12 percent of the inspected manholes. Figure 4 shows a breakdown of inspected manholes based on their condition.

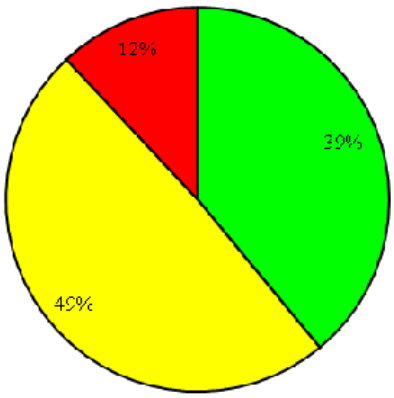

Figure 4. Percentage of green, yellow, and red manholes.

Smoke Testing – Service Laterals: Lateral sewers along with manholes were surveyed by smoke testing before visual inspection on manholes. Smoke testing verified inflow through manholes and revealed apparent defects on service laterals such as missing clean-out caps, illegal connections, and leaks. Rehabilitation of lateral sewers is not included in the current rehabilitation program, as they appear to be in better condition, hence have less priority in comparison with main sewers and manholes.

Anticipated Benefits of Rehabilitation

The rehabilitation program is primarily based on the defects noted and their consequences. For instance, a crack is identified as a defect to be fixed only if there is infiltration through it or imposes a risk of further propagation; hence failure in the long run. Likewise a loose joint was noted and included in the list of joints to be grouted only if there is apparent infiltration through it. The rehabilitation program is aimed at addressing all of the defects that has or will have an impact in the operation of the system in the desired level of service, which is essentially minimized infiltration and inflow and risk of failure. On the other hand, all of the yellow and red sanitary sewer pipes and manholes will be upgraded to green. In addition to minimized operational problems, this will increase the overall value of the wastewater collection system, an important capital asset of the City.

Conditions of the sanitary sewer pipes and manholes were predicted in long-term if a rehabilitation program was not implemented. This prediction is based on a linear correlation between degradation observed in 40 years to date and the degradation that would occur without rehabilitation in 70 years. Condition of the pipelines after 40 years (average age of the inspected pipes and manholes, which vary from 35 to 45 years) was broken down in accordance with the material (clay or PVC). Then it was assumed that the pipe degraded from green to yellow or red over this period in constant increments (i.e. linear degradation), which is a much greater value for clay pipes. To illustrate, the rate at which clay pipes turned yellow from green was 40 percent; whereas, this rate was 3 percent for PVC pipes. Figures 5 and 6 depict

predicted degradation of sanitary sewer pipes and manholes, respectively for the next 70-year term based on degradation in 40 years. It is more than likely that degradation of a sanitary sewer pipe or manhole is not linear over time as deterioration would be expected to occur at an accelerated pace when the pipes and manholes reach their design life. However, there isn't sufficient data to create a model for the deterioration of the pipes and manholes in long-term in the case of Marco Island, as the pipes were inspected once after 40 years. The nonlinearity in the condition of pipelines versus time plot is a result of different rate of degradation between PVC and clay pipes. All of the clay pipes are expected to sustain, at minimum, minor damage, and degrade to yellow in 40 years. In other words, there would be no green clay pipes in the system after forty years without rehabilitation. This results in a decline in yellow pipe quantity as yellow clay pipes proceed to degrade and turn red; whereas, available green PVC pipes turn yellow at a lower rate than transition to red pipes of clay pipes.

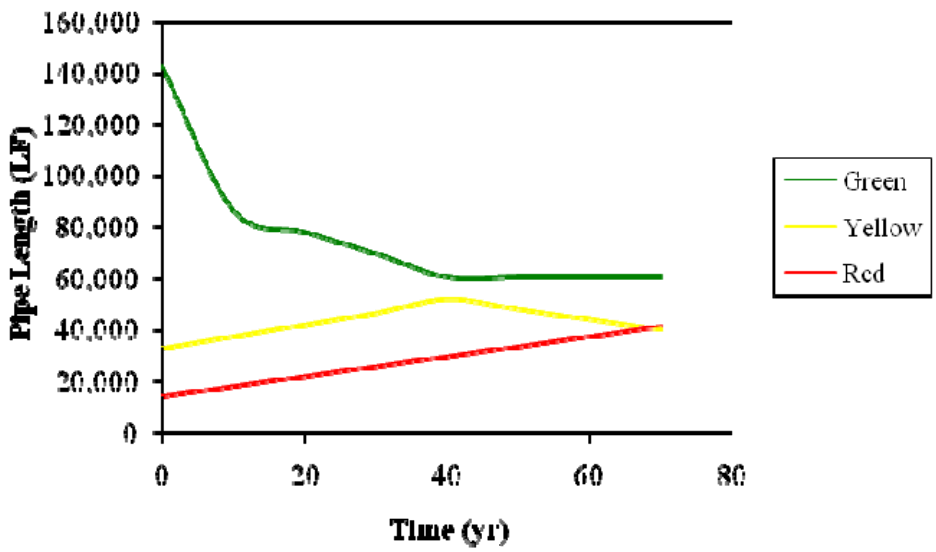

Figure 5. Anticipated change of condition of the sanitary sewer pipes without rehabilitation.

Anticipated benefits of rehabilitation in monetary terms were analyzed in long-term (70 years). Value of a green pipe segment was taken equal to a new sanitary sewer pipe, which is based on new construction ongoing on the other parts of the island. The average unit price ($/linear ft for sanitary sewer pipes) for new construction was amplified by 25 percent to account for relatively low quantity and additional cost of replacing the existing pipes (which would include flow bypassing and extra labor). On the other hand, there is a social cost associated with traffic interruption and nuisance to the public for new construction or open-trench replacement, which is very complex to define in mathematical terms and excluded from the value of a green pipe.

A yellow or red pipe segment is the cost of a green pipe segment (per linear ft) less the cost of rehabilitation required to bring these pipes' conditions to green. The cost difference between green and red pipes would be much greater if any of the red pipes required replacement.

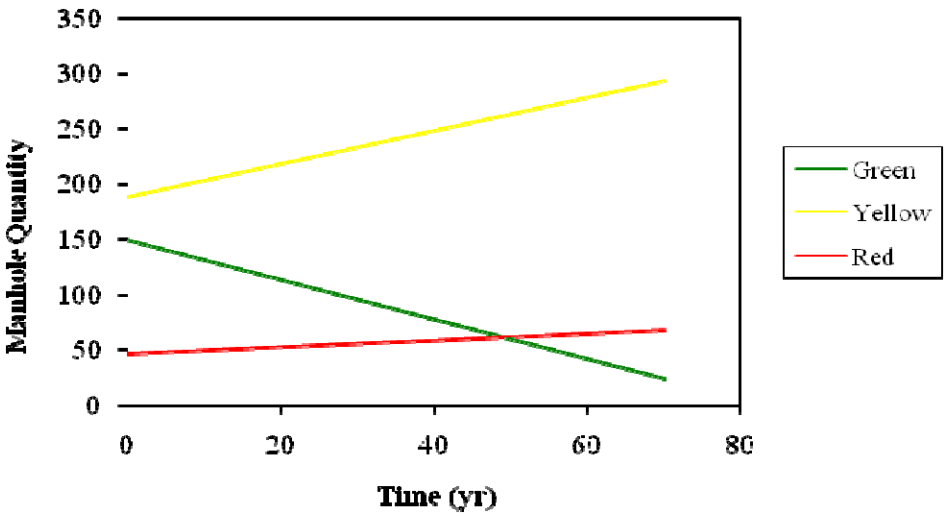

Figure 6. Anticipated change of condition of the sanitary sewer manholes without rehabilitation.

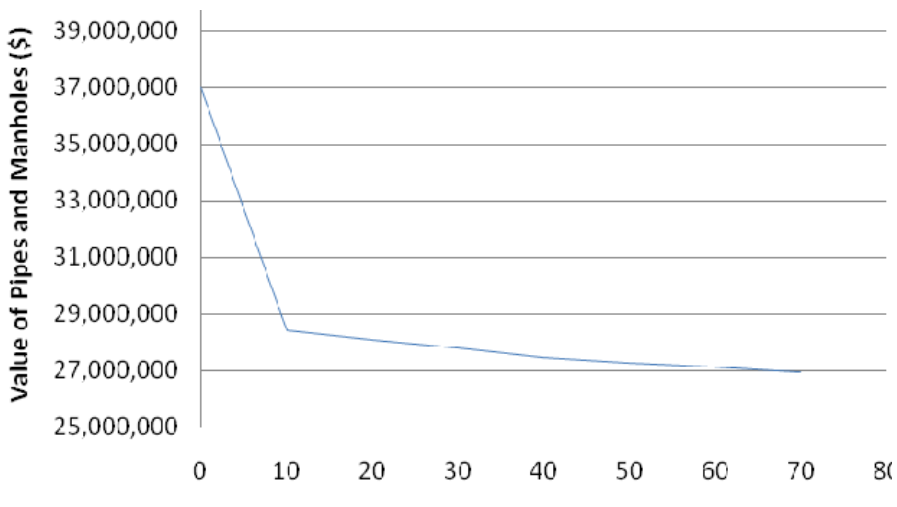

Figure 7. Anticipated depreciation in value of the sanitary sewer pipes and manholes without rehabilitation.

This would more than likely be the case in the future if rehabilitation was not implemented, as a significant portion of the red/yellow pipes would further deteriorate and require replacement. Long-term depreciation of sanitary sewer mains and manholes is shown in Figure 7. The dramatic slope change after ten years is a result of clay pipes being deteriorated and the trend is controlled by PVC pipes after this point, which deteriorate at a much slower rate than the clay pipes (as discussed).

Conclusions

The ongoing sanitary sewer rehabilitation program of Marco Island, Florida was evaluated as a proactive asset management practice. The rehabilitation program

for sanitary sewer mains and manholes consists of three phases: Condition assessment, rehabilitation design, and implementation. Currently, the program is at final phase of the design. Condition assessment for the pipelines is based on review of closed-circuit-TV (CCTV) survey conducted by an inspection company. Vitrified clay (VCP) and PVC pipes were used for the existing sewer system of the Island. Generally, older clay pipes had more damage than the PVC pipes. The most common damages noted were cracks, fractures, sags, and loose joints on the VCP pipes. Damage observed to PVC pipes included minor sagging and occasional holes due to penetration of a rock or another object. None of the inspected pipes were completely blocked or collapsed due to extensive damage. CCTV inspection did not provide a clear view of the manholes, and therefore, manholes in selected areas were visually inspected. The most of the defects were noted at the top part of the manholes. These defects include corrosion of frames and lids, damage to brick chimneys, and gaps between frames and chimneys/cones.

It is anticipated that by implementing this program, the City will eliminate the risk of failure of its sanitary sewers, reduce I&I, and increase the value of an important capital asset. It is also expected that by reducing I&I rehabilitation of defective sewer pipes will lower the cost of wastewater conveyance and treatment. The estimated cost of rehabilitation is approximately $1,600,000, which is approximately 16 percent of the anticipated depreciation without rehabilitation as present value.

The next steps are implementing the rehabilitation program and incorporating pre/post rehabilitation condition of the sanitary sewer system into the GIS database of the City. A continuous asset management with inspections/assessments and rehabilitation on a periodic base will maintain the level of service that will be achieved after rehabilitation and result in savings in economic and social cost by preventing a possible failure and avoiding pipe replacement.

Abstract

For the City of Damascus, Oregon incorporated in 2004, achieving sustainability includes balancing the preservation of natural capital and ecological services with provision of public facilities and services to support new development. This rural, forested and agricultural rich City is set among volcanic buttes and a network of perennial and ephemeral streams and riparian corridors tributary to the Clackamas River. Current residents value the diversity of the natural landscape for its scenic beauty as well as for its contributions to biodiversity, clean water, clean air, and the rural character of the area, as well as for the opportunities for income from use of their lands from timber sales and agricultural endeavors. These agricultural endeavors range from organic vegetable farms to Christmas tree lots. Inclusion of this area into the Urban Growth Boundary (UGB) in 2002 dramatically changed the land use regulations that had previously protected the forest and agricultural uses and opened the door to more intensive residential and commercial development.

The City, recognizes that the existing natural and modified ecosystems within and outside of their boundaries are providing benefits, that if lost would result in costs to the citizens of Damascus. This recognition of the services provided by natural resources has led the City to focus on identifying and quantifying these services so that decisions about there preservation, mitigation or restoration can be incorporated into their plans and implementation mechanisms. In initiating planning for provision of necessary public facilities such as water, waster water treatment, stormwater management and transportation, the City proposed an approach that explicitly accounts for changes in natural capital and its ability to provide valued ecosystem services for people.

The focus of this paper is on the conceptual approach to identifying, assessing, and valuing ecosystem services; and on the development of approaches for managing natural capital to provide valued ecological services.

What Are Ecosystem Services?

Ecosystem services are those flows of services from natural resources that are valued directly or indirectly by humans or contribute toward supporting the natural resource

base. Such ecological services can include capture of sunlight for food, shelter, nutrient recycling, capture of pollutants from runoff, nursery area for fish/shellfish, flood protection, recreational fishing, commercial fishing, etc. Researchers have found that as population, income, and consumption levels increase, humans put more and more pressure on the natural environment to deliver benefits. Sixty percent of ecosystem services assessed globally are either degraded or are being used unsustainably (Cowling, 2008).

Climate change, pollution, over-exploitation, and land-use change are some of the drivers of ecosystem loss, as well as resource challenges associated with urbanization. Often the benefit derived from altering the ecosystem is immediate and accrues to one individual, entity, or group, as in money made from the sale of clear-cut timber; whereas the cost, (erosion of soil, sedimentation of streams leading to loss of a fishery) is experienced by others and may not be realized for years or even decades. This unequal distribution of benefit obtained from use of an ecological good and the cost borne by its loss is evidence of the growing need for mechanisms for balancing use and loss of natural resources with maximizing the value of ecosystem services conserved.

Many of these goods and services are traditionally viewed as "public goods," that is free benefits to society. Without a formal market their important and even critical contributions are often overlooked in decision-making (USFS, 2009). When the ecosystem services provided by our natural and open space lands are not valued, or are undervalued, the areas supporting them are susceptible to development pressures and ultimately conversion to another use. When municipalities view their ecosystems as natural assets with economic and social value, these values can be brought into the overall balance sheet leading to more responsible decision-making (USFS, 2009).

Ecosystem Services: City Perspective

Damascus is the first new city in Oregon in over 22 years. The city was formed under regulatory circumstances, stemming from the expansion of the Portland metropolitan area's urban growth boundary in 2002. The Damascus area, which is predominately developed as rural residential, currently contains 9,775 people and is expected to accommodate 50,000 to 60,000 people in the future.

Oregon's land use planning framework was considered cutting edge for growth management in the late 1970s. Each City or metropolitan area must draw an urban growth boundary to contain urban development and provide urban services, such as sewer, water, stormwater, parks and transportation systems. The state mandated planning framework still exists today and has undergone many legal battles and refinement over the last 30 years. The incorporation of Damascus will challenge the regulatory, financial and technical standards that have been used over the last 30 years to build cities.

Damascus is currently 10,333 acres (16.15 square miles). Approximately 10% of the city is served by a sanitary sewer system. In addition, the community is rural in nature, where most properties are served by either wells, or small private water systems and on-site septic systems. No municipal stormwater system exists in

Damascus. Most of the roads are rural in nature, which contain two auto lanes, drainage ditches, no shoulders or curbs or sidewalks. It is estimated that it will take approximate $3 to 4 billion to provide needed infrastructure. (Metro, 2008).

Faced with limited financing from typical federal sources for wastewater, stormwater and transportation systems, the city is seeking creative alternatives to infrastructure development. Ecosystem Services approach will provide a way for the city to quantify natural resources contribution to the public facility system and, in the end reduce the cost of providing built infrastructure for the community. It is essential for the city to develop an analysis and system to provide developers and property owners certainty in the expectations and requirements for property development. The approach needs to be clear and understandable for a single property owner, in addition to staff, with limited scientific background to apply to situations on the ground.

Ecosystem Services – Identification, Assessment and Valuation

What is Net Environmental Benefit Analysis (NEBA)?

The net environmental benefit analysis framework shares the same theoretical foundation as benefit-cost analysis. The NEBA approach identifies and values the primary environmental services that an area or portfolio of holdings may provide given different land uses and actions (for example, wildlife management, building roads and infrastructure, siting facilities, discharging effluent, restoring stream habitat). The NEBA approach uses the recent emphasis in the ecological sciences to consider environmental services within a landscape context. Proposed actions will affect the valued quality and quantity of ecological services produced at the site or parcel differently depending upon the broader ecological and human landscapes. Some services may be improved, some may not be affected, and some may be harmed. A systematic evaluation of these service flows is needed to establish the existing condition, to make consistent comparisons across alternative actions affecting the City's natural resources, to evaluate trade-offs, to determine mitigation for offsetting losses, and to optimize the achievement of environmental objectives at least cost.

Even with advances in measurement, the services of nature are sufficiently varied, abundant, and specific to the human and ecological landscape, that it is not practical to attempt to assign a monetary value to every ecological service provided by every parcel. Fortunately, the quality and quantity of ecological services can be measured using ecological units. This can be accomplished at a high level using metrics that are intended to capture the aggregation of ecosystem service flows from each broad class of ecosystem/habitat types. This is the approach taken for incorporating natural resources and ecological services into the City's Public Facilities Planning Process. The basic economic principles guiding quantification of ecological services are straightforward.

1. Choose ecological metrics that capture the valued functions and services of the natural resources. A higher score on the quality scale and a larger number of units corresponds to an increase in value.

2. Ensure that these metrics are sensitive to the actions or changes to be evaluated. The application of the metric facilitates a credible and defensible priority ranking of different quality parcels of similar type ecosystems.
3. Finally, establish that the ecological metrics are understandable to decision-makers and other stakeholders.

When properly planned and implemented, the NEBA approach provides a systematic, consistent, and defensible process that can significantly enhance stakeholder support for selected environmental and land use planning decisions.

Ecological Service Value Quantification

The methodology adopted for the high level quantification of valued ecological services is the habitat equivalency analysis (HEA) methodology, which is used to quantify the ecological service value associated with selected parcels of similar functionality and ecosystem type. The HEA methodology is supported by many Federal Agencies (NOAA, DOI, USFWS, and NRCS) and in Federal Court Rulings (USA vs. M. Fisher et al. 1997) as a valid approach for quantifying impacts and benefits of ecological services associated with various actions, including preservation. The origin of this approach is presented in the 1991 USEPA commissioned paper entitled "*Scientifically Defensible Compensation Ratios for Wetland Mitigation*," (King and Adler, 1991). The HEA methodology has also been used with multiple state regulatory agencies across the United States (California, Texas, New Jersey, South Carolina, Virginia, Indiana, Louisiana, Florida, Oregon, Idaho, Alabama, plus others). Several peer reviewed articles have been published discussing the merits and limitations of this approach (King and Adler, 1991; Mazzotta, et al., 1993; Unsworth and Bishop, 1994; NOAA, 1995; NOAA, 1997; NOAA, 1998; Fonseca, et al., 2000; Nicolette et al., 2001; Efroymson et al., 2004).

The HEA methodology values natural resource assets in terms of the discounted sum of valued ecological service flows over time. Specifically, to quantify ecological service flows it uses indicators to measure the functionality of the ecosystem as a percentage of maximum functionality per acre (or an alternate spatial measure). An acre of wetland that is fully functioning for one year receives a score of 100% and provides one service-acre-year (SAY) of wetland services. However, an acre of wetland that is functioning at 80% of maximum potential provides only 0.8 service-acre-years of wetland services. Looking to the future, in the baseline condition, these wetland acres will continue providing a flow of ecological services, which are similarly measured in terms of their anticipated level of functionality. However, just as with valuing any asset based upon the stream of benefits that it "pays" over time, the future "payments" are discounted to reflect the preference for receiving the benefits sooner rather than later. Thus the total ecological service value of a natural resource asset is found by taking the discounted sum of service acre years or DSAYs. In the case of the City, it is assumed that the planning horizon extends for 100 years. If the wetland were to be developed in the future, the subsequent flow of ecological services (i.e., the future discounted SAYs) would be diminished.

Ecosystem Services Evaluation for City of Damascus, Oregon

The scale and complexity of evaluation is a key component in the cost and practicality of an approach to quantifying ecosystem services. The Natural Capital Project undertaken by a consortium of academics has laid out a 3-tiered approach to ecosystem services evaluation, moving from landscape level to detailed and site specific, that is a helpful starting place in determining the scale or level of detail appropriate for a given purpose or situation (Natural Capital Project, 2009) Using the concept of a three-tiered approach the definitions used for the City of Damascus evaluation are:

- **Tier 1** is fundamentally simple, provides a relative sense of the level of services provided across the landscape, and uses readily available data from standard municipal planning efforts.
- **Tier 2** provides a level of certainty based on more site specific data on current and future expected habitat characteristics.
- **Tier 3** is more in-depth with inclusion of parcel level data on habitat type and specific characteristics of the ecosystem dynamics and plant community characteristics linked to measurement of a specific ecosystem service. It is time, data, and cost intensive.

The Public Facilities Plan is a vehicle for a Tier 1 assessment that will introduce the concept of ecosystem services and allow discussion and action to incorporate these values as part of City policy and procedure. More in-depth analyses of ecosystem services at the Tier 2 and Tier 3 level can then be undertaken in partnership with landowners, developers and agencies when the need for these increasingly higher levels of resolution arise. For example, in the future, this high level assessment can be augmented with detailed evaluations of specific ecosystem services that stakeholders target for active management. The City of Damascus is specifically concerned about the thermal quality of their streams to meet temperature total maximum daily load requirements. In order to reach and maintain water temperature targets, metrics and measurement methods specific to this goal must be developed. Accounting for such individual services on an as needed basis is considerably more manageable then attempting to comprehensively identify and measure all of the ecosystem services provided by each land parcel, stream mile, and lake area.

The Tier 1 evaluation used existing natural features inventory mapping and habitat quality assessment to identify the location of the City's natural resources by ecosystem type and to assess their relative function. Habitat quality assessments were based on collection of field data related to provision of specific ecosystem services. Table 1 lists the habitat types and the ecosystem services evaluated in the functional assessment and Table 2 shows how the assigned alpha designators for function (e.g. A for high; B for moderate, and C for low) were translated to numeric scores of a measurement of how well each habitat type is providing its ecosystem services. Where data were not available, an assessment based on ecological principals was made using various geographic information system (GIS) tools.

Each ecosystem parcel in the GIS database was then identified by type of ecosystem and assigned the functionality score to estimate the ecological services per acre per

year that are supported by that ecosystem parcel. These DSAYs were computed for each ecosystem parcel and included in the inventory. For this purpose, it was assumed that the parcel would remain in its existing condition into perpetuity, if undisturbed. For example, an evergreen forest rated as 'A' quality by the City's assessment team was assumed to be providing the ecosystem services of an evergreen forest at 75% to 100%; 'B" at 50% to 74% and "C' at 25% -49% into the future.

Table 1. Ecosystem Services by Habitat Type

Habitat Type	Associated Ecosystem Services
Evergreen Forest	Wildlife habitat Erosion control Hydrologic control Water quality
Deciduous and Mixed Deciduous Forest	Wildlife habitat Erosion control Hydrologic control Water quality
Wetlands	Wildlife habitat Fish habitat Water quality Hydrologic control
Riparian Corridors/Streams	Wildlife habitat Fish habitat Water quality Streamflow moderation/water storage (Hydrologic control) Biodiversity support
Non-built/Non-native Lands (pasture and agricultural lands primarily)	Wildlife habitat Water quality

Table 2. Habitat Functional Rankings from City of Damascus, Oregon Natural Features Inventory Translated to Measure of Ecosystem Service Function

Habitat Functional Rating	Percent Ecosystem Service Function
A	75 % to 100% (mid-point 87.5%)
B	50%-74% (mid-point 62%)
C	25% - 49% (mid-point 37%)

Table 3 shows a portion of the results of the HEA value quantification for the evergreen forest habitat type. In this example there are 164.2 acres of 'A' quality

evergreen forest. For year 1 the 164.2 acres is multiplied by the percent function for an 'A' quality habitat shown in Table 2, or 87.5%. This yields the service acre years (SAYS) value of 143.68. This is discounted by 3% annually yielding the discounted service acre years (DSAYS) of 139.5 for year 1. The sum of the DSAYS for the 100-year model run yields the net present value (NPV) of the DSAYS for evergreen forest of 'A' quality, of 4, 540 DSAYS. Dividing this by the number of acres (164.2) yields the value of 27.65 DSAYS per acre when valued for 100-years. Discounting the SAYS out into perpetuity yields a NPV of 4,789. Dividing this by the number of acres (164.2) yields the value of 29.17 DSAYS when valued on into perpetuity. As seen in Table 3 the DSAYS for all 164.2 acres at year 100 is only 7.5 as compared with 139.5 in year 1. At some point after 100 years the DSAYS will approach zero. The Perpetuity NPV column accounts for the sum of DSAYS beyond 100 years until they approach zero.

Table 3. Sample Discounted Service Acre Years Calculations for 100 Years and for Perpetuity for Evergreen Forest 'A' Quality Habitat

Evergreen Forest									
Calendar Year	**Year**	**Discount Rate**	**Acres A**	**Quality**	**SAYS[1,2]**	**DSAYS[1,3]**	**Cumulative DSAYS[4]**	**NPV DSAYS/ acre[1,5]**	**Perpetuity NPV DSAYS/ acre[1,6]**
2008	0	0.03	164.2	0.875				27.65	29.17
2009	1		164.2	0.875	143.7	139.5	139.5		
2010	2		164.2	0.875	143.7	135.4	274.9		
2011	3		164.2	0.875	143.7	131.5	406.4		
Etc.	*	*	*	*	*	*	*	*	*
2108	100		164.2	0.875	143.7	7.5	4,540		
NPV[1]					4,540				
Perpetuity NPV					4,789.2	Perpetuity NPV			

Notes:
[1] SAY = service acre years; DSAYS = discounted service acre years; NPV = net present value
[2] *Acres* X *% function* = SAYS
[3] $SAYS/(1 + discount\ rate)^{year}$ = DSAYS
[4] Sum of annual DSAYS (i.e. year 1 DSAYS + year 2 DSAYS = year 2 cumulative DSAYS etc.)
[5] Cumulative NPV DSAYS for year 100/ total number of acres = net present value of discounted service acre years per acre
[6] Perpetuity cumulative NPV/ total number of acres = net present value of discounted service acre years per acre

Preservation of Ecosystem Services

Regulations or flexible ordinances, land acquisitions, conservation easements, and tax incentives are some of the tools that the City of Damascus can use to protect and conserve the public goods provided by their natural resources while providing for growth and development. Traditional conservation programs are not likely sufficient to safeguard the natural landscapes and traditional markets may not provide landowners with a sufficient economic incentive to own and sustainably manage their privately held lands for public benefits. To prevent the indiscriminate loss or degradation of ecosystem services, the City has the opportunity to incorporate into any decision-making the value of ecosystem services and to provide economic and financial motivations for conservation of high valued services (Cowling, 2008).

Mechanisms are being explored by which private landowners can seek returns on their land *in addition* to or in place of those commonly associated with urban uses. The ability to capture the financial value of ecosystem services may help landowners who currently do not benefit from the true value of their land and all of the goods and services their natural resources provide. Because ecosystem services are not traded and do not have a "price," landowners are not typically compensated for the critical benefits their land naturally deliver to the public. New natural revenue streams might help owners cover the costs of owning natural lands and provide them with incentives to hold onto their land in lieu of selling or developing. Valuing ecosystem services will encourage preservation and restoration and may provide a new means to finance these activities.

The Tier 1 ecosystem service assessment provides a screening level valuation that can form the basis for a scaled assessment fee for all City lands or to value lands for purchase of their ecosystem service value. Developers would be charged a fee for loss of the NPV DSAYS of their given property or required to purchase equivalent NPV DSAYS to compensate for loss of services. If a fee were assessed the City could use this revenue to purchase the development rights or conservation easements of high ecosystem service values lands, or to fund restoration efforts. Using the evaluation of NPV DSAYS completed for the City, the per acre NPV DSAYS of 29.17, shown in Table 3, can be used to quantify the lost ecosystem service value of developing anywhere from 1 to 164.2 acres of 'A' quality evergreen forest or to establish the acres of 'B' or 'C' evergreen forest necessary for restoration to an 'A' level as compensation for lost 'A' quality evergreen forest ecosystem service values.

Conclusion

The City Planners of Damascus, Oregon are charting new territory in their attempt to include the services that the region's natural assets provide their citizens into their Public Facilities Planning. Implementing a fair and equitable system for regulation of these areas or development of effective incentive based programs is challenging and as yet, untested. The goal is a practical integration of ecosystem services into decision-making, in a way that is credible, replicable, scalable, and useable. There remain many challenges to understand how human actions affect ecosystems, the provision of ecosystem services, and the value of those services, but the Tier 1 assessment provides a screening level valuation that can form the basis for

preservation of ecosystem service values. The City still faces the challenges associated with incorporating this understanding into effective policy that accurately reflect the social values of ecosystem services to its citizens (Daily, 2008)

ABSTRACT

Increasing demand for conservation of water resources has prompted the notion that the separation of graywater (all wastewater not including toilet and kitchen sources) from sewer effluents through the use of dual-plumbed systems may enable graywater to be reused. Constructed wetland systems for conditioning combined wastewater effluents are widely used, and offer an efficient solution for onsite wastewater treatment of a variety of pollutants. However, limited long-term research has been conducted to determine the effectiveness of such systems specifically on graywater. This paper aims to determine the viability and efficiency of constructed wetlands for graywater treatment, and assess the water quality produced from such systems. The experimental method involves monitoring of specific water quality constituents under varying operating conditions in a prototype constructed graywater wetland. Preliminary findings show the wetland significantly reduces many graywater contaminants including pathogens, biochemical oxygen demands, solids, and nitrogen and phosphorus species.

INTRODUCTION

Conventional wastewater management practices collect all used indoor water into a single pipe leading to the sewer and treat it at a wastewater treatment plant. Mounting pressure to conserve water supplies, however, has lead to the suggestion that the separation of wastewater at its source may enable graywater to be reused for such non-potable uses as landscape irrigation and toilet flushing.

Graywater Quantity and Quality Characterization

A general definition of graywater is any residential wastewater which has not come in contact with toilet water. This definition is restricted in the United States where graywater is defined as wastewater not originating from toilets, kitchen sinks, or dishwashers, and that is produced in showers, bathtubs, sinks, and cloths washers (Roesner et al., 2006).

An American Water Works Association (AWWA) sponsored study of water usage in 14 North American cities found that on average over 50% of all residential indoor water demands generate graywater (Mayer et al., 1999). This same study showed that outdoor irrigation constituted the largest of all total residential potable water demands, and that while highly variable depending on geographical location, on average over 50% of all residential potable water is used for landscape irrigation. Considering this large demand and the fact that the source water for outdoor irrigation water need not be of the same quality as indoor potable water, reusing graywater for outdoor irrigation offers a substantial and attractive water savings. In addition to landscape irrigation, recycled graywater is a potential source for other demands not requiring potable source water such as toilet flushing.

Graywater recycling in Europe and Australia is gaining in popularity; however, in the U.S. the practice is not yet commonplace. The degree to which graywater reuse can reduce household potable water demand is variable depending on geographical location, landscaping preferences, and personal water use habits. Rose, 1991; Karpiscak, 1990; and the City of Los Angeles, 1992 among others have estimated that reusing graywater for outdoor irrigation and toilet flushing could reduce household water demand by 25 – 50%.

The chemical, physical, and microbial qualities of graywater are highly variable depending on the source, and are influenced by many factors including the number of household occupants, types of cleaners and personal care products used, grooming and hygiene habits, and sink waste disposal practices (Eriksson et al., 2002). Concentration ranges for common water quality constituents and pathogen indicators compiled from three studies are listed in Table 1.

Constructed Wetlands

Constructed wetlands are treatment systems that replicate natural wetlands to improve water quality through physical, chemical, and biological treatment mechanisms (Kadlec and Knight, 1996), and are commonly employed to treat municipal wastewater (Metcalf and Eddy, 2003; U.S. Environmental Protection Agency (USEPA), 1999; Hammer, 1989). Not only can constructed wetlands provide important water quality improvements with low energy and maintenance requirements, they can also offer pleasing aesthetics, ecological benefits, and wildlife habitat (USEPA, 1999).

While treatment wetlands have been shown to effectively treat whole wastewater, their effectiveness in treating graywater has had limited research, especially in the United States. However, past studies involving graywater wetland treatment have shown promising pollution removal efficiencies (Dallas, 2004; Gross, 2007; Frazer-Williams, 2005).

Constructed wetlands can take on various designs, with two of the most common being the free water surface (FWS) and the subsurface flow (SF) wetland. FWS wetlands closely resemble natural wetlands in both appearance and function, and

feature elements typical of a natural wetland such as emerging vegetation and open-water areas (USEPA, 1999). SF wetlands, on the other hand, resemble natural wetlands very little, but instead contain a bed of media such as gravel or sand in which aquatic plants are rooted. Water passes through the media and root zone, but is not exposed to the surface, and is therefore not visible or accessible by humans or wildlife.

MATERIALS AND METHODS

Wetland Design

To evaluate the potential of graywater wetland treatment, a prototype graywater wetland and two dual-plumbed facilities were constructed at Colorado State University. The graywater wetland is a tandem wetland system consisting of a FWS wetland cell followed SF wetland cell. The combination of both a FWS and a SF wetland type was designed to enhance water contaminant removal, and to allow for each wetland type to be evaluated individually. Out of initial public safety concerns, effluent from the prototype system is currently routed to a sanitary sewer; however, future plans call for the effluent to be reused for non-potable demands.

FWS and SF wetland cells are arranged in series with the FWS being upstream of the SF (Figure 1) so that the FWS provides the bulk area for sediment settling and prevents clogging of the gravel matrix in the SF. Also, since the FWS is exposed to the atmosphere and the SF is not, having the FWS upstream of the SF also allows an aerobic/anerobic flow progression. The wetland includes flow distributing and collection headers to prevent flow short circuiting, diversion berms to prevent surface water runoff intrusion, and impermeable liners to restrict groundwater flux.

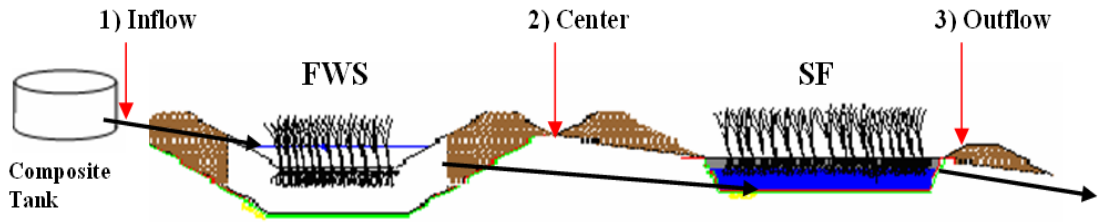

Figure 1: Graywater wetland schematic and sampling locations.

Graywater is provided to the wetland system from several of sources: lavatory sink water from a dual-plumbed office/laboratory facility, lavatory sink and shower water from a residential dormitory, and whole graywater (all wastewater except toilet and kitchen sources) from a single-family residence. Graywater from the office/laboratory facility is piped directly to the wetland. Graywater from the dormitory and residence is collected in batches onsite and hauled to the wetland where it is dispensed via metering pump. Hauling graywater proved necessary since the office/laboratory facility is not yet fully occupied and does not produce the flow rate of graywater desired. Hauled graywater is mixed with the graywater stream from the office/laboratory building before flowing to the wetland. A storage tank is provided just upstream of the wetland inlet, which is sized to collect approximately one day's flow volume, and it thus used to collect a daily composite of inflow.

Common Cattails (*Typha latafolia*) are planted in the FWS cell, and have been established since September, 2007. The SF is planted with Hardstem Bulrush (*Scirpus acutus*), which have been established since June, 2008.

Flow and Water Quality Monitoring

Flow and water quality measurements are made at three locations (Figure 1): the inflow to the FWS at the composite tank (Site 1; raw graywater influent), between the FWS and SF (Site 2; center; FWS effluent/SF influent), and the outflow of the SF (Site 3; system effluent). Site 1 is taken from the composite tank, and represents a daily composite. Sites 2 and 3 are located in manholes and are not composited.

Flow meters are located at each sampling site. The flow metering system features a dosing vessel that collects inflowing water until it is full, at which time a pump is activated which pumps the water through an inline, turbine flow meter. This design is necessary to accommodate the low flows produced by the office/laboratory building (down to 19 L/day), while being capable of handling large flow events (as in the case of heavy precipitation entering the wetland) with high solids concentrations. No data

recording hardware is used; instead, readings of the cumulative flow at each location are collected manually, and the flow computed as the difference in cumulative flows from two sequential readings divided by the time between readings. A counter switch is provided to count the number of times the dosing vessel fills and empties, which can be used in redundancy to compute flow.

Sampling was conducted starting in September, 2008. Sampling commenced weekly for four weeks, after which samples were collected every three weeks. Water quality measurements evaluated the physical, chemical, and biological composition of the raw and treated graywater (Table 2), and included measurements of the solids, carbon, nitrogen, phosphorus, and pathogen indicator content of the water. These measurements were chosen to evaluate the wetlands' treatment efficiency in removing such constituents, as well as determine the quality of the effluent produced from the system. In addition to the measurements listed in Table 2 other water quality measurements have been commenced to test for different pathogenic indicator species and trace organics. Standard analytical methods (Eaton et al., 1998) were used for all analyses, and quality assurance samples (blanks, duplicate analyses, and standards) were analyzed at a rate of 10%.

Table 2: Water quality measurements and analytical methods used to determine the treatment performance of the graywater wetland system.

Parameter	Analytical Method	Standard Method #
Ammonia	Ion Selective Electrode	4500-NH_3 D
5-day Biochemical Oxygen Demand (BOD_5)	5-day; Dissolved Oxygen Probe	5210 B
Dissolved Oxygen (DO)	Membrane Electrode	4500-O G
E. Coli	Enzyme Substrate	9223 B
Nitrate	Ion Chromatography	4110 B
Orthophosphate	Ion Chromatography	4110 B
pH	Potentiometric Probe	4500-H^+ B
Specific Conductivity	Electrical Conductivity	2510 B
Temperature	Thermometer	2550 B
Total Dissolved Solids (TDS)	Gravimetric, Dried at 103-105 C	2540 C
Total Nitrogen (TN)	UV Persulfate Digestion and Oxidation w/ Flow Injection	4500-N B
Total Organic Carbon (TOC)	Heater-Persulfate Oxidation	5310 C

Total Suspended Solids (TSS)	Gravimetric, Dried at 103-105 C	2540 D
Turbidity	Nephelometric	2130 B

RESULTS

Flow Monitoring

During the sampling period, graywater inflow to the wetland system averaged 318 L/day (Site 1, Figure 2). This inflow rate is averaged over two distinct periods. Prior to December 11, 2008 hauled graywater was collected from the dormitory and the average flow rate of inflow was 346 L/day. After December 11, the dormitory was unoccupied, graywater was collected from the single family residence, and the inflow averaged 154 L/day. For the entire monitoring period, flow between the FWS and SF wetlands (Site 2) averaged 282 L/day, and the system outflow (Site 3) averaged 245 L/day. Differences in flow rates between monitoring stations result from precipitation additions and losses attributed to seepage over the wetlands' liners and evapotranspiration. Losses diminished as weather cooled and the vegetation became dormant.

Wetland volumes were used to compute the hydraulic residence times (HRTs) in each wetland cell. The FWS volume was estimated at 2.0 m^3, assuming a porosity of 0.8 for the established cattails. SF volume was 2.9 m^3 assuming a porosity of 0.3 for the gravel and plant root matrix. Using these volumes and the average flows previously given, an average HRT of 6.3 days and 10.3 days were computed for the FWS and SF cells respectively over the entire monitoring period.

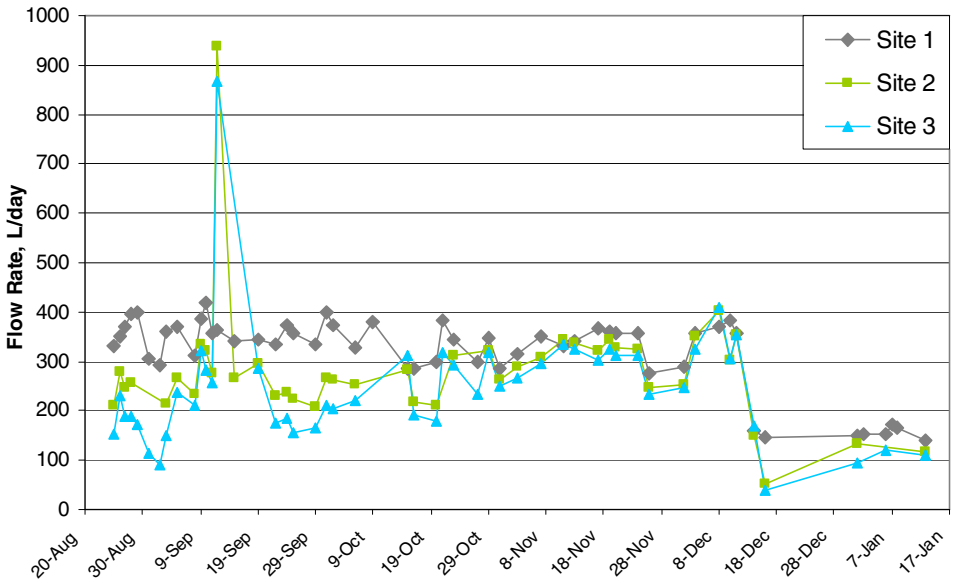

Figure 2: Flow rates measured at the graywater wetland system. The large flow rate increase at Sites 2 and 3 on 9/12/08 results from a precipitation event.

Water Quality Monitoring

Nine water quality sampling events were conducted over the monitoring period. All sampling sites were monitored during each sampling events except the first two; to allow for steady state conditions, Sites 2 and 3 were omitted from the first sampling event and Site 3 was omitted from the second event. Selected water quality measurements are presented subsequently (Figure 3 and 4; Table 3).

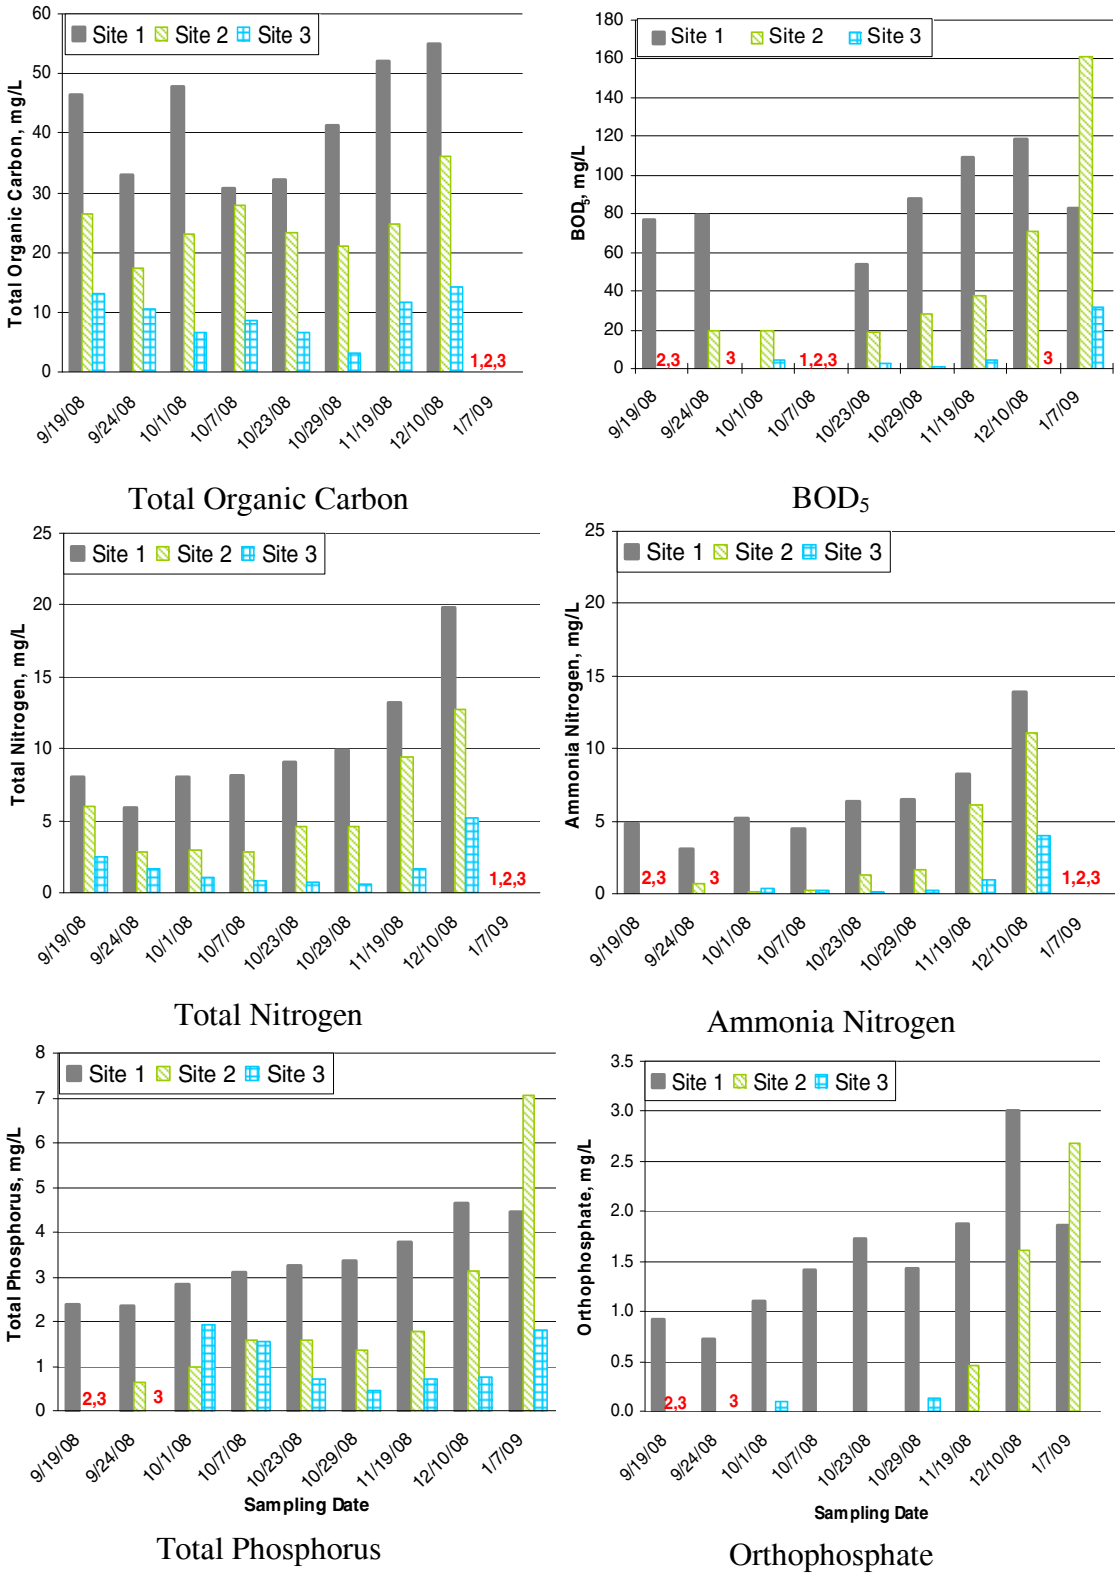

Figure 3: Average concentrations of carbon, nitrogen, and phosphorus water quality constituents at three sampling locations in the graywater wetland taken over nine sampling events. Numbers in red represent erred or omitted measurements.

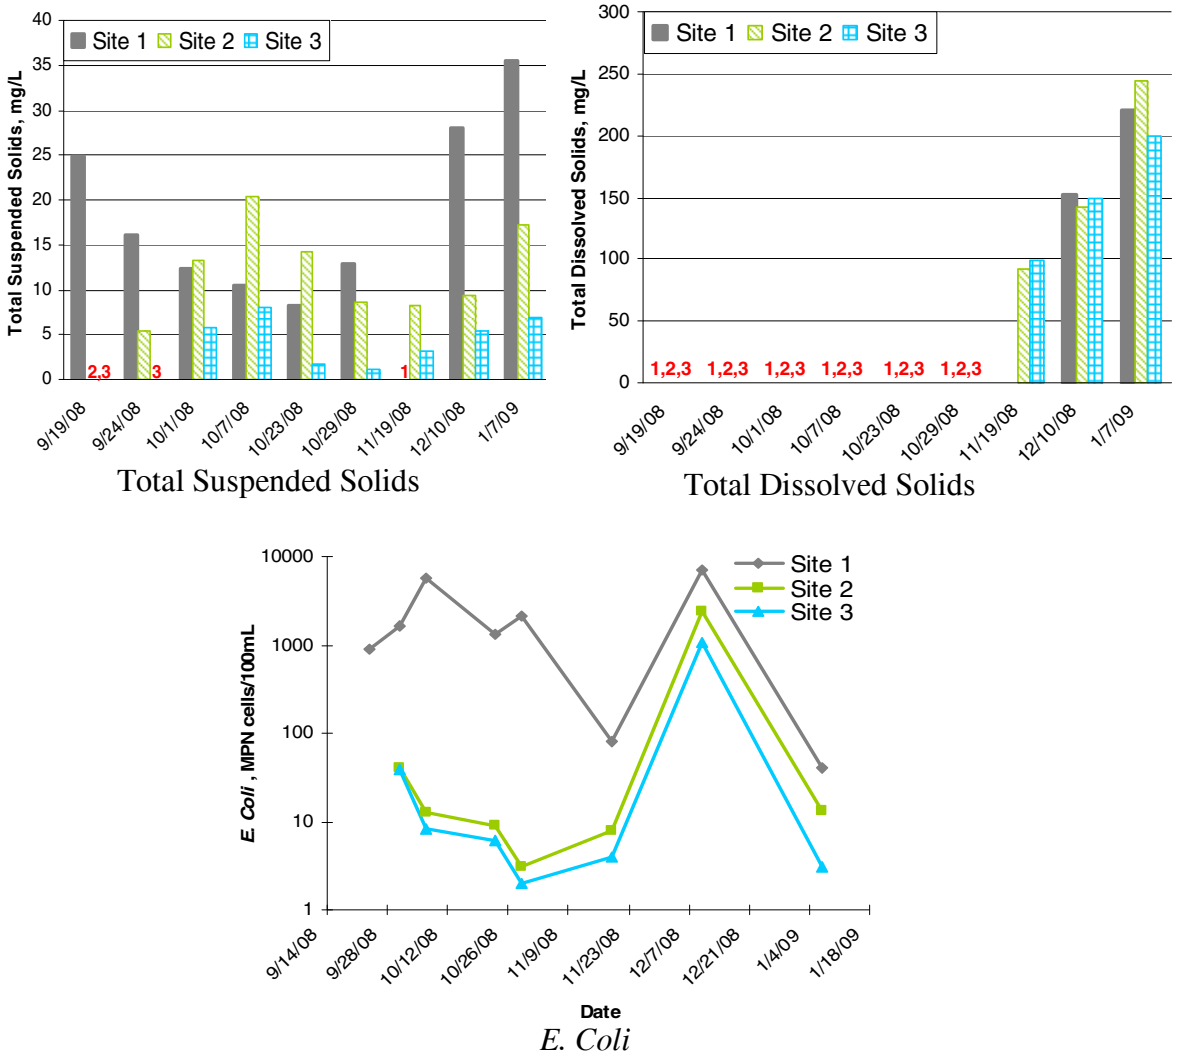

Figure 4: Average values of solids and pathogen indicator measurements at three monitoring locations in the graywater wetland. Red numbers represent erred or omitted measurements.

Table 3: Field measurements taken at graywater wetland.

		Site 1	Site 2	Site 3
Dissolved Oxygen, mg/L	Range	0.02 - 0.17	0.89 - 5.46	0.82 - 2.96
	Mean	0.11	2.65	2.18
pH	Range	6.0 - 6.7	6.3 - 6.9	6.3 - 6.8
	Mean	6.3	6.7	6.5
Specific Conductivity, uS/cm	Range	197 - 348	235 - 409	256 - 404
	Mean	232	276	299
Turbidity, NTU	Range	8.1 - 58.2	5.6 - 46.0	1.5 - 18.5
	Mean	27.4	17.7	7.9

Removal efficiencies were computed for each wetland cell and for the total system (Table 4), and were calculated from the average concentration values for all sampling events. Pathogen levels were shown to decrease approximately 0.8 and 0.4 orders of magnitude on average through the FWS and SF wetlands respectively. Removal efficiencies for all constituents were generally greatest in the FWS.

Table 4: Average removal efficiencies of various constituents in the graywater wetland. Values presented exclude the January 7, 2009 sampling event.

	FWS	SF	Total
BOD_5	63%	33%	96%
TOC	41%	37%	78%
TN	44%	39%	83%
TP	50%	18%	68%
Turbidity	42%	31%	73%
TSS	30%	44%	74%
E. coli	85%	9%	93%

DISCUSSION

As determined from repeat water quality analysis in the prototype wetland, treatment of graywater via constructed wetlands demonstrates great potential. Effluent water has shown to be of the quality suitable for reuse, as in the case of *E. coli* levels, which were shown to be below recommended single-sample levels for primary contact waters according to USEPA, 1986 for all but one sample. It should be noted that the one sample out of compliance was taken while significant ice had formed on the wetlands, greatly reducing the wetland's HRT. This problem is only expected in the winter when graywater reuse for irrigation is not needed.

Water quality monitoring is expected to continue through 2009, which should shed light on the long-term performance of the graywater wetland. Expanded water quality analysis, including those of additional pathogenic indicators and trace organics will further evaluate the graywater wetland's treatment potential.

Abstract

Compounds of nitrogen and phosphor in wastewater treatment plant effluents have caused serious and even dangerous problems including incidence of methemoglobinemia in new born babies as a result of consumption of water contaminated with nitrate and also nitrification in surface water. Various processes and methods at different scales have been used with the aim to remove effectively such compounds so as to prevent the potential of harmful and dangerous incidences mentioned above at its lowest level. One of these processes is the use of A^2/O (Anaerobic, Anoxic, Oxic) in activated sludge process. The purpose of this process undertaken in a pilot system is removal of carbon and phosphor over 90 percent and also reduction of nitrogen density in effluent in MLSS.

Keywords: Nitrification, Denitrification, A^2/O process, activated sludge, nitrogen and phosphor removal

1. Preface

Urban wastewater treatment plants were established in the past mainly with a view to remove organic pollutants, suspended materials and microbic contaminants. As the effects of nitrogen and phosphor compounds in water (mainly ammoniac poisoning, high growth of water plants and formation of nitrification, contamination of underground water by nitrate) and also incidence of methemoglobinemia disease in new born babies all of these have resulted in restricting density of such compounds in effluents flowing in the environment and also flowing into water streams. The main example of the effect of such pollutants entering the environment are the nitrification phenomena in the Caspian sea (fig. 1) and incidence of methemoglobinemia disease (fig. 2)

Figure 1. Formation of nitrification phenomena in the Caspian sea (green areas)

Figure 2. Child afflicted with methemoglobinemia disease or blue baby.

Consumption of water containing more than 50 mg/l nitrate ion, specially in children, causes methemoglobinemia due to compound of this ion with blood hemoglobin. This compound prevents oxygen reaching the tissues resulting in local suffocation and ultimately in death. On the other hand due to low bowel acidity of children (normally bowel acidity of children is more than 4.9) the bacteria transforming nitrate to nitrite have high activity and nitrite compounds with hemoglobin to form methemoglobinemia causing death. It is essential therefore that, in designing urban wastewater treatment plants (WWTP) to take into consideration the amount of such compounds and to eliminate compounds of nitrogen and phosphor in designing WWTP up to the standard level. To reach the standard level it is necessary to remove both nitrogen and phosphor. The biological process for removal of these pollutants easily compound with activated sludge. In all such processes the basic components are similar and include anaerobic, anoxic and aeration, their difference being in the number of components, their order and places of flow return [1]. One of these processes is A^2/O which is used when it is necessary to remove ammoniac alone (nitrification), or to remove nitrogen (nitrification-denitrification). In this process and

anoxic area locates between anaerobic and aerobic zones causing removal of ammoniac and reduction of nitrate charge present in sludge returned to anaerobic chamber. Because due to this area some of the nitrogen is eliminated under removal of nitrate this process improves phosphor elimination. Because presence of nitrate in returned sludge incoming to the anaerobic chamber causes slow down of phosphor removal process. By return of the solution mixed nitrified from aeration chamber, the oxygen present in the chemical compound is added to it in the form of nitrate or nitrite. The expected concentration of phosphor without being filtered is less than 2 mg/l. By filtering the outlet effluent, phosphor concentration could be less than 1.5 mg/l. The most important advantage of the A^2/O process can be described briefly as follows:

- Useful in high loading
- Sludge fertilizer value with high phosphor content (3-5%)

The only disadvantage of this process is its unreliability in cold weather where the anoxic/oxic A/O removal of phosphor only is more complex [3]. The schematic diagram of the process is shown in the following figure. The primary principle of the process in given below, and the pilot system used together with the results obtained is discussed below.

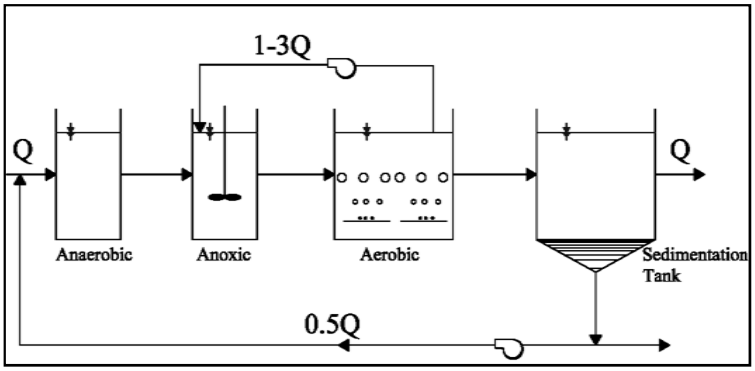

Figure 3. A^2/O process scheme [1]

2. Acquaintance with the primary principle used in A^2/O process compared with the usual activated sludge

Phosphor in wastewater is seem as orthophosphate (PO_4^{-3}) polyphosphate (P_2O_7) and phosphor organic compound, the last two compounds comprise up to 70% of the input phosphor. The microbes during cell synthesis and energy transformation consume phosphor. As a result 10-30 % of the inlet phosphor is separated in secondary biological treatment. But the main reason for success in biological phosphor separation is rendering microorganism alternatively in anaerobic an aerobic conditions. When the microorganisms are put alternatively in anaerobic and aerobic conditions, they are more agitated thus their consumption of phosphor is more than

normal. Phosphor is consumed not only for cell protection, synthesis and energy transformation but it is also reserved for later consumption of the microorganisms.

In urban wastewater, mainly of the residential type, nitrogen is found in the form of or organic and ammonia. This compound is the waste as a result of protein metabolism in human body. In fresh wastewater about 60% of nitrogen is in organic and 40% in ammonia forms. As a result of bacterial break-up (analysis) of the protein and urea hydrolyze compound, the organic nitrogen is converted to ammonia nitrogen. Normally, in fresh wastewater small quantity (less than one percent) nitrogen is found in the form of oxidized nitrate or nitrite.

Organic nitrogen present in untreated wastewater is changed to ammoniac by way of bacterial analysis of protein and ureas hydrolyze. In any biological treatment system, some bacteria growth take place, because 12-13% of the cell dry mass is composed of nitrogen, some ammoniac nitrogen is absorbed by the new cells. Also, self-oxidization and the cells becoming slippery would depend on the treatment process and the loading conditions. Thus, a protein of the ammoniac used for the cell synthesis is returned back again to the wastewater by way of becoming slippery and self-oxidization. The remaining absorbed nitrogen can be removed as pure growth or disposable biological sludge.

The main point in removal of both phosphor and nitrogen compound is the amount of dissolved oxygen in the wastewater. As can be seen in figure 4, in the (a) condition, the low dissolved oxygen concentration and F/M ratio, all the flocs are aerobic and the nitrification process continues by maximum speed. In the (b) condition, due to high F/M ratio, the oxygen consumption is higher, therefore nitrification process is halted. In (c) condition, by increasing the dissolved oxygen concentration together with higher F/M ratio, oxygen penetration is higher resulting in increased nitrification process rate.

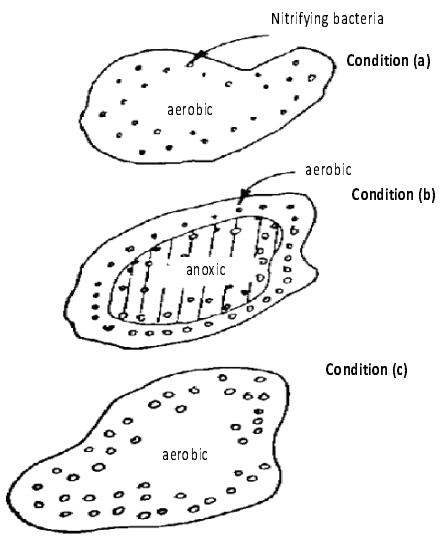

Figure 4. the effect of F/M ratio on nitrification process

Biological transformation of nitrate in more deoxidized forms, such as NO, N_2O, N_2 is called denitrification. This process is conducted by various facultative heterotrophic organisms (contrary to nitrification process microorganisms which are autotrophic), which can use nitrate instead of oxygen as final electron recipients. Analysis of carbon containing organic compounds in the denitrification process is similar to what takes place in aerobic process, the only difference being in the final stage of electron transformation. Consequently the term denitrification without oxygen is more suitable than anaerobic. This shows that in denitrification system a complete anoxic condition (DO concentration between 0.1-1 mg/l) is necessary.

3. The pilot system used in this experiment

With a view to study comparatively the presented data and more fully the A^2/O process and its effective role in elimination of pollutants a pilot system was set up on batch basis as shown in figures 5 and 6.

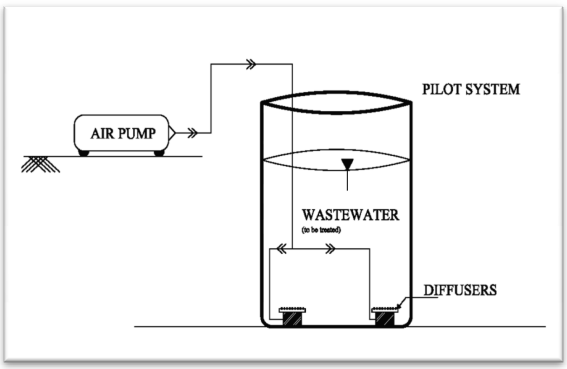

Figure 5. scheme of the pilot system

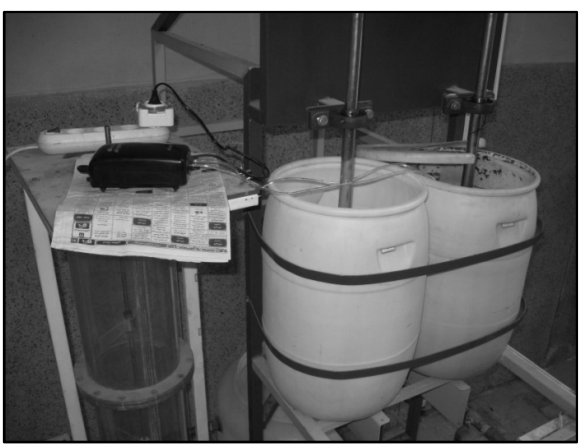

Figure 6. pilot system

The pilot specification is as follows:

Treatment pond with a capacity of 30 lit, aquarium air pump with a capacity of blowing max. 4.5 lit/min, mechanical timer. Aquarium hose and aeration stones as diffusers for air blowing.

In this study, the Tehran Ghaytarieh wastewater treatment plant returned sludge and also the raw wastewater after the screen bars has been used as raw wastewater. By adding phosphate and nitrate fertilizers and vinegar in the pilot pond, the concentration of the pollutants is increased, up to the desired level. As per the schedule anaerobic, anoxic and aerobic phases were set up. Then BOD, COD, PO_4, MLSS factors and also the nitrate were analyzed.

4. Findings

During the experiment, at various inflow concentration and retention time, results were obtained, according to the following tables. The various retention times and the influent and effluent of the treated wastewater are shown.

Table 1. experiment #1, (time left to right)

Phase	Anaerobic& anoxic	Oxic	anoxic	Oxic	anoxic	Oxic	Settling

Time (hr)	2		2	0.5	2	2

Table 10. experiment #5 results

Parameter	BOD	COD	PO4
Influent	200	240	4
Effluent	44	58	2

The first experiment indicates the effects of A^2/O process in removing the said pollutants. The amount of BOD and COD in the inflow proves low level pollution. As a matter of fact, the amount of carbonic source required to the removal pollutants was at an acceptable level. In the second and third experiments, the aeration is reduced gradually. In other words, the duration of aeration in further steps is reduced. This reminds us of the oxidization streams by tapered aeration. The amount of removal phosphate in the second experiment with a total aeration time more than two hours than the third experiment (14 hours against 12 hours) was a difference of seven percent. It may be noted that the effluent phosphate concentration in both

experiments was at the standard level recommended by the environmental department. The efficiency of this process in phosphate removal can be seen. As regards BOD and COD elimination, the same result is obtained and the difference in the two experiments is negligible. As a result the experiment shows that in longer aeration period, the removal of pollutants takes place more slowly, which means in case it is necessary to remove pollutants at a high level the cost should be high. As regards the amount of nitrate at nitrification stage which takes place at the aeration phase, an increased amount of nitrate is seen. The same case holds true in Tehran Zargandeh WWTP comparing the inflow and outflow whether at contact and stabilization and whether at extended aeration.

In experiment four and five, the main reason for selecting low period aeration was to experience the special condition of treatment. For example, in critical situation such as sudden electricity failure or a change in the inflow volume to the treatment plant (in most treatment plants there are bypass canals, but the canals may not be usable due to any reason), complete aeration of wastewater may not be possible. Moreover, it was required to determine the lower level of treatment so that by comparing it with the results of the other experiments the optimum aeration period and the number of aeration replication could be determined in a defined condition.

The dissolved oxygen concentration in all the experiments in the aeration period was about 2.5 to 3 mg/l and in anoxic period it was less than 1.5 mg/l.

Increase in nitrate concentration means oxidization of ammonia nitrogen. In case the effluent is in a situation lacking oxygen, denitrification process would occur, freeing nitrogen gas thus reducing the danger of nitrate in the effluent to surface water. the amount of MLSS in all experiments was about 2500 mg/l which is acceptable in normal WWTPs.

5. Conclusion

Considering that all the samples were analyzed in the Power and Water University of Technology laboratory, the function of A^2/O process in removal of phosphate and conversion of ammonia nitrogen to nitrite and then to nitrate can be seen.

With two hours aeration in the fourth experiment the amount of BOD was reduced from 133 to 44 mg/l. (67% removal) by doubling the aeration period that is by exposing wastewater to aeration for four hours, amount of BOD is reduced from 200 to 44 (78% removal). In other words, elimination of 70 to about 80 percent BOD can be attained fast and with rather low energy consumption. Should it be required to remove over 90 percent BOD, the aeration period would be approximately ten to fourteen hours. Elimination of phosphate to 90% has been experienced, one of the reasons being lack of nitrogen compound in the returned sludge (as the process here was not continuous). As described in the beginning, presence of nitrate in returned sludge is the reason for reducing the phosphate removal rate.

As regards other factors, the amount of microorganisms or MLSS can be mentioned. In case the amount of MLSS is increased and supposing the amount of BOD is stable during the same period of time, the amount of F/M is reduced, indicating increase of microorganisms compared to organic materials (food). Consequently, there would be more possibly of tread bacteria overtaking the round bacteria, causing the bulking of the sludge.

ABSTRACT

This project involved the design, operation, and testing of a bench-scale ozonation wastewater treatment system. Untreated municipal and industrial wastewater was collected from the influent chamber to the Rocky Creek Wastewater Treatment Plant (WWTP) in Macon, Georgia. The industrial wastewater consisted of paper mill effluent from the Graphic Packaging Plant adjacent to the Rocky Creek WWTP. The Rocky Creek WWTP treats wastewater in an extended aeration activated sludge process. To accomplish this research, a 10-liter clear PVC, semi-batch, bubble column was used to disperse ozone bubbles through a porous diffuser near the bottom of the column. Three 24-hour runs were conducted on each type of wastewater. The ozone was administered at loading rates of 0.60, 4.70, and 9.92 mg O_3/min, respectively, to 6 liters of either raw municipal or industrial wastewater. The following parameters were measured frequently during each 24-hour run: pH, chemical oxygen demand (COD), ammonia, nitrite, nitrate, phosphorus, conductivity, turbidity, total suspended solids (TSS), volatile suspended solids (VSS), total dissolved solids (TDS), and total volatile solids (TVS). Overall COD removal for the municipal and industrial wastewater averaged 82% and 84%, respectively, whereas, overall TSS removal averaged 83% and 81%, respectively. The ozonation degradation rate constant (K_D) based on TSS destruction ranged from 0.054 hr^{-1} to 0.072 hr^{-1} for the municipal wastewater and from 0.017 hr^{-1} to 0.066 hr^{-1} for the industrial wastewater.

BACKGROUND

Ozone is a powerful oxidizing agent that has been primarily used for disinfecting drinking water. In recent years, its use has been expanded and several applications for the treatment of municipal and industrial wastewater have been studied. Much of the research has focused on minimizing the quantity of sludge or biosolids produced at wastewater treatment plants (WWTPs). More recently, the pre-

treatment of wastewater and waste activated sludge (WAS) with ozone to enhance biological degradation in follow-up processes has been of much interest. Gonzalez et al. (2003) evaluated the combined sequential ozonation, activated carbon treatment, and aerobic biological treatment of a pulp bleaching effluent containing aromatic contaminants. Ozonating raw pulp effluent for 5 minutes at a rate of 2 mmol of ozone per minute decreased the average chemical oxygen demand (COD), five day biochemical oxygen demand (BOD_5), and total organic carbon (TOC) by 21%, 3%, and 18%, respectively. The BOD_5/COD ratio increased from 0.36 to 0.44 making the industrial wastewater more biodegradable. Pre-treatment of a textile finishing wastewater for 30 minutes at an ozone dosage of 18.5 mg/L resulted in overall removals of 64%, 39%, and 86% in total COD (TCOD), filtered COD, and color (Eremektar et al., 2007). Alvarez et al. (2005) indicated that pre-treating cherry stillage (high-strength organic wastewater generated from the manufacture of alcoholic products) at an ozone dose of 25 mg O_3 per gram of initial COD resulted in over 75% of raw polyphenols being removed and less than 5% overall COD removal. Dogruel et al. (2003) reported that complete color removal and a 21% reduction in TCOD were achieved by ozonating a textile wastewater at a rate of 62 mg O_3/min for 15 minutes. However, they also indicated that increasing the ozone contact time to 30 minutes only increased the COD removal to 32%.

Experimental results presented by Park et al. (2003) showed that an overall mass reduction of 70% and volume reduction of 85% was achieved by ozonating waste activated sludge at a dose of 0.5 gram of ozone per gram of dried solids (DS). Two main mechanisms were discussed in regard to biomass degradation: disintegration due to cell destruction of suspended solids in the sludge and subsequent oxidation of soluble organic matter into carbon dioxide. At an ozone dose of 0.5 g O_3 per g of DS, the mineralized, disintegrated solids, and residual biosolids fractions were 20%, 46%, and 34%, respectively. Pre-treatment of WAS at ozone dosages of 0.10 and 0.16 g O_3 per g of total solids (TS) was evaluated by Bougrier et al. (2006). Between 20% and 25% of the particulate fraction of the sludge solids was converted to a soluble fraction at these dosages.

MATERIAL AND METHODS

A 10-L, clear PVC, semi-batch bubble column was used for treating raw municipal wastewater and raw industrial wastewater with ozone. A peristaltic pump (Master Flex, Cole Parmer) operating at 290 ml per min provided a continuous recycle around the column to keep the contents of the bubble column well mixed and to suppress foaming. Untreated domestic and industrial wastewater samples were obtained from the influent structure to the Macon Water Authority's Rocky Creek WWTP, Macon, Georgia. The Rocky Creek WWTP uses an extended aeration activated sludge process for treating municipal wastewater. The influent structure is constructed such that the industrial wastewater does not mix with municipal wastewater and is treated in a separate train at the facility. Ozone was supplied by an Ozotech, Incorporated ozone generator (Model OZ1BTUSL). Table 1 provides a summary of the ozone application rates used during each run. Three different ozone

application rates were achieved by adjusting the rheostat setting on the ozonator to 40%, 70%, and 100%, respectively, resulting in application rates of 0.60, 4.70, and 9.92 mg O_3/min. The initial volume of wastewater added to the bubble column was 6.0 liters. The operating temperature of the bubble column reactor was maintained between 18 and 20°C.

During the 24-hour ozonation period, samples were withdrawn from the column at each of the following times: 0, 5, 10, 30, 60, 120, and 1,440 minutes. For each sample, the following analyses were performed: chemical oxygen demand (COD), soluble chemical oxygen demand (SCOD), total suspended solids (TSS), total volatile solids (TVS), total dissolved solids (TDS), volatile suspended solids (VSS), and pH. Also, the final concentrations of ammonia, nitrite, nitrate, and phosphate were determined at the end of the 24-hour run.

The ozone generated by the Oztech generator was quantified according to Standard Methods 2350 E, a titration method utilizing a 0.005N sodium thiosulfate solution. COD was quantified colorimetrically by HACH method 8000 utilizing the HACH DR/2000 spectrophotometer. Solids analyses were conducted in accordance with Standard Methods Sections 2540 B, D and E.

Table 1. O_3 Application Rates and Contact Time.

Semi-batch Bubble Column	Ozone Application Rate Used (mg O_3/min)	Contact Time (days)
Run #1	0.60	24
Run #2	4.70	24
Run #3	9.92	24

RESULTS AND DISCUSSION

pH. Figure 1 is a plot of pH versus ozonation time for the municipal wastewater runs. The initial pH of the municipal wastewater was approximately 7.0 at the start of each run and increased during the first 30 minutes of ozonation to between 7.5 and 7.8. At the lowest ozone application rate of 0.60 mg O_3/min, the pH increased to 7.9 at 120 minutes before decreasing to around 6.9 at the end of 1,440 minutes (24 hr). For the higher ozonation application rates of 4.7 and 9.92 mg O_3/min, the pH of the wastewater decreased after 30 minutes of ozonation, ending around a pH of 2.7 to 2.9. The drop in pH may be attributed to the increased presence of nitrate ions in solution (forming nitric acid) and the lowering of the buffering capacity of the wastewater due to air stripping (Metcalf and Eddy, 2003).

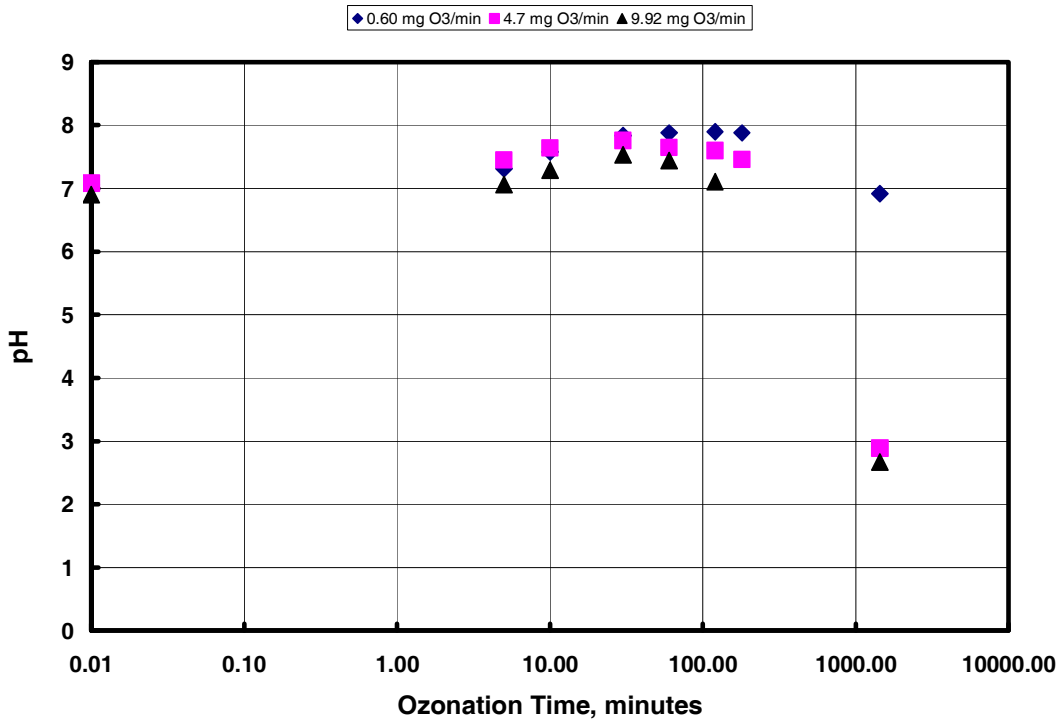

Figure 1. Plot of pH versus ozonation time for municipal wastewater runs.

Figure 2 is a plot of pH versus ozonation time for the industrial wastewater runs. For these runs, the initial pH was approximately 7.5 and generally increased to between 7.7 and 8.1 within the first hour of ozonation. Continued ozonation at the lowest application rate of 0.60 mg O_3/min caused the pH to remain near 8.0. At the higher ozone application rates of 4.7 and 9.92 mg O_3/min, the pH decreased with further ozonation resulting in pH values between 2.5 and 3.0 at the end of 24 hours. As previously stated, the drop in pH may be attributed to reduced buffering capacity and the presence of nitrate ions that are more prevalent due to the oxidation of ammonia.

Solids Removal. The total suspended solids removal levels achieved during the ozonation runs with municipal wastewater were slightly higher averaging 83% versus 81% for the runs performed on the industrial wastewater. Recognize that the average influent TSS concentration of the untreated municipal wastewater was 118 mg/L which is much different from the average TSS concentration of the industrial wastewater which averaged 298 mg/L.

The degradation rate constant (K_D) was determined for each run by plotting the natural logarithm of the TSS concentration remaining versus ozonation time. Figures 3 and 4 show the plots used to determine K_D for the municipal and industrial wastewater runs.

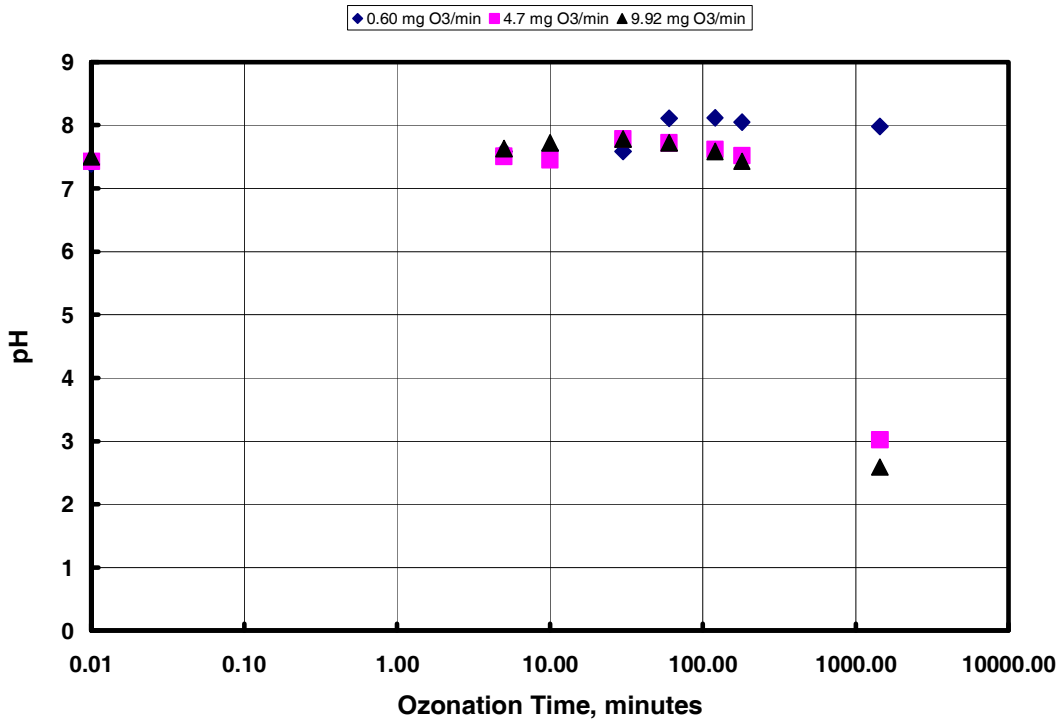

Figure 2. Plot of pH versus ozonation time for industrial wastewater runs.

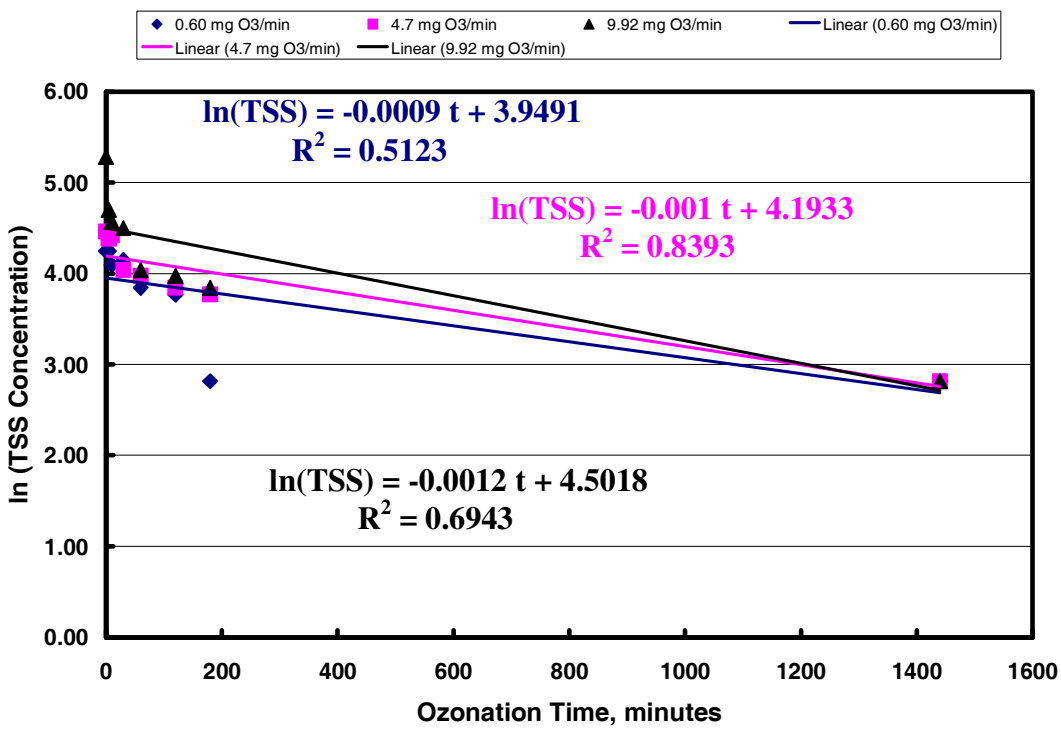

Figure 3. Plot of ln(TSS) versus ozonation time for municipal wastewater runs.

The degradation rate constants for the municipal wastewater runs and their associated R^2 values (square of the correlation coefficient) were: 0.054 hr^{-1} (0.0009 $min^{-1}\times$ 60min/hr) and 0.51, 0.06 hr^{-1} and 0.84, and 0.072 hr^{-1} and 0.69, respectively, for ozone application rates of 0.60, and 4.70, and 9.92 mg O_3/min. Overall, the ozone was more effective at degrading the municipal wastewater solids versus the suspended solids in the paper mill wastewater which contain cellulose and lignin particles which are difficult to oxidize. The degradation rate constants for the industrial wastewater runs and their associated R^2 values were: 0.066 hr^{-1} and 0.47, 0.042 hr^{-1} and 0.18, and 0.042 hr^{-1} and 0.18, respectively, for ozone application rates of 0.60, and 4.70, and 9.92 mg O_3/min. The pseudo-first order equation did not fit the data as well at the higher ozone application rates.

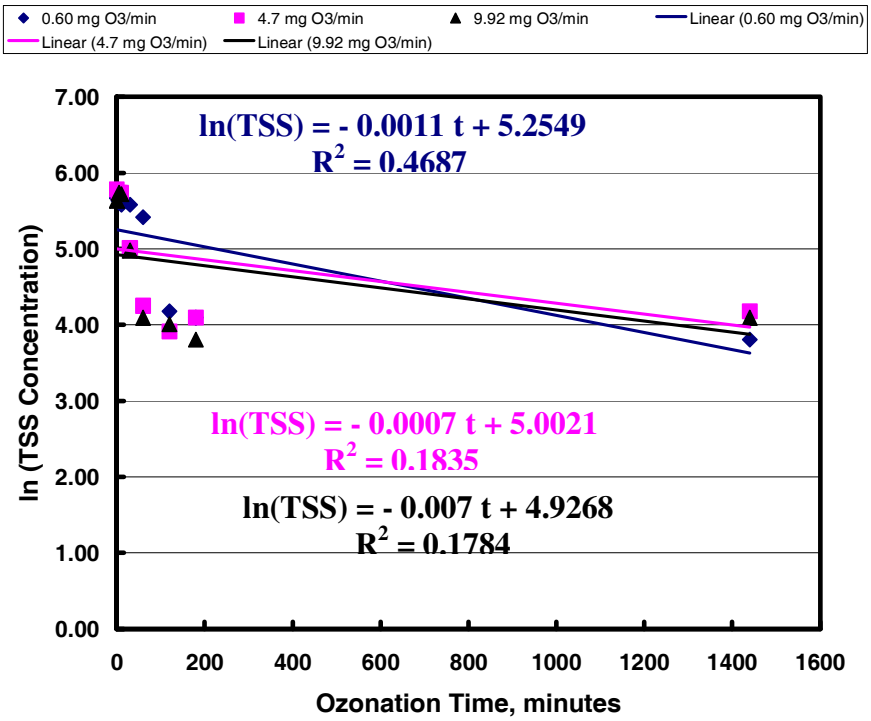

Figure 4. Plot of ln(TSS) versus ozonation time for industrial wastewater runs.

Degradation rates of volatile solids in aerobic digesters vary with temperature and have been reported to vary from 0.002 hr^{-1} at 15˚C to 0.007 hr^{-1} at 30˚C (EPA, 1979; Metcalf & Eddy, 2003) corresponding with our K_D values.

COD Concentration. Figures 5 and 6 are plots of COD concentration versus ozonation time for each run performed on the municipal and industrial wastewaters. The COD concentration decreased during both runs. Overall COD removal averaged 82% and 84% respectively, for the municipal and industrial wastewater runs. Although overall removals were essentially the same, the average COD concentration of the untreated municipal wastewater was 300 mg/L compared to 745 mg/L for the industrial wastewater.

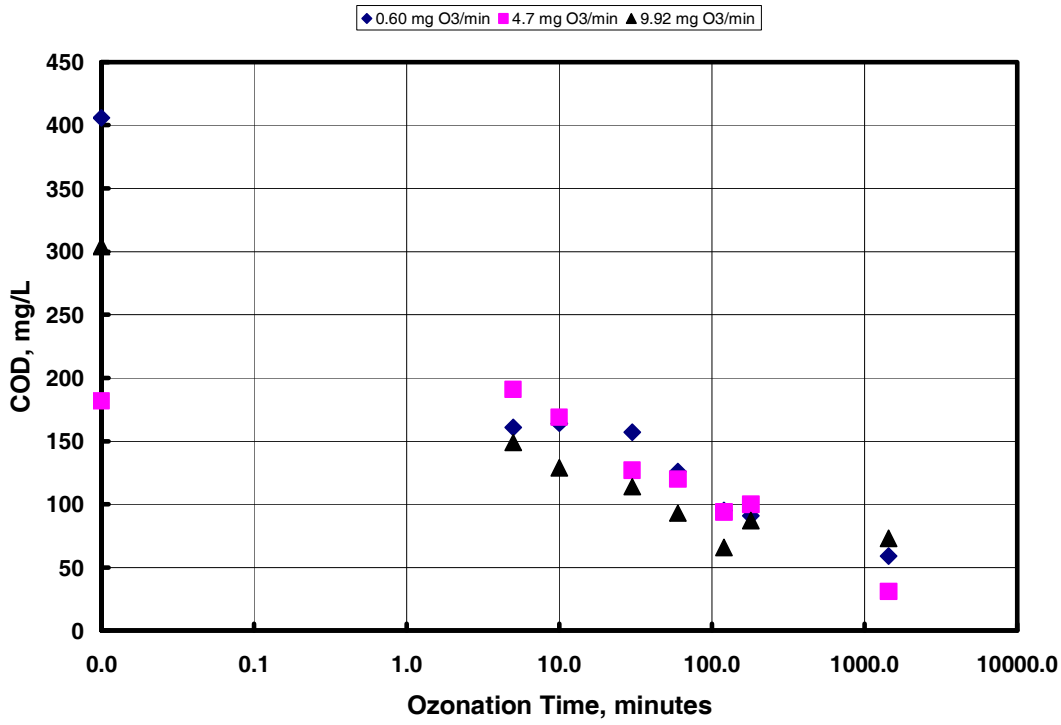

Figure 5. COD versus ozonation time for municipal wastewater runs.

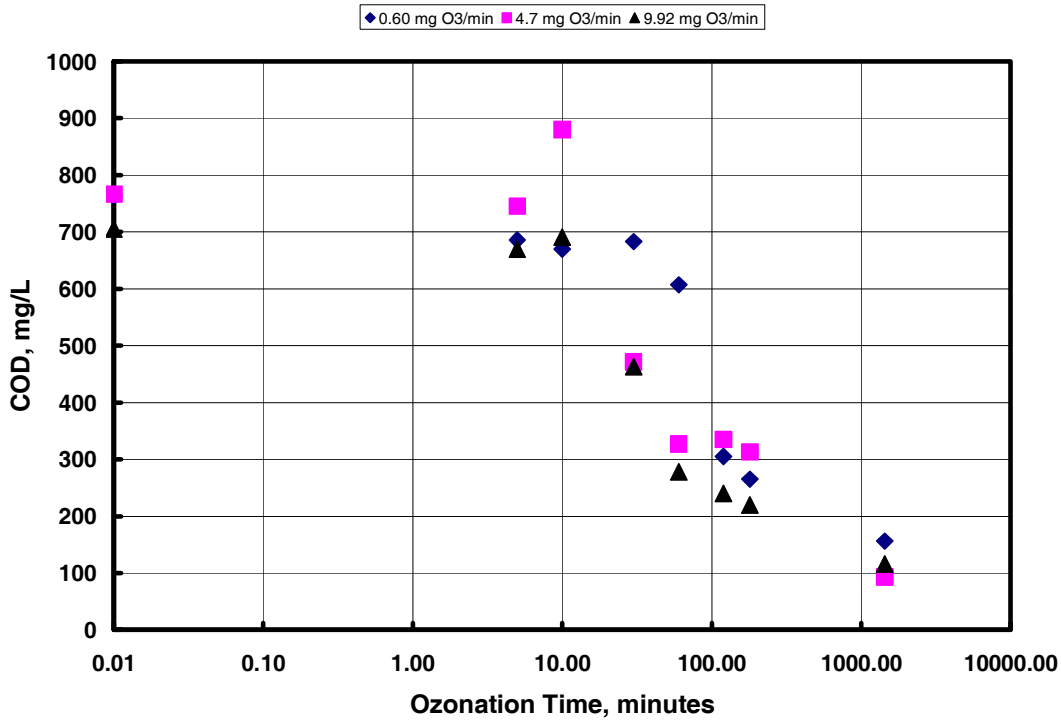

Figure 6. COD versus ozonation time for industrial wastewater runs.

Soluble COD Concentration (SCOD). Figures 7 and 8 are plots showing how the SCOD concentration varied as a function of ozonation time during the experimental runs with the municipal and industrial wastewater. Ozone was effective at solubilizing the suspended solids resulting in an increase in the soluble COD. In Figure 7, soluble COD concentrations increased as ozonation contact time increased until 10 to 20 minutes before decreasing for the ozone application rates of 4.7 and 9.92 mg O_3/min, whereas, for the lowest application rate, soluble COD concentrations generally decreased as ozonation time increased.

The SCOD concentrations for the industrial wastewater decreased as ozonation time increased for each ozone application rate (Figure 8). The average initial SCOD concentration in the industrial wastewater was 241 mg/L and at the end of the 24-hour ozonation period, the average SCOD concentration was 67 mg/L.

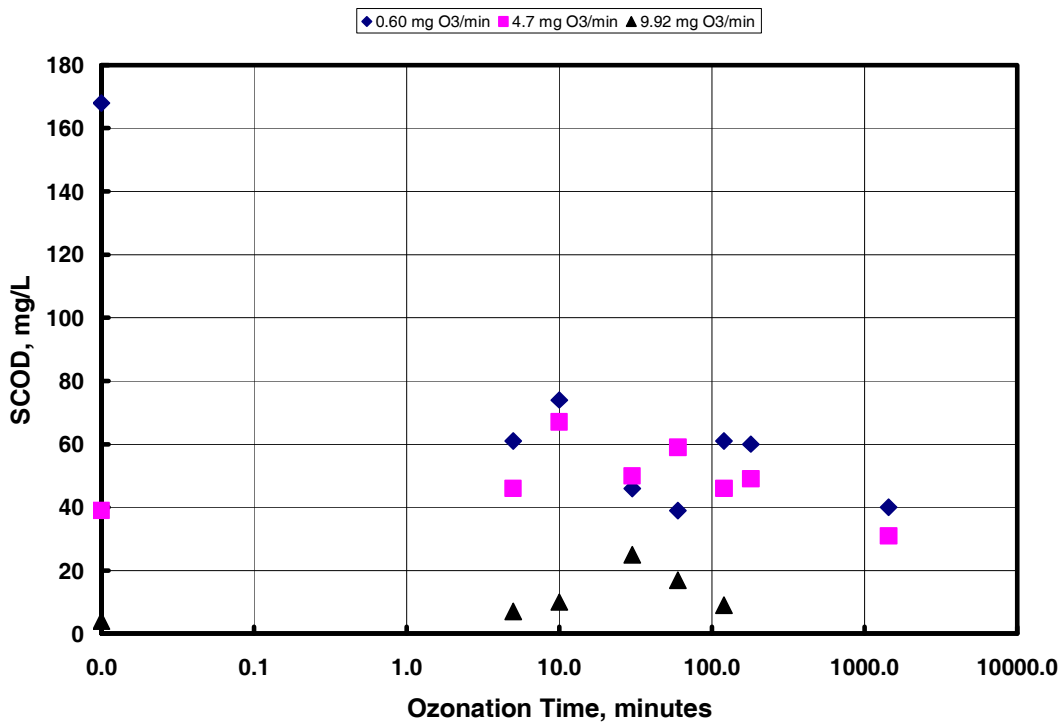

Figure 7. Soluble COD versus ozonation time for municipal wastewater runs.

Ozone Dosages. Tables 2 and 3 show the average ozone dosages used per mg of COD and TSS removed for the municipal and industrial wastewater runs. In general, the ozone dosages utilized increased as the quantity of ozone applied to the wastewater was increased from Run#1 to Run#3. The ozone dosages utilized were lower for the industrial wastewater runs since the initial concentrations of COD and TSS were higher.

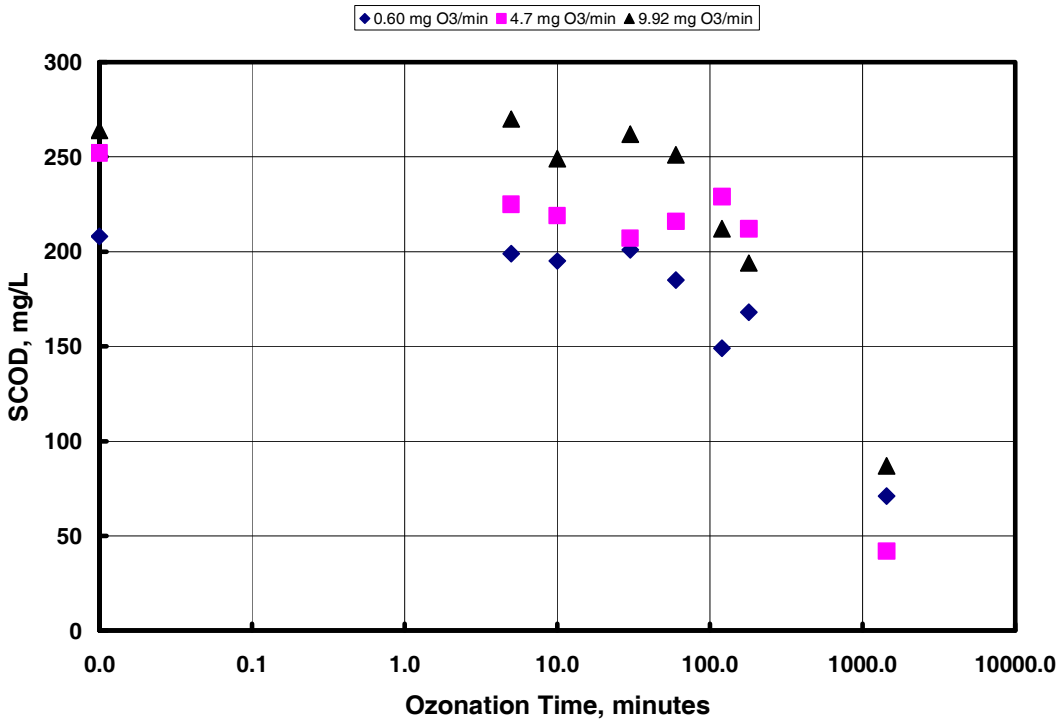

Figure 8. Soluble COD versus ozonation time for industrial wastewater runs.

Table 2. Average Ozone Dosage Utilized during Runs #1, #2, and #3 for Municipal Wastewater.

O_3 Dosage or Utilization	Run #1	Run #2	Run #3
mg O_3 /mg COD removed	0.41	7.47	10.3
mg O_3 /mg TSS removed	2.70	16.1	13.2

Table 3. Average Ozone Dosage Utilized during Runs #1, #2, and #3 for Industrial Wastewater.

O_3 Dosage or Utilization	Run #1	Run #2	Run #3
mg O_3 /mg COD removed	0.24	1.68	4.04
mg O_3 /mg TSS removed	0.59	4.34	10.8

Nutrient Concentrations. Figures 9 and 10 show the final nutrient concentrations in the wastewater for the municipal and industrial runs. The final ammonia and nitrite concentrations were low for both the municipal and industrial wastewaters. Effluent nitrate concentrations increased due to the oxidation of ammonia and organic nitrogen present in the wastewater. The phosphate concentration increased during ozonation and was more pronounced for the industrial wastewater.

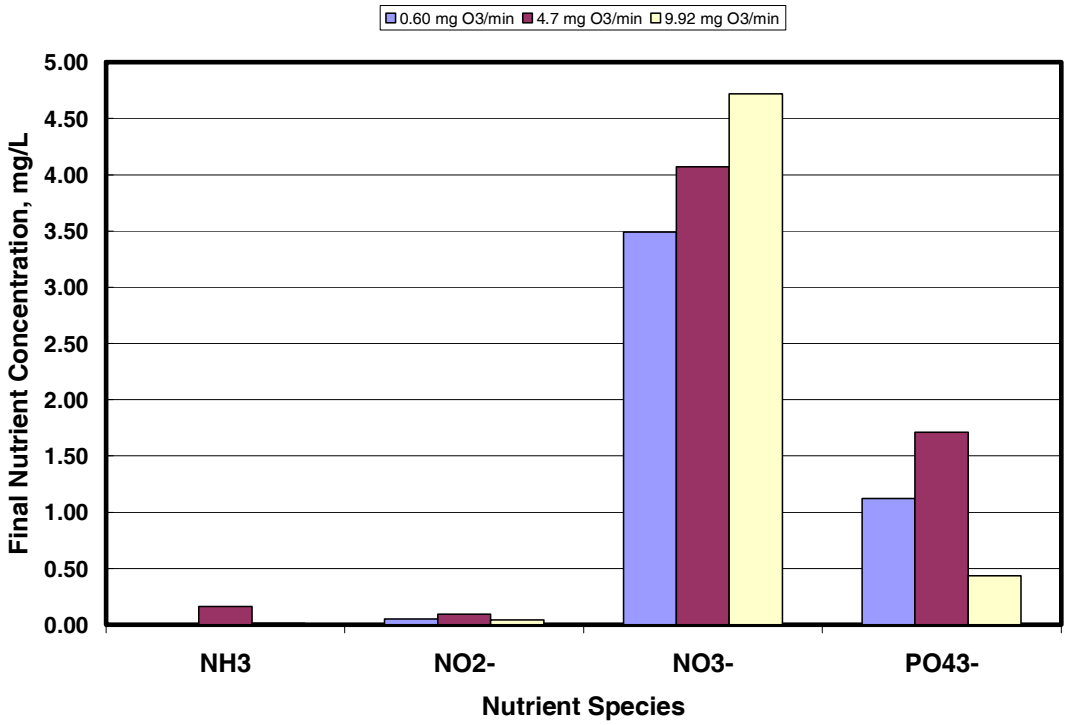

Figure 9. Final nutrient concentrations for municipal wastewater runs.

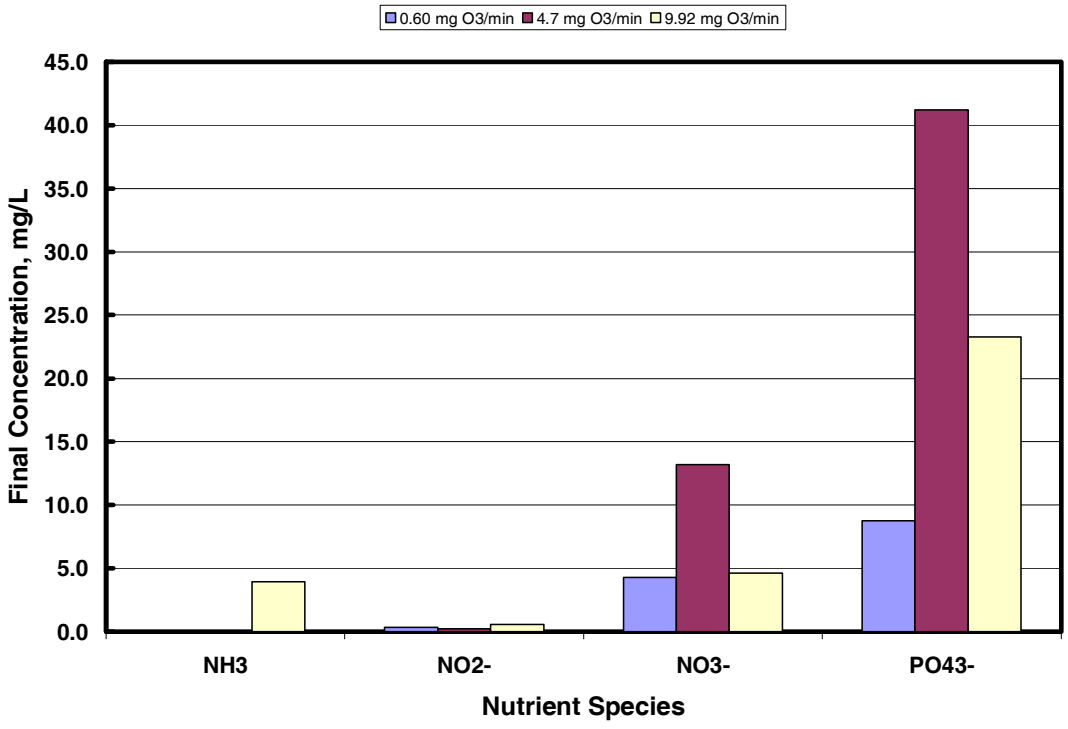

Figure 10. Final nutrient concentrations for industrial wastewater runs.

SUMMARY AND CONCLUSIONS

Ozone was applied to 6-liters of municipal and industrial wastewater for a 24-hour period. Three runs were made on each type of wastewater at ozone loading rates of 0.60, 4.70, and 9.92 mg O_3/min. A 10-L, semi-batch, bubble column reactor was used in the experimental study.

Major conclusions from the study are listed below:

1. Ozonation of both wastewaters caused the pH to decrease as a function of time. The final pH of the ozonated wastewater was approximately 2.6.
2. Overall COD removal averaged 82% for the municipal wastewater resulting in residual COD concentrations ranging from 31 to 73 mg/L. The average overall COD removal for the industrial wastewater was 84% with residual COD concentrations ranging from 93 to 156 mg/L.
3. Overall TSS removal averaged 83% for the municipal wastewater with an average TSS concentration of 17 mg/L remaining, whereas, for the industrial wastewater, overall TSS removal averaged 81% resulting in an average TSS concentration of 57 mg/L of TSS remaining.
4. The concentration of ammonia and nitrite after ozonating for 24 hours was negligible in the runs conducted on both the municipal and industrial wastewaters. The nitrate concentration remaining after 24 hours of ozonation averaged 4.1 mg/L for the municipal wastewater and 7.4 mg/L for the industrial wastewater.
5. The average residual phosphate concentration remaining after 24 hours of ozonating the municipal and industrial wastewater was 1.09 mg/L and 24.4 mg/L, respectively.
6. The ozonation degradation rate constant (K_D) based on TSS destruction ranged from 0.054 hr^{-1} to 0.072 hr^{-1} for the municipal and 0.042 hr^{-1} to 0.066 hr^{-1} for the industrial wastewater.

ACKNOWLEDGEMENTS

We extend our appreciation to Jeremiah Johnson and Stevie Odom for their assistance in the collection and analysis of the wastewater samples.

Biological nutrient removal from on-site wastewater treatment systems using a membrane aerated bioreactor

Zhihua Liang, Zhiqiang Hu
Department of Civil and Environmental Engineering,
University of Missouri-Columbia

Abstract

This study aimed to develop a low cost bioreactor process to efficiently remove organic compounds and nutrients from on-site wastewater treatment systems. A laboratory-scale anaerobic membrane-aerated biofilm bioreactor (ANMABR) using a gas-permeable silicone tubing covered with non-woven fabrics was constructed to evaluate the efficiency of chemical oxygen demand (COD) and nitrogen removal in the system.

After 250 days of continuous reactor operation, the experiment results showed consistent COD and NH_4-N removal efficiencies at 89±6 and 82±5%, respectively. The total nitrogen (TN) removal efficiency was 64±8% with an effluent average total nitrogen concentration of 11 mg/L. From day 89 to day 120 the biofilm reactor experienced a shock load running with C/N ratio of 2:1 with influent NH_4-N increased to 150 mg/L. The COD removal efficiency was not affected after the shock load, but NH_4-N and TN removal efficiencies were decreased down to 44 and 22%, respectively.This study demonstrated that gas-permeable tubing/membrane could be used to treat wastewater containing low organic and nitrogen loadings from on-site wastewater treatment systems. Improvement is still needed under the shock loading conditions for on-site wastewater treatment systems.

1. Introduction

Onsite wastewater systems are widely used in the United States because of its relatively simple components and low cost of operation and maintenance. It is estimated that 23 percent of 115 million occupied homes nationally use onsite wastewater systems for wastewater treatment. Because of the limitedremoval efficiency in onsite wastewater systems, effluent from onsite wastewater system still contains high concentrations of organic matters (BOD_5 > 100 mg/L), nitrogen (TN>30 mg/L) and phosphorus (TP>10 mg/L). These high level pollutants make onsite wastewater system a significant contamination source of nutrients to the receiving surface and ground waters. There are 4,773 water bodies around the states that are reported impaired by nutrients (USEPA 2002). It is needed to find a cost-effective and efficient treatment technology to remove nutrients and organics from onsite wastewater systems.

Recent research efforts proposed a novel membrane aerated biofilm reactor (MABR) to achieve nitrification and denitrification simultaneously. Walter et al. (Walter 2005) investigated a membrane tube module reactor with oxygen supplied on the inside of a membrane tube. The membrane module system used synthetic wastewater at which the COD level is around 900 mg/L and ammonium concentration 1000 mg/L to test the biological degradation capacity. Under the convective mass transport condition, combined nitrification and denitrification was proved on the heterotrophic and autotrophic biofilm which were developed at the membrane module surface. In their study of simultaneous COD removal, the nitrification and denitrification achieved in the membrane aerated biofilm reactor, Satoh et al. (Satoh 2004) constructed the membrane module which consisted of gas permeable, polyurethane hollow fiber membranes to treat synthetic wastewater at a COD loading rate of 1.0 g-COD/m^2/day and an ammonium loading rate of 0.5 g-N/m^2/day. Their results showed simultaneous COD removal, nitrification and denitrification achieved with 95% of nitrification and 90% COD removal efficiencies respectively, at low COD loading rate. At a high COD loading rate, to achieve stable nitrification, the MABR had to be supplied with high intra-membrane air pressure. In a similar study, Semmens et al. (Semmens 2003) constructed membrane module with polyethylene hollow fiber membrane to investigate COD and nitrogen removal of synthetic wastewater. After the start-up period, their experimental data showed effectiveness of MABR in removing COD and nitrogen as over 90% removal rate of COD and 90% total nitrogen removal. But with the thickness of biofilm increased, the performance of the bioreactor was diminished until the COD and nitrogen removal had no effect. Liu et al. (Liu 2007) selected microporous carbon tubes to construct the MABR for treatment of synthetic wastewater. Because carbon membrane have high ability of bacterial adhesion and good permeability, removal rate of ammonium and COD reached 35.6 g-COD/m^2/day and 9.3 g-N/m^2/day, respectively. But they reported excessive biofilm accumulation abated the mass diffusion rate and oxygen aeration impaired the performance of MABR treatment.

For MABR using microporous hollow fiber membrane to provide oxygen aeration there is a drawback of pore clogging make them unsuitable applied to the on-site wastewater treatment system which contains high contents of suspended solids and organics. To avoid this problem silicone membrane was used in membrane aeration for their high resistance to chemical and mechanical stress in the development of cost-effective and efficient environmental technologies to remove nutrients from onsite wastewater systems. The objective of this study was to evaluate the effectiveness of a silicone membrane aerated biofilm reactor system for COD and nitrogen from domestic wastewater.

2. Materials and methods

A 7.2L membrane-aerated biofilm reactor (MABR) was constructed with two identical vertical cross stands (6 cm x 16 cm), made of bamboo, evenly in the central chamber of reactor. The reactor consisted of three compartments: an anaerobic fermentation basin followed by an anoxic basin, and further followed by an internal clarifier. In the anoxic basin, a gas-permeable membrane aerated module covered was submerged (Figure 1).

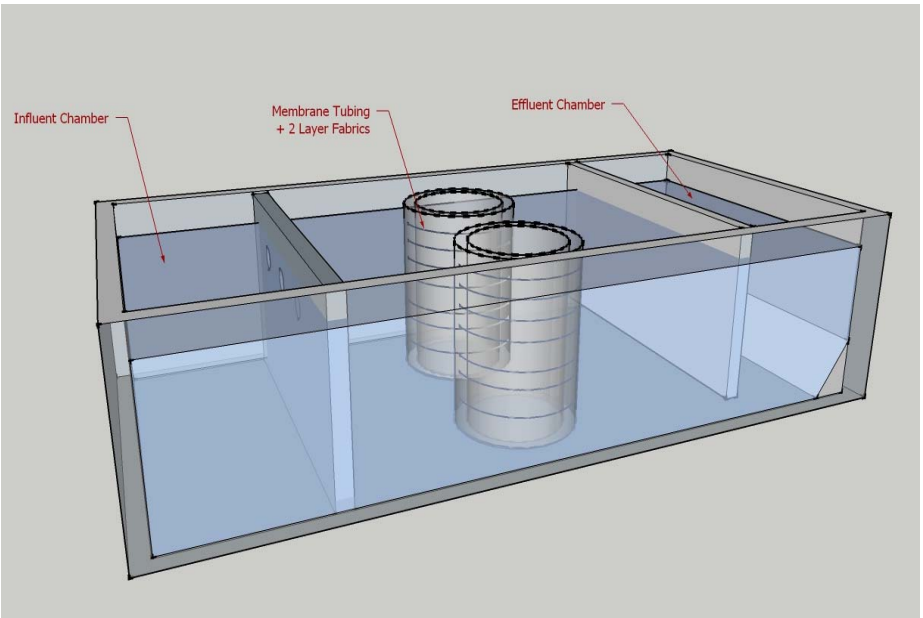

Figure 1. Scheme of membrane aerated biofilm reactor

The gas-permeable membrane tubings (Silastic® medical grade tubing, outer diameter = 2.0 mm and inner diameter =1.5 mm, Dow Corning, active length = 7 m) were arranged in a coiled form around inner layer of fibrous non-woven fabrics (diameter = 10μm, Kunin Group Inc., Hampton, NH) wrapped with cross stands. At the outside of the coiled gas-permeable tubing another layer of fibrous non-woven fabrics was wrapped. Oxygen was delivered to the inside of the membrane tube at an airflow rate of <1 ml/min. at atmospheric pressure throughout the experiment.

Reactor operation

The synthetic wastewater was fed into the reactor by a peristaltic pump (Cole Parmer, Chicago, IL) at a rate of 2.0 L/day. The synthetic wastewater components contained 300mg/L COD as sodium acetate, 30mg/L ammonium-nitrogen as ammonium chloride, 6mg/L phosphorous with a micro nutrient solution. The MABR was operated at 26^{o}C with a dilution rate of 0.29 day^{-1}. The biofilm was initially cultured in the fed-cycle mode for seven days with inoculation of 1 L nitrifying biomass from the active nitrifying reactor and 150mL secondary tank activated sludge taken from the Columbia Regional Wastewater Treatment Plant, Columbia, Missouri.

Analytical methods

The NH_4^+ concentration was determined by standard electrode method. The NO_2 and NO_3 concentrations were determined colorimetrically. The COD sample was analyzed using colorimetric digestion method. The DO in the reactor was measured by a YSI 550A Dissolved Oxygen and Temperature System (YSI Inc., Yellow Springs, OH).

3. Results and discussion

COD concentrations measured from the influent and effluent of the MABR reactor are shown in Figure 2. Similarly, the ammonium concentration of influent and effluent of the MABR reactors are shown in Figure 4. In Figure 5, the effluent concentrations of nitrogen species from the MABR are shown. After a short start-up period of 15 days, the MABR reactor reached 90% removal of organic matter. Simultaneously, nitrification was indicated because nitrate was observed in the effluents. Ammonium removal of MABR reached over 90% while the nitrate concentration of MABR effluent was low. This demonstrated that almost complete denitrification was achieved shortly after the start-up period.

During the period of nitrogen shock loading the behavior of COD removal for the MABR was not changed. When receiving much higher influent ammonium concentrations (>100 mg/L of NH_4-N), significant ammonia accumnulation was observed in the MABR reactor, indicating low shock buffering capacity of the MABR. Although effluent nitrate concentration of MABR increased with increase loading of influent ammonium, it only accounts for less than 50% nitrification for influent ammonium concentration.

After the shock loading period, the organic and ammonium nitrogen loading were switched back to a normal level of 300 mg/L and 30 mg/L respectively. The experimental data illustrated that the MABR reactor had stable performance on COD and ammonium removals for over 250 days. COD removal efficiency and ammonium removal efficiency of of the MABR reactor were 89% and 82%, respectively. The total nitrogen removal in the MABR reactor was about 65%.

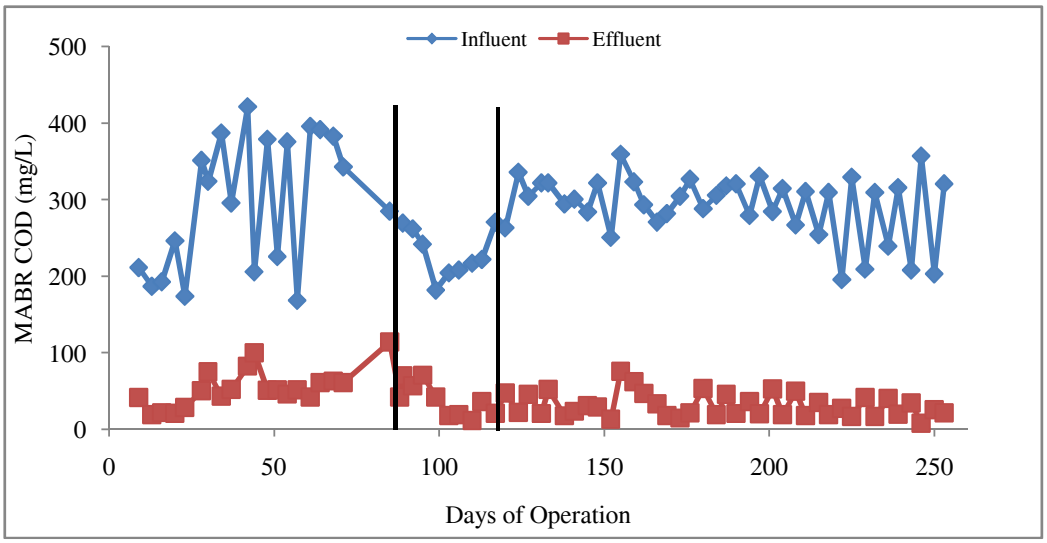

Figure 2. Influent and effluent COD concentration of the MABR over the whole period. Vertical lines indicate the nitrogen shock loading period.

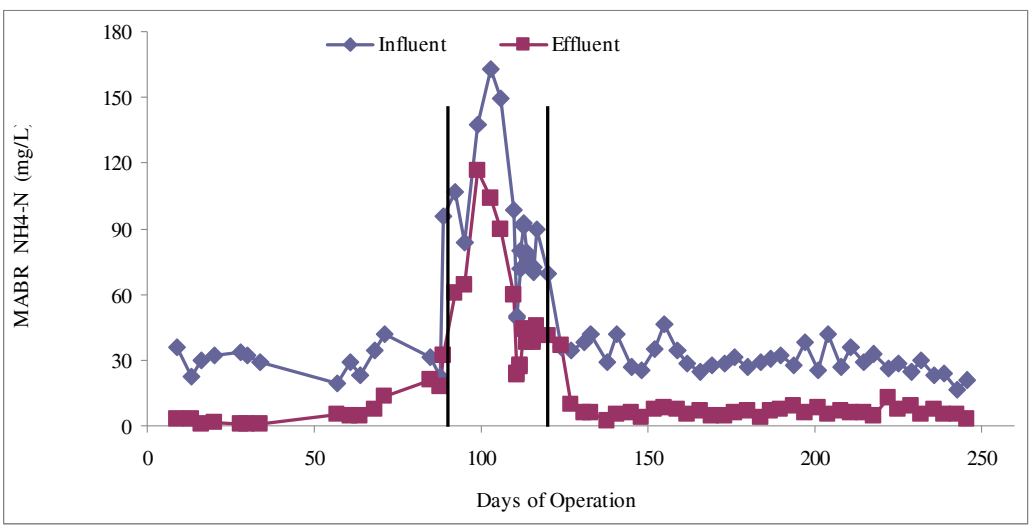

Figure 3. Influent and effluent ammonium-N concentration of MABR over the whole period. Vertical lines indicate the nitrogen shock loading period.

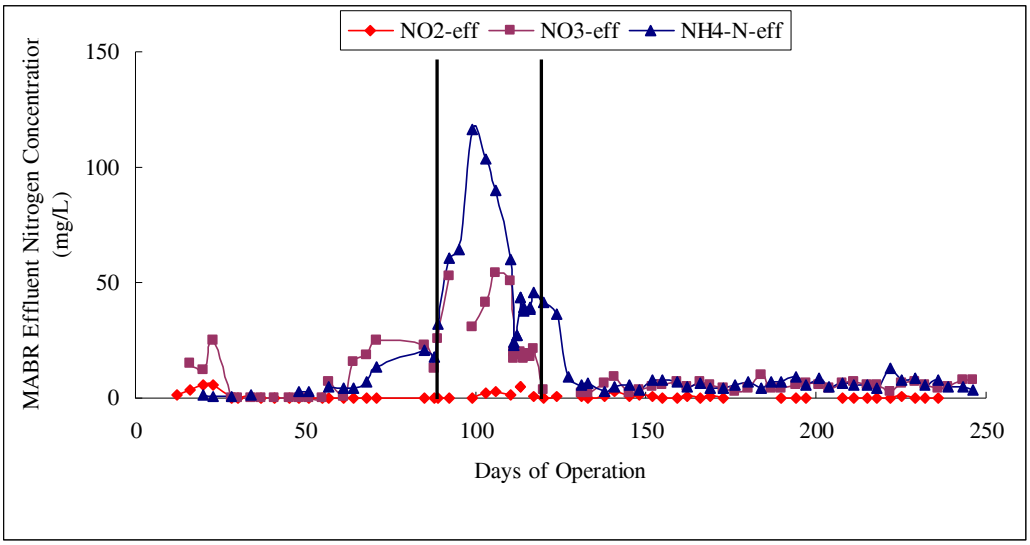

Figure 4. Effluent nitrogen species concentration of the MABR over the whole period. Vertical lines indicate the nitrogen shock loading period.

The configuration of gas-permeable membrane with non-woven fibrous fabric of MABR reactor makes it possible to develop a local nitrifying layer at the bottom of biofilm. These nitrifying bacteria existed in the favorable conditions of high oxygen concentration and low organic carbon concentration. Although no autotrophic activities of sedimentary biomass was inferred from the microbial activity measurements, the existing nitrifying bacteria layer contributed a significant extent of the nitrification to achieve ammonium removal from influent of MABR. Even the non-woven fibrous fabric can provide large surface area for bacteria adhesion thick biofilm formation after sufficient time increased the oxygen diffusive resistance and limited mass diffusive transport. This can explain after the shock loading period by the fact that the average effluent ammonium concentration was a little bit higher than that before the shock loading period. This thick biofilm resistance also limited the mass transport rate of nitrate produced in the deeper parts of biofilm to the outer layer of denitrification zone to be utilized as electron acceptor and cause the uncompleted denitrificaiton to achieve non-total nitrogen removal with some nitrate concentration in the effluent. Because the totally anaerobic conditions maintained at the outside layer of membrane module and in bulk liquid solution, the simultaneous sludge digestion was accomplished. In the whole operation period of the MABR reactor there was no wasted sludge produced except the sedimentary sludge taken out for microbial activity measurements. This characteristic makes ANMABR an attractive advantage with a minimum need of maintenance for actual application.

4. Conclusions

This study investigated the MABR system for simultaneous COD and nitrogen

removal by constructing a gas-permeable membrane aerated biofilm reactor with non-woven fibrous support. The configuration of the reactor was capable of forming different environmental zones in a single membrane module to achieve simultaneous nitrification, denitrification and COD removal. The long term operation of the MABR reactor showed the effective COD removal and nitrification rate of 89% and 82%, respectively at regular COD and nitrogen loading conditions. Improvements are needed under the shock loading conditions for keeping the efficient organic and nitrogen..

Abstract

This paper describes part of the work presented in León et al. (2009), which presents integrated boundary conditions (BCs) for simulating free surface, pressurized, and the simultaneous occurrence of free surface and pressurized flows (mixed flows) when the free surface region is modeled using the 1D Saint-Venant equations and the pressurized region is modeled using the 1D compressible waterhammer equations. The present paper describes the results of the application of the integrated boundary conditions for modeling free surface, pressurized, and mixed transient flow conditions in two test cases. The first test case is a hypothetical test and the second is an experimental work in an oscillation tube performed by the authors of this paper. Computational Fluid Dynamics (CFD) modeling results were used as frame of comparison for the first test case and experimental results besides CFD results were used for the second one. The results show that the integrated boundary conditions can be used with good accuracy for simulating complex storm-sewer systems in free surface, pressurized and mixed flow conditions. The integrated boundary conditions are general and they can be used to simulate point and storage junctions with any number of inflowing and outflowing pipes. The integrated boundary conditions were implemented in the Illinois Transient Model (ITM), which has been used to study hydraulic transients

in the Calumet system of the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC). The results of the latter study are not presented in this paper.
Keywords: Boundary conditions; Mixed flow; Open channel flow; Pressurized flow; Sewer; Transient flow; Unsteady flow.

1. Introduction

The simultaneous occurrence of free surface and pressurized flows (mixed flows) can be modeled using either a single set of governing equations or separate equations for free surface and pressurized flows (e.g., León et al. 2008b). With either approach, the Method of Characteristics (MOC) with space-line interpolation usually is used to connect the boundaries and the adjacent internal cells (e.g., Sjöberg 1976, Politano et al. 2007). Naturally, when using a single governing equation (1D Saint-Venant equations), the well-known Preissmann slot approach is used for simulating pressurized flows. In this case the boundary conditions (BCs) for mixed flows are equivalent to those used in free surface flows. When a different governing equation is used for free surface and pressurized flows (e.g., 1D Saint-Venant equations are used for free surface flows and 1D compressible waterhammer equations are used for pressurized flows), different MOC boundary conditions are specified for free surface and pressurized flows. The MOC approach is suitable for pure pressurized flows (e.g., Karney and Ghidaoui 1997, León et al. 2008a) and for free surface smooth flows (e.g., León et al. 2006, León et al. 2008b). However, for free surface flows in the presence of shocks, the MOC approach results in smoothing (damping) of waves (e.g., León et al. 2006). Naturally this restriction is extended to the boundaries. Furthermore in mixed flow conditions at the boundary, it is uncertain what equations should be used when the mixed flow interface is positive or negative. An open channel-pressurized flow interface is defined as negative or retreating if it is moving towards the pressurized flow region, and positive otherwise (e.g., Song et al. 1983). Current models based on the MOC approach cannot simulate open channel-pressurized flow negative interfaces at internal nodes in the pipe when the flow in the open channel region is supercritical (e.g., Cardle 1984). This limitation is also extended to the boundaries. Thus, when separate equations are used for free surface and pressurized flows, it is necessary an integrated approach at the boundaries for simulating free surface flows, pressurized flows and mixed flows (positive and negative interfaces).

Guo and Song (1991) suggested three equations for solving the flow variables at a drop shaft boundary. The aim of these authors was to simulate pressurized flows in a drop shaft (vertical shaft) under rapid variation with time of its water surface level. The equations suggested by these authors were the energy equation, a combined mass and y-momentum equation and an equation based on the Method of Characteristics (MOC) that connected the drop shaft boundary with an adjacent internal node of an horizontal tunnel. This model was tested by the authors of the present paper and it was found that it leads to numerical instabilities and to an inaccurate prediction of frequency and amplitude of water surface levels. Our reasoning about the source of these numerical instabilities are explained in the drop shaft boundary section. Because a drop shaft boundary is very common in storm-sewer systems, a robust approach for the treatment of this type of boundary is necessary.

This paper describes part of the work presented in León et al. (2009), which presents boundary conditions (BCs) for simulating free surface, pressurized, and the simultaneous occurrence of free surface and pressurized flows (mixed flows) when the free surface region is modeled using the 1D Saint-Venant equations and the pressurized region is modeled using the 1D compressible waterhammer equations. The present paper describes the results of the application of the integrated boundary conditions for modeling free surface, pressurized, and mixed transient flow conditions in two test cases. The first test case is a hypothetical test and the second is an experimental work in an oscillation tube performed by the authors of this paper. The CFD package FLOW-3D was used as frame of comparison for the first test case and the open source code OpenFOAM besides experimental results

was used for the second one. The integrated boundary conditions were implemented in the Illinois Transient Model (ITM) developed by the first author of this paper, which has been used to study hydraulic transients in the Calumet system of the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC). The results of the latter study are not presented in this paper.

2. Formulation of Boundary Conditions

In a typical storm-sewer system, various types of boundaries are present. These may include drop shafts, reservoirs, junctions, dead ends, control gates, pumping stations, etc. Following, a brief overview of the integrated boundary conditions for two types of boundaries is outlined.

2.1. *N-way junction boundary*

A N-way junction boundary (N pipes) is depicted schematically in Fig. 1 and consists of "p" inflowing pipes and "q" outflowing pipes, with $N = p + q$. A pipe is denoted as inflowing pipe when it conveys flow to the boundary in normal flow conditions (e.g., uniform flow). Likewise, a pipe is denoted as outflowing pipe when it draws flow from the boundary in normal flow conditions. If a pipe has zero longitudinal slope, the pipe can be treated as either inflowing or outflowing. In a N-way junction boundary, $2N+1$ variables are unknown, namely, the water depth and the flow discharge at each pipe boundary, and the flow depth at the junction pond (y_d). Thus, $2N+1$ equations are needed in order to determine the unknown variables. To fulfill the number of equations ($2N+1$), two equations are required for each pipe and an additional equation is needed at the junction pond. The reader is referred to León et al. (2009) for these equations.

2.2. *Drop shaft boundary*

As depicted in Fig. 2, a drop shaft consists of one vertical shaft connected to a drift tube, which in turn is connected to a main tunnel system. For a drop shaft boundary, three variables are unknown, namely, the water depth at the drop shaft (H), and the water depth (y_b) and flow discharge (Q_b) at the outlet pipe boundary. Thus, three equations are needed in order to determine the unknown variables. The reader is referred to León et al. (2009) for these equations.

As mentioned in the introduction, the approach used by Guo and Song (1991) for simulating pressurized flows in drop shafts under rapid variation of their water surface levels leads to numerical instabilities. We speculate that the reason for these instabilities may be due to coupling the energy and momentum equations. Notice that between sections 0 and 1 in Fig. 2, the head loss can not be quantified using the classical relation for a local head loss $[ku|u|/(2g)]$ because if k is constant the head loss between these sections is only a function of the flow velocity at the boundary. However in the actual case, the head loss depends not only on the velocity but also on the highly variable length of the water column in the vertical pipe (H). Under these conditions, the head loss between 0 and 1 (Fig. 2) is mainly due to frictional losses, which in turn are a direct function of the water column length in the vertical pipe. Clearly, variation of the frictional losses due to rapid variation of the water column length can not be taken into account by the classical local head loss relation. The incongruence described above for representing the head losses in the drop shaft is not critical when coupling the conservation of energy and mass equations. The reason is that in the latter case the flow dynamics in the vertical pipe are neglected. However this approach leads to inaccuracies on the frequency of oscillation of water surface levels in the vertical pipe as will be shown later. For the accurate prediction of frequency and amplitude of rapid variation of water surface levels in drop shafts the momentum equation and not the energy equation must be used. The equations presented by Guo and Song (1991) were

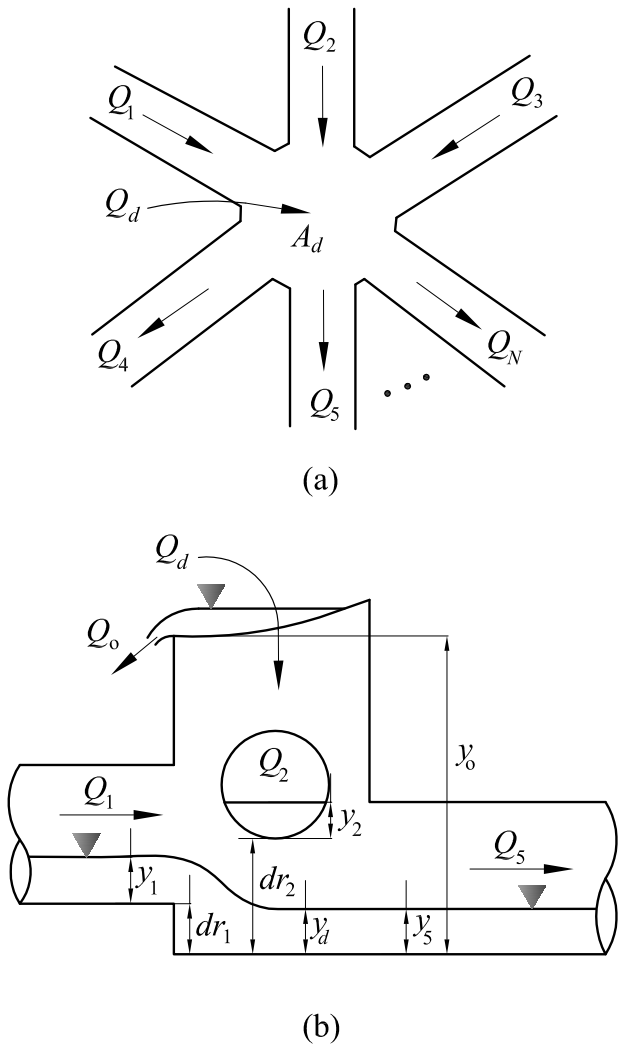

Fig. 1. Schematic of a N-way junction boundary (a) plan view, (b) side view [To avoid cluttering the side view only pipes 1, 2 and 5 were drawn]

modified/replaced by the authors of this paper to overcome the aforementioned problems. The reader is referred to León et al. (2009) for the modified/replaced equations.

3. Evaluation of the model

The purpose of this section is to evaluate the accuracy and robustness of the integrated boundary conditions for simulating free surface, pressurized, and mixed transient flows. Because of the lack of experimental data for the flows of interest in complex boundaries, the first test case presented herein considers a hypothetical test case, namely a three-way merging flow system. The second test case is an experimental work in an oscillation tube performed by the authors of this paper. In the first test case, the length of the pipes is intentionally chosen to be short so that the boundaries have a clear effect on the results. With the aim of evaluating the integrated boundary conditions, Computational Fluid Dynamics (CFD) modeling results were used as frame of comparison. The CFD package FLOW-3D (Flow Science Inc. 2005) is used as frame of comparison for the first test case and OpenFOAM (OpenCFD Ltd. 2007) besides experimental results is used for the second test case. The results of these two models can be trusted as they have been tested extensively with

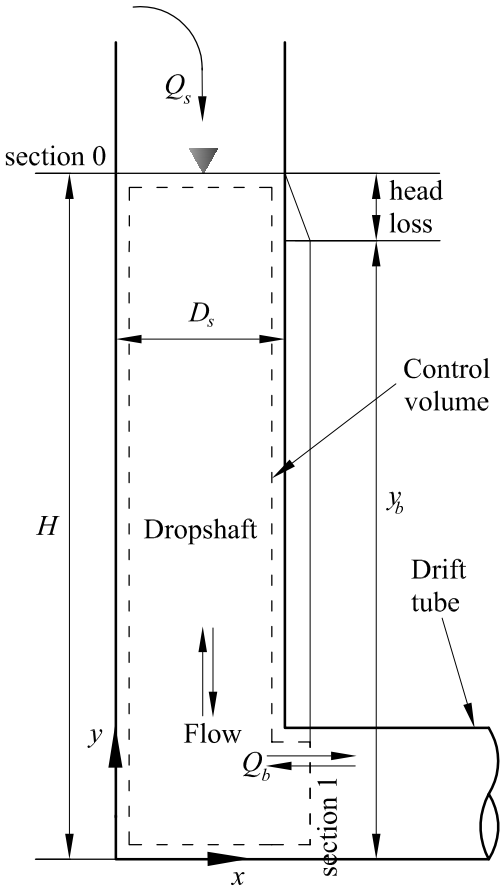

Fig. 2. Schematic of a drop shaft boundary

good success. Unlike OpenFOAM, FLOW-3D has a module that allows modeling acoustic waves in pressurized flow conditions. The propagation of acoustic waves is associated with the compressibility of the flow; however not all CFD compressible models can simulate acoustic waves. In the first test case pressure heads inside horizontal pipes are of interest, for which modeling of acoustic waves is important if pressurized flows are present. In the second test case, even when fully pressurized flows are simulated, modeling of acoustic waves is not important because in this test the interest is water level oscillations at drop shafts (vertical pipes) and not pressure heads inside the horizontal pipe. The main reason for using OpenFOAM in the second test case is that the unstructured mesh used by OpenFOAM allows a better representation of the pipe geometry (e.g., cross-sectional area) than the cartesian mesh used by FLOW-3D.

3.1. *Three-way merging flow*

The hypothetical test presented in this section considers a three-way merging flow system that is depicted in Fig. 3(a). As shown in Fig. 3(a), all pipes have a length of 5 m, the junction pond has a diameter of 1 m, the inflowing pipes (pipes 1 and 2) have both a diameter of 0.5 m and the outflowing pipe (pipe 3) has a diameter of 0.8 m. The Manning's roughness coefficient used in the 1D simulation is n_m = 0.015 $m^{1/6}$, the waterhammer wave speed considered is 100 m/s and the initial flow velocity in all pipes is 0 m/s. A waterhammer wave speed of 100 m/s was used because of PC hard disk storage limitations (200 GB) when running FLOW-3D. For instance when using a mesh of 6,000,000 cells,

a pressure wave celerity of 100 m/s, an output time of 0.001 s (to be able to capture the pressure head traces associated with a pressure wave celerity of 100 m/s) and a simulation time of 0.2 seconds, the storage required in the PC was about 150 GB. Given the PC hard disk storage limitations, it was decided to use a maximum pressure wave celerity of 100 m/s in this and the next test case. It is pointed out that the pressure wave celerity is not a limitation for the 1D integrated model. To ensure that the CFD results for this and the next test case are mesh independent a mesh convergence study was performed (not presented herein due to space limitations).

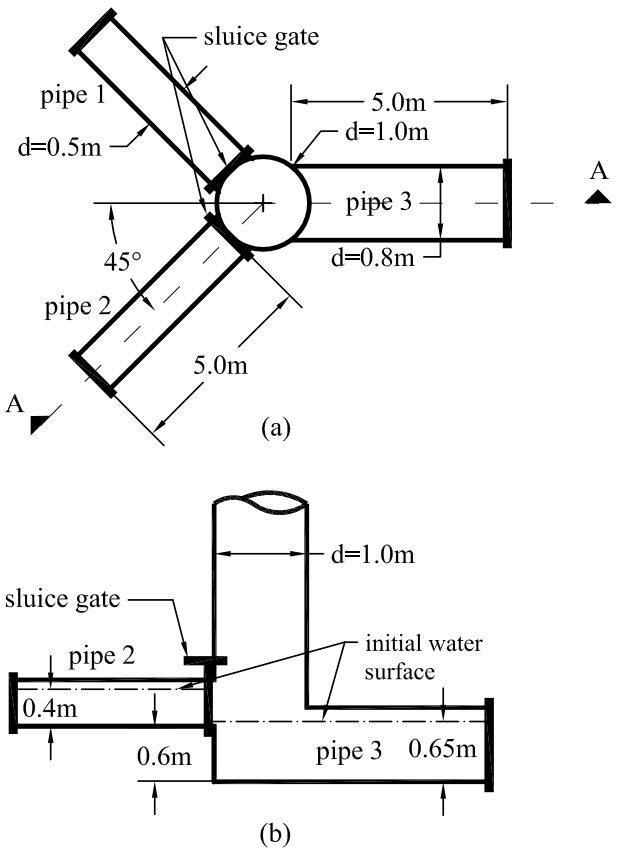

Fig. 3. (a) Plan and (b) section A-A view for three-way merging flow hypothetical case

The initial water surface levels for this test are presented in Fig. 3(b). As can be observed in Figs. 3(a) and 3(b), the initial zero-velocity water pools in each pipe are separated by two sluice gates located at the downstream end of each inflowing pipe. The boundary conditions at the upstream end of the inflowing pipes (pipes 1 and 2) and at the downstream end of the outflowing pipe (pipe 3) were assumed to be zero-flux boundaries, which represent a dead-end pipe. The transient flow is obtained after an instantaneous and simultaneous opening of the sluice gates at time $t = 0$.

The opening of the sluice gates generated a free surface flow surge at the upstream end of pipe 3 that moved in the downstream direction. The continuous supply from the inflowing pipes into the outflowing pipe (pipe 3) pressurized the upstream end of pipe 3 making the free surface flow surge become an open channel-pressurized flow positive interface that moved in the downstream direction. Once this positive interface reached the downstream end (dead-end) the whole pipe 3 was pressurized and remained that way during the entire simulation. At the inflowing pipes (pipes 1 and 2), the flow remained fully free surface

during the entire simulation, although some wave reflections originated at their boundaries (dead-end and junction pond) were observed during the visualization of the simulations. The simulated pressure head traces mid-way of pipes 2 (results for pipe 1 are the same as pipe 2 because of symmetry) and 3 are presented in Figs. 4 and 5, respectively. The simulation time for this test case was 12 seconds, however for pipe 3 (Fig. 5) that involves pressurized flows (high frequency of oscillations) the results are shown only for the first 2.8 seconds for better visualization. The simulated results using the proposed approach were obtained using 200 cells in each pipe and a maximum Courant number of Cr = 0.8.

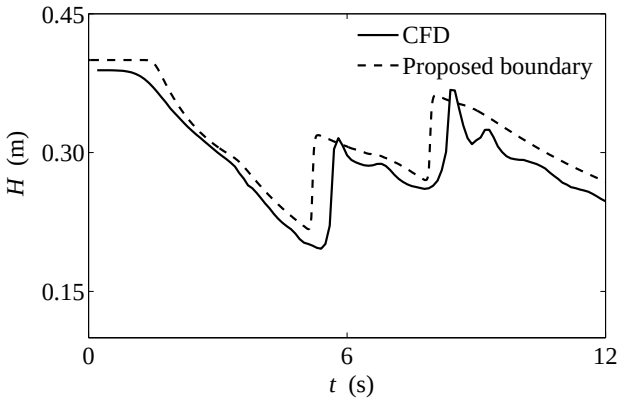

Fig. 4. Pressure head trace at mid-way of pipe 2

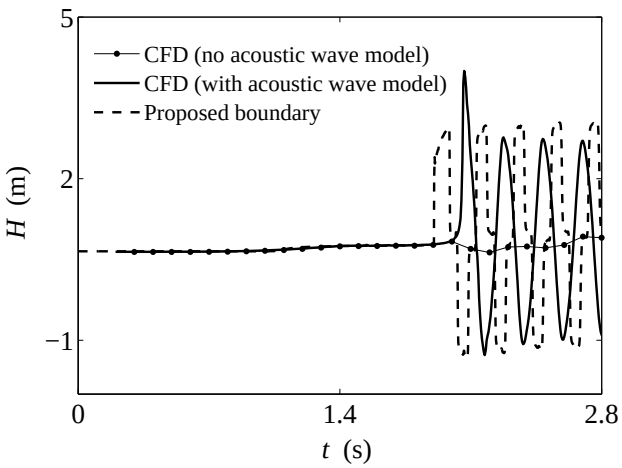

Fig. 5. Pressure head trace at mid-way of pipe 3

The results of pressure head traces for pipe 2 (Fig. 4) obtained using the proposed approach agree well with the results obtained using the FLOW-3D model, although the slightly earlier pressurization of the upstream end of pipe 3 when using the proposed model made the free surface flow surge generated at the junction pond arrive earlier at mid way of pipe 2. Fully free surface flow was achieved in pipes 1 and 2 during the entire simulation. The results for pipe 3 (Fig. 5), which undergoes a flow type change from free surface flow to mixed flow to pressurized flow, also show good agreement between the proposed approach and FLOW-3D (using the acoustic wave model), although this pipe is fully pressurized earlier when using the proposed model. Fig. 5 also shows the results of FLOW-3D without

using the acoustic wave model. These results show that for pressurized transient flows, the pressure heads obtained without using the acoustic wave model are much smaller than when using this model. The latter results show that the compressibility of the flow (associated with the propagation of acoustic waves) is very important when simulating pressurized transient flows. For simulating free surface flows, considering compressibility of the flow is not important as they produce identical results.

3.2. *Oscillation tube*

The purpose of this section is to test the ability of the proposed model in simulating pressurized flows in vertical pipes in which water surface level varies rapidly with time. With the aim of evaluating the proposed approach besides CFD modeling, laboratory results were used as frame of comparison. The experimental setup which layout is depicted in Fig. 6 (a) was built in the Ven Te Chow Hydrosystems Laboratory of the University of Illinois at Urbana-Champaign. As shown in Fig. 6, the experimental setup consisted of a 4.98 m long horizontal plexiglass pipe connected at its upstream and downstream ends by a 2.2 m long vertical pipe of the same material as the horizontal pipe. The inside diameter of all pipes was 50.8 mm (2"). At the center of the horizontal pipe, a quarter-turn ball valve was installed, which as shown in Fig. 6 (b), separated the initial water levels upstream and downstream of the valve. The length of the vertical pipes are intentionally chosen to be of the same scale as of the horizontal pipe so that the vertical flow has a clear effect on the results. The water levels in the upstream vertical pipe (left vertical pipe in Fig. 6) were recorded using a Canon GL2 color video camera. For a better visualization of the water levels, the water in the oscillation tube was previously dyed. The acquired images were post-processed using the Image Processing Toolbox of MATLAB. For the MATLAB analysis, the video images were converted first to gray-scale images that in turn were converted to black and white images (binary system: 1 = black and 0 = white). The water level for each image was determined by computing the maximum row that has a pixel with a value of 1.

The transient flow in the experiments was obtained by a rapid opening of the valve, which created periodic oscillations of water surface levels in the vertical pipes. The measured and simulated water level traces at the upstream vertical pipe (left vertical pipe in Fig. 7) are presented in Fig. 7. The simulated results using the proposed approach were obtained using 400 cells, a pressure wave celerity of 1000 m/s, a Manning roughness coefficient of 0.010 $m^{1/6}$ (typical for a plexiglass pipe), and a Courant number of Cr = 0.8. The results show a good agreement between the proposed approach, CFD, and measured results for the frequency and amplitude of water level oscillations. The results in Fig. 7 labelled "mass/energy" are obtained with the 1D FV model using the mass and energy equation instead of the mass and momentum equation (proposed boundary). As can be observed in Fig. 7, the former approach leads to inaccuracies on the frequency of oscillation of the water surface level. For the accurate prediction of frequency and amplitude of rapid variation of water surface levels in drop shafts the momentum equation and not the energy equation must be used.

4. Conclusions

This paper describes part of the work presented in León et al. (2009), which presents boundary conditions (BCs) for simulating free surface, pressurized, and the simultaneous occurrence of free surface and pressurized flows (mixed flows) when the free surface region is modeled using the 1D Saint-Venant equations and the pressurized region is modeled using the 1D compressible waterhammer equations. The key results are as follows:

(1) The integrated boundary conditions was used for modeling free surface, pressurized, and mixed transient flow conditions in two test cases, namely, a three-way

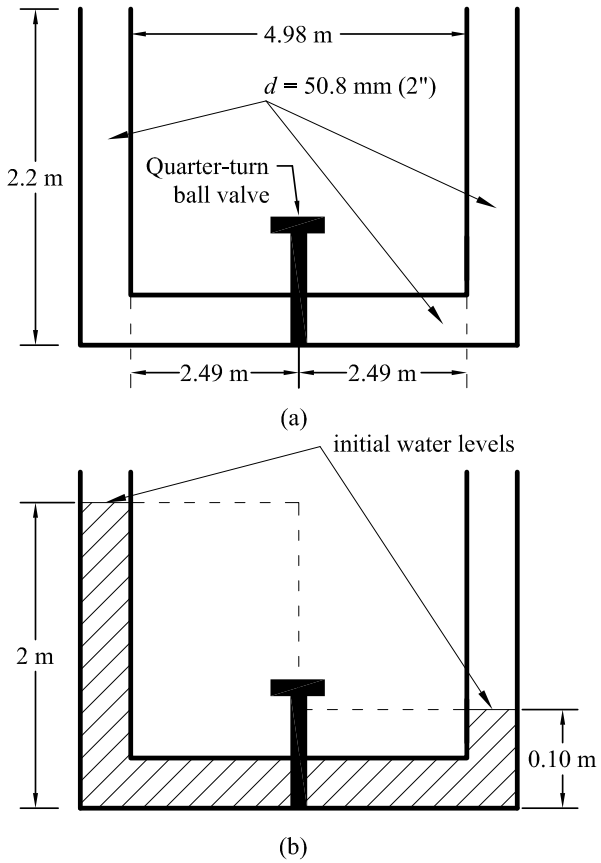

Fig. 6. Experimental setup (not to scale) (a) dimensions and (b) initial water levels

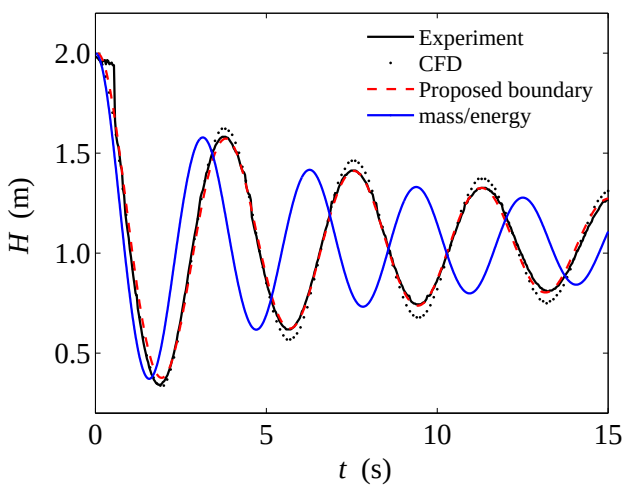

Fig. 7. Water level elevation at upstream drop shaft

merging flow boundary and a drop shaft boundary. The first test case considered a hypothetical test and the second test case is an experimental work in an oscillation tube performed by the authors of this paper. The CFD package FLOW-3D was used as frame of comparison for the first test case and the open source code OpenFOAM

besides experimental results was used for the second test case. The results showed that the integrated boundary conditions can be used for modeling free surface, pressurized, and mixed transient flow conditions at these complex boundaries with good accuracy.

(2) For the accurate prediction of frequency and amplitude of rapid variation of water surface levels in drop shafts the momentum equation and not the energy equation must be used.

(3) Overall, the integrated boundary conditions can be used to simulate any flow regime (free surface, pressurized and mixed flow) at complex boundaries such as drop shafts, reservoirs and junctions with any number of inflowing and outflowing pipes. The integrated boundary conditions were implemented in the Illinois Transient Model (ITM), which has been used to study hydraulic transients in the Calumet system of the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC). The results of the latter study are not presented in this paper.

5. Acknowledgments

The authors gratefully acknowledge the Metropolitan Water Reclamation District of Greater Chicago for their financial support. Special thanks to MSc. Andrew Waratuke and Ph.D. candidate Octavio Sequeiros for their assistance on the experimental work and to Engineer Nils Oberg for his assistance on the video image processing analysis.

1. Abstract

The City of St. Louis Board of Public Service (BPS) formed a partnership with the Missouri Department of Conservation (MDC), CH2M Hill, the Metropolitan St. Louis Sewer District (MSD), Southern Illinois University – Edwardsville (SIUE), and East-West Gateway Council of Governments (EWG) in mid-2007 to find ways to incorporate low impact development (LID) techniques into City of St. Louis projects. The team identified pervious paving as the first best management practice (BMP) to investigate due to the multiple benefits it provides and the ample opportunity to utilize the practice in City-owned projects. This project is one of many initiatives in the City of St. Louis Climate Change Plan.

Impervious surfaces, such as roads, rooftops and sidewalks within the City of St. Louis contribute to water quality and quantity problems as well as the urban heat island. Converting impervious surfaces to pervious paving, an Environmental Protection Agency (EPA) recognized best management practice (BMP), reduces stormwater runoff, captures peak flows, replenishes water tables and aquifers, minimizes flash flooding and standing water, prevents warm and polluted water from entering the streams, mitigates surface pollutants and reduces heat island effect.

Pilot study data will be used to support a change in City of St. Louis policy to potentially require pervious paving in its alleys citywide. The data will also be used to promote change in private developments and other City paving projects where appropriate. The results will be used by MSD to determine if permeable pavements can be used as BMP either in junction with other BMPs or as a stand-alone BMP.

2. Background

The City of St. Louis has approximately 485 miles of alleys, and is seeking to develop an alley replacement program to provide for pervious pavements to be constructed in lieu of the more traditional and conventional asphalt pavements that are now common to many alleys in the City.

This study aimed to evaluate the effectiveness of porous pavement on flow reduction and water quality improvement in combined sewers. The flows and water quality of samples taken from combined sewers at three alleys in the City of St. Louis are

compared between before and after porous pavements are implemented. The project consists of three phases: Phase I was to monitor and characterize the flows and water quality under existing conditions; Phase II is design and construction of the porous pavement; and Phase III is to monitor and characterize the flows and water quality under improved conditions where LID has been implemented. This report describes findings from Phase I study that was conducted from May to July 2008.

In order to generate needed data to determine the effectiveness of the practice in reducing stormwater quantity and improving stormwater quality in City of St. Louis conditions, justify the increased cost over conventional asphalt paving, and to select the best materials, the team chose to conduct a pilot project. Representatives investigated other projects and met with Chicago Department of Transportation (CDOT) staff to build on knowledge they had gained from internal sources as well as research. From visiting with CDOT it was determined the most feasible porous pavement design appeared to contain traditional concrete aprons with a porous center running the length of the alley. This design incorporated a reverse crown to direct runoff to the porous pavement section.

The three pilot alleys were identified and equipment was installed to measure stormwater quantity and quality along with rainfall. Results are currently being processed by SIUE. Phase II construction began with the permeable asphalt alley, which was completed in October 2008. Funding for the pervious concrete alley is being provided by the Ward 6 Alderwoman, Kacie Starr-Triplett. Funding is still being secured for construction of the permeable paver alley.

3. Methodology

Automatic samplers and flow meters were installed at three sites by the staff of Metropolitan St. Louis Sewer District (MSD), who also collected the samples and flow data and provided rainfall data. The alley sites are shown in Fig. 1 through 3. The manholes where automatic samplers and flow meters were installed are summarized in Table 1.

Composite samples from four storm events (May 7, 25, June 20, July 8) were collected. The sampler for the Cardinal site did not trigger during Phase I study, subsequently no data were available for this site. The sampler for the Eads site was not triggered during the June 20 storm event. The collected samples were split into subsets and preserved following the Standard Methods Table 1060:I (APHA 1998) and relevant MSD protocols. The staff of SIUE picked up the samples from MSD and delivered to the Madison County Environmental Laboratory in Edwardsville, IL. The following parameters were analyzed for each sample.

- Total Suspended Solids (TSS), Standard Methods 2540D (APHA 1998)
- Total Phosphorous (TP), USEPA Method 365.3 (USEPA 1979)
- Total Nitrogen (TN): TN was determined by summing the measured TKN and nitrate. Standard Methods 4500-Norg B for TKN (APHA 1998). Standard Methods 4500-NO_3^- D for nitrate (APHA 1998)

- Metal (Total Zinc), Standard Methods 3500-Zn and 3111B (APHA 1998)
- Metal (Total Copper), Standard Methods 3500-Cu and 3111B (APHA 1998)

Fig. 1 Eads Ave. Site in City of St. Louis

Table 1. Sites of Phase I Study

Site	Current Pavement	Location	Sampler MH	Flow-meter MH	Composite Period
3127 Eads Ave.	Asphalt	Parallel to Compton, between Eads and Henrietta	21F2-278C	21F2-284C	May 7, 6:55 May 25, 13:21-13:46 June 20, no data July 8, 19:04-19:23
3217 Geyer Ave.	Brick	Parallel to Compton Hill, between Geyer and I-44	21F2-147C	21F2-147C	May 7, 5:59 May 25, 13:20-13:56 June 20, 01:20-02:02 July 8, 19:06-19:32
1412 Cardinal Ave.	Brick	Parallel to Park and Caroline, between Montrose and Cardinal	21E1-383C	21E1-385C	No data

The MSD reports of flow monitoring show flow rates that were calculated using the measured depths and velocities. The depth and velocity data were recorded mostly in 15-minute interval or in one-minute interval during rain events. The flow reports show negative flows in a number of instances, due to negative velocities and were likely due to the malfunctioning of the flow meters. When the flow hydrographs were prepared, the negative flow rates were corrected zero values.

The rainfall data for the Eads and Geyer sites were based on data from MSD's rain gauge stations of C-24 and C-13, respectively. The rainfall data, although collected in

5-minute interval, were reported in hourly interval for clarity (i.e. cumulative rainfalls in each hourly interval were plotted).

The water qualities from samples taken at the studied sites are summarized in Table 2 and are illustrated in Fig. 4 through 8. Results indicate that pollutants in the samples from the Eads site are in lower concentrations than those from the Geyer site. For facilities that discharge to MSD sewers, the MSD Pretreatment Ordinance sets the daily average discharge limit of total Zinc and total Copper to be 3.0 mg/L and 2.7 mg/L, respectively; but doesn't set limits for TSS, TP and TN. TSS from a facility to MSD sewers is monitored for billing purpose and MSD wastewater treatment plants monitor TP and TN for operation information. For the flows in MSD sewers, currently, there are no target pollutant limits or desirable pollutant concentrations.

Table 2. Water Quality – Phase I Study

	Sampling Date	TSS	mg/L	TP	mg/L	TN	mg/L	Zn	mg/L	Cu	mg/L

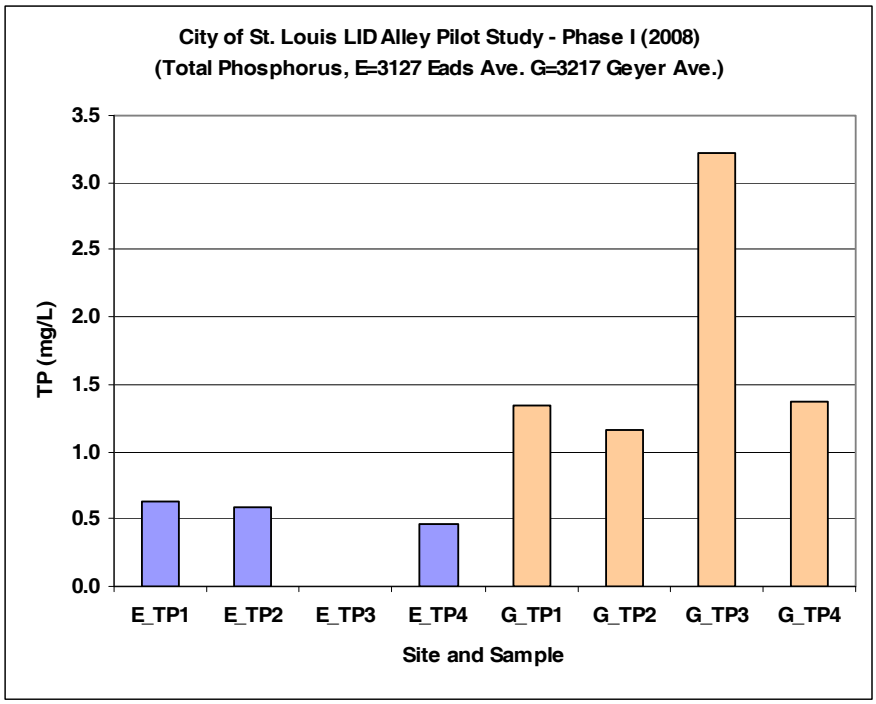

Fig. 5 Total Phosphorous (TP)

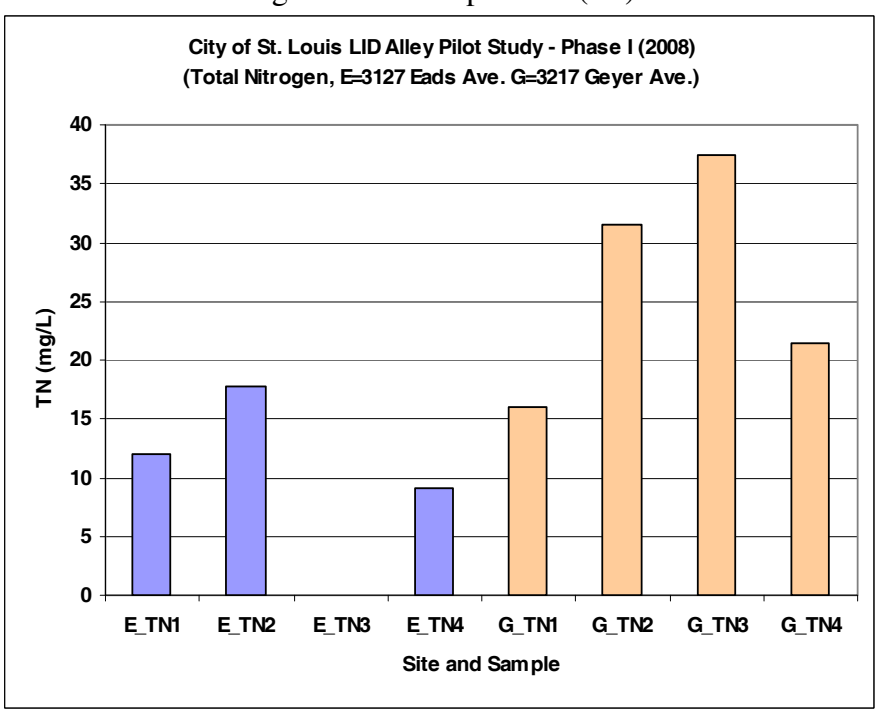

Fig. 6 Total Nitrogen (TN)

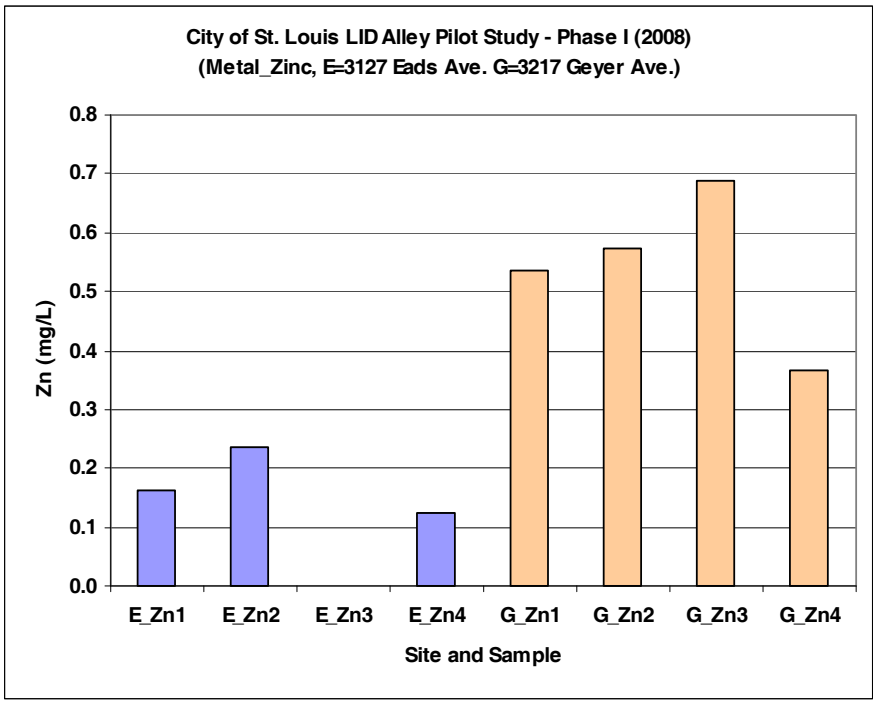

Fig. 7 Metal – Total Zinc (Zn)

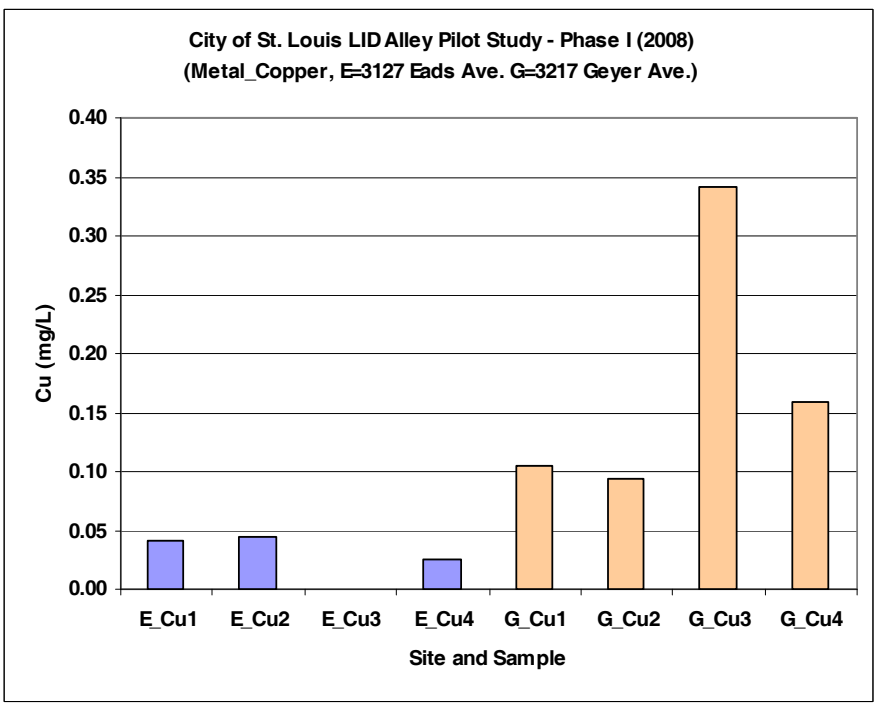

Fig. 8 Metal – Total Copper (Cu)

The flow and rainfall data for each site and each rainfall event were prepared. A sample graph is shown in Fig. 9 for the May 7 storm at the Eads alley, which shows the correlation between rainfall and metered flow in the combined sewer as expected. The peak flows and rainfalls are summarized in Table 3. It was found that flow rates

at the Eads site (up to 800 gpm) were much higher than those at the Geyer site (up to 35 gpm). For the Eads site, the two peak flows found on May 25 (564 gpm at 13.6 hr and 748 gpm at 22.3 hr) resulted from the two peak rainfalls (0.40 in/hr at 13 hr and 0.53 in/hr at 22 hr). When water quality and water quantity are correlated, it was found that the composite samples taken on May 25 at the Eads site also contained higher levels of pollutants when compared to other samples, suggesting the higher amount of stormwater runoff resulted in decreased water quality in the combined sewers. For the Geyer site, although some correlation was found between peak flows and peak rainfalls (e.g. 8.9 gpm at 14.3 hr vs. 1.20 in/hr at 13 hr on May 25), peak flows did not correlate well to peak rainfalls in many instances.

Table 3. Peak Flows and Rainfalls – Phase I Study

Site	Sampling Date	Peak Flows (gpm)	Hourly Rainfall (in/hr)
3127 Eads Ave.	7-May-08	111 at 14:00 hr	0.20 from 12:00 to 13:00 hr 0.17 from 13:00 to 14:00 hr
	25-May-08	564 at 13:38 hr 748 at 22:15 hr	0.40 from 12:00 to 13:00 hr 0.53 from 21:00 to 22:00 hr
	20-Jun-08	114 at 1:45 hr	0.11 from 0:00 to 1:00 hr

4. Results

This report describes findings from City of St. Louis low impact development alley pilot study - Phase I, which monitored and characterized the flows and water quality under existing conditions. Composite samples from the Eads and Geyer sites were obtained during four storm events in 2008. Studied water quality parameters included total suspended solids, total phosphorous, total nitrogen, total zinc and total copper. The study found that the flow rates at the Eads site were much higher than those at the Geyer site; pollutants in the samples from the Eads site are in lower concentrations than those from the Geyer site. For the Eads site, peak flows correlated well to peak rainfalls and higher amount of stormwater runoff resulted in worse water quality in the combined sewers. For the Geyer site, peak flows didn't correlate well to peak rainfalls in many instances, likely due to malfunctioned instruments. It is recommended that flow meters and automatic samplers are further verified and calibrated before they are used in Phase III study.

ABSTRACT

The analysis and characterization of competing risks for water resources rely on a wide spectrum of tools to evaluate hazards and risks associated with their management. For example, waters of the lower Colorado River stored in reservoirs such as Lake Mead present a wide range of competing risks related to water quantity and water quality. These risks are often interdependent and complicated by competing uses of source waters for sustaining biological resources and for supporting a range of agricultural, municipal, recreational, and industrial uses. USGS is currently conducting a series of interdisciplinary case-studies on water quality of Lake Mead and its source waters. In this case-study we examine selected constituents potentially entering the Lake Mead system, particularly endocrine disrupting chemicals (EDCs). Worldwide, a number of environmental EDCs have been identified that affect reproduction, development, and adaptive behaviors in a wide range of organisms. Many EDCs are minimally affected by current treatment technologies and occur in treated sewage effluents. Several EDCs have been detected in Lake Mead, and several substances have been identified that are of concern because of potential impacts to the aquatic biota, including the sport fishery of Lake Mead and endangered razorback suckers (*Xyrauchen texanus*) that occur in the Colorado River system. For example, altered biomarkers relevant to reproduction and thyroid function in fishes have been observed and may be predictive of impaired metabolism and development. Few studies, however, have addressed whether such EDC-induced responses observed in the field have an ecologically significant effect on the reproductive success of fishes. To identify potential linkages between EDCs and species of management concern, the risk analysis and characterization in this reconnaissance study focused on effects (and attendant uncertainties) that might be expressed by exposed populations. In addition, risk reduction measures that may be of interest to resource managers are considered relative to emerging contaminants in

treated effluents, interdependencies among biological resources at risk, and uses of reservoir waters derived from multiple inflows of widely varying qualities.

INTRODUCTION AND PROBLEM IDENTIFICATION

Lake Mead is located on the lower Colorado River on the border of Nevada and Arizona (Figure 1). The metropolitan Las Vegas area and growing urban development downstream of the reservoir in Arizona, Nevada, and California are highly dependent

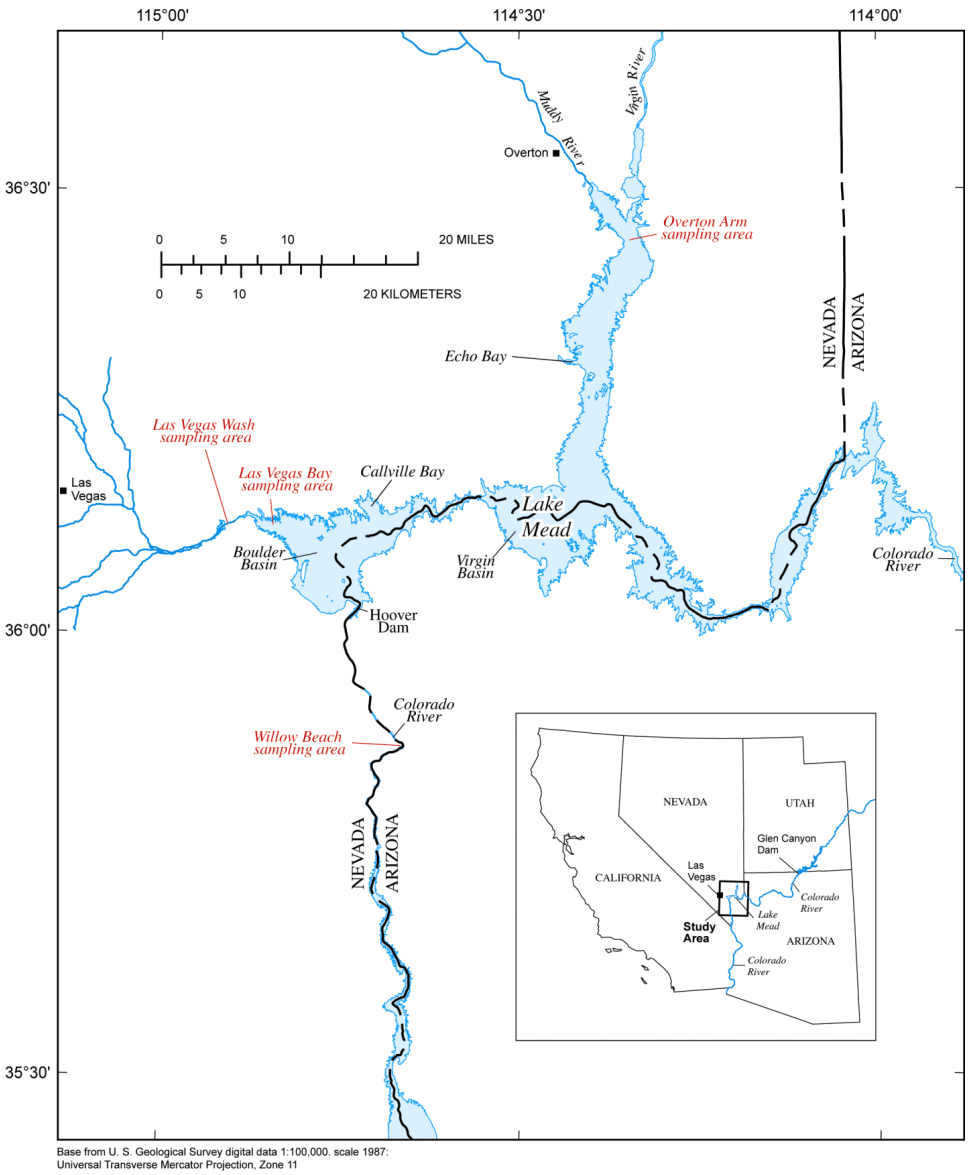

Figure 1. Lake Mead on the Nevada-Arizona border (map courtesy M. Rosen, USGS, Nevada Water Resources Center).

on water resources from the Colorado River system. Reduced water quantity associated with seasonal and decadal trends in precipitation have yielded drought conditions; degraded water quality associated with point source and non-point source inflows have also degraded water quality that may affect fish and wildlife dependent on the reservoir. Various federal and state agencies are involved in managing the Lake Mead National Recreation Area (LMNRA) including the National Park Service (NPS) which served 7.6 million visitors in 2007, and other state and federal agencies which manage the fish and wildlife resources. The states of Nevada and Arizona manage the recreational fisheries in LMNRA that are based on striped bass (*Morone saxatilis*), largemouth bass (*Micropterus salmoides*) and others sport fishes, and U.S. Fish and Wildlife Service (FWS) administers the Endangered Species Act (ESA) within LMNRA, given the occurrence of endangered species such as razorback sucker (*Xyrauchen texanus*) throughout the Colorado River system.

Chemical contaminants are among the multiple stressors that may affect the water resources of Lake Mead. EDCs have been identified in aquatic environments throughout the world including Lake Mead. Complex chemical mixtures released to surface waters in river-reservoir systems such as that at LMNRA may adversely affect endocrine systems of fishes, if effects thresholds are attained. Consequent effects on reproduction, development, and behavior of exposed fishes may occur. Many EDCs occur as constituents of sewage treatment effluents released to aquatic habitats, and some synthetic organic chemicals (SOCs) in these chemical mixtures may be unaffected by current treatment technologies. Several chemicals may be of concern relative to adverse impacts to the sport fishery and the endangered razorback sucker populations of Lake Mead that require characterization and mitigation. From existing ecotoxicological studies on contaminant-altered endocrine function, various aquatic organisms have displayed reproductive impairments, as well as altered thyroid function that may foreshadow impaired metabolism and development. Few studies, however, have addressed the wider question of whether these responses to EDC exposures in the field have ecologically significant effects on the biochemical and physiological processes and their associated reproductive behaviors critical to long-term reproductive success and maintenance of sustainable populations. The present reconnaissance-level analysis of risk and attendant uncertainties relies on existing literature and data, as well as study-specific data to estimate effect threshold concentrations for chemicals potentially affecting target species. A preliminary evaluation of bioaccumulation and food-chain partitioning of EDCs based on existing data and literature for EDCs will also be presented. This reconnaissance-level analysis will provide a preliminary assessment of EDC impacts occurring in Lake Mead and help inform NPS in developing their adaptive management plans..

BACKGROUND STUDIES

Prior studies of Lake Mead indicate the presence of numerous SOCs in water, bottom sediments, and fish, including chemicals capable of disrupting endocrine function in fishes (see, e.g., Bevans et al. 1996; Goodbred et al. 2007). Resource management issues associated with exposures of fish and wildlife to complex

chemical mixtures characteristic of surface waters and sediments in Las Vegas Wash (LVW) and Lake Mead were identified by USGS and FWS (Tuttle, et al. 2002). Presumptive links between EDCs and common carp (*Cyprinus carpio*) inhabiting waters of Lake Mead via treated wastewater discharges released to Las Vegas Bay (LVW) have been characterized (see, e.g., Goodbred et al. 1997; Patiño et al. 2003). Treated effluents include polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), chlorinated pesticides, and pharmaceuticals and personal care products (PPCPs). In addition to point sources such as treated wastewater discharges from municipal wastewater treatment plants in the Las Vegas Valley, non-point source inputs also contribute water inflows to LVW and include urban runoff from lawns, gardens, and golf courses, as well as storm-water runoff and subsurface inflow. Chemical constituents linked to point-source and non-point source inputs into Lake Mead are listed in Table 1. These constituents are similar to treated wastewater discharges from other urban systems (Koplin et al. 2002). Based on the literature the compounds included in Table 1 have environmental risks associated with chronic or acute exposures that may be linked to adverse effects observed in aquatic biota of Lake Mead. Many of these chemicals have different biochemical modes of toxic action, including endocrine disruption, that may cause or contribute to expression of adverse affects observed in aquatic biota of Lake Mead.

BOUNDING THE ANALYSIS OF RISK IN THE RECONNAISSANCE STUDY

To facilitate this reconnaissance investigation, a short list of chemicals of concern with known or presumptive modes of action through endocrine disruption was selected for our investigation (Table 1). The short list of chemicals was primarily focused on EDCs previously identified in the waters and sediments of Lake Mead, as well as tissue-residues of EDCs or metabolites of EDCs identified in fishes collected at various times and locations in Lake Mead in previous studies. In part, the short list of chemicals considered in the risk analysis reflected point-source and non-point source inputs observed in other systems experiencing chemical inputs and associated stresses.

Within the context of exposure risk, the Lake Mead system includes a number of aquatic biota that are representative of other species commonly encountered in riverine and reservoir habitats of the southwest U.S. and of endangered or threatened status under the Endangered Species Act. The conceptual model for this reconnaissance analysis of risk is illustrated in Figure 2, which highlights the primary focus on fishes and aquatic invertebrates dependent on habitats characteristic of Lake Mead and water inflows such as that illustrated by LVW. Here, our focus on fishes centered on striped bass and largemouth bass as representative sport fishes, and razorback sucker as a special status species. Because common carp inhabit a wide range of aquatic habitats within Lake Mead, this abundant species served as a surrogate species. Despite the initial emphasis on fish and aquatic invertebrates, past and ongoing studies have identified a wide range of aquatic receptors that should bring an ecological scale to future investigations.

Fragrances
- tonalide (AHTN)
- galaxolide (HHCB)
- indole
- benzophenone
- oxybenzone

Household chemicals
- caffeine
- butylated hydroxyanisole (BHA)
- triclosan

PAHs and Heterocyclic Aromatics
- naphthalene
- benzo[a]pyrene
- 2-methyl naphthalene
- acetophenone
- phenanthrene
- indole
- pyrene
- d-limonene
- 1-methyl naphthalene
- 2,6-dimethyl naphthalene
- p-cresol
- isoquinoline

Pesticides, Herbicides, & Commercial Biocides
- chlorpyrifos
- o,p-DDE
- triazine herbicides including atrazine and its metabolites
- acetochlor
- alachlor
- diazinon
- dichlorvos
- diuron
- isoproturon
- metolachlor
- DDT
- endosulfan
- methoxychlor
- cis/trans-chlordane
- HCB
- dacthal
- trifluralin

Other Chemicals Associated with Wastewater Treatment
- urobilin

Natural Products, Pharmaceuticals & Illicit Drugs
- methyl salicylate
- acetaminophen
- carbamazepine
- azithromycin
- erythromycin
- sulfa drugs and other antibiotics
- tetracycline antibiotics
- DEET
- 17-beta-estradiol, 17-beta-ethynylestradiol and their metabolites: estrone and estriol
- methamphetamine (MDMA)

Surfactants
- 4-tert-octylphenol
- alkyl phenols such as nonylphenol and octylphenol

Other Priority Pollutants Chemicals of Concerns
- PCB Congeners
- chlorinated dibenzodiox & dibenzofurans (2,3,7,8-TCDD; 2,3,7,8-TCDF)
- perfluorinated compoun (PFOS, telomer alcohol
- flame retardants (PBDE including PBDE 47, 99, 100, 138, 146, 160)
- tributyl tin
- diethylphthalate
- diethylhexylphthalate
- bisphenol A
- isophorone
- tris(2-chloroethyl) phosphate
- tris(2-buthoxyethyl) phosphate
- 5-methyl-1H-benzotriaz
- 3,4-dichlorophenyl isocyanate
- tributylphosphate
- triphenylphosphate

Table 1. Chemicals identified in surface water, sediment, and tissues collected during recent studies at Lake Mead. (List compiled from various sources, including Bevans et al. 1996; Covay et al. 1998, 2001; Goodbred et al. 1997, 2007.)

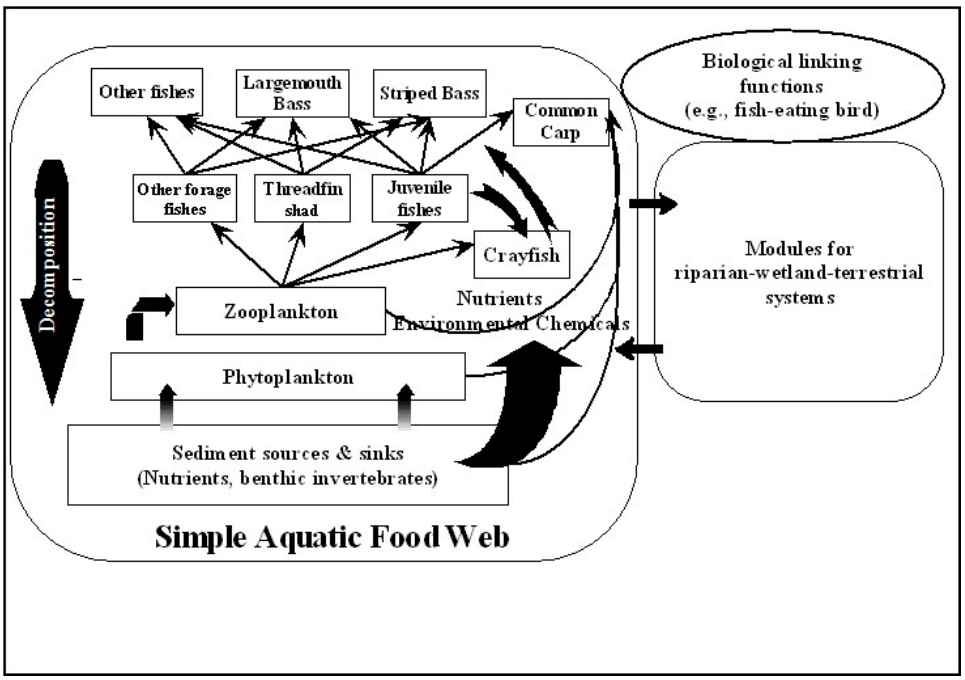

Figure 2. Conceptual model guiding reconnaissance level of analysis of risks associated with exposures of aquatic biota of Lake Mead to EDCs in surface waters and sediments.

The reconnaissance analysis of contaminant risks was focused on fishes and aquatic invertebrates (Table 2), because of their impairment as a result of exposure and their role in food-web transfer of contamination as depicted in the conceptual model in Figure 2. In addition to these representatives of the sport fishery at Lake Mead, razorback sucker was a key species in the analysis of risks, because of its endangered status.

Receptor	Scientific name
Largemouth bass	*Micropterus salmoides*
Carp	*Cyprinus carpio*
Striped bass	*Morone saxatilis*
Rainbow trout	*Oncorhynchus mykiss*
Threadfin shad	*Dorosoma petenense*
Razorback sucker	*Xyrauchen texanus*
Crayfish	*Pacifastacus gambelii*
	Pacifastacus leniusculus leniusculus
	Pacifastacus leniusculus trowbridgii
	Procambarus clarkii

Table 2. Species of concern in the reconnaissance level analysis of risks associated with the presence and inflow of EDCs in Lake Mead.

The conceptual model (Figure 2) guiding this reconnaissance analysis also includes microbial biodegradation studies (see, e.g., Kudłak and Namieśnik 2008) linked to the environmental fate of EDCs occurring in inflows to Lake Mead, and aquatic food-web studies that examined potential interactions among environmental chemicals characteristic of the point-source and non-point source inputs released to the Lake Mead system (see, e.g., Belgrano et al. 2005). When these ongoing studies are completed, a comprehensive analysis of ecological risks based on study-specific empirical data should follow this reconnaissance analysis and characterization of risks to fishes and other aquatic biota.

METHODS AND MATERIALS

Reconnaissance level risk analysis of EDC exposures to fishes and other aquatic biota inhabiting Lake Mead relied on study-specific investigations and data-mining tools.

Study-specific investigations

Project-specific field sampling events occurred during 2006 and were focused on potential effects of chemical stressors on fishes in LMNRA. Bottom sediments and fish tissue were sampled from LMNRA, Las Vegas Wash (LVW), Las Vegas Bay (LVB), Overton Arm (OA), and Willow Beach (WB) and were characterized for EDCs and other SOCs (Rosen et al. 2006a,b). For this initial report of findings derived from these reconnaissance investigations, fish, bottom sediments, and samples from semi-permeable membranes devices (SPMDs; Huckins et al. 2006) and polar organic chemical integrative samplers (POCISs; Alvarez et al. 2007) were evaluated for chemicals of concern. Samples were collected at LVB, OA, LVW, and WB and were analyzed for a variety of SOCs, including pesticides, PAHs, PCBs, BDEs, and emerging contaminants, including EDCs represented by pharmaceuticals and PPCPs and other constituents of treated wastewater discharges. The SPMDs/POCISs were deployed at various locations on Lake Mead, including venues close to locations where fish were collected. Fish were collected at sample locations four times during the year to cover a full reproductive cycle (March, July, and November 2007 and March 2008). Biomarkers for analysis included sex steroids (11-ketotestosterone, estradiol-17β), thyroid hormones (triiodothyronine, thyroxine), vitellogenin, gonadosomatic index and parameters of sperm quality (viability, mitochondrial function, motility by computer and unaided eye, DNA integrity and percent spermatogenic stage, sperm count). Whole fish were analyzed for a suite of pesticides, PAHs, PCBs, and for emerging contaminants including BDEs, musks, fragrances, and PPCPs.

Complementing these sampling efforts, food-web biota characteristic of Lake Mead were also used in developing models for food-web energetics and predator-prey dynamics. The SOCs accumulating in tissue of animals at each trophic level were measured for comparison to food-web models to determine biological pathways for organic contaminants in Lake Mead. Similarly, microbial sampling was

completed in parallel with sampling for fishes; microbial sampling was focused on species isolation and DNA sequencing to evaluate the biodegradation potential of microbial communities in sediments and the sediment-water interface. Isolated microbes that degrade SOCs may effectively reduce risk by mediating degradation and transport of EDCs such as ethinylestradiol (EE2).

Literature search and data mining

Review of existing toxicity data was accomplished through data mining of existing sources and through literature searches of primary data published in peer-reviewed literature and searchable public domain sources. Data mining and literature searches are complementary activities which may include redundancies that act as data quality measures. For example, existing databases may reflect a collection of original literature and original data/metadata supporting data compiled from publications encountered as part of the literature search. Analytical tools applied to the compiled data included traditional methods of environmental informatics (Avouris and Page 1995; Huang and Chang 2003), as well as supplemental tools applied as part of a comparative analysis. Databases queried in data mining included assembled data packages such as ECOTOXicology database (ECOTOX; http://cfpub.epa.gov/ecotox/ index.html last accessed November 8, 2008). ECOTOX integrates AQUIRE, TERRETOX, and PHYTOTOX which include toxicity data derived predominately from the peer-reviewed literature for aquatic life, terrestrial wildlife, and terrestrial plants, respectively. As noted in supporting documentation for ECOTOX, the database presents limitations related to data retrieval and requirements of the online implementation of search, as well as data gaps reflected by technically reviewed data published by research agencies such as USGS but not captured in ECOTOX. Such data gaps are most often offset by recently published literature that includes relevant toxicity data that has yet to be incorporated into ECOTOX. As recommended, original scientific papers were reviewed, as needed, to ensure an understanding of the context of the data retrieved from ECOTOX. Data collected outside EPA's efforts with ECOTOX revealed data sources previously published in technical reports by USGS and NOAA/NMFS that do not appear in ECOTOX.

In addition to assembled data packages such as ECOTOX, ongoing collections of existing data and information were also used as supplemental data sources for evaluation of toxicity thresholds for EDCs pertinent to exposures at Lake Mead. Nested literature search and acquisition of existing peer-reviewed data and literature were completed through:

- Focused search using on USGS/CERC data mining resources
- Open literature search using on PubMed-NLM
- Open literature search using on Synergy and ScienceDirect
- Focused manual search based on networked citations derived from data and literature sources encountered in directed computer-aided data mining searches

Literature searches relied on USGS/CERC resources and were initiated and completed using primary database providers Cambridge Scientific Abstracts (CSA) and OCLC FirstSearch. Databases searched in CSA included Aquatic Sciences and Fisheries Abstracts, Biological Sciences, Environmental Sciences and Pollution Management; and to a lesser extent, AquaLine, Water Resources Abstracts, GeoRef, Biology Digest, Conference Papers Index, Medline and Toxline. Databases in OCLC FirstSearch included Agricola, ArticleFirst, BasicBiosis, Dissertations, GeoBase, WorldCat, BioAgIndex, Electronic Collections Online, PapersFirst, and Proceedings. Ingenta database provider was also used for some searches.

Other than chemical name, searches for species of concern used the scientific name (at genus or species level), and common names, if applicable. Depending on the number of citations found, additional search terms were added. Terms also included keywords related, e.g., to distribution of the species, its life history and habitat, and its interaction with other species.

Independent literature searches relied on existing numeric ecotoxicological data that had not been captured in historic data collections from USGS sources, as well as recent data found in recent literature not included in ECOTOX (e.g., literature published after 2000, and more frequently, after 2006). Updated open literature searches were completed using available online search engines from PubMed-NLM, Synergy, and ScienceDirect. These searches focused on journal-specific peer-reviewed literature and provided limited redundancies relative to primary search accomplished using USGS/CERC sources. Focused manual searches of existing data and literature were initiated using networked citations discovered during the computer-aided searches. Once assembled, sufficient data were combined with toxicity data from ECOTOX and from supplemental literature and data searches. These compiled data provided a basis for evaluating presumptive threshold values for EDCs. In general, data analysis and application of empirically-based derived values were consistent with "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" (Stephan et al. 1985). Available data on chemicals of concern were reviewed with respect to their toxicity to and bioaccumulation by aquatic biota, including consideration of endpoints other than survival, growth, and reproduction which conforms to the "best available science" qualification implicit to Stephan et al. (1985) and posited by NAS (2000). For EDCs included in Table 1, data were frequently not sufficient to satisfy data specifications for each chemical concern; hence, three specifications for data were also considered within the reconnaissance level analysis for this investigation (modified from Stephan et al. 1985):

(i) Are "effects-no effects" ratio estimators (e.g., Acute-chronic ratios; ACRs) calculable for at least two different families of aquatic species?
(ii) Are toxicity data available for at least one freshwater plant (either algal or a vascular plant)?
(iii) Are bioconcentration or bioaccumulation data available?

Each of these data specifications was considered within the context of the exploratory data analysis for this reconnaissance investigation. Ideally, freshwater species toxicity data presented median lethal concentration (LC50) data and chronic (no-observed-effect-concentration) NOEC data of appropriate duration. In practice, most chemicals with water quality criteria have sufficient LC50 data to permit derivation of an acute water quality criterion from measured LC50 data, but do not have sufficient measured chronic NOEC to calculate reconnaissance level thresholds. Hence, ratio estimators reliant on "effect-no effect" empirical data provide measures analogous to the typical ACR values commonly encountered in regulatory applications.

Exploratory data analysis of encountered data compiled from the search of existing data and literature. For evaluating threshold effect levels for chemicals of concern, extrapolation methods were required for evaluating toxicity data for surrogate species regardless of whether the surrogate is a listed or non-ESA-listed species. Interspecies Correlation Estimation (ICE) models and species sensitivity distributions (SSDs) are commonly used in evaluating risks associated with chemical exposures to a wide range of species and can be used with toxicity data from multiple taxa levels. The SSDs, ICE, and development of ACRs (Mayer et al. 1999) for representative species and for threatened and endangered species served as the primary tools for extrapolations of toxicity data from traditional aquatic toxicity test species to other species presumptively protected by these surrogates.

The SSDs are based on the assumption that available toxicity data for a group of taxonomically related species are representative of the responses of other species for which toxicity data are not available. A statistical description of the toxicity data can then be generated which permits calculation of the proportion of all species that would be adversely affected by exposure to a chemical at a given concentration. As long as the toxicological endpoint for each species is the same (e.g. LC50s, NOECs), an SSD can be generated for any toxicological endpoint and mix of species. This feature of SSDs is one of their great advantages relative to other endpoint estimation methodologies, in that they explicitly consider the results of all available toxicological information for a given assemblage of species (Dyer et al. 2006; Awkerman et al. 2008; Raimondo et al. 2008; Posthuma et al. 2002). Although no one estimation method is universally used, the most commonly used distributions to estimate 5th percentiles from SSDs are the log-logistic and lognormal distributions. As such, cumulative probability distributions of toxicity values for multiple species were applied to this reconnaissance level analysis (Dyer et al. 2006), and SSDs were assembled based on single-species toxicity data to predict hazardous concentrations (HCps) affecting a certain percentage (p) of species in a community. The fit of the lognormal model and required number of individual species values were evaluated with published data sets. For this reconnaissance level investigation, tools of exploratory data analysis (e.g., percentile-based ratio estimators) were opted for rather than the common assumption that a lognormal model best fit the data assemblage (see Newman et al. 2000, 2003 for alternative methods).

The ICE models were also considered in extrapolation from literature-acquired toxicity data to representative species considered in this investigation. It is impractical for toxicologists to perform laboratory toxicity studies on all aquatic species present in North America with all chemicals to which they are exposed in the environment, and even more so for ESA listed species whose rarity or limited distribution in the environment generally precludes their use as test organisms in aquatic toxicology. The ICE models are statistical regressions that estimate LC50s for a species or higher taxa (genus, family) having no measured acute toxicity information from a species for which five or more LC50s have been measured. The detailed description of how ICE models were developed and their use to estimate LC50s for taxa for which no toxicity information is given in Asfaw et al. (2003). Toxicity of a chemical to one species can be predicted from toxicity to another species with a known certainty, which is expressed as the 95% upper and lower confidence intervals around the predicted LC50. Asfaw et al. (2003) recommend performing ICE model evaluations on species taxonomically no further apart than the family level. For higher taxonomic ICE models (e.g. genus or family), data from two surrogate species from the genus or family being estimated should be available before using ICE models for higher taxonomic groupings to ensure that the ICE models do not significantly over or under estimate the data. If evaluation of a chronic criterion was being performed, the lower 95% confidence interval of the predicted LC50 was divided by the acute-chronic ratio (ACR) to estimate a lower 95% confidence interval of the NOEC for the chemical and species under evaluation.

The ACRs are typically applied to acute toxicity data to estimate chronic values, yet for EDCs with modes of actions that do not typically yield diminished survival at environmentally relevant concentrations, reconnaissance level analysis relied on ratio estimators based on lowest-observed-effect-concentrations (LOECs)-to-NOECs for surrogate species, especially when special-status species were considered. In such a reconnaissance level analysis ratio estimators based on percentiles were applied to evaluation of effect *v.* no effect levels. In contrast to regulatory guidance wherein water quality criteria are not designed to protect all aquatic species from exposure to chemical concentrations, the reconnaissance level analysis of risk was intended to conservatively posit such levels, or in the absence of data sufficient to such an interpretation, provide a numeric estimate with statements regarding uncertainty about these estimates. For national water quality criteria, many are presumptively protective of more than 95% of aquatic genera from adverse effects, including ESA-listed species known to occur within discrete geographical areas. ESA-listed aquatic species as a group have not been consistently characterized as being more sensitive to chemicals than aquatic species as a whole (Dwyer et al. 2005, Sappington et al. 2001, Dwyer et al. 1995, 1999).

Exploratory analysis of data derived from study-specific investigations.

All data compiled from the data mining (principally through ECOTOX) and data compiled as outcomes of open literature searches were included in this analysis. As a preliminary data reduction effort, study-specific data were tabulated and

evaluated relative to biological effects data recorded from fishes collected in sampling areas at various locations at Lake Mead. Correlation analysis was completed using a binary rank-sums approach wherein estimates of location-specific concentrations of waterborne EDCs were compared to biological measures determined in co-located fish samples (Dietz 1985; Hollander and Wolfe 1999).

RESULTS AND CHARACTERIZATION OF RISKS AND UNCERTAINTIES

In this initial report of outcomes from the reconnaissance level analysis of risks, project-specific studies were considered in parallel with outcomes of the data mining efforts focused on characterizing existing toxicity data and supporting literature, with a particular focus on exploratory analysis for characterizing threshold effect levels for selected EDCs.

Preliminary findings of project-specific studies

Preliminary reports of technical findings from chemical and biological investigations were initially reported at the Lake Mead Science Symposium convened in early 2009 (http://www.lakemeadsymposium.org/ last accessed February 9, 2009). SPMD and POCIS estimates of concentrations of chemicals in surface waters collected during early sampling events are summarized in Table 3. Comprehensive data reduction and interpretation of results remains ongoing, yet preliminary results of the biological assessments based on fishes indicated the existence of location-specific environmental influences on indices of reproductive condition in male common carp from the LMNRA. From highest to lowest values, reproductive condition in common carp by site showed that OA > LVB > LVW > WB (see Patiño, et al. 2009 available at http://www.lakemeadsymposium.org/ program_e.htm last accessed February 10, 2009). These outcomes based on condition were consistent with results from exploratory correlation analysis wherein biological effects indicated by reproductive condition were correlated with rank-sum EDC scores (see Table 3). Although SPMDs and POCIS devices were not deployed in LVW, binary rank-scores for selected analytes were negatively correlated with biological effects and consistent with those trends noted immediately above, i.e., highest binary rank-sums for chemicals sampled via SPMDs occurred at locations near LVB which were characterized by lowest values for reproductive condition in male carp. In these preliminary findings of the reconnaissance investigation, low reproductive condition at WB is not uniquely linked to chemical exposures, as suggested by the low rank-sum score for selected chemicals at that location. Given the wide range of stressors potentially affecting biological organisms, clearly characterized linkages between chemicals and biological effects must be deferred until ongoing chemical and biological analyses are complete.

Exploratory data analysis and preliminary characterization of threshold effects concentrations

Exploratory data analysis was completed on toxicity data mined from available databases such as ECOTOX and compiled public domain data compilations and updated from existing literature sources. When these existing toxicity data

Table 5. Reconnaissance estimators of effects v. no effects estimators (based on LC50s as traditional acute values and NOECs as traditional chronic values) for 4-nonylphenol.

were sufficient, graphic summaries and exploratory data reductions for chemicals of concern listed in Table 1 were characterized as illustrated in Figures 3-6 and Tables 4-5 for estradiol and 4-nonylphenol. Graphic and tabular data summaries varied as a function of data availability; for many EDCs identified as chemicals of concern, toxicity data required for reconnaissance analysis of risks were highly limited, and in some cases insufficient for exploratory data analysis. For example, Figure 3 summarizes the available toxicity data for estradiol that includes predominately chronic data with relatively few high-quality data available from acute studies. In part, the paucity of acute data (e.g., LC50s) reflects a common attribute for EDCs that are similar to steroid hormones commonly measured in fishes. As a consequence, conventional guidance (Stephen et al. 1985) may not be sufficient to reliabily forecast threshold effects concentrations for selected EDCs (Table 1). Hence, alternative tools were employed within an exploratory data analysis completed for this reconnaissance investigation.

For example, in the absence of data sufficient to apply ICE models or to characterize ACRs, exploratory tools considered "effect *v.* no effect" estimators, in part, to characterize spreads between empirical distributions of traditional chronic toxicity endpoints (LOECs and NOECs) that might contribute to characterizations of risk. Given the mode of action of EDCs, it is not unlikely that spreads between effect and no-effect levels may reflect marked inflections in dose-response curves where upper critical points sharply delineate between nominal endocrine function and dysfunctional states linked to exceedance of threshold levels in field exposures.

In a similar manner, preliminary evaluations of bioaccumulation potential of EDCs have been included in this reconnaissance level analysis of risks. For example, early rounds in the reconnaissance studies focused on this aspect of the analysis of risks and uncertainties. Leiker et al. (2008) analyzed SOCs in tissues from common carp collected from LVB and SPMDs deployed in LVW and found methyl triclosan, which is likely a methylated product of the antibacterial agent triclosan (2, 4, 4'-trichloro-4-hydroxydiphenyl ether). The methylated product is presumptively a product of microbial activity in sediments and surface waters and was detected in all 29 male common carp from LVB with a mean concentration of 596 ug/kg wet weight (ww). These tissue levels are more than an order of magnitude higher than previously reported concentrations in the literature. Halogenated analogs of the methylated product were detected less frequently (21%–76%) and at much lower concentrations (< 51 ug/kg ww). None of these compounds was detected in common carp from a Lake Mead reference site in Overton Arm, Nevada.

In aquatic environments, triclosan is expected to adsorb to suspended solids and sediments, reducing its bioconcentration potential in water-only exposures. However, given the chemical's physicochemical properties, Leiker et al. (2008) confirmed that triclosan (K_{ow} 4.76) accumulates in fish tissues, although the relative contributions of dietary or water-borne sources remains unclear. Bioaccumulation of triclosan or its metabolites may be problematic for aquatic organisms and biota dependent on aquatic organisms as food sources. In surface waters hydrolysis is not expected to be an important environmental fate process, given the chemical's stability under environmental conditions commonly encountered in Lake Mead

surface waters. However, triclosan is susceptible to degradation via aqueous photolysis, having a half-life in lakes of between < 1 hour to 10 days under abiotic conditions. As suggested by Leiker et al. (2008), triclosan is susceptible to biodegradation based on the presence of methyl-triclosan following wastewater treatment.

As model EDCs from the short-list of chemicals of concern in this reconnaissance analysis of risks (Table 1), estradiol and 4-nonylphenol illustrate technical issues common to EDCs and the evaluation of their effects on aquatic biota and adverse expression of these effects at higher levels of biological organization. For example, Figure 3 clearly indicates a wide dispersion of toxicity data for estradiol, which is dominated by chronic toxicity endpoints such as NOECs and LOECs and a paucity of acute endpoints. As noted previously, this trend will be common, given the mode of action of most EDCs in receptors most likely exposed to these chemicals in the field and will require risk analysis tools beyond application of ACRs. If data are sufficient, ICE models may be applicable, yet in the absence of relational data linking acute effects and chronic effects, forecasts of threshold effects levels should be advanced with caution. For example, based on SSD for chronic LOECs and NOECs for estradiol (Figures 4 and 5), an HC5 would be about 0.0004 ug/L (see Table 4). Regulatory guidance indicates an HC5 is not intended to protect all species; hence, special status species such as razorback sucker may not occur in the 95 percentile protected category. From a conservative view opted for in this reconnaissance analysis of risks, an estimated HC1 based on the SSD for estradiol would be 0.0001 ug/L. Such thresholds are poorly supported by existing literature and region-specific empirical studies, and regulatory guidance values are lacking. Therefore, the value may be practically limited as an effects threshold. If viewed as a point of departure for future studies, however, these threshold goals may be applicable to the risk tolerance of resource managers facing decisions in the presence of uncertainty.

In contrast to estradiol, the available toxicity data for 4-nonylphenol is dominated by acute LC50s, e.g., for fishes (Figure 6). The ACRs based on the limited chronic data (as NOECs) would range from 4.2 to 7.5, depending on distribution assumptions framing the ratio analysis (Table 5). Although limited, available chronic toxicity data for 4-nonylphenol indicate that 15.6 ug/L and 18.2 ug/L would be forecast as HC1 and HC5 values, respectively. These threshold effects values are consistent with estimates based on LC50s modified by ACRs. In this instance, forecasts of NOECs for special status species such as razorback sucker is estimated at 54 ug/L based on fathead minnow (*Pimephales promelas*) acute and chronic data and their derivative ACRs. NOEC forecasts reflect inputs of empirical acute values for razorback sucker and an ACR equivalent to 5.1. Caution is recommended when interpreting either of these forecast threshold values, given the uncertainties linked to their derivation in this reconnaissance level analysis of risks.

CONCLUSIONS AND FUTURE STUDIES

Results of the reconnaissance studies, particularly those focused on field biomarker studies for fishes, indicate that reproductive condition of fish in the Lake Mead ecosystem was spatially variable, with markedly reduced fish condition at LVB relative to OA. Preliminary characterization of chemical constituents through SPMDs deployed in surface waters at various locations in Lake Mead indicated that exposure linked to altered endocrine function is possible. Reduced reproductive condition in fishes collected at locations spatially related to those where surface waters were sampled using SPMDs also indicated that other stressors may be acting independently or in concert with chemical stressors as indicated by fishes collected at Willow Beach that presented reduced condition, but at a low incidence of EDCs in SPMD samplers. Technical findings to date suggest that additional work could reduce uncertainties related to exposure, especially as those uncertainties serve as confounding factors in cause-effect analysis. These additional studies could be addressed through integrated field and laboratory studies if adaptive management plans are going to be developed within a multiple stressors context.

Prior studies at Lake Mead indicate the presence of numerous SOCs in water, bottom sediments, and fish, including identification of EDCs in waters and sediments capable of inducing biological responses in fishes and other aquatic biota. For example, altered gonad development and diminished reproductive capacity in fishes have provided evidence of endocrine disruption in common carp (Covay et al. 1998, 2001; Goodbred et al. 1997, 2007; Jenkins and Goodbred 2005, Patiño et al. 2003). These earlier studies determined that SOCs released to LVW entered Lake Mead via LVB, and included PAHs, PCBs, chlorinated pesticides, and PPCPs. Exposure to these compounds may be linked to altered system structure and function through diminished reproduction of aquatic life and expression of adverse effects at population levels of organization. The sources of SOCs include urban runoff from lawns, gardens, and golf courses, storm-water runoff, subsurface inflow, and sewage effluent from three municipal wastewater treatment plants (see, e.g., Covay et al. 1998, 2001; Goodbred et al. 1997, 2007; Jenkins and Goodbred 2005, Patiño et al. 2003).

Despite these earlier studies of Covay et al. 1998, 2001; Goodbred et al. 1997, 2007; Jenkins and Goodbred 2005, Patiño et al. 2003, few subsequent studies have considered the ecological significance of exposures to EDCs in the field. For example, population-level responses in fishes that are linked to their diminished reproductive success associated with the disruption in their normal biochemical and physiological processes have not been observed. Given that the reconnaissance level analysis of risks cannot answer questions related to the ecological significance of EDC exposures, this suggests that future studies be focused on the effects of exposure to EDCs on the reproductive potential of fish. Furthermore, outcomes of these reconnaissance investigations should contribute to design and implementation of future studies focused on toxicity assessment, including early life-stage and multiple generation toxicity tests or toxicity identification evaluations (TIEs) that contribute to risk reduction measures (US EPA 2005, 2002a,b,c).

Alternative water treatment regimens may be considered in parallel with TIE determinations. Combined water treatment technologies are currently being evaluated

with respect to their capacity to reduce risks associated with EDCs and may be applicable within a TIE experimental design targeted on changes to biological treatment, changes to wastewater treatment process (e.g., addition of ozone and biologically active carbon or addition of advanced membrane treatment and advanced oxidation; see, e.g., Westerhoff et al. 2005; WERF 2007; Linden and Kullman 2008; Snyder et al. 2008), infrastructure development intended to reduce risk (NPS 2008), or upfront planning for implementation of natural treatment options. In parallel with trophic transfer and biodegradation studies, outcomes of future investigations developed as outgrowths of reconnaissance analysis of risks and uncertainties will contribute to informed adaptive management plans for Lake Mead and the Colorado River below Hoover Dam. In contrast to initial discovery, future studies can build upon previous findings and outcomes of the reconnaissance level analysis of risk to address resource management queries that would benefit development of adaptive management plans for Lake Mead, Nevada based on countermeasures identified as part of risk trade-offs captured by ongoing risk reduction strategies (e.g., NPS 2008).

Acknowledgements. Much of the existing literature and existing data for Lake Mead and environs yields a long list of researchers and resource managers doing work as a result of past, ongoing, and future studies. Currently, research on environmental quality issues related to fish and wildlife, and complex chemical mixtures entering Lake Mead is being conducted by government and academic scientists working under the auspices of many funding mechanisms. Special thanks go to Erik Orsak, Dave Alvarez, Kathy Echols, Reynaldo Patiño, and Jill Jenkins for updates on their ongoing field and laboratory research.

CONSTRUCTION OF A LOW-FLOW CHANNEL IN BARBER CREEK: CASE STUDY IN THE POWDER RIVER BASIN, WYOMING

Robert W. Thoman, P.E.[1] and J. J. Brown[1]

[1]Lowham Engineering LLC, 205 South Third Street, Lander, Wyoming 82520, PH (307)335-8466; FAX (307)335-7343; email: bthoman@low-water.com, jjbrown@low-water.com

Abstract

Design and construction of low-flow channels to convey coalbed natural gas-produced (CBNG-produced) waters to higher-order streams is a relatively new water management option being employed in the Powder River Basin (PRB) of northeast Wyoming. In this case study, a low-flow channel was designed, constructed, and maintained on Barber Creek and South Prong Barber Creek in the PRB near Gillette, Wyoming. Engineering design challenges include large ephemeral flows, steep slopes, and cohesive soils. Initial design was based on aerial photography analysis, low-level reconnaissance flights, and field exploration. Existing channels were surveyed to establish representative channel sinuosity, depth, slope, and stability of streams in close proximity to the study area. The final design includes approximately 1,370 m (4,500 ft) of channel reconstruction on South Prong Barber Creek and 1,800 m (5,900 ft) of channel reconstruction on Barber Creek. Clay soils hardened by severe drought conditions presented an unexpected challenge during construction, as did several significant rainfall events which occurred immediately following initial construction, damaging design elements already in place. Automatic streamflow gages located upstream and downstream of the study area recorded the subsequent flood events. Post construction design considerations include stabilization of the existing channel and installation of erosion mitigation measures. This study provides a full range of design criteria, construction procedures, and mitigation efforts for consideration in the design of stable low-flow conveyance channels for CBNG-produced waters.

Introduction

Coalbed natural gas (CBNG) development has occurred in the Powder River Basin (PRB) of northeast Wyoming since the early 1990s. To extract CBNG, large quantities of water are pumped from coal seams to reduce pressure and allow the gas to disassociate. Produced water is often managed through storage in reservoirs, surface application (irrigation), reinjection, and/or direct discharge to ephemeral and perennial streams. Direct discharge in ephemeral headwater tributaries close to production wells is a preferred management tool for CBNG-produced water due to

low capital costs (Bank and Kuuskraa, 2006). This can be problematic in areas where a channel is discontinuous, contains erosional features, or produced water discharges exceed the carrying capacity of the channel.

Construction of a low-flow channel to convey produced water is a relatively new management technique. Many of the first channel construction projects were "field-fit" by contractors with little oversight and no engineering analysis. Successful projects were often short lived due to neglected maintenance following construction. Designing and constructing a low-flow channel involves many variables that are difficult to quantify and may result in increased mitigation costs if not addressed. An engineered design prepared by a qualified engineering firm will significantly reduce cost and construction time.

Due to the complex nature of stable channel design and construction, many stakeholders have expressed a need for methodology specific to the PRB. The objective of this study was to design, construct, and maintain a low-flow channel to convey CBNG-produced water and natural runoff specific to typical conditions encountered in the PRB. This study presents design criteria, construction procedures, and maintenance and mitigation efforts of a successful low-flow channel project in the Barber Creek drainage.

Background

Thoman and Niezgoda (2008) developed a method of estimating critical shear stress from cohesive soil properties in an effort to simplify the evaluation of stable channel capacity. In their analysis, Thoman and Niezgoda (2008) balanced the critical shear stress, τ_c, of the soil, determined by a submerged jet device, against the effective shear stress, τ_e, of the flowing water (also termed the tractive force). Erosion, ε_r, is assumed to occur when τ_e exceeds τ_c of the bounding soils

$$\varepsilon_r = k_d (\tau_e - \tau_c) \quad (1)$$

This equation is commonly referred to as the excess stress equation where, ε_r = erosion rate (m/s), k_d = erodibility coefficient ($m^3/N \cdot s$), τ_e = effective shear stress (Pa), and τ_c = critical shear stress (Pa). For channel stability analysis, the erosion rate is set to zero, which simplifies the equation to

$$\tau_e = \tau_c \quad (2)$$

In cohesive soils, τ_c is most commonly determined through laboratory or *in-situ* testing. One proven method of *in-situ* testing to determine τ_c is to use a submerged jet device developed by Hanson (1991) and improved by Hanson et al. (2002). Hanson and Cook (2004) provide detailed procedures for operation of the device.

Evaluation of τ_e requires channel geometry information. The effective shear stress under bare soils conditions is given as

$$\tau_e = \gamma d S (n_s/n)^2 \quad (3)$$

where, γ = unit weight of water, d = flow depth, S = friction slope (approximated by the channel bed slope for uniform flow), n_s = Manning's coefficient for soil grain roughness (equal to 0.0156) (Temple, 1980; Hanson, 1989) and n = Manning's coefficient for channel roughness. Temple (1980) modified the equation to account for vegetation by introducing an empirical vegetal cover factor

$$\tau_e = \gamma dS(1-C_F)(n_s/n_v)^2 \quad (4)$$

where, C_F = vegetal cover factor (common range is 0.5-0.9, values approaching 1 indicate increased vegetation density and uniformity) and n_v = Manning's roughness coefficient for vegetated channel roughness. A check of the vegetal stress must be made to ensure the vegetation remains intact

$$\tau_{va} = 35.91 C_I \quad (5)$$

where, τ_{va} = maximum allowable vegetal stress (Pa), C_I = dimensionless retardance curve index ($C_I = 2.5(h\sqrt{M})^{1/3}$; h = stem length, and M = stem density) (Temple et al. 1987).

Data Collection

A watershed study was performed by Lowham Engineering LLC (LELLC) to collect and compile data in the drainage of Barber Creek. The results of the watershed study are presented in the report, "The Hydrology of Barber Creek – A Tributary to the Powder River in Wyoming" (LELLC, 2005). The Barber Creek drainage is located 32 km (20 mi) west of Gillette, Wyoming, and covers approximately 192 km^2 (74 mi^2) (Figure 1). Barber Creek is an ephemeral channel with streamflow occurring in response to runoff events. Step-backwater surveys were completed at ten locations to indirectly evaluate bankfull channel capacity near the study area shown in Figure 2. Channel depth, slope, and sinuosity were established from the survey data. Bankfull estimates ranged from 1.05 m^3/s (37 ft^3/s) to 3.51 m^3/s (124 ft^3/s), corresponding to a return interval of 1.5 to 2 years. Return interval runoff was modeled using regional regression equations developed by Lowham (1988).

Data collected from aerial photography and low-level reconnaissance flights indicated locations where the natural channel was discontinuous and provided initial indications of erosion features. Field reconnaissance verified erosion features and locations of channel discontinuity. On South Prong Barber Creek, construction of two spreader dikes in the 1950's resulted in aggradation of the valley floor, obscuring channel characteristics. Aggradation of the channel in the study reach on Barber Creek was thought to be due to excessive sediment loading upstream (LELLC, 2005).

A related study was completed in 2006 to analyze natural streamflow data including quantity, quality, and relationships between the two (LELLC, 2006). Data were collected at six stream flow gages (2 automatic gages and 4 staff gages) located 11.2 stream km (7 mi) downstream of the study area. An additional automatic streamflow gage was installed 4.1 stream km (2.6 mi) upstream of the study area to

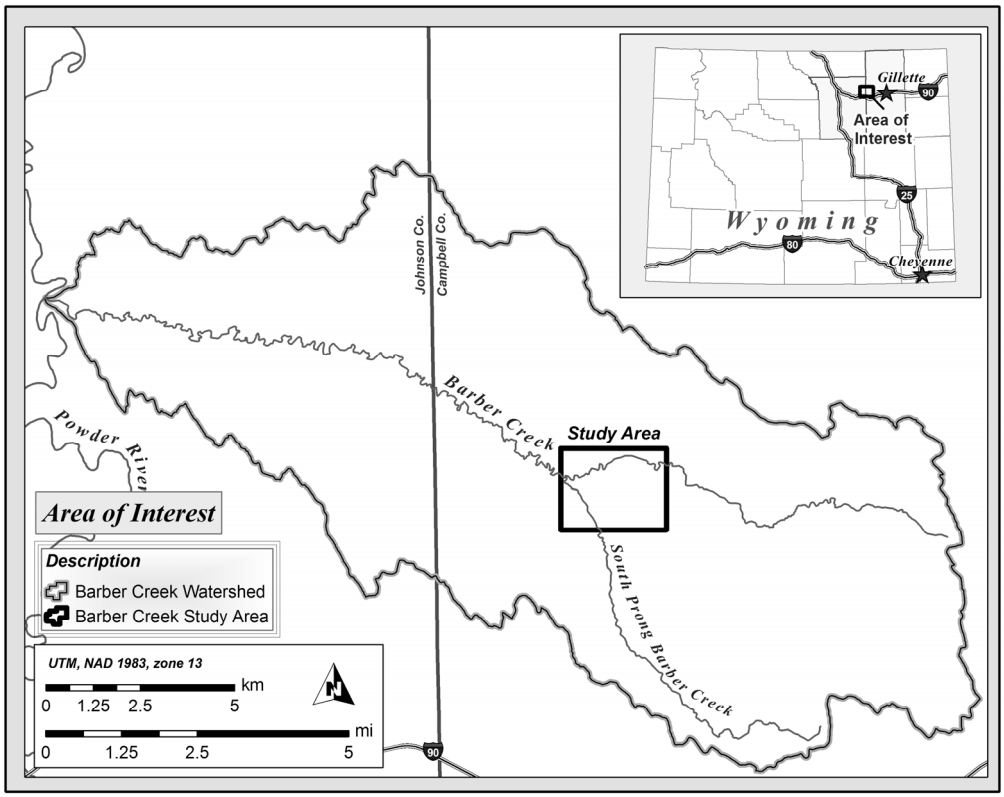

Figure 1. Overview of the Barber Creek drainage in the Powder River Basin of Wyoming

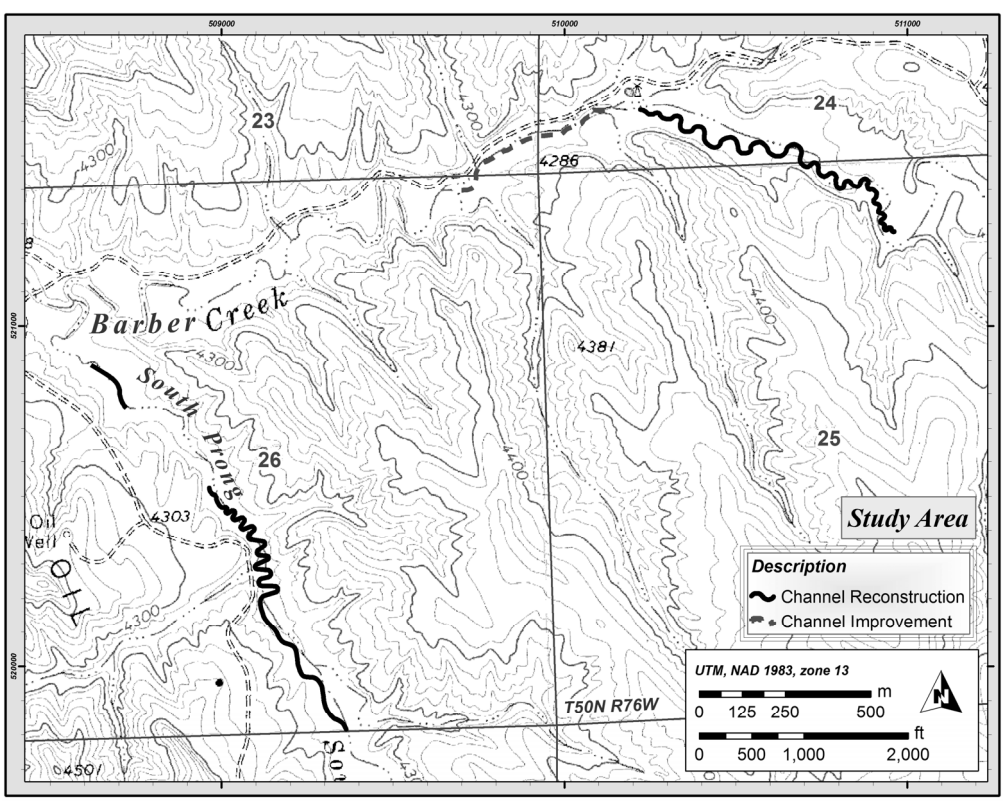

Figure 2. Channel design locations in the study area along Barber Creek and South Prong Barber Creek in Wyoming

characterize ephemeral stream flows upstream of the study area.

Critical shear stress estimates were needed to perform the stability analysis. A subset of the critical shear stress values collected by Thoman and Niezgoda (2008) was used to estimate a design value for the study area. Fifteen data points located within a 15.8 km (9.8 mi) radius of the study area were averaged to estimate a design critical shear stress that would account for local variability in soil conditions throughout the study area.

Channel Design

Design channel capacity was based on estimated planned development, well production, and dilution. Maximum well production was predicted to be less than 0.28 m^3/s (10 ft^3/s). Additional channel capacity of 0.28 m^3/s (10 ft^3/s) was required to ensure adequate dilution of CBNG-produced water with natural runoff prior to bank overflow, resulting in a design discharge of 0.57 m^3/s (20 ft^3/s).

Natural channel geometry, sinuosity, slope, and stability were evaluated near the study area to develop design parameters. Channel geometry needed to be conducive to establishing vegetation while also preventing ice sheeting and limiting total disturbance. Channel sinuosity is a controlling factor for promotion of conveyance losses by increasing channel length and decreasing channel slope. Proper channel slope is imperative to controlling erosion and plays a significant role in channel stability. Additional design considerations include soil type, livestock traffic and grazing, channel construction methods, and storm water runoff.

The valley slope in the study area was too steep to support a stable earthen channel. A slope of 0.5% achieved the goals of the design by providing stability and increasing sinuosity. Exceptions include the upstream, straightened section of the reach on South Prong Barber Creek and the channel improvement reach along Barber Creek (Figure 2). The reach on South Prong Barber Creek was designed with a channel slope slightly less than the valley slope of 1% due to landowner agreements. The channel improvement reach on Barber Creek consisted of cleaning an existing channel with slopes ranging from 0.6-1.2%. Final channel design lengths include 1,370 m (4,500 ft) on South Prong Barber Creek and 1,800 m (5,900 ft) on main stem Barber Creek (Figure 2).

Channel design geometry included a trapezoidal channel with a bottom width of 0.23 m (0.75 ft), depth of 0.64 m (2.1 ft), and 1:1 side slopes. Channel side slope steepness was of concern for establishment of new vegetation, but was weighed against the threat of ice sheeting that may develop with flatter slopes.

Shear stress and velocity profiles were used to evaluate stability of the channel design (Figure 3). Soil types in the study area ranged from clay loam on South Prong to silt clay loam on Barber Creek. A critical shear stress analysis of the soil and vegetation stability using Equations (2), (3), (4), and (5) is presented in Figure 4. Average critical shear stress for the study reach was 4.5 Pa, determined from data provided in Thoman and Niezgoda (2008). Figure 4 shows that for the design capacity, the unvegetated channel is not stable. However, the addition of minimal vegetation cover ($C_F = 0.6$) results in a factor of safety (FS) of 1.8. The unvegetated channel is stable (FS = 1) at a depth of 0.34 m (1.1 ft) for a discharge of 0.14 m^3/s (4.8 ft^3/s). Vegetation cover is

Figure 4. Shear stress analysis for Barber Creek channel design in the Powder River Basin of Wyoming

critical to ensure channel stability for the design discharge. Short growing seasons, drought conditions, and cohesive soils presented unanticipated challenges to constructing a stable, vegetated channel.

Channel Construction

Channel construction began on South Prong Barber Creek and Barber Creek in August of 2006. A 'V'-type ditcher (Figure 5) was used for channel construction to limit disturbance and reduce construction time. Hard soil conditions from years of drought necessitated the use of a ripper to loosen the soil. Tight meander radi had to be pre-cut with a road grader. The effective radius for channel construction with the ditcher was about 10 m (33 ft). Repeated passes with the ditcher were required to achieve the design depth. Hardened soil conditions required field modifications to repair and reinforce the ditcher. Constructed channel geometry is shown in Figure 6.

Eight culverts were installed at specific locations along the constructed channel to serve as livestock and access crossings and to provide locations for storm water overflow. The culverts were sized to only allow conveyance of the design flow. Drop pipes were installed through two spreader dikes on South Prong Barber Creek with erosion protect at the outlets. Following construction, the channels were hydroseeded and the banks and disturbed areas were drill seeded.

Figure 5. View of channel construction using a ditcher on South Prong Barber Creek in the Powder River Basin of Wyoming (August 2006)

Figure 6. View of completed channel construction on South Prong Barber Creek prior to hydroseeding (August 2006)

Channel Maintenance and Mitigation

Shortly after construction, a rainstorm and runoff event was recorded at the streamflow gage located upstream of the channel reach. Additional snowmelt and rainfall runoff events were recorded throughout the winter and spring of the following year. A site visit was conducted in May 2007 to evaluate channel conditions. Observations indicated that overbank flow had occurred from natural runoff events, as produced-water discharge had not begun. The South Prong channel was in excellent condition with emerging vegetation growth. The main channel of Barber Creek suffered from the formation of a headcut and channel erosion at the beginning of the construction reach shown in Figure 7. Vegetation had not established in the

channel bed or on the side slopes as hoped, likely due to the hard soil conditions. Sand and silt lenses that were not apparent during construction were noted in the channel bed. A mitigation plan was developed and implemented in August 2007. Approximately 190 m (620 ft) of channel was lined with turf reinforcement mat (TRM) to stabilize the reach and support revegetation efforts (Figure 8). The TRM used in this project is a propylene fiber matrix designed to protect bare soils up to shear stress levels of 98 Pa. Once vegetation has established in areas lined with TRM, allowable shear stress values increase to 384 Pa. Additional maintenance work performed in 2007 included placement of TRM below the culvert crossing outlets to prevent scouring, cleaning deposited sediments from the channel, and reseeding.

Figure 7. Downstream view of eroded channel on Barber Creek following a large runoff event on May 30, 2007

Figure 8. Downstream view of Barber Creek following channel lining with turf reinforcement mat (TRM) on August 28, 2007

The 10-year drought appeared to break in 2008 as evidenced by increased rainfall and associated runoff (Water Resource Data System, 2008). An increased number of runoff events were recorded at the upper streamflow gage during the spring and summer months. A project visit in June 2008 revealed channel conditions during the recession of a runoff event. Overland flow entering the channel on South Prong Barber Creek resulted in the formation of rills in the channel banks. The upper section of Barber Creek was unaffected by the flows, but the lower channel improvement reach experienced some minor erosion. Similar to the previous year, a maintenance and mitigation plan was developed. Implementation of the mitigation plan began in August 2008.

South Prong Barber Creek and the Barber Creek channel improvement reach were the focus of the mitigation efforts in 2008. Channel banks were ripped, reshaped, seeded, and lined with TRM (Figure 9). Approximately 122 m (400 ft) of channel on South Prong Barber Creek and 365 m (1200 ft) of channel in the improvement reach on Barber Creek were mitigated using TRM.

Maintenance was also required to repair erosion protection below the spreader dike outlet pipes and to clean channel sediment caused by debris jams at the culvert crossings. The erosion protection was repaired by placing another layer of TRM over the structure, and plywood checks were removed from the culverts to alleviate debris jamming and subsequent sedimentation.

Figure 9. Upstream view of sequence of channel mitigation measures (clockwise from top left) taken to repair rills in the bank from tributary flow entering the channel on South Prong Barber Creek in the Powder River Basin of Wyoming (August 20-22, 2008)

Summary and Conclusions

A low-flow conveyance channel was designed and constructed on Barber Creek and South Prong Barber Creek in August 2006. The channel was designed for conveyance of 0.57 m^3/s (20 ft^3/s) of CBNG-produced water and natural runoff. Channel geometry and bed slope were designed to remain stable with minor revegetation. To date, discharge of produced water has not occurred. However, numerous natural runoff events have been documented since construction, impacting the channel. Tributary flow entering the channel was responsible for the majority of the impact. Erosion mitigation plans were implemented following site inspections in the summer of 2007 and 2008. Channel banks were ripped, reshaped, seeded, and lined with TRM to mitigate destabilized locations along the study reaches. Annual maintenance was performed to remove debris from the channel and reinforce erosion protection below culvert outlets.

The results of this study provide design criteria, construction procedures, and maintenance and mitigation efforts for a successful low-flow channel project in Barber Creek in the Powder River Basin of Wyoming. The methodology presented in this study is intended to help stakeholders as they look to utilizing direct discharge to manage CBNG-produced water.

Decentralized Anaerobic Treatment of Blackwater:
A Sustainable Development Technology Concept for Urban Water Management

Gallagher, NT[1] and Sharvelle, S[2]

ABSTRACT

As populations continue to increase, the demand for limited water resources has increased. Sustainable water technologies and management methods are critical to our meeting future water quantity and quality demands. Decentralized treatment of blackwater under anaerobic conditions is a wastewater treatment technology being explored for application in new developments. Decentralized anaerobic treatment of blackwater stands out in its ability to conserve available green water and energy resources and promote reuse of these resources at a local level.

A pilot scale anaerobic reactor is under construction at the Colorado State University Foothills Campus to treat blackwater (toilet and kitchen sink wastewater) from a building occupied by laboratory and office space. This project is a demonstration study on the economic and technical feasibility of using anaerobic digestion for treatment of blackwater. Eventually, it is anticipated that biogas produced in digesters will be used as a green energy alternative to current energy sources and treated effluent water will be evaluated for reuse onsite for irrigation or other non-potable uses. Treatment efficiencies of the anaerobic process under varying loading and environmental conditions will be monitored in addition to methane production. A decision analysis tool for cluster decentralized wastewater treatment (DWWT) will be developed to assist decision making entities in determining the applicability of DWWT.

It is anticipated that the data provided by this study will also provide important data for basis of legislation related to the effectiveness and safety of DWWT and reuse of resources contained within wastewater. Such data is vital to encourage incorporation of sustainable treatment technologies, e.g. DWWT, as aging and failing infrastructure is rapidly becoming in need of replacement and new developments are constructed. This research is in line with recent study efforts put forth by the USEPA attempting to develop technologies and methods for new and existing developments to achieve both water and energy independence from typical centralized grid systems.

INTRODUCTION

In a 1997 report to congress, the United States Environmental Protection Agency (US EPA) noted that well managed decentralized wastewater treatment (DWWT) systems, including onsite (septic) and small community cluster treatment systems, were an economical and long-term option to meet both public health and water quality goals (US EPA 2009).

Decentralized wastewater treatment technologies have been used previously as some of the very first methods of primitive human waste disposal into the environment. In recent times, developed countries have drifted away from use of decentralized systems because of the federal money made available to research and implement centralized wastewater treatment plants. In the past 25-30 years, a progressive change in thought and the cost effective availability of advanced technologies has permitted DWWT to compete with centralized wastewater treatment.

Unfortunately, a minimal number of full scale DWWT systems have been put into practice and little data is available on their effectiveness, as well as their technical and economical feasibility. Further study and demonstration scale implementation is crucial to provide data as well as ensure public acceptance of DWWT technologies. DWWT systems are emerging as a potential challenger to supplement and replace commonly used centralized systems. In order to justify implementation of DWWT systems, it is necessary to gain both public support and legislative permission to construct and implement these systems on a larger scale.

Efforts are being made by Colorado State University (CSU) to implement DWWT technologies on their Foothills Campus. Currently, demonstration projects for treatment of blackwater and graywater are underway. In addition, a decision making tool is under development to determine the technical and economical feasibility of DWWT for specific applications. The purpose of this decision making tool is to assist decision making entities in finding the best wastewater treatment system layout for their chosen service area.

DECENTRALIZED WASTEWATER TREATMENT (DWWT)

Decentralized wastewater treatment provides a rational concept for wastewater treatment which resonates with the push for more sustainable development within the US and abroad. DWWT systems serve smaller footprints than their centralized counterparts.

In DWWT, wastewater streams can be separated by the relative amount of treatment and care in handling required. For example, graywater produced in showers, hand sinks, and laundry machines contains a relatively clean, low pathogen wastewater which can be easily treated for use in toilet flushing or directly reused for landscape irrigation. Blackwater, from toilets and garbage disposals contains high organic and high pathogen loadings and must be carefully handled and requires high levels of treatment.

More localized treatment and separated wastewater streams encourage extraction and reuse of valuable wastewater constituents by facilitating end user access e.g. methane biogas and nutrient rich effluent for irrigation. Capture and reuse of wastewater constituents reduces the amount of nutrient and organic rich effluent deposited into natural waterways by centralized treatment systems.

Figure 1 presents a comparison of (a) DWWT and (b) centralized wastewater treatment servicing identical development. As shown in the figure, DWWT encourages treatment for localized clusters of development. Because development often occurs in relatively dense clusters, DWWT concepts can drastically reduce both the diameter and length of required conveyance infrastructure. Smaller service areas require smaller infrastructure footprints and smaller piping, resulting in lower environmental impact from construction and reduced waterway crossings.

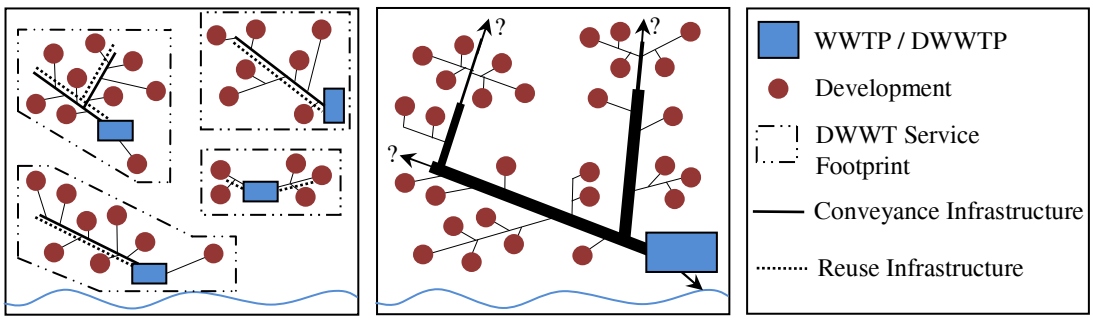

Figure 1: Comparison of (a) DWWT and (b) centralized treatment

Smaller service areas with generally known maximum wastewater demands facilitate conveyance infrastructure planning. Arrows at the ends of conveyance infrastructure in Figure 1(b) represent future development direction predictions often encountered during centralized infrastructure capacity planning. Centralized treatment requires infrastructure capacity planning to occur decades before capacity is required in directions of predicted development.

Two major roadblocks encountered in centralized planning include (1) conveyance infrastructure can flow at fractions of capacity for years, encouraging infiltration and requiring high capital investment long before capacity is needed and (2) predicted development directions change, resulting in unused infrastructure capacity and misspent capital.

DWWT systems can offer many benefits over centralized systems. However, typically these two systems must be compared on a case by case basis to effectively determine which is more feasible for specific applications. Higher costs associated with DWWT tend to surround economies of scale which benefit centralized treatment in dense service areas. However, DWWT has potential to reduce infrastructure costs by making more efficient planning possible, provide cost savings by increased capabilities for water reuse, as well as reduce the environmental impacts associated with centralized wastewater collection and treatment systems.

Decentralized wastewater treatment has global applications. According to the EPA, approximately one in four households in the United States relies on an onsite treatment system (US EPA 2009). DWWT is able to replace failing septic systems, providing higher levels of treatment and preventing nutrients and contaminants from leaching into natural waterways. New developments and small communities can capture and treat wastewater locally. Clusters of development, e.g. residential neighborhoods or commercial business parks, where centralized treatment is uneconomical or plant/conveyance capacity is not available are candidates for DWWT.

Developing communities in less affluent regions of the world also benefit from decentralized wastewater treatment. Many areas of the world do not have or have very minimal centralized wastewater infrastructure supporting communities. In these areas, creation of a centralized wastewater treatment network from scratch can be unaffordable. DWWT technologies present opportunity to provide treatment, greatly increasing sanitation and public health in regions which could otherwise not afford treatment. DWWT also has potential to provide these areas with useable biogas, as well as nutrients and irrigation water for non-consumptive agricultural uses.

CSU BLACKWATER DEMONSTRATION PROJECT

Colorado State University (CSU) department of Facilities Management has provided funding for a DWWT demonstration project to treat blackwater on the CSU Foothills Campus. Over the next 30 years, CSU plans to expand development within their Foothills Campus adding classrooms, offices and laboratories. With the expansion of the Foothills Campus, CSU intends to embody a demonstration of environmental sensitivity and sustainability (RNL Design 2003).

The blackwater DWWT demonstration project is among several studies underway to determine the best way to maximize sustainability in wastewater treatment on the CSU Foothills Campus including a wetland graywater treatment study and a wastewater planning study for the entire CSU Foothills Campus. This study will provide important data on the technical and economic feasibility of separated blackwater treatment as well as decision making for DWWT systems.

Currently, a process review is underway to determine the most appropriate available technology for demonstration process design. Both aerobic and anaerobic processes are being considered. However, because biogas from anaerobic digestion can be used to produce heat for the reactor, to heat buildings and provide steam to autoclaves in laboratories, it is somewhat favorable for application. Also, production of biogas and capture of valuable nutrients which can be used to replace synthetic fertilizers contribute to the sustainability of wastewater treatment and therefore it is likely an anaerobic process will be studied.

The source of blackwater being studied is a building located on the Foothills Campus with plumbing separated into three streams: blackwater, labwater and sinkwater. Toilets, emergency showers and kitchen sinks contribute to the blackwater line although toilets supply the majority of wastewater.

During blackwater sampling, efforts were made to capture composite samples. One 6" PVC sewer line leaves the study building containing blackwater. A valve was installed on this line and an access point was placed upstream of the valve. Sampling was performed by temporarily shutting the valve and routing blackwater through the access point into a 30 gallon drum. Once filled, the 30 gallon drum was disconnected from the blackwater line. Wastewater within the drum was composited by placing a laboratory bench mixer fitted with a 4 foot metal rod with two propellers into one of two access ports at the top of the drum. One propeller was oriented at the bottom of the drum to kick up settled solids and the second propeller was oriented midway in the barrel to assist in mixing. While the mixer was operating, a hand operated 1" drum pump was inserted into the second drum access port and approximately three gallons of sample was withdrawn for analysis.

Blackwater composition was analyzed for total suspended solids (TSS), volatile suspended solids (VSS), chemical oxygen demand (COD), dissolved COD (dCOD), dissolved organic carbon (DOC), dissolved total nitrogen (dTN) and dissolved ammonia (dNH_3). TSS, VSS, dCOD, COD and dNH_3 were measured according to Standard Methods for The Examination of Water and Wastewater (APHA 1998) methods SM2540-D (TSS & VSS), SM5220-D (dCOD & COD) and SM4500-NH_3-F (NH_3). DOC and dTN were measured using a Shimadzu TOC-V combustion analyzer with TNM-1 total nitrogen module.

Table 1 provides a comparison of CSU blackwater to typical household blackwater and untreated domestic wastewater. Total suspended solids composition of the blackwater is approximately 0.3%. These values have been determined from three sets of sampling data except for TSS, VSS, and dissolved ammonia which have been determined from two sampling periods.

Table 1: Blackwater Characteristics

	Units	CSU Blackwater	Untreated Blackwater[1]	Untreated Domestic Wastewater[2]	Notes:
TSS	mg/L	3,248	920 - 4,320	120 - 400	[1] Palmquist & Hanæus (2005)
VSS	mg/L	2,931	420 - 3,660	95 - 315	[2] Tchobanoglous et al. (2003)
dCOD[3]	mg/L	598	--	--	[3] 0.45μm filter
COD	mg/L	3,530	806 - 3,138	250 - 800	[4] 0.45μm filter
DOC[3]	mg/L	126	--	80 - 260	
dTN[3]	mg/L	128	130 - 180	20 - 70	
dNH_3[4]	mg/L	127	--	12 - 45	

Characterization of CSU blackwater shows values within the range of previous blackwater studies. As seen in Table 1, most blackwater constituents are higher in concentration than those found in untreated domestic wastewater due to the lack of dilution from a typical collection system as well as separated blackwater and graywater plumbing.

Initial characterization of CSU blackwater has been supplemented by two additional studies to determine the biochemical methane production potential and to determine the biodegradation potential of the stream. Results from these tests provide insight into the treatability of the waste subject to both anaerobic and aerobic processes. Potential for biogas production from the waste is also realized, giving an indication of the contact times necessary to reach optimal conditions and what those conditions may be in an operational reactor.

Biochemical Methane Potential

Biochemical methane production potential (BCMP) testing was performed on blackwater samples to determine the volume of CH_4 produced per liter of blackwater substrate. Tests were performed as 200 ml batch anaerobic reactors modeled after the bioassay method for testing biodegradation outlined in (Owen, Stuckey et al. 1979). Tests were performed at a constant temperature of 35°C. Gas samples were analyzed for methane concentration on a HP5980II Gas Chromatograph using a packed column and thermal conductivity detector.

Figure 2 provides a cumulative volume of methane gas produced by BCMP batch tests per liter of blackwater substrate. The final cumulative value shows that 0.34 liters of methane ware produced per liter of blackwater over the duration of testing. This value was used to determine a methane production of 100 liters CH_4 per day. Using a methane lower heating value of 35,800 kJ/m^3 (Tchobanoglous et al. 2003), at 100% efficiency this provides 3,600 kJ/day or 1 kilowatt hour of energy. This is enough energy to run a 100 watt light bulb for 10 hours.

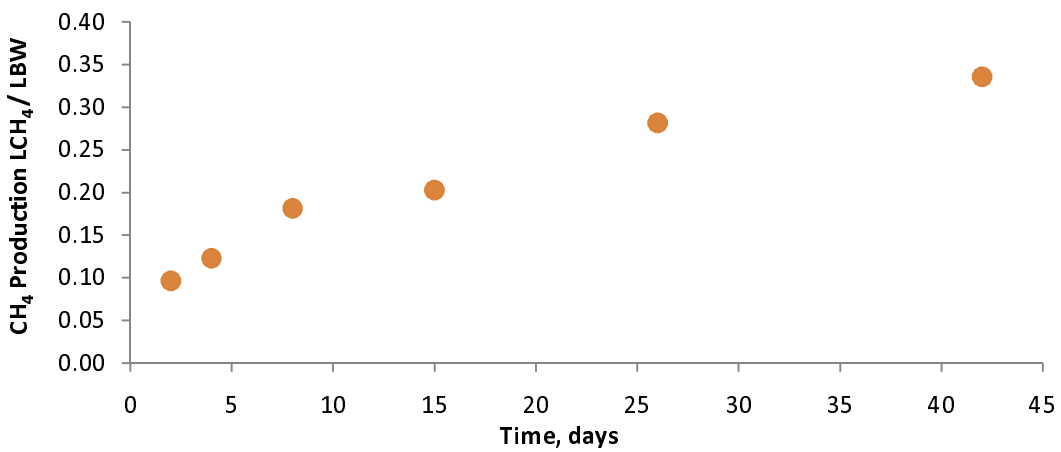

Figure 2: Cumulative CH_4 Production from CSU Blackwater

A study by (Luostarinen and Rintala 2005) of synthetic blackwater showed methane production of 2.5 and 0.81 liters CH_4 per liter anaerobic sludge in two respective reactors. Assays in this study were performed combining sludge, blackwater and distilled water to reach a volume of 60 ml. The methane production values provided included the entire assay and therefore can be expected to be somewhat higher than those provided in Figure 2 due to additional production from sludge.

It is expected that the process selected to treat backwater in the CSU demonstration project will be a high-rate flow-through reactor. BCMP tests are configured as batch reactors for convenience of study and therefore do not show the full potential methane production. Optimization and adjustment of environmental conditions within the flow through demonstration reactor provide for higher expected methane yields.

Aerobic & Anaerobic Biodegradation

Aerobic and anaerobic biodegradation tests were performed on CSU blackwater to gage both aerobic and anaerobic treatment potential. These tests were configured as simple batch reactors consisting of inoculum, nutrient solution (Owen, Stuckey et al. 1979) and blackwater substrate for a combined total assay of 1000 ml. Inoculum was taken from either the aerobic or anaerobic waste sludge

A total of six anaerobic tests were setup, three containing blackwater substrate and three controls. Each anaerobic biodegradation assay contained 500 ml blackwater and 500 ml anaerobic defined media (inoculum & nutrient solution) for a total average DOC of 392.9 mg/l and total average dTN of 154.8 mg/l. Anaerobic controls contained 500 ml DI water and 500 ml anaerobic defined media nutrient solution for a total average DOC of 34.7 mg/l and total average dTN of 108.23 mg/l.

Each aerobic biodegradation assay contained 500 ml blackwater, and 500 ml aerobic defined media (inoculum & nutrient solution) for a total average DOC of 74.9 mg/l and total average dTN of 110.5 mg/l. Aerobic controls contained 500 ml DI water and 500 ml aerobic defined media with a total average DOC of 15.2 mg/l and total average dTN of 48.1 mg/l.

DOC and dTN were measured using a Shimadzu TOC-V combustion analyzer with TNM-1 total nitrogen module. For aerobic tests, 15 ml samples were taken from assays by removing foam stopper and pouring composite sample into a 15 ml sample vial. Anaerobic tests were sampled by inserting a 16 gauge syringe through the rubber stopper located in the mouth of the test bottle and extracting 15 ml of sample. Extracted sample was then placed in a 15 ml sample vial for transport. Sample analysis was performed the day of sampling. Prior to analysis, samples were filtered through 0.45μm filter cartridges.

As seen in Figure 3 and Figure 4 below, identical trends in dTN were experienced in both assays over the first nine days of experimentation. On the second sampling date, 5.0% and 6.3% dTN increases were experienced in anaerobic and aerobic assays respectively. dTN is the sum of all dissolved species of nitrogen including nitrite, nitrate, organic nitrogen and ammonia. Nitrogen speciation was not performed. However, it is possible that this increase is caused by nitrogen fixing bacteria during the initial growth phase. An increase in dTN is also experienced at the end of testing in anaerobic tests which may be contributed to release via dying cell mass.

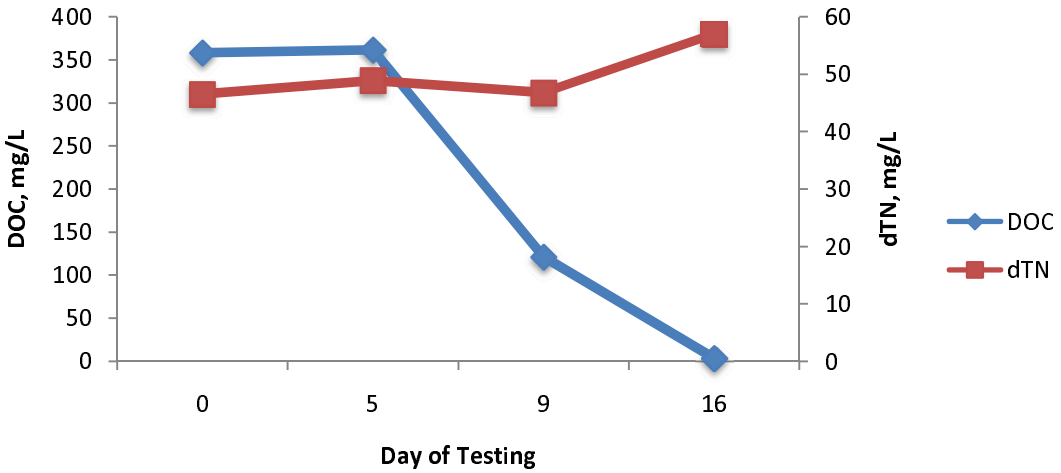

Figure 3: Anaerobic Biodegradation Results

DOC concentration did not change substantially between the first two sampling periods in anaerobic tests. Anaerobic assays were not prepared in an anaerobic environment and therefore this trend could represent a biomass startup phase caused by remnant oxygen in the headspace of the anaerobic bottles. However, effective DOC reduction was experienced between days 5 and 16.

Aerobic testing shown in Figure 4 experienced an increase in DOC at the end of testing. This increase may be contributed by DOC release from dying cell mass. Decreasing dTN in the final days of testing is noticed which may be due to biological uptake of nitrogen by nitrifying bacteria.

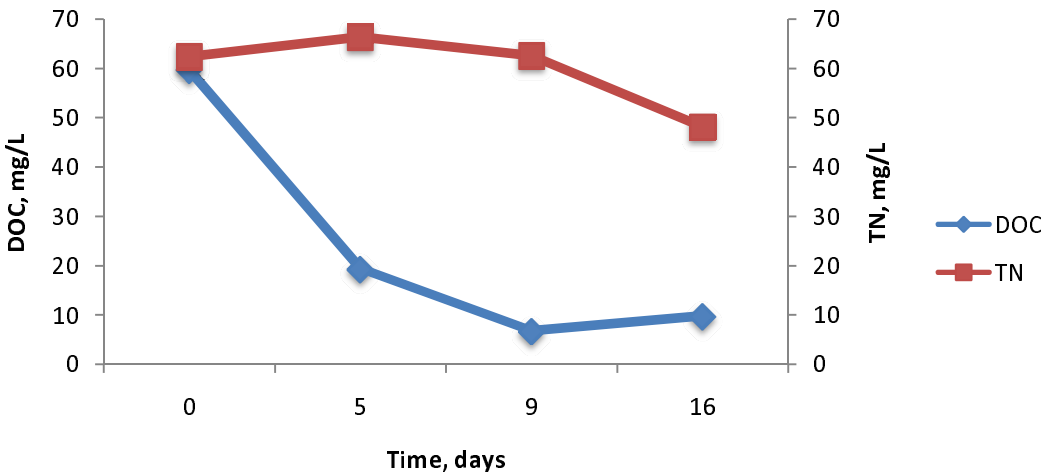

Figure 4: Aerobic Biodegradation Results

Percent reductions from initial DOC concentration during each sampling date are presented in Figure 5 below for both anaerobic and aerobic tests. As expected, substrates were degraded at a higher rate in an aerobic environment compared to an

anaerobic environment. However, it is anticipated that anaerobic tests most likely had some initial startup period due to residual oxygen present in the headspace of each assay. For this reason it can be expected anaerobic processes would degrade waste somewhat quicker in an acclimated reactor than what the results of these tests provide.

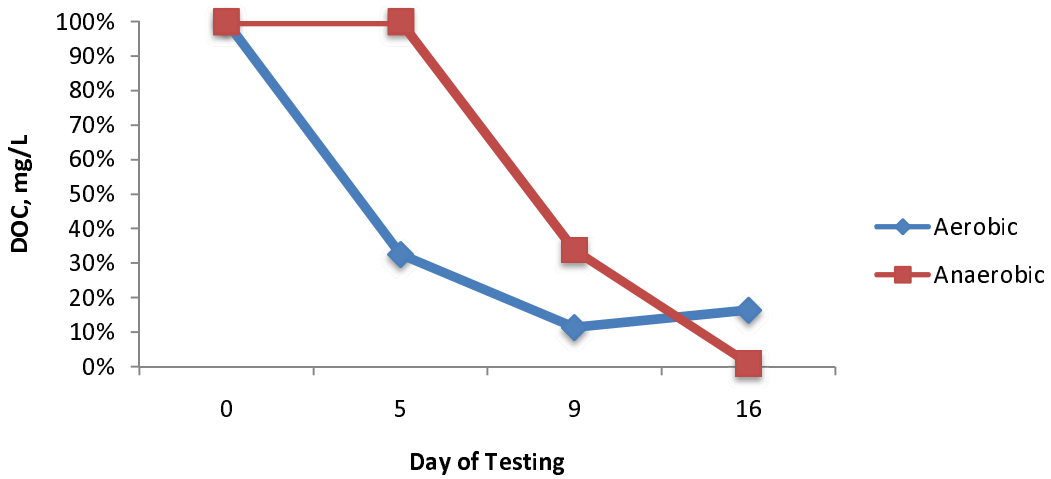

Figure 5: DOC Degradation during Experimentation

DECISION ANALYSIS TOOL

Decentralized treatment systems development clusters such as neighborhoods, business parks and small communities have potential to be more economically and environmentally favorable than routing these developments to centralized treatment systems. One major setback in current planning capacity is the absence of tools which provide technical and economical feasibility of DWWT by specific application to decision making entities. Access to such a tool would allow more effective comparison of DWWT with centralized treatment. One goal of the CSU blackwater demonstration project is development of a tool to facilitate wastewater infrastructure planning decisions.

Analysis for CSU Blackwater Demonstration Project

To facilitate decision making for the CSU blackwater demonstration project, basic economic analysis has been performed to provide a comparison between aerobic and anaerobic treatment processes. Table 2 provides examples of parameters used for comparison of processes. Currently all costs for treatment are lumped into one parameter, which represents the total cost for treatment processes including O&M, heating, aeration, lifetime capital and any other related costs. Valuable outputs include reusable water from both processes and biogas from anaerobic digestion.

Table 2: Example Economic Analysis Parameters

	Inputs	Unit	Value	Type	Description
Water	P^w	$/m^3	0.53	Input	Price of Water
	q^w_a	m^3/day	2500	Input	Quantity of Wastewater Treated Anaerobically
	q^w_b	m^3/day	2500	Input	Quantity of Wastewater Treated Aerobically
	Θ_a	%	97%	Calculated	Quantity of Water Produced Per unit of WW Treated Anaerobically
	Θ_b	%	89%	Calculated	Quantity of Water Produced Per unit of WW Treated Aerobically
	C^w_a	$/m^3	0.1	Calculated	Cost to Treat Water Anaerobically per Unit
	C^w_b	$/m^3	0.08	Calculated	Cost to Treat Water Aerobically per Unit
Energy	P^e	$/KWH	3.5	Input	Price of Energy
	Φ_a	KWH/$m^3	0.001	Calculated	Quantity of Energy Produced Per unit of WW Treated Anaerobically

These input parameters were analyzed under varying prices for water and energy to determine the breaking point at which either process became favorable. Analysis results showed that anaerobic digestion is far more economical mainly because biogas produced during treatment was valued at its ability to supplement natural gas usage BTU for BTU. The value of biogas produced in anaerobic treatment far outweighed the additional reusable water produced in aerobic treatment.

In addition to economical analysis of treatment alternatives, a criteria based decision making tool will be used to compare different treatment technologies for use in the demonstration project. Some of the criteria which processes will be compared based on include reliability, complexity of operations and maintenance, treatment quality, as well as resource extraction and reuse potential.

Future Improvements to Decision Analysis Tool

Eventually, economic feasibility modeling and criteria based technical applicability modeling will be combined into one tool to assist with wastewater planning. This tool will be tailored to provide insight into the feasibility of different types of treatment to treat wastewater on the CSU foothills campus.

The purpose of this tool is to provide a useful comparison of treatment options, including process selection, treatment area sizing and reuse scenarios such that reliable decisions can be made for application of the most suitable wastewater treatment system for specific sites. Additional parameters for comparison include: wastewater flow, wastewater quality, wastewater source, available sources of heat and energy, maximum footprint, operation and maintenance capacity, and regional development density.

CONCLUSIONS

Decentralized wastewater treatment provides an opportunity for cost effective advanced treatment in small communities and rural areas where centralized treatment is not feasible. Traditionally the majority of these communities have relied on septic systems. These septic systems are often in serious disrepair or not operated properly, contributing greatly to degradation of local ground and surface water quality.

Decentralized wastewater treatment systems have potential to offer many benefits and costs as compared to centralized systems. However, typically these systems have to be compared on a case by case basis to effectively determine which is more feasible for specific applications. Facilitated planning, potential for local reuse of valuable constituents of wastewater, prospect for graywater reuse, and ability to feasibly focus on a specific pollution type (e.g. household, industrial, or blackwater, graywater) allows for more efficient treatment.

Studies are underway at Colorado State University to show the effectiveness and applicability of DWWT technologies. The current blackwater demonstration project on the CSU Foothills Campus will provide a continuously operating DWWT process providing treatment quality data. Insight into the quantity and quality of nutrients and effluent water as well as biogas available for reuse within the Foothills Campus will also be made available. The availability of such data will allow improvements to be made to legislation and public perception of water reuse and land application of treated effluents for non-consumptive purposes e.g. landscape irrigation.

In addition to technical data, development of a decision analysis tool will assist decision making entities in providing the best treatment options to their service areas. Because DWWT systems are not largely implemented in full-scale treatment operations, it is necessary to provide decision makers with a tool to effectively compare the applicability of DWWT systems to the expansion or construction of centralized systems.

Development of a National GIS Database for Municipal Water and Wastewater Pipe Infrastructure System

Sunil Sinha[1], Randy Dymond[2], Rahul Vemulapally[3], Thomas Dickerson[4], Seth Perry[5]

ABSTRACT

The problems posed by aging infrastructure are receiving increased attention in the United States, thanks to critical reports by the American Society of Civil Engineers, and in some cases, due to public outcry in the wake of infrastructure failures. The U.S. Environmental Protection Agency (EPA) has a special interest in the operations and management of public drinking water and sanitary sewer systems. Infrastructure utilities are facing increasing pressure to implement advanced asset management plans in order to improve the efficiency with which their systems are operated and maintained. As a result, most utility operators are actively working to develop GIS mapping and databases of their pipe networks. However, there is no standard data model for water or sewer systems, thus each utility has developed its own method for storing data; this has created complex problems associated with multi-jurisdictional planning activities, research, and oversight.

The U.S. EPA, through the Buried Asset Management Institute – International, funded Virginia Tech researchers to investigate municipal water and sewer infrastructure databases, with an emphasis on the condition assessment aspect of asset management. A partnership of at least 17 major U.S. cities expressed an interest in advancing this research, and five municipal utility operators donated sewer and/or water infrastructure GIS data for this pilot project. First, researchers worked to define those data elements required for condition assessment of buried assets. With these data elements defined, the researchers developed a standardized data model to organize the previously identified data elements. This data model was tested against the real-world municipal utility datasets, documenting the methods and issues associated with transforming the disparate datasets to conform to the data model. Finally, data from multiple utility operators was loaded into a common, secured enterprise-class, web-accessible geo-database to demonstrate the future potential for cross-utility planning and analysis. The results of this investigation illustrated the challenges inherent in any effort to conflate disparate municipal utility datasets into a common data model, and demonstrated the scarcity of data relevant to water and sewer infrastructure condition assessment. By incorporating additional attributes related to condition assessment in publicly-promoted data models, municipal utilities will be better able to manage their infrastructure internally, and share their utility data with neighbors, researchers, and regulators.

INTRODUCTION

This paper presents a research project to create Center of Excellence for Municipal Asset Management (CEMAM), is a collaboration between the Buried Asset Management Institute – International (BAMI-I), participating municipal utilities, and researchers at academic institutions. The Virginia Tech team's research on this project includes defining data elements required for condition assessment of buried assets, and developing a standardized data structure to serve as a common foundation for future analysis and research. In addition to researching current literature, much of this work relies on relationships with participating utilities who have agreed to provide geospatial and asset management data to the researchers. After establishing standards for asset management data, Virginia Tech examined the implications of the standards on municipal utility programs, and created an example database that conflates the varied municipal data into a common data framework. Development and testing of related technologies, such as a web-based mapping application, is also pursued as appropriate. In summary, the utility data is collected, analyzed and transformed into the common data framework. The data has been collected from a majority of the participating utilities who agreed to provide data. The Virginia Tech team analyzed this data, by comparing the structure and content of the utilities' data to a desired list of attributes, to each of the other utilities. This center of Excellence will reap the following benefits:

- Will help in creating linkage to all utilities across the nation irrespective of utility size
- provide timely access to asset management information and resources that will lead to more efficient programs
- promote and provide training, education, research, and outreach programs
- provided the public with a convenient tool to learn about municipal water and wastewater infrastructure system
- develop a National database that will help in developing tools, techniques, models (Prediction and optimal performance) for data analysis

The initial work in this project consisted of forming relationships with municipal utilities and reviewing literature related to the development of a standard database model. This review of literature addresses current and proposed research related to the development of sanitary sewer database models, computer applications, and infrastructure management practices in other localities, states, and countries.

Autodesk Homeland Security Initiative Data Model

The Autodesk Homeland Security (HLS) Data Model is a collection of several individual data models that share the stated objective of supporting homeland security and promoting interoperability. The data models are intended to serve as the core of day-to-day utility management, although most users will need to extend the proposed data models with additional data relevant for utility management applications.

Atlanta Track – Paper Three: Clean Water Atlanta Enterprise GIS

The city's new management system uses an enterprise GIS with web-based user interface applications. The system is built on an Oracle database, with ESRI's ArcSDE providing a geographic interface to the database.

IBM Maximo Asset Management Software

At its core, Maximo is a database-driven application focused on tracking assets throughout their lifecycle, including the tracking of contracts and inventories, work order generation and tracking, and maintenance operations and planning. The system is generally installed on a central server, with editing of data distributed to a number of individuals through a web interface. Systems such as Maximo are intended to be implemented at the enterprise level, and provide structure and standardization for asset management record-keeping. Recently, Maximo has expanded into the geospatial sector by integrating their asset management system with the ESRI ArcGIS Server system. Termed "Maximo Spatial Asset Management," this system adds spatial context to the Maximo asset management system.

Shamsi: GIS Tools for Water, Wastewater, and Storm water Systems

U.M. Shamsi's book, GIS Tools for Water, Wastewater, and Storm water Systems, neatly condenses the concepts necessary for a civil engineer to begin implementing a GIS system to manage water, sewer, and/or storm water assets. In general, infrastructure data is divided into two categories: assets data and applications data. Assets data describe the composition, geometry, and physical properties of the infrastructure. Assets data is typically the core of the GIS data model. Applications data is that which extends the assets database into fields such as maintenance operations, business and accounting, planning, and modeling.

PROPOSED PIPE DATA PARAMETERS

In the recent months at Virginia Tech, about 100 parameters which may affect the pipe infrastructure have been identified each for the wastewater and water systems. This project is funded by Water Environmental Research Foundation (WERF) under SAM challenge program. The goal is to eventually create a national standard data model for the pipe infrastructure. This national standard data model was developed to aid the decision making process in asset management program. The data model can be used in developing of condition index, prediction model, prioritizing repair and rehabilitation, prioritizing inspection, planning operation and maintenance, developing capital improvement program and making high level decision etc. The parameters which may affect the pipe performance were divided into five classes based on their characteristics: Physical/Structural, Operational/Functional, Environmental, Financial, and Others. These classes are presented in Figure 1.

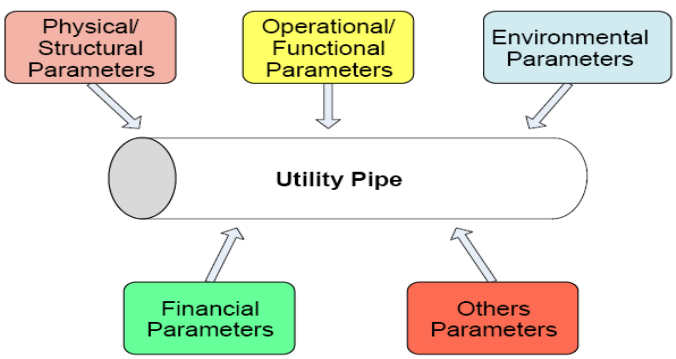

Figure 1: Parameter classes that effect pipe performance

The physical parameters include pipe related attributes like age, thickness, length, diameter etc while operational include general operational attributes of the utility such as capacity, connection density, population, sewershed and more . Attributes classified as environmental include soil parameters, climate, loads etc. Financial parameters are more into costs of operations, maintenance and some related attributes.

DATA MODELS

In this study, the research team has considered data from major cities as well as smaller towns within the U.S. The data model was broken into four separate models: **Wood, Bronze, Silver, and Gold**. Also, due to the utilities lack of readily available number of parameters, the wastewater pipe data model was broken into essential and preferable/desirable data.

The wood data model is for utilities which are very small and do not have resources to collect enough data. This model represents most important 6 essential and 5 preferable parameters for a wastewater pipe based on the research teams' knowledge of pipe infrastructure. The bronze data model is for utilities which are small and do not have a lot of man-hours due to a smaller workforce. This model represents most important 11 essential and 12 preferable parameters for a wastewater pipe. The silver data model is for utilities which are larger than bronze utilities; however, still may not have a special team designed to devote all their time to developing wastewater pipe data parameters within a system. This model represents most important 23 essential and 28 preferable parameters for a wastewater pipe. The gold data model is for the utilities which represent some of the largest cities within the U.S. and have a special team devoted to the continuation of updates to the wastewater data parameters. This model entails all 51 essential and 47 preferable parameters which affect the wastewater pipe.

GEOSPATIAL DATA STORAGE

After receiving the Utilities' GIS and tabular data, the Virginia Tech researchers are storing it at the San Diego Supercomputing facility, using an ArcSDE connection to Oracle tablespace at San Diego. The ArcSDE connection is being hosted by Virginia Tech's E-Corridors program. Once loaded through ArcSDE, the geospatial and tabular data may be viewed directly in GIS software (with appropriate access permissions). The access permissions have been given to Virginia Tech research people only as of now. The data from Seattle has been uploaded as a test trial to check for efficiency and speed of transfer. This trial proved to be a good test, with tabular data of around 30,000 pipes transferring in 2 hrs. Once the data is uploaded to the server, subsequent retrieval and viewing is very quick, almost as though it were hosted locally. The proposed effective structure to store data is to create a feature dataset for each city on its name and then create individual feature classes for manholes, pipelines etc in each dataset. The main advantage of this structure is that the data from each city is stored separately and can be retrieved also in a similar fashion. The illustration in Figure 2 gives a better understanding of the structured storage. The table names (manholes, pipelines, laterals, hydrants, valves etc) may change accordingly to the final proposed data model.

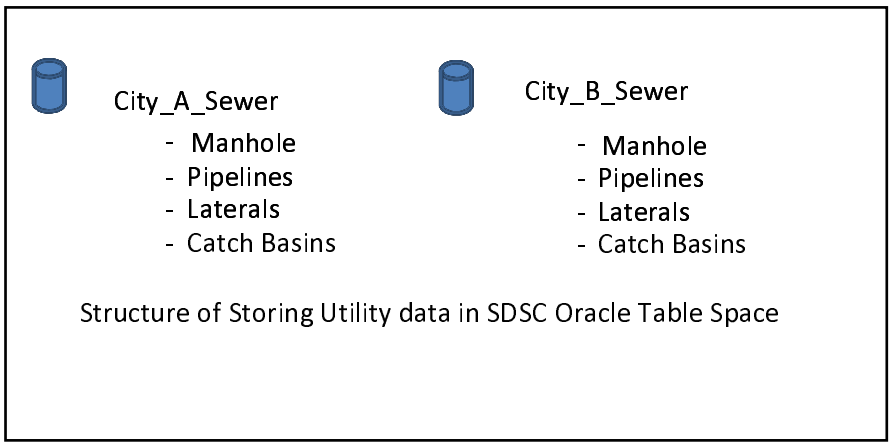

Figure 2: Storage of Utility Data in Standard Format

The data received from utilities would be reviewed and initial analysis would be done to familiarize with their fields and attributes. This data will be then loaded to the standard data model template, this would further be transferred to SDSC oracle table space. The schematic in Figure 3 gives a better understanding of the data transfer.

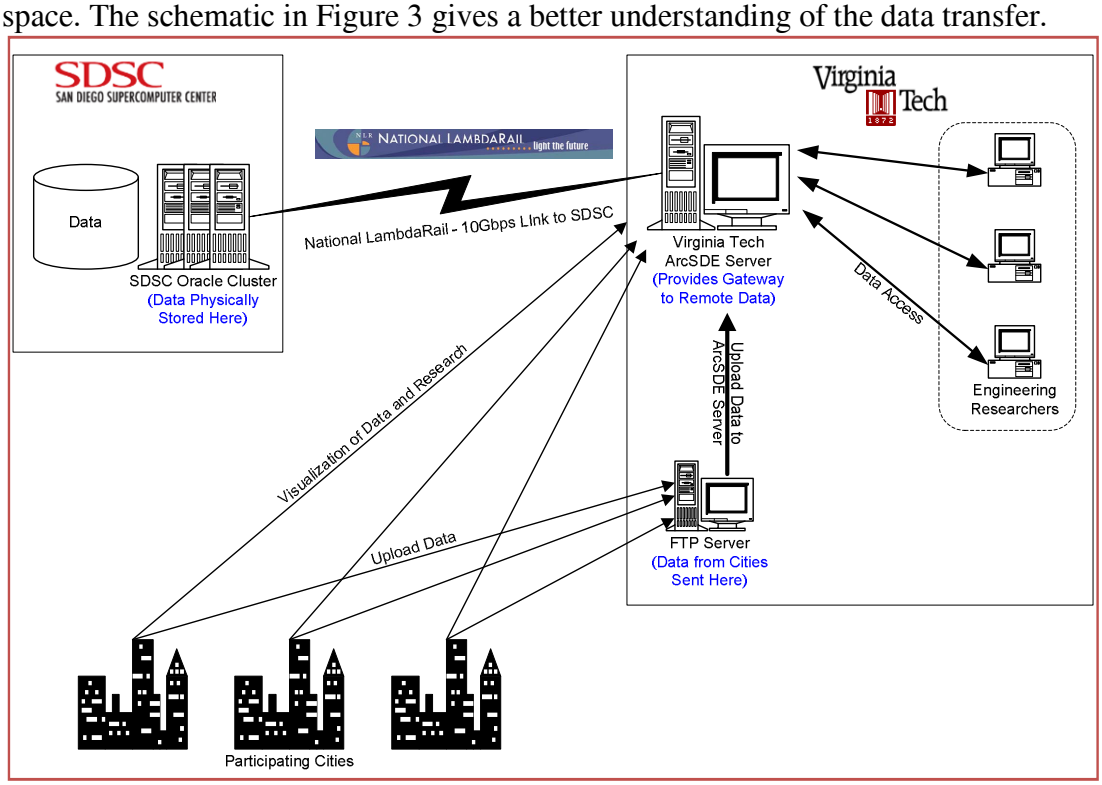

Figure 3: Data Transfer, Analysis, and Visualization Protocol

Virginia Tech team will construct an example geospatial database of aggregated wastewater pipe infrastructure data. As illustrated in Figure 4, a common data framework to support condition assessment have been defined and populated by conflating disparate datasets from several partner utilities.

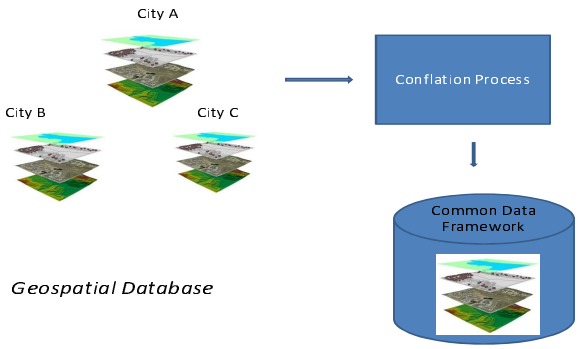

Figure 4: Conflation Process between Multiple Utilities

Existing Geo-Database - A Priori Data

There are several existing geo-databases relevant to pipe infrastructure which are available online or published. Some of these features included soil, geology, land cover, river, forcing, DEM, and stream flow. These geo-databases will help the research team in comparing the data provided from the utilities as well as filling in missing data parameters of the utility databases. For example, if the utility does not know the soil type within the area, the utility or the research team can visit online to the CONUS, Soil Survey Geographic (SSURGO) Database, or State Soil Geographic (STATSGO) Database websites to determine the type of soil. A sample of existing geo-databases relevant to pipe infrastructure can be seen in Figure 5.

GeoDataBase – A Priori Data

Feature	Property	Source
Soil	Porosity; Sand, Silt, Clay Fractions; Bulk Density	CONUS, SSURGO and STATSGO http://www.soilinfo.psu.edu/index.cgi?soil_data&conus http://datagateway.nrcs.usda.gov/NextPage.asp http://www.ncgc.nrcs.usda.gov/products/datasets/statsgo/

Security and Confidentiality of Participating Utilities Database

Utility Wastewater Infrastructure Data/Information is fully protected by MOU and at multiple points in our Cyber-Infrastructure System, as described in the following steps below.

1. Data is initially uploaded to the secure FTP server web.cgit.vt.edu
    a. Only the participating cities are provided with login credentials.
    b. The data only resides on this server as a staging area, until it can be uploaded to its permanent storage location, after which time it is deleted from the FTP server.

2. The data permanently resides on an Oracle Real Applications Clusters server at the San Diego Supercomputing Center.
    a. The data is owned by a single Oracle schema, and the only other user accounts that exist in this database instance are assigned to approved researchers at Virginia Tech.
    b. The owners of these accounts must request access to each individual GIS feature layer they need.
    c. Access is only granted on a "need to know" basis, and no user receives anything but read-only permissions.
    d. All IP addresses are blocked at the firewall at SDSC, with one exception: the ArcSDE middleware server we use as a gateway to access the data from ArcGIS.

3. The ArcSDE server functions as our gateway to the data.
    a. ArcSDE adheres to Oracle's authentication and authorization controls; any access that is prohibited in the database itself is likewise prohibited in ArcSDE.
    b. All IP addresses are blocked at the firewall on the ArcSDE server, with the exception of valid Virginia Tech IP addresses.

4. The Fiber-Optic Communication Link between VT & SDSC.
    a. The fiber-optic communications link between Virginia Tech and the San Diego Supercomputing Center is a dedicated point-to-point pathway.
    b. It is NOT part of the public Internet; rather, it is a link in the National Lambda Rail research network that is only used by major universities and institutions.

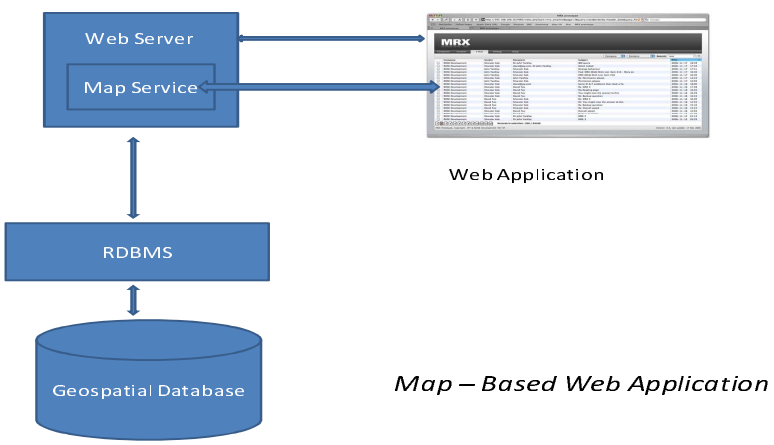
5. San Diego Super Computer Center.
    a. The primary goal of computer and network security activities at the San Diego Supercomputer Center is to protect the confidentiality, integrity, and availability of computing resources. As an Organized Research Unit at UCSD, SDSC Security Policies are consistent with UC and UCSD policies. The SDSC Security Manager and authorized designees have the authority to take actions necessary to prevent, detect, and respond to security policy violations involving SDSC

computing resources. These actions will be consistent with SDSC, UCSD, and UC policies, and applicable laws.

b. The Data Intensive Computing Environments (DICE) group at the San Diego Supercomputer Center (SDSC) has implemented software to make use of a variety of authentication/data-security systems in the SDSC Storage Resource Broker (SRB) and other distributed applications. These include the SSL(X.509 Certificate)-based Grid Security Infrastructure (GSI) developed by Globus with assistance from NCSA and others , Kerberos, DCE Security, and SDSC Encryption/Authentication system (SEA).

DATA QUERY & VISUALIZATION

A prototype web application has been developed to demonstrate how this aggregated data in the example geospatial database can be published, queried, and visualized in a map-based browser application (Figure 6). The application will deliver rich, interactive maps, data exploration tools.



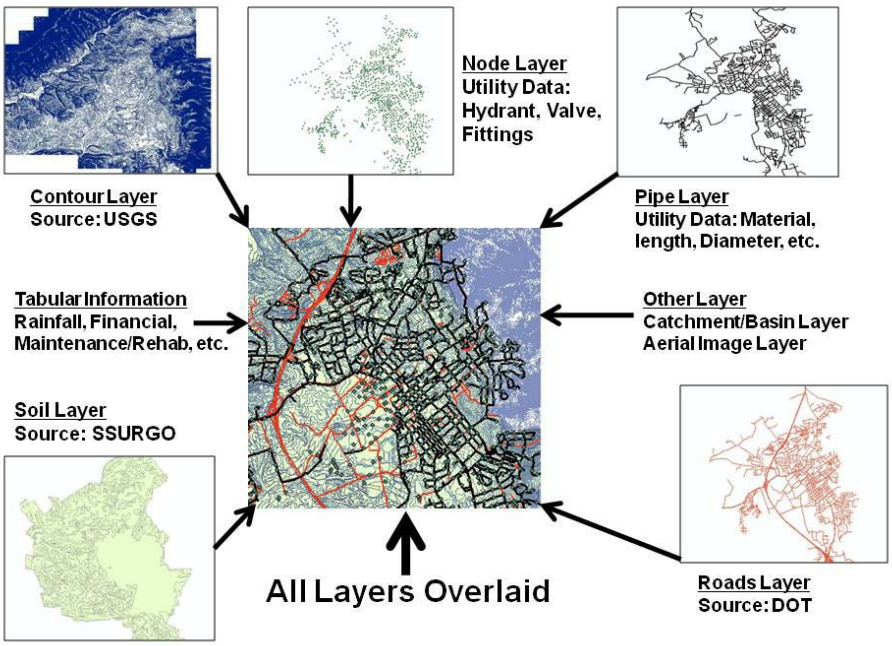


Figure 6: Map Based Web Application and Supporting Components

Data Visualization is one another important aspect which helps in making decisions for the utility officials. The main goal of data visualization is its ability to visualize data, communicating information clearly and effectively. Arc GIS can be very efficiently used to over lay shapefiles corresponding to soil, roads, land cover, elevation and many other types of data which are available in open source or collected by the utilities. The illustration in Figure 7 gives a better idea of data visualization system for City of Blacksburg, Virginia.

CONCLUSIONS

The existence of this data model can act as a standard database storage model for various utilities. Also, organized storage of data can be very crucial to take high level decisions for a utility. These models with stored data (with acceptable accuracy) can generate reports which can be vital for taking strategic level decisions. This can be a very useful tool for any utility (small, medium, and/or big) in managing their pipes strategically and cost effectively.

FUTURE WORK

With the existence of a standard database with utilities data stored, condition index of a pipe or predictive index of pipe condition can be developed. Also, dynamic data querying and extraction of data can be done with restricted privileges depending on the level of importance of data. Web applications can be developed to demonstrate such querying and map based visualization techniques. Alternatively, some of the pipeline data can be converted to KML file format and can be imported to Google Earth for an ultimate 3D visualization experience of the buried pipes.

The future of these geo-databases will ultimately lead to a realistic three dimensional (3-D) models and simulation, which can demonstrate the pipe infrastructure and its surroundings at the watershed scale. Presently, only air and water quality 3-D models are available for simulation at the watershed scale. Since a pipe database does not exist, this pipe infrastructure cannot be modeled and simulated. Once the pipe infrastructure database is created a simulated 3-D pipe infrastructure model can be produced. These models will benefit the utilities in simulating their actual environment and wastewater pipes.

ACKNOWLEDGEMENT
The authors would like to acknowledge various utilities across the country for their valuable comments and feedback related to this research project.

ABSTRACT

Selenium is among the pollutants of concern in a growing number of areas within California. TMDLs proposed by USEPA (USEPA, 2002) for the San Diego Creek watershed in Orange County, California (and in Ballona Creek and Los Angeles River in Los Angeles County) calls for an in-stream standard of 5 ppb total selenium. Selenium sources and treatment methods, however, are significantly different than those typically utilized as stormwater BMPs for metals such as copper, lead and zinc.

Studies on the sources of selenium in the San Diego Creek Watershed indicated that a major potential source is groundwater seepage, particularly in areas where the groundwater table is shallow. Thus dry-weather concentrations and loads are of the most interest. Within the San Diego Creek Watershed, flows appear to correspond to a location where historically, naturally occurring selenium became sequestered under anaerobic conditions in the peat soils within a swamp. Urbanization and draining of the swamp appears to have created aerobic conditions, releasing selenium from these sediments into groundwater in a soluble phase. Selenium concentrations in the surface water discharge have been observed in the 50 ppb range, and local groundwater selenium concentrations commonly exceed 100 ppb.

Several technologies potentially reduce selenium (Se) concentrations to low levels (<10 ug/L). Many of these technologies involve physical, chemical, and biological processes developed as part of the wastewater, agricultural and mining industries. Siting, sizing, and engineering constraints related to the volumes of water potentially requiring treatment, however, limit the applications of many of these technologies for storm water.

Foundational studies supporting IRWD's Cienega Filtration Demonstration Project supported a program to proactively reduce dry-weather Selenium loads in the San Diego Creek Watershed. The technology is an engineered and controlled system intended to mimic subsbsurface wetland processes that were in existence prior to urbanization. This effort included batch laboratory testing and mesocosm-scale tests, which confirmed the efficacy of the technology given conditions requiring treatment of significant flows. Pre-design optimization studies and a field demonstration have

an ultimate objective of developing a permanent, maintainable, and fully operative, subsurface treatment system that utilizes natural reduction processes to sequester and remove selenium from the creeks. Results from these studies provide engineers valuable design and process guidelines that should be considered before similar types of facilities are contemplated.

BACKGROUND: LOCAL AND SCIENTIFIC CHALLENGES

The focus of this paper is work done in the San Diego Creek Watershed. Selenium concentrations in the main stem of San Diego Creek as well as its tributaries have routinely been detected at levels well above the EPA's chronic criteria of 5 µg/L for surface waters. The US Fish and Wildlife service has suggested a TMDL of 2 µg/L should be adopted to ensure the protection of aquatic species and wildlife (RWQCB, 2001), as it is believed that concentrations as low as 3 µg/L may lead to detrimental bioaccumulation in some waterfowl and shorebirds.

Hibbs and Lee (2000) indicated that the selenium source is the historic "Swamp of the Frogs" and groundwater seeps distributed throughout the watershed. Selenium-laden sediments in the Swamp release soluble selenium (primarily in the form of selenate) as the historically anoxic soils oxygenate due to draining of the Swamp, applied irrigation waters and seasonal fluctuation of the groundwater table.

Many historical applications for selenium treatment originate from the wastewater, agricultural and mining industries. A review of selenium removal technologies that highlights potentially successful treatment mechanisms but also potential limitations with respect to storm water and urban runoff treatment – most notably the need for extened residence times. In the aforementioned San Diego Creek Watershed, it was desired focus on summer and winter dry- weather flows that have a groundwater origin. The highest selenium concentrations in the watershed are found in dry-weather flows that originate from a major tributary is on the order of 4 cubic feet per second. Preliminary results of this study indicate a treatment residence time as short as one-day can provide the desired level of treatment (below 5 ppb). Even at this low residence time, approximate land requirements to provide treatment of these flows are on the order of about 3.5 acres. Lastly, long term, sustainable hydraulic conductivity of treatment systems must be maintainable for the aforementioned flow rates. The following summary is presented in more detail in Susilo et.al (2005).

Selenium treatment objectives. Frankenberger (1999) noted that treatment for removal of selenium in subsurface agricultural drainage water has several regulatory considerations, that include (a) reducing constituents below hazardous levels (1000 µg/l), (b) meeting agricultural water quality goals, (c) meet water quality objectives in surface waters (5 µg/l), and (d) reduce constituents below the lowest risk levels for wildlife (2 µg/l). Most of the treatment approaches he described did not have selenium removal data. Of those that did provide data removal rates or treated effluent quality, percentage removals were high. Most systems, however, could not meet the latter two effluent target levels. (For example, Algal-Bacterial Selenium Removal systems and the recommended biological precipitation methods had effluent

concentrations of approximately 30 µg/l). In addition, agricultural influent selenium concentrations were generally significantly higher than the San Diego Creek concentrations (Kovac, 2005). Recent studies of low cost methods of treatment (Scheidlinger, 2005) confirm the ability to treat significant percentages of influent with high selenium concentrations, but these methods still do not meet water quality objectives for the effluent. These methods include the utilization of bio-barriers and straw-filled conveyance facilities.

Selenium speciation. In natural waters, selenium can exist in four primary oxidation states and as a variety of different inorganic and organic compounds. Inorganic selenium can exist as selenide, Se(-II); elemental selenium, Se(0); selenite, Se(IV); and selenate, Se(VI). Organic selenium species include selenoamino acids, seleno-amino acid derivatives, methyl selenides, methyl selenic esters, methyl selenones, and methylselenonium ions.

The volatile methyl selenide, dimethyl selenide (DMSe), is the product of selenium biomethylation; a natural process that detoxifies and removes inorganic selenium from soil/water environment. Selenate is the most soluble and, therefore the most mobile form of selenium in the aquatic environment. Selenite is less soluble than selenate and will often exist as a sorbed ion. Toxicity studies conducted by Yu et. al. (1997) found selenite to be the most toxic form of inorganic selenium in the aquatic environment. The oxidation of selenite to selenate is believed to be a slow process, so selenite is still common in oxygenated waters (Cooke and Bruland, 2000). Reduction of selenate to selenite is also a slow process and occurs within the nitrate-reducing zone of wetland soils, characterized by sub-oxic conditions having a redox potential of approximately +200 to +300 mV (Masscheleyn and Patrick, 1993).

Selenite has been reported to be reduced to elemental selenium and/or selenide species at a redox potential of 0 to -50 mV, which is well below normally oxidized surface soil conditions (+500 mV). Furthermore, the same species of bacteria that reduce nitrate also reduce selenium. Nitrate, however, is consumed preferentially so selenium reduction generally requires greater residence time than nitrate reduction (Reinsel and Botz, 1999). Under anoxic conditions, the dominant forms of selenium are elemental selenium and insoluble metal selenides (Cooke and Bruland, 1987). A selenium speciation study conducted at the Kesterson Reservoir in Merced County, California by Weres et. al. (1989) found that, in permanently wet areas, the highest selenium concentrations were found in the top organic/peat layers of the wetland soils, indicating that selenium would be reduced and immobilized in anoxic soils.

Methylation and volatilization. Selenium removal through volatilization received attention after high levels led to waterfowl deformities in the Kesterson Reservoir in Merced County, California during the 1980's. Several studies have been conducted to determine the optimal plant species and conditions to remove selenium from the soil and water through biomethylated volatilization (Zhang and Moore, 1997; Allen, 1991; Hansen et. al., 1998; Azaizeh et. al., 1997; Thompson-Eagle and Frankenberger, 1990a and 1990b; Frankenberger et. al., 1999; Zayed and Terry, 1994; Bañuelos et. al., 1997; Pilon-Smits et. al., 1999; Stork et. al., 1999).

Selenium volatilization through methylation is a biogeochemical process responsible for detoxifying and removing selenium from aquatic environments. Microbial and phyto methylation convert organically bound selenium into volatile forms (i.e. dimethyselenide (DMSe) and dimethyldiselenide (DMDSe)). Inorganic selenium species (particularly selenate and selenite) need to first assimilate to organic selenium before methylation can occur (Zhang and Moore, 1997). This intermediate reduction pathway is not well understood, however dimethyl selenone has been proposed as the primary organic chemical involved (Yu et. al., 1997). There are many conditions that affect the rates of methylation including: pH, temperature, redox potential, microbial activity, soil moisture, and trace element addition (Stork et. al., 1999).

Flooding and drying also may affect rates of selenium volatilization. An experiment conducted by Zhang and Moore (1997) showed that the rate of selenium volatilization from selenium-laden soils increased by 1-2 times during drying as compared to flooding. The theory behind this observation is based on the high solubility of DMSe in water determined by Karlson et. al. (1994). Periodic dewatering of anaerobic or anoxic sediments promotes the atmospheric release of dissolved DMSe as well as the decomposition of solid organic materials and oxidation of selenium in surface sediments to forms that are readily converted to DMSe (Zhang and Moore, 1997).

Adsorption and phytoaccumulation. Phytoaccumulation is a method of selenium removal from water and soil that is often coupled with volatilization. Plant uptake of toxic chemicals can lead to bioaccumulation in higher trophic levels if the plants are a significant food source. Horne (2001) believes the winter accumulation of resident birds at the Kesterson reservoir was due to the high selenium concentration in the seeds of widgeon grass. If phytoaccumulation is to be used as a selenium removal strategy, the plants selected should not be a significant food source and the remediation area should be designed to not attract wildlife. Of twenty different wetland plants studied, Pilon-Smits et. al. found that *Typha latfolia* L. (cattail) and *Scripus acutus* Muhl. (hardstem bulrush) accumulated the greatest amount of selenate and selenite, respectively, per square area. However, the seeds of bulrushes are significant food sources of waterfowl and terrestrial birds (NRCS, 2002). Cattail is not a primary food source for many wild animals, particularly most waterfowl.

The presence of trace elements may affect the rate of selenium uptake by plants. The chemical similarities between sulfur and selenium may promote competition for electron providers and therefore high sulfate concentrations can significantly reduce the rates of selenate reduction.

Sequestering selenium in the soils by promoting anoxic conditions is another method to remove toxic selenium from surface waters. Bacteria have been shown to reduce selenite to elemental selenium at a much faster rate under anoxic conditions than under oxic conditions (Kessi et. al., 1999). Significant selenate concentrations have been found in the soils of the anoxic waters of Drammenfjord, Norway, indicating that selenium is not always reduced under anoxic conditions (Abdullah et. al., 1995). However, the majority of the literature reviewed indicates that selenium will be

reduced to elemental selenium or metal selenides under oxygen deficient conditions.

Best demonstrated available technology. Ferric oxyhydroxide adsorption of selenium has been chosen as the EPA's Best Demonstrated Available Technology (BDAT) for the removal of selenium from wastewater, and shows the most potential (out of the other adsorption technologies). However, this method requires significant chemical additions and produces a highly concentrated sludge that must be dewatered and disposed of in a municipal landfill. Furthermore, adsorption processes are generally not very effective on selenate (Twidwell et al., 2000) and are designed for higher influent (wastewaterlevel) concentrations (MSE, 2001).

PRECEDENTS AND LIMITATIONS: SUCCESSFUL SELENIUM REMOVAL FIELDAPPLICATIONS

Chevron Richmond. A 36-ha constructed wetland was built at Chevron's oil refinery in Richmond, California to reduce selenium concentrations prior to discharging into the San Francisco Bay. A 16-week study conducted by Hansen et. al. (1998) showed that the wetland achieved significant selenium removal through volatilization, plant uptake and soil adsorption. Inlet selenium concentrations were consistently between 20 and 30 µg/L. Effluent concentrations were maintained below 5 µg/L. Flow rates varied between 1.2 and 4.1 cfs and the residency time over the entire wetland was 7-10 days. Therefore, while the treatment levels were adequate for meeting water quality goals for San Diego Creek, the required residence time exceeds engineering constraints for the urban runoff applications of interest as the residence time would require a land area 7 to 10 times larger than a 1 day residence time.

Corcoran-DWR, EPRI, UC Berkeley. A wetland study in Corcoran, California was initiated in 1996 on land donated by J. G. Boswell and Company (Warnert, 1998). Ten quarter-acre wetland cells were built to study selenium removal. With funding from the UC Salinity/Drainage Taskforce, the California Department of Water Resources and the Electric Power Research Institute, UC Berkeley plant biologist Norman Terry and his staff planted the cells with different combinations of wetland species to compare their effectiveness in reducing selenium. In the 1998 season, the average selenium concentration in the drainage water influent to the cells was 22 µg/L. With a 7-day residence time, selenium removal ranged from less than 30% in the unplanted cell and cells planted with cordgrass, salt grass, and a combination of bulrush and tule, to as much as 60% in the combination cell planted with cattail and widgeon grass. As with the Chevron example, the 7-day residence time makes direct application infeasible for large flows or in urban areas.

Stillwater Mine, Montana. Anoxic treatment of selenium at much higher concentrations was achieved at the Stillwater Mine in Montana. Hydrometrics, Inc. designed an Anoxic Biotreatment Cell (ABC) to treat nitrate, selenium, and perchlorate in the mining effluent discharge. The ABC is a "semi-passive" bioreactor, which utilizes pressurized flow and nutrient addition (Reinsel, 1999). Influent selenium concentrations to the ABC were between 1.2 and 0.30 mg/L (e.g.,

300 to 1200 ppb). These concentrations were reduced to 0.03-0.2 mg/L (30 to 200 ppb) prior to discharge. Flow rates varied between 0.2 and 1.0 cfs and the residency time in the reactor was 6-24 hours. No studies were found where the ABC was used to remove low selenium concentration from water, however the proprietors of the technology (Hydrometrics, Inc.) claim that the ABC can be designed for a variety of flow rates and concentrations. However, increased residence time and additional amendments would likely be necessary. For this example application, the effluent concentrations would not satisfy the San Diego Creek regulatory requirements.

Garfield Wetlands Kessler Springs, Utah. The EPA's Mine Waste Technology Program tested three technologies for the Kennecott Utah Copper Corporation's Garfield Wetlands Kessler Springs site. These three technologies were: 1) ferrihydrite adsorption (wastewater BDAT), 2) catalyzed cementation process, 3) and proprietary biologicial selenium reduction processes. For these studies the target effluent concentration was 50 ug/l, however, the proprietary biological system was able to reduce effluent concentrations to near detection limits for significant flow rates (300 gpm) with residence times less than 24 hours (MSE 2001).

IRWD Wetland Mesocosm Pilot Study, Irvine, California. This study was conducted by Geosyntec Consultants for the Irvine Ranch Water District in two phases. Phase one was a bench-scale study in which several media were examined for their potential effectiveness at reducing selenium from the source water using static column tests. Phase two of the study was a mesocosm-scale study that examined how well the selected media performed under dynamic conditions similar to what would be expected in a full-scale subsurface wetland like environment. The purpose of the mesocosm experiment was to estimate reduction rate, effluent quality, and effectiveness of the media at reducing selenium, as well as establish the design parameters for constructing a full-scale wetland. Study results indicated that subsurface treatment wetlands can achieve selenium reductions to water quality standards (5 ppb) with residence times of approximately 3 days or less. A full-scale project in the San Diego Creek watershed constructed with a similar soil depth and hydraulic characteristics, would require approximately 20 acres to treat a design flow of about 5 cfs, however additional testing for engineering parameters was required (GeoSyntec, 2003).

IRVINE RANCH WATER DISTRICT'S CIENEGA FILTRATION PROJECT

The Irvine Ranch Water District completed Pre-Design Optimization Studies (PDOS) and constructed a Field Demonstration to test and develop the next generation of selenium treatment best management practices. The project, named the *Cienega Filtration Project* was developed to recreate natural treatment processes found in the historic Swamp of the Frogs which naturally sequestered soluble selenium in native soils, removing it from the water column.

The underlying concept for these activities is that optimizing of bacteria populations, electron donors, and residence times will create anoxic, reducing conditions to reduce soluble selenium to its particulate form, so that it is removed from the water column

to be collected and disposed of. It is also recognized, however, that redox potential, as shown below in Figure 1, should not drop below -200 mV as below this level there is the potential for selenium gas formation.

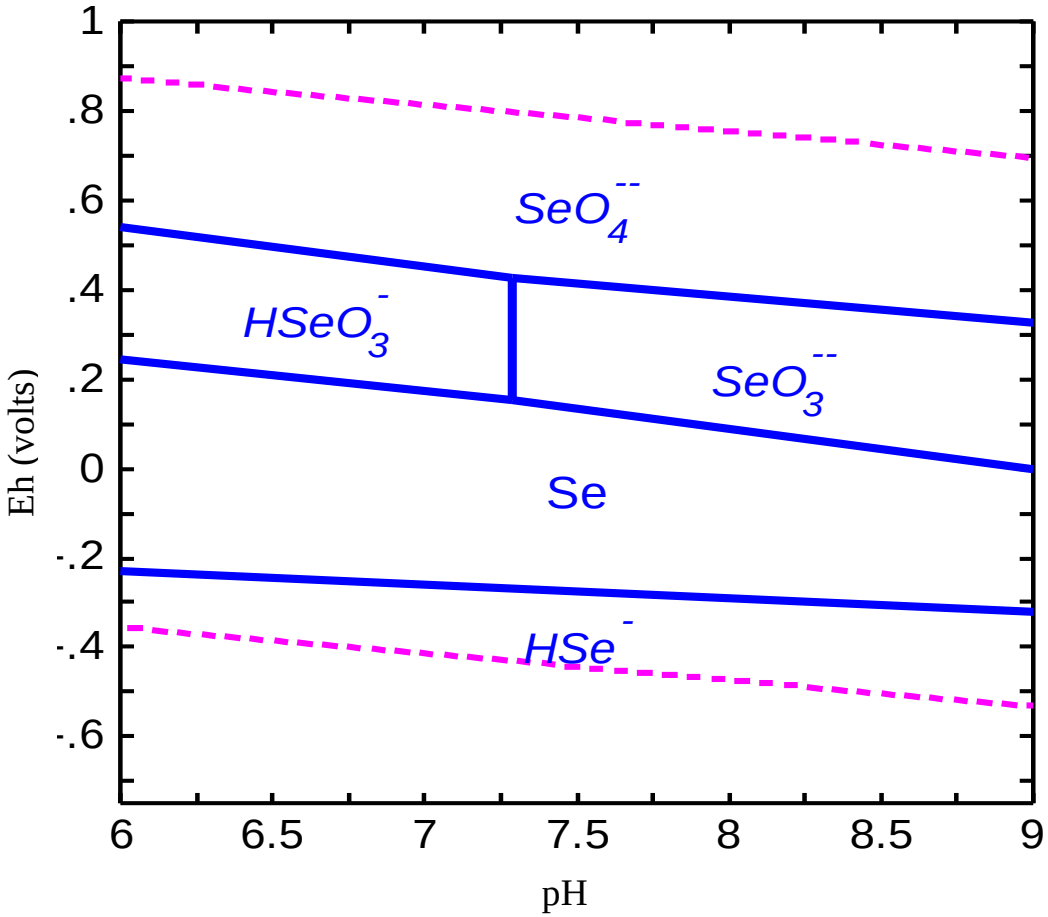

Figure 1. Optimal redox conditions for removal of soluble selenium.

PDOS Test apparatus. Seven continuous flow columns were designed to test the effectiveness and sensitivity to various levels of inoculation, electron donor, media matrix as part of the PDOS. Inoculation was tested by adding: a) native mud extracted from the source creek and b) chopped and mixed cattails. Electon donors included food grade citric acid and sodium benzoate at up to 2.5 times stoichometric-required levels. Media matrix materials included sand, 3/8" crushed rock, and ¾" crushed rock. A schematic of the testing apparatus is shown below in Figure 2.

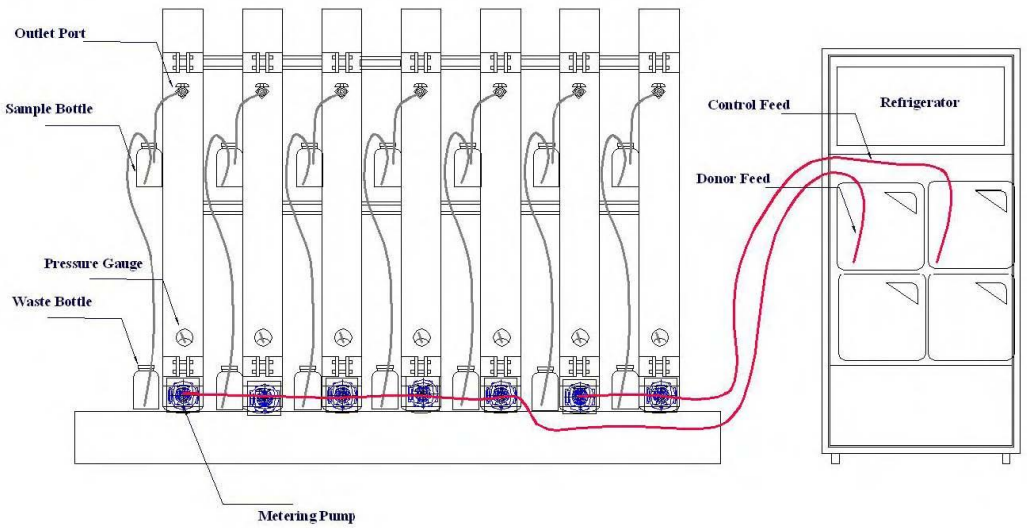

Figure 2. Pre-Design Optimization Study Apparatus.

CONCLUSIONS

At the conclusion of the PDOS, a number of preliminary conclusions were made to support the development of a Field Demonstration and future applications on a full scale. These conclusions are as follows:

Performance. The PDOS confirmed the efficacy of a Cienega Filtration Project type of system in reliably reducing soluble selenium below targeted levels of 5 ug/l, and that this can be achieved with a residence time of approximately 24 hours, with the precise addition of organic material to promote sufficient bacterial growth to achieve moderately reducing conditions.

Matrix materials. The PDOS concluded that the coarsest media – ¾" crushed rock, performed as well or better than sand. Thus for the Field Demonstration (and if confirmed) for full project implementation, it is recommended to utilize coarser-grained materials to allow for residence times to be controlled via inlet and outlet hydraulic controls rather than limited the hydraulic conductivity of the matrix. This also adds structural stability (reduces total and differential settlement).

Bacteria inoculation. It was established that the combination of naturally-occuring native bacteria found in the existing creek bed provides adequate inoculation of selenium-reducing bacteria. It was further found that without inoculation, appropriate redox conditions would eventually be reached. A significantly longer equilibrating start-up time, however, appeared to be required to begin selenium removal. It was also found that the inclusion of chopped cattails accelerated the selenium reducing process, but posed other engineering control issues and created less than ideal ancillary conditions (discussed below).

Electron donor. The need of an appropriate electron donor was confirmed, and various types of donors were considered. It is desired that a food grade supplement be introduced, and while both citric acid and sodium benzoate were tested, the sodium benzoate performed more satisfactorily. It was estimated that application levels should be 2.25 to 2.5 times the calculated stoichiometric nitrate levels. Figure 3 illustrates the drop in effluent selenium levels once electron donor addition was increased. Reducing conditions were more quickly and reliably established using citric acid, rather than sodium benzoate, as the electron donor; however twice the mass of citric acid was required for similar results.

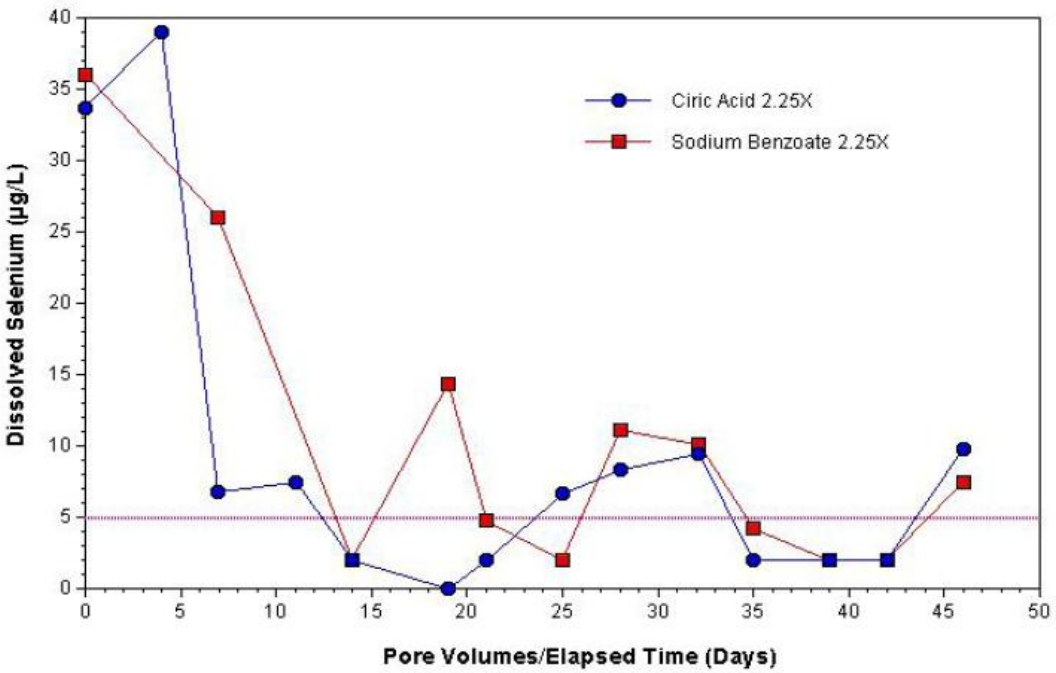

Figure 3. Dissolved Selenium with varying electron donor contributions.

Nitrate removal. The PDOS showed extremely efficient removal of nitrates. This is expected as at the target redox levels, nitrates are preferentially removed. Effluent nitrate concentrations were below detection limits.

Bacteria. While not a primary objective of this study periodic sampling for fecal indictor bacteria was conducted in the system effluent, yielding concentrations below detection limits.

Dissolved metals in effluent. The reductive dissolution of iron and manganese oxides present in the crushed rock media under selenium reducing conditions results not only in an increase in levels of these metals in the effluent, but the liberation other trace constituents metals and metalloids that are associated with these oxides. In the PDOS, the onset of iron and manganese reducing conditions occurs at 27 pore volumes. The magnitude of the release of these metals, however, was dependent on the media. As the supply of reducible iron and manganese become exhausted the levels of dissolved iron and manganese decline to the source water concentration so

the media is neither a source nor a sink. Although the potential for arsenic precipitation in the media had been identified as a potential limiting factor for long-term operations, secondary iron oxides generally control the mobility of arsenic when it is present in trace quantities. In an oxidizing environment arsenic is readily adsorbed by iron oxides, while the reductive dissolution of iron oxides released selenium. This pattern was also observed in the column study, where arsenic was adsorbed by the media until the liberation of iron and manganese. The release of arsenic ceased after the available arsenic in the media was exhausted, after which the source water arsenic concentration was unaffected by passage through the columns.

OTHER ISSUES AND CONSIDERATIONS

The PDOS revealed that there are a number of other issues that are directly relevant in the consideration of selenium treatment in urban areas for storm water and urban runoff. These must be carefully considered in conjunction with siting and design studies. These issues include:

- **Biofouling.** Maintenance of long term hydraulic conductivity is critical for system operations. Preliminary results indicate that after 8 weeks of operation, hydraulic conductivity remains sufficiently high to meet design requirements.
- **Accumulation and disposal.** For full scale implementation of the Cienega Filtration Project, decommissioning and disposal of a full scale project would be extremely expensive and cost-prohibitive. Refreshing could be accomplished by periodic aeration and flushing of the media with proper disposal.
- **Hydrogen Sulfide.** The conditions and bacteria required to reduce selenium to a solid form potentially causes the release of hydrogen sulfide gas. Various measures will tested in the Field Demonstration for implementation.

FIELD DEMONSTRATION

Prior to full scale implementation, a Field Demonstration (Geosyntec 2006b) was designed, built and is currently in operation by IRWD. The primary objective of this Field Demonstration is to test critical elements (such as large scale geometries, efficiencies of electron donor dosing, operations and maintenance considerations, etc.) prior to consideration of full scale implementation.

CONCLUSIONS

Treatment of selenium in dry-weather urban runoff can be achieved, by adopting technologies and concepts established in the wastewater, agricultural, and mining industries. This paper presents information from flow-through column testing that confirms the ability to achieve significant selenium reduction through a wetland-like treatment process with residence times as short as 24 hours and using food-grade carbon sources.

The challenges in the urban environment include the cost of land, public perception and environmental issues, the volume of water treated, and the standards for effluent quality. The work reported here and currently underway is believed to substantially advance the state of the practice in cost-effectively removing selenium in dry-weather flows.

Extension of an LA-QUAL model for evaluating a proposed wastewater discharge to realistic receiving water temperature and flow conditions

Chris Herrington[1], PE

1. City of Austin, Watershed Protection and Development Review Department, PO Box 1088, Austin, TX 78767. PH (512) 974-2840; email: chris.herrington@ci.austin.tx.us

ABSTRACT

Multiple steady-state LA-QUAL(version 8.0) models for varying temperature and flow conditions were evaluated and used to generate a time-series prediction of water quality impacts from a proposed wastewater discharge to Bear Creek (Hays County, Texas) at the upstream boundary of the Barton Springs portion of the Edwards Aquifer Recharge Zone. LA-QUAL predicted output is sensitive to dilution (amount of natural creek flow present) and temperature (removal rates are temperature-dependent) (Herrington 2008) . Although LA-QUAL (or QUAL-TX) models are commonly used by Texas Commission on Environmental Quality staff to evaluate potential dissolved oxygen degradation for new discharges (TCEQ 2003), typically only a single critical condition (low flow, high temperature) is considered. The use of multiple models is a more accurate representation of the temporal variability in flow and temperature. Using this approach, the proposed discharge is predicted to degrade the water quality of Bear Creek and the Edwards Aquifer. However, this analysis is still only a conservative approximation of the actual degradation potential and does not simulate more dynamic ecological responses such as nutrient spiraling or storm event driven sediment re-suspension.

INTRODUCTION

A residential development has applied to the Texas Commission on Environmental Quality (TCEQ) for a permit (Table 1) to discharge up to 500,000 gal/day (1,893 m^3/day) of treated wastewater directly to the headwaters of Bear Creek, Hays County, Texas. If approved, the discharge would be the first in the surface water contributing zone of the Barton Springs segment of the Edwards Aquifer. The aquifer provides drinking water for many central Texas residents and it's primary discharge point, Barton Springs, is the sole habitat for the federally endangered Barton Springs salamander (*Eurycea sosorum*). Bear Creek is an oligotrophic (Herrington and Scoggins 2006), intermittent, stream with many small perennial impoundments and primarily limestone bedrock substrate. The 62 km^2 watershed is bisected by the recharge zone of the aquifer. The discharge point is 12.5 km upstream of the recharge zone boundary.

The water quality of Bear Creek with the proposed discharge was previously predicted at the upstream recharge zone boundary of the Barton Springs segment of

the Edwards Aquifer using the steady-state one-dimensional LA-QUAL (version 8.0) model (Miertschin and Obenour 2006, COA 2006, Herrington 2008) for several varying temperature and flow scenarios. However, the temporal distribution of the varying temperature and flow scenarios has not been previously assessed against measured creek flow and ambient temperature. Thus, the increase in long-term average concentrations and mass loading from the proposed discharge to the Edwards Aquifer has not been accurately represented. By developing LA-QUAL models for multiple sets of temperature and flow conditions and then applying model output to measured daily time-series creek flow and temperature measurements, a more realistic assessment of the long-term impacts of the proposed discharge may be conducted. Utilizing these distributions of results allows toxicologists, aquatic scientists, and risk assessors a more familiar probability basis to evaluate impacts to aquatic ecology in the discharge route and the Edwards Aquifer.

Table 1. Final phase draft permit limitations for the proposed discharge (WQ0014293-001).

Effluent Characteristic	Daily Average	7-day Average	Daily Maximum	Single Grab Maximum
Flow, MGD	500,000	n/a	n/a	n/a
Carbonaceous BOD (5-day), mg/L	5	10	20	30
Ammonia Nitrogen, mg/L	2	5	10	15
Total Phosphorus, mg/L	0.15*	0.3	0.6	0.9

*expressed as a daily median

Previous LA-QUAL model results of the impacts of proposed discharge (Miertschin and Obenour 2006, COA 2006, Herrington 2008) have demonstrated that model predictions are highly sensitive to selected ambient temperatures and Bear Creek flow rates. TCEQ assessed the potential impacts of the discharge using the steady-state QUAL-TX model (version 3.5, updated November 1999) in a single condition with warm water temperature (29.7 ºC) and no ambient Bear Creek headwater or tributary flow additions. The low flow, hot temperature condition represents a system with maximum hydraulic residence time and maximum nutrient removal in the QUAL-TX or LA-QUAL models. Although this may be appropriate for assessing critical dissolved oxygen (DO) conditions, it may not represent time periods when biochemical oxygen demand (BOD) or nutrient loadings to the aquifer are higher. Therefore, it is only a local extreme of critical conditions whereas the low temperature and low dilution rates may yield a worse condition for the aquifer.

METHODS

Bear Creek daily average flow and average Austin air temperature are variable across the year (Figure 1). Bear Creek daily average flow may be represented by the United States Geological Survey (USGS) gage 08158810 upstream of the upper recharge

zone boundary from 1978 to present. Long-term records of daily Bear Creek water temperature are not available. Air temperature data at the Austin Mueller municipal airport station were obtained from the National Climatic Data Center of the National Weather Service from 1930 to 2007. Daily maximum and minimum air temperature values were averaged to yield daily average temperature. Daily average air temperature data were converted to daily average water temperatures by linear regression ($T_{water} = 0.8139*T_{air} + 3.3732$, $r^2=0.85$) of 99 ambient instantaneous water temperature readings recorded by the USGS and City of Austin (COA) at the Bear Creek gage 08158810 site and concurrent average Austin air temperature (Figure 2).

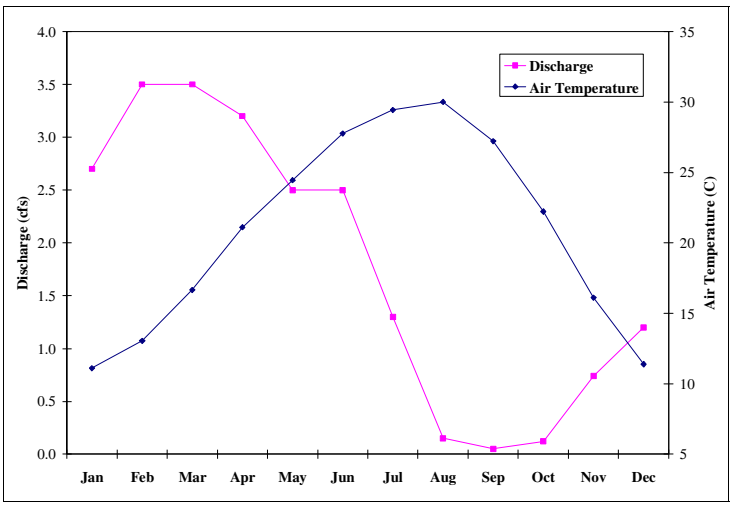

Figure 1. Monthly average Bear Creek flow at 08158810 (1978-2007) with monthly average Austin air temperature (1930-2007).

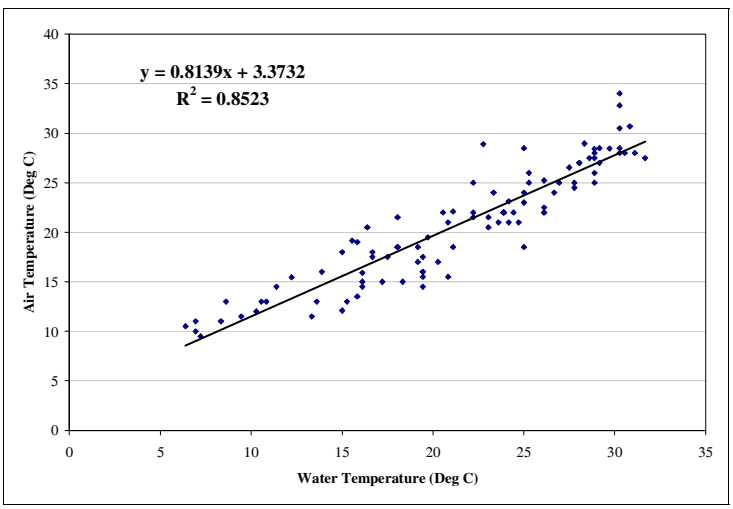

Figure 2. Scatter plot of daily average air temperature from NCDC Austin Mueller gage and instantaneous water temperature at Bear Creek USGS gage 08158810 with linear regression.

LA-QUAL reach identifications, program constants, temperature correction constants, reaeration coefficients and advective hydraulic characteristics were

identical to the original TCEQ model and previous COA model (Herrington 2008). Nutrient removal rates were also identical to the TCEQ and previous COA model (Herrington 2008) (Table 2). Effluent discharge concentrations were set to daily average permit limits (Table 1) except for total phosphorus, which was modeled at a concentration of 0.3 mg/L. Because the 0.15 mg/L daily limit for total phosphorus is calculated as a daily median, it is possible in any given month to meet the 7-day average, daily maximum and daily median permit requirements but maintain a daily average 0.3 mg/L total phosphorus concentration. The draft permit indicates that the 0.15 mg/L total phosphorus daily median limit is based on a long-term average of 0.10 mg/L but there is no description of how the long-term average should be calculated or any compliance restriction to insure that the 0.10 mg/L long-term average is achieved. From the TCEQ implementation manual for permitting, it is evident that this median permit limit is unique and does not follow the assumed distributions for effluent quality determined from statewide variability in discharge and stream water quality modeling. Additionally, a conservative material was modeled in LA-QUAL with a discharge concentration of 1.0, so that predicted output concentrations reflect the fraction of any conservative material remaining after dilution. Note that if dilution reduces the percentage of the conservative material to less than 1%, LA-QUAL output reports the percent remaining as 0.00.

Table 2. Nutrient removal rates.

Parameter	**Removal Rate (day^{-1})**
Organic Nitrogen	0.03
Ammonia (NH_3)	0.30
Nitrate (NO_3)	0.14
Total Phosphorus	0.08

Bear Creek ambient (background) concentrations were calculated using all available USGS and COA data at the USGS gage 08158810 (1978-2006), with mean values for parameters with censored observations (i.e., values less than detection limits) estimated by non-parametric Kaplan-Meier methods (Kaplan and Meier 1958, Allison 1995, Helsel 2005) (Table 3). Average ambient concentrations were estimated separately for storm and non-storm flow conditions. Current day mean daily flow was compared to previous day mean daily flow to determine if storm or base flow ambient concentrations should be used, following the procedures of Barrett and Charbeneau (1996). If the ratio of current day to previous day mean daily flow was greater than 1.5, the current day was considered a storm-influenced sampling event.

Table 3. Bear Creek ambient concentrations calculated from USGS and COA data, used for all natural incremental inflows in the model.

Parameter (mg/L)	Base Flow	Storm Flow
BOD_5	0.529	1.577
Organic Nitrogen-N	0.307	0.594
NH_3-N	0.034	0.038
NO_3+NO_2-N	0.117	0.233
Total Phosphorus	0.015	0.041
Total Nitrogen	0.458	0.865

Three water temperature ranges were evaluated (Table 4) using predicted water temperatures from NCDC average daily air temperatures. Five Bear Creek flow scenarios (not including the proposed discharge) were evaluated based on target flow as measured at the USGS gage 08158810 (Table 5). Flow ranges were selected based on ratios of wastewater effluent to ambient (natural) Bear Creek discharge at gage 08158810. Concurrent daily average Bear Creek flow and predicted water temperature (assuming water was present) were determined for the matched period of record of the USGS gage and NCDC climate data (07/07/1979 – 07/31/2007).

Table 4. Bear Creek ambient water temperature ranges (1979-2007) as represented in model scenarios.

Scenario Name	Range of Water Temp (ºC)	Water Temp Used in Model (º C)	% of Time
Cold	<15	10	23.6
Moderate	15-25	20	45.6
Hot	>25	30	30.8

Table 5. Bear Creek mean daily discharge ranges at 08158810 as represented in model scenarios (1979-2007). Percentile of all mean daily discharge measurements shown for target discharge value.

Scenario Name	Range of Daily Average Discharge (ft^3/s)	Target Discharge at 08158810 used in Model (ft^3/s)	Target Discharge as Percentile	Ratio of wastewater to natural flow (Qww/Qnat)	% of Time from period of record
No	0	0	16^{th}	∞	16.1
Low	0.01 – 0.5	0.10	28^{th}	∞ – 1.5	22.4
Median	0.5 – 1.5	1.1	50^{th}	1.5 – 0.5	16.9
High	1.5 – 15	10	85^{th}	0.5 – 0.05	35.4
Flood	>15	22	95^{th}	<0.05	9.0

Incremental ambient inflows were added at tributaries junctions to achieve the target discharge at the 08158810 gage. Bear Creek flow was apportioned based on fraction of drainage area relative to drainage area at the gauge 08158810 (Table 6).

Table 6. Incremental inflows in model for varying flow scenarios. Area fraction represents fraction of drainage area for reach relative to USGS gage 08158810 drainage area. Area fractions were multiplied by target flow at USGS gage to determine total flow in each reach. Incremental inflows were then determined by subtraction.

Reach ID	Name	Drainage Area (acres)	Area Fraction	Incremental Inflow in Model (m3/s)				
				No	Low	Median	High	Flood
1	headwaters	0	0.000	0.0	0.0000	0.0000	0.0000	0.0000
9	unknown trib	1021.3	0.130	0.0	0.0004	0.0041	0.0368	0.0809
24	spring creek	6479.1	0.824	0.0	0.0019	0.0216	0.1965	0.4324
30	friday mtn	6981.8	0.888	0.0	0.0002	0.0019	0.0181	0.0398
36	north fork	11483.2	1.460	0.0	0.0016	0.0178	0.1621	0.3566

Previous models have used ambient DO concentrations of 6.0 mg/L. In this evaluation, ambient DO was allowed to vary with temperature scenario (Table 7). Average DO concentrations were estimated from all available ambient instantaneous USGS and COA field measurements for the 3 temperature ranges (Table 4).

Table 7. Bear Creek ambient DO concentration (mg/L) by temperature scenario.

Temperature Scenario	Background DO (mg/L)
Cold	10.012
Moderate	8.157
Hot	7.091

Combining the flow, temperature and base/storm conditions yields 30 model scenarios (Table 8). LA-QUAL was used to determine predicted concentrations at the upper recharge zone boundary for each scenario. Predicted output were then applied to reported daily average discharge (without HCWID#1), water temperature and flow condition (storm/base) for the discharge data period of record to provide a daily estimate of Bear Creek concentrations at the recharge zone boundary. Essentially, the steady-state concentrations output from multiple LA-QUAL models were combined to generate a time-series record of predicted concentrations.

Table 8. LA-QUAL model scenarios evaluated, and fraction of time each scenario occurred from 1979-2007.

Scenario Name	Bear Creek Flow	Water Temperature	Storm Condition	Fraction of Time
Flood - Cold - Base	Flood	Cold	Base	0.0271

No Flow - Moderate - Storm	No Flow	Moderate	Storm	0.0000

Models were evaluated with and without the proposed discharge. Model output without the proposed discharge was used to represent adjusted background concentrations to determine the magnitude of the water quality impact of the proposed discharge. Using LA-QUAL to adjust background concentrations is a more

equivalent comparison than simply comparing predicted output to measured concentrations since some nutrient removal beyond what is observed is predicted to occur in Bear Creek in LA-QUAL even without the proposed discharge.

RESULTS

Predicted concentrations at the recharge zone boundary with and without the proposed discharge by model scenario are presented in Appendix A and B, respectively. Long-term averages were calculated for the period of record (1979-2007), and indicate that the proposed discharge will degrade Bear Creek concentrations of DO, BOD, nitrogen and phosphorus at the upper recharge zone boundary (Table 9). Phosphorus concentrations are predicted to increase 300% based on change in long-term average at the upper recharge zone boundary. Total nitrogen concentrations are predicted to increase 270% based on the change in long-term average concentrations at the upper recharge zone boundary. Additionally, on average 39.1% of any conservative materials in the proposed discharge such as chloride or any personal care and pharmaceutical products will be recharged to the aquifer.

Table 9. Long-term average (1979-2007) predicted concentrations at the upper recharge zone boundary from LA-QUAL output with and without the proposed discharge. CM = conservative material fraction remaining.

Parameter	Unit	With HCWID#1	Without HCWID#1
CM	*	0.391	0.000
DO	mg/L	8.316	8.409
BOD	mg/L	0.515	0.384
ORG-N	mg/L	0.370	0.252
NH3-N	mg/L	0.052	0.028
NO3-N	mg/L	0.583	0.091
TOTN	mg/L	1.007	0.372
TOTP	mg/L	0.028	0.009

Bear Creek concentrations at the upper recharge zone boundary with the proposed discharge are predicted to be degraded relative to predicted background concentrations for all modeled constituents for the majority of the time (Table 10). Relative to actual estimated long-term average concentrations input to the models, the proposed discharge is predicted to degrade the water quality of Bear Creek at the upper recharge zone boundary at least 30% of the time for all constituents and as much as 99% of the time for nitrate-nitrogen.

Table 10. Percent of period of record (1979-2007) proposed discharge is predicted to degrade Bear Creek water quality at the upper recharge zone boundary versus predicted and measured ambient (background) concentrations.

Parameter	% of Time Proposed Discharge Degrades Bear Creek Recharge	
	vs. predicted	vs. measured
CM-I	55.57	55.57
DO	78.29	30.76
BOD1	99.87	42.79
ORG-N	99.90	79.60
NH3-N	84.92	69.24
NO3-N	100.00	99.59
TOTN	100.00	99.46
TOTP	97.37	33.53

Daily loadings at the upper recharge zone boundary for each constituent were calculated using Bear Creek mean daily flow and predicted concentrations with and without the proposed wastewater discharge. The proposed discharge is predicted to increase loads to the recharge zone from Bear Creek for all constituents based on averages over the period of record (1979-2007) (Table 11). Expression of the average increase in daily loads with the proposed discharge as a percentage of the daily load discharged from the treatment plant based on permit limits is a representation of the average fraction of material in wastewater effluent that will recharge the aquifer.

Table 11. Wastewater discharge daily load from permit limits at point of discharge, average increase in daily load with discharge over the period of record at upper recharge zone boundary (1979-2007), and expression of the average increase in daily load as a percentage of daily load discharged by wastewater treatment plant.

CONCLUSIONS

The combination of multiple steady-state LA-QUAL models varying water temperature and creek flow with daily records of actual temperature and creek flow provide a unique opportunity to use LA-QUAL output to generate a time-series dataset. This method provides a more complete representation of the potential impacts of a proposed wastewater discharge using the LA-QUAL model as it more accurately represents the temporal scale of effluent dilution in ambient flow and sensitivity of removal rates to temperature. While this approximation is useful, a model capable of simulating natural processes occurring in the discharge route, particularly algal growth and nutrient re-release, would necessarily be dynamic in construction and necessary to accurately evaluate the full range of potential impacts.

Based on model output, the proposed discharge will increase the loads for all constituents from Bear Creek to the Barton Springs portion of the Edwards Aquifer, and will increase or degrade long-term average concentrations of all affected constituents in Bear Creek. These impacts are not predicted when using the LA-QUAL model in only a single discharge and flow condition.

Abstract

Graywater and treated effluent reuse is a concept that has been gaining favor in recent years. For reuse to be implemented, issues with water usage rights, health risks, and environmental impacts will need to be resolved. Even with the resolution of these issues, graywater reuse will not become prevalent until it has been shown to be cost effective. Cities looking to implement a city-wide or community graywater or treated effluent reuse system would be particularly interested in knowing the cost savings created by water reuse.

The reuse of graywater and treated effluent impacts demand for potable water supply as well as the loads placed on wastewater treatment facilities, therefore a fully integrated urban water system must be considered in any cost analysis. This report outlines a computer program developed to grapple with the problems of creating a fully-integrated urban water model. This program is capable of calculating the cost of a wide array of scenarios ranging from no urban water reuse to complete reuse of graywater and/or wastewater effluent. It considers factors such as rainfall volumes, population data, residential water demand, industrial water demand, and of course water supply and redistribution costs.

Furthermore, the program can perform analyses on a seasonal or annual basis to account for varying residential irrigation demands. Average household lawn area and lawn irrigation requirements can be changed and calculations are automatically updated based on mean temperature and rainfall frequency.

Several different combinations of reuse options are discussed in this report and the potential cost savings are analyzed for each. For the purposes of this report, the model was set to consider data from Fort Collins, CO. The potential cost savings are compared and the feasibility of each option is considered in detail. This report coupled with the program it describes, is a valuable tool in the process of considering graywater and treated effluent reuse.

1 Introduction

Graywater reuse has become a topic of concern particularly in areas where water supply is scarce. There have been several papers and publications regarding graywater research however there are still several areas that have not been adequately addressed. A report by the Water Environment Research Foundation (WERF) titled Long-term Effects of Landscape Irrigation Using Household Graywater – Literature Review and Synthesis was published in 2006. This report compiled the findings of previous graywater tests and studies and identified those areas requiring further research.

Graywater can be broadly defined as any household water that does not come from toilets. Most regulations in the United States also exclude water that has come into contact with food, such as water from kitchen sinks or dishwashers, from their definition of graywater (WERF 2006). For graywater reuse to become widely practiced and accepted, several obstacles will need to be overcome. The WERF report primarily focused on the environmental and health concerns associated with graywater reuse and only briefly touched upon the problems associated with graywater distribution. For graywater reuse to be implemented on a large scale, methods would need to be developed to make the use of graywater simple for the average homeowner and cost effective for communities.

1.1 Graywater Model

As a first step in a city or community graywater system, an integrated urban water model must be created to show the cost effectiveness of such a system. This report outlines such a model that has been designed to analyze various scenarios to determine cost-effectiveness of graywater reuse. The model has been designed on a community-wide basis. The reason for this, as mentioned previously was the variability and difficulty of implementing graywater reuse on a household basis. Additionally, a city-wide system would introduce such wide ranges of capital expenditures that its cost would have to be quantified on a city-by-city basis. For instance, a sprawling city such as Fort Collins, CO would require a vast network of pipes while a more centralized urban setting such as Denver would require graywater to be pumped a shorter distance but to higher elevations.

1.1.1 Capabilities

The Gray-Water and Treated Effluent Reuse program (G-WATER) was developed with the purpose of analyzing the cost for a city to implement community graywater reuse. As the name implies, G-WATER was designed to analyze the reuse of graywater and treated waste for use primarily in irrigation and toilet flushing. The program allows the user to do a variety of cost analyses by varying water consumption, reuse levels, and water use sources.

The program uses background average rainfall criteria to analyze irrigation demand and is capable of adjusting the daily irrigation requirement on a seasonal basis. Rain barrels can also be added to further reduce the lawn irrigation demand. By varying

vegetation types and areas, complex analyses can be completed based on average irrigation demands for a typical yard configuration.

Costs assigned to graywater supply, blackwater treatment, effluent reuse, and raw water treatment for potable use are applied to the water consumption data tabulated in G-WATER. The program provides the user a daily operation cost. The analysis can be run under a variety of scenarios to observe differences in cost.

2 Model Development

Development of the G-WATER model was based on the notion of an all-inclusive water balance from source water to receiving body. The model needed to be flexible so as to be capable of analyzing a variety of water usage and conservation techniques.

A raw water scenario exists only for collected rainwater from residential roof runoff. This is due to the complex nature of supplying industrial processes and residential landscape irrigation with stored or diverted raw water. The complicated interrelated combination of evaporation, evapotranspiration, seepage, inflow, and consumptive use are site-specific and therefore would need to be evaluated on a site-by-site basis.

Recorded values from NCDC rain gages in Fort Collins for the 2007 rainfall year were subtracted from required irrigation demand over the irrigation season. The exact calculation of demand is a function of temporally varied precipitation, maximum daily temperature, on-site temporary storage capacity, and vegetation type(s). Specific calculations are based on equivalent bluegrass demands, which vary depending on daily maximum temperature. Alternative vegetation such as xeriscaping and bedding plants can be selected by defining the area of coverage per household and average irrigation demands. Estimated demands found in the WERF report were used to calculate equivalent areas of bluegrass coverage. Residual irrigation demands were satisfied by graywater, wastewater effluent, and/or potable water, depending on the preferred source according to user inputs. The calculated data was divided into seasons (Spring, Summer, Autumn, and Winter) at the dates of bi-annual equinoxes and solstices. Daily average demands and irrigation volumes were then calculated for each season.

The residential demands were based on suggested uses published by the City of Fort Collins. These consist of irrigation, sinks, drinking, dish washing, clothes washing, toilets, showers, and baths. Each demand type was described on a per capita basis by number of uses per day. These were then multiplied by the determined volume (in gallons) per use.

The only remaining variables to be set were the costs associated with treatment and distribution of potable water, blackwater, and graywater, and the percentage of wastewater effluent being reused. The values gathered from the City were utilized throughout the modeling process without change. These can be seen in Table 1 of the Results section. Treated effluent reuse was permanently set as a secondary source to graywater. Additionally, the program combined any treated effluent with available

graywater therefore source inputs must be set to "graywater" to allow for effluent reuse.

3 Results

Several scenarios were analyzed using G-WATER to show the cost effectiveness of various water usage and output combinations. The results of these analyses can be found below.

Values outlined in Table 1 are the initial and unchanging inputs for the G-WATER model analyses performed hereafter. The following scenarios utilize variables that are described in more detail when applicable.

Table 1: Unchanging Inputs

Population	150,000
Households	43,857
Wastewater Treatment Cost	$2.40/1000 gals
Potable Water Base Cost	$13.86/month
Potable Water Treatment Cost	$1.24/1000 gals
Distribution Cost	$0.50/1000 gals

G-WATER was used to analyze a variety of scenarios. The first of these was a baseline estimate for water demand and cost to provide potable and wastewater treatment. Using standard water usage criteria shown in Table 2, from the City of Fort Collins, Table 3 was developed which shows base water demand and cost.

Table 2: Base Demands

Use	Uses/Day	Vol/Use (gal)
Industrial Processes	1	2000
Drinking	3	1
Sink	1	21
Dish Washing	0.15	16
Clothes Washing	0.3	50
Toilets	4	3.5
Shower	1	32
Bath	1	40

Table 3: Base Water Demand and Cost Analysis

Criterion	Daily Average	Annual Total
Volume Potable (gal)	32,200,000	11,750,000,000
Potable Treatment	$61,000	$22,300,000
Volume Waste (gal)	17,400,000	6,350,000,000
Waste Treatment	$42,000	$15,200,000
Total Cost	$103,000	$37,500,000

A second analysis was conducted for a conservative water demand pattern, set forth in Table 4 by the City of Fort Collins. This city-wide conservation also assumed an industrial usage reduction of ten percent. Table 5 shows the annual data from the G-WATER analysis given the conservative usage scenario. A comparative study is

presented in Table 6 showing the water and cost savings created as a result of implementing conservative usage demands.

Table 4: Conservative Water Demands

Use	Uses/Day	Vol/Use (gal)
Industrial Processes	1	1800
Drinking	3	0.1
Sink	1	2
Dish Washing	0.15	7
Clothes Washing	0.3	27
Toilets	4	1.6
Shower	1	8
Bath	1	15

Table 5: Water Conservation Demand and Cost Analysis

Criterion	Daily Average	Annual Total
Volume Potable (gal)	19,200,000	7,000,000,000
Potable Treatment	$45,000	$16,400,000
Volume Waste (gal)	5,700,000	2,080,000,000
Waste Treatment	$14,000	$5,000,000
Total Cost	$59,000	$21,400,000

Table 6: Conservative Use Savings

Potable Water (gal)	4,750,000,000
Treatment Costs	$16,100,000

Cost and water usage data for a scenario involving effluent reuse for landscape irrigation purposes is outlined below in Table 7. An additional cost of $0.50 per 1000 gallons of treated effluent delivered was applied to the total volume reused to represent the cost of pumping and distribution. Table 8 is a compilation of the annual wastewater reuse volume and cost savings as compared to the base values presented in Table 3.

Table 7: Wastewater Effluent Irrigation Reuse

Criterion	Daily Average	Annual Total
Volume Potable (gal)	19,300,000	7,050,000,000
Potable Treatment	$45,000	$16,500,000
Volume Waste (gal)	17,400,000	6,350,000,000
Waste Treatment	$42,000	$15,200,000
Effluent Reuse	$6,000	$2,300,000
Total Cost	$93,000	$34,000,000

Table 8: Wastewater Effluent Reuse Savings

Potable Water (gal)	4,700,000,000
Costs	$3,500,000

The effects of roof rainwater catchments on a residential level were also determined. This analysis assumed an average of two rain barrels at 50 gallons each, with no

additional cost to the city. The annual water volumes and respective costs are shown below in Table 9. The associated volume and cost savings are shown in Table 10.

Table 9: Rain Barrel Catchments

Criterion	Daily Average	Annual Total
Volume Potable (gal)	32,000,000	11,690,000,000
Potable Treatment	$61,000	$22,200,000
Volume Waste (gal)	17,400,000	6,350,000,000
Waste Treatment	$42,000	$15,200,000
Total Cost	$103,000	$37,400,000

Table 10: Annual Rain Catchment Savings

Potable Water (gal)	60,000,000
Costs	$75,000

Implementation of graywater reuse for residential landscape irrigation was analyzed for varying areas of bluegrass lawn. These areas represent the maximum and minimum values selected for analysis. The average daily and annual volumes and costs are shown in Table 11.

Table 11: Graywater Irrigation

	Bluegrass 5000sft		Bluegrass 1500sft	
Criterion	**Daily Ave.**	**Annual Total**	**Daily Ave.**	**Annual Total**
Volume Potable (gal)	24,900,000	9,090,000,000	19,300,000	7,050,000,000
Potable Treatment	$52,000	$19,000,000	$45,000	$16,500,000
Volume Blackwater (gal)	10,100,000	3,690,000,000	10,100,000	3,690,000,000
Waste Treatment	$24,000	$8,800,000	$33,000	$11,900,000
Graywater Reuse	$4,000	$1,300,000	$2,000	$700,000
Total Cost	$80,000	$29,200,000	$80,000	$29,100,000
Savings	Potable (gal)	2,660,000,000	Potable (gal)	4,700,000,000
	Costs	$8,300,000	Costs	$8,400,000

Under the assumption that 50 percent of non-consumptive residential indoor water use could be recycled for graywater reuse purposes, graywater was applied toward toilet flushing. The results of this analysis can be seen below in Tables 12 and 13.

Table 12: Indoor Graywater Reuse

Criterion	Daily Average	Annual Total
Volume Potable (gal)	30,000,000	10,980,000,000
Potable Treatment	$58,000	$21,300,000
Volume Waste (gal)	10,100,000	3,690,000,000
Waste Treatment	$37,000	$13,400,000
Graywater Reuse	$1,000	380,000
Total Cost	$96,000	$35,100,000

Table 13: Annual Graywater Reuse Savings

Potable Water (gal)	770,000,000
Costs	$2,400,000

The final scenario evaluated by the G-WATER model was a compilation of all the aforementioned water-saving scenarios. It was intended to generate the maximum water volume and cost savings for the City of Fort Collins. The results from this extreme analysis are described below in Table 14. Yearly totals for volume and cost savings can be seen in Table 15.

Table 14: Composite Water Savings Scenario

Criterion	Daily Average	Annual Total
Volume Potable (gal)	5,300,000	1,950,000,000
Potable Treatment	$28,000	$10,200,000
Volume Waste (gal)	3,500,000	1,260,000,000
Waste Treatment	$8,000	$3,000,000
Graywater Reuse	$1,000	408,000

Total Cost	$37,000	$13,600,000

Table 15: Optimal Scenario Savings

Potable Water (gal)	9,800,000,000
Costs	$23,900,000

4 Discussion

This analysis considers existing centralized systems as compared to individual household treatment systems, and the cost differences associated with the treatment and distribution of effluent reuse only. The cost associated with distribution is based solely on operational pumping costs. This was therefore assumed to be the same for graywater distribution.

The following parameters were held constant throughout the analysis: Population, number of residences and industries, negligible industrial irrigation demand, and typical residential and industrial consumptive water use. The number of residences was compared to the US Census Bureau data from 2000. The average number of persons per household was calculated based on these findings. Consumptive use is defined for the purpose of this analysis as the amount of water that leaves the urban water system through any number of immeasurable means.

4.1 Base Costs

Initial modeling efforts were conducted using standard water usage rates collected from the City of Fort Collins. The total volumes and costs associated with the treatment of raw and wastewater were evaluated on a seasonal basis. As expected, more water was required over summer months due to the higher temperatures, which correlated to an increased need for irrigation. This scenario represents typical water usage currently employed by the average citizens of Fort Collins, and thus represents the baseline for comparison.

When compared to other published data, these baseline values seemed accurate. Tables published in “Water Conservation In and Around the Home” by R. Waskom

and M. Neibauer (2006) and The Home Water Supply by Stu Campbell (1983) correlate well to data provided by the City of Fort Collins.

4.2 Water Conservation

Water conservation data, also from the City of Fort Collins, was analyzed in a similar fashion as the base data. These rates produced a 40 percent decrease in potable water demand, resulting in an overall treatment cost savings of more than $16 million annually.

It should be noted that these values push the limits of water conservation, and it would be difficult to implement and ensure continued practice of such rigorous expectations. Many people who lease their homes do not pay for water. In such instances, there is not financial incentive to practice water conservation.

4.3 Effluent Reuse

Using base conditions, treated wastewater effluent was reused for landscape irrigation purposes. This assumed that pathogen removal was sufficient such that the applied graywater did not represent a risk to public health. Due to the nature of the irrigation season, this condition incurred the most significant cost savings over the summer months. While the volume of wastewater treatment did not change, the amount of potable water demand was decreased by the less costly treated effluent. Hence, an annual savings of only $3.5 million was seen through this analysis. Again, 40 percent savings of treated potable water was seen, compared to the base values. The volume of treated effluent capable of being supplied was sufficient to meet the requirements of irrigation for all seasons except summer.

4.4 Rainwater Catchments

Under this scenario, rain barrels were used to collect runoff from residential roofs. The total household collection area was assumed constant at 2,750 square feet. This allowed for the capture of 100 gallons of rainwater based on an assumed average of two 50 gallon barrels per household. The initial runoff was used as raw water irrigation to supplement potable water use. Only during those rainfall events that exceeded the irrigation demand for a 5,000 square foot bluegrass yard, did the rain barrels begin to store water for future irrigation use. Data from an entire irrigation season was obtained from NCDC rain gauges located in the City of Fort Collins. The average seasonal daily demand was calculated to obtain a daily average of water applied for irrigation. The supplemental raw water collection was able to decrease annual potable water demand by 0.5 percent leading to a total annual cost savings of $75,000.

4.5 Graywater Reuse

Graywater reuse for residential irrigation was analyzed under the assumption that 50 percent of all non-consumptive indoor water use, excluding dishwashing and toilet flushing, could be converted to graywater. Initially, the analysis was performed with an average residential landscape area of 5,000 square feet of bluegrass. Under this scenario, an annual cost savings of approximately $8.3 million was realized. By

reducing the average landscape area to 1,500 square feet, annual cost savings were less than $100,000 greater than with 5,000 square feet. The reason for this was that the reduced area of landscaping did not require as much graywater and therefore, unused graywater had to be treated as blackwater. This additional treatment cost essentially negated the reduction in potable demand.

To fully utilize the potential for graywater reuse savings, the lawn area had to be optimized such that it required exactly as much graywater as was produced. This meant that no potable water was required for irrigation nor was any graywater being sent to waste treatment. Under these conditions, the optimal area was found to be 2,874 square feet of bluegrass at which point the annual cost was minimized. Furthermore, if water conservation was in effect, this optimal area was reduced to 908 square feet of bluegrass as the graywater available decreased.

Graywater reuse was next analyzed for use in residential toilets. Industrial toilet flows were not included due to the variability inherent in industrial graywater effluent. For this analysis, no graywater was used for outdoor irrigation. Again, 50 percent of non-consumptive indoor water use was applied toward available graywater volumes. Savings of $2.4 million and 766 million gallons of potable water annually were calculated.

This final scenario was unrealistic as it would be unlikely that graywater would be used indoors and not outdoors. If, however, the analysis were run with both indoor and outdoor graywater reuse, the entire graywater volume produced would be utilized and therefore would require potable water supplementation regardless of the application. This would make the cost and potable water use equivalent to the scenario applying graywater for irrigation only. The exception to this would be during the winter months when no irrigation is required.

4.6 Composite Water Savings Scenario

With this scenario, the total annual cost was minimized by combining all of the most useful scenarios mentioned above. Because water uses were conservative, the optimum landscape area was reduced as mentioned before. To get the optimum net irrigation demand and maintain a total yard area of 5,000 square feet, xeriscape and bedding plants were used instead of bluegrass, with the areas of 4,318 and 682 square feet, respectively. For these criteria, an annual cost savings of $23.9 million and potable water savings of 9.8 billion gallons would be realized.

It should be noted that this optimization of cost resulted in no reuse of effluent. This was because cost was saved by using graywater which was diverted from wastewater treatment. Conversely, effluent reuse requires wastewater treatment costs plus an additional charge for redistribution. This need for redistribution was eliminated by reducing the lawn area to an optimal value. However, if the lawn area were kept at 5,000 square feet of bluegrass, effluent reuse would be preferable to potable water for irrigation due to its lower cost.

5 Conclusion

Cyclic processes define water reuse practices. This is verified by either direct or indirect reuse, both of which can represent a "zero sum" water balance within a defined system. Typically, urban treated wastewater and collected stormwater are discharged to receiving bodies which inevitably supply populations downstream with a potable water source. The delaying of this discharge process or bypassing of raw water volume, in exchange for reused water, results in higher quality water sources downstream while providing necessary non-potable water for residential and industrial uses. Whatever the reuse technique, the importance of water reuse is growing due to increasing population densities around the world.

Rain catchments for individual households were found to produce negligible profits. A net gain of $75,000 per year was calculated assuming no cost for the implementation of rain barrels. For this scenario, over 80,000 barrels would be required. This would imply that residential capture of stormwater runoff would not be significant in reducing city potable water supply costs.

Graywater for toilet use was also determined to be inconsequential. Graywater could be completely consumed by irrigation, therefore requiring potable water. This potable volume would be the same irrespective of the use to which it was applied.

Considering the analysis of all scenarios calculated with G-WATER, it can be concluded that the most cost effective case is the final scenario which incorporates all possible water-saving techniques. However, due to the extremely strict nature of this scenario, prolonged application on a residential level would not be feasible. Therefore, the best reasonable scenario would be some combination of all of these cost reduction techniques. Though they may not be implemented to their theoretical potential, they still could contribute to significant savings.

Green Alternatives to Channel Stabilization

Richard E. Besancon, P.E.[1]

1. Burns & McDonnell Engineering; 9400 Ward Parkway, Kansas City, MO 64114; PH 816-822-3950; FAX 816-822-3514; email: rbesanc@burnsmcd.com

ABSTRACT

The purpose of the project was to improve water quality, repair and stabilize eroding banks, and add wetlands to the project site.

As mitigation for channel and wetland disturbance on a commercial and residential development in eastern Illinois, Burns & McDonnell performed channel restoration/stabilization using a combination of traditional and green techniques to repair severely eroded bank and construct additional wetlands adjacent to the creek.

Canteen Creek is a highly eroded and degraded due to uncontrolled stormwater discharges into the creek upstream of the site. The existing stream has degraded and left vertical banks in many locations.

The solution was a combination of traditional channel protection using a longitudinal peak stone toe protection and non traditional using root wad protection. Longitudinal peak stone toe protection is a windrow of rock at the toe of slope, while root wad protection is a method of channel stabilization where existing trees and roots are used to stabilize the bank in combination with large rock. Both stabilization plans incorporated live willow plantings and revegetation with native wetland and upland seed mixes.

The engineer and contractor worked together on site to install the toe protection. The interaction between the two parties worked to improve the design and increase the ease of construction. This worked to increase the speed of construction and improve the integrity of the protection.

After three years in operation, the longitudinal peak stone toe protection and root wad mitigation areas are performing exactly as hoped. Both applications are preventing additional erosion while providing an environment to grow willows and other native species. The root wad mitigation in particular allows sediment to settle out and collect, thereby rebuilding the stream channels and restoring previously destroyed habitat.

Green Alternatives to Channel Stabilization

Burns & McDonnell Engineering performed a design build project for a commercial and residential development. The development size totaled approximately one square mile. The area of western Illinois where the project is located consists of heavily treed loess hills with steep slopes. The overall project included providing infrastructure for the entire development. The roads on site required multiple stream crossings, impacts to wetlands and riparian areas. Based on the impacts to the streams, the U.S. Army Corps of Engineers required mitigation contiguous to the site. The mitigation included two thousand feet of stream bank stabilization and the creation of lowland wetlands along Canteen Creek, a creek which forms the north boundary of the site.

Canteen Creek has been degraded by increased storm flows due to development upstream. The flood events on Canteen Creek are characterized by short duration high peak events. The creek is incised due to the high flows and velocities and the loess soils that make up its banks. The loess complicates grading and mitigation practices due to the high potential for erosion. Erosion will occur in loess with velocities as low as two feet per second (fps).

To stabilize the banks of Canteen Creek a number of options were reviewed. An adjacent property had large quantities of broken bridge abutments, held over from a previous bridge replacement. The bridge material consisted of large chunks of concrete without any exposed rebar. The concrete piles had been in place for many years, however there was concern about using rubblized concrete as stream bank stabilization with the potential for leaching of the lime and chemicals from the concrete degrading the water quality in the creek. Corps, EPA, and county personnel examined the concrete, evaluated the time it had been in place and determined that the concrete posed no danger to water quality.

In addition of the recycled concrete, another resource was available on site to use to stabilize the banks. The project site was heavily treed and many acres of trees were cleared for the residential lots and roads. Based on these materials on site and readily available, Burns & McDonnell decided to use a combination of longitudinal peak stone toe protection (LPSTP) and root wad mitigation to stabilize the banks. Longitudinal peak stone toe protection is basically a windrow of stone at the toe of an eroded slope. The purpose is to keep the erosive forces of the water away from the toe of the slope. LPSTP is easily placed from the top of the slope, which was required due to the permitting restrictions not allowing any equipment in the channel. Root wad mitigation uses felled trees to prevent scour at the toe of slope. The trees are laid in the channel longitudinally with the root wad facing upstream. The trees prevent the erosion at the toe and the root wads accumulate silt and sediment, thereby aggrading the eroded banks. The typical installation includes trees placed longitudinally along the channel with other trees dug into the back with their root wads holding the longitudinal trees in place. Additionally, duckbills and cables are anchored into the banks and wrapped around the trees to hold the trees in place.

Both the LPSTP and root was mitigation incorporate willow plantings within the construction to develop a root system to add additional holding power into the bank and provide long term stabilization.

Burns & McDonnell was self performing the project as a design build, therefore the contractor worked hand in hand with the engineer to accomplish the stream bank stabilization. The only plans produced for the contractor were sketches of each method of stabilization and the locations each were to be installed. Due to the contractor's unfamiliarity with the techniques, the engineer traveled to the site to work with the contractor to get the project constructed.

The first item the contractor suggested was not to dig the trees into the bank because that introduces a point for erosion to work at the bank in high flow conditions. Especially considering the loess soil, any disturbance of the in situ material could lead to catastrophic erosion. Instead, the contractor used the trackhoe to push the trees in normal to the stream. He was able to use the trackhoe to shove the trees into the bank and anchor the longitudinal trees without digging into the slope.

Picture looking upsteam of the root wad mitigation; notice the longitudinal trees anchored by the trees pushed into the bank and large concrete chunks.

The root wad mitigation was installed in the flowline of the creek, thereby allowing bank aggradation and habitat creation.

Same location two years after construction; notice deposition on right.

After two years, the channel stabilization is working effectively and is producing deposition along the banks where the root wad mitigation was installed.

Outer end in Canteen Creek where root wad mitigation was installed. The bank has re-vegetated and stabilized.

The LPSTP has also performed well by preventing scour at the toe of slope and provide area for siltation to occur.

The overall keys to the success of these methods of channel stabilization in challenging soils were the anchoring of the trees into the banks and the upstream protection to prevent the water from getting a foot hold for erosion to begin. At the upstream ends of each root wad location LPSTP was used to provide a hard armoring to prevent scour and failure. The use of design build contract allowed for open and honest collaboration between the contractor and engineer and producing a higher quality project.

The site U.S. Army Corps of Engineers and the Illinois EPA continue to monitor the site to be sure the site continues to meet the permitting agreement.

Hydraulic Modeling and Engineering Evaluation of Fort Myers Beach's Water Distribution System

Jinsheng Huo, PhD, PE, BCEE[1], Robert Garland, PE[1], Doug Eckmann, PE, BCEE[1], Jack Green[2], Cathie Lewis[2]

Abstract

This paper applies hydraulic modeling to evaluate the water distribution system of the Town of Fort Myers Beach, Florida. Fort Myers Beach is a small island town located in Southwest Florida. The Town does not have its own water treatment plant. Instead, the finished water is provided by Lee County. To meet fire protection and other emergency uses, the Town has two ground storages and three booster pumping stations to provide adequate water flow and residual pressure. Like other coastal communities in Florida, the number of residence and water demand patterns in the Town vary significantly by two seasons (wet and dry). Therefore, it is a challenging task to design and evaluate a water supply system to meet two dramatically different demand characteristics. In this paper, engineers evaluate flow and pressure in the water distribution system under both PDD + FF (Peak Day Demand + Fire Flow) and PHD (Peak Hour Demand) scenarios, and the existing storage and pumping capacities as compared to the national standards and local ordinances. Based on the simulation results, critical areas with potential low pressures, especially when fire flow is needed, are identified and recommendations of system upgrading are also provided. The feasibility study of building the Town's own water treatment plant is also recommended due to increasing water demand at the south end of the island and raising water fees per the annual and monthly water bill reports. Furthermore, the additional ground storage tank capacity is suggested to meet fire protections and other emergencies (for example, hurricane events).

Keywords: Hydraulic Modeling, Evaluation, Water Distribution System, Pumping Stations, Ground Storage Tank, Simulation

I. Introduction

The Fort Myers Beach Water Distribution System (FMB Water System) includes two water supply lines from Lee County Utilities (LCU); three booster pumping stations (Marina, North, and South); two ground storage tanks (North and South); transmission piping, distribution piping; and fire hydrants.

Water Supply Lines from Lee County Utilities (LCU)

Potable water for the Town of Fort Myers Beach is provided by Lee County Utilities through 16-inch and 12-inch water supply lines. The master flow meter is located on the LCU side (mainland) and records the total water delivered. Both water supply lines operate at 50 psi and initial chlorine concentration of 2.0 mg/L.

Marina, North, South Booster Pumping Stations

The system has three booster pumping stations: Marina, North, and South. When discharge pressures at a pump station are below 40 psi, the booster pumps shall activate to maintain the discharge pressure at 50 psi or above.

Marina In-line Booster Pumping Station is located at Moss Marina, downstream of the 16-inch water supply line from LCU. As the water approaches the island, if the water pressures are below 40 psi, the booster pumps will activate to maintain pressure at or above 50 psi. As water passes through the initial booster pumps at Moss Marina, it has two functions: one function is to fill the two ground storage tanks (North and South); the other function is to serve water demands in the water system. This station is outdoors but protected with a chain link fence. This station has several components including two vertical turbine pumps (U.S. Electric 20-hp 1775-rpm Layne pumps), and one 200 KW portable backup power generator. Each has suction and discharge gauges. Flow rates and pressures are monitored at the Green Meadows WTF through a SCADA system. Controls for each unit are also at the WTF. Figure 1 shows the Moss Marina Pumping Station.

North Booster Pumping Station is located at 815 Lagoon Street, to the north of San Carlos Boulevard. If water pressures are below 40 psi, the booster pumps will activate to maintain pressure at or above 50 psi. This station has several components including one 0.50 MG Storage Tank (1973 Horton Tank Co.), one 10-inch Clay Fill Valve, three 75-hp 1750-rpm booster pumps (2 Aurora, 1 Goulds, one Aurora is out of service), online chlorine analyzer CL17, Tank Level Transmitter, Flow Transmitter, and one 200 KW portable backup power generator. Figure 2 shows the North Booster Pumping Station and 0.5-MG Ground Storage Tank.

Figure 1. Moss Marina In-line Booster Pumping Station.

Figure 2. The North Booster Pumping Station and 0.5-MG Ground Storage Tank.

South Booster Pumping Station: is located at 131 Lenell Road, on the south end of the island. If water pressures are below 40 psi, the booster pumps will activate to maintain pressure at or above 50 psi. This station was built in the mid-to-late 1980's. The South end of the island is more populated and houses the majority of the high rise hotels as well as permanent housing (condominiums). It also contains a golf course and a marina. Due to these dynamics, water is at a greater demand when compared to the North end of the island. This booster system also operates on system pressure. When called for, the water enters the tank via an altitude valve or fill valve and exits the tank via pumping. This station is enclosed with the exterior modeled to blend into the neighborhood. It includes one 1.0 MG Storage Tank (1987 Crom Corp.), one 10-inch Altitude Fill Valve, one Flow Meter (out of service), Tank Level Indicator (Monitored thru Green Meadows), 175 KVA CAT Diesel Generator, and three Gould pumps (30 hp, 50 hp, and 75hp). Figure 3 shows South Booster Pumping Station and 1.0-MG Ground Storage Tank.

Figure 3. The South Booster Pumping Station and 1.5-MG Ground Storage Tank.

North and South Ground Storage Tanks.

The North Ground Storage Tank is located at the North Booster Pumping Station and has a capacity of 0.5 MG, and the South Ground Storage Tank is located at the South Booster Pumping Station and has a capacity of 1.0 MG. This provides a total storage capacity of 1.5 MG for the Town.

II. Hydraulic Modeling and Discussions

2.1 Basis of Design

Based on the FMBPWSI Operations Manual, Lee County Utilities Operations Manual (2000) and AWWA M-31 (1998), AECOM established the following design criteria to be used for preparing the hydraulic model for the project:

Table 1. Design Criteria.

1	Pipe Material & C-Factor	• Ductile Iron Pipe or PVC Pipe for diameters larger than 12-inch (C= 100 for existing and 120 for new pipes) • PVC Pipe for diameters no larger than 12-inch (C= 100 for existing and 120 for new pipes) • HDPE Pipe for diameters no larger than 12-inch (C= 100 for existing and 120 for new pipes)
2	Water Usage per Capita	• 110 gpcd
3	Occupancy per ERU	• 2.5
4	Flow Peaking Factor	• Peak Day Factor = 2.5 • Peak Hour Factor = 3.5
5	Fire Suppression	• Fire Flow Demand = 1000 gpm [1]
6	Assumed conditions at two water supply lines from LCU	• Design Feeding Pressure = 50 psi (PHD Scenarios) • Design Feeding Pressure = 50 psi (PDD + FF Scenarios) • Working Pressure Range = 35 – 80 psi • Feeding Chlorine Concentration = 2.0 mg/L • Chlorine Decay Rate = 0.012/hr (Global Bulk = -0.288, and Global Wall = 0)
7	Proposed System Minimum Performance	• Minimum Residual Pressure = 20 psi (PDD+FF Scenarios) • Minimum Residual Pressure = 35 psi (PHD Scenarios) • Minimum Residual Chlorine Level = 0.6 ppm

[1] Fire flow estimation uses Insurance Service Office (ISO) procedure and was confirmed with the Fort Myers Beach Fire Control District.

Fire Flow Estimation Using Insurance Service Office (ISO) Procedure

Step 1: Needed Fire Flow (NFF)

For one- and two-family residences, the needed fire flow is determined based on the distance between structures, as shown in Table 2.

Table 2. Needed Fire Flow for Residences Two Stories and Less.

Distance Between Buildings (ft)	**Needed Fire Flow (gpm)**
More than 100	500
31-100	750
11-30	1,000
Less than 11	1,500

For commercial and industrial buildings, the NFF is based on building area, construction class, occupancy, exposure, and communication. The formula can be summarized as:

$$NFF = 18FA^{0.5}O(X + P)$$

Where NFF = needed fire flow (gpm)
F = class of construction coefficient
A = effective area (ft^2)
O = occupancy factor
X = exposure factor
P = communication factor

As shown the NFF for commercial and industrial buildings is estimated case by case. Therefore, in this paper, a NFF of 1000 gpm is selected to run fire flow scenarios after discussions with the Town and Fire Control District's representatives.

The Town of Fort Myers Beach Land Development Code requires buildings to be at least 7 feet away from the property lines, which provides at least 14 feet between two neighboring buildings (the code requires a minimum 5 feet for the side setback of non-waterfront SANTOS lots). Based on this code and Table 2, the needed fire flow is 1000 gpm. However, some areas of the Town were constructed prior to the adoption of the codes and might not meet the new development requirements. In these areas, distances between two buildings might be less than 11 feet, which could lead to a larger fire flow of 1,500 gpm. Figure 4 shows a residential neighborhood near the Fort Myers Beach Fire Control District. As discussed with the Town Staff and Fire Control District, AECOM recommends using a fire flow of 1,000 gpm.

Step 2: Fire Flow Duration Time

The duration of the fire is related to the fire flow, as shown on Table 3. With selected fire flow of 1,000 gpm, the duration of fire should be 2 hours.

Figure 4. Examples of the Close Distance between Two Buildings.

Table 3. Duration of Fire.

NFF (gpm)	Required Duration (hrs)	Class
More than 3,500	4	Individual Property Fire Suppression
3,000 to 3,500	3	Public Fire Suppression
2,500 and less	2	Public Fire Suppression

Other Parameters:

Based on the FMBPWSI Operations Manual and discussions with the Town's representatives, AECOM recommends the following parameters:

- The average population: The seasonal peak population is 25,000, which lasts about 3 months (February to April). Per 2006 census, the permanent population is 6,559. Therefore, the weighted average population shall be 25,000 * 3/12 + 6559 * 9/12 = 11,169 (11,100 is recommended).

- Average daily demand: From January 2007 to August 2007, the total water usage volume is 287,400,000 gallons for a period of total 242 days, based on the Monthly reports to FDEP (Florida Department of Environmental Protection). Therefore, the average daily flow is 287,400,000 gallons / 242 days = 1,187,603 gpd.

- Average daily demand per capita: 1,187,603 gpd / 11,100 persons = 107 gpd per capita (110 gpd per capita), as compared to the ratio of 100 gpd per capita as stated on FMBPWSI Operations Manual.

- Average daily demand per ERU: assume 2.5 person per ERU, the average daily demand per ERU = 110 gpd per capita * 2.5 persons per ERU = 275 gpd/ERU, as compared to the FMBPWSI and LCU's ratio of 250 gpd / ERU.

- The peak day factor (PDF) shall be 2.5 per FMBPWSI Operations Manual. The peak hour factor (PHF) shall be 3.5.

2.2 Water Demand

By applying the parameters previously stated in the Basis of Design, AECOM estimated the ERU-based water demand for the proposed water distribution network for four scenarios: AADD (Annual Average Daily Demand), PDD (Peak Day Demand), PDD+FF (Peak Day Demand + Fire Flow), and PHD (Peak Hour Demand). They are summarized on Table 4.

Table 4. Summary of Water Demands.

Scenario	**AADD**	**PDD**	**PDD+FF**	**PHD**
Total ERU[1]	9,589	9,589	9,589	9,589
Demand (gpm)	1,831	4,578	5,578	6,409
Demand (gpd)	2,636,975	6,592,438	8,032,438	9,229,412

Note: 1. The total ERU is counted from the water system plans and the GIS condominium data, provided by the Town.

The reported average daily demand and peak day demand are 1,187,603 gpd and 2,190,000 gpd, respectively, based on the monthly reports to FDEP. The actual reported average daily demand is approximately 45 percent of ERU-based calculated average daily water demand, while the actual peak day demand is approximately 33 percent of ERU-based calculated peak day demand. This is because the reported demands are based on the real water usage while the calculated demands are based on the design assumption that all residences are occupied. The ERU-based calculated flows are used in the hydraulic modeling.

2.3 Hydraulic Modeling

By applying the parameters previously stated in the Design Criteria (Table 1) and the estimated water demand (Table 4), AECOM developed a hydraulic model of the proposed water distribution network and evaluated it for two different modeling scenarios using H2OMAP: PDD+FF (Peak Day Demand + Fire Flow) and PHD (Peak Hour Demand).

PDD + FF (Peak Day Demand + Fire Flow)

The fire flow condition is simulated by adding a fire flow of 1,000 gpm to one of the nodes where a fire hydrant is located. The fire is assumed to last 2 hours As shown on Table 4, the total estimated flow at the PDD condition is 4,578 gpm, thus the total combined of water demand at PDD + FF is 5,578 gpm. The total water demand under this condition is the controlling factor that is used to size the water mains to maintain a minimum residual pressure of 20 psi. As stated in the Basis of Design, under this scenario the assumed feeding pressure and chlorine concentration at the entry point to the system is 50 psi and 2.0 mg/L. The fire flow condition is simulated separately at two different nodes: Fire Hydrant 731 (FH-731) located on Bay Beach Lane, Fire Hydrant 755 (FH-755) located at

the corner of Lagoon Road and Buccaneer Drive, Fire Hydrant 765 (FH-765) located on the south end of Estero Boulevard, and Fire Hydrant 200 (FH-200) located at the north end of Estero Boulevard. The selection of these fire hydrants is based on the Peak Day Demand condition simulations, which show the lowest pressures at the south end of the island. Therefore, the most sensitive fire hydrants were determined to be Fire Hydrants 731, 755, and 765. Fire Hydrant FH-200 is the farthest one at the north end of the island, which can serve as one pressure monitoring point of the system. Table 5 shows that the residual pressures at various critical nodes under these three fire flow conditions. All nodes on Table 5 meet the pressure requirements except for Node 600, and Fire Hydrants FH-731 and FH-755. The pressures at Node 600, FH-731 and FH-755 are 2.89, 2.26 psi and -2.96 psi, respectively. All three are below required residual pressure of 20 psi. Therefore, improvements are recommended to upgrade the hydraulic conditions along the Bay Beach Lane community and Buccaneer Lagoon community. The photos of four fire hydrants are shown below.

Figure 5. Critical Fire Hydrants (FH-731, FH-755, FH-765, and FH-200).

PHD (Peak Hour Demand)

The second condition evaluates the existing water distribution system and its capacity to perform under the Peak Hour Demand condition. As shown on Table 4, the total estimated

water demand under this condition is 6,409 gpm. Similar to PDD+FF, the assumed feeding pressure and chorine concentration are 50 psi and 2.0 mg/L, respectively. Table 5 shows that the residual pressures at various critical nodes under PHD scenario. All nodes on Table 5 meet the pressure requirements except Node 600. The pressure at Node 600 under the PHD scenario is 28.26 psi, which is less than 35 psi. Therefore, improvements are needed to upgrade the hydraulic conditions along the Bay Beach Lane community.

Based on the hydraulic analyses above, apparently, the Bay Beach Lane community where Node 600 is located is a potential problem area under both PHD and PDD+FF at FH-731 or FH-755 scenarios. This is because there is only one 10-inch water main to feed a heavy population dense area (high rise condominiums). Also, another potential problem area is Buccaneer Lagoon community, which cannot deliver required residual pressure of minimum 20 psi at the fire hydrant FH-755. The hydraulic modeling results match the reported low pressure complains received at FMBPWSI.

The FMBPWSI Operations Manual states: all water mains shall be sufficiently looped and in no case shall water mains be less than 8-inch in diameter unless specifically approved by FMBPWSI. Therefore, the minimum 8-inch pipe will be recommended to update the water system. For water mains at the dead end of side streets, a minimum 6-inch might be used based on case by case hydraulic modeling results. For water mains connected to fire hydrants, a minimum 8-inch pipe should be used to meet a fire flow of 1,000 gpm, based on the hydraulic modeling. However, about 30 years ago, most of the pipes along side streets from the Estero Boulevard to where fire hydrants are connected to were upgraded to minimum 6-inch PVC pipes. Based on the modeling results, 6-inch pipes can meet a fire flow of 750 gpm but cannot provide adequate fire flow of 1,000 gpm at minimum 20 psi residual pressure.

Based on the hydraulic modeling results, recommendations are:

- Bay Beach Lane community: the existing 10-inch pipe should be replaced with a minimum 12-inch pipe. The existing 10-inch PVC pipe is approximately 3,200 feet from the corner Estero Boulevard and Bay Beach Lane to the fire hydrant FH-731 on Bay Beach Lane. This pipe is still in operating condition but is already more than 30 years old. Therefore, AECOM recommends adding one 3,200 feet 12-inch PVC water main parallel to the exiting 10-inch water main instead of replacing the existing 10-inch PVC pipe. This can provide needed redundancy and add a loop to exiting water mains, which is important to the high-dense high-rise community.
- Buccaneer Lagoon community: the 4-inch and smaller pipes should be replaced with minimum 8-inch PVC pipes per FMBPWSI Operations Manual. As shown on the hydraulic model, approximate 6,000 feet 8-inch PVC pipes are needed to replace existing pipes.

III. Conclusions and Recommendations

The results of hydraulic modeling identified two areas with low pressure: Bay Beach Lane community and Buccaneer Lagoon community. Low pressure complains received at Beach Water Bay Beach Lane community and fire hydrant test data provided by the Fire Control District confirm AECOM's findings. Based on the hydraulic modeling, Recommended Standards for Water Works, and current updating FMBPWSI Operations Manual, AECOM recommends the following improvements:

- Bay Beach Lane community: the existing 10-inch pipe should be replaced with a minimum 12-inch pipe. The existing 10-inch pipe is approximately 3,200 feet from the corner Estero Boulevard and Bay Beach Lane to the fire hydrant FH-731 on Bay Beach Lane. This pipe is still in operating condition. Therefore, AECOM recommends adding one 3,200 feet 12-inch PVC pipe parallel to the exiting pipe. This can provide needed redundancy and add a loop to exiting water mains, which is important to the high-dense high-rise community.
- Buccaneer Lagoon community: the 4-inch and smaller pipes should be replaced by minimum 8-inch PVC pipes per FMBPWSI Operations Manual. As shown on the hydraulic model, approximate 6,000 feet 8-inch PVC pipes are needed to replace existing pipes.

Abstract

Innovative strategies alleviate water stress in South East Queensland, Australia

Brisbane, located in South East Queensland, Australia, is one of the fastest growing major metropolitan areas in Australia and Queensland's state capital. In the past seven years, rapid population growth and unprecedented drought has placed tremendous pressure on Brisbane's drinking water supply. As a result, in July 2007, the combined dam levels fell to a historical low of 17 percent, or less than 16 months supply. Recycled water is one of several strategies that the Queensland Government has adopted as part of its efforts to secure the region's drinking water supplies and to support sustainable economic growth. The Bundamba Advanced Water Treatment Plant (BAWTP) is part of the AU$2.5 billion Western Corridor Recycled Water Project that will produce up to 232 megaliters of purified recycled water each day for use in power stations, industry, agriculture and, should the regional water storages fall below 40 percent, to supplement the Wivenhoe Dam.

Black & Veatch entered a joint venture with Thiess to design, build, and commission the BAWTP. The BAWTP consists of two stages – Stages 1A and 1B – with a combined capacity of 66 million liters per day (ML/d) (17.4 mgd). The plant purifies secondary treated wastewater from four municipal wastewater treatment plants. Treatment trains feature pretreatment by coagulation/flocculation, followed by microfiltration, reverse osmosis, UV/hydrogen peroxide, and post-treatment/stabilization in series. Water that meets Australian Drinking Water Guidelines is produced and pumped to three power stations located at Swanbank, Tarong and Tarong north. These plants had previously sourced water from the Wivenhoe Dam - the main water supply for Brisbane and surrounding area. This paper will focus on the commissioning, startup and performance testing of the BAWTP Stage 1B. It will discuss individual treatment processes, waste treatment processes and their performance and optimization. This paper also discusses the plant's capability to manage contaminants, in particular endocrine disrupting chemicals.

Innovative strategies alleviate water stress in South East Queensland, Australia

Introduction

Brisbane is the state capital of Queensland, Australia. It is situated on South East Queensland's Brisbane River, on a low-lying floodplain between Moreton Bay and the Great Dividing Range. With a population of 1.8 million, it is Australian's third-most populous city and one of its fastest-growing metropolitan areas. From 2001 to 2008, Brisbane experienced the worst drought in more than 100 years (Queensland Water Commission, 2008). The drought, combined with the rapid population growth, generated tremendous pressure on the area's drinking water supply. As a result, the combined dam levels which provide Brisbane's drinking water supply fell to 17 percent in July 2007 (Queensland Water Commission, 2008). To cope with the water shortage and to support the region's sustainable development, the Queensland Government initiated the following strategies (Wallis-Lage et al. 2007 and Freeman et al., 2008):

1. Evaluation of new groundwater sources.
2. Seawater desalination.
3. Pipeline-interconnection projects.
4. Modifications to the elevation of the Mt. Crosby Water Treatment Plant (Brisbane's primary water treatment plant) weir.
5. System-pressure reduction to reduce leakage.
6. Water-saving initiatives.
7. Two new dams.
8. Water reuse.

The Western Corridor Recycled Water Project (WCRW) is an AU$2.5 billion water supply network designed to diversify South East Queensland's drinking water sources. The project involves treating wastewater to the highest standard – resulting in purified recycled water that is supplied to power stations, industry, agricultural customers and, should regional water storages fall below 40 percent, the Wivenhoe Dam. When completed, the project will have the capacity to deliver up to 232 megaliters (ML) of purified recycled water a day to end users. The Queensland Government is contributing $2.1 billion to the project and the Australian Government has contributed $408 million through the Water Smart Australia Program (WCRW, 2007a). This cost reflects the scale and aggressive schedule for this project. The project comprises three advanced water

treatment plants located at Bundamba, Luggage Point and Gibson Island, more than 200 kilometres of large diameter pipelines, as well as associated water storage tanks and pump stations. The plants treat wastewater from the region's six municipal wastewater treatment plants.

BAWTP was the first plant to be built and consists of two stages – Stage 1A and Stage 1B. Stage 1A was successfully designed, built, and commissioned in 17 months and has been in production since August of 2007 as scheduled (WCRW, 2007b). Stage 1B was commissioned in May 2008. This paper will focus on Bundamba Stage 1B and will discuss the performance test results.

Liquid Treatment Processes

Stage 1A of the BAWTP purifies treated wastewater from the nearby Bundamba Wastewater Treatment Plant (WWTP), and Stage 1B purifies treated wastewater from Bundamba, Oxley, Goodna, and Wacol WWTPs. The BAWTP has a rated plant capacity of 66 ML/d (17.4 mgd), which consists of 30 ML/d (7.9 mgd) for Stage 1A and 36 ML/d (9.5 mgd) for Stage 1B. The Stages 1A and 1B treatment trains consist of pretreatment by coagulation/flocculation/sedimentation, microfiltration (MF), reverse osmosis (RO), advanced oxidation with UV and hydrogen peroxide, and stabilization with lime and carbon dioxide. A schematic of the main liquid treatment processes is presented at Figure 1. The Stage 1A contract was awarded to a joint venture by Thiess (Brisbane, Queensland, Australia) and Black & Veatch (Kansas City, MO, USA) on March 30, 2006. The design was completed in October 2006, and construction began in November 2006. Stage 1A produced "first water" in August 2007. Construction of Stage 1B started concurrently with Stage 1A in November 2006; the facility was commissioned in May 2008. It has been pumping purified recycled water to Swanbank, Tarong, and Tarong north power stations ever since.

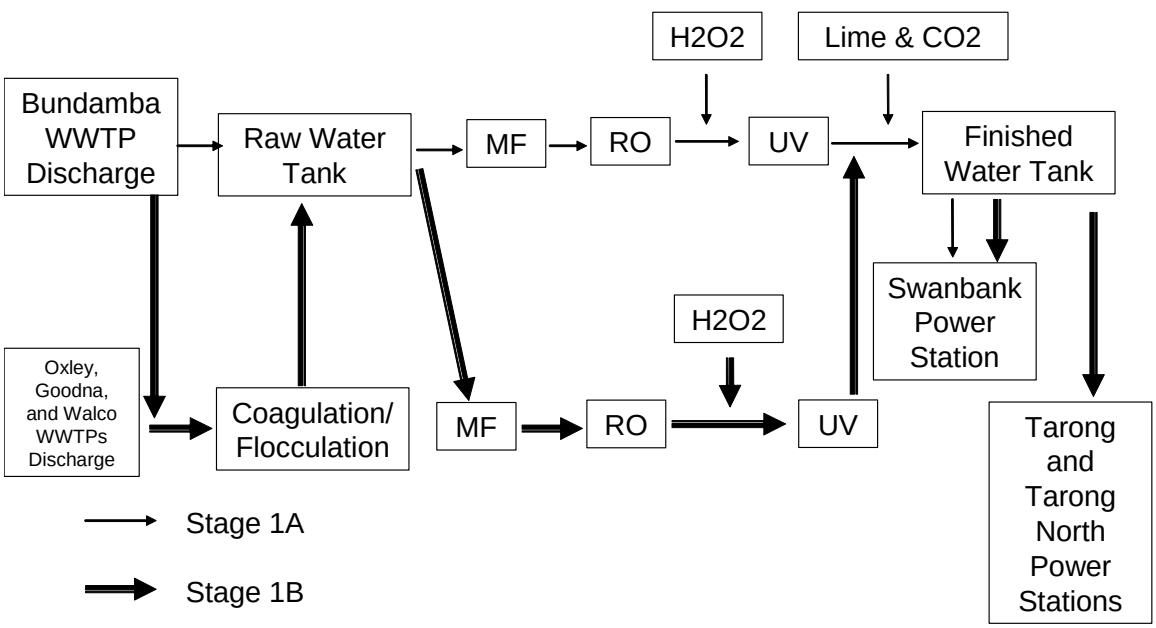

Figure 1. BAWTP main plant liquid treatment process schematic

Pretreatment. Pretreatment is provided for the influent to BAWTP to remove phosphorus. Ferric chloride is used as coagulant. Ferric ion reacts with phosphorus in the water to form phosphate precipitate. The basic overall reaction is shown below (Metcalf & Eddy, Inc, 2003):

$$Fe^{3+} + H_nPO_4^{3-n} \leftrightarrow FePO_4 + nH^+$$

The phosphate precipitates are then settled at the plate settler and removed as sludge. Pretreatment was not provided for the influent to Stage 1A as phosphorus in the Bundamba WWTP effluent is removed to insignificant levels before it enters BAWTP. Feedwater to Stage 1B includes effluent from additional WWTPs with elevated phosphorus levels, so the pretreatment process was incorporated with Stage 1B.

Pre-disinfection is provided to control membrane biofouling in the microfiltration (MF) and reverse osmosis (RO) downstream. Ammonia sulfate and sodium hypochlorite are added in series at a chlorine to ammonia ratio of 3.5 : 1 before the water enters the coagulation basin. The hypochlorite reacts with ammonia instantaneously to form chloramine. Hypochlorite is dosed at a dosage to produce and maintain a set level of combined chlorine residual in the RO feed water.

The pretreatment process at BAWTP includes two trains, each of which consists of two stages of rapid mixing/flocculation and a plate settler. Each rapid mixing/flocculation basin is sized 14 m X 5 m X 9 m and provides hydraulic detention time of about 12 minutes at a peak flow rate of 150 ML/d. The plate settler is manufactured by MRI (Golden, CO, USA). Each plate settler unit consists of eight plate pack rows and each row has three plate packs. The hydraulic loading is 0.60 m/h (0.24 gpm/ft^2).

Microfiltration. MF is used at the BAWTP Stage 1B facility to treat settled water and serve as a pretreatment step for the RO membrane downstream. The MF membrane is manufactured by Siemens/Memcor (South Windsor, New South Wales, Australia) and the treatment train consists of five MF units. Each unit has a capacity of 8.8 ML/d and the average net flux is 30.78 liters per square meter per hour (lmh) (18.13 gfd).

Reverse osmosis. The RO unit is at the heart of BAWTP treatment process. It removes most of the impurities from the influent water and produces a high-quality permeate. The RO process consists of five trains in parallel. Each train contains 11 pressure vessels and is configured in three stages (7 x 4 x 2) in series. Each pressure vessel houses five membrane elements. The RO membrane is 18 inch Koch MegaMagnum manufactured by Koch Membrane Systems (Willington, MA, USA). It is the largest commercial application of large diameter RO membrane by plant capacity. The RO train operates at a recovery of 85 percent. The feed water pressure is about 31 bar (450 psi). Conductivity of the feed water is about 1200 to 1400 μs/cm and combined permeate conductivity is about 50 μs/cm.

UV Advanced Oxidation. The RO permeate is further treated by a UV-hydrogen peroxide unit. Hydrogen peroxide is added to the permeate before it enters the UV unit. The UV unit consists of two trains, and each of which includes two reactors in series. The UV reactors are provided by Trojan Technologies, Inc. (London, Ontario, Canada) and are equipped with high-intensity low pressure amalgam UV lamps. Each reactor contains 72 UV lamps. The UV intensity of each reactor is in the range of 12 – 15 mW/cm^2. This process is designed to remove remaining micro-contaminants that may have passed through the previous treatment processes. Contaminants of particular focus are endocrine disrupting chemicals (EDC) and chloramine disinfection byproducts, such as n-nitrosodimethylamine (NDMA). The UV dosage applied is chosen to achieve 1-log removal of NDMA and 0.5-log removal of 1, 4-dioxane. These parameters were established as design basis factors during the projects' planning, even though the compounds and concentrations had not been quantified.

Stabilization and post-treatment. RO permeate is highly unstable and aggressive. Lime and carbon dioxide are added to the UV treated permeate before it enters the finished water storage tank. Quicklime is used at BAWTP and hydrated lime is generated onsite. Carbon dioxide is fed in gas form. Dosages of lime and carbon dioxide are determined to achieve a pre-set range of calcium carbonate precipitation potential (CCPP) of -5 to 0 at the inlet of the finished water storage tank.

Waste Treatment Processes

Sludge generated in the pretreatment process is thickened by a gravity thickener and dewatered by centrifuges. The centrifuge centrate is combined with RO brine and are treated further by nitrification and de-nitrification units before being discharged into the Brisbane River. The dewatered sludge is hauled off-site for disposal. The waste treatment process schematic is presented in Figure 2.

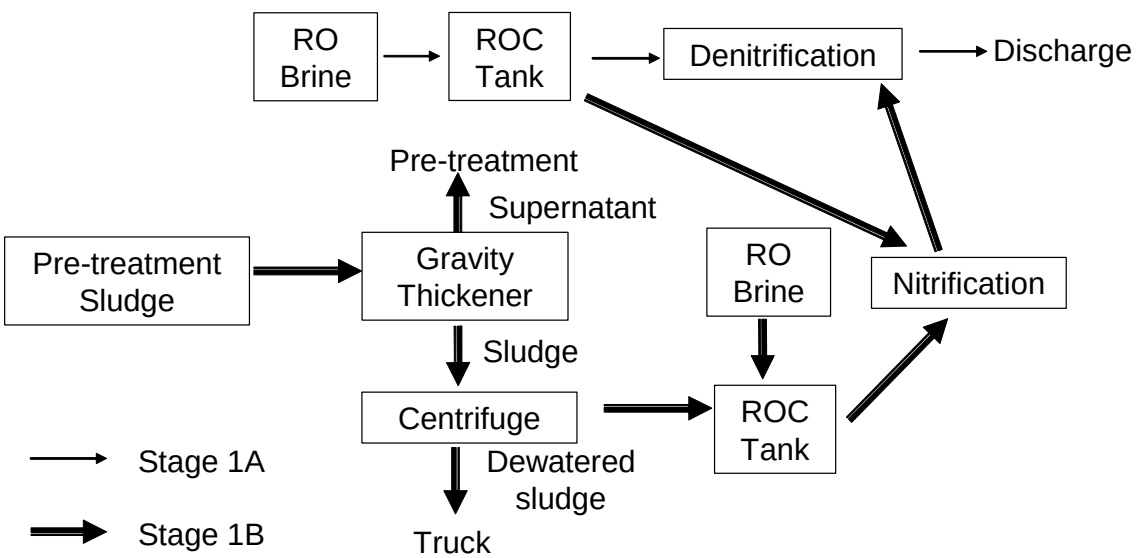

Figure 2. BAWTP waste treatment process schematic

Gravity thickener. Settled sludge is withdrawn periodically from the pretreatment basin and pumped to a gravity thickener. The gravity thickener at BAWTP is an above-ground, pre-manufactured circular structure by Outotec Pty Ltd (Frenchs Forest, New South Wales, Australia). It has an inside diameter of 10.5 m (34.4 ft). The thickened sludge is pumped to a holding tank for further processing. A polymer feed system is provided with the gravity thickener. To date, the polymer has not been required for the gravity thickener.

Centrifuge. Two centrifuges are provided at BAWTP. The centrifuges are manufactured by Alfa Laval. Polymer is fed to the sludge before it enters centrifuge. The dewatered sludge cake is trucked off-site. The centrate is pumped to a holding basin, mixed with RO brine, and then sent to the nitrification and denitrification units for further treatment before being discharged into to the river.

Nitrification. Nitrification followed by de-nitrification downstream is used to convert ammonia in the mixed centrate and RO brine to nitrate (nitrification) and then nitrogen gas (de-nitrification). The nitrification system at BAWTP consists of three identical basins. The first two basins are in parallel and the third basin is in series for effluent polishing. Each basin has a volume of 250 m^3 (8829 ft^3) and a working volume of 200 m^3 (7063 ft^3). The basin is filled with polyethylene discs that provide the surface area for nitrifying bacteria to grow with compressed air constantly introduced at the bottom of the basin. The ammonia concentration at the basin inlet and outlet is monitored online.

Denitrification. The denitrification unit is manufactured by Severn Trent Services (Pittsburgh, PA, USA). The unit consists of 4 basins that are loaded with high-grade silica sand media. Methanol is fed at the unit inlet to provide nutrients for the growth of denitrifying bacteria. The concentration of nitrate at the inlet and outlet of the unit is monitored by online analyzers.

Plant Performance

BAWTP Stage 1B performance testing commenced in April 2008 and lasted for 30 days. The performance goal was to meet contractual agreements relating to water quality and production capacity. The finished water was required to meet Australian Drinking Water Guidelines (Australian Government, 2004). One of the concerns regarding recycled wastewater is the presence of EDCs. The specific limits for the concentration of EDCs in finished water were included in the contractual agreement. Table 1 lists finished water quality goals and sampling frequency for the BWAT Stage 1B performance test. The finished water is defined as a 24-hour composite sample at the inlet of the finished water tank.

Table 1. BAWTP Finished Water Quality Goals

Parameters	Units	Specification Requirement		Sampling Frequency
Alkalinity	mg/L	>	40	Daily
Calcium Carbonate Precipitation Potential (CCPP)	-		0 to -5	Daily

Clostridium perfringens, 95%ile	cfu/100mL	<	10	Weekly
Clostridium perfringens, median	cfu/100mL	<	1	Weekly
EDC Estrone (E1)	nano-g/L	<	3	Daily
EDC 17-beta Estradiol (E2)	nano-g/L	<	1	Daily
EDC Ethinylestradiol (EE2)	nano-g/L	<	0.1	Daily
EDC Total PNEC	nano-g/L	<	1	Daily
EDC Nonlyphenol (NP)	nano-g/L	<	7	Daily
Hardness, as CaCO3, 21 Day average	mg/L	>	50	Daily
Nitrogen (Total), 50th Percentile	mg/L	<	0.8	Daily
Nitrosodimethylamine (NDMA)	nano-g/L	<	10	Daily
Phosphorus Total, 50th Percentile	mg/L	<	0.13	Daily
Total Organic Carbon (TOC)	mg/L	<	1	Daily
Acrylamide	mg/L	<	0.0002	Weekly
Antimony	mg/L	<	0.003	Weekly
Benzene	mg/L	<	0.001	Weekly
Bromate	mg/L	<	0.02	Weekly
Carbon Tetrachloride	mg/L	<	0.003	Weekly
Chlorine	mg/L	<	5	Weekly
Chlorine Dioxide	mg/L	<	1	Weekly
Chlorite	mg/L	<	0.3	Weekly
Chlorobenzene	mg/L	<	0.33	Weekly
Chromium as Cr (VI)	mg/L	<	0.05	Weekly
Cyanide	mg/L	<	0.08	Weekly
Cyanogen chloride	mg/L	<	0.08	Weekly
Dichlorobenzene (1,2-Dichlorobenzene)	mg/L	<	1.5	Weekly
Dichlorobenzene (1,4-Dichlorobenzene)	mg/L	<	0.04	Weekly
Dichloroethanes (1,2-Dichloroethane)	mg/L	<	0.003	Weekly
Dichloroethenes (1,1-Dichloroethene)	mg/L	<	0.03	Weekly
Dichloroethenes (1,2-Dichloroethene)	mg/L	<	0.06	Weekly
Dichloromethane	mg/L	<	0.004	Weekly
Epichlorohydrin	mg/L	<	0.0005	Weekly
Ethylbenzene	mg/L	<	0.3	Weekly
Ethylenediamine tetraacetic acid (EDTA)	mg/L	<	0.25	Weekly
Formaldehyde	mg/L	<	0.5	Weekly
Hexachlorobutadiene	mg/L	<	0.0007	Weekly
Iodide	mg/L	<	0.1	Weekly
Lead	mg/L	<	0.01	Weekly
Mercury	µg/L	<	1	Weekly
Molybdenum	mg/L	<	0.05	Weekly
Monochloramine	mg/L	<	3	Weekly
Nickel	mg/L	<	0.02	Weekly
Nitrilotriacetic acid	mg/L	<	0.2	Weekly
Organotins (Tributylin Oxide)	mg/L	<	0.001	Weekly
PAHs (Benzo(a)pyrene)	nano-g/L	<	10	Weekly
Plasticisers (Di(2-ethylhexyl)adipate)	mg/L	<	0.01	Weekly
Styrene	mg/L	<	0.03	Weekly
Sulfate	mg/L	<	500	Weekly
Tetrachloroethene	mg/L	<	0.05	Weekly

Toluene	mg/L	<	0.8	Weekly
Trichloroacetaldehyde	mg/L	<	0.02	Weekly
Total Trichlorobenzenes	mg/L	<	0.03	Weekly
Total Trihalomethanes	mg/L	<	0.25	Weekly
Uranium	mg/L	<	0.02	Weekly
Vinyl Chloride	mg/L	<	0.0003	Weekly
Xylenes	mg/L	<	0.6	Weekly
2-4-D	mg/L	<	0.03	Weekly

The following section was intended to cover plant performance test results. However, these data can not be published before the pending release of the water quality report by the Queensland Water Commission (Queensland Water Commission, 2009), therefore these will be not presented here. The test results will be ready to be presented at the conference. In the mean time, the reader can refer for detailed information to the pending water quality report which is due to be issued soon. Although not shown here, the performance test results indicate that the finished water meets the water quality goals outlined in the contractual agreements, and the finished water meets the Australian Drinking Water Guidelines.

Conclusion and Discussion

The 66 ML/d BAWTP, which incorporates innovative treatment processes such as MF, RO and UV-H_2O_2 to produce purified recycled water, has been successfully commissioned. The BAWTP has been providing up to 40 ML/day of high-quality treated water to three power stations located at Swanbank, Tarong and Tarong north since June 2008. Water produced at the BAWTP will also be used for industry, agriculture and, should regional water storages fall below 40 percent, the Wivenhoe Dam. The treatment process used at BAWTP produce water that has been verified to satisfy Australian Drinking Water Guidelines. The plant plays a significant role in alleviating water stress and supporting sustainable social and economical development in the region. Brisbane was able to lift extreme stringent Level 6 (Target 140) water restriction on July 31, 2008. The Queensland Government anticipates its new water infrastructure initiatives will remove the need to implement such tight restrictions in the future.

Acknowledgment

The authors thank WaterSecure of Brisbane, Australia for supporting this article. WaterSecure is a sustainable water business the develops new water sources for South East Queensland and manages the Western Corridor Recycled Water Project and Gold Coast Desalination Project on behalf of the Queensland Government. Special thanks are extended to Dr. Cedric Robillot and Paul Rees of the WaterSecure for reviewing this manuscript and for providing constructive comments.

ABSTRACT

The optimal design of a water distribution system under transient conditions is formulated as a two-objective optimization problem. The objectives are minimization of the total pipe costs and maximization of the hydraulic reliability for the transient network design model. Unlike most optimization models in which demands are set to their end-of-life levels, this approach assumes that the demand loadings vary throughout the design life of the system. Evolutionary algorithms are applied to support efficient search for Pareto optimal solutions to the dual-objective optimization problem. An example application is presented and relevant conclusions are stated.

INTRODUCTION

A water distribution system is a complex network of pipes, pumps, valves, reservoirs, and storage tanks that is used to transport water from source to consumer. It is designed and operated to consistently deliver water in sufficient quantity, of acceptable quality, at appropriate pressure, as economically as possible. Traditionally, after choosing critical loading conditions in distribution system design, the greater of peak-hour demand or peak-day demand and a chosen fire flow, optimization methods are applied to select the most economical set of pipe sizes that will produce the desired range of pressures in the network. The rationale underlying the economical design is that, by selecting the smallest possible diameter set to minimize cost, pressures are marginally above an acceptable level for the specified design loading conditions. However, because the design problem is posed as a static one (i.e., the design loads are not treated as dynamic variables), the conventional design could well be suboptimal under transient pressures, or even seriously inadequate for other design events.

The optimization of a water distribution system under hydraulic transient conditions is difficult due to the complexity of the transient flow problem. Although a transient analysis is essential to estimate the worst-case events in the system, its inherent complexities have induced hydraulic design engineers to focus perhaps too much on steady state conditions. However, transient regimes in water distribution systems are both inevitable and naturally occurring (Boulos et al., 2005). Recent water quality studies have emphasized the need for transient analysis of large pipe

networks to properly assess the potential level of intrusion associated with negative pressure events and the resulting impact on disinfectant residual effectiveness (Besner, 2007; Boulos et al., 2006; NRC, 2006; Fleming et al., 2006; Friedman et al., 2004; LeChevallier et al., 2002-2003; Kirmeyer et al., 2001). In reality, since all pipeline systems leak and hydraulic transients will occur continuously in a water distribution system, it is not surprising that low-pressure transient events offer considerable potential to draw untreated and possibly hazardous water into the piping system.

Numerous hydraulic transient approaches have been developed to identify system weak points, to predict the potentially destructive effects of hydraulic transients under various worst-case scenarios, and to evaluate how they may possibly be eliminated or controlled (e.g., Wylie and Streeter, 1993; Chaudhry, 1987; Thorley, 2004; Boulos et al., 2005; Wood et al., 2005; Ghidaoui et al., 2005; Jung et al., 2007). In particular, Boulos et al. (2005) provided a detailed transient analysis flow chart for the selection of components for surge control and suppression in water distribution systems, and concluded that a transient analysis should always be carried out to determine the impact of each proposed strategy on the resulting system performance. Jung et al. (2007) argued that only a systematic transient analysis can be expected to resolve complex transient characterizations and adequately protect water distribution systems.

In addition, optimization methods have been widely applied to many problems associated with water distribution system design, management and operation. Alperovits and Shamir (1977) applied linear programming and Lansey and Mays (1989) suggested using nonlinear programming to optimize component sizing and the operational decisions arising in water distribution systems. Simpson et al. (1994) and Dandy et al. (1996) compared a Genetic Algorithm (GA) approach to both complete enumeration and nonlinear programming in the context of pipeline optimization. Much of the pipeline optimization literature has been concerned with systems under steady or near steady flow conditions; however, a few optimization approaches dealt with operating conditions pertaining to system integrity, safety and performance. Laine and Karney (1997) applied optimization to a simple pipeline connecting a pump and a storage reservoir. A complete enumeration scheme as well as a probabilistic selection procedure were incorporated with both transient and steady state analysis. Lingireddy et al. (2000) described a surge tank design model based on a bi-level genetic optimization framework that produces optimal tank sizes while satisfying a specified set of pressure constraints. Jung and Karney (2004) considered the impact of transients on the choice of optimal diameter in a network considering both steady and transient criteria. More recently, Jung and Karney (2006) presented an optimum selection approach of hydraulic devices for water hammer control in a water distribution system. GA and Particle Swarm Optimization (PSO) were used to optimize the preliminary selection, sizing and placement of surge protection devices.

In this paper, the optimal design of a water distribution system under transient conditions is formulated as a two-objective optimization problem. The objectives are

minimization of the total pipe costs and maximization of the hydraulic reliability for the transient network design model. Unlike most optimization models in which demands are set to their end-of-life levels, this approach assumes that the demand loadings vary throughout the design life of the system. Evolutionary algorithms are applied to support efficient search for Pareto optimal solutions to the dual-objective (pipe costs and hydraulic reliability) optimization problem. The model is tested (by simulation) on the classical New York tunnel system and relevant conclusions are stated.

MATHEMATICAL FORMULATION

Whether designing a water distribution system (WDS) using trial-and-error enumeration methods or with formal optimization tools, a broad range of concerns must be considered. Cost is likely to be the primary emphasis and includes the costs for construction, operation and maintenance. The initial capital investment for the system includes pipes, pumps, tanks, and valves. Energy consumption occurs over time as the system is operated. The main constraints are that the nodal demands are supplied at a minimum pressure. In addition, the network flows and pressure heads must satisfy the governing equilibrium laws of conservation of energy and mass.

In this paper, the optimal design of a water distribution system under transient conditions is formulated as a two-objective optimization problem. The first objective is formulated in Equation (1) as a least-cost optimization problem with the selection of pipe diameters as the decision variables. The second objective is to maximize hydraulic reliability for the transient network design model. This objective given in Equation (2) is formulated to minimize the integration of the transient pressures that are lower than the minimum required level (e.g., datum) or higher than the maximum allowable transient pressure level (e.g., pipe ratings). In contract with traditional optimization models in which demands are set to their end-of-life levels, this approach assumes that the demand loadings vary throughout the design life of the system. The pipe network layout, nodal demands, and minimum head requirements are assumed known. The optimal design of water distribution networks can be stated mathematically as:

$$\text{minimize} \sum_{k \in N_{pipe}} C_k(D_k, L_k) \tag{1}$$

$$\text{minimize} \sum_{i \in N_{node}} \int^{\forall Time} |H_i(t)| dt \text{, where } H < H^*_{\min} \text{ or } H > H^*_{\max} \tag{2}$$

Subject to the governing transient equations

$$\frac{1}{gA_p}\frac{\partial Q}{\partial t} + \frac{\partial H}{\partial x} + \frac{R}{\Delta x} Q|Q|^{n-1} = 0 \tag{3}$$

$$\frac{\partial H}{\partial t}+\frac{a^2}{gA_p}\frac{\partial Q}{\partial x}=0 \tag{4}$$

and a set of algebraic constraints:

$$H_i(t)=C_1,\ \ Q_i(t)=C_2, \text{ where } t=0,\ \ \forall i\in N_{node} \tag{5}$$

$$f(H_i(t),Q_i(t))=C_3, \text{ where } t>0,\ \ i=\text{boundary nodes} \tag{6}$$

$$H_i(t)\geq H_{\min i}, \text{where}\ \ t=0,\ \ \forall i\in N_{node} \tag{7}$$

$$D_k\in\{D\},\ \ \forall k\in N_{pipe} \tag{8}$$

where D_k = discrete pipe diameters selected from the set of commercially available pipe sizes $\{D\}$[Equation (8)]; $C_k(D_k\ L_k)$ = cost of pipe k with diameter D_k and the length L_k; H = piezometric head; and $H^*_{\max}$ and $H^*_{\min}$ are the maximum and minimum permissible heads (say representing pipe ratings or health concerns for negative pressures), respectively. Equations (3) and (4) represent the momentum equation and mass conservation for transient flow in closed conduits (Wylie and Streeter, 1993). Here, x is distance long the centerline of the conduit; t is time; Q = volumetric flow rate; a = celerity of the shock wave; A_p = cross-sectional area of the pipe; and g = acceleration due to gravity. The friction term R in the Equation (3) can be represented by

Darcy-Weisbach: $R=\ f_p\Delta x/2gD_pA_p^2,\ n=2$ (9)

or

Hazen Williams: $R=\ \Delta x/(0.278CD_p^{\ 2.63})^{1/0.54},\ n=1/0.54$ (10)

in which f_p = Darcy-Weisbach friction factor; and C = Hazen-Williams roughness coefficient. The two hyperbolic partial differential equations in (3) and (4) are subject to the initial conditions of Equation (5) and boundary conditions of Equation (6), where C_1, C_2 and C_3 are constants. Initial conditions are typically taken as steady. Simple boundary conditions of constant reservoir level and fixed demand are assumed, but combined relationships between H and Q are typical for most boundaries. Equation (7) requires that the nodal pressure H for any node i (where total number of nodes is N_{node}) is equal to or greater than a specified minimum pressure $H_{\min}$ for steady state condition.

The remaining and challenging question is how to apply an optimization method to the suggested problem of water distribution optimization. Gradient-based mathematical optimization methods (Alperovits and Shamir, 1977; Bhave, 1985) have been widely applied and have provided efficient computational procedures for

achieving a lower cost solution but the methods suffered from some disadvantages, such as: (1) being ineffective at reaching the least cost solution due to zero-gradient optimality criteria, which easily trapped a search process at a local optimal solution; (2) the lack of flexibility in handling discrete design variables and optimizing a partial network that is often required for many practical engineering designs; (3) the complexity of implementing and using the techniques (Wu and Simpson, 2001); and (4) the requirement to compute either first or second derivative information in order to generate improvements in the objective function. Recently, several researchers have used genetic algorithm (GA) optimization for solving such complex WDS optimization (Simpson et al., 1994; Dandy et al., 1996). Ant Colony Optimization (Maier et al., 2003) and Shuffled Frog Leaping Algorithm (Eusuff and Lansey, 2003) have also been applied for obtaining specific optimal designs of WDSs. These methods offers significant advantages over gradient-based optimization approaches in that they do not require any gradient information and search for the optimal solution by continuing to evaluate multiple solution vectors simultaneously.

For the given dual-objective (pipe costs and hydraulic reliability for the transient network design model) problem, genetic optimization is used to circumvent subjective decision making and to generate Pareto optimal solutions for the multi-objective optimization problem. In this study, Nondominated Sorting GA (NSGA), developed by Srinivas and Deb (1994), is employed to find the Pareto optimal solutions. Figure 1 depicts a flowchart of the framework for optimizing the pipeline system considering the dual-objective problem. First, an optimization program initializes the pipe sizes as decision variables, and the pipe cost is calculated. The hydraulic model then analyzes the given system and uses the optimization program to check if the solution satisfies the required constraints given by Equations (3) to (8) and then computes the second objective function shown in Equation (2). With the dual objective function values, the optimization model then evaluates the system and creates a new set of system alternatives for the next iteration. The iterations continue until the optimal solution is reached. This allows rapid solutions to be obtained with a minimal computational overhead.

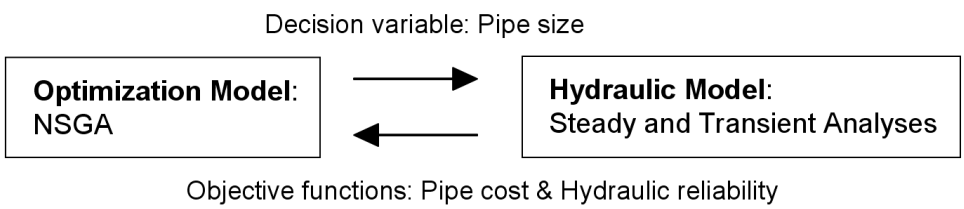

Figure 1. Flowchart of pipeline optimization

CASE STUDY

The proposed method is illustrated using the classical New York tunnel system (Schaake and Lai, 1969). The network, which is shown in Figure 2, has been extensively studied for steady state conditions. It comprises 22 nodes (20 demand

nodes), 21 pipes, and one source node. The system is gravity driven and draws water from the Hillview reservoir to the downstream network. The objective of the optimization problem is to add new pipes parallel to the existing ones. The new pipe diameters need to be selected from 15 available sizes. A single demand pattern (57,130 L/s) was considered and a minimum allowable hydraulic grade was specified for each node. The network and cost data are given in Dandy et al. (1996).

Since the system was first examined in 1969 by Schaake and Lai, numerous subsequent researchers have used it to test the numerical effectiveness, efficacy and performance of their respective techniques (Dandy et al., 1996; Savic and Walters, 1997; Wu et al., 2001; Eusuff and Lansey, 2003; Maier et al., 2003). However, all these approaches were based on steady state optimization only. In this paper, not only the steady state problem is considered, but also the transient analysis is included in the optimization process. By doing so, it is shown that different design decisions would be required, and the restrictive search based on limited operating conditions is likely suboptimal for a broader range of demand loadings.

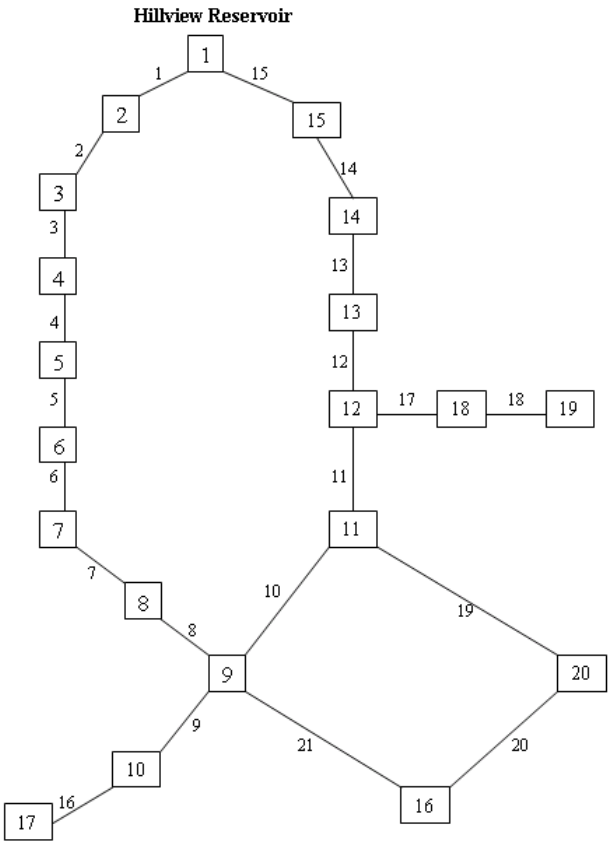

Figure 2. New York tunnel system schematic

To introduce transient conditions into this case study, a variety of possible causes could be selected. For convenience, a valve opening that increases the demand at node 10 from 28 L/s to 4814 L/s for a 1 second period is chosen to characterize the transient performance of the system. This increased demand may represent a fire

flow, a pipe burst, an operator error or a temporary increased in water consumption. The maximum permissible heads $H^*_{\max}$ and $H^*_{\min}$ in Equation (2) are assumed to be 304.8 m and 54.9 m, respectively, for the whole system. Due to the rapid demand increase at node 10, a reduced pressure wave moves through the system. This wave is reflected from the upstream reservoir and then propagates back and forth in the system, being tracked numerically using the method of characteristics (Wylie and Streeter, 1993). The different pipe lengths and sizes in the system create uneven computational lengths in the characteristic grids. The smallest Courant number in the system is 0.019 and it can be adjusted to unity by dividing the pipes into smaller computational units. The process of discretization is repeated until the smallest Courant number exceeds 0.75. After discretization, the smallest Courant number and the computational time step are 0.755 and 1.11s, respectively. For the uneven computational units, a linear timeline interpolation is used to obtain head and flow at a grid point in the characteristic mesh.

The multi-objective method, NSGA, is considered to satisfy Equations (1) to (8). For this problem, the probability of mutation is set to 0.025, the probability of (single-point) crossover is set to 0.9, the population size is set to 400, the length of each chromosome is set to 84, and the simulations are run for 100 generations. For this problem, 16 decision variables including the "do nothing" option make up a solution space of 16^{21} or 1.93 x 10^{25} possible pipe combinations. The NSGA initializes the population of pipe diameters, and then calculates the cost of pipelines and the hydraulic reliability of transient network design model satisfying the given constraints, and then create a new population for the next generation. After 100 generations, the resulting Pareto optimal solutions are shown in Figure 3 and Table 1. The hydraulic reliability results indicate that the previous approaches that considered only steady state design are inadequate for coping with water hammer events. The results also suggest that the proper sizing of pipe diameters is crucially important to prevent water hammer as well as to decrease cost.

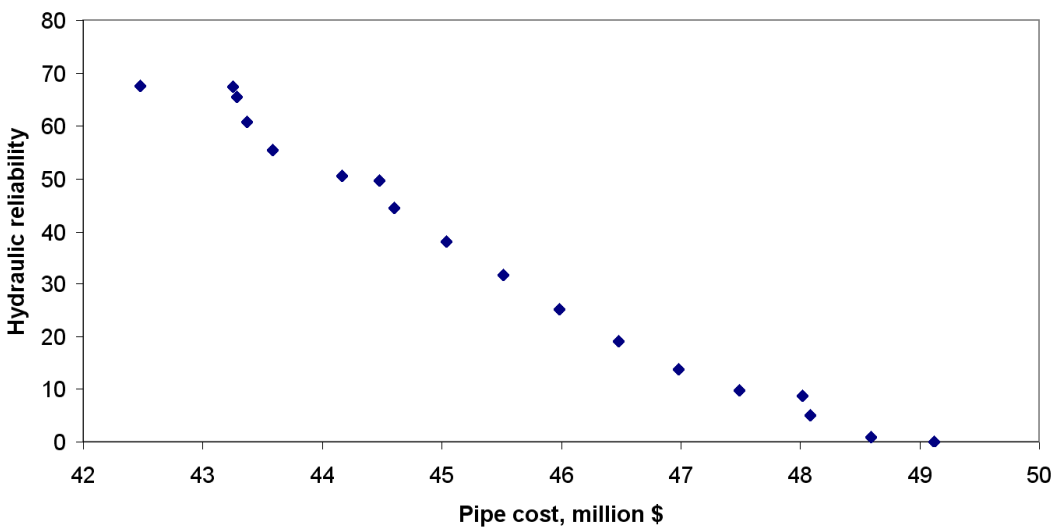

Figure 3. Pareto optimal solutions of pipe cost and hydraulic reliability

Table 1. Pareto optimal solutions for pipe sizes

Pipe	Pipe size (mm)		
1 – 8	-	-	-
9	3900	2700	-
11 – 15	-	-	-
16	3000	3000	3000
17	2100	2100	2100
18	3000	3000	3000
19	2100	1800	1800
20	3000	3000	3000
21	-	-	-
22	1500	1500	1500
Pipe Cost, $ million	49.12108	45.98196	42.47795
Hydraulic Reliability	0	25.21	67.51

CONCLUSION

Transient analysis, despite its significant concern for water distribution system design, is a complicated problem and so is the optimization of a transient control strategy for water distribution systems. The purpose of this paper is to obtain the optimal design of a pipe network by considering simultaneously steady and transient states. The objectives are minimization of the total pipe costs and maximization of the hydraulic reliability for the transient network design model. Unlike most optimization models in which demands are set to their end-of-life levels, this approach assumes that the demand loadings vary throughout the design life of the system. To achieve the dual-objectives, evolutionary algorithms based multi-objective optimization is used to circumvent subjective decision making and generate Pareto optimal solutions.

The case study using the New York tunnel system indicates that the previous approaches that considered steady state design only are inadequate for coping with water hammer events. In addition, the study suggests that proper sizing of pipe diameters is crucially important to prevent water hammer as well as to decrease cost. Although this paper considers the optimal selection of pipe diameters for a surge protection strategy, a more global and comprehensive approach is ultimately needed. Water distribution system optimization should also consider, in addition to pipe size, the transient properties (e.g., operation speed), system characteristics (e.g., system topography, pipe material and thickness) and transient protection devices. This comprehensive design framework will offer a more complete range of systematic surge protection strategies resulting in more reliable cost optimization solutions.

MUNICIPAL WATER SYSTEMS IN THE COLUMBIA RIVER BASIN: A PORTFOLIO MANAGEMENT APPROACH FOR MULTIPLE BENEFITS

Mark A. Anderson[1]

[1]CH2M HILL, Inc., 2020 SW 4th Avenue, 3rd Floor, Portland, Oregon, 97201; PH (503) 872-4700; e-mail: Mark.Anderson@ch2m.com

ABSTRACT

The City of Gresham, Oregon has a population of 100,000 people. On the eastern edge of the Portland metropolitan area, Gresham is located on the south shore of the Columbia River. Gresham's water supply is anticipated to be adequate until at least 2050 from surface and groundwater sources.

Wastewater is collected for secondary treatment. Treated effluent is discharged directly to the Columbia River. This reach of the Columbia River is designated as a temperature-limited stream under Section 303(d) of the Clean Water Act. A number of other potential nutrient and pollutant limits may affect permitted effluent discharge in the future. A draft Total Maximum Daily Load (TMDL) for temperature assigns a heat load allocation to Gresham that is projected to be exceeded by as early as 2020.

A water reuse evaluation was performed to address the City's goals of meeting water quality requirements for the Columbia River and providing a sustainable water supply, including preservation of aquifer integrity. The study evaluated the feasibility of non-potable blended use and re-use, utilizing treated effluent, industrial water, stormwater runoff, and agricultural wells. Potential applications included landscape irrigation, multi-family domestic and commercial/industrial non-contact flushing water, industrial process use, and aquifer recharge. Recycling of a fraction of non-consumptive use was expected. Seasonal storage evaluated included aquifer storage and recovery, wetlands, and surface storage options.

A dynamic, object-oriented system model was built to evaluate feasibility of alternatives. The model evaluated water balance and storage characteristics for combinations of source, treatment, storage, and demand options. Cost functions were applied to relate conceptual capital and operating costs for a preferred alternative to expected benefits in source water supply preservation and reduced effluent discharge to receiving waters. Non-financial elements were assessed with multi-criteria analysis.

Results of the study indicate that reuse within Gresham alone does not provide sufficient financial advantage. However, regional or watershed-scale solutions, wherein adjacent single-purpose utilities and neighboring municipalities join to share resources across jurisdictional boundaries, indicate promise for solutions that are cost effective and meet sustainability goals, including efficient use of resources, protection of surface water quality, and prudent management of limited groundwater resources.

Keywords: Watershed planning, Integrated water supply, Reuse, Systems modeling

INTRODUCTION

The City of Gresham, Oregon has a population of 100,000 people. On the eastern edge of the Portland metropolitan area, Gresham is located on the south shore of the Columbia River. The area within the City corporate limits includes 23.44 square miles (Metro Regional Land Information System, 2008).

The City is composed of four watersheds: Fairview Creek, Johnson Creek, Kelly Creek, and the Columbia Slough. The planning area comprises a variety of different land covers, including significant amounts of forest, agricultural lands, and rural residential areas.

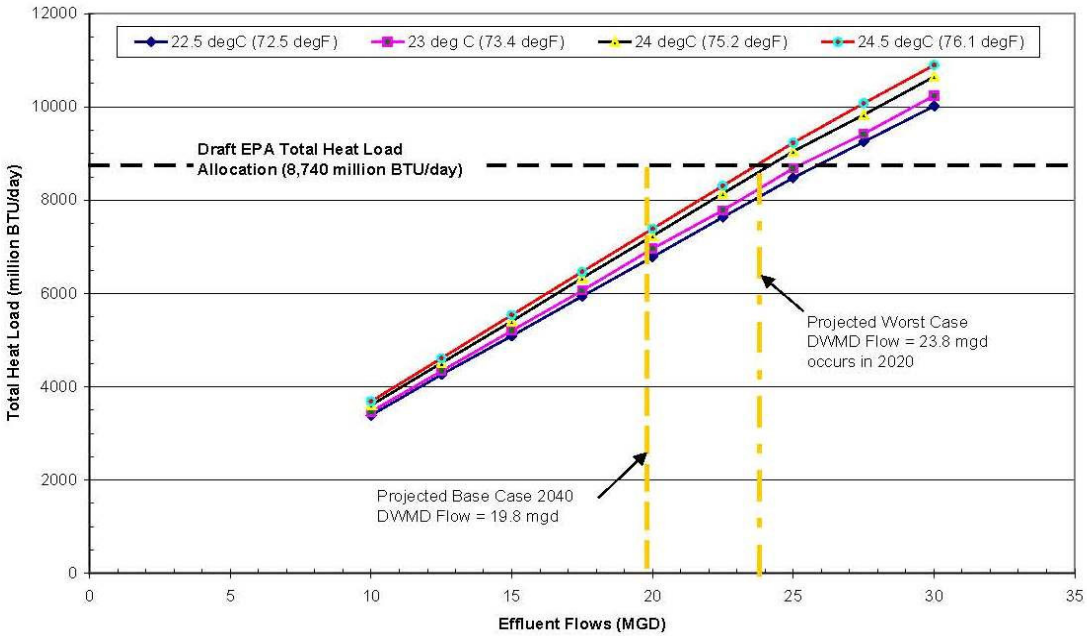
The City climate is marked by cool, rainy winters and warm, dry summers. As a result, little or no supplemental water is required for landscape purposes from October through April.

Water Portfolio Services

The City owns and operates water facilities serving a majority of City residents. Approximately one-third of City residents are served by the Rockwood Water People's Utility District (RWPUD). Gresham purchases water through metered connections with the Portland Water Bureau (PWB) Bull Run watershed surface supply, as well as a connection to the RWPUD groundwater system. Recent average day water demands are about 8 million gallons per day (mgd). These supplies are anticipated to be adequate to 2050.

In the coming years, Gresham's water system area will be expanded to include large portions of two urban reserve areas (URA) that are included in the study area: Pleasant Valley and Springwater. These two areas will add approximately 20,000 people to the City's water service population.

The Gresham wastewater treatment plant (WWTP) is located near the Columbia River. The WWTP receives domestic, commercial, and industrial wastewater from incorporated areas of Gresham and nearby communities and treats the wastewater using a suspended media-activated sludge process.



The Gresham WWTP currently discharges oxidized and disinfected effluent to the Columbia River at river mile (RM) 117.5 under a National Pollutant Discharge Elimination System (NPDES), as issued by the State of Oregon. The current permit expired in May 2007 and stipulates limits that vary seasonally for BOD_5 and TSS as well as E. coli, residual chlorine, and total silver. The draft permit expires in April 2012.

The discharge permit for the Gresham WWTP does not currently include limits for thermal mass load, ammonia, phosphorus, or mercury.

The U.S Environmental Protection Agency (EPA) has issued a draft temperature TMDL for the Columbia River that includes a total heat load allocation of 106.7 megawatt (MW) (8,740 MBtu/day) for the City. Figure 1 illustrates the total heat load for the City's discharge based on a range of four effluent temperatures. This plot illustrates the rate and point at which the City's discharge would approach such

a total heat load limit. Using the projected worst-case conditions, the City will exceed its current total heat load allocation in Year 2020, with a projected flow of 23.8 mgd and temperature of 24.5°C.

FIGURE 1
Projected Gresham Discharge Total Heat Loads for Range of Effluent Flows and Temperatures

A reuse project could reduce the amount of water discharged to the river and, therefore, reduce or delay potential temperature compliance issues.

Several sources of nonpotable water could be included in a reuse program for the City. These include WWTP effluent, industrial effluent, a decentralized membrane bioreactor wastewater treatment facility, stormwater runoff, agricultural well water, and harvested rainwater. Each of these sources has unique water quality characteristics, use applications, and treatment requirements.

In Oregon, reuse of treated municipal wastewater is regulated by Oregon Department of Environmental Quality (DEQ). The reuse of industrial wastewater is also regulated by Oregon DEQ.

The reuse of gray water has been approved in Oregon on a case-by-case basis. The reuse of gray water for systems discharging to public wastewater systems would require plumbing code approval and treatment specific to a particular use.

Rainwater harvesting is currently permitted in Oregon for a variety of indoor uses including toilet flushing and landscape irrigation. A rainwater harvesting system will usually collect water from rooftops and store the collected rainwater in catchment areas.

METHODS

A water reuse evaluation was performed for the Springwater development area (as part of a larger study) to address the City's goals of meeting water quality

requirements for the Columbia River and providing a sustainable water supply, including preservation of aquifer integrity. The study evaluated the feasibility of non-potable blended use and re-use, utilizing treated effluent, industrial water, stormwater runoff, and agricultural wells. Potential applications included landscape irrigation, multi-family domestic and commercial/industrial non-contact flushing water, industrial process use, and aquifer recharge. Recycling of a fraction of non-consumptive use was expected. Seasonal storage evaluated included aquifer storage and recovery, wetlands, and surface storage options.

The study evaluated direct non-potable reuse. Potable (direct or indirect) reuse has not been considered in this evaluation.

Monthly precipitation data for the Portland International Airport were obtained from the National Oceanic and Atmospheric Administration (NOAA) for water years starting October 2000 and ending September 2007.

Monthly evapotranspiration data were obtained from the Pacific Northwest Cooperative Agricultural Weather Network (AgriMet) for an evapotranspiration station in Aurora, Oregon. The evapotranspiration rates tabulated for the Aurora station are for alfalfa, bluegrass, and established poplar trees, which should be representative of the water needs of landscaping materials in Gresham.

A water balance approach was used to evaluate supply and demand options to serve Springwater, a 1,272-acre area to be developed immediately south and east of the City.

The evaluation included 19 criteria covering cost, environmental, societal, and management impacts of the water resources alternatives.

Cost estimates presented are screening level (Class 5) estimates. They are suitable for comparing alternatives. The cost estimates would be updated as the level of project definition increases, the scope of each project is better established, and the timing of construction is determined.

Databases maintained by the State of Oregon Water Resources Department show existing agricultural wells in Springwater with a total capacity of 1.4 mgd.

Combinations of the alternative sources were evaluated for their ability to deliver the 4.6 mgd of peak water use anticipated in Springwater.

A dynamic, object-oriented model, Voyage™, was used to provide the quantitative analysis needed to evaluate reuse alternatives. The model evaluates alternative supply options based on the specific characteristics of each demand needed to meet cost or non-financial criteria.

Alternatives would supply the water use projected for Springwater, including water for indoor, landscape, industrial, and firefighting. The peak total water supply use in Springwater was estimated as being 4.6 mgd based on analysis of land uses and evapotranspiration. For this analysis, landscape water needs were estimated at evapotranspiration less rainfall. Indoor water use was estimated at 80 gallons per resident per day for residential land uses and 15 gallons per employee per day for

industrial and commercial land uses. The water supply alternatives included the following:

- Base Case—Supplying all potable water use in Springwater from the City's potable water system
- Alternative 1—Supplying 1.4 mgd of landscape water use with a raw water system drawing from agricultural wells and supplying the remaining water use from the City's potable water system
- Alternative 2—Supplying 0.3 mgd of reuse from industrial sources and supplying the remaining water use from the City's potable water system
- Alternative 3—Supplying 2.6 mgd of reuse from stormwater detention basins and supplying the remaining water use from the City's potable water system
- Alternative 4—Supplying 0.63 mgd of reuse from a satellite WWTP and supplying the remaining water use from the City's potable water system
- Alternative 5—Supplying 0.63 mgd of use from rainwater harvesting and supplying the remaining water use
- Alternative 6—Onsite/distributed system using membrane bioreactors as in a distributed ISDS system operated by a district, municipality, or similar regional entity

The qualitative scoring was based on comparison of each alternative to supplying water use in Springwater from the City's potable water system. An alternative that offered no advantage compared with supplying use from the City's potable water system scored zero. An alternative offering an advantage compared with supplying water use from the City's potable water system scored positively. An alternative that was not as favorable as supplying water use from the City's potable water system scored negatively. These scores are shown in Table 1.

RESULTS AND DISCUSSION

Based on the evaluation of water supply alternatives for Springwater, water use in Springwater could be supplied cost effectively using a combination of potable water from the Gresham potable water system, agricultural well water, and industrial reuse. A dual distribution (purple pipe) system would be needed to distribute reuse water provided by agricultural wells and industrial reuse. The cost of such a system was not included in this analysis and was assumed to be borne by private development.

Reuse could become more cost effective if discharge requirements for the Gresham WWTP become more restrictive in the future. In particular, Gresham should monitor phosphorus limits and mixing zone requirements.

Table 2 indicates the result of financial and non-financial evaluation of the alternatives.

TABLE 1
Reuse Scoring Table
City of Gresham Reuse Study

	Springwater Evaluation Factors															
	Investment		Environmental							Societal		Management				Sum of Qualitative Rankings
Description of Alternative	Reduces Capital Cost	Reduces O&M Cost	Impact on Ambient Water Quality (Augmentation of Johnson Creek)	Reduces Peak Potable Water System Demands	Reduces Greenhouse Gas (Carbon Dioxide and Nitrogen Oxide Emissions)	Less Groundwater Impact	Better WW Discharge Quality	Improves Long-term Reliability of Water Supply	Less WW Discharge/Productive Use of WW	Enhances Public Trust	Beneficial Land Use Impact—Reduces Footprint	Ease of Management	Implementability	Skilled Workforce Availability	Compatible with Codes

TABLE 2
Springwater Water Supply Alternatives

Description of Springwater Water Supply Alternative	Capital Cost Factors		Estimated Sales Price		Sum of Qualitative Factors*	Notes
	Capital Cost	Ranking	Sales Price per HCF	Ranking		
All potable, 4.6 mgd total peak day demand for Springwater	$6,730,000	1	$1.88 to $2.84	3	0	Purchase price of $0.54 per thousand gallons
Agricultural wells at 1.4 mgd plus 3.2 mgd potable	$6,400,000	2	$0.85 for wells	2	-1	0.9 mgd available in Springwater
Industrial effluent reuse at 0.3 mgd plus 4.3 mgd potable	$6,624,000	3	$0.45 for 0.3 mgd of Water from Industrial	1	2	Assumes water quality similar to current industrial users
Storm water collection at 2.6 mgd, ASR 1.6 mgd, agricultural wells at 1.4 mgd, 0.63 mgd potable	$8,220,000	4	$3.80 for Stormwater Recovery Including Surface and ASR	4	-2	1 mgd capacity, 30 acres of impoundments 15 feet deep, pumps, self-backwashing strainer, no land costs, piping required;
Satellite reuse at 0.63 mgd plus 0.3 mgd industrial reuse plus 3.7 mgd potable	$14,400,000	5	$7.40 per for Satellite Reuse	5	-5	Membrane bioreactor with disinfection, Seasonal operation, Solids discharged to sewer and treated at Gresham WWTP, Does not include land or permitting costs, piping
Membrane bioreactors operated by regional entity	$21,000,000	6	$19.40 for ISDS Systems	6	-6	4,000 distributed units
Rainwater harvesting at 0.63 mgd plus 4 mgd potable	$35,800,000	7	$21.00 for Rainwater Harvesting	7	-1	100 gpd systems, 2,100 square-foot catchment area, roof washer,10,000-gallon tank, pump, and disinfection

* Sum of Qualitative Evaluation Factors: Zero is based on maximizing use of existing potable water supplies, +1 indicates better -1 indicated not as good

Notes:

(1) Estimated sales price based on 20-year present worth analysis of capital and operating costs discounted at 3.5 percent.

(2) Cost estimates are Class 5, suitable for comparison of alternatives in a planning study.

(3) Cost estimates include contingencies at 30 percent, engineering and legal costs at 25 percent, and City administrative costs at 14 percent.

mgd = million gallons per day

The following three alternative water supplies for Springwater had substantially similar costs and high qualitative evaluation scores:

- Reusing water produced by industrial operations and supplying the remainder of water demand from the Gresham potable water system scored the highest qualitatively and was similar in cost to supplying all water use from the Gresham potable system. This alternative had an evaluation cost of $14.3 million and qualitative evaluation scores with a total value of 2. In addition to constructing the potable water system, a reuse supply pipe system would be needed to convey industrial reuse water to point of use.
- Constructing a reuse system supplied from converted agricultural wells coupled with supplying the remainder water demand from the Gresham potable water system had the lowest evaluation cost of $13.8 million and qualitative evaluation scores of -1. In addition to constructing a reuse supply system to convey water from the wells to points of use, existing agricultural wells would need to be converted to supply the system.
- Supplying all water demand in Springwater from the Gresham potable water system had the second lowest evaluation cost at $14.1 million and qualitative evaluation scores totaling 0 because it was the alternative all other alternatives were compared against.

Based on current conditions and assumptions (e.g., potable water quality, quantity, and costs to further develop), the other alternatives should not be considered further at this time.

CONCLUSION

Water reuse in the Pacific Northwest is driven primarily by increasingly strict wastewater discharge limits. However, the global focus on water supply and climate change impacts on water supply reliability are other key factors driving wastewater reuse. The recommendations of this study are based on conditions that may change over time, possibly making reuse a more cost-competitive water resource.

Results of the study indicate that reuse within Gresham alone does not provide sufficient financial advantage. However, regional or watershed-scale solutions, wherein adjacent single-purpose utilities and neighboring municipalities join to share resources across jurisdictional boundaries, indicate promise for solutions that are cost effective and meet sustainability goals, including efficient use of resources, protection of surface water quality, and prudent management of limited groundwater resources.

The City should continue to consider the possibility of constructing a large, regional reuse system supplied from the Gresham WWTP over the next 5 to 10 years. A 4-mgd or larger regional system would achieve economies of scale that would start to make the cost of reuse water competitive with potable water from existing sources. Estimated sale price of such a source is $3.95/hundred cubic feet supplied. A regional reuse system would be cost competitive only if the Gresham WWTP needs to be modified to remove phosphorus seasonally in the future.

Reuse would add a water resource to the City's water supply. The reliability or cost of either existing source may change in the future as a result of regulatory changes, climate change, overdrafting of the aquifer, and other causes. If the reliability of sources of supply changes, the City should re-evaluate reuse as a source of supply.

If the City needs to construct significant conveyance infrastructure to transport wastewater from new development in Springwater to the Gresham WWTP, distributed or satellite reuse may be used to postpone investment in additional pump stations and pipeline.

Meaningful public involvement is critical to the success of reuse programs. The public often supports nonpotable reuse programs. Where concerns emerge, they generally include environmental safety, bacteria, and health risks to children. The acceptance of reuse projects is enhanced when the project is perceived as being part of a total water resources management program, the public has confidence in government's ability to protect public health, benefits of the project are quantified, and personal exposure is limited.

Abstract

Optimization of water distribution networks (WDN) has been one of the main challenges of researchers for many years. By paying one-dimensional attention to the minimization of WDN costs, one would ignore efficiency factors such as the reliability in delivering nodal demands with desired pressure. By considering the nodal pressure satisfaction as a rigid constraint, the maximum reliability will occur not reflecting the influence of a minor reliability reduction in the system cost. Hence, there is a need for designers and decision makers to have a landscape of the system performance, considering the flexible permissible nodal pressure and its effect on the system cost. In this paper, honey-bee mating optimization (HBMO) is applied in a benchmark WDN (two-loop) problem. The objective is minimization of cost with respect to different levels of reliability in the system during the operational period. Because in WDNs the decision variables are in a discrete domain, a minor decrease in the reliability of nodal pressure can yield a major cost reduction. Furthermore, by, considering different nodal pressure reliabilities, critical nodes of the network can be determined.

Keywords: WDN, Optimization, Reliability, HBMO.

Introduction

In the design of water distribution networks in spite of considering the system robustness in supplying nodal demands, reduction of the network capital cost should be taken into consideration. This necessity has prompted investigators to develop different methods and models to optimize the design of WDNs. Walski (2001) noted that "over the past decade and a half, distribution system optimization has not become the tool of the practicing engineer and, with good reasons, in spite of the several hundred research papers written on the subject." In his opinion, too much concentration on minimizing the cost of WDN without enough attention to the WDNs efficiency had been the main reason these methods had not become applicable. Thus, in the optimal design of WDNs, achieving the minimum cost in

addition to the analysis of network reliability should be considered as the basis of the optimization process.

Stanic et al. (1998) showed that if the objective function of the design problem is only minimizing pipe costs, the optimization model will definitely result in a tree-shaped network. On the other hand, the main reason of preferring a loop WDN to a tree-shaped one is having a more reliable network or, in other words, ensuring the supply of water with desired pressure especially under pipe failure conditions. This simple example showed that design of a WDN relying upon the minimization of its capital cost, regardless of analyzing the reliability factors in the system is not sufficient for designing a reliable network.

According to Mays (1996), there are two types of pipe failures in WDN; mechanical and hydraulic failures. Considering these two types of failures, many investigators have tried to introduce a well-defined reliability factor by combining both types (Todini, 2000). Nevertheless, reliability consideration in the water distribution network's design is really a complicated issue (Goulter & Bouchart, 1990). Moreover, existence of a large number of investigations on finding a unique definition for reliability and risk in WDNs indicates the lack of a universally accepted definition for this important issue in the networks (Todini, 2000). In this regard, Walski (1987) mentioned that a reliability factor should be able to reflect the condition of consumers during different failures in the network. Mainly, reliability in a water distribution network is the probability of meeting a desirable operation in the system, as it had been expected in the designing period (Farmani et al., 2005).

In what follows, the HBMO method is used to minimize the capital cost of a well-known two-loop network. With the aid of developing a simple definition of pressure reliability in the network nodes, a reliability measure is implemented in the optimization model by adding a penalty function. The results are assessed based on the final curve for network expenditure against different levels of reliability in the system. Identification of the network behavior during the years of operation for different levels of reliability and cost is the main objective of this study. Finally a simple approach for the recognition of critical nodes in the network is presented.

Honey-Bee Mating Optimization (HBMO) Algorithm

The Honey-Bee Mating Optimization (HBMO) algorithm is mainly inspired from the special manner of honey-bees living and mating in the beehive. In each hive there is a queen which is in fact the best bee of the colony. In the mating season the queen flies to a proper place and attracts the attention of the drones with a special dance. Afterwards with a fast sudden move, it flies towards the sky, which is known as mating flight, and in this manner only some of the best drones will be able to mate with the queen. After the mating flight the queen returns to the hive and starts laying eggs. Then the workers breed the broods and the best broods will be selected for becoming a new queen. Selected broods are fed by a special nutrient called royal jelly. After growing up, the best nurtured brood will replace the present queen provided that it is better than the queen. Hereby successive generations of honey-bees in the hive will move toward evolution.

Inspiring this natural process, Bozorg Haddad et al. (2006) developed a new heuristic approach named HBMO for engineering optimizations. In this algorithm, firstly a random set of decision variables is generated and is assumed as the queen. Then some other random answers will be generated and best ones will be combined

with the queen (queen generation). Afterwards, the new answers (broods) are improved by some predefined functions, and then the best answer is replaced by the queen if it is better. For a more comprehensive definition of the HBMO algorithm as a generalized metaheuristic, the reader is referred to Bozorg Haddad et al. (2006).

The HBMO algorithm was also applied on some mathematical optimization problems as well as a reservoir optimum operation. Since the results were promising, the HBMO algorithm has been selected as the optimization algorithm in this study.

Problem Formulation

With the aid of the HBMO algorithm, the optimization of pipe diameters in order to find the least-cost solution is performed. Thus, the objective function is minimizing pipe costs and the decision variables are pipe diameters. Furthermore, the problem consists of two integrated stages: optimization and simulation. In the optimization stage, the optimum diameters for all of the pipes are searched and in the simulation stage, for each set of decision variables the system performance is evaluated during the operational period. The optimum network cost for different levels of reliability is obtained by the optimization model, and in this way, comparison of different designs is possible. The following are the objective function and subjected constrains in the optimization model.

$$Minimize \quad OF = \sum_{i=1}^{NI} Cost_i + PF \tag{1}$$

$$Cost_i = C(D_i) \times L_i \tag{2}$$

$$PF = K \times (NF - \alpha)^2 \quad , \quad IF \quad NF > \alpha \tag{3}$$

$$NF = \sum_{t=1}^{T} \sum_{j=1}^{Nj} F_{j,t} \tag{4}$$

$$F_{j,t} = \begin{cases} 0 & , \quad If \quad h_{j,t} \geq h_{\min} \\ 1 & , \quad If \quad h_{j,t} < h_{\min} \end{cases} \tag{5}$$

$$h_{j,t} = \varphi(De_{j,t}, C_{(H-W)i}, D_i, L_i, H_R, Z_1, Z_2, ..., Z_j) \quad \begin{cases} \forall\ j = 1 \ \ to\, Nj \\ \forall\ i = 1 \ \ to\ NI \\ \forall\ t = 1 \ \ to\ T \end{cases} \tag{6}$$

$$De_{j,t} = EXP(Ln(De_{j,T}) - K_g \times t) \tag{7}$$

where: $Cost_i$ = cost of pipe i; $C(D_i)$ = unit cost of pipe i with diameter D; L_i = length of pipe i; PF = penalty factor; NF = number of failure conditions occurred in the simulation period; $F_{j,t}$ = failure condition in junction j and year t, which is zero if the pressure head in that junction is equal to or greater than the minimum permissible pressure head and is equal to one if the pressure head of the abovementioned node is less than the minimum head; α = allowable number of observing a pressure head less than h_{min} in network nodes during the operational period; h_{min} = minimum permissible pressure head in the network; $h_{j,t}$ = pressure head of junction j in year t; $De_{j,t}$ = demand discharge in junction j in year t; $C(H\text{-}W)_i$ = Hazen-Williams roughness coefficient for pipe i; H_R = reservoir head; Z_j = elevation of junction j on the ground; $De_{j,T}$ = demand of junction j in the final year of operational period; Nj = number of junctions in the network; T = number of years in the operational period;

K_g = coefficient of geometrical progression in equation (7); and K = a constant value dependant on the problem condition.

Network hydraulic analysis is performed using EPANET 2.0 hydraulic solver. Meanwhile the demand pattern during the operational period is considered as a geometrical progression.

In this study, according to the number of times that the pressure head in different nodes during the operation period is less than minimum permissible head (NF), I_{pr}[1] index is defined as

$$I_{pr} = 1 - \frac{NF}{T \times Nj} \tag{8}$$

Theoretically, the value of the pressure reliability index (I_{pr}) may vary between zero and one. If the summation of failures occurred in the operational period (NF) is equal to the denominator of the above fraction, the reliability of the network is zero and it means that in all junction nodes of the network, and in each year of operational period, it can not find any desirable condition in securing the minimum allowable pressure head. Subsequently, if the system is able to deliver water with at least the minimum desirable pressure head in all nodes during the operational period, numerical quantity of NF will be zero and therefore I_{pr} will be equal to one. It means that the reliability of the network is 100%.

Case Study

In this study, the benchmark problem developed by Alperovits and Shamir (1977) is used for testing the proposed approach. The two-loop network is a simple gravity-fed WDN, consisting of eight pipes (each 1000 m long with Hazen-Williams C value of 130), seven nodes and a single reservoir (Figure 1). The minimum pressure head requirements are 30-m for each node. Table 1 contains the commercially available pipe sizes and corresponding cost per unit length while the information of the network nodes is given in Table 2.

Furthermore the operational period is considered to be 30 years and the K_g coefficient is equal to one. Using the concept of the simple reliability index developed in this study, design of the two-loop network is performed in different levels of pressure reliability or for different quantities of α equal to 0, 3, 5, 8, 10, 13, 25, 62 and 124 which will correspondingly lead to the reliability values (I_{pr}) equal to 100%, 98.39%, 97.31%, 95.7%, 94.62%, 93.01%, 86.56%, 66.67%, 33.33%.

Results and Discussion

The results obtained using the HBMO for minimization of the network cost under different levels of reliability are shown in Table 3. In this study, for each level of reliability, six different runs of the HBMO algorithm were conducted. The average and the least costs obtained out of these six runs are also reported in Table 3 and the diameters mentioned in this table are relevant to the best runs (minimum cost). As it can be seen in this table, for the reliability measure of 100% (NF = 0) the network cost obtained is 419,000, which has been reported by other investigators (Savic and Walters 1997; Cunha and Sousa 1999; Zong Woo Geem 2006). The succeeding columns are relevant to the higher values of NF or in other words lower levels of I_{pr}, which have resulted in lower expenditures for the two-loop network. Clearly, by decreasing the level of I_{pr} or increasing the value of NF applied in the optimization model, the HBMO is able to consider lower diameters for the network pipes and consequently the network capital cost will be decreased. In Table 3, optimum commercial diameters for the two-loop network under different levels of reliability are also shown.

Table 3. Optimum diameters (inch) for designs under different levels of reliability and their costs

I_{pr}	100	98/38	97/31	95/69	94/62	93/01	86/56	66/67	33/33
NF / Pipe No.	0	3	5	8	10	13	25	62	124
1	18	18	16	16	16	16	14	12	10

5	16	14	14	12	14	10	10	8	1
6	10	12	12	8	8	1	3	6	1
7	10	10	10	10	10	6	1	1	1
8	1	1	1	4	1	8	6	1	1
Mimimum Cost	419000	377000	346000	318000	301000	287000	233000	157000	85000
Average Cost	419000	387250	350000	319000	309167	292833	241333	159333	89666

The changing manner of I_{pr} against network cost can be seen in Figure 2. The first noticeable point in this figure is the close proximity of the average cost graph to the minimum cost graph which shows the appropriate convergence of the HBMO algorithm in different runs. Second point is the low gradient of both graphs within the area of I_{pr} changing between 90% to 100%. This indicates that a slight decrease in the system reliability will result in a large decrease in the cost of the network. As shown in Table 3, if the network design is done based on the reliability level of 98.38%, the network cost will be 377,000 which is 10 percent less than the design with reliability of 100% and associated cost of 419,000. In this case, in the total 30 years of operation, only in two nodes; one during two years and the other during one year, a minor pressure deficit will occur (Table 4). Thus, for reliability levels of I_{pr} equal to 97.31%, 95.7%, 94.62% and 93.01%, we observe a cost decrease of 17.42%, 24.1%, 28.16% and 31.5%, respectively.

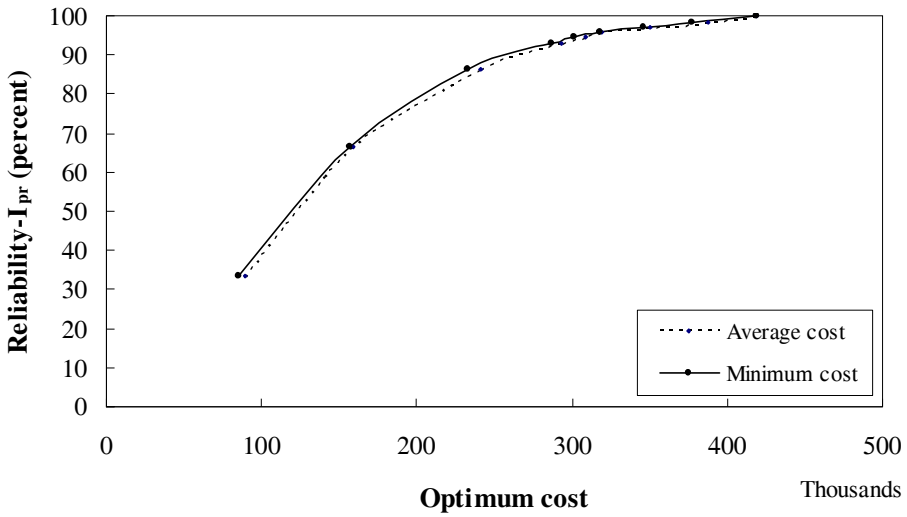

Figure 2. Changing manner of reliability against optimum cost

In contrast, by taking an overall look on the pressure matrix of six network nodes during the 30 years of operation, we can evaluate the performance of the system in supplying consumer's requirements. Nodal pressures for networks with reliabilities of 98.38% and 95.69% are shown in Tables 4 and 5 and Figures 3 and 4. As it can be seen in these tables and figures, nodal pressures in the first years of operation are much more than 30 m (minimum permissible pressure), and in the following years, because of the increase in the nodal demands, the pressure heads get nearer to 30 m. However, if the reliability of the network (I_{pr}) is equal to 98.38%, the maximum allowable number of pressure deficit is three, and for the reliability of 95.69% eight deficits are acceptable. As it can be seen, pressure deficits only occurred in nodes 6 and 7. Thus, these two junctions can be reported as the critical nodes of the two-loop network. Hence, if failure conditions occur because of the aging of the pipes and also due to the increasing of the network demands, the failures can be explored in these two nodes with acceptable probability. In the renewal and rehabilitation periods, finding the most impressive pipes and making decision about the kind of activities; such as changing, relining or adding pipes, are the most important challenging issues for the decision makers (Luong and Nagarur, 2005). Thus in these cases, having prior

information about the critical nodes can be a very good guide for engineers and water distribution network's decision makers.

Table 4. Nodal pressures for reliability level of 98.38%

Year / Node	1	2	3	…	27	28	29	30
2	59.97	59.97	59.96	…	56.13	55.34	54.39	53.25
3	49.92	49.91	49.89	…	38.60	36.28	33.48	30.12
4	54.94	54.93	54.91	…	45.92	44.07	41.85	39.17
5	59.90	59.88	59.85	…	44.64	41.51	37.74	33.20
6	44.92	44.90	44.88	…	32.61	30.09	27.07	23.42
7	49.91	49.89	49.87	…	36.46	33.71	30.40	26.41

Table 5. Nodal pressures for reliability level of 95.69%

Year / Node	1	2	3	…	27	28	29	30
2	59.95	…	57.32	56.78	56.13	55.34	54.39	53.25
3	49.93	…	42.13	40.52	38.60	36.28	33.48	30.12
4	54.92	…	48.73	47.45	45.92	44.07	41.85	39.17
5	59.89	…	49.39	47.23	44.64	41.51	37.74	33.20
6	44.87	…	36.45	34.71	32.61	30.10	27.07	23.42
7	49.87	…	40.65	38.75	36.46	33.71	30.40	26.41

Finally, Tables 4 and 5 (especially Table 4) indicate that by accepting a minor decrease in the reliability of the network; which will not lead to a major failure in its performance, we can reach a noticeable decrease in its capital costs. This can be valuable in developing countries facing severe cost limitations, and can be suggested to decision makers as a logical and economical option.

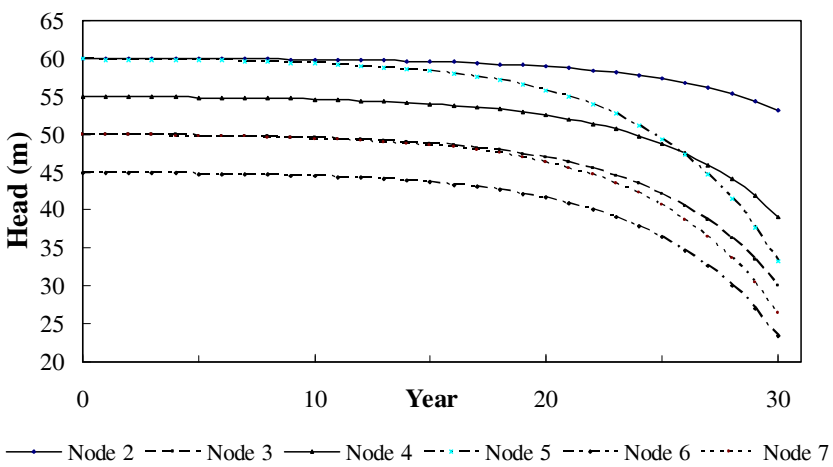

Figure 3. Changing manner of nodal pressures for I_{pr} = 98.38%

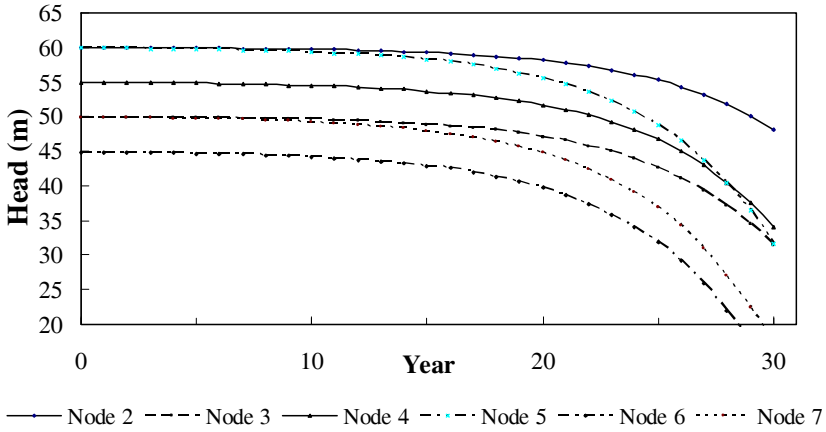

Figure 4. Changing manner of nodal pressures for I_{pr} = 95.69%

Concluding Remarks

This paper presented the optimization of a water distribution network under different levels of reliability. A constrained, single-objective HBMO is used as the optimization algorithm and by developing a simple definition for pressure reliability in network nodes, the proposed reliability index is placed in the constraint of the optimization model. Based on the results of this study, acceptance of a minor decrease in the network reliability yields noticeable cost savings. In fact, provided that it is possible to tolerate minor failures in the network in final years of operation or even if it is acceptable to renew the system in final years, one can decrease the network's capital costs by a small decrease in the system's reliability. Furthermore, by decreasing the reliability of the system during the optimization process, one can find critical nodes in the network. Since a decrease in the pressure reliability in a WDN is due to the reduction of its nodal pressures, by imposing a minor decrease in the reliability of a constrained optimization model one can easily find the critical junctions in the network.

Abstract

Many surface waters throughout the United States exceed one or more common forms of regulated contaminants. This study describes a pilot-scale facility that was designed to remove nitrate and selenium (selenate) from surface waters by microbial processes. In an oxygen-free environment, nitrate is reduced to nitrogen gas and selenate is reduced to an insoluble salt that precipitates onto the biofilm. Based on the results from bench-scale tests, a demonstration facility was designed and constructed adjacent to a creek in Irvine, CA. This paper describes the design, construction and lessons learned in the development of a gravel-filled filter whose effluent will meet the current standards for nitrate and selenium in surface waters. The facility treated in approximately 194,000 gallons per day and was designed to run in a contaminant removal, recycling and back-flush mode. The benefits of this system are the consistent removal of nitrate and selenium throughout the year with a low O&M cost and the possibility of multiple uses of the land that could include both the below-grade filter and a parking lot or recreational area at the surface. This project is an example of a local water district assuming the role of environmental steward whose projects provides multiple benefits to the community and wildlife within the watershed.

Introduction

This is a companion paper to the presentation and paper entitled “Engineering Natural Filtration Systems to Remove Selenium, Nitrate, and Bacteria from Impaired Surface Waters - Foundational Studies” by Ken Susilo, Eric Strecker, and Randy Sundberg. This first paper deals with initial bench-scale studies to determine the feasibility of removing nitrate and selenium from surface waters using a bacteria-based filter. The use of bacterial filters for contaminant removal is in-part is based on the earlier studies of gravel-based subsurface flow constructed wetlands such as the works by Gersberg et al. (1989, 1986 and 1985). There is a substantial body of scientific literature that characterized the microbial processing of contaminants such as selenium and nitrate (Rege et al., 1999 and Takada et al., 2008). The complex microbial communities that form on gravel have the abilities to remove a broad spectrum of dissolved pollutants. By understanding the principals of

oxidation/reduction potential (ORP) and microbial ecology, systems can be designed to treat contaminated water on a scale of gallons to millions of gallons per day. By developing a slight gradient in ORP within the facility, it is possible to remove both the nitrate at the ppm level and selenium at the ppb level.

There is always a certain level of difficulty in making the transition from bench-scale studies to full-scale operations. This report describes the design and construction of a field-scale project entitled the "Cienaga Filtration Project Field Demonstration Facility". The source water comes from Peters Canyon Wash in Irvine, CA. The companion paper to this report describes the basic biogeochemistry that is involved in the simultaneous removal of nitrate and selenium from surface waters and the optimal conditions needed to consistently perform this task on a continuous basis. Figures 1 and 2 below show the various oxidation states of selenium and how it can be reduced from its most oxidized form of selenate (SeO_4^-) to elemental selenium or an insoluble selenium salt.

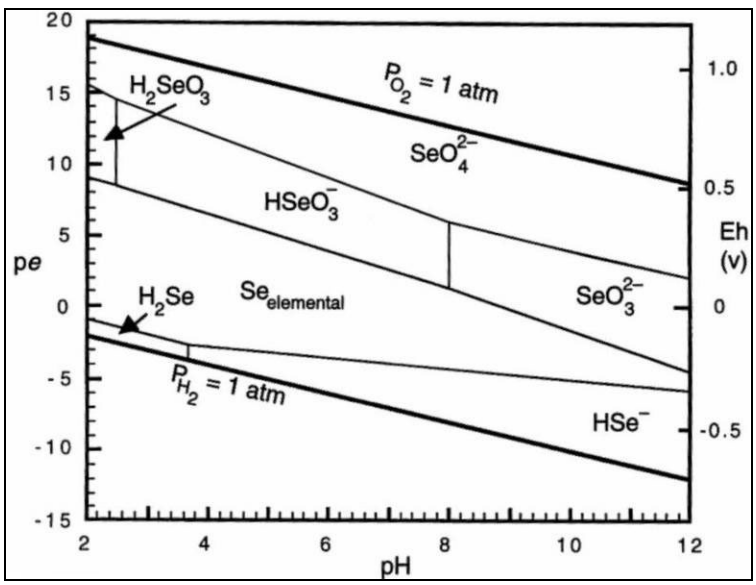

Figure 1. A plot with the ORP shown on the Y axes expressed at p*e* or Eh and the X axis as the pH showing the different oxidation states of selenium.

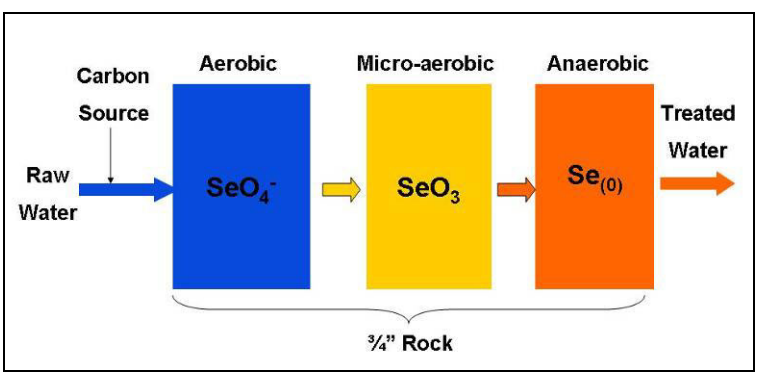

Figure 2. A simplified flow diagram showing the reduction of selenate to elemental selenium.

Background
The Irvine Ranch Water District (IRWD) service area encompasses a large part of San Diego Creek watershed. IRWD voluntarily proposed the Cienega Filtration Project (Project), included in the Natural Treatment System (NTS) Master Plan as Site No. 67, for the removal of nitrogen and selenium from Peters Canyon Channel, a tributary of the watershed. The environmental impacts of the Project were evaluated in accordance with the requirements of the California Environmental Quality Act (CEQA) in the NTS Environmental Impact Report, which was adopted on April 24, 2004.

Project Location
The Project is located on Irvine Unified School District (IUSD) property, at the site of the IUSD new Creekside Continuation School in the City of Irvine in Orange County, California. The Project is constructed within a 3.75-acre utility easement on the eastern, down gradient, end of the IUSD property.

Project Description
The proposed Project will intercept surface flow from Peters Canyon Channel and pump it through a subsurface filter, consisting of an aggregate matrix encased within a geomembrane cell, to remove nitrogen and selenium through a microbial reduction process. Treated water will be adjusted for minor hydrogen sulfide levels and restored to a proper dissolved oxygen level prior to being reintroduced to Peter Canyon Channel. The proposed Project will be implemented in two phases: Field Demonstration Phase and Full Size Phase.

Field Demonstration Phase
The Field Demonstration Phase will process approximately 0.3 cfs of diverted flow from Peters Canyon Channel. Once constructed in June 2008, this phase will operate for approximately two years during which data will be collected in order to set the design criteria for the Full Size Phase.

The Demonstration Phase consists of the following elements:
Intake System - The Intake System includes collection piping, wet well structure, and pump to intercept surface flow from Peters Canyon Channel. Water from the channel will be directed to an intake wet well from where it will be pumped to the subsurface filter through the Pretreatment System.
Pretreatment System - Pretreatment includes filter units and electron donor injection. The filters are intended to remove particles from water while the electron donor is intended to encourage bacterial growth in the subsurface filter bed.
Subsurface Filtration - Subsurface filtration consists of a below grade 200'x40'x10' (Length x Width x Depth) media matrix cell. This media matrix will be below finished grade by at least 3 feet and will be sealed using geomembrane fabric.
Post-treatment System - Post-treatment includes an oxygenation cascade structure and an off-gas collection and polishing system. The oxygenation cascade structure will be

located west of the proposed process area pad and will be few feet above finished grade. It will also house the finished water pump needed to return the treated flow back into the creek. The gas polishing system will consist of carbon filters.
Full Size Phase - The Full Size Phase will adopt the same operational methodology as the Field Demonstration Phase. The design criteria for this phase will be refined per the information that will be learned during the operation of the Field Demonstration Phase. The overall subsurface filtration will include 10 individual below grade cells, which are expected to treat up to 3.0 cfs of creek diverted flow.

The challenge in designing this demonstration facility was to create an environment that maintains a constant oxygen-free (anaerobic) condition that allows for the removal of nitrate and selenium. The addition of an electron donor in the form of a carbon source that is easily assimilated by the bacteria helps to create necessary reducing conditions. The processes in the demonstration facility are given in the summary below.

- A temporary diversion structure will be installed in Peters Canyon Wash to channel water to a wet-well.
- Within the wet-well, a pump station will provide the necessary lift to feed the treatment system.
- A self-cleaning pressure filter will be installed on the discharge side of the pump to remove solids from the influent water prior to introduction to the treatment wetland.
- The influent will be amended with an electron donor in the form of a soluble carbon-containing compound to encourage bacterial growth in the media bed.
- A distribution network will introduce water uniformly along the upstream cross-section of the underground media bed that is enclosed by a watertight barrier. The media matrix is an inert mass of coarse aggregate that provides attachment sites for bacteria.
- The amended water will flow by gravity through the media bed where it will come in contact with nitrate and selenium reducing bacteria. As the amended creek water passes though the media matrix, bacteria utilize the food and oxygen for respiration establishing complex community of organisms called a bio-film. After all of the available oxygen in the water has been consumed, some bacteria will begin to use other substances (electron donors) to fuel their respiratory cycle. Under these anoxic conditions, soluble selenium (selenate and selenite) lose electrons and become reduced to insoluble elemental selenium or combine with other elements to form selenides which are also insoluble. The insoluble forms of selenium become trapped in the bio-film as long as the reduced oxidation state is maintained.
- If the system becomes too reduced, sulfate could be reduced liberating hydrogen sulfide gas (H_2S) which, if present in high enough concentration, can be an odor nuisance or even create a public health risk. In the pre-design optimization study (PDOS), appropriate conditions for selenium removal were achieved without generating noticeable amounts hydrogen sulfide gas. However, the PDOS was conducted under laboratory conditions and was monitored frequently for chemical

constituents, (ORP), and mechanical conditions. The Field Demonstration will not receive the same frequency of attention and a number of factors could result in the system becoming too reduced and H_2S being generated. Therefore, a gas monitoring, collection, and treatment system will be included as a contingency.

- A collection network will convey the treated water to a discharge wet-well.
- Within the discharge wet-well, a pump will provide the lift required to discharge the treated water.
- A pressure filter on the discharge line will remove biosolids entrained in the effluent stream. Similar to the influent stream, the amount of solids collected from the effluent stream is anticipated to be small, and will not reach hazardous levels of metals of interest or legacy pesticides. This will be confirmed during the Field Demonstration by laboratory testing. Solids will be handled, stored, and disposed of in accordance with all applicable regulatory requirements.
- A system will be provided to re-oxygenate the effluent prior to discharge to the Peters Canyon Wash.
- An energy dissipater will be installed where the treated water is reintroduced to Peters Canyon Wash to prevent erosion and scour when treated flows and untreated flows are mixed. (GeoSyntec, 2005)

Having tested a variety of substrates, the research team from GeoSyntec developed a set-criteria for the gravel substrate in the demonstration facility as shown in Table 1.

Table 1. Specification for Filter Media

$C_u=D_{60}/D_{10}$ =	<2.5
$C_c=D^2_{30}/(D_{10}\ D_{60})$ =	1.0<Cc<3.0
Specific Gravity, Bulk S.S.D.	NA
Absorption, %	<4%
Cleanness Value	>70
Abrasion Loss, C 131	<35%
Sodium Soundness, C 88	<15%

Figure 3 below shows a schematic of the demonstration facility where the water can be distributed from the side and collected in the middle or distributed at one side and can be collected at on the opposite side. The system was designed to be 40'W X 200'L X 10'D and have a one day residence time. The was designed to treat 0.3 CFS (194,000 gallons/day) which is one tenth the flow needed to be treated in Peters Canyon Wash. Figure 4 is a schematic diagram of the flow from Peters Canyon Wash through the system and back to the wash.

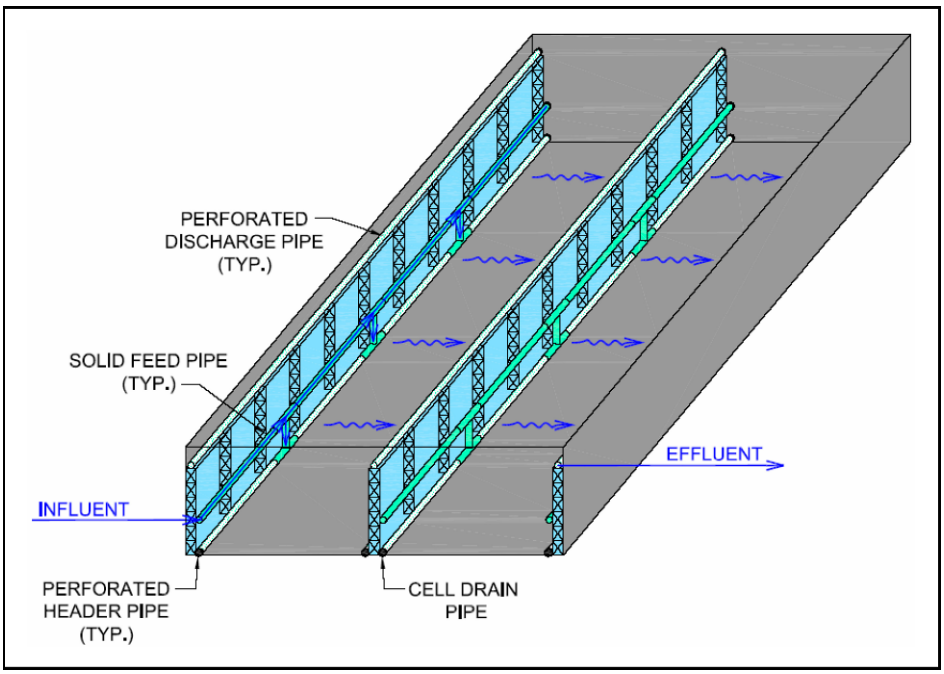

Figure 3. Schematic diagram of the water distribution system within the demonstration facility.

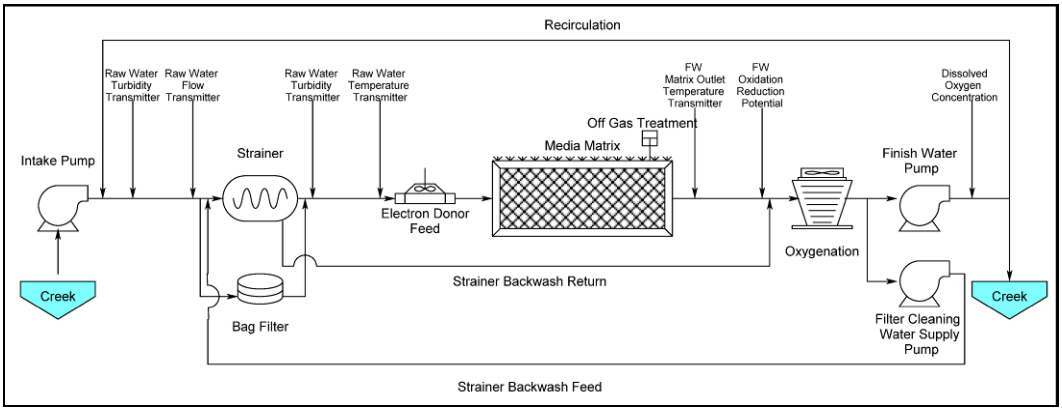

Figure 4. Flow diagram of the demonstration facility in its normal operation mode.

The demonstration facility was designed to operate in three modes. In the normal operating conditions the water goes from highly aerobic conditions to anaerobic, the selenium and nitrate are removed, the water is filtered, oxygenated and returned to the wash. During storm events the flow in the wash can increase by one to two orders of magnitude and can carry a high solids load. During these times the facility goes into a recycle mode where the effluent is fed back to beginning of the system and no new water is brought into the system until the storm has passed and the solids load in the wash has decreased. Over time, there will be an accumulation of biosolids within the facility. A full-scale version of this facility will also have a back-wash mode that will allow the excess biomass to be removed from the gravel matrix and sent to a waste treatment plant. This aspect of treatment was not incorporated in the demonstration phase of the project.

In order to build the demonstration facility it was necessary to obtain permits from several agencies. These agencies included; USACE - Nationwide Permit (404 compliance), The Santa Ana River Regional Water Quality Control Board - 401 Water Quality Certification, The California Department of Fish and Game - Streambed Alteration Agreement (Section 1602), The Orange County Flood Control District - Encroachment Permit, The Orange County Sanitation District - Special Purpose Discharge Permit (periodic back flush water) and The South Coast AQMD - Air/Odor Control Permit. Construction of the facility began in July 2007 and took one year to complete. The approximate cost of construction was $ 2.2 million and the facility was to be operated for two years.

The facility was designed to operate with a minimum of maintenance or oversight. All the electrical components and sensors were linked into a SCADA system and connected to the IRWD Michelson Treatment Plant. During normal operations a field worker would visit the site once each day for approximately one hour. The authors of the companion report will discuss the results from the first year of operations of this facility with regards to water quality and optimization of operating conditions.

Abstract

With the growing demands on better effluent quality and higher cost-effectiveness wastewater treatment systems, the traditional methods to design and manage the Wastewater Treatment Plant (WWTP) by experiences and current standards could not meet rapidly developing wastewater industry. As a result, it is an inevitable trend to develop mathematical models and corresponding simulating software for wastewater treatment processes to improve the performance and cost-effectiveness of critical environmental protections. Based on International Water Association (IWA)'s activated sludge models (ASMs), an Activated Sludge Process Simulator – Carbon Oxidation (ASPS-CO) program is developed to simulate and optimize the design, operation, and management of WWTPs. With the focus on the carbon oxidation only, the ASPS-CO program models three typical biological processes: aerobic growth of heterotrophs, death and lysis of heterotrophs, and "hydrolysis" of particulate organics. This ASPS-CO program also develops its own sub-modules to calibrate model parameters, convert traditional measured data, and replace commonly missing data, etc. Therefore, it can simulate not only the water quality of influent and effluent in WWTPs, but also the operating conditions of series continuous stirred-tank reactors (CSTRs): for example, concentration and composition of biomass, and quality and composition of the wastewater, etc. The simulations of the Tianjin Ji-zhuang-zi WWTP using the ASPS-CO program indicate that the results closely match the measured data, which proves to be a reliable method to simulation other WWTPs. In conclusion, this method can provide a reliable theoretical foundation for engineers and researchers to design, operation, and management of wastewater treatment processes. Furthermore, it provides confidences in decision-makers to use this method as an important reference to make critical decisions.

Keywords: ASM (Activated Sludge Model), Activated Sludge Process, Mathematical Model, Wastewater Treatment Plant (WWTP), Simulation, Calibration, ASPS-CO

1. Introduction

With the growing demands on better effluent quality and higher cost-effectiveness wastewater treatment systems, the traditional methods to design and manage the Wastewater Treatment Plant (WWTP) by experiences and current standards could not meet rapidly developing wastewater industry. As a result, it is an inevitable trend to develop mathematical models and corresponding simulating software for wastewater treatment processes to improve the performance and cost-effectiveness of critical environmental protections. There are several mathematical models available for activated sludge wastewater treatment processes, of which the most widely used ones are Activated Sludge Model (ASM) series by International Water Association (IWA). However, current design, operation, and water quality measurement of wastewater treatment make it difficult to apply the complicated ASM models. Therefore, based on experience on ASM models and process design, the ASM No.1 model is simplified to be applied specifically to conventional carbon-oxidation plug-flow activated sludge process. The simplified activated sludge process simulator – carbon oxidation (ASPS-CO) model is developed on MATLAB platform and includes 8 components, 3 biochemical processes. Related parameter optimization and conversion module between conventional measured and new modeling data are also developed to be applied to simulate the real operation in Tianjin Ji-zhuang-zi wastewater treatment plant (WWTP).

2. Mathematical Modeling

2.1 Model Assumptions

The mathematical model is specifically for conventional plug flow activated sludge process. The simplified model only considers the carbon-oxidation and lysis of particulate organic matters by heterotrophs under aerobic condition. This model includes three key biochemical processes: aerobic growth of heterotrophs, death and lysis of heterotrophs, and "hydrolysis" of particulate organics. Therefore, the simplified model is called Activated Sludge Process Simulator – Carbon Oxidation (ASPS-CO). The model assumptions are:

- System is operated under constant temperature.
- Constant pH and close to neutral.
- Reaction rates are constant and not affected by wastewater characteristics.
- Do not consider the effect of N, P and other inorganic nutrients on the organic matter removal and cell growth.
- Assume secondary clarifier has only physical sedimentation and no biochemical reactions.

2.2 Biochemical Process and Component Matrix

Table 1 shows the 8 components and three biochemical processes in ASPS-CO system. Table 2 shows the symbols and definitions of components and parameters on Table 1.

Table 1. ASPS-CO system matrix of components and biochemical processes.

i–Components / j-Biochemical process		1 X_S	2 X_{BH}	3 X_D	4 S_S	5 S_O	6 S_{ALK}	7 X_I	8 S_I	Biochemical reaction rate r_j
1	Aerobic growth of heterotrophs		1		$-\frac{1}{Y_H}$	$\frac{1-Y_H}{Y_H}$	$-\frac{i_{N/XB}}{14}$			$\hat{\mu}_H(\frac{S_S}{K_S+S_S})(\frac{S_O}{K_{OH}+S_O})X_{BH}$
2	Death and lysis of heterotrophs	$1-f$	-1	f'_D						$b_{LH}X_{BH}$
3	"Hydrolysis" of particulate organics	-1			1					$k_h\frac{X_S/X_{BH}}{K_X+X_S/X_{BH}}(\frac{S_O}{K_{OH}+S_O}$
	Observed convention rates	$r_i=\sum_{i=1}^{3}\psi_{ij}r_j$								

Table 2. Symbols and definitions of the ASPS-CO system components and parameters.

Component No.	Component symbol	Definition
1	X_S	Slowly biodegradable substrate, mg/L as COD
2	X_{BH}	Active heterotrophic biomass, mg/L as COD
3	X_D	Debris from biomass death and lysis, mg/L as COD
4	S_S	Readily biodegradable substrate, mg/L as COD
5	S_O	Oxygen, mg/L as COD
6	S_{ALK}	Alkalinity
7	X_I	Inert particulate organic matter, mg/L as COD
8	S_I	Inert soluble organic matter, mg/L as COD
9	Y_H	Heterotroph yield rate, mg biomass/mg COD removed
10	f'_D	Debris to active biomass ratio, dimensionless
11	$i_{N/XB}$	Nitrogen content rate of biomass, mg N / mg biomass
12	$\hat{\mu}_H$	Heterotroph growth rate, hr^{-1}
13	K_S , K_X	Half saturation coefficient, mg COD / mg biomass COD
14	K_{OH}	Soluble oxygen switch coefficient, mg/L as O_2
15	b_{LH}	Heterotroph decay rate, hr^{-1}
16	k_h	Hydrolysis rate, mg COD / (mg biomass COD·hr)

2.3 Simulation System with 5-CSTR Model

Conventional activated sludge processes commonly use rectangular plug-flow aerobic reactor, where the influent and recycled biomass are met at the front end of the reactor. For simulation purposes, the reactor is usually assumed to be 3-5 continuous stirred tank reactors (CSTR) in series. In this paper, 5-CSTR in series is used and its schematic diagram is shown below on Figure 1.

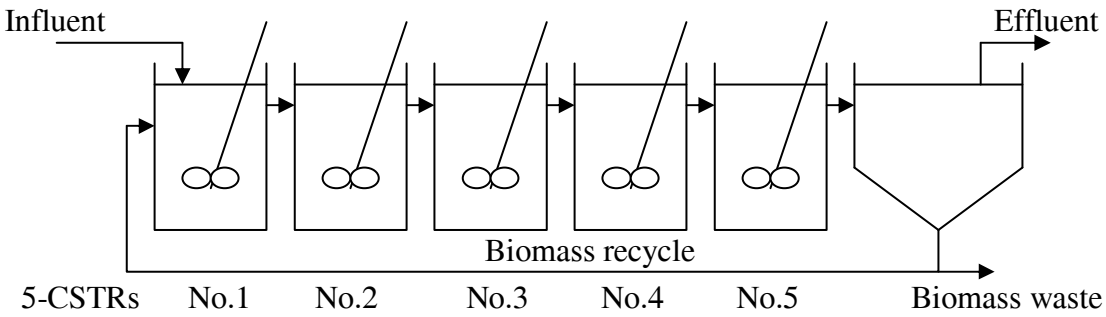

Figure 1. Schematic diagram of five CSTRs in series with all influent and all biomass recycle to the first reactor.

3. Data Conversion Methods

The traditional measurement only includes COD, BOD, SS, which are different from what are used in the ASM model. Therefore, a proper conversion method is required to convert between the traditional data and modeling data. The ASPS-CO divides the total COD (COD_{TO}) into four parts: (1) particulate slowly biodegradable COD (X_{SO}), (2) soluble readily biodegradable COD (S_{SO}), (3) inert particulate COD (X_{IO}), and (4) inert soluble COD (S_{IO}). The influent and effluent conversion methods are shown below.

Influent conversion method:

$$COD_{TO} \approx (2.1)(BOD_5) \quad (1)$$

$$COD_{BO} \approx (1.14)(BOD_u) \approx (1.71)(BOD_5) \quad (2)$$

$$COD_{IO} = COD_{TO} - COD_{BO} \quad (3)$$

$$X_{IO} \approx (0.375)(1.50)(VSS) = (0.56)(VSS) \quad (4)$$

$$S_{IO} = COD_{IO} - X_{IO} \quad (5)$$

$$X_{SO} \approx (0.375) \times (COD_{BO}) \quad (6)$$

$$S_{SO} = COD_{BO} - X_{SO} \quad (7)$$

Effluent conversion method:

$$BOD_5 \approx X_S + S_S \quad (8)$$

$$COD_{Cr} \approx (X_S + S_S + X_I + S_I)(0.9) \quad (9)$$

$$SS = X_I / 0.56 / 0.75 \quad (10)$$

4. Simulation of Tianjin Ji-zhuang-zi Wastewater Treatment Plant

Tianjin Ji-zhuang-zi wastewater treatment plant was constructed in 1980s, which adopts the conventional activated sludge process. In order to consider the temperature effect, the simulation is divided into four "seasons": Winter, Spring, Summer and Fall. The simulation results as compared to the real measured data for Winter and Summer are shown below.

Winter:

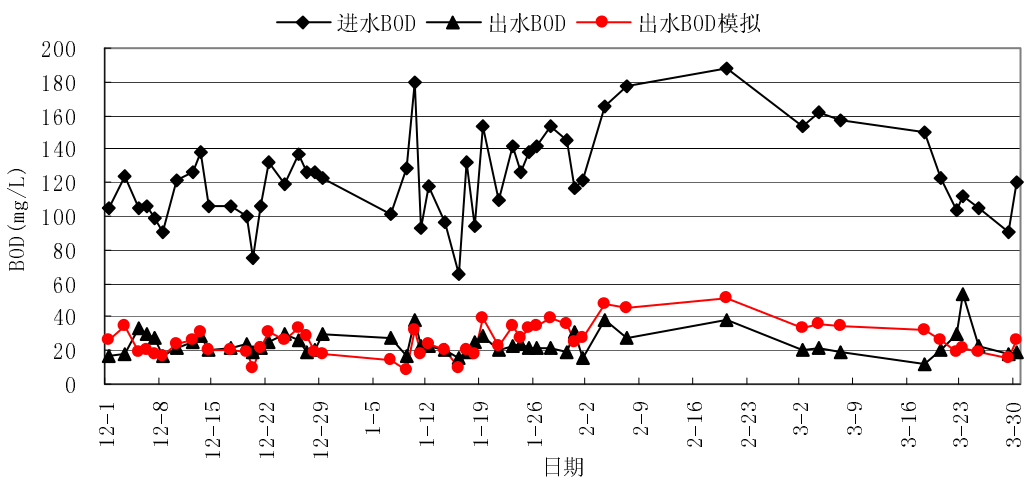

Figure 2. BOD_5 of influent measured (diamond), effluent measured (triangle), and effluent simulated (circle) at Tianjin Ji-zhuang-zi WWTP in Winter.

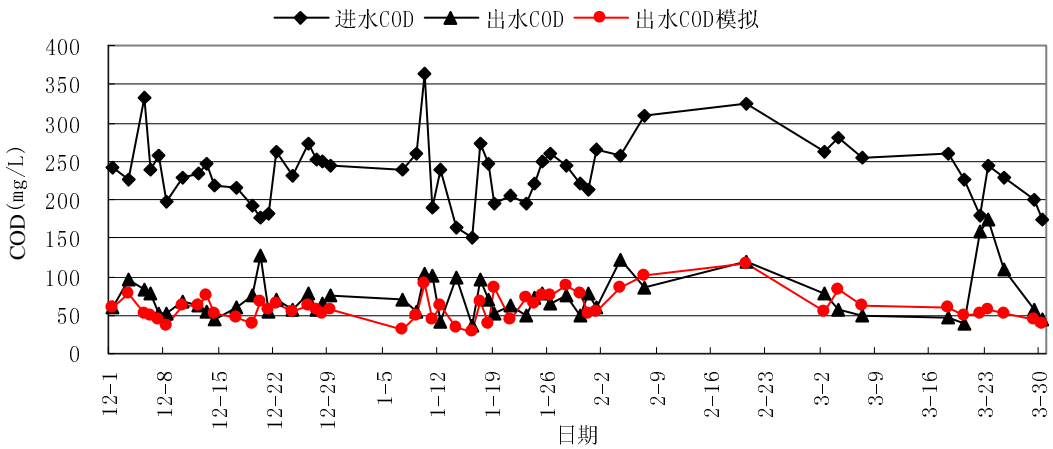

Figure 3. COD_{Cr} of influent measured (diamond), effluent measured (triangle), and effluent simulated (circle) at Tianjin Ji-zhuang-zi WWTP in Winter.

Summer:

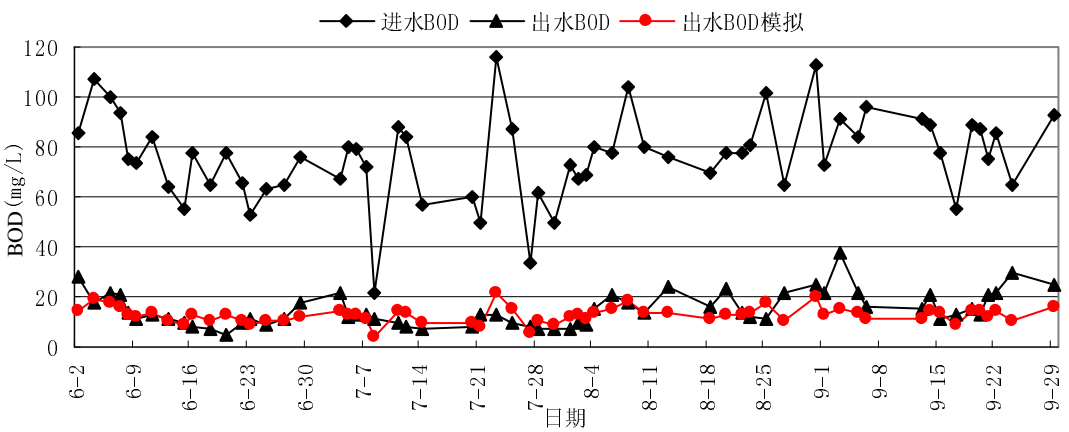

Figure 4 BOD_5 of influent measured (diamond), effluent measured (triangle), and effluent simulated (circle) at Tianjin Ji-zhuang-zi WWTP in Summer.

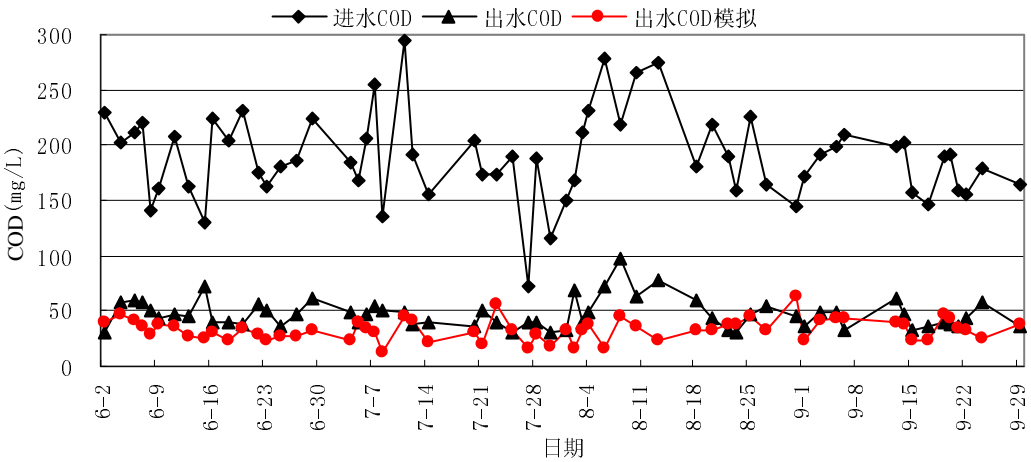

Figure 5. COD_{Cr} of influent measured (diamond), effluent measured (triangle), and effluent simulated (circle) at Tianjin Ji-zhuang-zi WWTP in Summer.

As shown on Figures 2-5, the modeling results match the measured effluent data very well, which reflects the influent wastewater characteristics and changing trends. It should be noted that the simulated results are finalized after several rounds of systemic calibrations. At the beginning, the default parameter values are used. Then the measured effluent data are used to calibrate corresponding model parameters. This calibration step will be repeated until the simulation results are satisfied to a preset standard.

5. Conclusions

The practical application of the ASPS-CO program to Tianjin Ji-zhuang-zi WWTP indicates the simulation results are very close to the real measured data, which proves that the ASPS-CO can be applied to activated sludge processes. The ASPS-CO simulation can reflect the effect of parameters and operation conditions on the treatment performance, which can assist in optimizing the treatment facility during the design and operation phases. In other words, this method can provide a reliable theoretical foundation for engineers and researchers to design, operation, and management of wastewater treatment processes. Furthermore, it provides confidences in decision-makers to use this method as an important reference to make critical decisions.

It should be noted that the ASPS-CO model is only one model module of the whole simulation system. The whole simulation system will be a powerful application program that includes different programming modules and various treatment process models. Therefore, continuous development of computing technologies and wastewater treatment process models will significantly affect the improvement and widely applications of the modeling and simulation system.

Risk Assessment to the Environment Due to Anionic Surfactants in Treated Sewages and Dried Sludges

ABSTRACT

Paper presents the outcome of a 21 month monitoring study on the anionic surfactants (AS) at the 70 ML/d UASB-PP (up-flow anaerobic sludge blanket - polishing ponds) based sewage treatment plant (STP). The average removal of AS was only around 30%. Appreciable concentration of AS was being discharged to the watercourse (average 3.60 mg/L; range 1.69 – 4.94 mg/L). Compare to this >92% removal was found in an 18 ML/d activated sludge process (ASP) based STP with an average 0.13 mg/L of AS is discharged to the surface waters. AS concentrations averaged 5909 and 810 mg/kg dry wt. in wet UASB and dried sludges respectively.

Treated sewage from UASB-PP based STP when discharged to aquatic ecosystems are likely to generate substantial risk. Post-treatment using 1 day detention, anaerobic, non-algal polishing ponds was found ineffective. Need of utilizing an aerobic method of post-treatment of UASB effluent in place of an anaerobic one has been emphasized. Natural drying of UASB sludge on sludge drying beds (SDBs) under aerobic conditions results in reduction of adsorbed AS by around 86%. Application of UASB sludges on SDBs was found simple, economical and effective. While disposal of treated UASB-PP effluent may cause risk to aquatic ecosystems, use of dried UASB sludges is not likely to cause risk to terrestrial ecosystems.

Key words: Anionic surfactants; up-flow anaerobic sludge blanket process; sand drying beds; risk assessment; aquatic risk; terrestrial risk.

INTRODUCTION

Advantages of anaerobic technology over aerobic in terms of production of biogas, less sludge production, less land requirement, etc., up flow anaerobic sludge blanket (UASB) based sewage treatment plants (STPs) are more preferred than activated sludge process (ASP) based STPs (Mahmoud, 2002). Anionic surfactants (AS) specially deserve special interest since they (i) show a pronounced ecotoxicological effect on aquatic/terrestrial organisms and (ii) are used in large quantities in consumer products like laundry detergents, cleaning and dish washing agents and personal care products, which are discharged into wastewater after use. Largest group of anionic surfactants (AS) is linear alkylbenzene sulfonate (LAS) and it may enter the aquatic environment when raw or partially treated sewage is discharged. Venhuis and Mehrvar (2004) has reported that 0.02 to 1.0 mg/L LAS in aquatic environment can damage fish gills, cause excess mucus secretion, decrease respiration in the common goby, and damage swimming patterns in blue mussel larva. van de Plaasche et al. (1999), Belanger (2002), HERA (2007) reported no-effect concentration of 0.27 mg/L for LAS to aquatic organisms. The key for protecting the environment from the negative impact of down-the-drain-chemicals (surfactants) is the treatment of the sewage in a (biological) wastewater treatment plant (WWTP).

In the last 20 years, over 150 UASB reactor units have been built in the world for treating high BOD industrial wastes. More than 900 UASB reactor units are currently operating all over the world (Alves et al., 2000). Nearly 35 plants already exist in India, which treat wastewaters from widely varying sources like distilleries, dairies, pulp mills, pharmaceutical units, starch maize units, textile units, tanneries and sewage (Arceivala, 1999).

Anaerobic sewage treatment technology has been successfully used in India as a large number of UASB based STPs (over 25 in number with total installed capacity more than a million m^3/d) are currently working. However, in spite of the full-scale application of UASB since over fifteen years, fate of AS in UASB based STPs is not known. Limited information available is based on research carried out in laboratories and reported results are varying in nature as the experiments and scenarios investigated by the authors were different (Denger and Cook, 1999; Angelidaki et al., 2000; Mogensen and Ahring, 2002; Sanz et al., 2003). Risk generated by UASB effluents and sludges to both aquatic and terrestrial environments is not assessed. This paper presents results of an extensive risk assessment study carried out over a period of 21 months using European Union Technical Guidance Document (EU-TGD).

MATERIALS AND METHODS

UASB and ASP based STPs located in Ghaziabad (28^0 40′ N, 77^0 28′ E) and in Haridwar (29^0 58′ N, 78^0 13′ E) were selected for the study. Their installed capacities are 70 and 18 ML/d respectively. Ghaziabad is situated along river Hindon and Haridwar is

situated along river Ganga respectively. A general schematic flow diagram of the combined upflow anaerobic sludge blanket-polishing pond (UASB-PP) system along with sampling locations is shown in Fig. 1. Study was carried over a period of twenty one months covering different seasons. One conventional ASP based STP of 18 ML/d capacity situated at Haridwar was selected for the study.

At the STP, sewage reaches after multistage pumping. It is primarily because of flat topography of the city and presence of number of water channels. At every stage, sewage is detained for a short time and gets mixed up in the sewage sump. It is finally collected at the main pumping station (MPS) just ahead of each STP. From MPS, it is pumped round the clock more or less at a uniform rate. It flows through the STP by gravity. Based on this, it was decided to collect only grab samples during the present study. Grab samples of wet UASB reactor and dried SDB sludges were also collected in polyethylene containers. All samples were collected, preserved, and transported as per methods listed in Standard Methods (APHA, 1998, 2005).

AS were measured in samples of sewage as methylene blue active substances (MBAS) as prescribed in Standard Methods (APHA, 2005). LAS (Hach, USA) was taken as a reference. AS in sludge samples were extracted by soxhlet extraction technique using methanol (Marcomini and Giger, 1987) and than analyzed using MBAS method. All AS concentrations are reported in this paper as "mg/L for sewage and mg/kg dry wt. for sludge samples (calculated as LAS, mol. wt., 318)". A spectrophotometer (DR 4000, Hach, USA,) was used for colorimetric measurements.

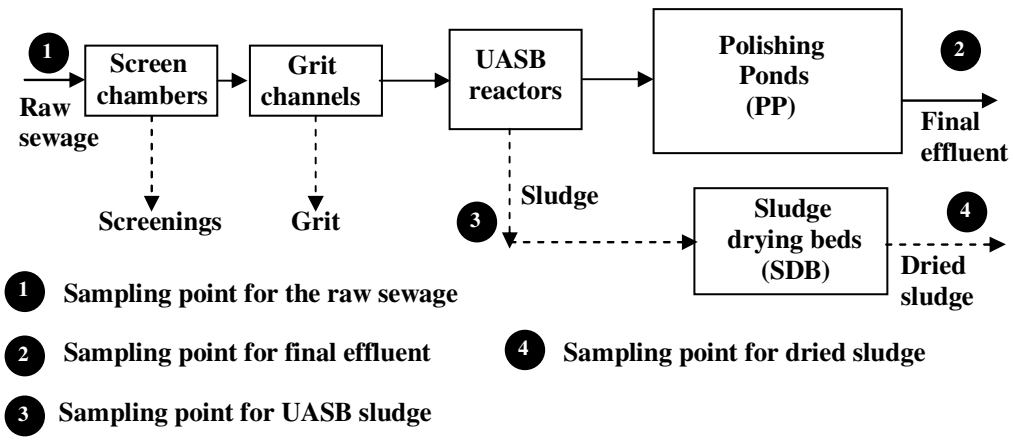

Fig. 1 Typical flow diagram of UASB based STPs studied along with sampling locations.

RESULTS AND DISCUSSION

UASB-PP based STP

Wide variations in influent characteristics were noticed. Over the period of study, total AS averaged 5.16 mg/L. Table 1 presents the influent and effluent concentrations of AS with standard deviations. The average removal of AS was only around 30%. Appreciable concentration of AS was being discharged to the watercourse (average 3.60 mg/L; range 1.69 – 4.94 mg/L). On the contrary, average BOD removal was 81%. In a UASB-PP system aerobic conditions do not develop at any stage. The polishing ponds that receive effluent from UASB reactors are different than conventional waste stabilization ponds that treat raw sewage. PPs were designed for a significantly shorted hydraulic retention time (HRT) of 1 days compared to oxidation ponds (20-30 days). Algal growth is not expected at HRT < multiplication rate of algal cells at 20^0 C i.e. 2 to 2.5 days. PPs could be defined as non-algal, anaerobic, and having short HRT of 1 days. Use of such PPs for post-treatment of UASB effluents is a widely accepted practice especially in India. It can be attributed mainly to low initial cost and their easy design, operation, and maintenance. Accordingly, effluents were found to be devoid of oxygen at all the STPs throughout the study period. This was perhaps the main factor which contributed towards limited reduction 30% of AS. AS is strongly sorbed to sludge due to its hydrophobic character. Prats et al. (1997) have also suggested that a large amount of the load of AS into sewage treatment plant is associated with suspended material. It is subsequently withdrawn from UASBR as sludge is removed. Part of it is also removed in PP as biosolids escaping from UASB settle. It is presumed that aerobic post-treatment of UASB effluent can substantially reduce AS concentration rather than an anaerobic option like PP. Many aerobic post-treatments have been tried including ASP, trickling filter (TF), aerated lagoon (AL), and down-flow hanging sponge (DHS) etc. However, MBAS has been measured as a parameter only by Gasi et al. (1991) while using ozonation as post-treatment of UASB effluent. The effluent from UASB reactor contained 4.63 to 5.30 mg/L of AS. Application of ozone for 30 and 50 minutes resulted in effluent AS concentrations of 1.52 and 0.53 mg/L respectively. Ozone oxidized AS effectively.

Average concentrations of AS in wet UASB and finally dried SDB sludges over a period of twenty one months are given in Table 2. UASB wet sludges contained considerable amount of AS concentration. Average values ranged from 5909 mg/kg dry wt. (70 ML/d STP, Ghaziabad). Municipal sludges in India have not been analyzed for AS concentrations earlier. The AS concentrations in dried-stabilized sludges were also found to be averaged 810 mg/kg dry wt. for the five STPs. Drying on SDB on an average resulted in an overall AS reduction of around 86% Application of anaerobic wet UASB sludge on SDBs not only resulted in drying and volume reduction but also in considerable elimination of AS.

ASP based STP

Final effluent contained on an average 0.13 mg/L AS with a removal of around 94%. Removal of AS was found to be much higher compared to that found in UASB-PP system.

Removal efficiencies of AS in different treatment systems: A comparison

Average AS concentration in the treated effluents and percentage removals for different STPs are summarized in Table 1. Concentrations of LAS (or AS) in treated sewage from previous studies and present work are compiled in Fig. 1. Low effluent LAS (or AS) concentrations (<0.2 mg/L) in case of ASP are quite clear. Compared to this UASB-PP effluents contain very high concentrations of AS (>3.5 mg/L). LAS (or AS) removals >99% have been reported by several researchers for ASP while in case of UASB it was found to be ≤30%.

Risk assessment: Aquatic environment

The risk assessment to aquatic environment due to the presence of AS in treated sewage was evaluated according to the procedure laid down in European Union Technical Guidance Document (EU-TGD, 1996, 2002). Risk is assessed depending on (a) predicted environmental concentration (PEC) of AS, and (b) predicted no effect concentration (PNEC) i.e. the concentration below which unacceptable effects on organisms are not likely to occur. Risk assessment is based on the risk quotient (RQ) which can be calculated by using Eq. 1.

$$RQ = PEC/PNEC \quad (1)$$

RQ>1 indicates a risk of adverse effect to the environment.

PEC_{Water} **:** The measured average concentrations of anionic surfactants in final effluents from different STPs are summarized in Table 1 (column 4). EU-TGD has suggested a dilution factor of 10 (TGD default dilution coefficient) which was used to calculate predicted environmental concentration in receiving water (PEC_{water}, Table 1, column 7).

$PNEC_{Water}$ **:** No observed effect concentrations (NOEC) of LAS worked out by Peterson et al. (2003) based on long-term laboratory screening tests for aquatic plants/organisms at three trophic levels (algae, crustaceans, and fish) are 18, 0.27, and 0.90 mg/L respectively. SIDS (2005) has also mentioned several references in which NOEC of 0.27 mg/L has been utilized for assessment of risk to aquatic environment. Values reported are for LAS while in the present work AS were determined. However, since LAS predominate among AS, NOEC values reported for LAS were used to calculate PNEC. An assessment factor of 10 has been suggested (EU- TGD, 2002) for the estimation of PNEC for LAS. An assessment factor of 10 is normally applied when long-term toxicity NOECs are available for at least three species across three trophic levels. This yields lowest value of predicted no effect concentration in receiving water ($PNEC_{water}$) of 0.027 mg/L.

Calculated values of RQ for different STPs are also given in Table 1. Values of RQ were also calculated using LAS or AS concentrations in treated effluents as reported

by several research workers (Fig. 2). These values are much greater than 1. Even ozonation of UASB effluent as tried by Gasi et al. (1991) did not reduce RQ to <1 (Fig. 3). Treated effluents from UASB based STPs when discharged to aquatic ecosystems are likely to generate substantial risk. There is a need to provide effective aerobic post-treatment to UASB effluents. The RQ values in case of ASP reported by various research workers and also found in the present work were <1. Compared to UASB based STPs, RQ for ASP is quite low.

It could be concluded that present method of post-treatment of UASB effluent is not effective as far as removal of AS is concerned. Use of any of the aerobic methods e.g. ASP, DHS, AL, TF, OP etc. may yield better removal of AS. Recently, at some of the STPs in India, aerated lagoons have been installed for post-treatment in place of PPs. At one of STPs in Karnal (India) of treatment capacity of 40 ML/d, a 1 ML/d DHS post-treatment experimental unit is being operated since last 4 years. However, since AS is not a monitoring parameter in India, no data regarding concentrations of AS in influent and effluent is available for ALs or DHS system.

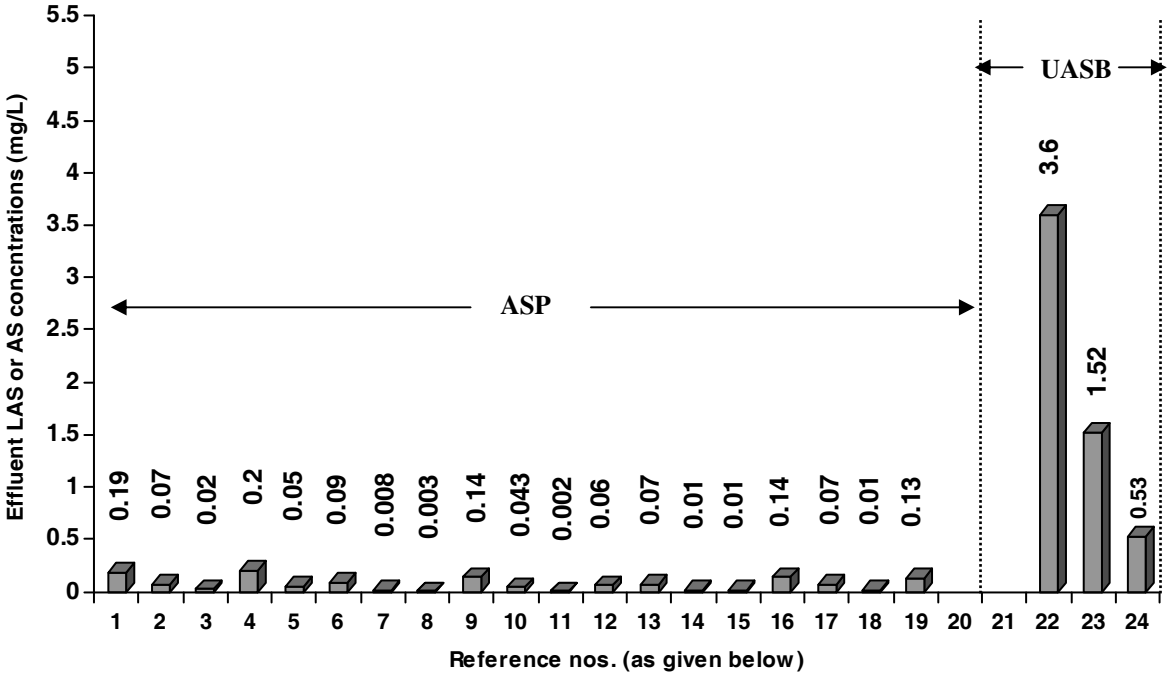

Table 1: UASB and ASP based STPs: Effluent Concentrations and Estimated PEC, and RQ Values (aquatic ecosystem).

STP	Capacity (ML/d)	Average AS conc. (mg/L)		Average % Removal		PEC_{water} (mg/L)	RQ
		Influent(±SD)	Effluent(±SD)	AS	BOD		
UASB	70	5.16 (± 0.78)	3.60 (±0.81)	30	81	0.360	13.3
ASP	18	2.05	0.13	94	92	0.013	0.48

$PNEC_{water}$= 0.027 mg/L (Petersen et al., 2003; HERA, 2004)

Risk assessment: Terrestrial environment

The PEC is used for characterization of risk to (a) terrestrial organisms: direct exposure and (b) to humans via crops and /or cattle product: indirect exposure. A value of PNEC of 4.6 mg/kg dry wt. has been as suggested by Gejlsbierg et al. (2001), Jensen et al. (2001), and HERA (2004) with an idea to protect all terrestrial microbial processes and functions.

Fig.2. ASP and UASB based STPs: Concentration of LAS or AS in treated effluent.

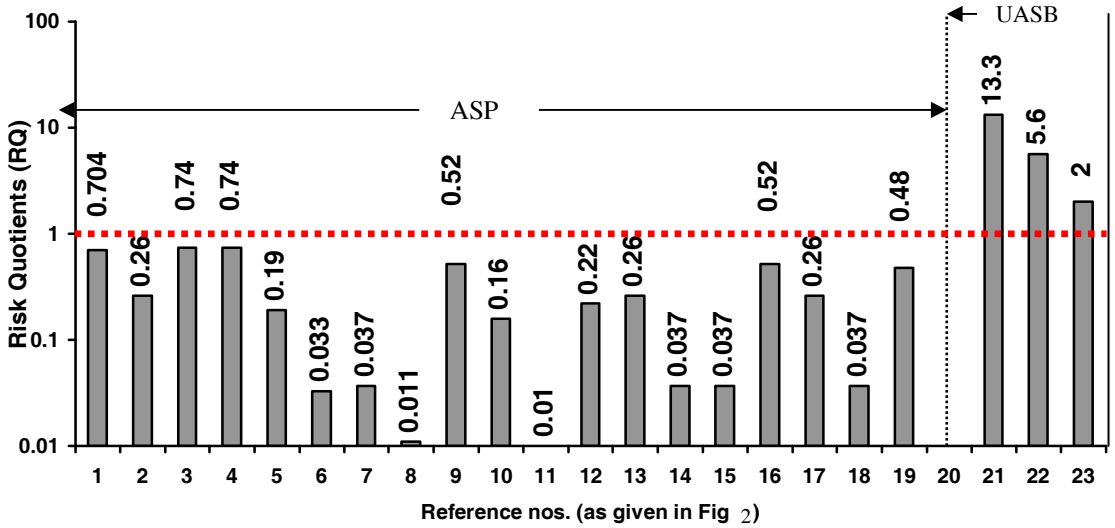

Fig. 3. Values of risk quotients to aquatic environment due to discharge of ASP, OP, and UASB effluents.

The starting concentration at time t = 0 in soil ($C_{o\ soil}$) due to one sludge application in the year can be calculated using Eq. 2 as suggested by EU-TGD (1996).

$$C_{o\ soil} = C_{sludge}\ APPL_{sludge} / DEPTH_{soil}\ RHO_{soil} \quad (2)$$

Where:

C_{sludge} = average concentration of AS in dry sewage sludge (mg /kg dry wt.) (Table 2, column 2)

$APPL_{sludge}$ = dry sludge application rate (kg/m^2 yr)
Soil and agricultural soil: 0.5 kg/m^2 yr (EU-TGD 1996)
Grassland: 0.1 kg/m^2 yr (EU-TGD 1996)

$DEPTH_{soil}$ = mixing depth of soil (m)
Soil and agricultural soil: 0.20 m (EU-TGD 1996)
Grassland: 0.10 m (EU-TGD 1996)

RHO_{soil} = bulk density of wet soil (1500 kg/m^3)

The concentration of AS will be high just after sludge application (in the beginning of the growing season), and much lower at the end of the year due to removal processes. Therefore, the concentration of AS in soil needs to be averaged over a certain time period. Different averaging times are considered (EU-TGD 1996) for different end uses of sewage sludge. For the soil based ecosystems a period of 30 days after application of sludge is suggested. In order to determine biomagnification effects and indirect exposure to man, extended period of 180 days has been recommended.

The average concentration of AS over a certain period of time can be calculated considering the first order biodegradation rate in the top soil. Summation of all concentrations over a certain period (30 or 180 days) and dividing by the corresponding days gives the average daily concentration. This is achieved by integrating the equation given in the EU-TGD (1996), which simplifies to the following expression (Eq. 3) if one neglects the contribution of aerial deposition.

$$PEC_{local} \text{ or } C_{avg.\ soil} = C_{o\ soil}\ \{ (1- e^{-kt}) / k\ t\} \quad (3)$$

Where:

k = first order rate constant in top soil (d^{-1})

t = averaging time (d)

AS monitoring studies in sludge amended soil (Holt et al., 1992) have indicated a biodegradation rate corresponding to a half-life of 10 days, namely $k = \ln 2 / t_{0.5} = 0.0693\ d^{-1}$. Taking $k = 0.0693\ d^{-1}$, values of $C_{avg.\ soil}$ (PEC local) were calculated for the three different end uses two STPs (Table 2).

Taking values of PEC and PNEC, RQ were calculated for different applications and STPs (Table 2). RQ values were found <1 It could be concluded that (a) aerobic digestion or (b) natural drying on SDBs of aerobic and anaerobic sludges result in biodegradation of AS in sludges to such a level that there subsequent application on land for any end use is not likely to pose any risk.

Table 2: Estimated PEC and RQ values for three different applications of dried sludges

STP: capacity (ML/d)	Dried-stabilized sludge: average AS concentration (mg/kg dry wt.)	Soil		Agriculture soil		Grassland	
		PEC local (mg/kg dry wt.)	RQ	PEC local (mg/kg dry wt.)	RQ	PEC local (mg/kg dry wt.)	RQ
UASB: 70	810	0.57	0.12	0.11	0.02	0.04	0.01
ASP:18	760	0.53	0.12	0.10	0.02	0.04	0.01

PNEC = 4.6 mg/ kg dry wt. (Jensen et al., 2001; Gejlsbierg et al., 2001; HERA, 2004)

CONCLUSIONS

1. In a UASB-PP system, removal of anionic surfactants were found only 30%. Removal of AS were found much less compared to ASP based STPs.
2. UASB-PP effluents were found to have very high concentrations of AS (>3.5 mg/L) compared to low concentrations of AS in ASP (<0.2 mg/L) effluents.
3. AS concentrations averaged 5909 and 810 mg/kg dry wt. in wet UASB and dried-stabilized sludges from sludge drying beds respectively.
4. Post-treatment using 1 d detention, anaerobic, non-algal polishing ponds was found ineffective in reducing risk generated by UASB effluents to aquatic ecosystems. Need of utilizing an aerobic method of post-treatment of UASB in place of anaerobic one has been emphasized.
5. Natural drying of UASB sludges on sludge drying beds (SDBs) under aerobic conditions results in reduction of adsorbed AS by around 86%. Use of dried UASB sludges is not likely to cause risk to terrestrial ecosystems.

ABSTRACT

The efficiency of three RBF systems has been presented. At Haridwar dug wells are water abstraction devices and the source water is the River Ganga which is relatively less polluted. In non-monsoon months, RBF reduced turbidity and coliform by 1 and 3 logs respectively. Removal in monsoon increased to more than 2 and 4 logs for turbidity and coliform respectively. Vertical tube-wells in the vicinity of the Lake Nainital pump lakebank-filtrate at Nainital. The well water when compared with lake water showed 5.2 log removal of total coliform, 4.2 log removal of fecal coliform, 1.4 log removal of turbidity and 1.6 log removal of COD. At Mathura, water is collected by a radial collector well placed in the bed of the River Yamuna, a polluted river. Reduction in DOC and UV absorbance was 0.3 log. Colour decreased by 0.4 log. Total and fecal coliform removals were 2.6 and1.3 logs respectively.

INTRODUCTION

In India, in almost all major cities, raw waters exhibiting wide range of temporal variations are drawn from surface sources and treated to provide safe drinking water for human consumption. Natural purification of polluted river water through riverbank/riverbed filtration (RBF) could be one of the alternatives to attenuate organic, microbial and other pollutants. RBF is a process in which surface water is subjected to ground passage before being collected, treated and used as drinking-water. During infiltration and travel through aquifer, surface water contaminants are attenuated as water is subjected to a combination of processes such as filtration, microbial degradation, attachment to aquifer grains, and dilution with background groundwater to name a few (Kuehn and Mueller, 2000; Ray et al., 2002; Worch et al., 2002, Partinoudi and Collins, 2007). Bank-filtration facilities constructed in favorable hydro-geological settings yield high-quality waters that need little further treatment.

In many countries of the world, alluvial aquifers hydraulically connected to a watercourse are preferred sites for drinking water production given the relative ease of shallow groundwater exploitation, the generally high production capacity and the proximity to demand areas (Doussan et al., 1997). In Europe, river and lake-bank filtration sites are in operation over a century to provide safe drinking water to cities

like Dusseldorf, Berlin, Dresden, Amsterdam, Zurich, Bratislava, Budapest, Belgrade etc. The success of such schemes is dependent on the microbial activity and chemical transformations that are commonly enhanced in the colmation layer within the riverbed compared to those that take place in the surface or ground waters. It has been found to effectively remove pollutants like particulate matter, man made or natural organic compounds, bacteria, protozoa, algae, viruses, disinfectant byproduct precursors and a large number of chemical micro pollutants (Kühn and Müller, 2000). The process is also in use in many communities in the USA like Louisville, Jacksonville, Sonoma County, Lincoln, Cedar Rapids etc. However, designs of RBF facilities vary. Grischek et al. (2002) have summarized data from some RBF sites in United States and Europe. They have found that the most sites are located in alluvial sand and gravel aquifers having hydraulic conductivities more than 1×10^{-4} m/s (more than 9 m/d). The thickness of exploited aquifers ranges from 5 to 60 m. At most sites in Europe, the distance between river bank and production wells is more than 50 m and travel times are more than 50 days.

In India, riverbank filtration is in practice for more than 25 years. However, scientific background and documentation is lacking. RBF sites have a wide range of variation in (a) nature of the abstraction devices (b) quality of the source water and (c) hydro-geological characteristics of the aquifer. Efficiency of three RBF systems, in terms of quantum of removal of river-borne pollutants through the geological material has been presented in this paper. These systems are widely different from each other. At one of the sites dug wells are water abstraction devices and the source water is the River Ganga which is relatively less polluted. Vertical tube-wells in the vicinity of the Lake Nainital pump lakebank-filtrate at the second site. At the third site, water is collected by a radial/horizontal collector well placed in the bed of the River Yamuna, a polluted river. RBF has special relevance for India where most of the rivers receive domestic, industrial and agricultural wastes. A few rivers in certain stretches are quite polluted. Despite pollution, these rivers continue to be used as the source of water for the water supply schemes. This article presents the results of field monitoring from 2005 to 2006 (Haridwar), 1997 to 2006 (Nainital), and 2006 to 2008 (Mathura) covering non-monsoon and monsoon months.

STUDY SITES

At Haridwar (29° 58' N, 78° 13' E; State-Uttarakhand; Northern part of India), sixteen dug wells abstract nearly 22 ML of bank-filtrate every day. Study was carried out at one of the dug wells (partially penetrating, large diameter, bottom entry, lined well; diameter = 10 m, depth = 8.7 m) located on an island. The well is made-up of bricks. The bottom is open and packed with gravel and course sand to allow the water to enter. In the east River Ganga flows at a distance of 320 m while Upper Ganga Canal (UGC) and New Supply Channel (NSC) flows at distances of 252 and 90 m respectively. River Ganga is polluted by municipal wastewater from small communities and non point urban and agriculture surface runoff. Water is filtered through 17 m thick unconfined sand-gravel aquifer which is in direct hydraulic contact with the river and its two canals. Over a period of 25 years, production capacity has reduced by around 83% (3.28 to 0.55 ML/d) due to aquifer clogging.

At Nainital (29° 23' N, 79° 27' E; State-Uttarakhand; Northern part of India), between 1990 and 2005, five tube-wells were installed adjacent to the Nainital Lake. The depths of these tube-wells range from 22.6 to 33.4 m. The sixth and seventh tube-wells of 36.7 and 35.9 m depths respectively were commissioned in 2006. At present, 24.1 ML/d of water is drawn from the tube-wells located at a distance of less than 100 m from the lake. They abstract (a) lake water after passage through the bank/bed (b) subsurface water flowing towards the lake and (c) groundwater during non-monsoon. However, as the wells are located in unconsolidated landslide debris very close to the lake, a substantial portion of the pumped water is replenished by the sub-surface out flow from the Lake Nainital as seepage. The proportion of lake water in the water delivered by wells located near the lake was estimated to vary from 25% to 80% in the non-monsoon and monsoon seasons respectively (Nachiappan et al., 2002).

Mathura (27° 28' N, 77° 41' E; State-Uttar Pradesh; Northern part of India) was selected for the investigations based on the two reasons. The first reason concerns the characteristics of the Yamuna water exploited for the water production. At Mathura, river water is polluted, coloured and unacceptable. According to Central Pollution Control Board (CPCB, 2006) about 85% of the total pollution in the river is caused by the domestic sewage, mainly from the urban centers. The second reason was the placement of the well in the centre of the river which is quite different than the well established practice in Europe and USA (Hunt et al., 2003). Sub-surface water is collected from a radial well having thirteen radials (total length of 522 m) laid at 15.5 to 18 m below the bed of the river. The detailed water quality studies for such a centrally placed well have not been reported.

MATERIALS AND METHODS

At the first site i.e. Haridwar, water samples from production well, River Ganga (3 locations), NSC (3 locations) and UGC (3 locations) were collected nine times during non-monsoon and monsoon periods starting from November 2005 (beginning of the winter) to September 2006 (end of the monsoon) at regular intervals. At the second site i.e. Nainital, water samples from tube-wells (1-5) and Nainital Lake (12 locations) were collected six times during non-monsoon and monsoon periods from 1997 to 2006. At the third site i.e. Mathura water samples from the Yamuna at several locations and riverbank filtrate were collected 7 times starting from the month of November, 2006 to May, 2008. Temperature, pH, conductivity, and dissolved oxygen (DO) were measured on-site by Thermo Orion 4 Star pH and conductivity meter, and DO meter (Hach HQ10). Samples were transported to the Environmental Engineering Laboratory, IIT Roorkee and analyzed for turbidity, major ions, residues, DOC, colour, UV-absorbance, ammonium nitrogen, and most probable number (MPN) of coliform bacteria in accordance with the procedures laid down in the Standard Methods (2005). DOC concentrations of water samples were determined using a TOC-V CSN Total Organic Carbon Analyzer (Shimadzu). UV-absorbance at 254 nm was measured using Hach DR/4000U Spectrophotometer. Hach 2100AN turbidity meter was used to measure turbidity. Colour on Pt-Co scale (expressed in colour units, CU) was determined using Hach DR/890 colorimeter with 25 mm cell.

RESULTS AND DISCUSSIONS

Site 1: Haridwar. The range of values of water quality parameters are compiled in Table 1. Water from river and canals was 50-100 times more turbid in monsoon than non-monsoon. The increased bacterial count by around 10 times and decreased conductivity by around 0.6 times were also noticed in the monsoon samples as compared to non-monsoon period. The quality of water from the production well, however, was not found to vary significantly in monsoon and non-monsoon periods. Water from canal and/or river becomes rich in minerals as it flows through the aquifer to the production well. The extent of mineralization depends on the rate of water flow, extent of groundwater mixing, duration for which water is held up in the aquifer, chemical nature of the aquifer material, and the nature of water flowing through the aquifer. Cumulative effect of these processes was judged by measuring and comparing the conductivity and total dissolved solids (TDS) in water from river/canal and production well.

As the river water passes through the aquifer, the water also gets filtered and most of the turbidity and organics are removed. This is quite clear from the results compiled in Table 1. Reduction in turbidity, total coliform, fecal coliform and organics in the water samples collected from the production well are quite noticeable (Fig. 1). The water from production well when compared with the source water showed 2.5 log removal of total coliform, 3.5 log removal of fecal coliform, 0.7 log removal of turbidity in non-monsoon period and 4.7 log removal of total coliform, 4.4 log removal of fecal coliform and 2.5 log removal of turbidity in monsoon period. A removal of 1.0 log is also observed for organics (in terms of UV absorbance) during the monsoon period. The removal can be attributed to physical filtration and straining of particles.

Site 2: Nainital. Water samples from the tube-wells (1-5) and from the lake at different depths were analyzed separately during monsoon and non-monsoon periods. The detailed observations regarding water quality parameters are compiled in Table 2. Tests for total coliform in all the tube-well samples yielded negative results indicating that water is free from any fecal contamination and is fit for drinking purpose as per Indian Standard (IS 10500, 1991).

The lake is fed by surface, sub-surface and groundwater. The water from tube-wells is the groundwater under the direct influence of (i) surface water from Lake Nainital and (ii) seepage water flowing through faults and fractures from Sukhatal sub-catchment. The water drawn from the tube-wells is expected to be different from the lake water depending upon the mixing of the bank filtrate and groundwater during different months in a year. Following were the main points of difference:

- TDS, electrical conductivity : Tube-well water > Lake water
- Organic matter : Lake water > Tube-well water
- Total coliform : Lake water > Tube-well water

Lake water of widely varying characteristics e.g. temperature, TDS, oxidation reduction potential (ORP) etc. (due to seasonal variations, depth stratification,

Table 1. Water Quality Comparison: River/Canal Water vs. Production Well Water.

Parameter	River and canals		Production well	
	Non-monsoon	Monsoon	Non-monsoon	Monsoon
pH	7.9–8.5 (8.3)	6.9–8.1 (7.5)	7.3–7.9 (7.6)	7.5–7.7 (7.6)

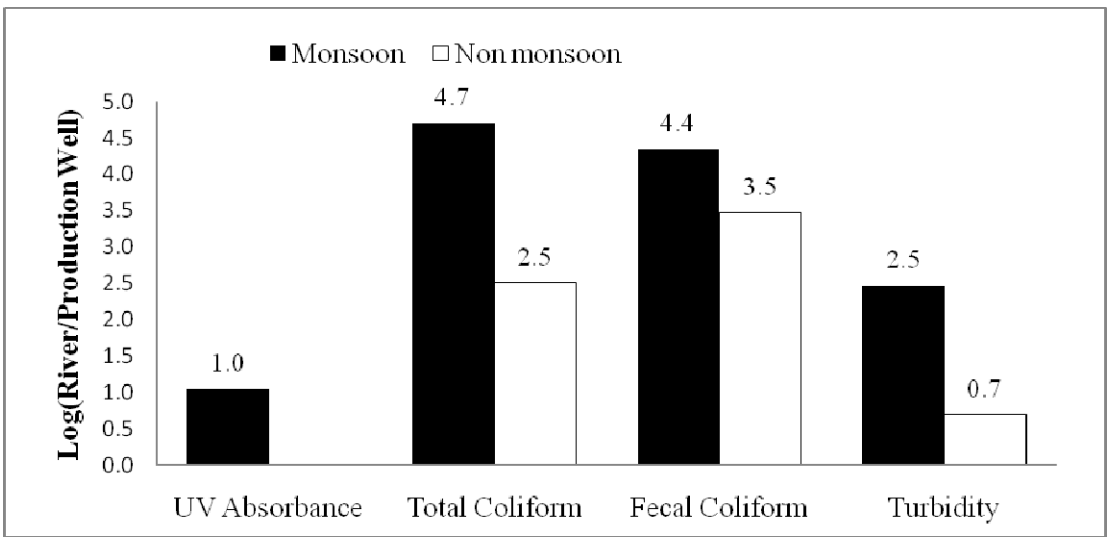

Figure 1. UV absorbance, turbidity and coliform counts of production well relative to river/canal water.

seasonal overturn, and yearly changes) enters into slotted pipes of tube-wells at different levels after traveling through the aquifer formed by natural deposits around the lakebank. During bank filtration the water from the lake presumably causes weathering and/or leaching of materials from the deposits. Average electrical

conductivity of lake water increases from 577 μS/cm in monsoon period to 640 μS/cm in non-monsoon period. It therefore, seems that processes operating in monsoon and non-monsoon seasons are somewhat different. It has been shown that during monsoon, more water flows (80% lake water + 20% groundwater probably from fault and fractures, Nachiappan et al., 2002) through the deposited aquifer material, causing weathering and/or leaching of material. During non-monsoon, however, the flow of lake water through deposits is reduced considerably resulting in reduced level of leaching. The proportion of mixing of groundwater predominates and most probably leads to significant increase in minerals.

Table 2. Water Quality Comparison: Lake Water vs. Tube-Well Water.

Parameters	**Monsoon**		**Non-monsoon**	
	Lake water	**Tube-well water (Nos.1-5)**	**Lake water**	**Tube-well water (Nos.1-4)**
Temperature (^{0}C)	18-24 (21)	16.5-17 (17)	NA	NA
Turbidity (NTU)	6.7-7.3 (7.1)	0.1-0.4(0.25)	3.7-6.1 (4.9)	0.1-0.3 (0.2)
Conductivity (μS/cm)	544-605 (577)	821-954 (869)	631-653 (640)	573-708 (655)
Total dissolve solids (mg/L)	361-398 (376)	542-639 (580)	324-472 (407)	471-528 (501)
Suspended solids (mg/L)	24-31 (28)	ND	18-31 (25)	ND
pH	8.4-8.8 (8.64)	8.1-8.24(8.16)	7.6-8.1(7.9)	7.6-7.7(7.68)

COD (mg/L)	19-42 (31)	ND	20-80 (57)	ND
UV absorbance at 254 nm (cm^{-1})	0.056 – 0.061 (0.059)	0.002-0.009 (0.007)	NA	NA
Total coliform (MPN/100 mL)	$0.5x10^2$-$50x10^4$ ($17x\ 10^4$)	<2	$4.6x10^4$-$24x10^4$ ($14.3\ x\ 10^4$)	<2
Fecal coliform (MPN/100 mL)	$0.5x10^2$-$50x10^3$ ($19x\ 10^3$)	<2	$5x10^3$-$24x10^3$ ($14.5\ x\ 10^3$)	<2

NA not available; ND not detectable .Values in parenthesis are average values

The impact of catchment activities on the quality viz. chemical oxygen demand (COD), coliform, nutrients of lake-water is quite evident. Nevertheless, during lake bank filtration all the suspended solids, COD, chlorophyll-a and bacteria are reduced to less than the detection limit of the method(s). The tube-well water when compared with lake water showed 5.2 log removal of total coliform, 4.2 log removal of fecal coliform, 1.4 log removal of turbidity and 1.6 log removal of organics (in terms of COD) (Fig. 2). The removal can be attributed to physical filtration and straining of particles.

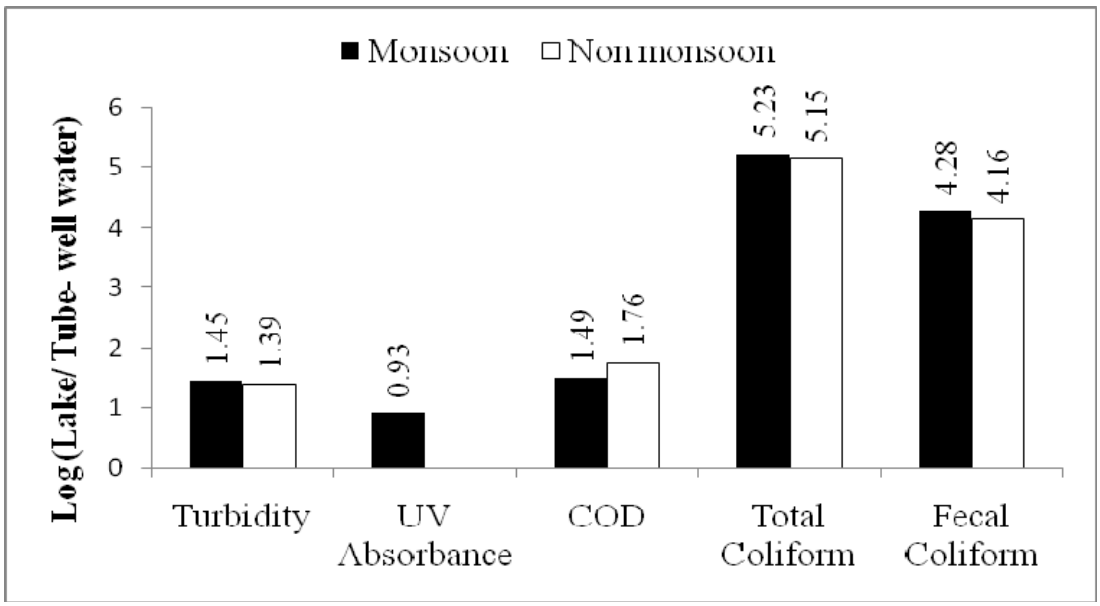

Figure 2. Turbidity, UV absorbance, COD and coliform counts of tube-well water relative to lake water.

Site 3: Mathura. The water bearing strata at the RBF site at Mathura was estimated to be up to around 26 m below the bed of the river. The horizontal collector well at Mathura which was constructed about 25 years back is placed in the centre of the river. All the laterals are completely beneath the river bed. Indian practice of using the horizontal collector wells in general, is different than the practice in Europe and USA. In India, it is a common practice to place the caisson in the river bed so that all the laterals remain completely below the river bed. Water supply scheme of Ahmedabad, India where seven radial wells are placed in the centre of the River Sabarmati is another example. Although exact comparison has not been attempted, Indian practice is quite successful where groundwater is saline. The aquifers in and around Mathura are characterized by varying hydro-geological conditions, even within short lateral distances. Placement of the well in the centre of the river in such a situation yields filtered river water with little or no mixing with groundwater. One of the major disadvantages is that the travel time is relatively short and accordingly limited purification is expected particularly in terms of organics and microorganisms.

Range of the values of some selected water quality parameters for the River Yamuna and riverbed filtrate are presented in Table 3. Perusal of the data indicates variation of turbidity of the river water only up to around 14 NTU. This was due to the reason that samples were collected in pre- and post-monsoon periods only. Turbidity of the Yamuna water during monsoon ranged from 70 to 180 NTU (CPCB, 2006). pH of the river water varied from 7.4 to 8.2. River water on an average contained dissolved salts of around 800 mg/L which is more than the desirable limit of 500 mg/L. Average conductivity (~1390 μS/cm at 25^{o}C) and alkalinity (~320 mg/L as $CaCO_3$) were also high. Average values of dissolved organic carbon (DOC) (~7 mg/L), UV-absorbance (~21 m^{-1} at 254 nm) and colour (~63 colour unit, CU) indicated the presence of organic compounds in the Yamuna water. The colour due to inorganic metal ions at pH 7.4 to 8.2 is unlikely. River water as well as filtrate was

found to be contaminated with coliform bacteria having MPN in the range from 23 x 10^2 to 15 x 10^5 per 100 mL.

Larger values/fluctuations of conductivity indicate substantial feeding of the river by ground water/effluents particularly during the non-monsoon months. Bed filtration effectively reduced UV-absorbance and DOC by 0.3 log and colour by 0.4 log. Accordingly, radial well water was found to have an average UV-absorbance of around 10 m^{-1} at 254 nm, DOC of 3.2 mg/L and colour of 23 CU. Total coliform of the river water (23 x 10^2 to 15 x 10^5 MPN/100 mL) were reduced to 43 to 75 x 10^3 MPN/100 mL, a reduction of around two logs.

Table 3. Water Quality Parameters: River Water vs. Radial Well Water.

Water Quality parameter	River water (n=17)	River bed filtrate (n=13)
Temperature (ºC)	19.8 - 21.6 (20.8)	21.4 - 24.7(22.2)
Conductivity (µS/cm at 25ºC)	1170 – 1527 (1390)	1292 – 1483 (1404)
Total dissolved solids (mg/L)	690 – 902 (804)	622 – 934 (817)
Turbidity (NTU)	3.83 - 13.6 (7.3)	0.67 - 4.29 (1.3)
pH	7.43 - 8.2 (7.9)	7.18 - 8.23 (7.8)
Colour (CU)	40 – 166 (62.8)	18 – 29 (23.3)
UV absorbance (cm^{-1} at 254 nm)	0.11 – 0.28 (0.21)	0.07 – 0.13 (0.1)
DOC (mg/L)	4.04 - 29.1 (7.0)	1.65 - 6.3 (3.2)
DO (mg/L)	5.14 - 7.17	0.22 - 0.97
TC (MPN/100 mL)	23×10^2 - 15×10^5	43 - 75×10^3
FC (MPN/ 100 mL)	150 -23×10^4	43 - 93×10^2

n is number of observations**.** Values in parenthesis are average values.

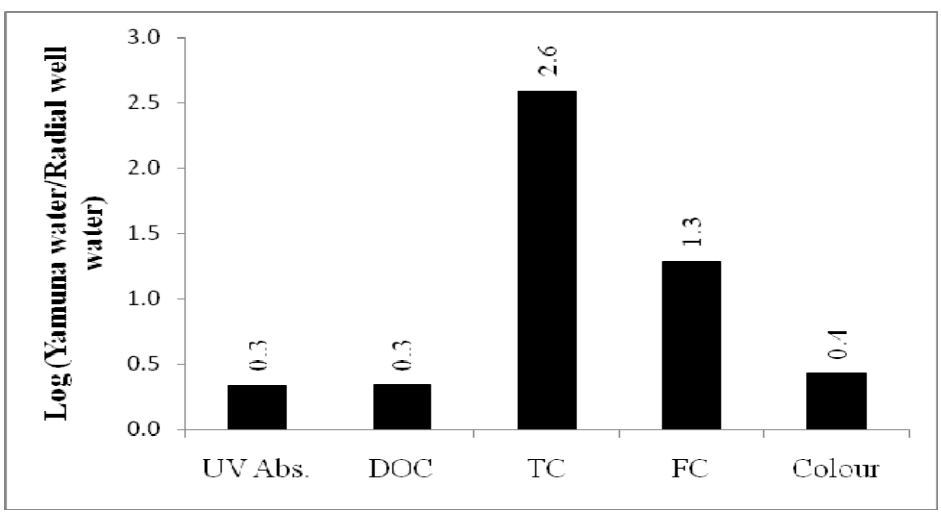

Figure 3. UV Absorbance, DOC, Coliform counts and colour of radial well water relative to river Yamuna water.

CONCLUSIONS

This study clearly illustrates the benefits of riverbank filtration as an alternative to direct surface water abstraction.

Sustainable Design and Construction of Earthen-dam Reservoirs for Water Produced in Association with Coalbed Natural Gas in the Powder River Basin, Wyoming

J. J. Brown[1] and Robert W. Thoman[1]

[1]Lowham Engineering LLC, 205 South Third Street, Lander, Wyoming 82520, PH (307) 335-8466, FAX (307) 335-7343, jjbrown@low-water.com, bthoman@low-water.com

ABSTRACT

Surface impoundment of produced water from coalbed natural gas (CBNG) development is a water management option routinely employed by operators in Wyoming's Powder River Basin (PRB). A substantial increase in CBNG development in recent years has resulted in the need for documented guidance and standards regarding the sustainable design and construction of impoundment structures; specifically earthen-dam reservoirs. Earthen-dam reservoirs are a cost effective, relatively low-impact management alternative for produced water, which also allows for a variety of secondary water management options such as evaporation, infiltration, local aquifer recharge, irrigation, and livestock and wildlife watering. Earthen dams are also high-risk structures with the potential for extensive property damage and possible threat to public safety upon failure. A guidance document is beneficial to all stakeholders, from regulators and local governments to land and resource management agencies, ranchers, and landowners. Design elements and construction procedures presented in the guidance document are based on data collected during the design and construction of nearly 1,000 large reservoirs and more than 4,000 smaller stock reservoirs in the PRB over the past eight years. Soil conditions, subsurface and surface hydrology, topography, and geology specific to the PRB are considered, as are the regulatory requirements of the Wyoming State Engineer's Office and the Wyoming Oil and Gas Conservation Commission. While design considerations vary depending on intended beneficial use, landowner requirements, and pertinent regulations, sustainability and minimal disturbance are the governing objectives in all circumstances. Remediation and mitigation procedures for potential short and long-term concerns such as differential settlement, piping, excess surface erosion, and seepage are derived from field trial observations. Design aspects specific to on- and off-channel impoundments, planned long term use, and reclamation following short term use are provided.

INTRODUCTION

The Powder River Basin (PRB) in northeastern Wyoming is a strategically important gas producing area that has seen a dramatic increase in coalbed natural gas (CBNG) development over the last decade. The development of CBNG reserves in the PRB

produces relatively high volumes of fresh to very brackish waters. Water is pumped from coal seams in order to release methane gas trapped in solution by groundwater pressure and to cause migration of the gas toward the recovery wellbore. The water produced from CBNG wells varies in quality from high quality (meeting state and federal drinking water standards) to having very high total dissolved solids (TDS) concentration (ALL Consulting, 2003). Landowners and livestock have come to rely on CBNG-produced water during the drought conditions that have persisted over the last ten years, and natural flood flow chemistry has not been affected by discharge of produced water to major drainages (Sanders et al., 2007).

While there are a number of management options for CBNG-produced waters, construction of earthen-dam reservoirs for surface impoundment is the most cost effective, low-impact storage option preferred by operators and landowners. Hundreds of new earthen-dam reservoirs were constructed and existing reservoirs were upgraded during the initial rush of CBNG development in the PRB, with very little engineering design or construction oversight. As regulatory agencies caught up with the flurry of development, inspection revealed numerous concerns regarding dam safety, location, construction methods and landscape disturbance. Regulators, operators and landowners called for design standards and procedural guidance specific to earthen-dam construction in the PRB.

The design elements and construction procedures presented here represent a sample of the specifications developed in response to the construction challenges and conditions routinely encountered in the PRB. Each design is based on numerous field trial observations, with sustainability and minimal disturbance as the governing principles in all cases. This guidance is based on data collected during the design and construction of nearly 1,000 large reservoirs and 4,000 smaller stock reservoirs in the PRB over the past eight years. Additional information and input was provided by regulatory agencies and industry members directly involved with CBNG development in the PRB.

REGULATORY AGENCIES

The primary agencies responsible for regulating impoundment of CBNG-produced waters in the state of Wyoming are the State Engineer's Office (WSEO) and Wyoming Oil and Gas Conservation Commission (WOGCC). Regulatory authority is dependent on the type of impoundment and proposed beneficial use(s) of the water. On-channel reservoirs are created to hold coalbed methane water in existing ephemeral drainages where water normally flows only in response to precipitation events or snowmelt. Off-channel reservoirs are essentially pits which have associated beneficial uses, and are constructed outside of an existing drainage course. Off-channel reservoirs with no other beneficial use than storage of produced water are regulated by the WOGCC. On-channel and off-channel reservoirs with additional beneficial use are regulated by the WSEO.

Reservoirs permitted by the WSEO fall into two general categories. Reservoirs greater than 2.5 ha (20 ac-ft) in capacity require a detailed design completed by a professional engineer or land surveyor licensed to practice in Wyoming. Smaller reservoirs that are designated for stock use and have a dam fill height of 6.1 m (20 ft) or less do not require detailed designs and permit applications can be completed by the landowner or appointed agent.

If water from oil and gas related operations is discharged to an off-channel site and construction will occur on fee, patented, or state leases, a permit from the WOGCC must be submitted and approved prior to construction. If these facilities have a beneficial use (stock, wildlife, irrigation, etc.) then they must also be permitted by the WSEO (2000). If not permitted for beneficial use, off-channel reservoirs must be fenced to prevent access. The Bureau of Land Management (BLM) will approve, bond, inspect, and enforce compliance on all off-channel pits receiving discharge from federally leased CBNG wells. The BLM also requires an on-site review for all reservoirs located on federal surface, over federal mineral interest, or on fee or state surface if it contains water produced in association with the extraction of federal minerals.

RESERVOIR SITING

The Powder River Basin lies within the Great Plains physiographic province described by Fenneman (1931) and Keefer (1974). It is both a topographic drainage and a geologic structural basin, generally bounded by mountainous terrain to the south, east and west and by the Missouri Plateau to the north. The landscape is characterized by rolling to fairly steep, grass and sage covered plains dissected by incised tributaries. Topographic relief is typically moderate, except where steep-sided, flat-topped buttes rise sharply above the surrounding plains, and where rugged badlands exist near major rivers.

Siting an earthen-dam reservoir in the PRB can be tricky due in part to the local climate, and more so due to soil conditions specific to the region. Climate in the PRB is semi-arid to cold continental, with dry winters and warm summers (McNab and Avers, 1994). Annual precipitation ranges from 25 to 51 cm (10 to 20 in), most of which falls as spring and fall rain (Lowham, 1988). Local drainage is typically ephemeral, and streamflow occurs in direct response to storm events and snowmelt. These ephemeral streams are especially vulnerable to gullying and destruction of vegetation.

Surficial deposits are composed of Quaternary colluvial and alluvial clay-rich soils over interbedded coal, shale, siltstone and sandstone of the Tertiary Fort Union and Wasatch Formations (Ellis et al., 1999). In places, a relatively thick mantle of collapsible windblown silt is present above the bedrock. Soils in the PRB tend to be very fine grained and highly erodible, and shallow, transmissive seams of coal (lignite) and associated organic soils are common (Figure 1). These seams tend to pinch and swell over short distances, making it difficult to define the areal extent of a

particular deposit. Fractured clinker and scoria deposits are often associated with larger coal beds; large, shallow head basins underlain by coal or scoria are regional water collection areas (McNab and Avers, 1994). Subsurface deposits of these materials are difficult to identify based on topography alone.

Figure 1. Shallow coal seam and associated organic soil typical of the PRB

An acceptable reservoir site contains a sufficient amount of soils suitable for use as construction material and a minimal amount of deleterious materials that might promote seepage, erosion or excessive settlement. Mild topography with relatively small contributing drainage area is preferred in order to maximize storage for CBNG-produced water. These ideal conditions are not often readily available, however, and mitigative measures must be incorporated into the reservoir design. Mitigative measures may include the addition of a chimney drain, toe drain and sand blanket, intercept trench, and/or a sump and pump-back system.

DESIGN ELEMENTS

Embankment

In order to facilitate the safe operation of heavy equipment, the top width of the dam should be a minimum of 3.7 m (12 ft), though WSEO (2000) regulations specify a 2.4-m (8-ft) minimum. The upstream slope should be no steeper than 3:1 and the downstream slope no steeper than 2:1. In all cases, a 3:1 downstream slope is easier to seed and maintain than a 2:1, and provides improved stability. If significant wave action is anticipated, the upstream slope may be flattened to 4:1 or designed with a wave shelf. For long term protection, turf reinforcement mat (TRM) or rip rap may be required on the upstream face of the dam along the high water line. Rip rap should consist of dense, competent rock such as granite or limestone.

Spillway

The emergency spillway is designed to accommodate flood flows and prevent overtopping of the earthen dam. A natural spillway across a flat area, away from the embankment, leading to a stable side drainage or a low-gradient bench is ideal. If a natural spillway does not exist, a stable spillway must be constructed around at least one end of the dam with a dike to prevent erosion at the groin. Earthen spillways will not sustain continuous flows and will eventually erode. Where continuous flows are expected, install a separate pipe structure (trickle tube) to protect the spillway from erosion. For spillways with higher velocity flows, the contact area between the spillway and embankment will need protection to at least the design flow depth. Required spillway width will vary based on site-specific conditions including dam height, high water line area, and contributing drainage area.

Outlet Works

If continuous low flow through the reservoir is expected, a trickle tube is useful to prevent erosion of the earthen emergency spillway (Figure 2). The invert of the pipe in the upstream face of the dam is installed at the elevation of the desired high water line, typically 0.3 to 0.6 m (1 to 2 ft) below the elevation of the spillway. High-density polyethylene (HDPE) storm drain pipe with watertight fittings works well for the trickle tube, as it is durable, easy to install, and has excellent hydraulic characteristics. A 46-cm (18-inch) diameter pipe is recommended for most reservoir sites. A pipe of this size can carry as much as 0.4 m^3/s(15 ft^3/s) during occasional flood events and is large enough to pass debris. A 30-cm (12-in) diameter pipe is acceptable for small drainages of less than 16 ha (40 ac). Corrugated metal pipe (CMP) is not recommended because it is susceptible to corrosion and the formation of anchor ice during the winter months. High-density polyethylene pipe (ASTM D3350 Cell Classification 335420C) or HDPE heat-welded pipe (minimum SDR-17, 689 kPa, 100 psi) are suitable alternatives.

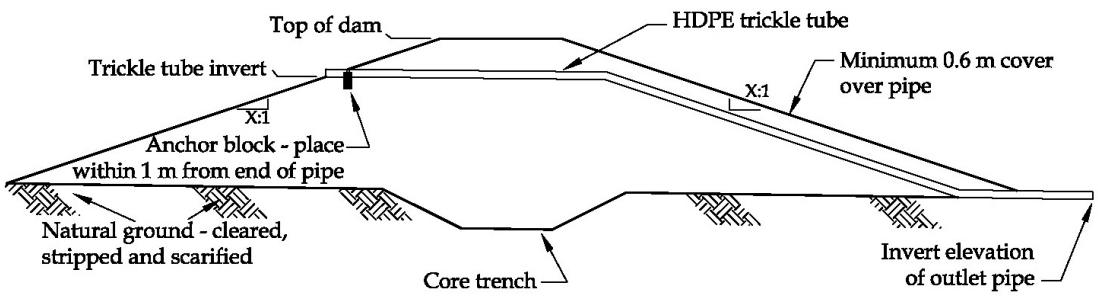

Figure 2. Dam cross-section with trickle tube design detail

The WSEO specifies that all new, on-channel reservoirs built to store CBNG-produced water must be equipped with a controllable, low-level outlet (Figure 3). The minimum diameter for the low-level outlet pipe is 30 cm (12 in). This requirement was expanded in scope to include existing, unpermitted reservoirs that contain CBNG-produced water. High-density polyethylene pipe (minimum SDR-17, 689 kPa, 100 psi) with heat-welded joints and a resilient wedge gate valve with mechanical

joint adapters (AWWA C509) have proven effective for this use. Locating the valve in the downstream face of the dam allows safe, easy access for maintenance and operation. Installing the valve on the downstream side of the dam results in a pressurized pipe beneath the embankment. Regulators were initially resistant to this design modification due to the potential for leakage at the valve or other pipe seams. However, careful pipe installation using bentonite slurry bedding has proven effective to prevent piping, and this configuration is now an accepted standard.

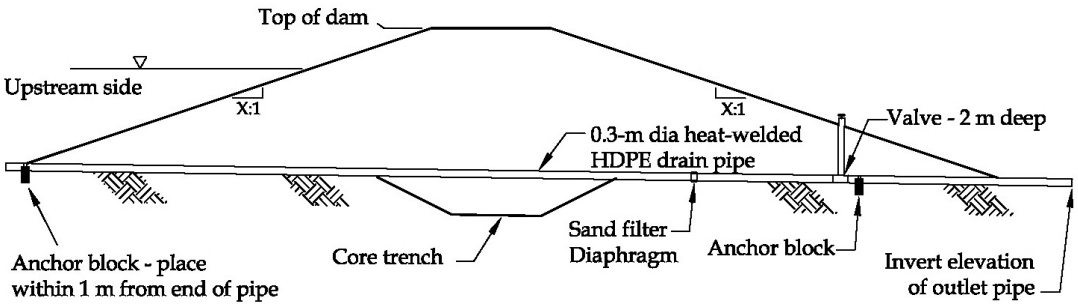

Figure 3. Dam cross-section with low-level outlet design detail

A valve riser is required to operate the gate valve from the ground surface. The riser typically consists of a 30-cm (12-in) diameter polyethylene pipe and cap. The pipe is centered over the top nut of the gate valve. Fill is compacted around the pipe using hand-operated mechanical compaction equipment, and a minimum of 0.6 m (2 ft) of the riser is left exposed above the finish grade. A rebar livestock guard can be installed over the top of the riser to prevent damage from livestock and to aid in locating the valve.

Installing a traditional low-level outlet in an existing dam requires draining the reservoir and excavating to the base of the existing embankment. This is a costly procedure that can compromise the integrity of the dam, and landowners and operators called for an alternative design. The siphon-style outlet design has proven to be a safe and effective option that greatly reduces the cost and construction effort (Figure 4). The siphon consists of a 30-cm (12-in) diameter heat-welded HDPE (minimum SDR-17) pipe. A saddle tee with riser pipe and ball valve are set at the highest point of the siphon tube, near the upstream face. A valve at the downstream toe of the dam enables the siphon tube to be primed when closed.

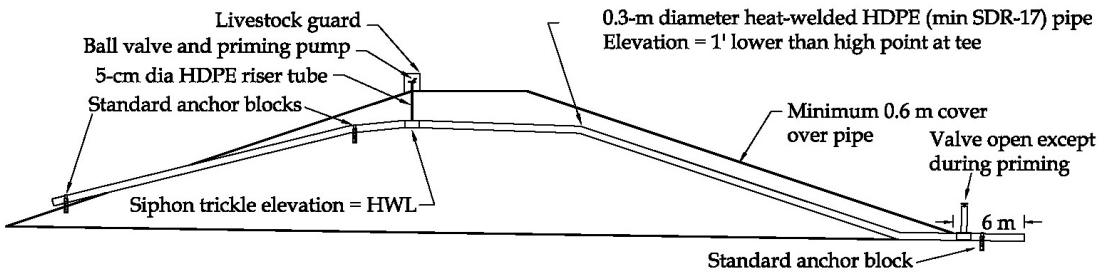

Figure 4. Dam cross-section with siphon-style outlet design detail

A mechanical or hand operated pump is required to prime the siphon pipe and drain the reservoir whenever the water level is below the level of the pipe. The priming pump is attached to the priming tube at the completion of construction. The primer pipe should extend 0.9 m (3 ft) from the ground for ease in operating the priming pump. A livestock guard can be installed to protect the pump and priming tube. The ball and downstream valves must be carefully attended to limit the potential for self-priming by floodwaters. If the siphon is installed near high water line and the downstream valve is left open while the ball valve is closed, floodwaters could potentially prime the siphon and evacuate the entire reservoir.

WATER RIGHTS AND DESIGN FOR COMPLIANCE

WSEO (2004) requires that new reservoirs located above permitted irrigation with catchments larger than 16 ha (40 ac) have a self-regulating bypass structure installed. This can be waived through submittal of a signed waiver by the downstream irrigator. The self-regulating bypass is intended to convey runoff around the impoundment so that irrigation rights downstream are not compromised. The type of self-regulating bypass is depends on the drainage, the amount of the downstream water right, water quality of the discharged water and local topography.

Water Level Control Structure

Water level control structures enable the water surface elevation to be preset and controlled during a runoff event. The structure has a low-level outlet pipe and a riser conduit with stop logs that are set to the desired water level (Figure 5). For some drainages in the PRB, including the Belle Fourche River, Cheyenne River, Horse Creek, Wild Horse Creek and Wildcat Creek, water level control structures meet the WSEO requirement for a bypass structure to provide natural runoff to downstream users with senior irrigation rights. The level of the CBNG-produced water is maintained within approximately six inches from the top stop log of the riser structure so that runoff pass through the reservoir. This requires close monitoring by the operator as storage in the reservoir fluctuates.

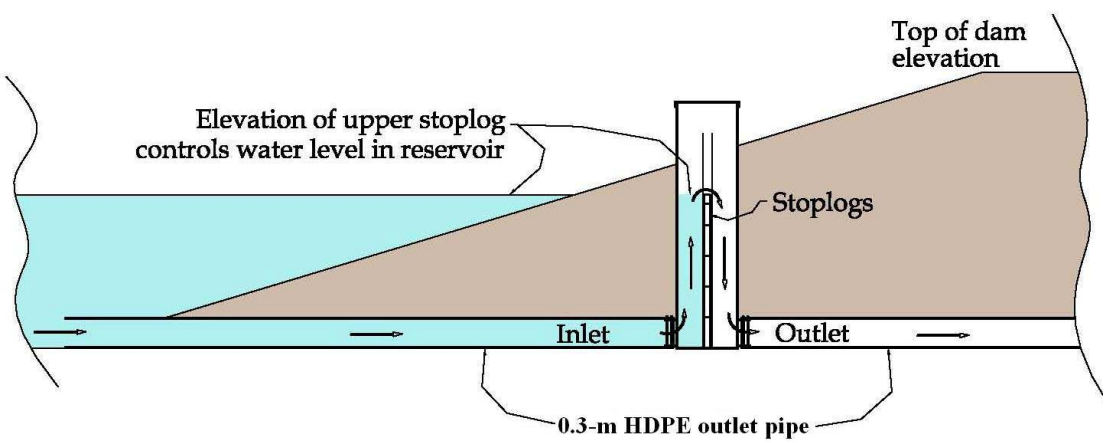

Figure 5. Conceptual design of a water level control structure

Water level control structures using stop logs work best for reservoirs less than about 4.3 m (14 ft) in water height. The increased water pressure in deeper reservoirs can cause leakage around the stop logs.

Flow Bypass

While a water level control structure will serve as an adequate bypass system in some drainages, other drainages, such as SA, LX Bar, Dead Horse, and Spotted Horse Creeks require bypass of natural runoff around the reservoir. The type of bypass depends on the amount of water diverted and the type of terrain. Designs using either a ditch or a pipe have proven effective.

The ditch bypass design includes a diversion dike, a ditch around the reservoir and erosion protection (Figure 6). The ditch is designed with a cross-sectional area and

Figure 6. Ditch flow bypass system to convey runoff around a CBNG reservoir

slope to accommodate the necessary discharge and is seeded to establish vegetative cover for erosion protection. The ditch system can bypass relatively large flows, but requires periodic maintenance and may be subject to erosion, particularly at the point where the bypass channel merges with the original channel downstream of the impoundment.

The pipe system (Figure 7) is an effective alternative to the ditch system when topography or soil conditions are not conducive to ditch construction. Maintenance is minimal after installation, but includes keeping the pipe full of water. Relatively high water velocity during flood events prevents suspended sediment from settling out in the pipe.

HDPE pipe with heat-welded joints (minimum SDR-17), sized to pass the required flow, can be used to construct the bypass. Polyethylene has a lower specific gravity

than water and unless the pipe is anchored, it will float, even when filled. The pipe will require concrete anchor blocks at intervals along the alignment.

Figure 7. Downstream view of a pipe flow bypass and diversion dike

The pipe and anchors can be buried, if desired. From the diversion dike, the pipe is placed on the ground surface or buried up to the face of the dam. The pipe is then buried over the upstream face, through the dam (at trickle tube elevation), and down the downstream face to the drain pipe outlet. An eccentric reducer is required at the beginning of the bypass pipe in the diversion dike. Fitting a vent tube in the pipe will prevent siphoning of the pipe following a runoff event. The vent tube is placed on the upstream face of the dam before the highest point of elevation so that it can be used to fill the upstream portion of the bypass pipe with water.

Both bypass systems require placement of a diversion dike upstream of the high water line. The size of the diversion dike depends on the flow to be bypassed while allowing excess runoff to overflow into the reservoir. The diversion dike is the controlling device for the pipe bypass system as it will encase the pipe, create a pool, and direct flow into the pipe. A dike constructed with a minimum top width of 2.4 m (8 ft) and a minimum height of 0.9 m (3 ft) will allow a pool to form and create minimal head for full pipe flow.

SUMMARY AND CONCLUSIONS

Large numbers of hastily constructed earthen-dam reservoirs built to accomodate increased CBNG production in the PRB over the past decade precipitate the need for engineering oversight and procedural guidance. Standard design specifications based on regulatory requirements and proven construction techniques promote sustainable development with minimal environmental impact.

Additional design elements and construction procedures specific to earthen-dam construction in the PRB can be found in the guidance document *Procedures for Permitting and Constructing Reservoirs* (Lowham, 2008).

ABSTRACT

World Commission on Environment and Development in "Our Common Future" (**Brundtland, 1987**) defines the sustainable development as "a strategy that meets the needs of the present without compromising the ability of future generation to achieve their own requirements". Developing countries have to face double challenge for sustainable agriculture, firstly to increase food production and secondly to maintain if not to improve resource and environmental quality. **EI Bassam** (1998) reported that per capita land required for food, oxygen and water security are 15-20 m^2, 6-10 m^2 and 3-6 m^2, respectively under controlled conditions. This could be achieved if innovative technical means and efficient material recycling systems are implemented.

One of the biggest problems that agriculture will face in the years to come will be of availability of good quality water for irrigation purpose. The water available and the ultimate irrigation potential do not level up. Under ground water contributes to more than 70% of the total ultimate potential through minor irrigation. To cater to the depletion of good quality water alternate sources are being looked into.

Domestic effluent or waste water generated from urban areas is generally being disposed off into the existing natural streams or water bodies. Rivers passing from the big cities have become heavily polluted and need immediate attention. Huge quantity of waste water is being generated in cities every day. Domestic waste water may be used as an alternate resource for irrigation. Only a fraction of this is being treated at present and reused for various purposes. Waste water reuse may have one or combination of several objectives such as: 1. Use of a reliable water source for irrigation, 2. Fertilization of infertile lands; 3. Re-use of scarce water resources; 4. Safe disposal of waste water to avoid contamination; and 5. Ground water recharge.

The population of the countries and size of the cities are growing rapidly. According to a survey, more than 50% of the population will be in urban areas by 2050 against present level of 30%. Domestic and industrial sectors use 15% of the present water resources which will grow to 30% by the year 2050. Waste water generated from concentrated population will increase in similar proportion. Waste water may be used as water resource for agriculture and aquaculture. Domestic waste water need to be diverted for irrigation purposes. Typical waste water is composed of 99.5% to 99.9% of water and remaining percentage is composed of inorganic and organic solids,

colloids and dissolved solids, which contain major nutrients and trace elements. Average annual application of waste water may correspond to about 300 kg/ha.N and 50 kg/ha P. Waste water irrigation in over-exploited ground water areas may arrest the decline of ground water table. Growing pressure on available fresh quality irrigation water resources and increasing awareness to environmental issues among human masses will force researchers and planners to design waste water disposal system in such a way that it could be safely made available to its users. This is the right time to give a rational thought in this direction to make the waste water a safe water resource for irrigation and make agriculture sustainable for the future.

INTRODUCTION

Domestic effluent in most developing nations, are being discharged into the inland water bodies or streams without any pretreatment deteriorating water quality. This has created a matter of great concern in developing countries. Streams and rivers passing from the large cities in India have become a sewage disposal channel deteriorating environmental quality as overall impact and interest killing of down stream users as specific impact.

The demand for good quality water by the industry and domestic sectors are continuously growing. Available share of good quality water for irrigation is being diverted to these sectors making less and less good quality water available for irrigation making horizontal expansion of irrigated area almost impossible with conventional irrigation methods. To increase total agricultural productivity, cropping intensity needs to be increased (it has already increased in many regions and continuously increasing in other pockets) demanding more and more water with decreasing share of good quality irrigation water. With diminishing share of good quality water for irrigated agriculture is left with no option other than to utilize poor quality water (saline, high RSC water, domestic and industrial effluents) for crop irrigation. Industrial effluents needs special attention and treatment before it can be used for irrigation purposes. Domestic effluents have great potential to be used as irrigation source. Conventional irrigation methods offer little flexibility to utilize such a poor quality water.

Conventional water management techniques have spelled disaster in the past. A vast area has gone out of cultivation due to excessive water logging and salt build up in the root zone and the problem is still increasing. More than 8.2 million hectares of land has become salt affected and about 12 million hectares of land is suffering due to water logging in the country.
Ground water was used as assured source of irrigation water and also for domestic and industrial uses. Excessive utilization of ground water has resulted in steep decline in ground water table failing thousands of shallow tube wells in country like India. Conventional irrigation methods have become incapable to avoid such problems.

Increasing threat to environment be it water logging, Stalinization, problems associated with large scale water storage and diversion structures, deteriorating surface and subsurface water quality and disposal of sewage water and associated problems or decreasing flow of water in rivers have become a matter of great

concerns to the common people with increasing awareness of deteriorating environmental health. More and more advanced technologies are required to avert the impending problems with past interventions of technologies and management strategies.

INCREASING DEMAND FOR WATER WITH INCREASING POPULATION

The population of the world and India in rural as well as in urban areas are growing and consequently the demand of water is also growing. **Table 1** shows the population distribution of the world content wise. **Table 2** shows the growth in urban and rural areas. Population is a direct index for water demand and hence the rising demand and crises may be looked accordingly. As table shows more than 70% population of the country lives in rural areas. Agriculture is the main occupation of rural mass. Major share of fresh water supply is being used by the agriculture sector. More and more water is being extracted from ground water reserves for crop irrigation. The excessive pumping for intensive cropping and high water demanding crops are main reasons for water table decline in rural areas.

Table 1. Continent wise population distribution.

	population estimate/projected			
continent	**1950**	**1975**	**2000**	**2030**

GLOBAL WATER RESOURCES

The distribution of global water resources are given in **Table 3**. Major share of fresh water is in form of polar ice (77.2%). Ground water reserves have a share of 22.4% and need to be wisely planned and utilized. Water available in rivers and lakes are too less and all the countries are not blessed with good perennial streams and rivers. The river water supplies are going to be critical in many developing countries due to diversion for different users and further pollution of streams in lack of strict regulation to dispose pollutants.

Table 3 Distribution of global water resources.

Water Resources	Share
Total Water Resources	1460 Million BCM
Saline water	97.3%
Fresh Water	2.7%
o Polar Ice Caps	77.2%
o Ground Water & Soil Moisture	22.4%
o Lakes, Swamp & Reservoirs	0.35%
o Atmosphere	0.04%
o Rivers & Streams	0.01%

WATER RESOUCES OF INDIA

The water resources of the India are presented in **Table 4.** It may be seen from **Table 4** that out of total precipitation of 400 million ha-m, 115 million ha-m goes as surface runoff, 215 million ha-m as percolation and 70 million ha-m as immediate evaporation. Total ground water available in the country is 85 million ha-m and total surface runoff to the tune of 180 million ha-m. The usage of ground water on full development will be 42.3 million ha-m.

Table 4. Water Resources of India.

	Hydrologic units	Amount of water million ha-m
Total precipitation		400
1.	Percolation	215
1.1	Percolation of rainfall to soil moisture	165
1.1A	Percolation of irrigation to soil moisture	+ 5
	Total evapotranspiration	**170**
1.2	Percolation of rainfall to ground water	50
1.2A	Percolation from rivers, streams, seepage	+35
	Total ground water	**85**

2.	Immediate evaporation	70
3.	Surface runoff	115
3.A	Regenerated flow from ground water	+45
3.B	Flow brought from outside India through streams and rivers	+20
	Total surface water	**180**

GLOBAL WATER USE

Global water withdrawal and use for selected categories are presented in **Table 5.** It may be seen from the table that agriculture is the major water user on the globe and demand is growing continuously with increasing population. Industries are the second largest user and the domestic supplies come at the last. Irrigated areas of the world had continuously increased from 47.3 million ha in year 1900 to 264 million ha in year 2000.

Table 5. Global water withdrawal and use for selected categories (1900-2025)

Category	**1900**	**1950**	**1980**	**2000**	**2025**
Population (million)	-	2542	4410	6181	7877
Irrigated area (million, ha)	47.3	101	198	264	329
Agricultural use (km^3/year)					
Withdrawal	525	1122	2179	2560	3097
Use	406	849	1688	1970	2331
Industrial use (km^3/year)					
Withdrawal	37.8	181	699	768	1121
Use	3.4	14.4	59	85	133
Municipal use (km^3/year)					
Withdrawal	16	53	207	389	649
Use	4.2	14	42	64	84

The total water demand for agriculture, domestic and industrial sectors of India in 1995 was estimated to be about 650 km^3, of this about 90% is withdrawn for agriculture sector alone. Government of India had given great emphasis from time to time to create more and more water potential for bringing more and more agricultural area under irrigation in order to increase total food grain production in the country. Coming section will be discussing about the irrigation status in the country.
Table 6 presents the estimates of future water demands in India

Table 6. Estimates of future water demands (billion cubic meter) in India.

Category	Year 2010			Year 2025			Year 2050		
	Low	Medium	High	Low	Medium	High	Low	Medium	High
Irrigation	489.0	536.0	556	619	688	734	830	1008	1191
Domestic	39.4	41.6	61	47	52	78	59	67	104
Industrial	37.0	37.0	37	61	67	79	69	81	116
Total	555.4	614.6	654	727	807	881	958	1156	1411

IRRIGATION POTENTIAL CREATED AND UTILIZED THROUGH GROUND WATER

The use of ground water for irrigation purposes had increased continuously after the independence. Ground water may be used as 100% source for irrigation or as a source for assured irrigation. Government of India and various State Governments have continuously worked for creating more and more irrigation potential through ground water utilization. The present potential created at the end IX Plan was 44.98 million ha and potential utilized is 37.09 million ha(**Table 7).** Sources of irrigation water are mainly tanks, canals, tube wells and different type of wells. Out of total irrigated areas in the country about 48% is through wells and 38% through canals and 8% through tanks and 6% from other sources.

. **Table 7. Irrigation potential created and utilized through ground water.**

Plan	**Potential Created (in m. ha)**	**Potential Utilized (in m. ha)**
Pre Plan upto 1951	6.50	6.50
I Plan (1951-56)	7.63	7.63
II Plan (1956-61)	8.30	8.30
III Plan (1961-66)	10.52	10.52
Annual Plan 1966-69	12.50	12.50
IV Plan (1964-69)	16.50	16.50
V Plan (1974-78)	19.80	19.80
Annual Plan (1978-80)	22.00	22.00
VI Plan (1980-85)	27.82	26.24
VII Plan (1985-90)	35.62	33.15
Annual Plan (1990-92)	38.89	36.25
IX Plan (1997 -2002)	44.98	37.09

The numbers of ground structures have increased significantly after the independence. **Table 8** shows the growth of ground water structures after the independence of India. Shallow tube wells are cheap and easy to construct if the site is favorable. The continuous increase in ground water structures in lack of strict ground water legislation is one of the reasons for ground water decline

Table 8. Growth in number of ground water structures.

Years	**Dugwells**	**Shallow**	**Tube wells**	**Pumsets**	
				Electric	**Diesel**
1950-51	3860000	3000	2400	21000	66000
1973-74	6700000	1140000	22000	2460000	175000
1979-80	7786000	2132000	33300	3265000	265000
1989-90	9407000	4754000	63600	8766000	446700
1991-92	10120000	5379000	67600	9336000	458500

MAJOR ASSOCIATED PROBLEMS WITH AGRICULTURE

1. WATER LOGGING

Water logging is the major problems in canal irrigated areas. Excessive seepage from the canals and field channels, high rainfall, field losses, insufficient drainage facilities and blockage of natural drainage systems are the main reasons for water logging. Introduction of high water demanding crops such as paddy, sugarcane and mentha resulting higher losses from the fields further aggravates the problems. Now a days in many parts of the country such as Punjab and Haryana double crops of paddy is being taken resulting more losses. **Table 9** shows the extent of water logging in different states of the country. There are various estimates presented in this table showing the seriousness of the problems. Area under water logging is increasing continuously.

Table 9. Extent of Water logging areas in million hectare estimated by various agencies.

2. SALINITY PROBLEMS

Rising water table due to increased recharge of ground water (excessive seepage from canals, field channels and deep percolation losses from agricultural fields) dissolves salts from deeper profiles and brings it near to the ground surface. Because of solar radiation water gets evaporated leaving salts behind. The water received through rainfall dissolves these salts and moves them down to deeper soil layer. If the annual evaporation is higher than the annual precipitation the salt deposition is more pronounced and area becomes salt affected. Salinization is generally coupled with the water logging. There are various estimates for salt affected lands in the country. More than 8 million ha of land is salt affected in the country causing a huge loss to the nations and suffering to the farmers.

National Remote Sensing Agency has given an estimate of salt affected soils in different state (**Table 10**).

Table 10. State-wise extent of salt affected soils in India (based on 1986/87 satellite data with adequate field checks)

S.N.	State (ha)	Saline soils (ha)	Sodic soils (ha)	Total (ha)	Total in million ha

Source: National Remote Sensing Agency and Associates, 1996
Total salt affected land in the country is 8.57 million ha out of which 2.07 million ha is costal salinity, 3.47 million ha is salinity in canal command and 3.027 million ha is salinity outside the canal.

3. GROUND WATER DEPLETION

Total area irrigated using ground water reserves is higher than canal irrigated areas. Shallow tube wells have becomes quite common to be used by the farmers due to low cost, subsidy and lack of legislation for ground water utilization. The numbers of ground water structures have increased several folds after the independence of the country. **Table 8** shows the increase of ground water structures in the country from 19950-51 to 1991-92.

Ground and surface water constitute an integral part of the hydrologic cycle and form the available resource of water supply on earth. In the event of failure of monsoon ground water becomes more assured water supply. This has brought about rapid acceleration of well construction in the country. Old water lifting devices are becoming obsolete and being replaced by tube wells.

Ground water development in different parts/regions of the country is not uniform and influenced by hydrological parameters as well as agricultural and socio-economic activities of the regions. Over exploitation of ground water has become a well known fact in the state of Haryana, Punjab, Western UP and Tamil Nadu etc. As per the

National Water Policy ground water development is limited to annual replenishable ground water resource. Guidelines for status of ground water utilization are presented in **Table 12**. **Table 13** shows the stage of ground water utilizations in different states of the country The problem of over exploitation of ground water is becoming increasingly worse and requires immediate attentions of planners and researchers. The irrigated agriculture is going to face severe water shortage in years to come in many parts of the country.

Table 12. Guidelines for classifications

4. WASTE WATER GENERATION, DISPOSAL AND IRRIGATION

Demographic growth, increasing urbanization, industrialization, improving living standard and changing life style triggering greater use of detergents, domestic sprays, medical wastes, etc. expected to produce large quantities of anthropogenic wastewaters with different compositions. Population growth rate in rural and cities are indicative of future trends of liquid/solid wastes. Untreated domestic and industrial effluents are being disposed in natural streams and water bodies posing a great threat to environment. Domestic and industrial effluents if used for irrigation without treatment, proper selection of crops and irrigation methods it may affect the health of end users of agricultural produce, irrigation water handler and field workers. A large numbers of associated health hazards have been published in the literature with waste water irrigation without proper planning and selection of crops. **Table 14**

presents the basin wise waste water generation and **Table 15** presents disposal modes of waste water in class I cities.

Table 14. Basin-wise wastewater generation, collection and treatment in class-I cities.

Water quality deterioration is matter of great concern due to increased withdrawal of river water for agriculture and domestic supplies and increased flow of untreated domestic effluents.

Disposal of untreated industrial effluents is further worsening the water quality of river.

The domestic waste water need to be treated reused, and discharged in the streams to preserve water ecosystems

Table 16 shows the effect of long term effect of sewage irrigation on physical properties of the soil. Table shows that after long term sewage irrigation will reduce the bulk density but the aggregate stability, stability index, water holding capacity, hydraulic conductivity, total porosity and organic carbon will increase.

Table 16. Effect of long term sewage irrigation on physical properties of the soil.

Properties	**Fresh water**	**Sewage water after**

5. BUILD-UP OF DISEASES AND PESTS

There is a great risk of occurrence and build up of some obnoxious pests and diseases in the area of crop intensification under high input use. This factor hinders the vertical growth and questions are obvious about the sustainability of the environment under intensive input use which is unavoidable for maximizing crop yields. Heavy infestation of Phelaris minor in continuous rice-wheat cropping system in north-western plains, increasing occurrence of sheath blight in rice and the incidence of

Altenaria and Helminthosporium leaf blight are eye catching example. Under extreme situations further strong repulsive response of nature is yet to come.

6. LOW INPUT USE EFFICIENCY

Water application and water use efficiency are quite low (30-40%) in developing countries like India. Cropping intensity in the country is only about 135%. The Indian agriculture is running a net negative balance of 8-10 million tones per year. In addition, about 8 million tones of nutrients is lost annually due to soil erosion. The present efficiency of nutrient use is about 30-40%. The long-term experiments have shown a decline in organic carbon, nitrogen and phosphorus in cereal-cereal intensive cropping.

7. SLOW GROWTH IN RAIN-FED AREAS

About 70% of the agriculture in India is under rain-fed conditions and contributing about 40% of the national food grain production. The productivity of the rain-fed agriculture is quite low (0.8 tonne/ha) against the productivity of irrigated agriculture (2.0 tonne/ha). Erratic behaviour of monsoon has started precipitating and changing climatic conditions may further worsen situation of rain-fed agriculture in years to come due too global worming and deforestation. Natural resources will be over burdened in these areas and their trafficking will become essential making the ecosystems more fragile and unsustainable.

8. INCREASING POPULATION AND SHRINKING RESOURCE BASE

Growing population of the country is reducing the per capita natural resources share. Country's population has already reached a level of one billion. The per capita land availability for cultivable land will reduce to about 0.14 ha in 2025 A.D. compared to about 0.17 ha at present level. Livestock population has increased from 292 to 416 million and is still increasing with a rate of 2% per annum mounting a tremendous pressure on land, water and forest resources. The availability of drinking water per capita per annum is 2001 m^3 at present which will reduce to a level of 1700 m^3 in the next 2-3 decades. Below this threshold, water availability will be considered a severe constraint to socio-economic development and environmental quality. This is mere a statistic. At present, water supply in the cities are not in good shape at all. If we apply quality constraints of the country or WHO and international norms the availability will go further down. Ground water and surface water is subjected to great risks of pollution. Almost all the rivers passing from a big city are highly polluted and have become a sewage disposal channels. They are not suitable for human use. Lack of supervision and strict regulation allows people to discharge highly polluted industrial effluent into the natural streams and rivers. Presently agriculture sector is utilizing 85% of total developed potential and is likely to be reduced by 10-15% to meet the growing demand for drinking and industrial usage. Shrinking natural resources will force fast recycling of many natural resources such as water and forest making system more fragile than ever. Near 30% population in the country is residing in the

cities against about 11% during the year 1901. Demands for natural resources have risen steeply with increasing population and will grow further not only to match increasing population but also to match the living standards of the people with growing economy. More efforts and huge money will be needed to tackle on this front for reaching sustainable level. For developing countries like India, with the growing population and rapid urbanisation, the demand for fresh water is growing up from all the competing sectors - agriculture (demands about 80-90% of fresh water), domestic (about 5-7%), industry (about 10-15%), environment & ecosystem, etc. Inter and intra sectoral conflicts are growing up, almost all the surface flows are consumptively utilised, and there is no left over for environmental flows, as a result less groundwater recharge and more wells failure. Apart from that surface water (river water) based drinking water schemes are also get very much affected during dry seasons, as only municipal sewage (mostly untreated or partially treated) feeds the rivers. Since there is no groundwater recharge from surface water, only options for groundwater recharge is rainfall. However, rising variability in rainfall along with the encroachments of traditional water harvesting structures resulted in less recharge. So, only recharge is possible from agricultural return flow laced with deadly pesticides and fertilizers. Recently, there is an increasing trend for all the sectors to go for groundwater to meet the demand, as a result groundwater quantitatively depleted and qualitatively degraded in many basins. In this scenario, both the regulators and so-called experts are suggesting for waste water (untreated or partially treated sewage water) based irrigation activities, and there are provisions for industries to discharge their effluents on land. Since the land disposal is less stringent, hence most of the industries are going for that. As a result, groundwater water is getting polluted and application of polluted groundwater for irrigation is degrading the soils.

WASTE WATER: A WATER RESOURCE FOR AGRICULTURE

Demographic growth, increasing urbanization, industrialization, improving living standard and changing life style triggering greater use of detergents, domestic sprays, medical wastes, etc. expected to produce large quantities of anthropogenic wastewaters with different compositions. Population growth rate in rural and cities are indicative of future trends of liquid/solid wastes. Untreated domestic and industrial effluents are being disposed in natural streams and water bodies posing a great threat to environment. Domestic and industrial effluents if used for irrigation without treatment, proper selection of crops and irrigation methods it may affect the health of end users of agricultural produce, irrigation water handler and field workers. A large numbers of associated health hazards have been published in the literature with waste water irrigation without proper planning and selection of crops.

Table 18 presents the details of sewage farming in class I cities in India. The cities where more than 1000 ha under sewage irrigation are Chandigarh, Hyderabad, Rajkot, Vadodara and Varanasi. Charges for sewage irrigation ranges from Rs. 30.60 to Rs. 400.00 per hectare per annum. **Table 19** presents effect of sewage irrigation on

alkalinity and salinity of the soil. There is not much problems with the salinity but the alkalinity may become prominent in several cases if proper attentions is not paid.

POTENTIAL OF DOMESTIC WASTE WATER

Potential for wastewater irrigation still exist in many countries and with growing populations in urban centers, the availability of domestic wastewaters will rapidly increase. Nevertheless, it is estimated (early 1980s) that in 80% of the situations where wastewater is collected and water is an agricultural development constraint, wastewater, either raw or treated, is already used for permanent or seasonal irrigation (Wright/Quick in: Shovel et al. 1986). The use may be direct via immediate use of the effluent or indirect by using groundwater or surface water resources with effluent additions further upstream.

Waste water reuse may have one or a combination of the following objectives.

1. Use of waste water for reliable irrigation.
2. Fertilization of marginal lands having poor fertility or specially inert medium.
3. Reuse of scarce water available in the arid and semi-arid areas.
4. Safe disposal of waste water in order to avoid ground water or surface water pollution by direct mixing.
5. Ground water recharge.
6. Safe disposal of waste water containing toxic concentration of inorganic or organic chemicals.

GENERAL PRINCIPLE FOR CONVENTIONAL WASTE WATER IRRIGATION

General principle for waste water irrigation to reduce potential negative health and environmental impacts are,

1. Soil should not be contaminated with persistent toxic organic solids.
2. Waste water should not be contaminated with excessive concentrations of pathogens which may cause an outbreak of infectious diseases.

3. Water application rate should be moderate to avoid ponding conditions like in paddy crops. Actually application rate should match the intake rate of the soils.
4. Waste water should not contain sodium, trace element, heavy metals in excess that the required by crops and buffering capacity of the soils.

Waste water utilization may be beneficial in one way or ht more as given below.

1. Reuse of waste water will create additional water resource for irrigation.
2. Cost pr unit sewage water volume may be much lesser than the fresh water and hence cost of irrigation may go lower.
3. Extra investment in normal sewage water treatment or special treatment for its safe disposal or reuse for domestic supply could be minimized to a greater extent.
4. Associated health hazards and environmental problems due to raw sewage disposal in to natural streams of water bodies could be checked.
5. Waste water irrigation has potential to decrease the net demand of chemical fertilizer like N and P and also trace elements as these nutrients are present in waste water.
6. Excessive pumping can be minimized by utilizing waste water for irrigation.
7. Salt intrusion in costal and arid areas could be prevented.
8. Overall a healthy atmosphere could be given to the city people.
9. Natural streams and rivers could be brought back to live conditions just by checking or minimizing raw sewage disposal into them.

PROBLEMS ASSOCIATED WITH WASTE WATER DISPOSAL

Volume of waste water generation from house hold is increasing due to increasing population and urbanization in developing countries and problems associated with its safe disposal is becoming threat to environment. In country like India where large cities are generally situated over a river bank is facing real problem of surface and ground water pollution. Urban population is direct measure of waste water generation and growth rate of cities indicates associated problems to be faced in future. The rivers passing from large cities have become a sewer drain due to indiscriminate disposal of domestic effluent without any treatment. **Table 22** presents disposal modes of waste water in class I cities. The problem of water quality deterioration is increasingly becoming a matter of great concern due to increased withdrawal of river water for agriculture and domestic supplies and increased flow of untreated domestic effluents. Disposal of untreated industrial effluents is further worsening the water quality of river. The domestic waste water need to be treated and then discharged in the streams to preserve water ecosystems and overall environmental quality for coming generation. Reuse of domestic waste water for irrigation of agricultural crops will reduce the pollution load of streams and rivers and also the treatment cost of the effluent. For diverting domestic effluent for agricultural use sewage disposal system need to be designed separately carrying water directly to the fields or to some common conveyance system optimizing cost of the system

HEALTH HAZARDS ASSOCIATED WITH WASTE WATER

A wide variety of bacteria, viruses, protozoan, helminthes, worms are found in waste water. Pathogens in waste water are high and can survive in extreme conditions. There is a great risk of infection to the people exposed to the soil and the crops irrigated with waste water. Cereal crops irrigated with waste water are safe for human consumption but the field losses in long run may pollute ground water of the area. Vegetables have risk for spreading epidemic among people. Cholera outbreak in Jerusalem during year 1970 was due to unauthorized irrigation of salad crops with untreated waste water (**Cohen et al. 1971, and Fattal et al. 1986b**). In India and other developing countries there are several cases reported for out break of various diseases due to leakage in water supply lines and sewage disposal systems. **Gunnerson et al. (1985)** reported that the full spectrum of excreted human pathogens endemic in the community is present in sewage. **Table 23** presents list of such pathogens.

ASSOCIATED BENEFITS OF WASTE WATER IRRIGATION

Wastewater reuse may have several benefits, among which are the following;
- Reuse of water can be considered as an additional source of water for irrigation,
- The marginal cost of providing the same volume of good quality water is generally higher than the cost of producing wastewater under conditions of water shortage; wastewater will be produced irrespective of whether or not it is used since sewage treatment works are essential to prevent groundwater pollution, and hence, it makes sense to use it beneficially,
- Properly planned use of wastewaters can reduce environmental and health impacts which have been observed with traditional wastewaters can reduce environmental and health impacts which have been observed with traditional wastewater disposal practices in developing countries,
- Wastewater reuse can prevent or reduce environmental of water bookies, especially closed ones such as lakes, where uncontrolled disposal can contribute to nutrient overloading,
- Wastewater can provide nutrients to soil and plants, especially N and P but also trace elements, and thus may reduce the need for fertilization, which may increase the total economic return to farmers,
- Salt water intrusion in coastal areas can be prevented by recharge of groundwater with treated wastewater.

Constraints to Development

1. Site Suitability

Suitability of locations depends on technical aspects;
- Irrigation areas should be close to the treatment plant (effluent source) to avoid transportation costs, risks of exposure, unfavorable changes in water quality during transport (especially in pipelines) and maintenance problems in conveyance canals or pipelines,
- Irrigation areas should be at a safe distance from settlements, usually >1 km to avoid odor nuisance and aerosol pollution of nearby settlements,
- Irrigated areas should be close to markets to minimize transportation of goods,
- There should be non irrigated areas in the vicinity which can be used outside the cropping season for safe disposal (rapid infiltration fields) or groundwater recharge, if no groundwater induced salinity problems exist; this applies also in emergencies for example in the case of treatment plant failure, if polluted water is released from the plant which does not meet quality standards for use in irrigation.
- Size of irrigated areas must be adapted to the quantity of available water (or vise versa) to avoid over irrigation and the consequent contamination of soils,
- If effluent quality does not meet standards, the ability of mix it with freshwater (ground or surface water) must be ensured at the site; this mixing may be required necessary temporarily or routinely,
- For deep percolating water (unavoidable groundwater recharge) the quality standards of maximum permissible concentrations of chemical constituents (e.g. toxic heavy metals) must be met; if soil filtering capacity is too low, e.g. in sandy soils, then other sites must be selected if groundwater pollution would cause problems (e.g. if groundwater is used for domestic supply to the local population),
- Water quality standards must also be observed for surface drainage outflow.

Site specific criteria are;
- Suitability of the terrain for a specific irrigation method (topography, micro relief, general slope),

- Climatic water balance and temperature, e.g. evaporation rates will affect the salt balance, and temperature and soil moisture regulate the transformation of constituents in the soil,
- Soil properties regarding the in-suitability to filter, buffer and transform inorganic and organic constituent s of wastewaters (precondition to avoid pollution of groundwater),
- Infiltration and permeability properties (precondition to avoid water logging in the root-one and allow the movement of wastewater constituents; precondition for well aerated soils),
- Adequate land drainage (precondition for sustainable irrigation to avoid water logging and salinity build up; either natural or artificial, or both),
- Nutrient status (determines the acceptable level of additional nutrient supply),
- Risk of solidity and alkalinity (affects structure and mobility of elements).

If follows that most soils are suitable for wastewater applications but not all wastewaters are suitable for all soils if the above objectives are to be met.

2. Socio-Cultural Aspects

It is essential that the acceptance of excreta or wastewater reuse by farmers, farm-workers, consumers and people living in the vicinity is ensured before it is considered for irrigation. Socio cultural studies or other information is required to ensure that there are no objections. Suitably designed information programmes may contribute to increased acceptance.

The introduction of human/animal excreta or wastewater use and the adoption of health safeguards related to wastewater irrigation may require changes in behavioral pattern. Human societies have evolved very different responses to the use of excreta, e.g. in many African communities it is regarded with disaffection whereas the use of excreta (or derivates) for fertilization of soils and its use in aquaculture has been common in Asian communities for thousands of years .Often, no distinction is drawn between products irrigated or fertilized with excreta or wastewater; the reuse of wastewater is not often hampered by socio-cultural disgust, although the possibility should be given serious attention.

3. Crop Selection

Crop selection should be based on the following criteria:

- Suitability to general agronomic and economic criteria (e.g. climate, soils, markets),
- Suitability to salinity and specific toxicity criteria
- Constraints to marketing imposed by public health concerns or regulations related to pathogens and toxic chemicals.

The most obvious problem related to health constraints is the contamination by wastewater of plants destined for human consumption without further processing, within a short time after contamination. The most effective precaution would be to irrigate only wood and fiber crops (e.g. cotton). Safety rules for the cultivation of food crops should observe:

- Minimal contact between effluent and edible crop part, e.g. tall growing fruit crops and trees,

- Preference for crops which are normally washed or treated before consumption, e.g. olives, citrus, avocados,
- Crops which are exposed for some days (or weeks) to desiccation and ultraviolet radiation before being marketed, e.g. crops which are not irrigated for several weeks before harvest,
- Low growing but erect crops if grown in furrows, ridge and furrow or drip irrigation systems.

Toxic chemicals in the form of heavy metals may occur in soils or in irrigation waters; some of them are taken up and accumulate in plants. Toxic concentrations must be avoided in both fresh water and wastewater. Similar regulations are applicable for both waters.
Guidelines for restrictions on types of crops irrigated with wastewater can be an effective remedial strategy. Crops can be grouped into three broad categories in increasing order of public health risk involved. Regulations exist for example in the USA (1977).Guidelines for crop categories have been established by WHO (1973). They have been effective in some countries with efficient means of control.
Careful cleaning and disinfection of contaminated crops at the point of use (i.e. consumer) may be effective in industrialized countries where public health standards are high and high quality freshwater is available. It is not applicable on a larger scale for developing countries. Market disinfection stations (e.g. at vegetable markets) may be theoretically considered, especially for large scale, centralized irrigation schemes.

Survival and retention of pathogens in the soil is of great interest. Moisture content, water holding capacity, pH, solar radiation, salinity and alkalinity, organic matter content and mineral composition etc are the deciding factors for survival and retention of these pathogens in the soil. It has been observed that bacterial pathogens survive only for a limited time compared to protozoa and helminthes. Survival time of pathogens in soil is longer than the plants. Enteric virus diseases are least effectively transmitted by waste water irrigation where as helminthes diseases are prone to be transmitted by waste water irrigation. Helminth like ascaris, hook worm and teniasis have high risk, protozoan infection like amoebiasis, and giardiasis have low risk and viral infection like viral gastro-entritis and infectous hepatitis have least associated risk. Generally sewage farm workers (87%) have been found seriously infected with more than one parasite. Epidemiological studies from developed and developing countries showed evidence of transmission of certain diseases associated with the use of raw or partially treated waste water. People consuming salad and other raw vegetables irrigated with waste water have great risk to hook worms. In developing countries in lack of proper legislation raw domestic effluent being used for irrigation and agricultural produce are being marketed without knowing much about associated health hazards.

WASTEWATER TREATMENT FOR IRRIGATION

Wastewater treatment is the most effective remedial measure in reducing health effects and soil contamination due to wastewater irrigation. The primary objectives in the following order of priority are:
- Maximum removal of helminthes (close to 100%),
- Effective reduction in bacterial and viral pathogens (minimum 99 to 99.9 %)
- Effective reduction of suspended load (site and irrigation type specific criteria),
- Maintain aerobic conditions,
- Production of nuisance and odor free effluent which is attractive to users.

These criteria are different that the traditional waste water treatment. Well designed and well operated stabilization ponds can meet all four criteria in warm climate like India.

A typical sewage treatment plant in tropical regions may have the following layout:
(i) Anaerobic ponds, at least two in parallel, with a minimum of 2 days total retention time: effects on helminthes; BOD,
(ii) Facultative pond(s),usually 5-10-15 days total detention time (temperature dependant) to reduce BOD, to remove bacteria by one or two orders of magnitude, and to serve as a security factor for Delmont eggs carried over from anaerobic ponds,
(iii) Maturation ponds(s) in series to achieve reasonably high bacterial removal; a standard unit for each location is recommended ideally, a retention time of 5 days each.

There are a number of options to consider in the final selection of initial and final treatment systems
The removal of heavy metals as well as removal of synthetic organic trace compounds (eg carbohydrates, organic acids, organic bases, poly-nuclear hydrocarbons (HC), halogenated HC, phenols, aliphatic and aromatic materials) are not primary objectives in developing countries, since waters contaminated with these industrial chemicals or metals should not even be considered as a source of irrigation water in developing countries. Removal of metals requires more sophisticated secondary biological treatment stages, e.g. activated sludge, bio-filters or algal ponds. These are complicated in design, difficult to operated and expensive in comparison with the pond system.

The advantages of ponds are: low costs for design, construction, operation and maintenance; no expenditures of energy (run by solar energy); high ability to absorb organic and inorganic shock loads; extreme simplicity of operations (fool proof) and ability to treat a wide variety of different domestic wastewaters (Mara/Cairn-gross 1989). The main disadvantage of pond systems is the large area of land they cover. However, recent research has shown that increasing pond depth (from 1-2 m to 2-3 m) may be successful in metropolitan areas with limited land resources.

An efficient reduction of COD and BOD, aimed at minimizing the potential eutrophication of surface or groundwater by effluents, is not a primary objective for wastewater treatment because the water is used on fields where biodegradation of organic materials (mainly C and N) takes place in the soil and many organic compounds and minerals are considered as useful agents to improve soil fertility and the aggregation of soils.
Disinfection, usually chlorination of raw sewage can reduce the number of bacteria but it is, unlike chlorination of fresh water, a vastly more compiled and unpredictable operation for wastewaters. Except when high levels of operation and maintenance are guaranteed it cannot be recommended as a general treatment, because irregular or inadequate disinfection is of little use for health protection. Effluent chlorination may have, in addition to its costs, a number of detrimental effects: treated effluents, rich in nutrients but low in microbiological activity, are ideal for the growth of some surviving bacteria; secondly it may contribute to proliferation of simple or complex chlorinated organics (chloramines) that may be toxic to fish or carcinogenic and mutagenic (Pescod/Arar 1988); further, some solutions will react with emulsifiers, fertilizers and pesticides and reduce their effectiveness. Occasionally chlorination may be used to reduce clogging hazards in drip irrigation systems or if bacterial

slimes and algae within the water transfer system pose serious problems. Dosages are in the range of 0.5 to 1 mg/l to control algae, iron bacteria and slimes

Table 25. Suggested treatment processes to meet the given health criteria for wastewater reuse

	Irrigation			**Recreation**		**Industrial reuse**	**Municipal reuse**	
	Crops not for direct human consumption	**Crops eaten cooked: fish culture**	**Crops eaten raw**	**No contact**	**Contact**		**Non potable**	**Potable**
Health criteria (see helow for explanation of symbols)	A + F	B + F OR D + F	D + F	B	D + G	C or D	C	E
Primary treatment	●●●	●●●	●●●	●●●	●●●	●●●	●●●	●●●
Secondary treatment		●●●	●●●	●●●	●●●	●●●	●●●	●●●
Sand filtration or equivalent polishing methods		●	●		●●●	●	●●●	●●
Nitrification						●		●●●

Chemical clarification						●		●●
Carbon adsorption								●●
Ion exchange or other means of removing ions						●		●●
Disinfection		●	●●●	●	●●●	●	●●●	●●●

Health criteria:
A freedom from gross solids: significant removal of parasite eggs.
B as A. plus a significant removal of bacteria.
C as A. plus more effective removal of bacteria. Plus some removal of viruses.
D not more than 100 coli-form organisms/ 100 ml in 80 % of samples.
E no facial coli-form organisms in 100 ml. plus no virus particles in 1000 ml. plus no toxic effects on man. And other drinking water criteria.

F no chemicals that lead to undesirable residues in crops or fish.
G no chemicals that lead to irrigation of mucous membranes and skin.

In order to meet the given health criteria. Processes marked ●●● will be essential. In addition, one or more processes marked ●● will also be essential, and further processes marked ●may sometimes be required.
· Free chlorine after 1 h.

SUITABILITY OF METHODS

Waste water irrigation does not require additional factors to be considered in designing the irrigation system however special attention is required to minimize direct contact and contamination of field workers working with waste water in fields. Water should be applied to achieve higher distribution efficiency of waste water in order to avoid or minimize the deep percolation losses.

1. Wild flooding is most simple method of irrigation in generally leveled fields for wide varieties of crops. The method is not suitable for waste water irrigation because of low irrigation efficiency (30%-40%) and irrigators have to stand in waste water or the mud while working in the fields. Field may get inundated and depth of application may vary significantly in the field.

2. Check basin irrigation are most commonly use irrigation methods in India and other developing countries with small stream size for most of the crops. It is suitable for fairly leveled fields. The method offers better control over the amount of water to be applied and possible most suitable surface irrigation method which can handle waste water safely. The method is labour intensive and there is risk for labourers for exposure to waste water and produce contamination.

3. Furrow irrigation is suitable for row crops grown over ridges. Actually ridges are well above the water surface and hence have least risk for contamination of agricultural crops from erect crops. It is most flexible among all methods in terms of length, slope limitation and stream size. Accumulation of salts on the top of the ridges due to peculiar wetting pattern may impair the crop growth and may need leaching. There remains the risk of contamination of agricultural produce specially for the vegetable crops.

Table 26. Factors affecting choice of irrigation method, and special measures required when wastewater is used

Irrigation method	Factors affecting choice	Special measures for wastewater
Border (flooding) irrigation	Lowest cost, exact leveling not required	Thorough protection for field workers, crop-handlers and consumers
Furrow irrigation	Low cost, leveling may be needed	Protection for field warders, possibly for crop-handlers and consumers
Sprinkler irrigation	Medium waster use	Some Category B crops,

	efficiency, leveling not required	especially tree fruit, should not be grown. Minimum distance 50-100 m from houses and roads.
		Anaerobic wasters should not be used because of odour nuisance
Subsurface and localized irrigation	High cost, high water use efficiency, higher yields	Filtration to prevent clogging of emitters.

REDUCING HUMAN EXPOSURE

Four groups of people can be identified as being at potential risk from irrigation use of wastewaters: farmers and agricultural field workers, crop handlers, consumers, and those living near affected fields.
Regarding on farm risks, exposure to many parasites can be reduced by adoption of certain health safeguards, e.g. use of footwear. Rigorous health education programmes are needed to propagate meticulous personal hygiene.
Immunization is not possible against helminthes infections ad control of other infections (e.g. typhoid and hepatitis) is not feasible on a large scale. Additional protection may be provided by the availability of medical facilities to treat diarrhoeal disease and by chemotherapeutic control of nematode infections.
Many risks can be reduced by strict personal, kitchen and food hygiene, e.g. by thorough cooking of vegetables, meat, milk, etc. regular health education campaigns are required to improve standards, especially in societies with poor education.
Local residents should be kept fully informed about the location of irrigated fields, so that they may avoid entering them and also prevent children from doing so. Warning notices may be posted and fences may be erected.

MONITORING AND EVALUATION

Without regular and effective surveillance during project implementation, the anticipated benefits from the project will be endangered and there may be real possibilities that the project may contribute to the development or serious health and environmental hazards. Thus, a monitoring system should be implemented which focused on targeted outputs in terms of water quantity and quality, delivery of water to the irrigated area, quantity and quality of agricultural products, and compliance with health standards on the part of farmers, treatment plant workers, traders or consumers of irrigated crops. Since the aim of monitoring and evaluation is to achieve successful project performance, it should be an integral part of an effective management information system in orders that:

- Timely corrective actions can be taken to reduce the probability of occurrence of any environmental or health hazard,
- Project assumptions are seen to be value and can be verified,
- Achievement of project objectives and impacts can be determined,

Lessons for other projects can be learnt for more effective planning and operation in future

CONCLUSION

The unchecked and uncontrollable population of the world has increased the stress on the recourses available to mankind. Agriculture being the primary need of, the biggest problem faced is the decline good quality ground water. Major problems arising with the conventional irrigation methods followed like, water logging, salinity problem, ground water depletion and waste water disposal add to the stress on the global water recourses.

Major problems arising with the conventional irrigation methods followed like, water logging, salinity problem, ground water depletion and waste water disposal add to the current issues. More over the irrigation potential of India and the actual irrigation are two distant neighbors.

As the population in the urban areas increase so does the effluent domestic water. Due to this increase the amount of waste water being disposed into the rivers and other water bodies add to the unavailability of good quality water. This is a direct impact on the environment and affects the ecosystem. The waste water having high nitrogen and nutrient content can best be seen as a source for Eutrophication. Using waste water as a medium of irrigation fulfills many objectives such as ground water recharge, fertilization of land and safe disposal of toxic concentrations of organic and inorganic chemicals. But using waste water can lead to numerous health hazards as well. Proper selection of site and selection of crop is required where domestic effluent is to be used. As the waster water contains numerous pathogens and bacteria the farmers working in close contact with it should take proper safety measures. Moreover the waste water used should be treated first and then applied to the fields. This can be done effectively and economically by the use of stabilization ponds.

Growing pressure on available fresh quality irrigation water resources and increasing awareness to environmental issues among human masses should force researchers and planners to design waste water disposal system in such a way that it could be safely made available to its users. This is the right time to give a rational thought in this direction to make the waste water a safe water resource for irrigation

Abstract

The operation of wastewater lagoons systems located in the South Yungas Province of Bolivia has been analyzed over a 2-year period. Facultative and maturation lagoons were evaluated for their performance in removing total suspended solids (TSS), biochemical oxygen demand (BOD), chemical oxygen demand (COD), nitrogen, phosphorus, and coliforms. Facultative lagoons operating in San Antonio were found to remove approximately 74% total suspended solids, 70-89% BOD, 62-85% COD, 53% nitrogen, 52% phosphorus and 97.8-99.9% coliforms. Maturation ponds were found to remove 74-93% total suspended solids, 22-62% BOD, 10-95% COD, 3% nitrogen, 20-95% phosphorus and 77.4-99.96% coliforms. Results from the 2-year study indicate that these wastewater treatment systems are currently performing as expected; however regular maintenance, specifically removing algae every (2 weeks) is required. The removal percentages of the treatment systems (comparing influent to effluent) ranged from 74-97% TSS, 78-98% BOD, 70-99.7% COD, 58-77% nitrogen, 62-99.9% phosphorus, and 99.99% coliforms.

Introduction

Improved water sources, sanitation, and hygiene are key factors in improving health and reducing deaths in developing countries. With 900,000 people lacking access to improved water sources (WHO, 2008), and 2.5 billion having no access to improved sanitation (WHO, 2008), the need for appropriate, cost-effective technologies in addressing some of these issues is becoming increasingly important. In addition, the maintenance and operation of these technologies is critical to the systems performance in achieving the desired objectives related to protecting public health and water quality, as measured by the presence of pathogens and physical-chemical parameters (e.g., biochemical oxygen demand, nitrogen, phosphorus).

Implementation of alternative wastewater technologies such as lagoons in addressing sanitation issues has been reported in countries such as Mexico and Honduras. There is however, minimal research on evaluating the performance of these lagoons in most developing countries. The performance of lagoons (serving population sizes – 800; 7,280; 11,000) in Mexico in terms of sludge accumulation/removal and inactivation of fecal coliforms and *Ascaris* eggs has been studied by Nelson et al., (2004). The performance of lagoons in removing *Escherichia* coli, fecal coliforms, suspended solids (SS), five-day biochemical oxygen demand (BOD_5) in Honduras has also been studied (Oakley, 2005). However, the performance of lagoon systems in South America, for example in countries such as Bolivia, remains largely un-evaluated.

Accordingly, the objective of this study is to evaluate the performance and effectiveness of lagoon systems operating in the South Yungas Province of Bolivia in removing total suspended solids, BOD, chemical oxygen demand (COD), nitrogen, phosphorus, and coliforms. The lagoons are used in two small communities: San Antonio (950 inhabitants) and Sapecho (1,030 inhabitants).

Bolivia is particularly unique because it the most indigenous country in South America, with almost 40% of the country's population representing indigenous people. It is the poorest country in South America and the 3rd poorest country in the Americas with per capita GDP of less than US$1,000 per year and 64 percent of its population living below the poverty line. The mean income per capita in indigenous households was approximately US$46 per month in 2001 compared with US$74 for non-indigenous households (World Bank, 2008). STATcompiler (2008) reports that La Paz has the highest percentage of untreated diarrhea cases (28.2% compared to 18.6% average of Bolivian departments). Further, lack of access to sanitation and unhygienic practices has lead to diarrhea diseases that cause 6% of all deaths in Bolivia. It is estimated that in Bolivia, only 22% of the rural population has access to improved sanitation (WHOSIS, 2006). Thus, understanding how existing community-based systems operate is important if sanitation technologies are to be implemented successfully on a wide basis.

Background

Demographics, location, and costs

The South Yungas region is characterized as the transition zone between the Andes Mountains and the Amazon River basin: smaller mountain ranges paralleling the Andes are divided by rivers which generally flow north to the Amazon (Fuchs et al., 2008). Income of people in the South Yungas is derived from agriculture, primarily

from coffee, cacao, citrus and bananas. These are the main exports that contribute to the economic activity of the area (Palos Blancos Municipal Report, 2007). A majority of the people living in communities such as San Antonio, Sapecho and Palos Blancos are immigrants from the higher elevation Alto Plano region near La Paz. The population growth is estimated to be greater than 3% per year, as migrants move to this agriculturally productive area and the communities urbanize (Fuchs et al., 2008).

The community of San Antonio is located in the South Yungas Province, northeast of La Paz city, and at 1,500 feet above sea level. There are 950 habitants of this community. The community is served by a wastewater treatment/collection system. There are reported to be 130 connections to the sewage systems. This serves "almost all" of the urban population of San Antonio. However, several outlying agricultural regions which are served by San Antonio's water supply are not connected to the sewage system. The neighborhood of Nueva Esperansa is not connected because it lies to low for sewer connections, and instead utilizes composting latrines.

The total capital cost of the wastewater treatment and collection system of San Antonio was US$231,748. US$62,790 of the total was covered by the habitants of San Antonio. This local cost includes home installations of bathrooms and household sewer connections. The remainder of the cost included items such as the preliminary investigation, land costs, infrastructure for the sewer system, transmission of potable water, and hygiene education. The costs were financed by the U.S. Agency for International Development (USAID) through ACDI/VOCA (Meredith et al., 2007). ACDI/VOCA is a non-governmental organization that implements sanitation measures in rural communities in eastern La Paz department, in the province of South Yungas.

The community of Sapecho is also located in the South Yungas Province at 1,500 feet above sea level. There are 1,039 habitants of this community. During the research period, the number of sewage connections ranged from 150-180 as more residents connected to the system. The system was designed for 201 connections. The water distribution system serves approximately 300 connections, including several in rural areas outside of the town center. Due to the rapid rate of connections that was taking place during the first year of our research project, it was difficult to estimate what percentage of the population was served by the sewage system (Meredith et al., 2007).

The total cost of construction and installation of the Sapecho wastewater treatment and sewer system was US$321,655, paid for by contributions from ACDI/VOCA and the community. US$134,372 of the total was paid by the community and included the cost of home installations. The remainder of the cost included items such as the preliminary investigation, land costs, the infrastructure for the sewer system, transmission of potable water, and the reactor for wastewater treatment (Meredith et al., 2007).

Wastewater Treatment System

San Antonio: The town treats its wastewater with a lagoon system. One facultative lagoon is followed by two maturation lagoons in series (Figure 1). The facultative

lagoon is 28 m × 55 m and approximately 1.5-m deep. A facultative lagoon consists of three layers. The upper-most layer is oxygenated by photosynthesis and wind-induced mixing. In this aerobic zone, bacterial action provides biological treatment. This is followed by a facultative layer which can have varying oxygen concentrations. The deepest layer is anaerobic. Large biological solids (solids in influent, algae, etc.) settle on the lagoon bottom. These settled biological solids create a sludge which is estimated to require removal every ten years. San Antonio's lagoons were implemented in 2006, therefore no sludge has been removed from the lagoons as of June 2008. After leaving the facultative lagoon (point B in Figure 1) wastewater flows through two maturation lagoons which continue the process of treating the wastewater. The other two lagoons (maturation) are smaller than the facultative lagoon, at 13 × 39 m. These lagoons are also half as deep as the facultative lagoon. While they also provide some suspended solids removal, their primary function is pathogen and nutrient removal.

Sapecho: The Sapecho wastewater treatment system (Figure 2) has the following processes: i) grit removal - 6.15 m × 1.45 m × 0.95 m; ii) upflow sludge blanket reactor (UASB) - 9.84 m × 6.35 m (length × height)(extending tube for biogas collection and release: 3.50 m (height)); iii) sludge drying beds (two beds of 10.30m × 12.45m (designed for 30 cm gravel, 10 cm of sand, and 25 cm of sludge); and iv) two maturation Lagoons (two lagoons)- total dimensions 74.40m × 61.35m (1^{st}: 51.50m × 12.50m and (2^{nd}: 49.50m × 12.50m).

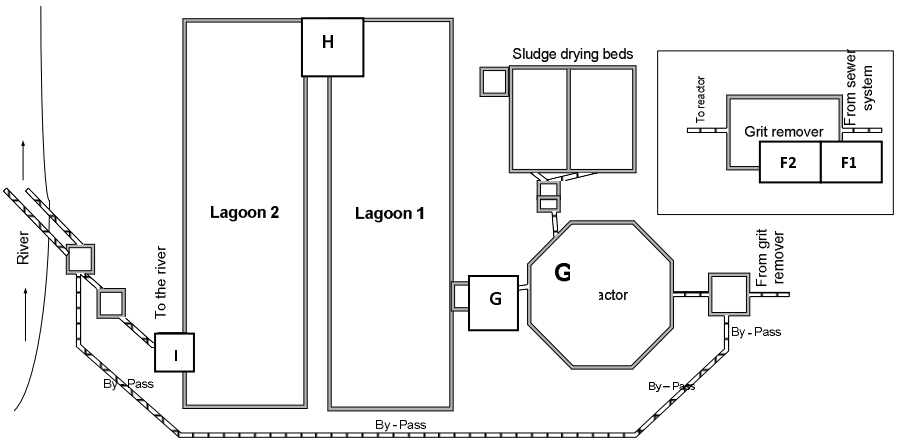

Figure 2 Wastewater treatment systems in Sapecho, Bolivia, with sampling locations from the plant and receiving water body labeled F,G, I. Flow of wastewater is right to left.

Methodology

Measurements have been made over a 2-year period (June/July 2007, and June/July 2008) by undergraduate and graduate students participating in an NSF Research Project. For both years, samples were collected and tested for TSS, BOD, COD, nitrogen, phosphorus, and coliforms. The results from 2008 were compared with the results from 2007 to monitor changes in the lagoon's removal efficiencies.

San Antonio. The first wastewater samples in San Antonio were collected at four different locations sites A, B, C, D (Figure 1). These sites are accessed through inspection boxes where wastewater is entering or exiting a particular lagoon.

Using a 2.5-L plastic container a grab sample was collected in the morning from these four separate inspection boxes. Grab samples at each site were then poured into 2-L and 300-mL sample bottles and sent to an approved laboratory. The 2-L sample bottles were tested for several chemical and physical properties: e.g., TSS, BOD, COD, nitrogen, and phosphorus. The 300-mL samples were tested for total fecal coliforms, an indicator of the presence of *E. Coli*. All samples were immediately transported by boat and taxi to Palos Blancos, Bolivia where they were immediately packed in ice and shipped overnight to La Paz, Bolivia by bus to the Instituto de Ingeniería Sanitaria y Ambiental (IIS) laboratory.

Additional measurements were performed on the facultative lagoon. These measurements compared the difference in dissolved oxygen and pH to provide information on how the facultative lagoon is functioning over the day. Using a reach pole with a 2-L attachment, grab samples were collected throughout the day to monitor changes in the lagoon biochemistry. Grab samples were taken from the surface of the lagoon with minimal disturbance and mixing with the atmosphere. Each grab sample was tested two to three times. In this sampling dissolved oxygen was measured with a handheld Hach® DR/820 Colorimeter and *Dissolved Oxygen Reagent High Rand Cat. 25150-25.* A pH reading was taken using *AquaCheck* litmus

paper, and results were interpreted by color differential of the paper and the scale provided on the bottle. The pH and DO readings were taken over a 16-hour period.

Sapecho. Similar sampling procedures employed in San Antonio were also administered in Sapecho. Using a 2-L plastic water bottle, a grab sample of wastewater was collected from sites F1, F2, G, and I, Figure 2. A 300-mL sample bottle was filled at sites F2, G, and I. These sites are accessed through inspection boxes where waste is entering or exiting a specific part of the system. Samples were immediately transferred to Palos Blancos by taxi where they were immediately packed in ice with the 2-L plastic water bottle samples and shipped overnight to La Paz by bus.

The 2-L sample bottles were tested for the following chemical and physical properties: BOD, COD, nitrogen, phosphorus, total coliforms, total solids, and volatile, fixed, and total suspended solids. The 300-mL samples were tested for total fecal coliforms which is an indicator of the presence of *E. Coli*.

The research conducted in Sapecho also involved determining the composition of methane gas that was produced by the upflow sludge blanket reactor. For methane determination, a sample of the biogas exiting the reactor was collected on June 29, 2008 in a 20-mL syringe. The attachment on the top of the gas tube was removed and replaced in order to read the pressure of the gas. The attachment had a small opening to allow the release of gas. This small opening was covered with rubber to ensure only biogas entered the syringe at the time the sample was retrieved. A test was first performed to make sure biogas was entering the syringe. After gas was collected by directly inserting the syringe through the rubber and into the small opening, it was exerted over a lit match. The match held flame, and it was concluded that the gas did enter the syringe. Next, two real samples were obtained. Immediately after the syringe was filled, it was capped with a small piece of rubber. A masking tape was then used to seal shut the syringe. The next morning another flame test was performed successfully. The first sample was collected and sent to the Facultad de Ingeniería Química laboratory in La Paz to determine the composition of the biogas. A second sample was collected on July 3, 2008 and sent to the lab for similar analysis.

Results

San Antonio-Facultative Lagoons: Results of removal efficiency in facultative lagoons operating in San Antonio are shown in Table 1. The results obtained in 2008 are compared 2007 results. Total suspended solids in the influent from 2007 to 2008 rose significantly. Influent biochemical and chemical oxygen demand have also risen to a large extent from 2007 to 2008.

All measurements suggest the wastewater has gotten stronger over the 2-year sampling period. The BOD/COD ratio of the samples has remained relatively similar over the sampling period (0.56 and 0.63) which suggests the organic and solid loadings to the treatment plant are municipal sewage. No water conservation measures were implemented over the course of the year that might explain the higher influent concentrations; however, the community uses significant less water than North American communities which will result in a higher strength wastewater. The high values for the wastewater constituents along with the large differences between

the two years point to a difficulty in designing and operating treatment plants in these settings; that is, the strength of the wastewater and variability in wastewater characterization and subsequent plant loadings.

Important to these communities, coliform removal has been in the 98-99% removal range for the two years of sampling (the expected removal in these types of systems is 92-99.8%) (Crites and Tchobanoglous, 1998).

Even with the increase in concentration, Table 1 shows that the facultative lagoon has been able to function as designed as indicated by the percent removal of BOD, COD, TSS, nitrogen, and phosphorus. The removal for TSS and BOD for both years is slightly lower than typically expected for TSS and BOD removal in a facultative lagoon system (the expected removal in a facultative lagoon is 90-95% TSS and 75-95% BOD) (Crites and Tchobanoglous, 1998). However, measurements we made for turbidity indicate that it decreased by approximately 66% across the facultative lagoon (Point A and Point B) and 77% (Point A and Point D) across the whole lagoon system. The turbidity results are comparable to TSS removal which is in the range of 74% (2007) and 55% (2008).

Table 1 Removal efficiency results (2007/2008) of facultative lagoon operating in San Antonio, Bolivia. Results are from Sampling Points A and B, Figure 1.

Parameters	**Infl.**2007**	**Infl.** 2008**	**Effl.^ 2007**	**Effl.^ 2008**	**% Rem.* 2007**	**% Rem.* 2008**
Total Suspended Solids (mg/L)	215.0	850.0	56.0	384.0	74.0	54.8
Biochemical Oxygen Demand (mg O_2/L)	190.0	340	58.0	38	69.5	88.8
Chemical Oxygen Demand (mg O_2/L)	444.0	700	168.0	102	62.2	85.4

Infl.**=influent; Effl.^=effluent; Rem.*=removal

The measured nitrogen removal of 53% in the single facultative lagoon was found to be in the expected range of 43-82% (Crites and Tchobanoglous, 1998). Nitrogen removal in the lagoons is dependent on mechanisms of volatilization, for example of ammonia which is pH-dependent, algal uptake, nitrification and denitrification, sludge deposition, and adsorption onto bottoms soils. A higher number of facultative ponds in series, increased number of detention time, water temperature and pH all play a significant role in nitrogen reduction (Crites and Tchobanoglous, 1998). Phosphorus removal was determined to be 52%, which is within the expected removal range for lagoon systems (expected removal is 10-50%) (Muga and Mihelcic, 2008).

Overall, the system in San Antonio appears to be operating well. It is believed that if the community continues to use the system appropriately and the water committee ensures the maintenance of the lagoons the wastewater system will be a sustainable and functioning asset to the community.

Dissolved oxygen and pH were also measured in this study and used as an indicator of photosynthetic processes occurring in the facultative lagoon. Over the 16-hour period, the DO concentrations increased steadily throughout the period from 0.5 mg/l to 7 mg/l. However, temperature and pH remained stable (temperature over the day ranged from 22-27^{o}C). The ambient temperature ranged from 25-28^{o}C. The pH remained stable in the range of 7.5-8.0.

Dissolved oxygen and pH were also measured at San Antonio in 2008 and used as an indicator of photosynthetic processes occurring in the facultative lagoon. Over the 16-hour period, the DO concentrations increased steadily throughout the period from 0.5 mg/l to 7 mg/l (data not shown). However, temperature and pH remained stable. The lagoon temperature ranged from 22-27^{o}C over the sampling period while the ambient temperature ranged from 25-28^{o}C. The pH remained stable over the sampling period in the range of 7.5-8.0.

An explanation for the low concentrations of DO observed early in the morning could be because microscopic, aquatic animals and plant life present in the lagoon have utilized any oxygen present in the water. The low level of DO usually begins late in the afternoon and at night when photosynthesis ceases, but animal/plant respiration continues. A lower DO level could also indicate decomposition, whereby bacteria utilize oxygen to breakdown dead material. An increase in DO during the day indicates photosynthetic activity from the plants.

However, in contradiction of the DO data that suggests that photosynthesis was taking place, stable pH values were also observed. This suggests that aeration was not due to photosynthetic algae as they would contribute DO to the system (unless the alkalinity was so high to buffer any pH change; however, we did some screening alkalinity measurements which suggested the alkalinity was not abnormally high). Instead, the increase in DO concentrations may be attributed to wind-driven mixing. On the days the lagoons were monitored, wind was sufficient to move surface flocs across the lagoon to the down-wind side of the lagoon.

It should also be noted that in a stratified lagoon, the DO should decrease with depth, with lower DO expected at the bottom of the lagoon near the decomposing sludge, then on the surface. Temperature, pH and alkalinity also change with depth and may influence how physical-chemical parameters such as nitrogen, phosphorus and coliforms are removed. Future studies should consider collecting samples at different depths and analyzing for the different physical-chemical characteristics.

Dark brown-black flocs on the surface of the facultative lagoon were also observed. These flocs were identified as a build-up of floating solids, fats, grease and scum. Regular maintenance is required to remove the solids from the lagoon surface about every three days (Oakley, 2005).

San Antonio Maturation Lagoons: These lagoons are smaller than the facultative lagoon; specifically 13 × 39 m. They are also half as deep as the facultative lagoon. While they also provide some suspended solids removal, their primary function is pathogen and nutrient removal.

As shown in Table 2, the percent removal changed significantly in the maturation lagoons from 2007 to 2008. In 2007 the maturation lagoon removed 20% of phosphorus and 95% of coliforms. Phosphorus removal in ponds is usually limited and application of chemicals such as ferric chloride may be utilized for high strength loadings (phosphorus concentrations of 15 mg/L) (Crites and Tchobanoglous, 1998). The effluent concentration of phosphorus of 3.2 mg/L in 2007, was still higher than effluent target of 1 mg/L in the U.S (Crites et al., 2000).

There appears to be minimal removal of nitrogen, about 1% in 2008. Nitrogen removal in maturation and facultative ponds may occur through several processes, for example, nitrification, denitrification, uptake by pond algae, and accumulation in the pond sediments associated with dead algae. The lack of reduction in nitrogen removal, as observed from the 2007 data may be due to organic nitrogen associated with dead algae. Hence, as previously suggested, regular cleaning and removal of the algal biomass is required to enable proper functioning of the maturation pond.

Coliform removal was found to be 95% in 2007 and 77.4% in 2008. These removal values especially for 2008, is below the expected removal of 1-2 orders of magnitude (Crites and Tchobanoglous, 1998). Removal of bacteria and viruses in maturation and facultative ponds is highly dependent on temperature and detention time (Crites et al., 2000). High temperatures and longer detention times are conducive to bacteria and virus inactivation.

When compared to the facultative pond, the maturation pond has comparable removal of TSS, but lower removal of BOD, COD, nitrogen, phosphorus and coliforms. The results show that a majority of these physical-chemical parameters are removed in the facultative lagoon.

Table 2 Removal efficiency results (2007/2008) of maturation ponds operating in San Antonio, Bolivia. Results are for Points C and D, Figure 1.

Parameters	Influent 2007	Influent 2008	Effluent 2007	Effluent 2008	Percent Removal 2007 (%)	Percent Removal 2008 (%)
Total Suspended Solids (mg/L)	215.0	265	56.0	260	74.0	2.0
Biochemical Oxygen Demand (mg O_2/L)	54.0	22	42.0	14	22.2	36.4
Chemical Oxygen Demand (mg O_2/L)	166.0	76	134.0	68	19.3	10.5
Total Nitrogen (mg Nt/(Kt)-N/L))	19.6	31.5	22.4	31.15	Increase	1.0
Total Phosphorus mg P/L	4.0	5.74	3.2	5.24	20.5	9
Coliforms (U.F.C. per 1000mL)	1.0×10^5	2.7×10^5	5.0×10^3	6.1×10^4	95	77.4

Overall Removal in Santonio: When looking at removal of pollutants across the whole facultative-maturation lagoon treatment process, overall the system removed 74% TSS, 78% BOD, 70% COD, 58% nitrogen, 62% phosphorus, and 99.99% coliforms. The system is performing well in removing TSS, BOD, COD, nitrogen, phosphorus and coliform.

Sapecho - Anaerobic Reactor: Table 3 shows data from the 2007 sampling period. It shows that BOD, COD, nitrogen, phosphorus and coliforms were decreased by 75%, 80%, 76%, 85%, 97%, respectively in the anaerobic reactor (between Points F and G, Figure 2). The anaerobic reactor significantly reduces the BOD and COD concentrations from 972 mg/L to 252 mg/L and 1,914 mg/L to 394 mg/L, respectively. It also reduces nitrogen from 26.6 mg/L-N to 6.4 mg/L-N, phosphorus from 64 mg/L-P to 9.07 mg/L-P, and coliforms from $9.0x10^8$ UFC/100 mL to $2.7x10^7$ mL.

The first gas sample collected from the reactor had the following gas composition: 77% methane, 15% carbon dioxide, and 8% other gases. The second sample had the following gas composition: 56% methane, 11% carbon dioxide, and 33% other gases. According to the EPA if the recovered gas is between 60-80 percent methane, the gas can be used to produce electricity or it may be directly combusted as a cooking fuel. It was concluded however that it was not feasible at this time to collect and utilize the gas because no users were identified physically close by to the reactor.

Sapecho - Maturation Lagoons: Data obtained between Points G and I as shown in Figure 2, are used to calculate the removal efficiency in the maturation lagoons. Data collected for these two points in 2007 are shown in Table 3. Data collected for these two points in 2008 are shown in Table 4.

Removal efficiency calculations between Points G and I in 2007 show there is 93% removal of TSS, 98% removal of BOD, 98.6% COD, 3% nitrogen, 99.8% phosphorus, and 99.96% coliforms. The lagoon is functioning well, with high removal percentages in TSS, BOD, COD, phosphorus, and coliforms.

Removal efficiency calculations between Points G and I in 2008 show there is 71% removal of TSS, 80% removal of BOD, 48% COD, 36.5% nitrogen, 16.7% phosphorus, and 98.8% coliforms. The lagoon is functioning well, with high removal percentages in TSS, BOD, COD, phosphorus, and coliforms. These results indicate a properly functioning lagoon.

Overall Removal in Sapecho: When the overall removal efficiency of the system is considered, the data obtained from influent (Point F of Figure 2) to the effluent discharge point (Point I of Figure 2), we see that there is a 98% reduction in BOD, 99.7% reduction in COD, 77% reduction in nitrogen, 99.9% reduction in phosphorus and 99.99% reduction in coliforms (2007 data). These values are shown in Table 3.

When 2008 data are considered for Points F and I (Table 4), we see 97% reduction in TSS, 97% reduction in BOD, 91% reduction in COD, 61% reduction in nitrogen, 7% reduction in phosphorus, and 99.90 reduction in coliforms.

When maturation ponds operating in San Antonio and Sapecho are compared, we find that the maturation ponds in Sapecho are performing more efficiently than

the maturation ponds in San Antonio. Regular maintenance is important in proper functioning of lagoon. The use of an appropriate technology net device for regular cleaning (for example a net to skim algae of lagoon surface) and the introduction of ducks to eat surface vegetation were proposed to operators as needed for proper lagoon functioning.

Table 3 Comparison of influent, reactor effluent, and system effluent characteristics in Sapecho, Bolivia (Points F, G and I of Figure 2, 2007)

Parameters	**Units**	**Point F** (influent)	**Point G** (exiting anaerobic reactor)	**Point I** (effluent	**% Removal** (between influent and effluent)

Coliforms	U.F.C./100 mL	6.8×10^7	6.8×10^6	8.0×10^4	99.9

Conclusions

Results from the 2-year study indicate that the wastewater treatment systems in the South Yungas, Bolivia are currently performing as they should, and the overall wastewater treatment systems are not having a large impact on the receiving stream. However, regular maintenance, for example manually cleaning/removing algae from the lagoons is needed in order to ensure their proper operation. Frequent cleaning/removal of sludge from the exit/entrance pipes are needed to enable smooth flow of the wastewater. The energy content and gas composition evaluation from a

wastewater reactor in Bolivia is an initial star to determining the feasibility of using methane as an energy source. More experiments/tests are however needed to determine the composition of gases over a continuous period of time. Also of interest is the volume of methane gas that is produced during a day and whether that can be used by a local domestic or industrial user.

Understanding and Controlling Fouling in Membrane Bioreactors

Roger Babcock Jr.

University of Hawaii, Civil and Environmental Engineering Department, 2540 Dole Street, Honolulu, Hawaii 96822; PH (808) 956-7298; FAX (808) 956-5014; email: rbabcock@hawaii.edu

ABSTRACT

Membrane bioreactors (MBRs) are an activated sludge process in which the conventional secondary clarifier is replaced by a membrane separation process (either microfiltration or ultrafiltration). As with other membrane systems, the most important characteristics are the membrane flux and the membrane permeability both of which are highly dependent upon temperature and degree of fouling. Like other membrane systems but to a greater degree, MBRs are susceptible to biofouling. Biofouling is not well understood but does increase operating pressure, reduce maximum flux, increase recovery cleaning requirements, and possibly reduce total membrane life. All of these effects of biofouling have adverse effects on either initial capital cost or ongoing operation and maintenance costs for MBRs. The overall goal of this research is to obtain a better understanding of biofouling in MBRs and methods to control said fouling in order to improve the economics of water recycling. The conclusions thus far from the pilot and bench-scale studies are that SMP and EPS are very important relative to biofouling in MBRs and that several tools are useful to examine biofouling trends. These tools include the critical flux test, resistance in series component analysis, and measurement of different fractions of EPS and SMP.

INTRODUCTION

Membrane bioreactors (MBRs) are a relatively new wastewater treatment technology which is nearly ideal for water recycling operations including satellite reclamation (sewer mining) due to exceptional processed water quality and minimal footprint compared to conventional treatment process trains. MBRs are quite simply an activated sludge process in which the conventional secondary clarifier is replaced by a membrane separation process (either microfiltration or ultrafiltration). The MBR can be operated either with or without primary clarification, but always requires fine screening (3 mm or smaller) to protect the membranes from abrasive and stringy waste components (hair in particular). Due to the presence of an absolute barrier for suspended solids, MBRs are able to maintain very high solids concentrations (8,000 to 20,000 mg/L) and solids retention times which allows for smaller aeration basins and high BOD removals. Since MBR effluent is micro- or ultra-filtration permeate, effluent suspended solids are typically near the detection limit and turbidities are typically less than 0.2 NTU. As with other membrane systems, the most important characteristics are the membrane flux and the membrane permeability both of which are highly dependent upon temperature and degree of fouling. Flux is often expressed as gallons permeated per day per square foot of membrane area (GFD) and permeability is usually the water flux per unit transmembrane pressure (TMP). Like other membrane systems but to a greater degree, MBRs are susceptible to biofouling. Biofouling is not well understood but does increase operating pressure, reduce maximum flux, increase recovery cleaning requirements, and possibly reduce total membrane life. All of these effects of biofouling have adverse effects on either initial capital cost or ongoing operation and maintenance costs for MBRs. Because MBRs are quickly becoming the process of choice for water recycling, there is a need to improve cost efficiency by controlling biofouling.

METHODS

The overall goal of this research is to obtain a better understanding of biofouling in MBRs and methods to control said fouling in order to improve the economics of water recycling. Membrane flux (J) is directly proportional to transmembrane pressure drop (TMP) and inversely proportional to viscosity (η) and a "resistance" factor (R_T).

$$J = \frac{TMP}{\eta R_T}$$

The resistance to passage of water through a membrane submerged in activated sludge mixed liquor has been modeled as consisting of at least three components including the inherent membrane resistance (R_m), the resistance of the cake layer (R_c) and the resistance of the foulants (R_f) (Chang et al, 1998). It may also be possible to separately quantify the biofilm resistance (R_b) as a portion of the foulants. Thus,

$$R_T = R_m + R_c + R_f + R_b$$

Experimental methods have been developed to estimate each of these individual resistances. The foulants may consist of fine colloidal particles that can block pores, macromolecules that coat and narrow or block pores, or even complex biofilm communities consisting of organisms engaged in community sensing, voids, extracellular polymers, and cellular debris. We are attempting to catalog the types and quantities of microorganisms present in MBRs. Comparisons are being made between MBRs operated under different conditions such as flux rate, hydraulic retention time, solids retention time, and organic/nutrient loading rate. In addition, we are quantifying various parameters such and transmembrane pressure (TMP), biofilm thickness, soluble microbial products (SMP), extracellular polymeric substances (EPS), viscosity, particle size distribution (PSD), soluble COD, and filterability and looking for correlations with microorganisms/biofouling. One goal is to correlate microorganism population dynamics with biofouling conditions and system operating conditions. This presentation will describe relationships between biofouling (expressed as increased transmembrane pressure (TMP)), operating conditions, predominance of certain bacteria types, and measured water quality parameters observed in bench and pilot MBRs.

RESULTS AND DISCUSSION

Six different brands of MBRs have been pilot tested side-by-side in Honolulu, Hawaii. The pilot testing began in September 2003 and is on-going. Pilot MBR units from Zenon Environmental (vertical hollow fiber UF), US Filter (vertical hollow fiber MF), Ionics Inc (horizontal hollow fiber MF), Enviroquip (vertical flat panel MF), Huber Inc (rotating flat panel UF), and Koch (vertical hollow fiber MF) have been tested. The Enviroquip MBR was converted to a membrane thickener/aerobic digester (PAD-K) for a period of time. In addition to the pilot MBRs, two bench-scale MBRs; one employing Enviroquip membrane panels and one using Ionics horizontal hollow fiber membranes were started-up in November 2005 for additional studies on membrane fouling due to SMP, EPS and the specific bacteria that produce them.

The Koch pilot MBR, was operated at an average flux of approximately 10 GFD, an average TMP of -1.0 psi, and the MLSS increased in the first 30 days from an initial seed value of 3,000 mg/L and then

was maintained at a steady value of 11,000 mg/L. The carbohydrate fraction of EPS appears to have initially increased and then reached a semi-stable value of 50 to 60 mg/g VSS. The protein fraction, was lower in magnitude (15-25 mg/g). The average values for the SMP fractions are 5.9 and 6.3 mg/L for carbohydrates and proteins, respectively. In contrast to this are the observations in relation to experiments on sludge thickening using the Enviroquip PAD-K thickener/digester system. The PAD-K conducted thickening/digestion of TF/SC waste sludge. With the intentional creation of high-fouling conditions, the carbohydrate SMP increased dramatically (from approximately 20 mg/L to approximately 200 mg/L), while the carbohydrate EPS also went up a lot (from 36 to 160 mg/L), the protein SMP also went up a lot (from < 1 to 10 mg/L), and the protein EPS did not change very much (from 25 to 30 mg/L). The most important is the SMP which can foul the membranes by blocking membrane pores. These data indicate that carbohydrate microbial products and to a slightly lesser extent, protein products, were elevated when the membranes approached a fouled state. In addition, it appears that the production of excessive extracellular products could be a biological response to the presence of excess ammonia.

The bench-scale reactors (one flat-plate type and one hollow fiber type) are operated via PLCs and SCADA. Table 1 shows average SMP values and reductions across the membranes which are 40-50% for Enviroquip and 5 to 40% for Ionics. The reductions across the membrane indicate the potential for fouling. Monitoring total filtration resistance and critical flux periodically can be useful for determining fouling rates. The first values for critical fluxes were estimated to be 26 and 32 GFD for the Enviroquip and Ionics MBRs, respectively (Figures 1 and 2). These values are interpreted to indicate the maximum flux that can be sustainably utilized. If the membranes become fouled during operation, the critical flux values (and therefore the maximum sustainable flux) are expected to decline. Values of total resistance were also monitored in the bench reactors. The slope of the total resistance verse time is the fouling rate. Figures 3 and 4 give the fouling rate as a function of various operating conditions. Tests were conducted to estimate the components of the membrane resistance to flux at the beginning of bench tests and after the membranes were quite well fouled. The resulting data are presented in Table 2. These data indicate that resistances due to both foulants and the cake layer increased significantly during the 65 day operating period. Many bulk sludge and several cake/biofilm samples have been collected from the pilot and bench reactors for PCR/DGGE genetic fingerprinting analyses. A general description of the findings are that the microbial diversity within each type of MBR are somewhat different, that as MBRs enter fouling conditions there are shifts in bacterial speciation, and that the organisms in the cake/biofilm are dissimilar to those in the bulk sludge.

CONCLUSIONS

The conclusions thus far from the pilot study are that SMP and EPS are very important relative to biofouling in MBRs and that several tools are useful to examine biofouling trends. These tools include the critical flux test, total resistance slope, resistance in series component analysis, and measurement of different fractions of EPS and SMP. Future results collected under different operating conditions will allow correlations between fouling rates, bacterial species, and environmental/growth conditions.

Using Media Filters in a Distributed Wastewater System Serving an Ecotourism-Oriented Development

Kevin M. Sherman[1]

ABSTRACT

Ecotourism developments are becoming popular worldwide. The term is being used by those who may not fully understand its implications, yet still wish to exploit the concept's popularity. One of the ways an ecotourism operator's true intent is revealed is through their choice of wastewater treatment. A historically important and ecologically unique island is being developed in Northwest Florida using ecotourism principles. Distributed wastewater clusters are being installed with fixed film treatment and drip irrigation. Central to these decisions was the preservation of the numerous palm trees found throughout the island. A pretreatment system using the recycled husks of coconuts was chosen to treat wastewater from 26 single-family cottages, a restaurant, and bar. This paper provides information on the design concept and treatment train of this fixed film treatment system. The paper concludes with an update of the longevity of media from the longest continually operating coir fiber system in the United States.

INTRODUCTION

In recent years, various locations around the world have labeled themselves as ecological tourism (or ecotourism), responsible tourism or sustainable tourism destinations. The concept of ecotourism is widely misunderstood and, in practice, is often simply used as a marketing tool to promote tourism that is related to nature. Most definitions of ecotourism boil down to a form of tourism that provides for environmental conservation, includes community participation, and is profitable and environmentally, economically and socio-culturally sustainable in the long-term.

Critics of ecotourism claim that ecotourism as practiced and abused often consists of placing a resort in a splendid landscape, to the detriment of the surrounding ecosystem. According to them, ecotourism must above all sensitize people with the beauty and the fragility of nature. They condemn some operators as "green-washing" their operations — that is, using the label of "ecotourism" and "green-friendly", while behaving in environmentally irresponsible ways.

One of the ways ecotourism operators distinguish their true intent is in their choice of wastewater treatment. In many developing countries, wastewater regulations are virtually nonexistent. Developers are often left to their own consciences in dealing with the wastewater to be generated by their operations. In order to live up to the ideals of ecotourism, the wastewater system selected will far exceed local regulations and integrate with the nearby environment to better protect the special places they inhabit.

Historical Background of Study Area

In Florida, one ecotourism destination is Black's Island. Located in Port St. Joe Bay in Northwest Florida (Figure 1) this nearly seven-acre island holds an important place in Florida's history. Archeological investigations of the island (Mayo, 2003) show extensive temporary use of the island as fishing and hunt camps by Native American peoples. The French explorer Jean Beranger was the first European to survey and name the island in 1718. He chose the name Ile de la Tortue (Island of the Turtle) to highlight the sea turtles who nested on the shores of the island every summer.

Figure 1. Black's Island within the context of Port St. Joe Bay, Cape San Blas, and Florida.

The town of Port St. Joe sprang up the in the 1820's and by 1835 was one of the largest seaports in Florida, along with St. Augustine, Pensacola and Key West. During the mid 1830's, Captain Black, an English sea captain, arrived in St. Joe Bay to carry on his trade. Captain Black is the first recorded owner of the island and is the person for whom the island is still named. The date of platting of the island preceded Florida's statehood by ten years.

In 1970, the island became a camp for young men. This camp was destroyed by a hurricane in 1975. It was reestablished as Camp Nautilus by one of the current owners, William Koran, in 1976. After several unsuccessful attempts to interest the State of Florida in purchasing the property for preservation or as an adjunct to nearby Cape San Blas State Park, Mr. Koran and Mr. Grimsley the current owners set upon the current path for developing an ecotourism-related property.

The island and its surrounding waters boast several unique ecological resources. The bay scallop *Argopecten irradians* is plentiful in the shallow turtle grass beds offshore of the island (Sherman, 1985). A relic population of Black mangroves is found on the island. Their nearest living relatives exist more than 100 miles south of the island on the Florida mainland.

The current development consists of 26 single-family cottages, connected to each other and to a community center, restaurant, and bar (not open to the public) by an elevated, 10 ft wide boardwalk. Cottages are either one-story 2 bedroom units (floor plan 1,156 square feet) or two-story 3 bedroom units (floor plan 1,350 square feet). All are built on elevated pilings ten to twelve feet above the ground. The colors of the vertical wood surfaces and the greenish color of the roofs closely match those of healthy palm trees. This means that a visitor must get relatively close to the island before they recognize that development has occurred (Figures 2 & 3).

Figure 2. Black's Island from the water. Camera is approximately 500 m from island.

One of the hallmarks of a visit to Black's Island is isolation and the corresponding tranquility it brings. Central to this concept is the large number of palm trees throughout the island. There are over 700 palm trees on the island. The primary species are Cabbage Palm *Copernicia cowellii* and Palmetto *Sabal palmetto*.

Figure 3. Black's Island from the water. Camera is approximately 50 m from island.

The wastewater system selected for this island had to mesh with the presence and continued health of these palm trees. Because palm trees have a compact root ball (Figure 4) and are resistant to soil burial, drip irrigation was chosen to preserve as many palm trees as possible. An advanced treatment fixed film system was selected to pretreat the wastewater prior to drip irrigation. Per State of Florida Rules, the systems have to meet an effluent standard of 30 mg/L $CBOD_5$ and TSS (64E-6, FAC).

Systems serve either three to four cottage clusters (distributed system) or the community center and food service operation. Tanks are whenever possible placed below the 12 to 15 foot elevated walkway or under adjacent walks toward the shore, thereby eliminating the need to remove or relocate trees to set tanks. All tanks will be accessible for service through hinged access lids where necessary. Graded service paths from the dock to each tank have been designed onto the property. Some trees were relocated because their existing location placed them in danger of being damaged inadvertently during construction. They are surviving quite satisfactorily, only occasionally needing hand watering.

Typical Treatment Train – Residential Cluster Systems

All clusters on the island were designed based on a 1000 gpd cluster of two 3-bedroom plus two 2-bedroom cottages flowing to one system. Only two of the eight clusters achieve this flow. The most common estimated sewage flow from a cluster was 700 gpd (Table 1).

Under Florida's code (64E-6, FAC) the minimum size of the septic tank would be 2200 gallons for the 1000 gpd flow from a 4-home cluster. The minimum size of the dose tank would be 1050 gallons.

Figure 4. A trio of cabbage palms await replanting. The entire root ball is directly below the trunk.

Design Concept for BioCoir Fixed-Film Wastewater Systems

Fixed-film wastewater systems share several design considerations (Jantrania and Gross, 2006). The first is the effective loading rate. In other words, how much media will be needed to treat a known volume of wastewater? With regard to recycled coconut fibers (trade name BioCoir™), the effective loading rate is set by the manufacturer at 12.5 gpd per cubic foot of media. This loading rate is similar to the loading rate suggested for open cell foam media (Jowett, 1997). This loading rate was nearly cut in half with the restaurant and lounge system, anticipating a higher strength wastewater. The anticipated BOD loading for the high strength waste system is 0.032 pounds per cubic foot per day. Oversized grease interceptors and servicing on a 3 to 6 month basis in season is anticipated.

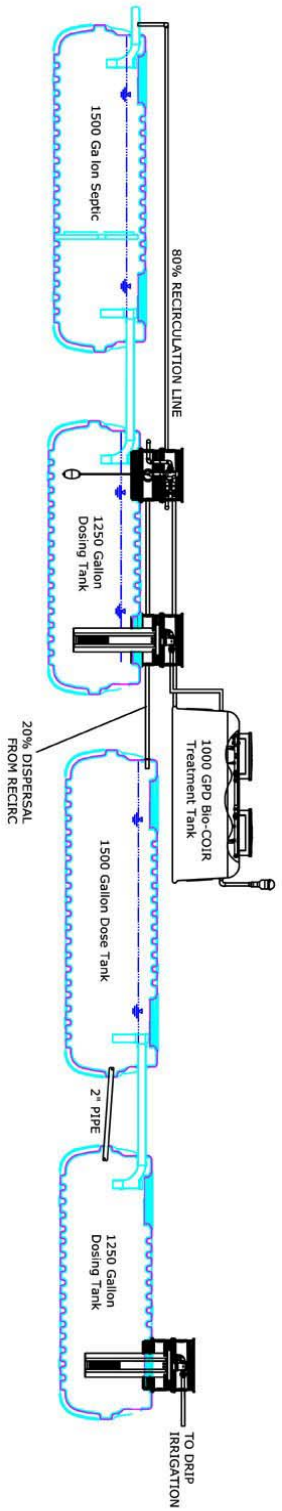

Figure 5 – Typical Tank configurations for residential clusters.

Table 1. System data for Black's Island

Serves	GPD	Septic volume	Treatment capac.	Dose tank vol	Linear feet Drip tubing	2nd drip**
Units 1, 3,5, & 26	1000	2750	1000	2750	418	0

* also includes 2 – 1250 gallon grease interceptors in series

** if not 0, a second area of drip irrigation was used, supplied by a sequencing valve if a single area was not large enough by itself

The second design consideration is uniform surface coverage with wastewater without channeling. The BioCoir system achieves this through use of pumps connected to helical spray nozzles pointed down. The uniformity of surface coverage is improved even more when the pumps serving the modules use time dosing. The septic/recirculation tank volume is larger than required (2,750 gallons actual versus 2,200 gallons) and allows for storage of dose volume until called for by the time dose control panel.

The third design consideration is biological nutrient reduction. The critical influence of nitrogen on the health of turtle grass *Thalassia testudinum* beds and the scallops that rely on them for settlement of juveniles has been elucidated over the past two decades by the Tampa Bay National Estuary Program (Johansson and Greening, 2000). Nitrogen reduction will be accomplished in this project, although such treatment was not required for system permitting. The anticipated effluent standard for these systems is 5 mg/L $CBOD_5$ and TSS, 10 mg/L TN and TP, and fecal coliform 200 colonies per 100 ml. Effluent sampling will be accomplished by the certified maintenance entity annually.

Recirculation of nitrified effluent is accomplished using a variable splitting device. Because occupancy and therefore sewage flow will be peaked throughout the year, this sort of device is ideal. Once again, tank volumes in the dosing tanks 2,750 gallons versus 1,050 gallons far exceed code requirements. The pump will be set to activate below 2/3 of the total tank volume. The rest of the volume is surge volume

to be used only during peak holiday weekends. The 2" line connecting the tanks below the mid-seam ensures that the tanks will act in unison as a single surge tank.

During periods of normal usage, the float inside the first 1,250 gallon tank will allow 80% of the treated effluent to return to the head works of the septic/recirculation tank. This is the theoretical optimum recirculation value for denitrification. The remaining 20% will flow into the 1,500 gallon dose tank, to be pumped out to drip irrigation, once again using a time dosed control panel. If the majority of homes on the cluster are unoccupied, or the flow is below normal for other reasons, the effluent level in the first 1,250 gallon tank will be below normal. Now the float in the dose tank closes off the 20% outlet and 100% of the flow is routed to recirculation. Use of this relatively simple device ensures the media will be moistened (and fed) regularly regardless of whether the homes in the cluster are occupied.

Other considerations with biological nutrient reduction are effluent temperature at or above 10^{o}C, alkalinity at or above 200 mg/L as $CaCO_3$, and keeping acetone and other nitrification inhibitors out of the system (Oakley et al., 1996).

The final design consideration for these kinds of systems is they must be designed for maintainability. If these systems are difficult to maintain, they simply will not be properly maintained, with disastrous consequences. Specific to this design, nozzles in the coir modules are attached with a simple snap. This allows easy removal and cleaning of nozzles during every six-month maintenance visit. . Tank locations are accessible to pumping. A ground-level pathway to each cluster's tanks avoids driving over drip irrigation areas. Extra grease interceptor volume will allow grease trap cleaning to occur when other service visits occur.

During biannual service visits, the certified maintenance entity will examine the coir media, sludge judge tanks, check nozzles for plugging, service filters and clean pump chambers filter plates. Data will be retrieved from the control panels, such as the number of alarm conditions since the last visit.

Coir Longevity- an update

An important consideration in natural media is longevity. In other words, how long will it take before the media will need to be replaced? Over time, peat materials degrade to a muck material. The time required to degrade varies from peat source to peat source, but ranges from 4.5-16 years. Coir material will also degrade to a muck-like material over time. When its treatment ability is exhausted, it can then be pumped out of its container with a liquid vacuum pump truck. The spoil material will be taken to a septage processing plants and can be land applied.

The coir system with the longest continuous use in the country was installed on July 1, 2004 as a single pass addition to an existing system in Oldham County, Kentucky. In Sherman, 2006 media sampled from the surface of the unit on July 2006 was contrasted with fresh media from the warehouse (reprinted as Figure 6). Continuing in that vein, photos of coir fiber sampled from the surface of this system on January 29, 2007 showed a lightening of the original coir characteristics from the

July sample (Figure 7). In other words, this sample looked more like virgin material than a sample taken 1.5 years earlier. Based on these early results, longevity of about one decade remains a reasonable
estimate

Figure 7. Coir media after 1 year, 11 months of continuous use (left) versus virgin material (right).

Figure 7. Virgin material (left) versus material collected January 26, 2009 (4.5 yrs continuous use).

Abstract

Water is an essential ingredient for life. Our current pricing system does not reflect the value of water nor account for its scarcity. Current water rates are inefficient and subject to government subsidies resulting in wasteful water usage practices. Additionally, the inefficiencies in the market place act to discourage competition and improved water practices. Policies to internalize the externalities inherent in our water rates would help make the market more efficient as well as changes to the tax code to allow for tax exempt status for private debt for domestic firms engaging in water supply projects. This improvement would improve domestic competition in the marketplace.

Introduction

Water is essential for life and critical for security. In fact, the United Nations has gone so far as to declare access to clean water as a human right (Brundtland, 2003). Publically owned treatment works dominates the water supply industry in the United States. This trend is prevalent throughout the globe but not a universal constant. The water industry is supported by subsidies and regulations distorting the supply and demand relationship. This paper will describe the water market and the industry that supplies water along with outlining the peculiarities that exist with in the market. Finally recommendations will be made to reform the market pricing and competition for this vital resource.

Water Market

The U.S. consumes 408 billion gallons of water per day generating $30 billion in revenues for the industry (Hutson, 2004) (Environmental Business International, 2005). Thermoelectric plants use 48 percent of this water or 195 billion gallons per day mostly for cooling at power plants (Hutson, 2004). The next biggest consumer is the agricultural sector using about 137 billion gallons (Hutson, 2004). Public supplied and self supplied industrial consumption complete the spectrum at 43 and 20 billion gallons per day respectively (Hutson, 2004).

The world's water market generates about $73 billion dollars in revenue if water used for agricultural purposes is included gross revenues could reach $7 trillion according to industry estimates (Buisnessline, 2002). Globally the demand for safe drinking water in some cases is not being met. According to the United Nations Environmental Program report *Our Planet,* the uneven distribution and increasing demand creates regions of water stress. Currently 40 percent of the world's population, about one billion people, is under water stress and will increase to 67 percent by 2025 (U.N. Environmental Program, 2003). Another billion people live in regions with adequate water supply but cannot afford water (Economist, 2006). The largest user of water

is the agricultural sector using 3,000 liters of water to grow food per person per day. Domestic and industrial water use is very small when compared to agricultural use (Economist, 2006).

Consumers have very little choice in their water service provider. Large capital investments are required to construct and operate treatment works. Usually the government determines the water supplier and regulates operation. Governmental control over the market acts to distort the industry and limit competition. In the case of water subsidies and marginal costing strategies have acted improperly value water causing wasteful practices and making technological conservation practices uneconomical (Clark, 2007).

Water Industry Infrastructure

The infrastructure that delivers the water to the market consists of a wide variety of size and span of various systems that deliver water to the market. The U.S. has about 58,000 water distribution networks serving 80 percent of the population (Environmental Business International, 2005). These organized systems can be further subdivided into 311 large networks serving 43 percent of the population (Environmental Business International, 2005). This leaves the remainder 36,000 systems serving populations that are fewer than 500 people. The variety of sizes in distribution systems causes inefficiencies in the market place. There are small community water systems located next to larger water systems not taking advantages of the economies of scale that declines with the size of the system (Renzetti, 1999)(USA Today 2007).

The water industry must make a substantial capital investment to ensure the presence of an infrastructure and water supply to meet demands. In some regions of the U.S. water demand has exceeded the ground water supply and according to the National Research Council resulted in over pumping of aquifers leading to the saltwater contamination of 300,000 wells. The cost to clean up these sites could reach one trillion dollars over the next 30 years (Howard, 2003). Deterioration of existing infrastructure will impact the industry. The American Water Works Association estimated that $250 Billion over the next 30 years to ensure a reliable source of water (National Academy of Sciences, 2002).

Water Supply Industry

Most people connected to a water distribution network get their water from a government owned and or operated utility (Barlow, 2004). A few companies are in the small privately owned or operated water supply market. The top three industry leaders are Veolia and Suez, both French companies, followed by RWE a German company (Barlow, 2004) (Economist, 2003). There are a few American owned firms in the market such as Bechtel Utilities and CH2MHill. Few companies are working water supply projects in developing countries. Pricing policies and governance seems to be preventing most companies from entering the world market (Economist, 2003). One notable exception is another French company Saur a 1.45 billion euro company who is supplying water to Abjijion, Cote' D'Ivore (Economist, 2003). Absent additional world regulations, we can expect more firms to enter this market as climate change drives regional water scarcity increasing the value of water.

The water supply industry in the U.S. is dominated by publically owned treatment works supplying 84 percent of the water. Private sources control the remaining 16 percent of the market (Environmental Business International, 2005). The two largest private water suppliers in the U.S. are the American Water Company and U.S. Filter and are owned by RWE (German) and Veolia respectively (Economist, 2003). There is a pronounced absence of domestic firms providing water. Market segmentation and government regulations are acting to keep private companies from entering into the U.S. market (National Academy of Sciences, 2002).

Factors Effecting Market Performance: Marginal Cost and Subsidies

Existing water rates are adversely affecting the U.S. water supply system and to some extent the world. A study published by the *Canadian Journal of Economics* concluded that existing water rates are inefficient. They stressed the importance of a marginal costing system that would account for all costs and capital expenditures including accounting for distance and time costs associated with providing water service (Renzetti, 1999). Costs should include externalities like watershed conservation expenses. Current marginal costing in the U.S. does not include many pieces like infrastructure maintenance and aquifer development. The study showed that residential and non residential demands for water demonstrated elasticity and that a marginal cost system would impact demand (Renzetti, 1999). Another significant pricing error occurs when moving to a marginal cost system by failing recapitalization expenditures (Renzetti, 1999).

Water subsidies affect the market by not reflecting the true cost of water. Subsidies are also applied unequally across the market benefitting specific groups. In developing countries, water infrastructure is present in wealthy neighborhoods where water subsidies are good. However, poorer areas lack water infrastructure and people get water from truck vendors paying from $1 dollar per cubic meter (Clark, 2004). Agricultural water subsidies also impact the water market. According to the Earth Policy Institute, California farmers use 20 percent of the region's water and pay only one cent per cubic meter, about two percent of what residents of Los Angles pay for their water (Clark, 2004).

Water Market Reforms

Publically owned treatment work's in the U.S. need to establish a comprehensive marginal cost system for water based on volume used. The price must include production, pumping, and infrastructure costs and all other externalities like aquifer development and watershed protection. The marginal cost system cannot include subsidies. Complete marginal costs for water will cause consumers to realize increased water costs but this will drive innovation in water conservation especially in the agricultural sector. Perhaps if consumers were actually charged the value of the water it would become more economical to expand water distribution systems to poorer regions. Additionally, a marginal cost system will encourage competition in the industry as firms see the potential for profit they will enter the market. As city budgets become more and more constrained the tax base will no longer be able to support subsidies and must institute marginal costs. Additionally, charging water for what its worth will discourage wasteful use of the resource such as water intensive agricultural practices.

The U.S. needs to encourage the development of domestic water supply industries. Domestically we have firms that could be competitive in this industry like Bechtel, CH2MHill, and URS to name a few. Domestic firms could be encouraged to enter the market by changing the Federal tax code to allow private debt for municipal infrastructure to be tax exempt as currently done for municipal debt. This would encourage private investment in the water infrastructure and allow private firms to compete with the existing publically owned treatment works allowing municipalities to make better financial decisions. At the very least the policy would push publically owned treatment works to become more efficient.

Conclusion

Water is a basic ingredient in any civilization and is required for economic development. In most cases in the U.S. and in parts of the world water is treated as if it were in infinite supply. Unfortunately, this is not the case; requiring our country and the globe to institute price reform to properly incorporate all the marginal costs and externalities into a volumetric water charge.

Instituting comprehensive marginal costs along with allowing for tax exempt status for private debt for domestic firms engaging in water supply projects would encourage the creation of domestic water supply companies. This would improve the country's water supply system and would be in the best interest of our national security.

ASSOCIATED DISASTERS TO THE DEBRIS FLOWS

Guillermo Cardoso-Landa[1]

[1]Land Sciences Department, Instituto Tecnológico de Chilpancingo, Av. J. F. Ruiz Massieu # 5, Col. Villa Moderna, C. P. 39000, Chilpancingo, Gro., México; PH (747)4725899; e-mail: gclanda@prodigy.net.mx

ABSTRACT

In this article some of the disasters associated to the presence of the debris flows are described briefly happened in some countries of the world in recent years, which have been observed and, in some occasions, measures its fundamental characteristics, for example: The United States, China, Japan, Italy, Taiwan, Central Asia, Germany, Switzerland, Russia, the Philippines, the Ukraine, Canada, Brazil, Ecuador and Venezuela. In the country of Mexico have appeared great amount of debris flows in the recent years, many of them in the Mexican trans-volcanic axis and coastal mountain ranges, such as the happened ones in Popocatepetl volcano, the volcano Pico de Orizaba, the volcano Nevado de Toluca, mountains of Puebla, in Acapulco, Gro., in the city of Tijuana, B.C. and in the coastal mountain range of Chiapas and Oaxaca, to only mention those that have produced important disasters in recent times. In the article the characteristics of the disasters produced in different regions from Mexico are also described.

To identify the mechanisms that they involve to the solid material within a liquid flow, it is necessary to analyze the roles played by the several operating forces in the genesis of the movement in a debris flow. The developed approaches to date are the following ones: model of stability of infinite slope, approach of Shields, approach of Takahashi and recent developments.

In order to be able to apply the previous models it is necessary to have very great information of diverse points on the land, with which a calculation mesh forms, therefore is essential to develop a GIS in the analysis site. A model appears in the complete article to determine the characteristics in the zone of beginning of a debris flow, which includes the development of a SIG.

INTRODUCTION

A disaster associated to a natural phenomenon is defined as a serious upheaval triggered by a phenomenon of the nature that causes human losses, material, economic and environmental, that exceeds the capacity the affected ones to fight with them.

The associated disasters to natural phenomena constitute a serious obstacle for the human development and the fulfillment of the Objectives of as important Development of the Millennium as the reduction of the extreme poverty to half before year 2015. Not in vain the natural disasters caused annual economic losses that go from the 75.500 million American dollars in years 60, 138.400 million in

years 70, 213.900 million in 80 and 659.900 million in the 90, most of them in the developed world. However, the economic estimations suitably do not catch the impact of the disasters in the poorest countries, where the costs in terms of human lives, of means of subsistence and destroyed infrastructure reconstruction more are elevated. At the moment, the 85 percent of those who is exposed to earthquakes, tropical revolving storms, floods and droughts, lives in countries whose human development is average or low. In absolute terms, it has been demonstrated that the economic cost of the disasters has increased in the course of the last decades.

The data base EMDAT offers a very precise panorama of the total losses by disasters with a suitable level of national detail. The period of chosen time it is sufficient to represent the fluctuations whereupon they are pronounced most of the natural threats and also it agrees with the more trustworthy period of data of the EMDAT. In figure 1 the total number of disasters registered by the EMDAT appears entre 1900 and 2000.

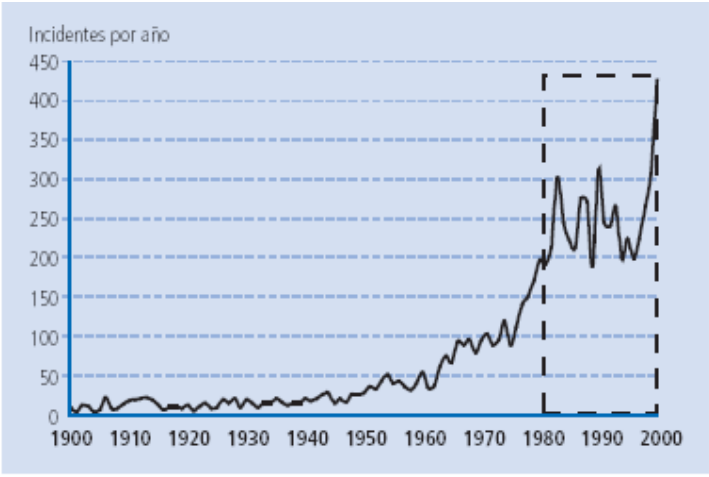

Figure 1 Disasters registered by the EMDAT

The tendency in increase suggests, first, an exponential increase of the frequency of the disasters, although the factor that contributes more is the improvement in the elaboration of information on disasters. Although the one cannot be discarded that it has increased the number of hydrometeor logics catastrophes, that the denounced disasters tend to probably increase has more to do with the advances in the technology of the telecommunications and the cover of the different alert networks that every time arrive at more corners of the world. Therefore, nowadays there are more possibilities of denouncing and of registering the casualties inflicted by the disasters.

DISASTERS ASSOCIATED TO THE DEBRIS FLOWS

The debris flows are the fast landslide earth movements, caused by hyper concentrated flows of water and sediments, which happen in a great variety of environment throughout everybody. They are particularly dangerous for the life and the properties due to its high speeds and great destructive force, lowering natural

houses, ways, bridges, trees and cultures, currents and ecosystems throughout its trajectory. The debris flows are generally associate with periods of high precipitation and intensities of snow-covered very strong rains or with intense that tends to appear as reconciled of mixtures sediment-water with catastrophic results for the zone in where they appear.

Next some of the disasters associated to this phenomenon in some countries of the world in recent years are described briefly, which have been observed and, in some occasions, measures its fundamental characteristics.

UNITED STATES

Utah received national attention and his first presidential declaration of zone of disaster in the spring of the year 1983 due to the floods, earth sliding and debris flow caused by severe snow storms in the region (Wieczorek et al, 1983). The worse damages caused by the debris flows appeared in the County Davis, in the opening of the Rudd stream. Some debris flows happened in at least 600 tributary ones of the Colorado River in Great the Canon, between Less Ferry and Surprise Canyon, Arizona (Melis et al., 1994; Griffiths et al., 1996). Most of the flows they appeared during convective storms of the summer with intensities of rain of the order of 40 mm/h.

More than 1.000 debris flows they happened in wooded slopes of the County of Madison, Central Virginia, during an intense happened storm the 27 of June of 1995 (Wieczorek et al., 1996).

Numerous observations of the occurrence of debris flows have been made in the mountainous areas of the Southeastern of British Columbia in the last decade. In November of 1995 two debris flows appeared in Pierce Creek in Valle Chilliwack and Hope Creek, with 50.000 m^3 of rubbish carried during two hours, closely together of the city of Hope (Jacob et al., 1997).

A series of debris flows appeared in several canyons to 35 miles to the east of Portland, Oregon, days 7 and 8 of February of 1996, near the small localities of Dodson and Warren dale, destroying 84 interstate highway as well as the railroad and having to be evacuated the residents from the area the being destroyed their houses (Powell et al., 1996).

CHINA

The Liaoning province is located in the south of the northeast region of China between 118°53' and 125°46' of length and from 38°43' N to 43°26' N of latitude, divided in four regions.

The 28 of 1981 July an intense extreme precipitation produced avalanches, rock sliding and debris flows in more than 100 ravines and slopes of the Laomao mountain in this province, having themselves like result 115 villas affected in 6 counties affecting to 556.000 people, destroying 38.517 houses, 60.000 hectares of cultures and 4, 9 kilometers of the line of the Changchun-Dalian railroad were destroyed. The Chinese economy losses ascended to 547' 000.000 of yeans (Zhao Huanchen et al., 1992).

In the presented/displayed relation next, table 1, some places affected by this type of phenomena in recent years in China are appraised.

Table 1 Affectations produced by debris flows in China

LOCATION	PROVINCE	DATES
Pingwu, Songpan, Disable,	Sichuan	16-08-76 to 24-08-76
Songpan, Wenchuan,	Sichuan	16-07-77 to 17-07-77
From Baoji to Tianshui,	Shanxi	12-07-78
Dongchuan,	Yunnan	22-10-80 to 25-10-80
Zhaojue	Sichuan	22-10-80 to 25-10-80
Shanxi, Gansu, the Sichan northeast,	Sichuan	19-08-81 to 22-08-81
Rangtang, Jinchuan, Heishui	Sichuan	20-07-83 to 29-07-83
Hanzhong,	Shanxi	12-07-84 to 18-07-84
Wenchuan, Nanping,	Sichuan	12-07-84 to 18-07-84
Dongchuan,	Yunnan	26-07-85
Dandong, Fuxian,	Liaoning	14-08-87 to 20-08-87
Dangchang, Zhuoni, Jingxi,	Gansu	06-07-88 to 14-07-88
Miduogou, Midui	Sicuani, Xizhang	85 to 88

JAPAN

In Japan during twenty years, between 1967 and 1987, 4598 people were killed by natural disasters, of who 1257 passed away due to the debris flows, which corresponds to the 27,3% (Takahashi, 1991). This high percentage must to that every time most frequently the people tend to live in zones on high risk on the foot of mountains where they appear this type of draining.

In 1990 volcano Mount Unzen, in Japan, made eruption and they appeared but of 114 debris flows (lahars) that deposited near 8' 000.000 of m^3 of debris that destroyed 1123 buildings. The number of refuges required by this event was greater to the 11.000 in August of 1991 (Suwa & Yamakoshi, 1997).

ITALY

Day 19 of 1985 July the fault of two dams in the Valley of the Stava River, to the northeast of Italy caused a catastrophic debris flow, which destroyed 2 villas and killed 270 people (Berti et al., 1997).

A debris flow happened day 18 of October of 1990 in Pomonte Creek, with flows towards waters underneath Monte Capanne in the Elbe Island, of the Archipelago of Toscana, Italy, with approximately 34.000 ms^3 of debris, (Iotti & Simoni, 1997).

TAIWAN

During the last decade, hundreds of deaths, hurt losses and people, as well as damages in houses, schools, ways, bridges and other public and deprived properties happened several disasters produced by debris flows in Taiwan, causing (Cheng et al.). In table 2 the characteristics of 6 disasters produced by debris flows appear in recent years in this region.

Table 2 Zones affected by debris flows in Taiwan

LOCATION	DATE	IMPACTS
Tug-Men, Hualien, Taiwan	23-06-90	29 deads, 6 lost, 7 wounded, 24 destroyed houses, 68 victims and important damages to ways.
Chun-Keng Kuo, Nantou, Taiwan	31-07-96 a 01-08-96	4 deads, important damages to houses, ways and other properties.
Er-Bu-Keng, Taiwan	31-07-96	5 deads, 10 houses and 3, 78 hectares of fruit destroyed, important stream damages.
Feng-Chiu, Nantou, Taiwan	31-07-96 a 01-08-96	2 deads, 10 houses and 14 hectares of cultures destroyed, serious damages in 18 ways, prey and rivers.
Tung-Fu, Nantou, Taiwán	31-07-96	2 deads, 18 destroyed or damaged houses.
Shen-Mu Village, Nantou, Taiwan	31-07-96 a 01-08-96	5 deads, 6 wounded, 8 destroyed houses and bridges, important damages to 3 hectares of cultures.

SWITZERLAND

The debris flows are a phenomenon common in the Swiss Alps, as well as in other mountainous zones of the world. A tool important to understand the mechanics of this type of flows is the installation of observation stations that allow collecting data in real times. They settled this type of stations in 3 river basins of Switzerland, equipped with ultrasonic video cameras, devices, radars, geophones and instruments for measurement of the precipitation. In figure 2 appears the location of these stations.

Figure 2 Location of the 3 stations of observation of debris flows in Switzerland

They appear in graph 3 the number of events of debris flow per year that has been registered in two of these hydrological river basins of Switzerland.

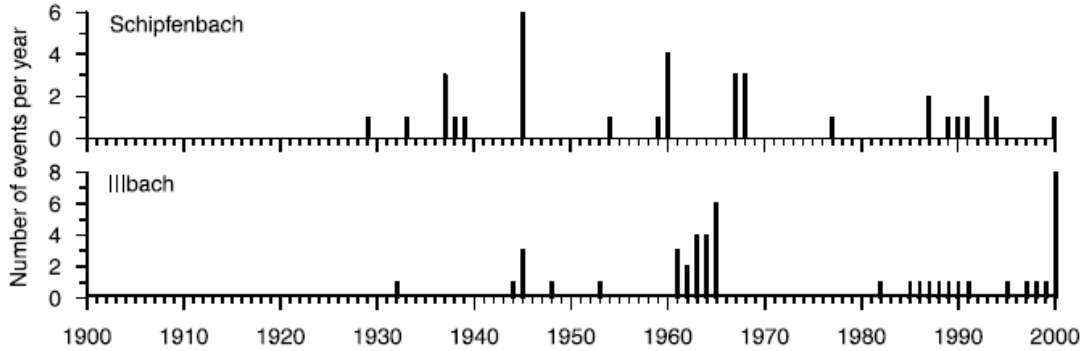

Figure 3 historical Registries of debris flows during century XX in Schipfenbach and Illbach, Switzerland. (Hurlimann et al., 2003)

In year 2000 four important debris flows were observed in this zone of Switzerland, being moderate their more outstanding characteristics, varying the volume of material deposited from 5.000 m^3 up to 35.000 m^3; the rank of average speeds was of 2,0 m/s up to 5,0 m/s and the maximum expenses of flow appeared between 20 m^3/s to 125 m^3/s.

CENTRAL ASIA

Central Asia is an area with a high degree of risk by debris flows, being the most important hills of Valle Fergana, Valle Zerafshan, the Issyk-Kul river basin, the central and south part of Tdjikistan and also the hills of Kopetdag. In all these areas the destructive flows happen during the period of the spring-summer in small rivers and ephemeral channels (Salikhova & Liahovskaya, 1992).

GERMANY

The villa of Tramin in the south of Tyrolia was affected by a sudden debris flow which day 23 appeared during a severe storm of June of 1986, that it completely destroyed the new local rest center and damaged a wine cooperative seriously, being considered the total damage in 6 million dollars (Strunk, 1990).

RUSSIA

The areas in where greater amount of debris flows has appeared in this country are three regions: to the east of the Sayan mountains, the mountain to the Southeastern of Baikal Lake and the northeast of the Baikal region, with registries from 1871 to 1971, (Makarov and Agafonov, 1977).

The PHILIPPINES

The eruption of Monte Pinatubo in June of 1991 deposited of 7 to 8 km^3 of pyroclastic material in slopes of the volcano. These pyroclastics deposits formed the sediment sources for the rubbish flows of volcano (lahars) frequent and great scale, that appear each season of rains causing great morphologic changes and massive devastation in the zone. To the date more than 400.000 people they have been moved

and around 350 km^2 with territories of agricultural culture they are covered with material of lahars.

The number of died in a series of debris flows happened in the Philippines after six days of intense rains can surpass the hundred, said the authorities of the country, after 35 corpses were recovered and tens of people followed disappear, in December of 2003, 300 people were evacuated towards safer zones after the soldiers got at the zone of disaster to rescue to victims cached under mud and the rubbish come off hills of the environs, said the authorities.

The UKRAINE

The combination of natural conditions in the mountains Carpathian, Crimean and the defiles along the rivers Dnieper and Dniester is favorable for the formation of the debris flows, (Yablonskiy et al, 1992).

CANADA

Howe Sound is a region prone to the presence of debris flows, which extends from the Horseshoe bay (20 km to the northwest of Vancouver) to Squamish, in Canada, where they have appeared a great number of these events due to the type of ground, slopes in his valleys as well as the deforestation and fires in the zone.

B*RASIL*

At the beginning of August of 2000 great debris flows took place caused by five days of torrential rains in the northeast of Brazil, causing 28 died and 90.000 abandoned. Bad weather caused the most serious damages in the states of Pernambuco and Halagaos, affecting to 46 localities.

ECUADOR

At least 36 died people, 11 disappeared and 212 families damaged were the balance who left to the debris flows happened in Ecuador day 13 of June of 2001, affecting the provinces of Papallacta, Amazonia, Tungurahua and Zamora Chinchipe.

MÉXICO

In our country great amount of debris flows has appeared in the recent years, many of them in the Mexican trans-volcanic axis and coastal mountain ranges, such as the happened ones in Popocatepetl volcano, the volcano Pico of Orizaba, the Nevado de Toluca volcano, in the mountains of Puebla, in Acapulco, Gro., in the city of Tijuana, B.C. and in the coastal mountain range of Chiapas and Oaxaca, to only mention those that have produced important disasters in recent times.

VENEZUELA

Probably one of the disasters produced by the combination of diverse processes of removal in mass, including the debris flows, greater dimensions in recent years, is due to the storm from the 14 to the 16 of December of 1999 in the coasts of Venezuela, particularly in slopes of the Mountain range of Avila, to the north of Caracas, Venezuela.

The severe storm from the 14 to the 16 of December of 1999 caused to catastrophic sliding of earth and floods with debris flow throughout 40 kilometers on the coast of Caracas, between the Guaira and Naiguita, located in the coastal state of Vargas, Venezuela. The damages to the communications and the infrastructure of this zone were very ample. In Vargas more than 8.000 individual residences and 700 buildings of departments completely they were destroyed (Salcedo, 2000). In photography 4 some damages in this zone are observed.

Photography 4 some damages in buildings and located houses in the main trajectory of the debris flows in Vargas, Venezuela.

The ways, the telephone services, of electricity, water and sewage system severely were damaged. Total the economic losses calculate in $ 1,79 trillions and preliminary estimations established that between 5.000 and 50.000 people they passed away (Brandes, 2000; Sancio and Districts, 2000; Salcedo 2000; and USAID; 2000). The handled present number of people died by this catastrophe is of approximately 30.000 (USAID, 2001), although has been difficult to need the exact number of victims, due to the zone of disaster which the city of Vargas and to the drag bodies towards the sea was turned, being obtained to recover around 1.000 bodies. The estimation of the number of inhabitants of Vargas was of 300.000 inhabitants before the catastrophe, which means that approximately 10% or passed away more by this event.

MODELS FOR THE DETERMINATION OF THE BEGINNING OF THE DEBRIS FLOWS

The analysis of the main leading mechanisms of the beginning of the movement in a debris flow emphasizes that the factors causes of this phase of the process are the location of the leading area and the leading main mechanism (actions geotechnical hydrodynamics, causes and mechanical balance). In a prognosis level it is difficult to identify which of these mechanisms is most probable or makes the greater contribution; in any case, some of these types of mechanisms can include

others, or rather, within he himself event different leading mechanisms can happen in different areas from the river basin.

In some studies relative to the conditions of outbreak of followed noncohesivos debris flows of a superficial water flow, the analysis is concentrated in the study of the instability of the accumulation of materials that takes place after the saturation. A superficial flow that slips throughout a slope, originating of an intense rain, firstly saturates the alluvium layers; next it mobilizes, causing them in this way the dispersion of solid particles of the accumulation throughout the complete depth of the superficial draining, which becomes a debris flow finally.

In order to identify the mechanisms that they involve to the solid material within a liquid flow, it is necessary to analyze the roles played by the several operating forces in the genesis of the movement. The developed approaches to date are the following ones, (Lorenzini et al., 2004):

a. Model of stability of infinity slope.
b. Approach of Shields.
c. Approach of Takahashi.
d. Recent developments.

The process of beginning of the debris flows is influenced by great amount of factors, emphasizing: geologic and morphologic, hydrologic, vegetal cover, topographic and atrophic; being necessary to establish a methodology that takes in consideration these aspects most of. Some investigations have tried to understand the relation between the geomorphologic processes and the climatic ones that trigger the debris flows. In these works they have been analyzed physical properties of the failed slopes, the effects of the rake and the pore pressure in grounds, the mechanics of the movement of the debris flows and the properties of the resulting deposits, (Scott 1972, Williams and Guy 1973, Hollingsworth and Kovacs 1981, Istok and Harward 1983, Pierson and Costa 1987, Montgomery and Dietrich, 1994; Wu and Sidle, 1995; Pack, 1995; Morgan et al. 1997, Reid et al. 1997, Griffiths et al. 1997, Wieczorek et al. 1997, Tognacca & Bezzola 1997, Gregoretti 2000, Iverson 2000, Chen & Jan 2003, Reid et al. 2003, Savage & Baum 2003).

In most of these works of investigation the necessity is observed to carry out a series of determinations and calculations on a great land extension affected by the presence of an debris flow , which originates the necessity to develop a GIS , that it allows to carry out the calculations of way ordered in the propose mesh of calculation.

GEOGRAPHIC INFORMATION SYSTEMS

According to the necessary requirements for the determination of the zones of beginning produced by the debris flows in a mountainous region, it is possible to be selected the use of the software developed by ESRI for a GIS, call 3,3 Arc View GIS or some more recent other, had to its versatility and characteristics.

Throughout the decade of the 1990, the packages for designed professional GIS for heavy productive work were of not-friendly use for accidental users of a GIS. For example, older versions of Arc Info and MGE were systems of complex software that required a special training and technical abilities. Most of the users of

application of a GIS, such as the civil engineers and the environmental engineers, do not have the technical experience to develop, to run and to maintain a GIS complicated.

On the other hand, Arc View 3.x is software for mapped with friendly atmosphere and a tool for SIG that can be learned by most of the people without extensive training or experience in a GIS. Arc View 3.x is sophisticated software for mapped and a package for GIS that brings the power of a usury GIS to the average of PC (Personal Computer). With more than 500.000 users, Arc View can be considered like the package for a more popular GIS in everybody.

CONCLUSIONS

The increase of the presence of the disasters associated to the natural phenomena in the territories at world-wide level and Mexico has been increased of significant way in the last decades, as it is the case of the disasters associated to the debris flows. Reason why it is necessary to implement models, studies and developments that allow to know the genesis this type of natural phenomena, which allow to implement systems of early alert in the different territories, that allow to reduce the magnitude of the losses of human and economic lives that are associate to these phenomena of the nature.

The four developed approaches were analyzed to date to identify the mechanisms that they involve to the solid material within a liquid flow, also analyzed the roles played by the several operating forces in the genesis of the movement of an debris flow and it selected to the use of the model of stability of infinite slope and the development of a GIS in the zone of the debris flow.

The calculation of the factor of safety (FS) is based on the form for infinite slope of the law of fault of Mohr-Coulomb, expressed by means of the stabilizing force ratio with respect to the destabilizing forces in a parallel plane of fault to the surface of the ground, (Hammond et al., 1992, Montgomery and Dietrich, 1994) that compares the no equilibrants components due to the action of the gravity and the resistive components of friction and cohesion on a parallel plane of fault to the surface of the land with despicable effects of edge. The pore pressure due to the ground mixture reduces the effective normal effort, which thanks to the angle of internal friction is related to the sharp effort. The hydraulic pore pressure is calculated supposing a hydrologic properly dressed be with the depth of the saturated ground sufficiently calculated to maintain proportional a lateral unloading to the area of specific pick up (the area slope arrives by unit of contour length). These relations are expressed through the general equation of stability of infinite slope, that it displays the following form:

$$FS = \frac{C_r + C_s + \cos^2\theta\left[\rho_s g(D - D_w) + (\rho_s g - \rho_w g)D_w\right]\tan\phi}{D\rho_s g \sin\theta\cos\theta}$$

In this expression the variables immediately have the meaning shown in figure 5,

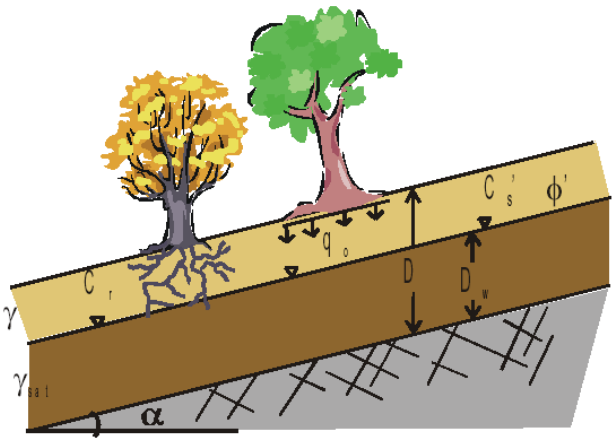

Figure 5 Variables used in the equation of
Model of stability of infinite slope

Taking care of the leading factors of the process of beginning in the debris flows the subjects enlisted to continuation like integral part of the analysis of a debris flow set out by means of a GIS:

Layer 1 Topography of the zone of study.
Layer 2 Superficial hydraulic data.
Layer 3 Angle of internal friction of the ground.
Layer 4 Density of the ground.
Layer 5 Cohesion of the ground.
Layer 6 Vegetal cover (force by the root of the trees).
Layer 7 Underground hydraulic data.

In the scheme displayed in figure 6 the subjects or layers proposed for the development of a SIG used in the study of a debris flow are observed:

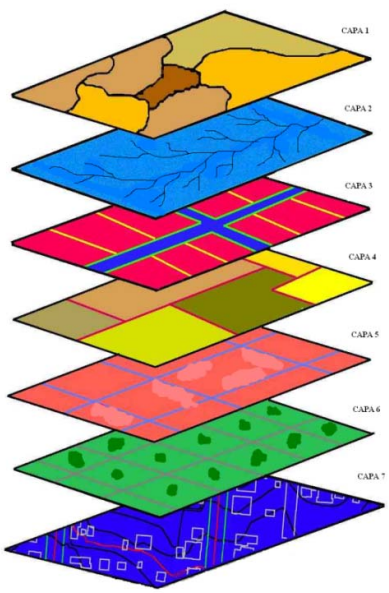

Figure 6 Subjects or propose layers in the selected model
in order to carry out the analysis of a debris flow.

FUTURE WORKS

It is required to apply to the model of stability of infinite slope and the propose layers for a GIS to an debris flow happened somewhere with real measurements in field of its characteristics, which will allow to carry out the validation of the model proposed in this article, with which it is working in the present, hoping to be able to present the numerical results in the future next.

Abstract
Debris flow is a very destructive flood. These floods mostly occur in high steep mountain areas, and cause lots of economic damages and live claims. The flood contains very dense mixtures of different grain size sediment.
In recent years, open-check dams, specially slit dams, are widely used to control debris flows.
Slit dams are one of the open check dams presenting one or several vertical openings, going from the dam's base up to the weir. The slit has decreased the dam sedimentation.
Analyzing the results in this study shows because of the slit in these dams, sediment evacuation has been increased and Trap Efficiency (TE) has been reduced significantly.
In this study, to indicate the sedimentation in the dam reservoir 25 experiment had been set up in a steep tilting flume (22 degree) for 5 width of slit and 5 different particle size, sedimentation is function of volume of the flood in the dam's reservoir, slit width and the particle size. After analyzing the sedimentation profile a dimensionless equations is proposed for the sediment distribution in these dam's reservoir.

Keywords: Debris flow, Trap Efficiency, Slit dams, Slit width, Particle size, Sediment distribution in the dam reservoir.

1. Introduction

Debris flows are floods with a large volume sediment and water with viscid mud. These floods mostly occur in very steep mountainous rivers [1]. To control these heavy floods check dams are usually proposed. They were not very successful; hence they are filled up with sediments before debris flow happen. Usually the factors listed below are effective in the debris flow phenomenon:

a) enough rain
b) presence of enough initial soil moisture
c) enough sediments

To defeat these destructive floods, check dams that are built in series are proposed, but they weren't very successful. Because usually these dams are filled up with sediments and boulders before debris flow happens and so open check dams are used in Austria, Japan Taiwan and Italy [2]. In recent years very good researches were down in the field of slit dam.

The researches that were done in this filled can be categorized as follow:

- equations that estimates sediment deposition in the dams reservoir
- relations that estimate the height of the sediment behind the slit dam
- design of slit dam, slit width and the spacing between posts
- the criteria that's denotes the requirement of the slit dam

These equations are mostly experimental and are the results of modeling the slit dam in an elevated flume. The particle size was not considered in any of the equations, so 25 experiments had been set up with 5 different particle sizes of sediments and 5 different slit width.

2. Methods and Material

2.1. Experiments

Experimental set up is built up from five major parts which are: high slope tilting flume, slit dam, ultrasonic point gage, and digital point gages.

Slit dam was modeled in a high slope tilting flume with 7.6m length, 0.3m width and 0.25m depth. This flume has been made up of plexiglass with the body of iron. The slope maximum is 22 degrees. To know the slope of the flume in any time a slope meter was used. Figure 1 shows the flume general shape. Different parts of the flume are shown in this figure.

Main reservoir is the reservoir with dimension of 0.6*0.6*0.6 m that would make a 0.256 m^3 volume. This reservoir has an inlet of 2" from the pump with an evaluation valve in the bottom. Sediment reservoir is just after the main reservoir with a 0.4*0.3*0.2m dimension and a volume of 0.024m^3. It is also used as a energy dissipater.

Slit dams are made up of plexiglass and it is placed 137.5 cm from the flume end.

The average thickness of these dams is 6 mm and slits are 1,2,3,4 and 5 cm in the middle of the dam. Fig 2 shows a picture of the flume and the slit dam in the 22^0 slope.

Ultrasonic energy is an electromagnetic sound wave that is above the human ability of hearing. This part of electromagnetic waves has the characteristic that when they face an object that is denser than air they reflect to the source that they are spread from. This border between air and water is called an interface. This interface shows the water level using this rule we can obtain the fluid depth. To have precise measurement of the

sediment thickness deposited in the dam reservoir a digital point gage is used. This point gage is placed vertical to the flume and it can measure three points in a section. These three points are in the middle, right and left axis. The right and the left axis are 8 cm away in the left and right side of the middle axis.

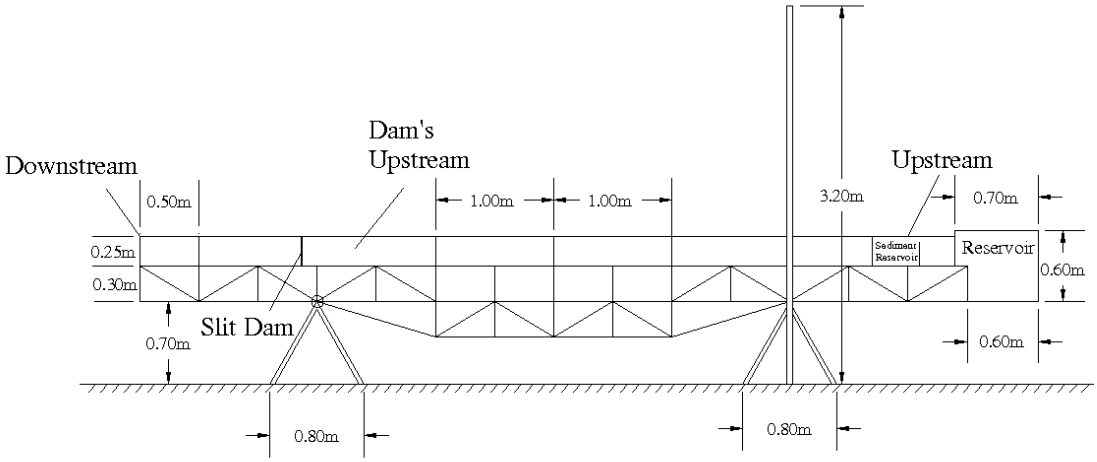

Fig. 1 high slope tilting flume general shape

The experiments were done for five different slit widths and five different particle size of sediment that makes 25 exterminates overall. In theses experiments the slope was constant at 22^0. To begin the experiment first we place the sediment with a known weight in the sediment reservoir, and then we slowly saturate the sediment with water the amount of water is written down. A known water volume also is added to our saturated soil as apart of flood volume. The sediment that is used in the experiment is five different particle sizes as we can see in table (1).

Table 1. Sediment characteristic used in the experiments

Sediment	characteristics	Mean particle diameter(d_{50})mm
First Size	Finer than no. 4 sieve remains on no. 10 sieve	3.55
Second size	Finer than no. 10 sieve remains on no. 16 sieve	1.59
Third size	Finer than no. 16 sieve remains on no. 30 sieve	0.89
Fourth size	Finer than no. 30 sieve remains on no. 40 sieve	0.5125
Fifth size	Finer than no. 40 sieve remains on no. 100 sieve	0.2875

In the next step flume is moved upward to a specific height until the 22 degrees angle is gained. Now the sediment reservoir gate is opened suddenly and the flood moves toward the slit dam and debris flow occurs. Some of the sediments deposit at the dam reservoir or they are trapped indeed, some of them would escape to the downstream. The ultrasonic

sensors have recorded the data i.e. the water depth in three different positions of the flume with the precision of ±0.1mm. The temperature is also recorded. After the experiment is done the water and sediment volumes are measures in the downstream. The profile is gained using digital point gages. The sediment deposited in the dam reservoir, upstream, downstream and between the ways, is dried and weighted.
To investigate the flood concentration we have used the equation below:

$$C = \frac{V_{sed}}{V_{total}} \tag{3}$$

In this equation C is the mean volumes concentration, V_{sed} is the sediment volume, V_{Total} is the total volume of the flood. To calculate the trap efficiency equation (4) is used:

$$T_e = \frac{W_{sediment}}{W_{flood}} \tag{4}$$

Where $W_{sediment}$ is the dry weight of the sediment in the dam's reservoir and W_{flood} is the weight of the sediment of the flood.
Trap efficiency in different experiments are shown in table 2. In the first five experiments the slit width 1 one centimeters. Investigating these data shows that the smallest slit has bigger trap efficiency and as the particle size decreases the trap efficiency decreases too. In the sixth experiment that the slit width is changed, the biggest particle size is used again. So the trap efficiency increases and the procedure is repeated for the other slit width and particle size. For example sediment profile for the first experiment in the right, left and middle axis is shown in figure 2.3D view of the sediment in the dam's reservoir is also shown in figure 3.

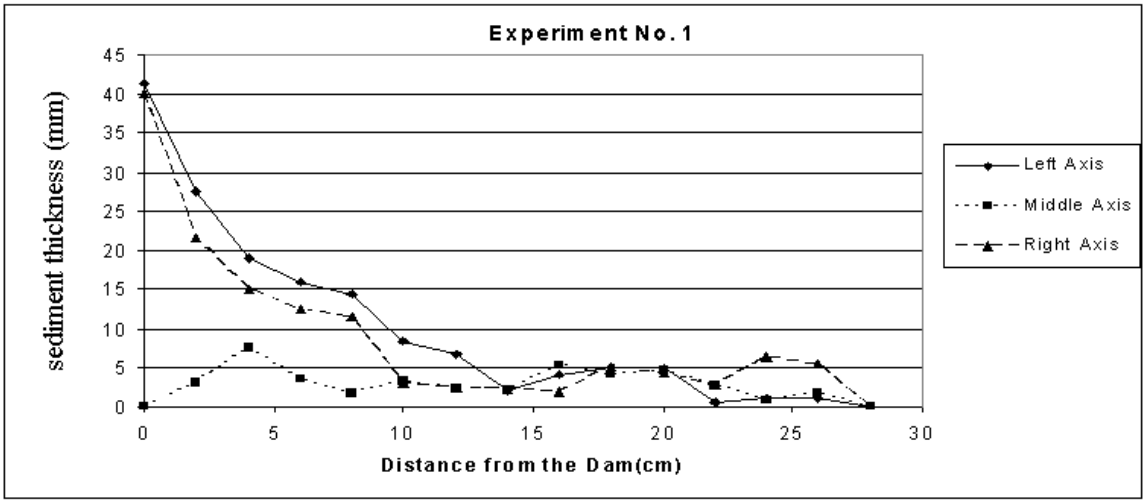

Fig. 2 profile of sediments in the right, left and middle axis in the first experiment

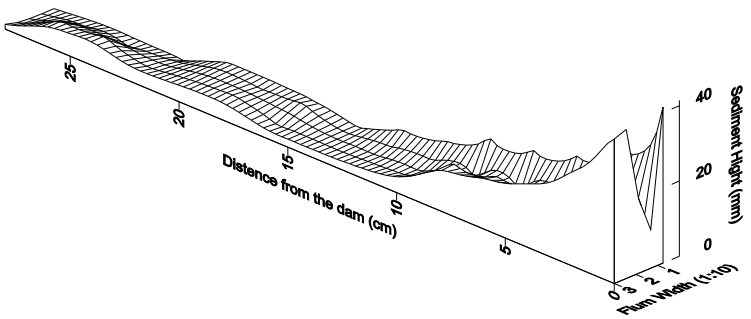

Fig 3. 3D view of sediment in the dam s reservoir

2.2. Dimensional analyses

Effective factors on the deposition in the slit dam reservoir in the experiments are defined as:

$$V_s, V_T, B, b, d_{50}, C, T_{s\max}, L_{s\max}, D_{\max}, L_{w\max}, x, y \quad (1)$$

Where V_s is the slit dam reservoir maximum volume, V_T Total flood volume, B canal width, b slit width, d_{50} mean grain diameters, C volumetric concentration, T_{smax} maximum deposition thickness, L_{smax} maximum deposition length, L_{wmax} and D_{max} maximum length and maximum water level in the reservoir when flood occurs, x distance point from the dam, y is the sediment thickness on that point. According to Π dimentional analysis method we have:

$$\Pi_1 = V_s / V_T \quad (1) \qquad \Pi_5 = x / L_{s\max} \quad (5)$$

$$\Pi_2 = B / b \quad (2) \qquad \Pi_6 = y / T_{s\max} \quad (6)$$

$$\Pi_3 = d_{50} / b \quad (3) \qquad \Pi_7 = T_{s\max} / D_{\max} \quad (7)$$

$$\Pi_4 = C \quad (4) \qquad \Pi_8 = L_{s\max} / L_{w\max} \quad (8)$$

Dimensionless parameters Π_5 and Π_6 denotes the dimensionless profile factors, so the equation (9) is used to define the dimentionless profile in this research:

$$y / T_{s\max} = f_1(x / L_{s\max}) \quad (9)$$

To specify the length and the thickness of the maximum deposition equations (10) and (11) are used:

$$T_{\max}/D_{\max} = f_2(V_s/V_T, B/b, d_{50}/b, C) \quad (10)$$

$$L_{s\max}/L_{w\max} = f_3(V_s/V_T, B/b, d_{50}/b, C) \quad (11)$$

To evaluate different linear and exponential equations, correlation coefficient and mean average relative error:

$$MARE = \frac{\sum_{i=1}^{n} \frac{|X_{0i} - X_{ci}|}{X_{0i}}}{n} \quad (12)$$

In that equation X_{0i} is the observed quantity, X_{ci} is the calculated quantity and n is the observed data.

3. Results and Conclusion

To find the mean longitude profile of the deposition in the slit dam's reservoir we use the right, left and middle axis average. Then the thickness of the sediments and distance of the point from the dam is obtained by dividing to the maximum thickness(T_{smax}) and the maximum length(L_{smax}) to have the dimensionless relation. Obtained points are the dimensionless profiles and they are shown in fig. 5. Data procedure of the profile shows that a 3-variant power curve can be trended with a square correlation coefficient of R^2=0.94. This equation is also shown in Fig.5. to define the thickness and the length of the maximum deposition sediment multi variant exponential and linear equations are discussed.

Determining the equation to gain the maximum sediment deposition relation
Investigating the proper relation to define the maximum deposition thickness are like relations (12) and (13) as a function of the dimensionless factors Π_1 to Π_4:

$$T_{s\max}/D_{\max} = \alpha_1 + \beta_1\left(\frac{V_s}{V_T}\right) + \gamma_1\left(\frac{B}{b}\right) + \theta_1\left(\frac{d_{50}}{b}\right) + \eta_1(C) \quad (12)$$

$$T_{s\max}/D_{\max} = \alpha_2 . \left(\frac{V_s}{V_T}\right)^{\beta_2} . \left(\frac{B}{b}\right)^{\gamma_2} . \left(\frac{d_{50}}{b}\right)^{\theta_2} . (C)^{\eta_2} \quad (13)$$

Table 2 and 3 shows the linear and exponential multi variant equations to define the dimensionless equations. R^2 and MARE indexes are shown in the last column for comparison. Investigating the linear equation in table (2) shows that A1 has the largest R^2

and A4 has the smallest MARE. Investigating the exponential equation in Table 3 shows that B1 has the largest R^2 and also has the smallest MARE. Comparison between R^2 and MARE in the equations A7,A4 and B1 shows that B1 has the largest R^2 and the smallest MARE. Investigating the indexes in the one and two variant exponential equation factors in table 1, shows that the factors V_s/V_T and B/b has the most correlation with T_{smax}/D_{max}. This investigation also shows that the important factors in defining the dimensionless factors in the maximum deposition are V_s/V_T and B/b.

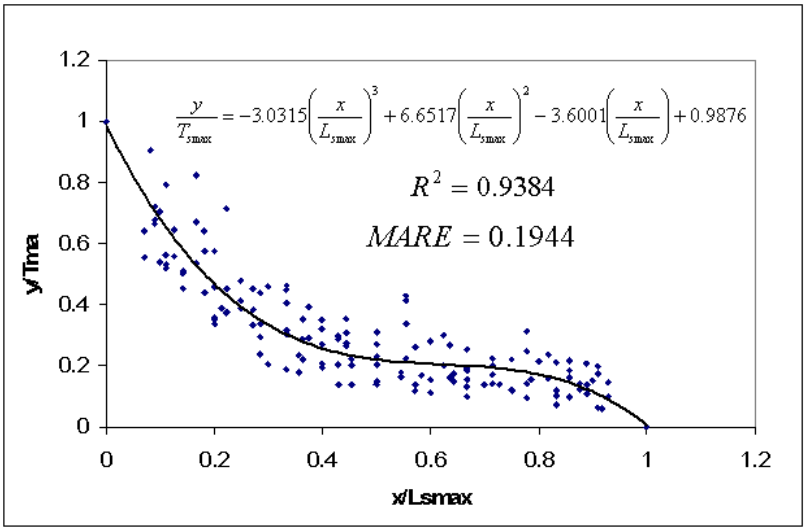

Fig 5. dimensionless deposition profile

Investigating the three-variant equation in that table shows adding dimensionless factors d_{50}/b has increased the correlation more than the factors C. so the third effective factor in determining maximum deposition thickness is d_{50}/b and the proper equation is the A2 relation. Comparison between equation and four variant equation A1 shows that although we have added C, there is no significant change in R^2 and MARE indexes. So the proper relation for the maximum deposition thickness is:

$$T_{s\max}/D_{\max} = 1.775\left(\frac{V_s}{V_T}\right)^{5.2271}\left(\frac{B}{b}\right)^{0.2403}\left(\frac{d_{50}}{b}\right)^{0.4720} \quad (14)$$

Linear and exponential multi variant relations for estimating the maximum deposition length are similar to equations (15) and (16) and they are a function of dimensionless factors Π_1 to Π_4 . the result of investigation are shown in table 4 and 5.

$$L_{s\max}/L_{w\max} = \alpha_3 + \beta_3\left(\frac{V_s}{V_T}\right) + \gamma_3\left(\frac{B}{b}\right) + \theta_3\left(\frac{d_{50}}{b}\right) + \eta_3(C) \quad (15)$$

$$L_{s\max}/L_{w\max} = \alpha_4 \cdot \left(\frac{V_s}{V_T}\right)^{\beta_4} \cdot \left(\frac{B}{b}\right)^{\gamma_4} \cdot \left(\frac{d_{50}}{b}\right)^{\theta_4} \cdot (C)^{\eta_4} \quad (16)$$

Investigating these tables shows that the exponential equations have more correlation and less MARE. So the exponential relation are investigated similar to the discussion we had in determining the maximum deposition thickness different relation indexes are investigated and the effective factors defined as B/b,d_{50}/b and V_s/V_T in order. Comparison between the three variant relation D2 and 4 variant relation D1 shows that the D2 indexes does not have a significant different with D1. So D2 is the proper relation for estimating maximum deposition length:

$$L_{s\max}/L_{w\max} = -0.7608\left(\frac{V_s}{V_T}\right)^{0.7325} \cdot \left(\frac{B}{b}\right)^{0.3358} \cdot \left(\frac{d_{50}}{b}\right)^{0.349} \quad (17)$$

4.Conclusion

In the present paper, the results of 25 experiments in a in high steep tilting flume for modeling slit dam is analyzed. The effective factors on deposition profile in the slit dam reservoir are discussed and according to the multi variant correlation analyses the following results are gained:

- deposition profile can be expressed as a 3-variant power equation
- the effective dimensionless factors in determining the maximum deposition thickness are V_s/V_T, B/b and d_{50}/b respectively.
- the effective dimensionless factors in determining the maximum deposition length are B/b, d_{50}/b and V_s/V_T respectively.

ABSTRACT

Alaska is already beginning to be affected by changes in global climate which make it a good location to study the feedback effects between climate, the water cycle and the carbon cycle. Using river dissolved elements and Sr isotopes we examine changes and/or differences in chemical weathering between watersheds in predominantly permafrost areas and glacial watersheds. Tributaries of the Tanana, Yukon, Nenana and Copper rivers were sampled during the early snow melt in late May and the late permafrost/glacial melt period in September of 2007. Waters are predominantly Ca–HCO_3^-/SO_4 which is typical of glaciated terrains. $^{87}Sr/^{86}Sr$ isotopes indicate three potential end-members, young basalts, radiogenic silicates and marine carbonates. The results are consistent with weathering observed in glaciated regions with trace calcites and salts dominating the dissolved load; however we have evidence for silicate weathering. Results also indicate that permafrost watersheds experience more progressive silicate weathering than glacial watersheds.

MOTIVATION, BACKGROUND AND SCOPE

Geochemistry and isotope geochemistry of rivers are often used to understand hydrogeological processes in watersheds. For example, we can get a better understanding of the interaction between the carbon and hydrogeological cycles. An important issue that has recently received attention, and is partially motivating the proposed study, is calculating atmospheric CO_2 drawdown as a function of the type of silicate mineral being weathered. Weathering of certain types of silicates, especially calcium and magnesium silicates, are of interest because it removes atmospheric CO_2 through transport of bicarbonate to the ocean (Berner et al. 2003). The long-term carbon cycle is an important component of climate on a geologic time scale.

Weathering of silicate and carbonate material is shown through the following reactions (Dupré et al. 2003);

$$CaCO_3 + H_2O + CO_2 = Ca^{2+} + 2HCO_3 \quad (1)$$

$$CaSiO_3 + 3H_2O + 2CO_2 \rightarrow Ca^{2+} + 2HCO_3^- + H_4SiO_4 \quad (2)$$

$$Ca^{2+} + 2HCO3 = CaCO_3 + H_2O + CO_2 \quad (3)$$

The carbonate dissolution reaction (1) requires one mole of CO_2 which is taken up from the atmosphere and then released with precipitation of calcites (3) while during silicate weathering (2) two molecules are taken up and only one is released via calcite precipitation on geological timescales. Therefore, carbonate dissolution or weathering is not expected to contribute to changing climate. This reaction applies not only to Ca but Mg silicates as well. According to several studies, lithology is the major control on river dissolved chemistry (Miller 1961; Garrels and Mackenzie 1971; Drever 1988). Therefore, river dissolved chemistry is often used to determine contributing lithology and estimate atmospheric CO_2 drawdown. One of the challenges with this fluvial method is that water entering the rivers has traversed over several different types of lithology so discriminating sources and climate variables is not trivial. Traditional methods of calculating weathering rates of different lithologies have included using major elements in combination with strontium (Sr) isotopes in river dissolved loads where, $^{87}Sr/^{86}Sr$ ratios were used to distinguish radiogenic and non-radiogenic silicates (Brantley et al. 2006).

The overall goal of the larger study is to determine if CO_2 drawdown will increase along with silicate weathering as climate changes. However, while weathering of most silicates is a CO_2 sink, weathering of carbon rich lithologies such as shale is a net source for CO_2. Quantifying net CO_2 drawdown by taking weathering of shales into account is still elusive and is one of the main goals of the larger study. Before net CO_2 fluxes can be determined we need to examine the contributions from different lithologies especially silicates and shales. In addition, weathering reactions are more likely to have progressed to a greater extent in permafrost watersheds as opposed to glacial watersheds; the river dissolved load chemistry will reflect this control. We use major ions and isotopes to distinguish sources and relative contributions from lithology and with the help of isotopes look for variations caused by greater chemical weathering. Using trace elements requires that watersheds be pristine, free from anthropogenic effects.

Rivers in Alaska (see Figure 1) were chosen for this study for several reasons. Briefly, Alaska is relatively pristine, at a latitude which is currently seeing effects of climatic change, we can study both permafrost and glacial fed watersheds, and the geology is very diverse. Permafrost cover is decreasing in the study area and is predicted to be gone in 25 years. In addition, in the future we can examine the effects of tectonic activity and exhumation on weathering. The rapid exhumation and increase in elevation apparently controls the weather and climate patterns in the area.

A number of tributaries on the Tenana, Nenana and Copper were sampled during the early snow-melt period (May) and again later in the summer (September) of 2007. It should be noted that not all of the rivers sampled in May were also sampled in September. Since permafrost has a very low flow rate the increased contact time between the water and minerals will result in a higher relative proportion of chemical weathering than the glacial areas. The glacial areas will more than likely see an increase in physical weathering due to more rainfall and more melt water runoff but the relative proportion of chemical weathering will still be small because there is less time for the water to remain in contact with the lithology. We will also examine any differences between the early and late melt seasons probably caused by the extended duration of water-rock interaction and increasing temperature.

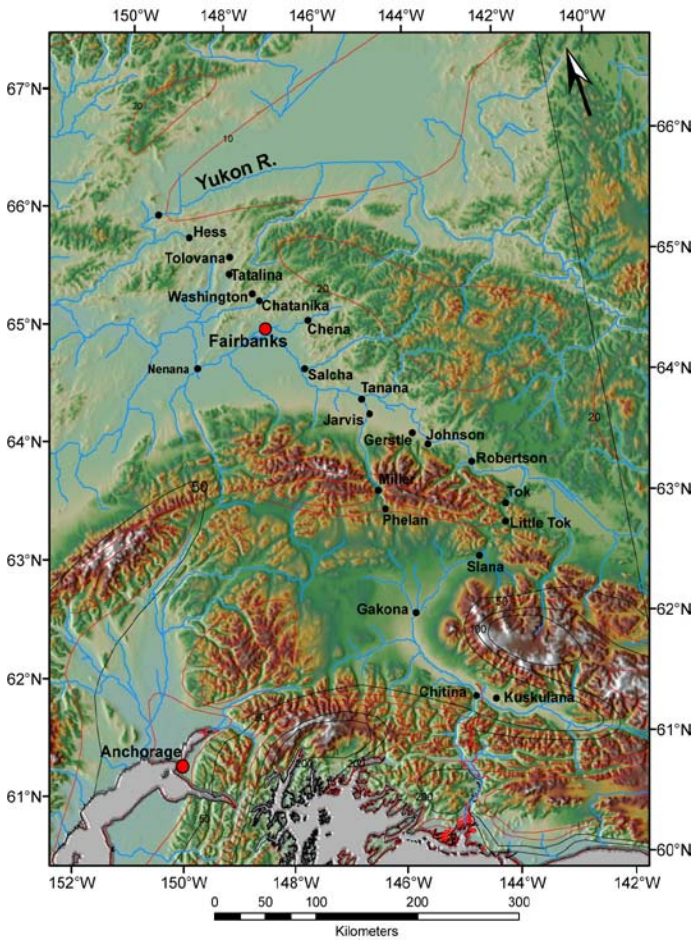

Figure 1. Study area and rivers sampled. Precipitation contours show variation consistent with topography and circulation patterns.

METHODOLOGY

Sample Collection:

Water samples were collected at the locations shown in Figure 1. All sites were sampled near the road and unless otherwise noted, all rivers were sampled upstream of the bridges. Field parameters measured on site include temperature, pH, dissolved oxygen and redox potential. All samples were filtered in the field using 0.4μm filter, half of the filtered samples were acidified with nitric acid to a pH~2.0.

Analytical Methods:

Major Ions and Trace Elements

Ion Chromatography was used to measure the anions (Cl^-, SO_4^{2-}, NO_3^-). Samples for cations and trace element analyses were sent to Activation Laboratories in Canada

and measured on an Inductively Coupled Plasma-Mass Spectrometer (ICP-MS). For quality control purposes as well as to obtain data not acquired by Activation Laboratories the same samples were run on an Inductively Coupled Plasma-Optical Emission Spectroscopy (ICP-OES) in the Geology Department at the University of Texas at El Paso.

Sr Isotope Purification and Analysis

Strontium was enriched and separated from interfering ions by using ion exchange chemistry. $^{87}Sr/^{86}Sr$ ratios were measured on a Nu Plasma multi-collector ICPMS at the University of Illinois at Urbana-Champaign, Urbana, IL. $^{87}Sr/^{86}Sr$ ratios are normalized to the $^{86}Sr/^{88}Sr$ ratio of 0.1194.

RESULTS AND DISCUSSION

Major ions and River Geochemistry:

The major ion geochemistry of these rivers essentially shows a Ca-Mg/HCO_3-SO_4 type water (Figure 2). Most of the rivers appear to be dominated by carbonate

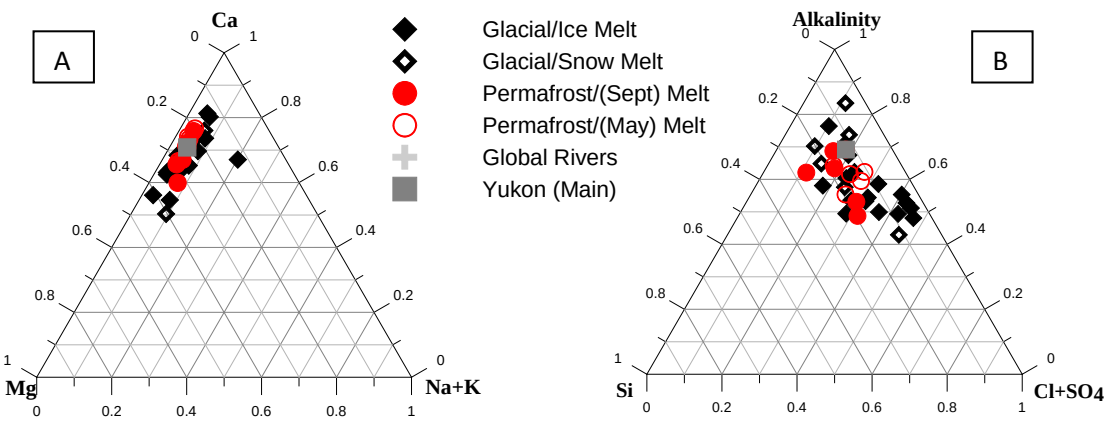

Figure 2. (A) Cation Ternary. (B) Anion Ternary. All the following figures use the same symbols.

weathering with varying degrees of contribution from silicates and salts. Although carbonate weathering appears to be dominant, the data does not completely lie on the alkalinity - ($Cl+SO_4$) tie line but shows up to 30% silica indicating substantial contributions from silicate weathering. On the cation ternary diagram (Figure 2A) the Alaskan rivers plot in the carbonate fields typical of most global rivers. Ca ranges from 50-80% though Mg can be as high 40%. The "excess" Mg could from silicate weathering but is more likely from Mg-sulfates (see below). The exception to the above is Chitina which has Na+K value as high as 20%. The glacial fed rivers sampled late in the season appear to be influenced more by evaporite dissolution than the other groups. Except for the above, there appears to be no significant difference in major ion chemistry between the four sampling groups (late season, early season, permafrost and glacial). The contribution from carbonate weathering is clearly evident from plots of Alkalinity vs Mg/Na (Figure 3). The river samples are generally clustered near the carbonate end-members and appear to fall along the typical mixing

line of carbonate and silicate/evaporite end members. For comparison, data from a number of global rivers (taken from Gaillardet et al. (1999)) are plotted in the background. It should be noted that the global rivers are averages and measurements are from the main channels.

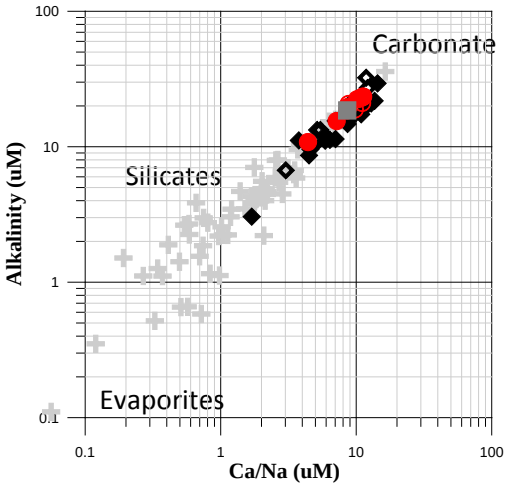

Figure 3. Alkalinity/Na vs Ca/Na. Generalized fields are adapted from Gaillardet (1999).

Sources contributing Na can be examined using a Na vs Cl plot (Figure 4A). Rivers that plot below the 1:1 line show excess Na that cannot be associated with halite dissolution. The excess Na is likely from the weathering of silicate minerals. There are rivers sampled from the late melt for both permafrost and glacial areas where the Na appears to be in excess and independent of Cl which may indicate a relative increase in silicate weathering. Further examination of the progression of weathering is done by plotting Si versus Na*+K which shows silicate weathering without the influence of carbonate or evaporite weathering (Figure 4B). Na* is Na without any Na associated with Cl removed (Na* = Na-Cl). As weathering progresses with silicates, the resulting sequence of clay formation is beidellite->kaolinite (for a more detailed description refer to Huh et al. (1998)). All of the rivers show that aluminosilicate weathering has gone through limited progression. It appears that the aluminosilicate weathering occurring in the permafrost regions has progressed farther than the glacial watersheds; this is significant because the information implies that there may be more silicate weathering in the permafrost regions. At this point it is unclear what is causing the excess Cl but local anthropogenic contamination cannot be ruled out. Sr isotope ratios increasing with Na*+K concentrations typically indicates weathering of aluminosilicates containing radiogenic strontium (Moon et al. 2007). Some of these

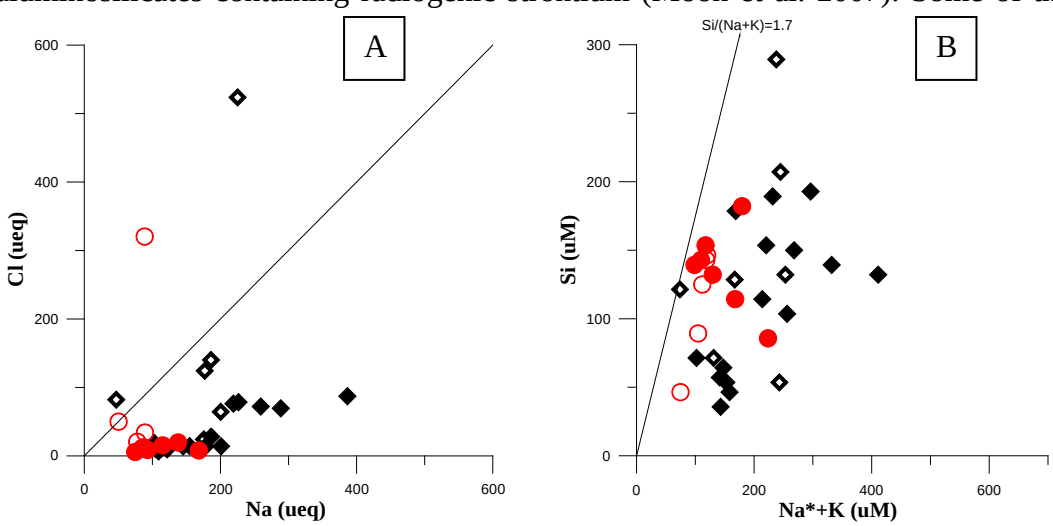

Figure 4. (A) Cl vs Na (B) Si vs Na*+K

watersheds clearly show weathering of depleted Sr isotope minerals are associated with ultramafic silicates (Figure 5). The permafrost and glacial snow melt rivers show that the Sr isotope ratios increase independently of the Na*+K concentrations. Glacial (ice melt) rivers show a decrease in Sr isotopes occurring with an increase in Na*+K concentrations. This is opposite of the trend usually seen for silicate weathering. This result indicates that weathering of trace calcites is contributing radiogenic Sr.

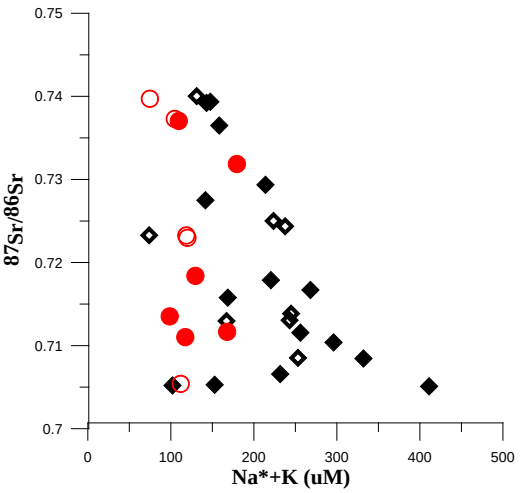

Figure 5. $^{87}Sr/^{86}Sr$ vs Na*+K

Evaporite minerals are the most easily dissolvable minerals and therefore even though they may not be the dominant lithology, they may still have significant influence on the river water chemistry. Gypsum ($CaSO_4$) is an evaporite mineral which may be contributing to the dissolved chemistry of the rivers sampled. It is clear from Figure 6 that SO_4 in glacial (ice melt) is well correlated with both Ca and Mg indicating the presence of Mg-sulfates associated. But that does not appear to be the case for the glacial (snow melt) or the permafrost samples. The Mg/Na vs SO_4/Na graph shows a mixing line between a

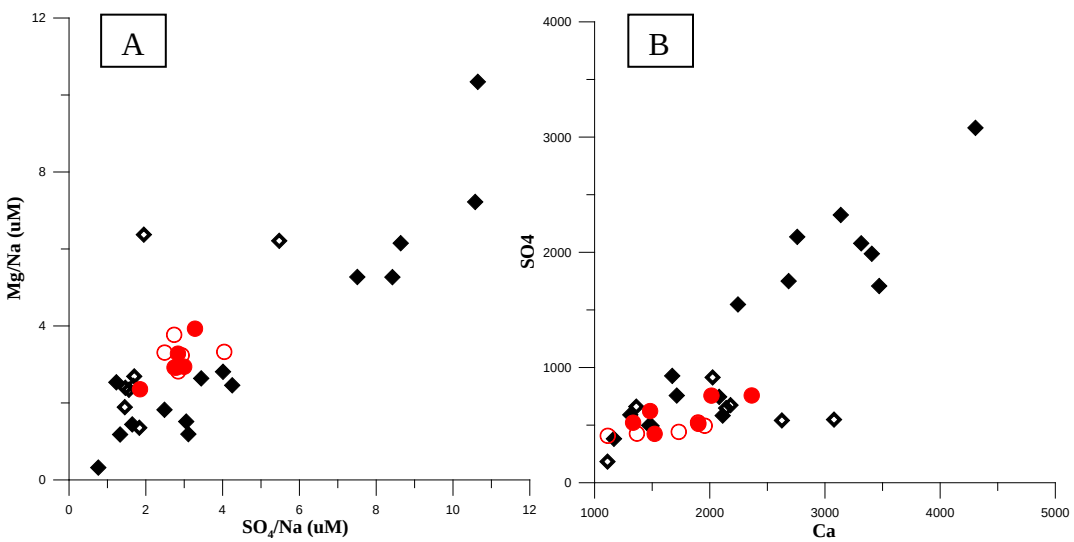

Figure 6. (A) Mg/Na vs SO_4/Na (B) SO_4 vs Ca

silicate end member and a possible $MgSO_4$ end member.

CONCLUSION

Major ions in the rivers of the central Alaskan region show dominance of carbonate weathering with evidence of silicate weathering. This is expected because carbonates

weather more easily than silicates. There also appears to be evidence in the glacial ice melt samples that dissolution of evaporites is a major contributor. Sr isotope ratios indicate two potential silicate end members, one radiogenic and the other depleted. There is some evidence that the permafrost regions are experiencing more intensive aluminosilicate weathering than the glacial regions. Through previous work it has been found that radiogenic Sr isotopes can be consistent with trace calcite weathering but further evaluation is needed to verify that it is the case in this area.

Abstract

A GIS-based hydrological model, namely HATWAB - Hybrid Atmospheric and Terrestrial Water Balance (Alemaw, 2006), was developed to compute water resource availability, simulating its spatial and temporal distribution over the CRB. HATWAB model simulates the Integrated Moisture Convergence (C), soil moisture (SM), Actual Evapotranspiration (AET) and Runoff (ROF). The spatial distribution of the simulated parameters shows a strong correlation with the rainfall pattern, especially in the high rain fed region (Effective Rainfall >1100 mm/year), corresponding to the heart of the equatorial forest which extend between 5 and -5 degrees of latitude; whereas some disturbances are observed in the lowest rain fed (Effective Rainfall <1000 mm/year) regions of the basin located the south-eastern and the up-north part of the CRB. The Evapotranspiration Ratio (ETR) defines two main climatic regions, ETR close to 1 for region 1 and ETR < 7, with an intermediate zone between (07 < ETR < 0.8). The Annual average SM varies between 0 and 400 mm while the AET varies between 400 and 1700 mm/year with highest values on the water bodies. The total annual grid ROF varies between 0 and 1400 mm. Swamps are characterised by 0 to 40 mm values while highest runoff (> 900mm) are computed on the rivers and lakes. The inland grid ROF varies between 50 and 900 mm per year with an average of 324 mm/year. The accumulated ROF computed final outlet reaches 44700m^3/second which is within an error margin of 5 % compared to the observed discharge. The HATWAB model still proved its ability of simulating water balance for large scale basins such as the CRB if input data are available and well prepared at acceptable resolution.

1. INTRODUCTION

During the last decade African continent has been characterised by a shortage of water, electricity and food. This situation seems to endure and requires serious attention. The evaluation of spatial and temporal distribution of water resources of the Congo River basin is of great importance as the basin and its equatorial forest play an important role in the sustenance of the global climate equilibrium and the ecosystem stability. The fifth-longest river in the world and the second longest in Africa, Congo River basin (CRB) contains the second largest forest in the world, after the Amazon. Its watershed measures over 4.1 million sq. km with 4375 km of length and 0.8 to 16 km of width. In order to understand and evaluate the spatial and temporal

distribution of the CRB water balance, a distributed GIS-based hydrological model, namely Hybrid Atmospheric and Terrestrial Water Balance (HATWAB) (Alemaw, 2006) was developed and parameterised for the Congo basin using GIS and computational hydrology techniques. The HATWAB model is based on consideration of surface and subsurface processes (Fig. 1). In the subsurface zone, soil moisture accounting technique of Thornthwaite and Mather (1957), modified as part of this study, is used to compute the water balance components known as actual soil moisture (SM), evapotranspiration (AET) and runoff (TRO). The surface abstractions in terms of overland runoff, interception and integrated vertical convergence are accounted for by HATWAB model (Alemaw 2006) which is a soil water balance method.

The model leads to the creation of high-resolution data sets of SM, AET and TRO over the several catchments in the Central African region, which are represented by geographically referenced grids of 12x12 degree resolution.

2. DATA PROCESSING AND METHOD

Developed in MS FORTRAN studio and supported by GIS packages, the HATWAB model estimates the SM, AET and ROF based on the equations listed below.

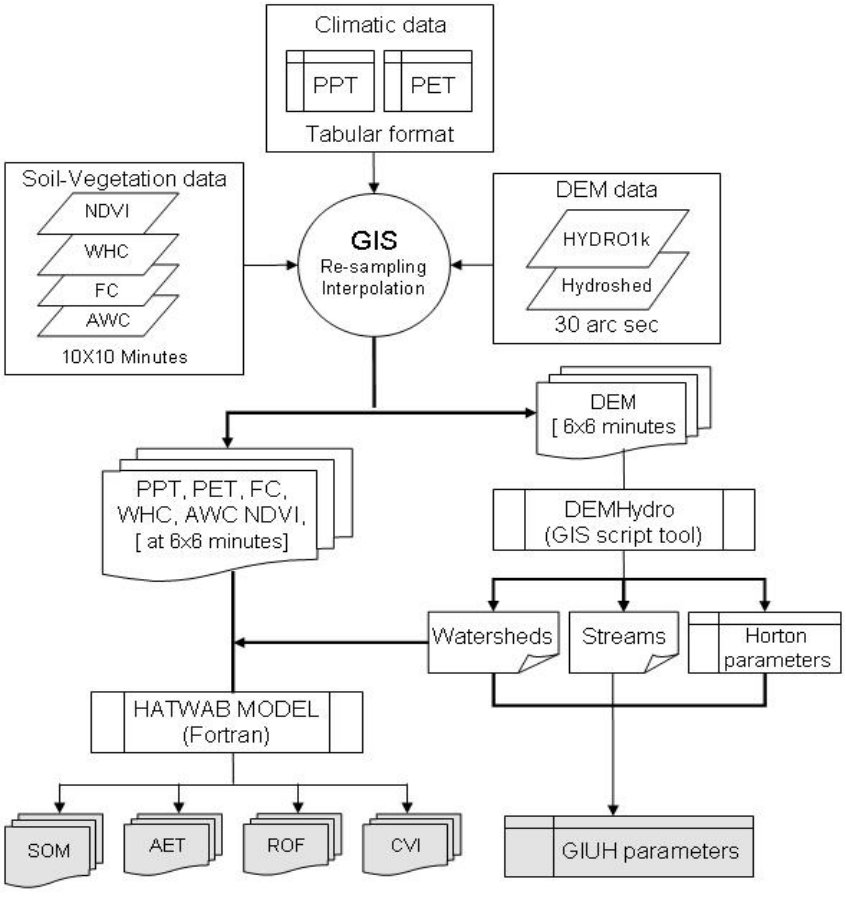

Figure 1 General terrestrial Water Balance model structure

2.1. Water Balance Model Development

Supposing the principle of continuity in hydrologic system, Chow (1998) assumes that the time rate change of storage is equal to the difference between the input and the output of the hydrologic model (equation 1).

$$\frac{ds_t}{dt} = I_t - O_t \tag{1}$$

where, S_t is the time-variant storage in a grid cell, I_t , the summation of input coming into the cell from upstream cells and the runoff generated in the cell, and O_t , the outflow from the cell which is calculated by various methods such as the linear reservoir method.

2.1.1. Atmospheric water balance

The atmospheric component of the water balance model is expressed as

$$\frac{dW}{dt} = -P + E + C \tag{2}$$

$$C = -\nabla \times Q \tag{3}$$

Where dW/dt is the amospheric storage change, C is the vertical integrated moisture convergence and was expressed as a function of the water vapour flux (Q) in Equation (3).

$\nabla \times Q$ is the divergence or net outflow of water vapour across the sides of the atmospheric column, Q is the vapour flux, E is evaporation, and P is precipitation.

The quantity W is also referred to as the precipitable water and may be expressed in units of mass per unit surface area or converted to an equivalent depth of liquid water by dividing by the density of liquid water (1000 kg m^{-3}).

In mean water balance computation like the HATWAB model which is a monthly water balance model, the atmospheric storage change is often assumed to be negligible (Reed et al, 1998 and Marengo, 2005); thus equation (3) is reduced to

$$P - E = C \quad or \quad P - E = -\nabla \vec{Q} \tag{4}$$

From Equation (4), it is seen that if the divergence ($\nabla \vec{Q}$) in a region is positive, then evaporation is greater than precipitation (P-E < 0), while a negative divergence or "convergence" indicates that precipitation is greater than evaporation (P-E > 0).

2.1.2. Terrestrial water balance

At monthly time scale a terrestrial water balance model is written as follow:

$$\frac{ds}{dt} = P - E - R \tag{5}$$

Where *S* is soil moisture storage; *P* is precipitation; *E,* actual Evapotranspiration; and *R*, the observed runoff.

Linearising Equation (4), the terrestrial water balance has the following form,

$$SM_1 = SM_{t-1} + P_t - E_t - R_t \tag{6}$$

Where t is the time period, which is a single month is this model, P is precipitation, E is the Evapotranspiration, and RO is the runoff.

Once the initial soil moisture (S_{t-1}) and the actual soil moisture (S_t) are determined, the monthly Actual Evapotranspiration E_t and the Runoff R_t can be calculated.

2.1.3. Imbalance estimation

Combining Equations (5) and (6), the vertical integrated moisture convergence (C) is computed as follows

$$C - \frac{dS}{dt} = R \tag{7}$$

In a steady state $P - AET = R$. Changes in storage could however lead to $P - E$ being different from R. These could also be due to certain errors in representing rainfall within the Congo River Basin. These lead to the expression of an *imbalance equation*

$$I_{mb} = \frac{C - (ds/dt + R)}{R} \tag{8}$$

The imbalance in I_{mb} is calculated using equation 9:

$$I_{mb} = \frac{C}{R} - \frac{ds/dt}{R} + 1 \tag{9}$$

Contrary to the formulation adopted in this study based on (9), Marengo (2005) assumes that *dS/dt* is negligible for monthly time scales and applied it in the Amazon basin, which reported unaccounted residuals in his water budgets. Whereas in the proposed model in this study, the soil moisture variation *dS/dt* is varying from season to season as a function of the prevailing *PET* and *PPT* at a given location according to Equation (5), in which the imbalance should also cater for this variability according to Equation (9). One of the contributions of this study is that, once the imbalance is kept to a minimum in the water balance computation at each grid, then the simulated variables and water balances, *PPT*, *ET*, *RO*, *RO/PPT*, *ET-PPT*, *ET/PET, S* and *C* can then be used to investigate the seasonal and temporal variability of water budget of the Congo basin.

The amount of precipitation and potential evapotranspiration determines soil moisture availability, which in turn is controlled by the water holding capacity of the soils.

2.1.4. Rainfall-Actual, Evapotranspiration-Soil moisture-Runoff modelling

2.1.4.1.Effective Precipitation (EPPT) and overland runoff (Direct runoff DRO)

One of the main inputs required in the proposed water balance model is the effective precipitation (EPPT). At a monthly time scale, the effective precipitation is calculated as per the formula of the USDA soil conservation available from FAO (1990) as follows:

$$EPPT = PPT(\frac{125-0.2PPR}{125}) \quad for\ PPT < 250 \tag{10}$$

$$EPPT = 125 + 0.1\ PPT \quad for\ PPT \geq 250 \tag{11}$$

Where $EPPT$ is effective precipitation and PPT is the total precipitation

The direct runoff (DRO) is the difference between the precipitation (PPT) and the Effective precipitation (EPPT).

2.1.4.2.Soil moisture estimation (SM)

Soil moisture is determined from the interaction between effective PPT and PET. During wet months (when effective PPT in excess of PET), soil moisture can increase up to a maximum of field capacity determined by soil texture and rooting depth.

$$\frac{dSM}{dt} = PPT - PET \quad when\ PPT > PET\ \ and\ SM < FC \tag{12}$$

$$\frac{dSM}{dt} = 0 \quad when \quad SM = FC \tag{13}$$

$$\frac{dSM}{dt} = a\,SM\,(PET - EPPT) \quad when \quad EPPT < PET \tag{14}$$

Where, FC is the soil moisture at field capacity of the soil millimetres, PPT is precipitation in mm/month; PET is potential evapo-transpiration in mm/month.

During the dry periods where the EPPT < PET, the soil becomes increasingly dry, soil moisture becomes a function of potential soil loss. Thus, different authors assumed different relationship to find the soil moisture during the dry periods (Thornthwaite, 1948; Vorosmarty *et al*., 1989).

For a particular soil, there is a linear relationship between Log (SM) and Σ(EPPT-PPT) summed from the start of the dry season to the current month. Thus, to calculate the rate of change of soil

moisture (ΔSM) through the dry season, the soil moisture is directly estimated from the empirical relation suggested by Vorosmarty *et al*. (1989). To calculate dSM/dt through Equation (14) for intermediate field capacities, the HATWAB model defines a slope a to the retention function as:

$$a = \ln(FC)/(1.1282\ FC)^{1.2756} \tag{15}$$

where the numerator represents the soil moisture (millimetres) with no net drying. The denominator is the accumulated potential water loss or APWL $\left(\sum [PET - PPT]\right)$ in mm at SM=1 mm. With a determined, the model can calculate dSM/dt as a function of soil dryness and update SM. The following Figure 2 shows the relationship between soil moisture and the Evapotranspiration.

Calculations commence at the end of the wet season when it is assumed the soil is at the field capacity. Soil water stocks are then depleted during the dry season in accordance with the moisture retention function. For each wet month, soil moisture is determined by incrementing antecedent values by the excess of the available water over PET. This recharge may or may not be sufficient to bring the soil to field capacity at the end of subsequent wet season.

Analysis of the ratio PPT/PET at the various grids in Central Africa has shown that the region can not be represented by one homogeneous climatic zone; rather it is a combination of climate influenced by the diversified hydro-climatic conditions in the region. In this analysis, it has been observed that the long-term monthly rainfall distribution varies greatly in the region.

It is assumed that the ratio PPT/PET could be a good indicator of the seasonal distribution of monthly rainfall, and accordingly the wet season ends when the ratio PPT/PET just starts to fall below unity. In line with this, therefore, the soil moisture can be assumed to be at its field capacity. Consequently, HATWAB fixes a starting month of any grid across the region according to the aforementioned criterion. The solution of the basic mass balance equation for the subsequent months can determined once the initial soil moisture state is obtained.

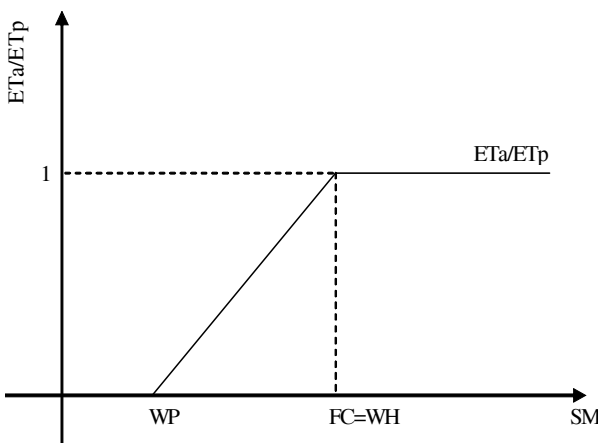

Figure 2 Functional relationship between soil moisture and Evapotranspiration (ETa is the actual Evapotranspiration, ETp is the potential Evapotranspiration, SM is the soil moisture, FC is the field capacity and WP, the Wilting point

2.1.4.3.Actual Evapotranspiration (AET)

Once the actual soil moisture is determined, the corresponding actual evapotranspiration (AET) is calculated for the month. Following the Thornthwaite and Mather (1957) approach, AET is set equal to PET in wet months, when EPPT > PET. During this time it is assumed that EPPT is in sufficient abundance to satisfy all the potential water demands of the resident vegetation. During dry season when EPPT < PET, the monthly average AET is modified down wards from its potential value as shown below.

$$AET = PET \quad when \quad EPPT > PET \tag{16}$$

$$ET = PPT - \frac{dSM}{dt} \quad when\ PPT < PET \tag{17}$$

Where the soil moisture drops below the wilting point, the AET is equal to the EPPT but if there is no EPPT at all time, AET becomes zero.

2.1.4.4.Total runoff (TRO) generated at a grid spatial scale

Most of the water does not leave the basin as soon as it becomes available as surplus. The portion that constitutes overland flow is assumed to flow out of the watershed within the month it occurs but the portion that infiltrates may take a number of months to move slowly through upper layer of the soil column to emerge in the surface water courses as base flow. The lag or delay factor depends not only the size of the basin but also on the vegetation cover and the soil type, degree of slope, characteristics of the soil layers, etc. over and added to the surplus of the next month. This factor is set according to Thornthwaite & Mather (1957) which is equal to 0.5.

$$RO = 0.5*(D + (EPPT - PET)); \quad when\ \ SM = FC\ \ \&\ \ EPPT > PET \tag{18}$$

$$RO = 0.5 * D, \quad when\ SM < FC\ \ \&\ EPPT < PET \tag{19}$$

Where, RO is rainfall-driven runoff or surplus runoff (mm/month) and D is the amount of detention storage in millimetres that is assumed to leave each grid cell next month.

Thornwaite suggests that 50% of the water surplus could be assumed to runoff each month from large basins with the remainder being held.

2.2. Study region and Data used

The Congo drainage basin is situated in Central Africa. Its hydrological system straddles several countries; Congo and the Democratic Republic of Congo for the most part, but also Angola, Cameroon, the Central African Republic, Zambia and Tanzania, stretching through Lake Tanganyika. The fifth-longest river in the world and the second longest in Africa, Congo River

contains the second largest forest in the world, after the Amazon. Its watershed measures over 4.1 million sq. km with 4375 km of length and 0.8 to 16 km of width

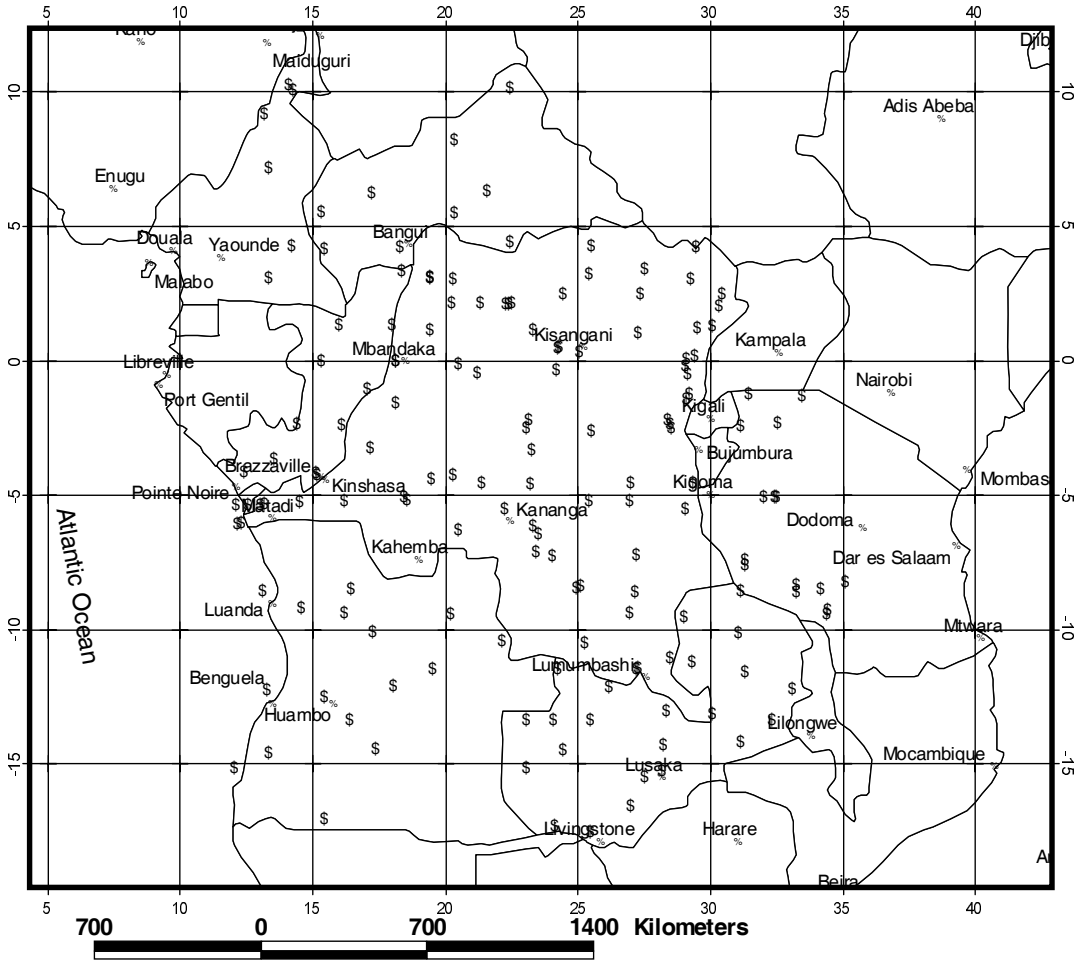

Figure 3: Distribution of Climatic stations in the study area. The study area covers more than 145 stations:

2.2.1. Meteorological data sets

Free meteorological data for 3262 global climatic stations are available at FAO-UNESCO /CLIMWAT, with a record time of 30 years (1961 -1990) at a monthly scale; where 145 climatologic stations covering the study area (Figure 3 and Appandix B) were extracted to compile the meteorologic database for the model. These climatologic data sets include monthly averages of maximum and minimum of temperatures, mean relative humidity, wind speed, sunshine hours, radiation data as well as rainfall and Reference Crop Evapotranspiration (ETo) calculated with the Penman-Monteith method (Allen et al, 1998). Below, Figures 4 and 5 show the Potential Evapotranspiration and Rainfall distribution in the basin, respectively.

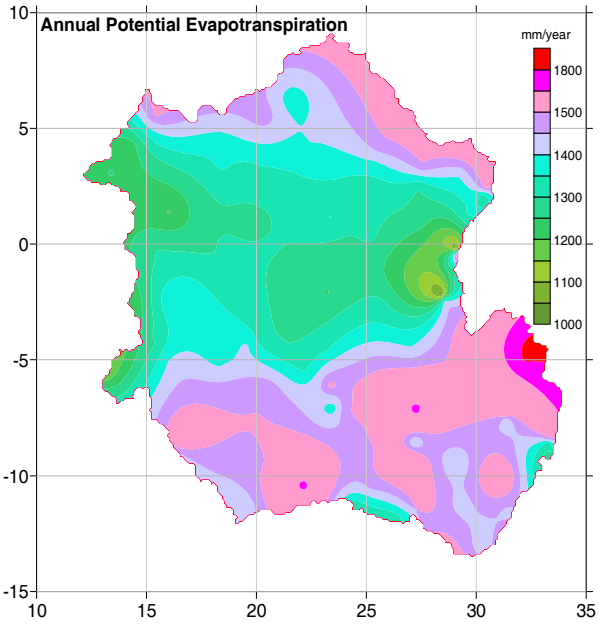

Figure 4 Mean Annual Potential Evapo-transpiration (1961-1990) map

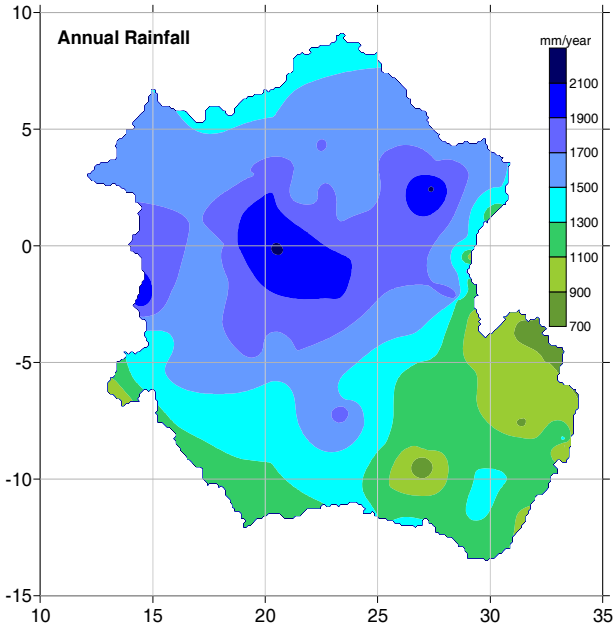

Figure 5 Rainfall averaged (1961-190) data from 145 stations. 1. Rainfall,

2.2.2. Discharge data

There is a lack of discharge data in the Congo Basin. The availability of recharge data is limited to a few numbers of rivers gauges. At the basin final outlet, discharge has been amounted to an average of 45000 m^3/sec (Asante, 2000). Discharge data indicates a series of four distinct phases in the Congo and the Oubangui since the beginning of the 20th century. During the 1960s they increased, overtaking their average over a century. The Congo discharge then fells, returning in 1970 to what had been the normal level, whereas the Oubangui entered a drought phase. This trend accentuated from 1980 and, until 1996, the Congo discharge weakened by 10% (37 400 m3/s in 1992 compared with an average of 40 600 m3 /s over that period as a whole), which was the most dramatic decrease of the century. This fall is much stronger in the Oubangui (- 29%), yet negligible (- 0.2 %) in the Kouyou sub-basin.

2.2.3. NDVI and vegetation database

The monthly NDVI images for each basin were acquired from the Global Land Cover Characteristics database. Satellite data have been used extensively for mapping the land use and for monitoring the seasonal change of vegetation of river basins (Nemani & Running, 1989).

The Normalized Difference Vegetation Index (NDVI) is commonly applied to derive the leaf area index (LAI) from channels 1 and 2 of NOAA-AVHRR data at 1-km^2 resolutions. Monthly twelve NDVI images, expressed in percentage, for 1987 are acquired from USGS database. Based on NDVI values the LAI for different land use groups can be estimated by empirical formulae. Table 13 presents rooting depth assigned for various soil textures and SCS soil groups.

2.2.4. Soil properties

A global Soil map at 10x10 minutes resolution is freely available at FAO/UNESO database (FAO, 1984). This map is used to extract the submap of the study area and later re-sampled to a spatial resolution of 6x6 minutes so that it can overlay onto the model.

Table 1 Rooting depth assigned for various soil textures and SCS soil groupings

Veg. Group	NDVI	Assigned Root Depth (M) For Different Soil Types					
		Sand	Sandy Loam	Silty Loam	Clay Loam	Clay	Lithosol
VEG2	>50%	2.5	2	2	1.6	1.2	0.1
VEG1	≤50%	1	1	1.3	1	0.7	0.1
SCS soil group (Singh, 1992)		A	B	D	C	C	B

Table 2 Soil texture distribution in the Congo River basin

Class ID	1	2	3	4	5	6	0	
Soil type	Sand	Sandy Loam	Silty Loam	Clay loam	Clay	Lithosol	Water body	Total
No grids	4847	0	58	21867	989	2374	513	30640
% gris	15.8	0	0.2	71.3	3.2	7.7	1.7	100

Since the Soil Water available to plants depends on soil water content, soil texture, and consequently, the rooting depth of vegetations, the 133 agronomic groups of FAO agronomical soil map were therefore used to derive and reclassify textural soil classes which are required as input data for the model. For this matter a FORTRAN algorithm was developed and six hydrological textural classes of soil (Table 1) were identified in the study area.

The reclassified textural soil and vegetation maps are used to derive the soil retention parameters such as Field Capacity (FC), Wilting Point (WP) which determine the soil moisture capacity known as Available Water Content (AWC) for each soil group. Based on field measurements, Saxton *et al.* (1986) have developed a technique to estimate the matrix potential of different soils by using multiple regression techniques. Therefore, at a matrix potential equivalent to field capacity (33 KPa) and wilting point (1500 KPa) for a unit meter depth of soil, approximate values of FC and WP for the various soil textures have been extracted. Accordingly, the FC and WP values as per the rooting depth are then derived for the whole region.

Available water content (AWC) of a soil of given texture is defined as the difference between the field capacity and wilting point. The depth of soil water which can be used by the crop, the Total Available Water (AWC), depending on the root depth of the crop and on the soil moisture holding properties of the soil (Eilers et al, 2007), Equations (20 and 21) bellow shows the relationship between these soil parameters:

$$AWC = (UFC - UWP)R \tag{20}$$

$$\text{With} \quad \begin{aligned} FC &= UFC \times R \\ WP &= UWP \times R \end{aligned} \tag{21}$$

Where AWC is the available water content per root depth; *FC* and *WP* are the field capacity and wilting point, respectively; R is the current depth of the roots; UFC and UWP are the field capacity and the wilting point per unit volume of the soil, respectively.

3. RESULTS

3.1. Soil Moisture

Figure 8 shows the Annual average Soil moisture. The mean annual soil moisture for the entire basin ranges between 0.7 and 431.4 mm, with highest mean monthly soil moisture of 546.2 mm during November and lowest, in July (146.2mm). A general trend is observed in the spatial distribution of the moisture: the regions around the equator are characterised by high soil moisture and this is reduced as the distance to equator is increased (Figure 9).

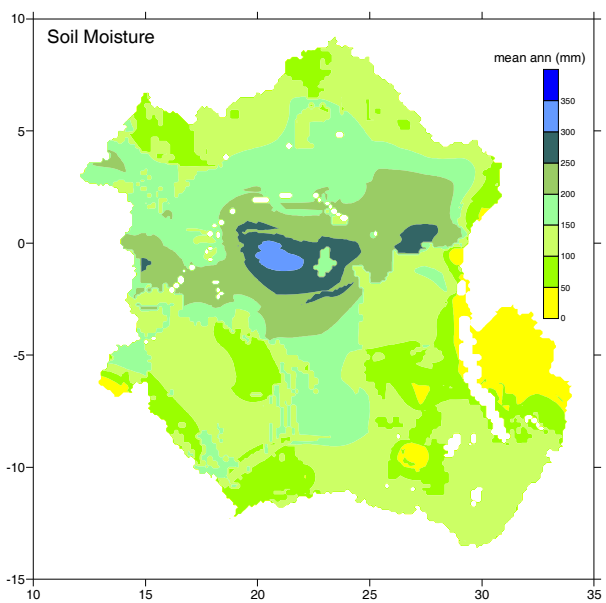

Figure 6 Mean annual moisture (in mm) over the Congo basin.

Spatially, the highest values are located in the centre of the basin which coincides with the core of the dense equatorial forest. These values range between 200 and 432 mm (mean annual). The lowest value ranging between 0 and 50 mm are located in the western part on Tanzania (eastern part of Tanganyika Lake). This region is also characterised by the small amount of annual rainfall (< 800) compared to other region inside the basin. Statistically, the soil moisture distribution over the basin correlates strongly with the hydrological soil group and the climatic parameters such as rainfall and Evapotranspiration. “Lithosol” is the type of soil Available Water content (<120 mm/root depth). The computed soil moisture values would be better interpreted as indexes of relative wetness rather than absolute estimates because none are calibrated against measured values in the field.

3.2. Actual Evapotranspiration (AET)

The simulated Actual Evapotranspiration (AET) over the basin is shown is Figure 10. The mean annual AET ranges between 564.13 and 1576.8 mm/year with a mean of 1098 mm/year. It is well observed that the AET trends similarly with the Rainfall and the existing land cover map of the basin. Consequently, the area with lowest AET is located in the south-eastern region of the basin which coincides with low rain feed region of the area.

High annual averaged AET values are sequentially observed over the water bodies such as the Tanganyika with a maximum of 1576.8 mm/year, followed by Upemba, Rukwa, Mweru, Delcommune, Bangwelungu Lakes (1300 - 1531 mm/year) and Kivu, Mai-Ndombe Lakes (>1250 mm/year). Some portions of the Congo River inside the heart of the Tropical forest present also high annual values of AET. Excluding the water bodies, the density of the equatorial forest varies positively with AET distribution.

The seasonal distributions of AET are characterised by alternation of high values in the northern hemisphere during the two seasons of December-February and March-May and low values in the southern hemisphere; inversely during the other 2 seasons (June-August and September-November

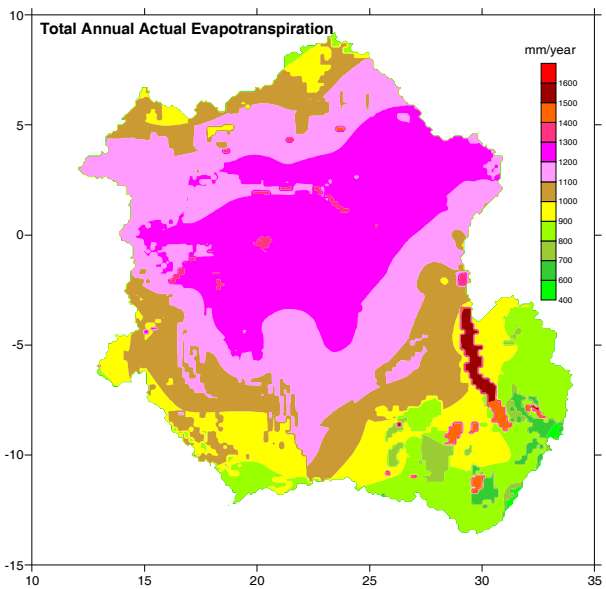

Figure 7 Mean Annual Actual Evapo-transpiration over the Congo River basin

3.3. Runoff

The simulated Annual Total runoff is shown in Figure 11. The mean annual Runoff for the Congo Basin varies between O and 1945 mm with a mean annual runoff of 342 mm. The highest values are concentrated in the heart of the equatorial forest along the Middle Congo river branch. This area records higher rainfalls in the whole basin. The lowest value is simulated in the southern hemisphere around the grid of coordinate 31^0E and 6.73^0S (western part of Tanzania). A part the lakes, the highest values of runoff are simulated in the heart of the equatorial forest across the equator, and decrease

progressively towards the tropics. This trend is relatively disturbed with the soil types especially in the south-eastern, the extreme north region and along the main Congo River.

The annual simulated runoff show a general trend strongly influenced by the distribution pattern of precipitation (Figure 12) in the basin, while seasonal and monthly runoff correlate strongly with both rainfall and soil type during dryer seasons. The area with zero runoff values corresponds to swamps and some inland lakes where there is negligible flow to the river system.

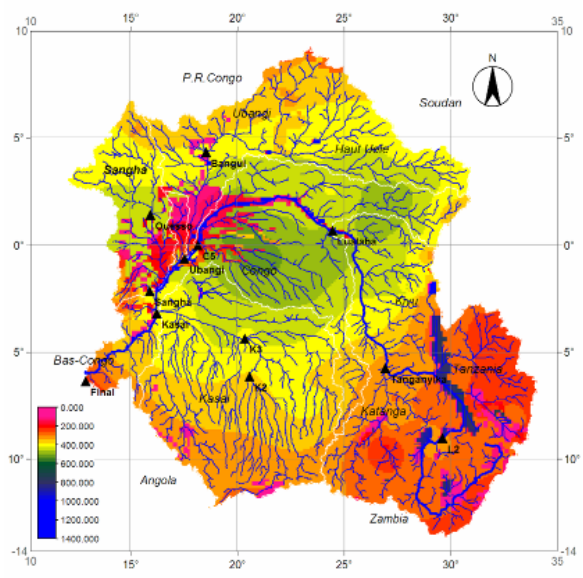

Figure 9 Mean annual runoff over Congo basin (mm/year)

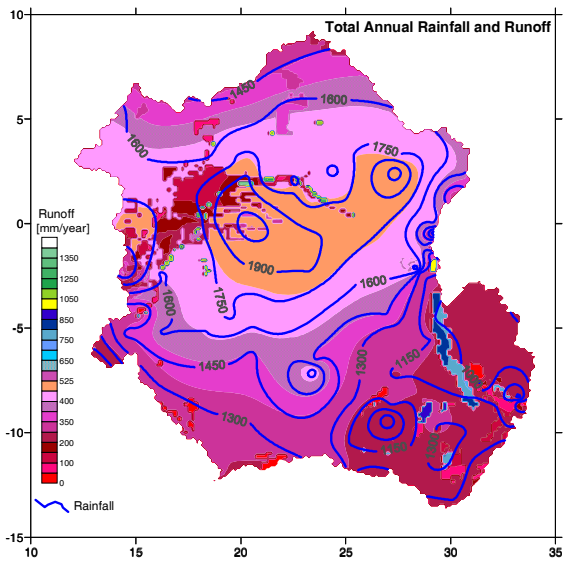

Figure 8 The relationship between precipitation and gridv- simulated runoff in the CRB

Seasonally, the September-November period records the highest amount (658432 mm. /season) of runoff whereas the lowest (358223 mm/season) is generated during June-August. This shows again the influence of rainfall on the generated runoff pattern in the Congo basin where , in general, the period June-July season records the lowest rainfall in the southern hemisphere which occupies more than 55% of the basin area. Two picks runoff are observed in March-May and September-November (658432 mm.) seasons which record higher rainfall during the year in the southern region.

3.3.1. Simulated sub-watershed and basin-wide runoff

Table 3 Subwatershed runoff averages

Area name	ROF Mean Ann	ROF Simulated (m3/sec)	ROF Observed (m3/sec)	Error (%)

Kasai	344.7	11,545	No data	-
Lualaba	297.3	12,314	No data	-
Congo	385.5	12,177	No data	-
CRB	342	47,418	45,000	5.1

The runoff averages for each subwateshed are given in table 18 below. The Lualaba subcatchement knows the highest runoff than others. The higher amount accumulated runoff was expected in the Congo but this is not the case due to the presence of swamps in the subcachements where are simulated small values averaged to 0 mm per year. At the basin scale, the total annual runoff is about 47,418 m^3/sec. This amount is comparable to those reported in literature (45,000 m^3/sec; Asante, 2000) with a marginal error of 5.1%.

3.3.2. Local water balance over the Congo river basin

Appendix 1 shows the local water balance graphs for 11 grid cells around some meteorologic stations used in the model. The hydrological behavior correlates strongly with the rainfall betwenn -5 and 5 degree latitude zone. In the South-eastern region (Lubumbashi, Urambo, South-westen) and the Up-North station, runoff starts to increase in the mid-year as well as the soil moisture. An inverse situation is observed in the high rain fed region.

CONCLUSION

The HATWAB model permits to establish the hydrologic regimes of the Congo River Basin. Spatial and temporal distribution of the major components of water balance (Soil moisture, Actual Evapotranspiration and Runoff) were estimated.

This work is the first comprehensive distributed hydrological model that utilises the hydroclimatic, soil texture and Vegetation information, using the state of the art GIS technique to compute the water balance for the whole Congo River basin.

This model approach provides an operational hydrological tool to deal with national, or regional planning and developing decision support systems, with possible linkage with the inter-related multi-sectoral nature of the natural resources, socio-economic and climatic dynamics of the region and beyond.

ACKNOWLEDGEMENTS

I wish to express my thankful words to the German Academic Exchange (DAAD) for the fellowship which enabled us to complete this study at the University of Botswana, leading to a M.Sc. degree in Hydrogeology. The HATWAB model was originally developed by B.F. Alemaw. He is also the supervisor of this research.

APPENDIX A. LOCAL WATER BALANCE FOR SELECTED GRID CELLS IN THE CONGO RIVER BASIN (GRAPHS)

Preliminary assessment of planform change at low flows with vegetation expansion: Platte River, Nebraska

Lisa M. Fotherby[1]

[1] River Engineer, Sedimentation and River Hydraulics Group, Technical Service Center, Bureau of Reclamation, Denver, Colorado; email: lfotherby@do.usbr.gov

ABSTRACT

A central reach of the Platte River in Nebraska has braided, anastomosed, meandering, and wandering channel form. Proliferation of phragmites (*Phragmites australis*) and other in-channel vegetation during eight years of low flow may be altering channel shape. Deterioration of braided reaches, as represented by decreases in width-to-depth ratios (W/D), could reduce habitat for three endangered and threatened bird species. In this preliminary assessment, W/D values for ten cross sections at five study sites surveyed in 2008, are compared to W/D values from surveys at the same locations in 2005, 1998-2001, and 1985. All ten cross sections are on managed lands where vegetation is controlled and removed. ANOVA and paired t-tests showed no significant difference in primary indicator W/D_{ave} between 1985, 2000 and 2005 data sets, but some indication of planform change between 2005 and 2008 (P=0.052). No change between 1985, 2000, and 2005, and significant change between years 2005 and 2008 (P=0.01) are confirmed using a second indicator W/D_{max}. Finding is not the result of vegetation stabilized banks at the sites, or hydrologic regime, but may be due to sediment-short flows. Recommendations are made to extend this study with surveys on unmanaged lands and at sites of meander planform. Future studies may determine if vegetation is altering planform through bank stabilization, and assess if sediment trapping by vegetation and phragmites in overbank areas is reducing sediment transport during high flows.

Key words: low flow, vegetation, invasive species, phragmites, Platte River, planform, braided, width-to-depth ratio, sediment

INTRODUCTION

The study area is a 150-km reach of the Platte River between the cities of Lexington and Chapman in central Nebraska. Although river alignment in this reach forms a large bend to the south, flow is generally west-to-east and discharges to the Missouri River near Omaha, 265 river km downstream of the study area on the eastern border of Nebraska. With no large tributary convergence within the central Platte River study area, flow is relatively consistent from Overton, NE to Chapman, NE. Exceptions are variations at low flow due to small tributaries and groundwater losses and gains, and variations at high flows due to temporary bank storage.

Historically, the river is a sand bed, braided system with a wide shallow channel and multiple instream sand bars. In conjunction with large water resource development in the twentieth century, river planform evolved from predominantly fully-braided to a blend that includes island-braided, anastomosed, wandering, and meandering river

(Fotherby, 2008). The endangered whooping crane (*Grus americana*) uses the river during spring and fall migrations, and the endangered interior least tern (*Sternula antillarum*) and threatened piping plover (*Charadrius melodus*) nest on bare sand areas from May to August (USDOI, 2006). Beginning operation in 2007, the Platte River Recovery Implementation Program (Program) seeks to improve tern and plover productivity and whooping crane migration survival through implementation of adaptive management actions including Program land and water resources (AMP, 2006).

Low Flow and In-Channel Vegetation

Beginning in year 2000 and continuing to year 2008, only one flow approaching 140 m^3/s (Figure 1) was recorded on the Platte River near Kearney (river km 346). Vegetation expanded into the former active channel area while low flows remained concentrated in main channels. In 2005 a rainfall-driven high flow event centered downstream of Kearney, caused a peak flow of 210 m^3/s at Grand Island (river km 265) but less than 85 m^3/s at Kearney. In 2008, a 370 m^3/s high flow at Kearney inundated overbank areas and interrupted an extended period of low flows.

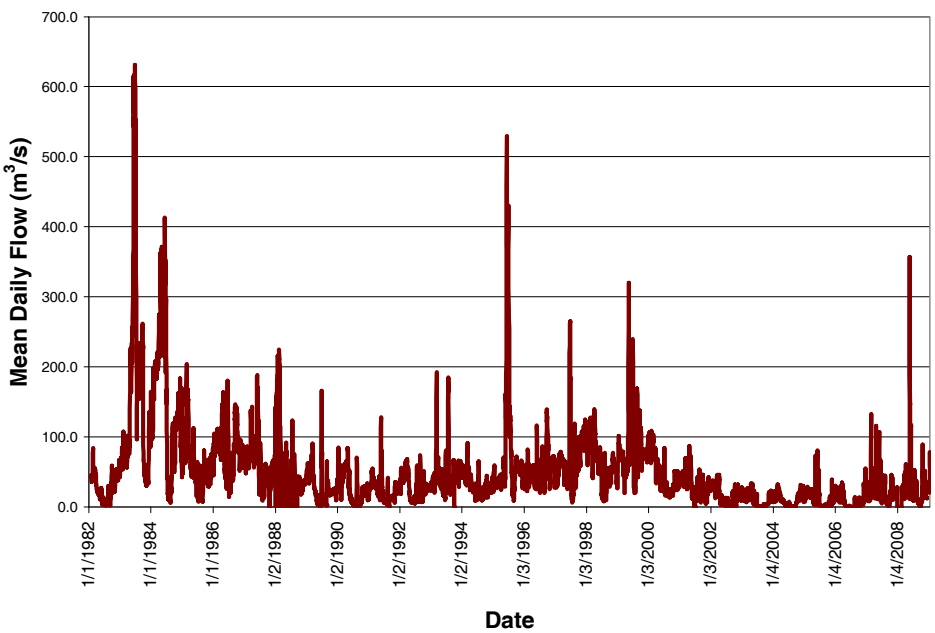

Figure 1. USGS mean daily flows for Platte River nr. Kearney, Nebraska (USGS Site 06770200). Kearney is located at river km 346.

Prior to the low-flow years of 2000-2008, Eastern cottonwood (*Populus deltoides*) and willow species were often the first vascular plants to colonize new sandbars with annual herbaceous also a component of this early succession community (Johnson, 2000). Cottonwood and willow were the plant species believed to have the largest influence on geomorphic processes through bank stabilization. Phragmites (*Phragmites australis*), an invasive plant that has become prevalent during the low-flow years, is now suspect for having a greater affect than cottonwood or willow on physical river processes. In 2005, phragmites was identified as a cause of reduction in floodplain

capacity at North Platte, 100 river km upstream of Lexington (J.F. Sato and Associates, 2005). A 2005 GIS vegetation data base, jointly developed by the Program and the Platte River Whooping Crane Maintenance Trust, shows intermittent phragmites infestations throughout the study area from Lexington to Chapman.

This pervasive species spreads through seeds, rhizomes, and stolons. Stolons can extend thirty feet across the dry bed of a channel and plants can establish on bare sand or in areas of less dense vegetation that are not shaded. There is also a relatively wide elevation band for phragmites to establish since the roots appear tolerant of some submergence, and the stands can establish high on the banks and still reach surface or groundwater through root extension.

Figure 2a and 2b. Figure 2a (left) shows a phragmites thicket on a stabilized bar with a stolen, held aloft by photographer, extending from the thicket. Figure 2b (right) shows flow debris and stolons from 2008 high flow, protecting undercut bank vegetated by young phragmites.

Proliferation of this species produces a great deal of biomass. During higher flows, stolons lay across the submerged banks creating a protective mat, while floating detritus, often broken pieces of upstream phragmites, also catch on the banks adding to the protective cover. As the plant forms impenetrable stands contributing to a protective mat of coverage, bank and bar resistance values for the channel increase. Sediment can also be trapped amongst the plants in bar or overbank areas during high flows. Based on field observations, thickets of phragmites are resistant to erosion in the central Platte River in most locations, but are occasionally susceptible to undercutting due to a shallow root system (0.3 – 0.4 m estimated). Plants and roots on high, steep banks or bars can be undermined by flow directed towards a bank, or undermined by erosive shear forces from secondary currents. Bed incision can also promote failure.

Vegetation and River Planform

Stabilizing effects of vegetation on banks have been reported in foundation papers on river planform by Friedkin, 1945, Lane, 1957, and Brice, 1964. Papers by Murray and Paola (2003), Tal et al., (2003), Tal and Paola (2007), Griffin and Smith (2004) further demonstrate planform transitions between braided and single channel with the expansion or reduction of riparian vegetation. Width-to-depth ratio, W/D, can be used as an indicator of planform change (Fergusson, 1987). As vegetation stabilizes banks and bars, and stores sediment in overbank areas, erosion resistant banks concentrate

flow in the channel. Gran and Paola (2001) report an order of magnitude difference in W/D between channels with vegetated and unvegetated banks in laboratory studies. Trimble (2004) provides field examples where streams with grassed banks have smaller W/D than streams with forested banks, and store more silts and fine sands.

Purpose

Field observations of more prevalent steep banks and fine to coarse gravels in the bed of many sub channels, in addition to the pervasiveness of phragmites and other vegetation in the channel floodplain, suggest a relatively rapid change in channel conditions. An opportunistic survey in the summer of 2008, following a high flow event, provides data for preliminary analyses to assess changes in river form. However 2008 cross sections are only available from managed sites where vegetation was periodically removed to improve bird habitat. In future studies, cross sections from unmanaged sites can be used to extend findings from this study.

River changes that decrease braided channel and increase meander channel are believed to reduce the occurrence of desirable habitat for target species in this study area. Program management actions were developed prior to the period of low flows and the advance of phragmites and other vegetation. Proposed management actions can be modified under adaptive management to accommodate identified changed conditions. In addition to aiding Platte River management efforts, conclusions from this paper contribute to improved understanding of vegetation impacts on river form.

Purpose of this paper is to assess river planform change coincident to the recent period of low flows, rapid spread of phragmites, and general expansion of vegetation into former areas of active channel in the Platte River study area. Change in planform is assessed using indicators of W/D computed from four sets of cross sections in different years, with two sets surveyed during the period of low flows.

METHODS

Between 1983 and 1988, 85 transects at 16 local areas of the river were surveyed two to nine times (USDOI, 1989: Farmer et al., 2000). Surveys were for whooping crane habitat studies and the sites were primarily selected at locations of fully braided river. Reclamation resurveyed some sites between 1998 and 2001, and again in 2005. Three transects from six sites were selected in the 2005 survey based on the presence of active sand bars at transect locations. Transect data, a description of surveys, and description of data reduction from repeat surveys in July 1985, the 1998 to 2001 period (described here as year 2000), and in 2005 are reported in Holburn et al., 2006. A fourth survey in June 2008 of two transects at five sand bar/habitat sites was conducted by the Executive Director's Office of the Program. Habitat transects are also referred to here as cross sections.

Transect data from each survey year are entered as sets of cross sections in a HECRAS 4.0 Beta program to compute water surface and flow area of the main channel. Cross sections are assigned a spacing of 305 m at a thalweg invert slope of 0.0012. A steady reference flow of 57 m^3/s is input for computing flow area, wetted width of the main channel, maximum flow depth, and hydraulic depth of the transect (Table 1). As an indicator of planform change, W/D is normally defined by an average value of depth (Lane, 1957; Brice, 1964; Gran and Paola, 2002; Kiss and Sipos, 2006). Main indicator

W/D_{ave} is computed as wetted main channel width divided by hydraulic depth (D_{ave}) of the main channel at every transect (Table 2).

2000* data from 1998 to 2001 Average Variance W/D_{ave} = 53,112 Average Variance W/D_{max} = 5,417

Kiss and Sipos (2006) used D_{max} values to assess the variability in the channel bed. Disparity between mean depth (D_{ave}) and maximum depth (D_{max}) can represent a more expressed thalweg and less homogeneity of the channel bed although there may be little variation in bed shape outside the limits of concentrated low flow. Wetted width and depth values are listed for comparison in Table 1. W/D (Table 2) is also computed as wetted main channel width divided by maximum depth of the main channel (D_{max}) to provide a second indicator of planform change.

Assessment of W/D is aided by a statistical examination (Excel Analysis ToolPak) using paired t-tests and ANOVA evaluations of variance. Statistical assessments of the primary indicator W/D_{ave}, a second indicator W/D_{max}, and review of plotted results are

used to determine if there is a significant difference in river planform at study cross sections between survey years.

RESULTS

Information from Table 2 is presented in a series of figures. Plotted in figures 3 and 4 are W/D_{ave} and W/D_{max} with respect to time for each transect surveyed. There are two lines in Figure 5, the W/D_{ave} mean for all transects and the W/D_{max} mean for all transects. In Figure 6, all study W/D_{ave} and W/D_{max} values are plotted by river km.

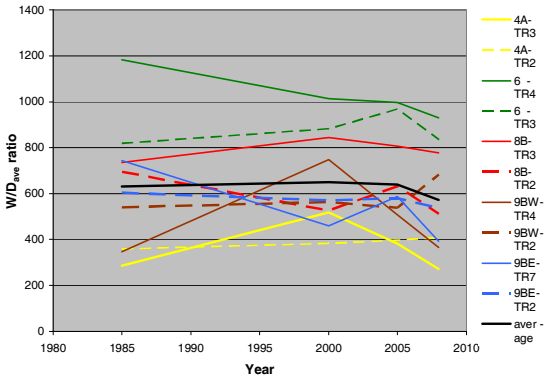

Figure 3. W/D_{ave} for each transect.

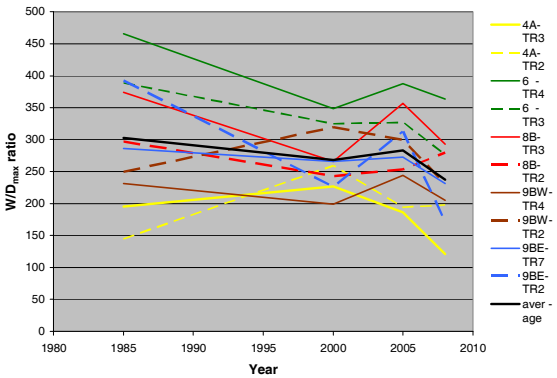

Figure 4. W/D_{max} for each transect.

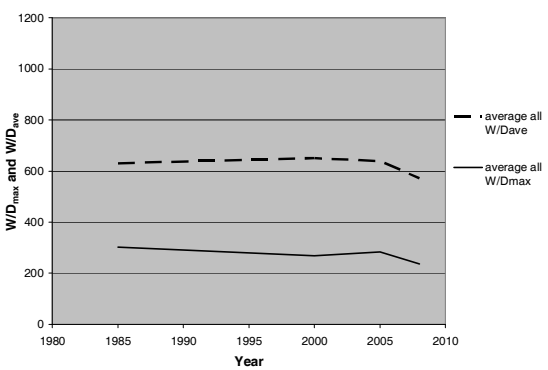

Figure 5. Average W/D_{ave} (dashed line) and W/D_{max} (solid lines).

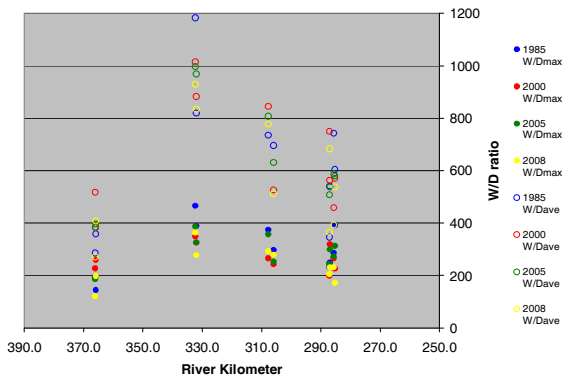

Figure 6. W/D_{ave} and W/D_{max} by river kilometer.

W/D_{ave} Results

There is no consistent trend in W/D_{ave} between 1985 and 2000, and between 2000 and 2005 in Figure 3; however seven of ten transects had a decline in W/D_{ave} between 2005 and 2008. Average values in Figure 5 are consistent from year 1985 to 2000, and from year 2000 to year 2005, but between year 2005 and year 2008 there is a decrease in W/D_{ave}. Statistical assessments using ANOVA Single Factor and ANOVA Two Factor with Replication indicate there is no significant difference in mean W/D_{ave} between all four years of transects (Table 3). An exception is site data: ANOVA with Replication testing confirms significant differences in means for transects at each site.

Based on ANOVA testing, the average decline (Table 3) in W/D_{ave} between 2005 and 2008 is not significant and could be the result of random occurrence of values. Paired

t-tests (Table 4) provide specific information between years, with some indication that the average decline in W/D_{ave} between year 2005 and 2008 is significant. To be a significant change, probability from the paired t-test for 2005 and 2008 should be 0.05 or less. Computed probability from this paired t-test was slightly higher at 0.052.

W/D_{max} Results

Planform comparison is based on W/D_{ave}, but W/D_{ave} results are ambiguous in comparisons of 2005 and 2008 data. To resolve the question of significant differences, a second indicator, W/D_{max}, is also examined. Values of W/D_{max} in Figure 4 are more consistent than W/D_{ave} values in Figure 3, and have smaller variance within the data set for each year (Table 2). Data from six out of 10 transects have a decline in W/D_{max} between years 1985 and 2000, and 8 out of 10 transects have a decline in W/D_{max} from year 2005 to year 2008. Consistent with W/D_{ave} results, there is no clear pattern of change for W/D_{max} between years 2000 and 2005.

Results of the second indicator W/D_{max} appear to be more sensitive to changes in the channel bed. Both ANOVA tests (Table 3) indicate the difference in means between years is significant and probably not the result of random chance. Paired t-tests (Table 5) provide specific information confirming a significant difference between channel planform in years 2005 and 2008 (P=0.010), and also indicate significant difference between years 1985 and 2008 (P=0.019). Wetted top width is the same value in both W/D indicators so increased sensitivity is a function of maximum depth.

DISCUSSION

As presented in Holburn et al., 2006, habitat sites were originally selected by searching for the widest reaches of river and the locations with highest use by sandhill cranes. Sites in 2005 and 2008 were also selected because of relatively easy access provided by the owners who were in most cases non-government organizations (NGO's). NGO's actively manage their lands for bird use by periodically removing vegetation from the banks and within the active channel. In effect, this study looks for phragmites and in-channel vegetation impacts to W/D ratios, with cross sections from lands where vegetation is mechanically removed by discing (tractors pulling agricultural discs turn over the upper soil layer and chop vegetation).

If the cross section sites were successfully managed to restrain vegetation, the expectation for these sites is that there should be no change in planform as represented by the indicator W/D_{ave}. ANOVA tests detect no significant difference between W/D_{ave} values for each year when all years are considered. Paired t-tests support this conclusion between W/D_{ave} values from 1985, 2000, and 2005, but there is a near-significant finding (P=0.052 instead of 0.050 or smaller) when 2005 data is paired with 2008 data. Because this result is not conclusive, a second indicator is considered.

Secondary Indicator, W/D_{max}

W/D_{max} is based on thalweg geometry and was selected because of the significance of thalweg slope to hydraulic computations and to planform determination. W/D_{max} values prove more consistent than W/D_{ave} values, having an average variance one-tenth (Table 2) the magnitude of the average variance for the W/D_{ave} values. This second indicator is also more sensitive to differences between years of data. Paired t-tests confirm W/D_{ave} results of no significant differences between 1985, 2000, and 2005 planform; confirm there is a difference between 2005 and 2008 planform; and also detect a difference between 2000 and 2008 planform.

A finding of significant difference in 2008 planform sites managed to restrain vegetation, prompts consideration of factors beyond the presence or absence of vegetation at the site.

Hydrologic Regime

Timing and occurrence of high and low flow events can affect channel shape, but with one exception, the data sets represent similar hydrologic conditions: surveys occurred within two years of a high flow event that had a recurrence interval greater than 1.5 years. Data from July 1985 represent a wet period with high flows occurring in 1983 and 1984, less than one year prior to the survey. The 2000 data set was surveyed, depending on location, from 1998 to 2001 and there was no more than two years of low flow succeeding a high flow event. A 510 m^3/s peak flow in 1995 at Kearney (Figure 1) was followed by a 255 m^3/s peak flow in 1997 and a 340 m^3/s peak flow in 1999. Sites 4A and 6 in 2005 are the one exception where the survey was preceded by five years of low flow. Although sites 8B, 9BW, and 9BE were surveyed at the same time as sites 4A and 6 in 2005, a rainfall event downstream of Kearney generated high flows at sites 8B, 9BW and 9BE four months previous to the survey.

Results from paired t-tests of both the primary and secondary indicators indicate no difference in planform between the 1985, 2000, and 2005 data sets, measured from

four months to two years after a high flow event. Surveys in 2008 represent channel conditions immediately following a high flow event and there is less than four months of low flows preceding the measurements.

Sediment Transport

Sediment regime in conjunction with flow regime can also affect channel bed shape. Kiss and Sipos (2006) describe a braided river in South Hungary that aggrades in wide braided channel during the falling limb of a high flow event, but narrows and deepens channel when flow is concentrated during low flow periods with less sediment transport. In Colorado River studies, high flow events cause greater aggradation when sediment is delivered by tributaries and stored in the channel previous to the high flow event. Platte River 1985, 2000, and 2005 cross sections were used to compute area changes in the channel bed in Holburn et al., 2006. Cross sections at sites 4A and 6 have more aggradation (increases in area at the transect) in 2005 succeeding five years of low flow, than measured in previous surveys. Downstream cross sections at Sites 8B, 9BW, and 9BE conveyed high flows from a rainfall event in 2005. At these locations there was no measured aggradation, and the channel bed area was similar to previous years.

A shortage of transported sediment during the 2008 high flow event could account for the narrowing and deepening of the channel at the study sites. Sediment-short flows were computed to extend as far downstream as site 4A under conditions existing previous to 2002, and to cause some erosion (Holburn et al., 2006, Murphy et al., 2006). Downstream limits of this erosion process may have been extended by increased presence of instream vegetation and phragmites. Phragmites are observed to trap sediment and 2008 planform change at the managed study sites could be due to sediment trapping in extensive phragmites thickets and other instream vegetation at unmanaged sites upstream.

Future Directions

With this preliminary study, we begin to assess impacts of an eight-year low flow period on river morphology in the central Platte River. Results indicate planform change has occurred between 2005 and 2008 at fully braided and managed sites, and change may be a result of upstream sediment shortage. It is surmised that in channel vegetation upstream of study sites could be a contributing factor to the sediment shortage. Future studies should include surveys at 2008 cross sections, surveys at unmanaged sites, and surveys at sites with meander form to continue an investigation of geomorphic change; specifically to measure impacts of phragmites and other in channel vegetation on bank stabilization and on river sediment storage.

ACKNOWLEDGEMENTS

My thanks go to reviewers Jason Farnsworth and Chad Smith, from the Executive Directors office of the Program, for their constructive comments during preparation of this paper; and to the Executive Directors Office of the Platte River Recovery Implementation Program for use of the 2008 survey data.

ABSTRACT

For the last several years the Corps of Engineers has engaged in a major effort to restore Shallow Water Habitat (SWH) on the Lower Missouri River to prevent continued jeopardy of the federally-endangered Pallid Sturgeon. Much of the SWH has been restored through the mechanical creation of side channel chutes, river top-width widening, and backwater excavation. Almost all methods require the removal of previously deposited alluvial sediments existing adjacent to the river as well as in the floodplain. The number and size of these projects have created new challenges in the management of this sediment. Issues with the reintroduction of sediment into the active river system, such as nutrient loads, contaminants, impacts on downstream interests, and public perceptions, illustrate the wide variety of topics that complicate the management of those sediments. Some of the issues are not well understood and the process of sediment reintroduction can appear to be at odds with current national priorities to keep sediments out of rivers. To help clarify the issues related to sediment management associated with SWH creation and to provide guidance for future projects, the Corps of Engineers (Corps) has initiated an independent review of its practices by the Water Science and Technology Board of the National Research Council (NRC). Description of sediment displacement activities on SWH projects and details of the NRC review will be discussed.

BACKGROUND

Prior to 1900, the Missouri River existed in its natural state and meandered across the river valley eroding approximately 9,100 acres per year in the meander belt (USACE, 1981). Subsequently, the habitat in and around the river was varied and dynamic as the erosion and related deposition reshaped the river and floodplain. However, from 1912 to 1945, seven Congressional Acts set in motion the Corps' Bank Stabilization and Navigation Project (BSNP), which was completed in 1981 and reshaped the face of the river by the construction of revetments, dikes, and side-channel closures that effectively locked the river in place and created a reliable navigation channel.

A less desirable effect of the BSNP was the loss of 100,200 acres of aquatic habitat and over 421,800 acres of terrestrial habitat (USACE, 1981). With various acts between 1986 and the present, Congress authorized the Corps' Missouri River Mitigation project to acquire land for habitat development to replace 32 percent of that which was lost due to construction of the BSNP (USACE, 2003).

The U.S. Fish and Wildlife Service completed a Biological Opinion (BiOp) in 2000, amended in 2003, in regard to Corps operation and maintenance of the BSNP, the six Corps dams on the Missouri River, and the Kansas River Reservoir system. The BiOp offered measures and alternatives to avoid continued jeopardy of three threatened and endangered species on the Missouri River, including the pallid sturgeon. As outlined in the BiOp, a component of the reasonable and prudent alternative for recovery of the pallid sturgeon was to restore 20 percent of the shallow water habitat (SWH) that historically existed on the river. For the lower 752 miles of river below Gavin's Point Dam, a target was set to restore 19,565 acres of SWH, or approximately 20-30 acres per mile of river, by the year 2020 (USFWS, 2000).

Figure 1. Typical Chute Project on the Missouri River

The BiOp provided for restoration of SWH by either mechanical manipulation of the river itself and/or modification of the flow regime by Corps operated upstream dams (USFWS, 2000). Since altering the flow regime could negatively impact other users of the river, the Corps of Engineers focused on reaching the target acreage through mechanical manipulation of the river itself. This entails the modification of the Corp's river training structures to increase top-width and the creation of side channel chutes. The mechanical excavation of chutes (Figure 1), and top-width widening

(Figure 2) involve the removal of large quantities of alluvial sediments from the bank or floodplain adjacent to the river.

Figure 2. Typical Bank Notches for Increasing Top Width

ISSUES

Overview. The Corps' management of the displaced sediments from SWH projects has been questioned by the Missouri Clean Water Commission (MCWC) and has given rise to ongoing discussions on Missouri River sediment management that highlight the numerous related issues that complicate the decision making process including nutrient loads, contaminants, impacts on downstream interests, and public perceptions. While much has been done in an attempt to resolve issues through communication between the Corps, the MCWC, and various other state and federal agencies, questions still remain as to an appropriate path forward. To assist in evaluating these issues, the Water Science and Technology Board of the National Research Council (NRC) was engaged to perform an independent review of the Corps' sediment management on the Missouri River.

SWH Construction. The Corps has designed projects that include multiple methods of addressing the sediments that must be displaced to restore SWH. The most common methods fall into three categories: side-casting the material directly adjacent to the chute or bank work, mechanical placement of the material in the river channel to be gradually removed by natural river flows, and dredging of the material and discharging directly into the river channel to mix with the existing bed sediment load.

In nearly all cases, the designs also involve construction of a narrow pilot channel, then allowing natural river processes to redistribute the adjacent sediments over time and enlarge the projects to the designed size but with controls to prevent unchecked expansion beyond the design limits. After development, the projects would continue to meander and promote natural riverine processes, but without significant changes in channel width.

Per the BiOp, the Lower Missouri River is impacted by reduced sediment inputs that are important to creating and maintaining the diversity of habitats important for pallid sturgeon reproduction and survival. In addition, the reduction of turbidity has highly altered the river environment, impacting pallid sturgeon capability to forage successfully, increasing competition with other species and making the species more susceptible to predation (USFWS, 2000). Due to these reasons, the Corps viewed placement of the excavated or dredged sediments into the river as not only an economical alternative, but as potentially beneficial to the river. However, the MCWC raised questions as to the potential water quality impacts of placing the sediments in the water. In particular, they expressed concern that there could be agricultural chemicals present in the sediments since some of the sites had been farmed in the past, prior to being used for SWH construction.

To address the MCWC concerns, the Corps implemented a coordinated soil and water testing program to evaluate both the sediments that would be removed for the SWH projects as well as the impacts those sediments would have on water quality if reintroduced into the river. The water quality variables that were analyzed are shown in Table 1. The Corps began this program in 2007 with five SWH chute sites in Missouri that were either under construction or scheduled to be constructed. The testing and analysis showed that there was no reason to believe the placement of the sediments in the river would cause the violation of any water quality standards for the sampled variables (CDM, 2007a,b,c,d,e; CDM, 2008).

Table 1. Water and Soil Quality Variables Analyzed at SWH Chutes

Ammonia	Metals – Total and Dissolved
Biological Oxygen Demand (BOD)	Cadmium
Chemical Oxygen Demand (COD)	Chromium
Nitrogen – Total	Copper
Nitrogen – Total Kjeldahl Nitrogen	Lead
Kjeldahl Nitrogen	Nickel
Nitrogen – Total Nitrate/Nitrite as N	Zinc
Phosphorus – Total	
Phosphorus - Soluble Reactive	Pesticides
Total Organic Carbon	Chlordane
PCBs – Total	Dieldrin
TPH -DRO	DDT and metabolites
BTEX	

Despite the results of the soil and water testing, the MCWC continued to express concern with the implications of allowing the sediments to be placed back into the river for several reasons. Among these concerns were the perceived contradiction

with Missouri's soil conservation efforts, questions as to whether sediment itself is a pollutant, and the concern that *any* increase in nutrient load, even if not violating water quality standards, could be increasing the Missouri River's contribution to Gulf of Mexico hypoxia.

While the Corps and cooperating agencies continued communications with the MCWC, a fundamental difference of interpretation of the role of sediment in a river system, with regards to soil conservation efforts and the Clean Water Act led to significant impasses for State of Missouri permitting of the SWH projects. As a result, nearly all SWH projects that were either underway or planned in Missouri were suspended and/or terminated during 2007 and 2008.

PATH FORWARD

With support of a joint federal position between the Corps, the U.S. Fish and Wildlife Service, and the U.S. Environmental Protection Agency, the Corps requested the National Academies to provide an unbiased, independent look at the issues, suggest a path forward, and evaluate the Corps sediment management on the Missouri River. In mid 2008, the NRC assembled a committee to conduct a two year review to answer the following questions regarding sediment issues on the Missouri River:

1) How and why is sediment a significant variable in the environmental restoration of a river system like the Missouri River?
2) What is the significance of the Missouri River sediments to the Gulf of Mexico Hypoxia problem?
3) What is the significance of the Missouri River sediments to the restoration of Louisiana coastal wetlands?
4) What are the key environmental and economic considerations regarding nutrient loads and/or contaminants in Missouri River sediment? To what extent can such issues be addressed with management strategies?
5) Are there long-term consequences to the lack of sediment in the system to the human environment, either environmentally or economically?
6) Are there alternatives for reintroducing sediment into the system? What are they and what are the key constraints surrounding these alternatives?
7) Are current Corps' management strategies, restoration tools (e.g., channel widening, creation of chutes, shallow water habitat, etc.), and other activities adequate and comprehensive enough to address issues associated with sediment and nutrients in the system? If not, how might such strategies and activities be improved?

While constraints on SWH construction in Missouri have indefinitely suspended many projects and reduced options for others, the Corps plans to use the NRC report to gain clarification on the controversial issues and suggestions for a path forward that will enable the Corps to continue the restoration of SWH on the Missouri River in an environmentally conscious, and socially acceptable manner.

Abstract

Accurate measurement of solar radiation via optimal number of ground sensors and their respective location is important to estimate evapotranspiration (ET). One way of estimating ET on regional scales at high spatial resolution (~2 km) on daily time scales is through the use of GOES Satellite solar radiation data. The goal of this study is to perform analysis that helps determine the design of a ground-based solar radiation sensor network that can accurately estimate solar radiation spatially. This paper developed several optimal sensor network designs considering different levels of accuracy characterizing the spatial and temporal variability of solar insolation data. GOES Satellite-estimated solar insolation and ground sensor network based data were used for this purpose. A regular array analysis blocks with two different sizes (20 and 40 km) were used to account for the spatial variability of solar insolation data. Geo-spatial along with geo-statistical analyses were used to assess the spatial variability of the solar insolation within each analysis block. The methods and analysis were performed for the solar radiation sensor network of the South Florida Water Management District (District). Through use of ArcGIS geostatistical processing, the spatial statistical analysis, sensor network design was formed. The existing ground sensor network of the District was evaluated. A proposed sensor network that is expected to provide a standard error of 5.0 MJ $day^{-1}m^{-2}$ was recommended. Recommendations for an enhanced sensor network design across the District were made.

Introduction

Acquisition of hydrologic and hydraulic data is the key component of water resources management in south Florida. The Operations and Hydro data Management Division of the Supervisory Control and Data Acquisition (SCADA) system and Hydro Data Management Department at South Florida Water Management District (District), shown in Figure 1, is responsible for the collection, validation, and archiving of the District's hydrologic data. The types of data include rainfall, evaporation, water levels (stage), water control structure (gate and pump) operations, and flow. In addition, several meteorological parameters (such as barometric pressure, solar radiation, air temperature, relative humidity, and wind speed) are measured at the weather stations that form the District meteorological monitoring network. The District requires accurate data collection, processing and archiving of these data for the purposes mentioned above. There is a constant need for adding new sites with instrumentation for hydrologic data collection within the

District, and this need will be growing at a faster pace as more Comprehensive Everglades Restoration Plan (CERP) projects are implemented. The District's broad objective is to optimize the regional hydro-meteorological monitoring network of the District. This study is Part I of the ET network design study. In this study, the solar radiation network design is considered as the spatial optimization of the network. The proposed design and optimization studies are a prerequisite to expanding and refining the District's hydrologic network to meet the needs of CERP projects.

Evapotranspiration (ET) is a major component of the hydrologic cycle. This hydro-meteorological parameter is needed for various water budgeting purposes, which accounts for surface and groundwater. Potential ET (PET), and reference ET (RET), are the hydrologic parameters needed to estimate ET which is the rate at which water loss to the atmosphere occurs from well-watered soil and plant surfaces. Methods available for PET estimation are generally classified into three groups: energy balance methods, mass balance methods, and combination methods The District developed historical and current daily PET data sets for wetlands using Simple Method (Abtew et al., 2002).

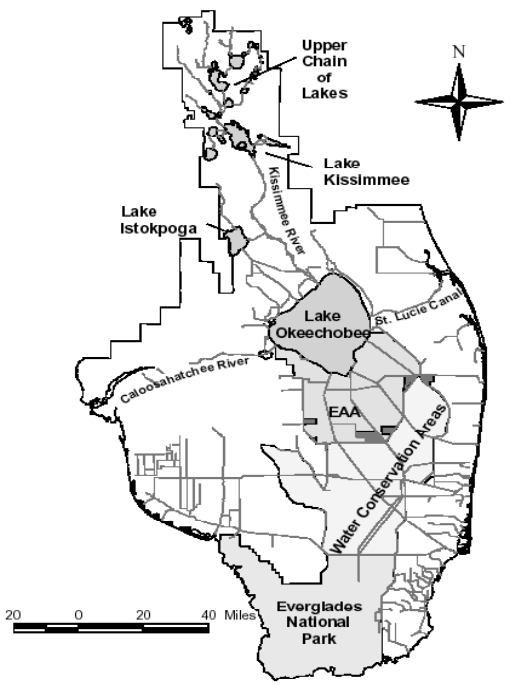

Figure 1: Project Study Area: South Florida Water Management District.

The most desirable ET datasets for these purposes are spatially continuous, rather than point values derived from the traditional field weather station networks. These datasets (enhanced estimates) of ET across Florida are needed. An important parameter for estimating ET (Potential ET and Reference ET) is net radiation (R_{net}). A main component of R_{net} is incoming (downwelling) solar radiation, which can be estimated as solar insolation from geostationary satellite data. Figure 2 illustrates this via a simple energy balance model.

Solar radiation amounts vary geographically within central and south Florida. For example, radiation characteristics and patterns on land surrounding Lake Okeechobee and ocean are different from that of central overland mass. In addition, spatial variation in radiation amounts for shorter durations, such as one-day, is significantly greater than monthly, seasonal and annual radiation. Therefore, in this study, it was recommended that spatially varying sensor density should be considered based on varying solar radiation conditions during dry and wet periods. In addition, solar radiation estimates of local patterns should be used for determining optimum sensor placement as opposed to laying out the sensor in an evenly spaced grid.

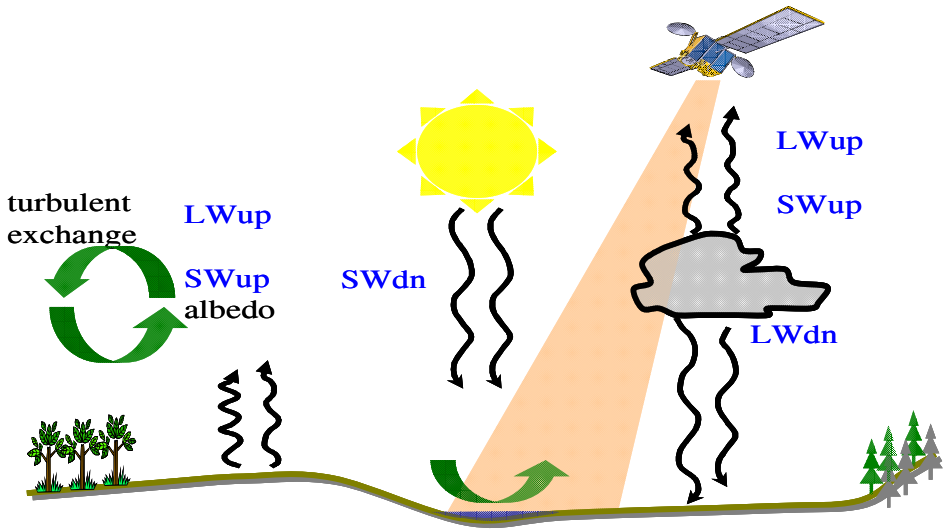

Figure 2: Simplified energy balance model. Here, "up" and "dn" pertain to the upward and downward components, respectively. "SW" is shortwave radiation, and "LW" is longwave radiation.

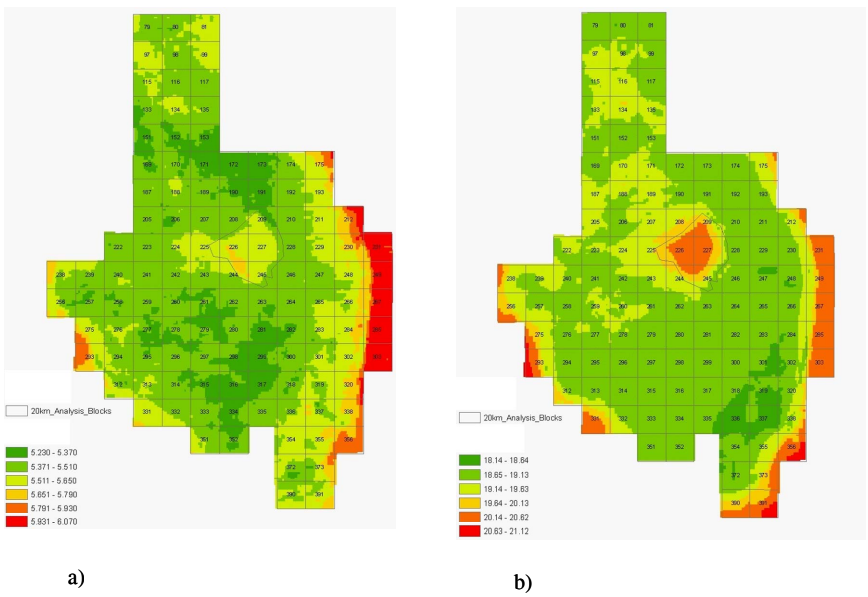
The goal of this study is to understand the spatial and temporal variability of Geostationary Operational Environmental Satellite (GOES)–estimated solar insolation at a resolution of 2 x 2 km using geo-spatial analysis. The results from spatial analysis are used in a geo-statistical framework to assess the spatial variability of the solar insolation across the District, and for determining optimal sensor location so to properly capture the spatial variations. The goal is to design network that recommends: (i) total number of ground sensors; (ii) location of sensors and (iii) frequency of data sampling that provide equivalent or better data quality (or data accuracy/data representability) with same or less number of sensors. A properly sized and optimized network can result in significant increased efficiencies of the monitoring network in terms of extensive spatial and temporal coverage of parameters of interest.

Methodology



The available solar radiation data from GOES satellite based daily solar radiation data from 1995 to 2004 available from University of Alabama in Huntsville (UAH) was used to evaluate the District's solar radiation ground sensor network. In addition, daily solar radiation data from 29 ground-based sensors known as Pyranometers are available in DBHYDRO database and was used for this study. Pathak (2008) provide details of pyranometers (i.e. the ground sensors) used in the current study. For this study, the existing data and the network of sensors was evaluated, and a review of the existing location for suitability was performed (SFWMD, 2008).

Insolation data were processed from the 2 x 2 km resolution onto a 20 x 20 km analysis block covering the District. A total of 119 non-intersecting blocks for the District region were used. Each 20 x 20 km analysis block contains approximately 100 insolation pixels at 2-km resolution. Due to spatial projection limitations, this number varies from 81 to 100 2 x 2 km pixels. These insolation data were mapped and processed, with use of the ArcGIS package. A sensitivity analysis between the block size and correlation lengths was performed. As a result, block sizes of 40 x 40 km and 80 x 80 km were used in this sensitivity analysis. The computed correlation lengths (i.e. "range parameters from semi-variograms") defined the optimal distances between the ground sensors for the network design, which were determined as a function of location across the District.

The insolation data were divided by seasons that exist across south Florida. The climatology of South Florida demands that the data set be sub-divided into a "cool" and "warm" seasons, as well as a "transitional." After initial analysis, the datasets were divided into the following time periods: (a) dry season – November-March, (b) wet season – April-October, (c) a set of completely (100% cloud cover) cloudy days, and (d) a set of completely clear days. Transitional time periods were not considered to add significance to these analyses. For sets (c) and (d), considerable effort was needed to identify days with these characteristics, given the relative rarity of clear and cloudy days across the entire District, especially during the wet season. Using 2 x 2 km gridded insolation data, polygons of homogeneous areas were developed. This used mean, standard deviation, and coefficients of variation. The covariance structure of insolation was formulated across the District. This required formation of analysis blocks large enough to encompass the range of existing spatial correlation but sufficiently small to capture climatological gradients near coastal areas and inland water features such as Lake Okeechobee. This is very important given the driving force for cumulus convection across South Florida. In particular, time-dependent changes in cumulus due to land, lake and sea breeze circulations were considered. **Figures 3a and 3b** present the homogeneity analysis across the District, for mean insolation (**Figure 3a**), standard deviation (**Figure3b**) for the wet season. These values are derived from measures of temporal variability at each 2 km pixel, based on daily values. **Figures 3a and 3b** also shows layers of 20 x 20 km analysis blocks over the District. There are 119 intersecting blocks for the District.

Figure 3a shows that the mean values *decrease* slightly from north to south, reaching maximum values in the east (and over approximately Lake Okeechobee). Values are mainly from 18.6-19.6 $MJm^{-2}day^{-1}$ in the north and west, yet locally decrease to near 18 $MJm^{-2}day^{-1}$ in the far southeast. Note that these values are ~8 $MJm^{-2}day^{-1}$ below the maximum values that would be expected under clear-sky conditions, yet this is not unexpected given the high-frequency of convective and other clouds across this portion of Florida during the wet season. Values over the ocean and Lake Okeechobee are much higher, ≥20 $MJm^{-2}day^{-1}$. Standard deviations (**Figure 3b**) show several features. First, values are lowest over land ~5.2-5.8 $MJm^{-2}day^{-1}$. Second, higher values to near 6 $MJm^{-2}day^{-1}$ are found near the coasts. This could be caused by a high variability in convective clouds (varying largely from day to day, specifically either mostly clear or mostly cloudy), which is especially exemplified near lakes and the ocean. The analysis of coefficient of variance indicated that the gradients in insolation along the east coast, with values exceeding 0.3 in these areas (SFWMD, 2008).

The variability in the entire wet-season of daily solar insolation dataset and the histogram for all approximately 10,186 days (April-October, 1995-2004) were determined. Here, the data are binned about the mean (19.13 $MJm^{-2}day^{-1}$). The highest frequency of days with a given values occur at ~1.0 $MJm^{-2}day^{-1}$ above and below 19.3, which suggests a delineation between cloudier and clearer days, and land versus water regions, across the District. From a mesoscale weather perspective, this would denote days with either a low or high coverage of convective storms, which is not atypical of tropical (or subtropical) weather). The analysis of insolation data over the District was performed to compute the statistical variation of these data (SFWMD, 2008).

a) b)

Figure 3: Mean solar insolation and Standard deviation map for 2 km pixels and overlay of 20 km blocks for the wet season (April-October) from years 1995- 2004 in $MJm^{-2}day^{-1}$.

Detrending of the insolation data sets were performed for purposes of identification of spatial correlation through a (semi-)variogram analysis approach. Detrending specifically will remove the means of the data, and any trend in insolation not yet addressed in the calibration work of Paech et al. (2008) so to better isolate the true variability within the data. The "parametric" form of detrending in each analysis block was intended to remove non-stationarity. Without detrending, correlation length of the insolation magnitudes can become spuriously large (Wilks, 2006). This processing resulted in the eventual subtraction of the mean structure from the insolation. The detrended data were then be used to compute empirical semivariograms within ArcGIS, as well as for the covariance analysis (Pathak and Vieux, 2007). The semivariogram analysis is applied to the daily insolation data, by the breakdown over the 10-year period. As stated above, the detrended data were used to compute the empirical semivariograms. For each analysis block, the semivariogram analysis was applied to the daily insolation, over subsets of the 10-year long data set (e.g., wet and dry seasons, cloudy days). Because there should be relatively weak correlation in space for insolation, especially when the small-scale (2-25 km) convective clouds dominate the cloud climatology (and hence the insolation variability), the mean empirical semivariogram ordinates were selected. Subsequently, an "exponential" semivariogram model was fitted to empirical semivariograms of mean detrended pixel values in

each block. The "upper quartile" pixel values were used, but did not provide useful results because it changed the data's distribution away from "normal." A robust nonlinear estimator was used to obtain the optimal range and sill parameters of the two-parameter model. The nugget variance of insolation was often zero.

In summary, the following items were concluded from these efforts:1) Wet season insolation had lower range values than those from the dry season. Therefore, wet season insolation data were used for the network design analysis. This is due to the higher frequency of occurrence of small cumulus clouds; 2) Upper quartile and mean detrended insolation data, which were derived from daily insolation values for the wet season over the ten-year period, were evaluated; 3)Mean detrended data provide reasonable and more stable (i.e. consistent across years) range values, and were used in the following analysis; 4) Range values were highly variable in time. Therefore, annual mean insolation data for the wet season, and for each year, were used for the following analysis; 5) Range values were highly variable in space for 20-km, 40-km, and 80-km block sizes. Therefore, based on preliminary results, a mix of 20 and 40 km blocks across the District were chosen for the detailed semivariogram analysis.

Ground Sensor Data Analysis

Ground sensors measuring solar radiation are shown in **Figure 4**. Solar insolation data collected from 29 ground sensors in the District were analyzed. Details of the ground sensors, data collection methods and frequency are discussed by Pathak (2008). The satellite based solar insolation data were obtained from the study that produced daily solar radiation data for the entire State of Florida over ten years from 1995 to 2004. An initial assessment of available solar insolation data from the District revealed several limitations of ground sensors due to observational and systematic errors. The suspicious data, flagged by the District, were removed prior to the subsequent outlier identification analyses. Outlier tests using standard statistical methods were performed for identification and removal of outliers from the data. A variant of the standard normal test for outlier detection was used. The satellite data were used for this outlier test. The standard deviations for the satellite data, at each of sensor locations, were calculated. Sensor observations that lie outside the range of "satellite data $\pm$ standard deviation" were identified as outliers. The satellite-sensor paired observations were eliminated if the sensor data on any given day was identified as an outlier.

The analysis of point data from ground sensors was performed. The point variance and mean values were obtained from 29 ground sensors for the wet periods in each of the years from 1995 to 2004. In order to spatially characterize the solar insolation data, the variance of the point measurements needed detailed analysis. Spatial interpolation methods were used to obtain a surface from the point variances of solar insolation values. Two different interpolation methods: 1) *Inverse Distance Weighting Method* (IDWM) and 2) *Ordinary Kriging Method* were used (SFWMD, 2008). The two interpolation methods performed well in estimating the values at validation sensor locations. The inverse distance weighting methods performed better than the ordinary Kriging method. The overall error was higher for the Kriging method. Based on error statistics, inverse distance weighting method was recommended for the analysis.

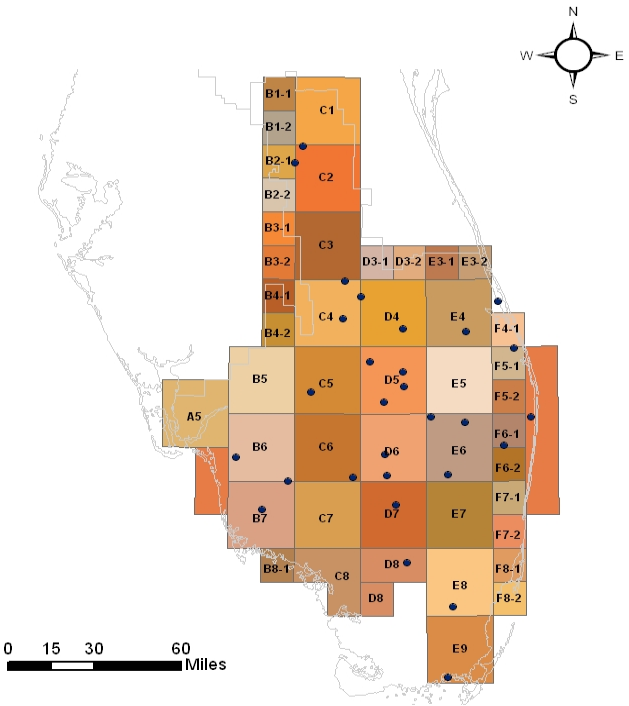


Figure 4: Existing active solar radiation sensor stations in the District.

Effective Sensor Network Design

The design of sensor network is aimed at capturing and characterizing the spatial variability of the solar radiation across the District. The standard error of mean was used, as a metric, to identify the optimal number of ground sensors in the study (SFWMD, 2008). The required number of sensors in a specific analysis block can be obtained by improving the accuracy of the mean solar insolation measurement (SFWMD, 2008). An exponential semivariogram, used to model the covariance structure of the solar insolation from satellite data, provided the decorrelation lengths as range parameters of the model. The effective number of sensors was obtained from the correlation distance from satellite data and point variance from sensor data for each analysis block. Matalas and Langbein (1962) described the information contained in a number of correlated stations. The information contained in data from n stations in a region having a correlation of ρ is equivalent to the information contained in n' uncorrelated stations (sensors) in the region, where n' is given by Equation 1:

$$n' = \frac{n}{1 + \rho_{ave}(n-1)} \qquad (1)$$

where, n' is effective number of stations, n is the total number of stations, and ρ_{ave} is the average correlation coefficient among n stations. Equation 1 suggests that as n increases, n' approaches $1/\rho_{ave}$. The effective number of sensors n' was related to separation distance "h." The covariance structure defined by spatial correlation coefficient was modeled by exponential semivariogram in each analysis block. The standard error of the mean (*SE*) was calculated for all the blocks. The standard error is calculated based on effective number of sensors (n'). Depending on the value of

the average correlation coefficient, range parameter and inter-sensor distance, the values of n' have an increasing trend up to a threshold value and then they decrease as the number of sensors increases. The variations in standard errors in relation to number of sensors are evident from plots shown in **Figure 5.** The exponential decay curves between *SE*, and number of sensors in all the 40-km analysis blocks are also shown in the same figure. This information is used to estimate the number of sensors needed per block, which is identified as the location on the graph where the lines begin to become level, which is between about 2 and 4 sensors per block (SFWMD, 2008).

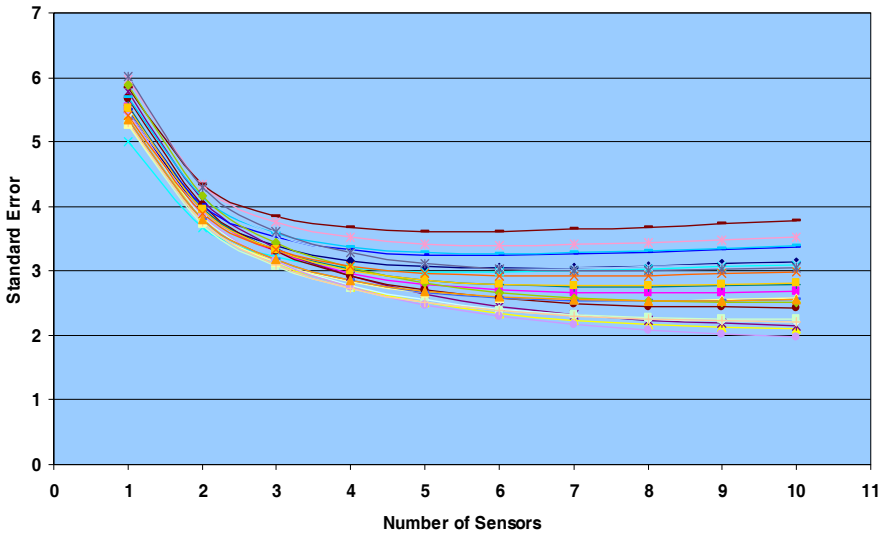

Figure 5: Exponential decay curves between standard error and number of sensors in all the 40-km analysis blocks.

Optimal Network Design

The optimum network design was based on the standard error and the number of gauges in each block. Based on the covariance structure of the solar insolation data, it is evident that there is no uniform analysis block size that is identifiable for the region under consideration. Two analysis size blocks, 40 km x 40 km and 20 km x 20 km, were identified for the use of optimum design of sensor network. SFWMD (2006) outlined two methods of optimum network design in a study related to rain gauge network optimization. The network designed is optimal considering the stipulations imposed on the block size and other constraints. The detailed analysis was conducted based on the historical data available from the network of 29 sensors for wet season. However, recently changes to the sensor network have occurred. The existing sensor network in the District is shown in the **Figure 4** (SFWMD, 2008). In this study, the approach with uniform standard error was adopted to obtain the optimum number of sensors for each block. Once the optimum number was obtained for each block, this number was compared with existing number of sensors in each analysis block. If the existing number of sensors in a block was higher than the optimum number, then a recommendation was made to remove the additional number of sensors. When the existing number of sensors was less than the optimum, additional sensors were recommended for that block.

Proposed Ground Sensor Network Recommendation

For recommending an optimal sensor network to the District, three standard errors of 4.5, 5.0 and 5.5 MJday^{-1}m^{-2}, and a total umber of required new sensors of 50, 19 and 16 respectively, were considered. Based on discussion and consultation with District staff, the proposed ground sensor network with standard error of 5.0 MJday^{-1}m^{-2} would require 19 additional new sensors was recommended. The selection of this network was based on two facts: (a) the standard deviation of satellite solar insolation data from wet seasons over ten years varied between 5.23 and 6.07 MJday^{-1}m^{-2} (**Figure 3b**), which is in the range of the selected standard error (5.5 MJday^{-1}m^{-2}) of the proposed network; and (b) the selected proposed network required three additional sensors (19 minus 16 sensors) compared to 16 new required sensors for the proposed network with the standard error of 5.5 MJday^{-1}m^{-2} that was considered to base optimal network. Therefore, the recommended optimal ground sensor network would need a total of 19 new sensors with the standard error of 5.0 MJday^{-1}m^{-2}. **Figure 6a** shows insufficient sensor distribution and **Figure 6b** shows excess sensor distribution of the District.

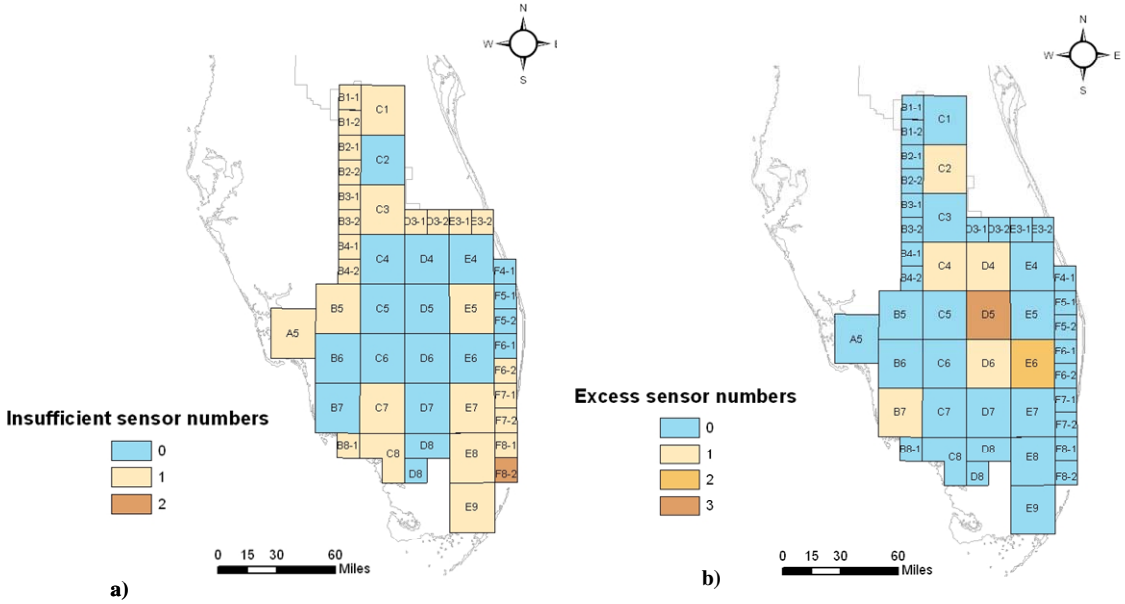

Figure 6: Insufficient and excess ground sensor numbers to achieve a 5.0 MJday^{-1}m^{-2} standard error across the District.

Conclusions

Accurate measurement of solar radiation via optimal number of ground sensors and their respective location is important to the District. This report developed several optimal sensor network designs considering different levels of accuracy characterizing the spatial and temporal variability of solar insolation data. Satellite and ground sensor network based data were used for this purpose. A regular array analysis blocks with two different sizes were used to account for the spatial variability of solar insolation data. Geo-spatial along with geo-statistical analyses were used to assess the spatial variability of the solar insolation within each analysis block. In

addition, the existing ground sensor network was evaluated. A proposed sensor network that is expected to provide a standard error of 5.0 $MJday^{-1}m^{-2}$ was recommended. The standard error used in the currently study is based on time-averaged solar insolation. Recommendations based on two procedures for both sensor assignments and placements were also provided.

Abstract

Lack of information to prepare erosion maps for quantitative and qualitative sediment evaluation is a major need in watershed management in Iran. The goal of this study was to use EPM model and apply GIS to minimize the probable errors in evaluation of soil erosion and sedimentation in Ghareh Aghach watershed in central part of Iran. To achieve this goal, in the first step a topographic map in 1:25000 scale of the study area was digitalized by ILWISE program to provide a contour map. Using the contour map, the slope and aspect maps as well as the digital evaluation model (DEM) of the site were prepared. In the second step the satellite images, aerial photos of 1:40000 scale and data obtained from the field visits were used to provide with geological, geomorphologic, vegetation cover, peddological and land use maps of the study area. By integration of geological, geomorphology facieses and slope maps and classifying them in 5 categories (0-10%, 10-20%, 20-30%, 30-40% and >40%), 21 homogenous uniform sampling units were identified to apply EPM model. Model information layers comprised of nine effective factors in erosion and sedimentation in the watershed site were obtained by digitalizing and classifying the basic information data in GIS program. In frequent field visits all the necessary data for EPM model were collected, checked and improved in 21 homogenous and uniform sampling units. Following of finalizing the information layers, all of them were integrated to create the final erosion map. The results of EPM model for homogenous and uniform sampling units indicated that 0.19% (16.69 ha) of the total watershed area was classified at class I of erosion category with very low sedimentation and 15.1% (1352.64 ha) was classified at class II of erosion category with low sedimentation and 41.3% (3698.8 ha) was classified at class III of erosion category with medium sedimentation and 13.2% (1175.3 ha) was classified at class IV of erosion category with high sedimentation and finally 30.2% (2711.41 ha) was classified at class V of erosion category with very high sedimentation, respectively. The result of comparing erosion and sediment values by EPM model with measured values showed that no significant difference between estimated and measured values ($P<0.05$).

Keywords: EPM model, GIS, sedimentation, erosion, watershed

Introduction

The over population in the world have lead to an increased demand for food and other necessities of human beings (Lu. et. al., 2001). The gradual soil salinization along with deterioration of rangelands vegetation covers have caused accelerating soil erosion and sedimentation in water reservoirs (Meijering, A., 1995). United Nation in its development plan has reported that at present the soil erosion in Iran is about 20 ton/he , which has in creased by 10 ton/he compared to the last decade (UNDP, 1999). There is not enough sediment measurement stations in most watersheds in the country which makes it more difficult to provide with a specific models based on local watershed characteristics. One of the most important problems with empirical models of soil

erosion is its lack of accuracy in processing the huge number of data which should be digitalized by GIS system and analyzed by mathematical models. EPM is an empirical model to estimate the quantity and quality of sediment. In fact quantifying and digitalizing the sediment data is an important break through in sediment assessment models development (Nearing et. al., 1999). This problem could be partially solved by estimating models (Lufafa et.al., 2003). Since soil erosion is a product of few different interacting factors, there is not a simple model to assess all the contributing elements in the same time (Daroussin and King, 2001).

The goal of this research was to apply EPM model and GIS system (to reduce the error level to the minimum) to have the most possible accurate assessment of the soil erosion and sedimentation in the study area and make the best applicable suggestions to control it.

Material and Methods

1. The Experimental site

The area of Ghareh Aghach watershed is about 8954. 8 hectares which is located between 51º 45' 53" and 51º 34' 54" eastern latitudes and 31º30' 28" and 31º26' 19" northern altitudes. The maximum and minimum heights of the area are 3810 and 2630m from the sea level. The mean altitude of the watershed is 2936 meters from the sea level. The watershed area is divided in five major hydrologic sections according to its topographic feature. Long term mean annual precipitation and temperature are 358 and 10.5 degrees Celsius which classifies the site in semi-arid climatic conditions according to Ambergie (Q= 40.7) and Demartin (Ia= 17.4) categories. There are about 17 different vegetation types and four major landscapes of mountainous lands, hilly lands, plateau and gravel lands consisting of nine minor land units (Isfahan Regional Water Organization, 2006).

2. EPM Model

EMP model is the other package which has been used to estimate soil erosion in Iran. However, since fewer environmental factors are considered in this model, its accuracy in sediment estimation is less them the other models (Ahmadi, 2006, Rafahi, 1994). This model was created based on erosion measurements during 40 years in previous Yugoslavia and for the first time was introduced in River Stream International Conference (Gaverlovic, 1988). Sediment estimation in this model is based on four factors consisting:

Ψ : Erosion coefficient of watershed, X: Land use Coefficient, Y: susceptibility of rock and soil to erosion, I: mean watershed slope each one of these factors will receive a proper value according to its contribution to erosion process (Table 1).

Table1. The contributing factors in EPM model to estimate the soil erosion

Factor	necessary information	results
1	Slope map	I: mean watershed slope
2	aspect map	Ψ : value for different erosions
3	land use	Xa: value for different land uses
4	rock and soil susceptibility to erosion	Y: value for rock and soil susceptibility

3. The relationship between erosion and sedimentation in EMP model

This model is able to measure erosion, sediment carrying capacity as well as a primary as estimation of sediments behind the reservoirs.

The coefficient of erosion intensity (Z) is calculated by the following equation in this model:

$$Z = Y. Xa (\Psi + I\ 0. 5) \quad (l)$$

Were:

Y: susceptibility of rock and soil to erosion, Xa: land use coefficient, Ψ : Erosion coefficient of watershed , I: mean watershed slope

The volume of soil erosion is calculated by the following equation in this method.

$$WSP = T. H. \pi. Z^{1. 5} \quad (2)$$

Were:

H: mean annual rainfall (mm), π: 3. 14, WSP: the volume of soil erosion (m3/km2/yr)

T: coefficient of temperature which is calculated by equation No. 3 :

$$T = (t/10 + 0. 1)^{0. 5} \quad (3)$$

Were: t: mean annual temperature

The sediment production rate in this model is calculated based on the ratio of eroded materials in each section of the stream to the total erosion in the whole watershed area (Equation No. 4)

$$Ru= 4 (P. D) 0. 5 /L+10 \quad (4)$$

Were:

P: circumference of the watershed, L: watershed length (km), D: height difference in watershed area (km), After calculation of Ru value the special sediment rate is estimated by equations No. 5 and 6 (9).

$$GSP = WSP. Ru \quad (5)$$

$$GS = GSP. F \quad (6)$$

Were:

GSP: special sediment rate, WSP: volume of special erosion, Ru: coefficient of sedimentation

GS: total sediment rate (m^3/yr) , F: total watershed area (Km^2) (Ahmadi, 2006, Rafai, 2004).

Results

When the proper maps are prepared in EPM model, different contributing factors in erosion and sedimentation will receive their values in GIS system.

1. EPM model

Using the EPM model to estimate the erosion, the boundary of units and subunits of the watershed were identified based on proper maps (land use, soil map and etc.) (Figure1). The maps were matched by GIS and then the mean coefficient values for each homogenous and uniform sampling units and subunit were calculated. The calculated values of four contributing factors for Ghareh Aghach watershed in EPM model is presented in Table 2 and 3. The maps of susceptibility values for each contributing factor created by ILWIS3.3 system are presented in figures 2 to 5. After the information layers were valuated to produce the erosion map, the map of erosion intensity (Z) was prepared and the susceptible sites to erosion were identified. The volume of erosion (WSP) was then calculated by equation No. 2 (Table 4) Figure No. 4 shows the erosion in the watershed area. The sedimentation yield in the Ghareh Aghach

watershed was classified in four categories eroded (low, medium, high and very high) using EPM model.

Table 2. Coefficients of four contributing factors in erosion and Erosion intensity by EPM model

2. The efficiency of EPM model to estimate erosion and sedimentation in Ghareh Aghach watershed

GIS system minimizes the personal effects in integrating the different information layers to identify the working units and detects and classifies the different erosion sites in the watershed. t student test was employed to compare the estimated erosion and sediment values by EPM model with measured values using SPSS statistical package (Isfahan Regional Water Organization. 2006.). the results in Table 5 showed that there

were no significant differences (P < 0. 05) between the estimated and measured values. These results support the pervious achievements by the other researchers (Gaverlovic 1988, Shakeri,*et al*., 1996. and Shahbazi kia, *et al*., 2006).

Table 4. The calculated erosion and sediment for Gharehach watershed by EPM model

Subunits of watershed	C1	C2	C3	C4	C5

Abstract

Historical rainfall records are of extreme importance to most hydrologic analyses, including water resources evaluation, impact of land use changes, urban runoff volumes and durations, hydro periods, flood analyses, climate variability, among many others. However, daily precipitation records are rarely complete and suffer from occasional and extended periods of missing values. This study involves evaluation of deterministic and stochastic interpolations methods to fill the gaps in daily precipitation records. Evaluated methods include four improvised methods as well as three benchmark methods, with implementation variations for all methods. Benchmark methods are selected to provide a basis against which the evaluated methods performance can be quantified and compared. Evaluated methods include variations of Inverse Distance Weighting Method (IDWM), Correlation Coefficient Weighting Method (CCWM), Linear Weight Optimization Method (LWOM) and Artificial Neural Networks (ANNs). Benchmark methods are variations of the Single Best Estimate (SBE) method and spatial and climatological mean estimators (SME and CME). In addition, two classification methods were evaluated in combination with the estimation methods in an attempt to separate zero and non-zero precipitation estimates. The evaluated classifiers are Support Vector Machine (SVM) and variations of a Single Best Classifier (SBC). The methods are tested for application at 53 NOAA rain gauges that cover areas of interest to the Southwest and South Florida Water Management District regions in South Florida.

Introduction

Availability of continuous precipitation data at different spatial and temporal scales is essential for hydrologic simulation models that use precipitation as input for accurate prediction of watershed response to different precipitation events. Often hydrologists encounter the problem of

missing data due to a variety of reasons. Also, measurement of hydrologic variables (e.g., rainfall, stream flows, etc) is prone to systematic and random errors (Larson and Peck, 1974; Vieux, 2001). The task of estimating missing precipitation data is generally achieved by traditional weighting and data-driven methods (Smith, 1993), distance based weighting methods (Simanton and Osborn, 1980; Wei and McGuiness, 1973), non-linear deterministic and stochastic interpolation methods (e.g. kriging) and regression and time series analysis methods (Salas, 1993). The handbook of hydrology (ASCE, 1996) recommends two methods for estimation, namely 1) normal-ratio method, and 2) inverse distance weighting method. Comparative study of rainfall estimation using some of these methods can be found in Singh and Chowdhury (1986) and Tung (1983). Inverse distance weighting method (IDWM) is most commonly used method for estimating missing data in hydrology and geographical sciences. Recent studies of Ahrens (2006), Teegavarapu and Chandramouli (2005), and Teegavarapu (2007) provided several variants of IDWM. Global interpolation methods that use trend surface analysis with polynomial equations of spatial coordinates (Chang, 2004) and regression are also applicable for spatial interpolation. All these traditional and more recent variants still have several limitations. The main motivating factors to re-visit the inverse distance weighting method and develop a new variant of this method are described in the arguments here. The success of inverse distance weighting method depends primarily on the existence of positive spatial autocorrelation. The existence of negative autocorrelation may be become a major limitation as distance alone is not the measure of strength of spatial autocorrelation. Distance, a surrogate for strength of correlation, often works well when all the rain gaging stations are located in one meteorologically homogeneous and topographic region. In the current study four improvised methods or variants of traditional methods to estimate missing precipitation data are proposed and investigated. The performance of these methods is compared with three benchmark methods using several error and performance measures.

Improvised Estimation Methods

Four methods ranging from simple distance and correlation based weighting techniques to an artificial intelligence (AI) paradigm support were selected. The brief description of each method in the following sections is summarized in SFWMD (2007) with additional implementation details.

Method I: Inverse Distance Weighting Method (IDWM)

The inverse distance (reciprocal-distance) weighting method (Simanton and Osborn, 1980) is the first recommend procedures for estimating missing data. The missing value α_m at base gauge m, based on observed values at other gauges is given by

$$\alpha_m = \frac{\sum_{i=1}^{n} \theta_i d_{mi}^{-k}}{\sum_{i=1}^{n} d_{mi}^{-k}} \qquad (1)$$

where n is the number of gauges with recorded daily rainfall values on the estimation day, θ_i is the recorded observation at gauge i, d_{mi} is the distance from the location of rain gauge i to the gauge m, and k is denoted friction distance (Vieux, 2001). Values from 0.1 to 10.0 were evaluated for parameter k using direct search until an optimal value was found to minimize the method's RMSE.

Method II: Coefficient of Correlation Weighting Method (CCWM)

The success of the inverse distance weighting method (IDWM) depends on the existence of large positive spatial correlations between the observations being used for infilling. One way to determine this needed correlation is to obtain the coefficient of correlation (CC) between any two data sets at different locations. Since CC is one way of quantifying the spatial correlation, it is reasonable to replace the weighting factor by CC. In case of CCWM, the weighting factors are replaced by the correlation coefficients, with the resulting estimation method given by:

$$\alpha_m = \frac{\sum_{i=1}^{n} \theta_i R_{mi}^k}{\sum_{i=1}^{n} R_{mi}^k} \qquad (2)$$

where R_{mi} is the coefficient of correlation, i.e., the ratio of covariance of the two data sets at stations m and i to the product of their standard deviations. Coefficient R_{mi} is obtained using the data at station m and any other station i. The correlation coefficient is calculated using the entire data set, including zero and non-zero values of precipitation. That is, the available historical data are used tor derive R_{mi}. This method was used by Teegavarapu and Chandramouli (2005) for estimating missing daily precipitation data. Preliminary evaluations of this method indicated that superior performance could be obtained if an exponent value is used. As in Method I, a direct search algorithm is used to obtain the optimal value of k (in the range 0.1 to 10) that minimizes the RMSE.

Method III: Ordinary Kriging (OK) and Linear Weight Optimization Method (LWOM)

Ordinary kriging (Journel and Huijbregts, 1978; Webster and Oliver, 2001) is widely recognized as an optimal estimation method based on scalar measurements at different locations based on spatially dependent variance. The degree of spatial dependence in the kriging approach generally is expressed using a semi-variogram. The expression generally used to estimate the semi-variogram is given by

$$\gamma(d) = \frac{1}{2n(d)} \sum_{d_{ij}=d} (\theta_i - \theta_j)^2 \qquad (3)$$

where $\gamma(d)$ is the semi-variogram which is defined over observations θ_i and θ_j lagged successively by distance d. Surface estimation using kriging depends on the semi-variogram model that is selected which must be fitted with a theoretical form that can be used to estimate the semi-variogram values at arbitrary separation distance values. Depending on the shape of the

semi-variogram, several models are possible, including linear, spherical, circular, exponential, and Guassian forms. A typical spherical semi-variogram is shown in Figure 1.

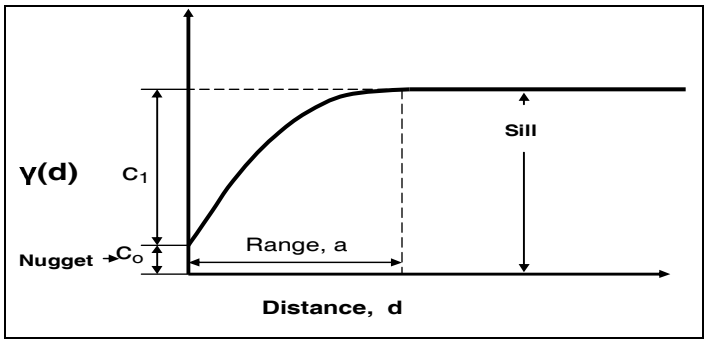

Figure1. Typical parameters of a semi-variogram.

The parameters C_o, d, and a are referred to as nugget, distance, and range, as shown in Figure 24. The sum of C_o and C_1 is referred to as sill, and the semi-variogram at range, a, nearly equals the sill value. The values of C_o and C_1 are obtained using either trial and error or an optimization formulation. Weights in the kriging approach are based not only on the distance between the measured points and the prediction location, but also on the overall spatial arrangement among the measured points and their values. The weights mainly depend on the fitted model (i.e., the semi-variogram) to the measured points. The general equation for estimating missing value, α_m, is given by

$$\alpha_m = \sum_{i=1}^{N} \lambda_i \theta_i \qquad (4)$$

where λ_i is the weight obtained from the fitted semi-variogram through the solutions of a system of linear equations (Journel and Huijbregts, 1978), and θ_i is the value of the observation at location i. The observed data are used twice, once to estimate the semi-variogram and then to interpolate the values. In kriging application, adequate number of semi-variogram forms are evaluated to provide the best possible fit for the spatial correlation structure obtained from the data set. It is important to note that the kriging estimate shown in equation 4 is in the form of a linear estimator, with the weights, λ_i, determined from the spatial correlation structure. Other linear methods can be easily applied with the weights assigned based on some optimization criterion. A variation of the ordinary kriging is to start with alternative initial values for λ_i in equation 2 then use an optimization algorithm to find the optimal values for the linear weights, λ_i, to minimize the estimation RMSE. This method will be referred to as a Linear Weight Optimization Method (LWOM). This LWOM approach is equivalent to multiple linear regression. A common implementation of the multiple linear regression model uses a stepwise procedure to ensure that each rain gauges appearing in the final linear model contributes to the estimation accuracy without degrading the estimation's standard error.

Method IV: Artificial Neural Networks Estimation Method

Artificial neural networks (ANN) have been used extensively during the past decade to estimate and forecast hydrologic variables (Govindaraju and Rao, 2000). A wealth of literature on the architecture of neural networks, including their training and testing can be found elsewhere (e.g., Freeman and Skapura, 1991). The architecture (Figure 2) used in the current study for infilling purposes is a feed-forward network, consisting of one or two hidden layer neurons. The number of hidden layer neurons is typically selected using trial and error and professional judgment. The input neurons use values selected from all gauges except the gauge of interest. The output neuron provides the missing value at the gauge of interest. The input to ANN is the daily observed precipitation values at pre-selected rain gauges. The input gauges are selected based on a pre-assigned threshold value of correlation coefficient calculated from the historical data. The number of inputs selected will depend on the computational resources available for executing the ANN models and any other issues related to training and testing. During the ANN evaluation, preliminary data analysis can be used to identify the stations and finalize the number of inputs.

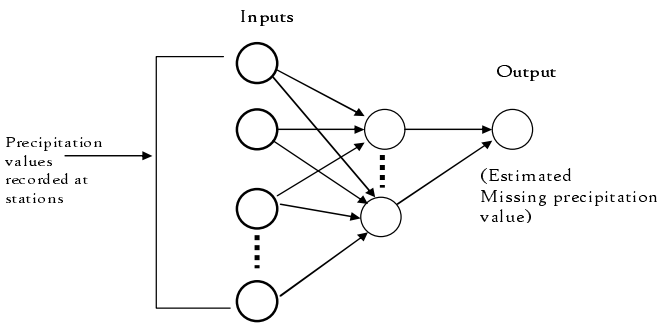

Figure 2. Architecture of ANN method

Benchmark Methods

Three conceptually simple benchmark methods to evaluate the methods are recommended. These methods are described in the SFWMD (2007) and are discussed briefly below.

Benchmark Method 1: Single Best Estimator (SBE)

The Single Best Estimator (SBE) procedure is one of the simplest methods for estimating missing data. Data from the gauge "closest" to the gauge with missing data are used for in-filling. This closest station is not selected by Euclidean separation but by using information about the strongest positive correlation. The availability of historical data again is essential to use this estimator. Eischeid et al. (2000) has described the use of the SBE method for estimating time series of temperature and precipitation.

Benchmark Method 2: Gauge Mean Estimator (GME)

Estimating missing precipitation values by this method is an arithmetic average of all the gauges reporting observed rainfall. The method is a special case of inverse distance weighting and

correlation coefficient weighting where all the weights are raised to an exponent of zero. It is similar to the average precipitation method recommended by McCuen (1998).

Benchmark Method 3: Climatological Mean Estimator (CME)

This Climatological Mean Estimator method is similar to GME but the estimate is an average based on the climatological mean for the day based on the available historical record at the gauge. This method requires at least one available measurement for each day of the year.

Application to Case Study

The four missing data estimation methods are tested for application at 53 NOAA rain gauges that cover areas of interest to the Southwest and South Florida Water Management District regions in South Florida. Rainfall rates across Florida are known to exhibit strong seasonality is known to exist in the rainfall values across Florida. In this study the definition of wet and dry seasons follows that of (SFWMD, 2007), with the dry (winter) season lasting between November and April when precipitation is dominated by frontally-induced widespread storms. The wet (summer) season accounts for approximately 70% of the annual rainfall and has a greater frequency of convective storms whose size is relatively small. Further, the evaluation data set is broken into two sets, before and after January 1, 1950. The rain gauges have considerably more gaps in the record before 1950. Results from all methods are rounded to the nearest 0.01 inch to match the precision of the daily rainfall values obtained from the National Climatic Data Center (NCDC). Further, the two evaluated methods (linear weights, ANNs) can produce negative estimates for daily precipitation. To ensure that the results are physically meaningful, a lower limit of zero was imposed on results from these methods. That is, any negative estimate was replaced with a zero value. All evaluation results are based on these rounded non-negative estimated values. It must be noted that the ANN method uses a training (calibration) and a verification data set to terminate the training algorithm. Therefore, the verification data set was extracted from the available training data in order to maintain the same evaluation data set for all methods.

Several quantitative and qualitative measures were developed to evaluate the benchmark and estimation methods. The quantitative measures included: 1) Root Mean Square Error (RMSE, inches); 2). Mean Absolute Error (MAE, inches); 3). Mean Error (ME, inches); 4. Correlation Coefficient (*CC*); 5). Percent of Correct State for Wet Days (P_w); 6) Percent of Correct State for Dry Days (P_d) and 7) Percent of Correct State for All Days (P_A).

Evaluation of Benchmark Methods

Three benchmark methods (single best estimator method, gauge mean estimator and climatological mean estimator) are initially evaluated. The two mean estimator methods are straightforward and were applied as described above. However, the SBE method was applied using several definitions of the "best" estimator. In the first variation, distance was used to define the best estimator. That is, the best estimator ($\alpha_{m,i}$) for rainfall at gauge m on day i is taken as the same rainfall value recorded at the nearest gauge k ($\theta_{k,i}$) with observed daily rainfall on the same day as the missing datum; $\alpha_{m,i} = \theta_{k,i}$. Other variations of the SBE method used correlation or

seasonal correlation instead of distance. When correlation was used, the best estimator ($\alpha_{m,i}$) for rainfall at gauge m on day i was taken as the same rainfall value recorded at gauge k ($\theta_{k,i}$) having the highest correlation and with observed daily rainfall on the day in question, regardless of season. When seasonality was considered, two sets of correlation coefficients were calculated; one each for the wet and dry seasons. Then the selection proceeded in the same way, with possibly different gauges selected for different seasons based on the different correlation coefficients.

Table 1 summarizes the evaluation metrics for all three benchmark methods. The results lead to several important conclusions. Results of the various benchmark methods were very similar for the time periods before and after 1950. This suggests that the methods do not depend on the number of available measurements on a given day. All benchmark methods appear to be unbiased, i.e., with very small values of mean error (ME). The accuracy of all benchmark methods is similar (as measured by the RMSE and MAE), with the GME method exhibiting the smallest value of RMSE. However, SBE is superior to the GME and CME methods, as measured by the small ME, similar CC and highest percentage of correct state identification, albeit with larger RMSE than the GME method. The large differences between the RMSE and MAE suggest that the error statistics may be dominated by a few large values. This will be explored later using graphical techniques. The SBE methods show significantly better success for determining the rain state at a given gauge (rain/no rain), with a correct classification rate of about 79%, compared to 56% and 31% for the GME and CME methods, respectively. This suggests that that SBE can be used as a classifier. That is, using the SBE method to determine whether zero or non-zero rainfall value should be predicted at a given gauge on a given day. Variations in the SBE method yielded similar results, with slightly better results for the version based on daily seasonal correlation values (as seen in Table 1). However, the accuracy of state determination is not improved by considering the seasonality. The SBE is the best benchmark method and will be the method against which the other methods will be evaluated. Daily Rainfall Estimation Methods Evaluation

The results from the four evaluation methods selected for this Table 2 are the ones that showed the best overall performance or are different enough from other methods to warrant comparison. In this table, the best value for each statistic is highlighted in yellow and the second best value is highlighted in green. As can be seen from this table, the LWOM or ANNs show the best overall performance with an RMSE value of 0.33 and an MAE value of 0.13, which is very close to the minimum MAE value of 0.12. The ME value for the LWOM is fairly close to the minimum value and is order of magnitude lower than the ANN ME value. Finally, the correlation coefficient values obtained for the LWOM are the highest across all evaluated methods, with the ANNs showing very close values. The results show a virtual tie between the LWOM and ANNs, with both methods providing much improvement over the best benchmark method (SBE) as indicated by the smaller RMSE (0.33 vs 0.45), smaller MAE (0.13 vs 0.17), and higher correlation coefficient (0.66 vs 0.45). Simplicity of the LWOM led us to the recommendation of the LWOM over ANNs. Finally, the cumulative errors calculated for the LWOM results show that very small cumulative errors are exhibited by the LWOM-predicted daily precipitation values.

The LWOM has the additional advantage of providing standard error values for the predicted daily rainfall. It must be stated that standard errors (or variance values) can be calculated for the ANN predictions but this requires more complex procedures to be applied. The LWOM standard error values were found to be fairly large, ranging between 0.43 and 0.66. This shows that each predicted daily value has a large variance associated with it making the method not suitable for providing a single prediction. That is, the evaluated methods should only be used for long-term filling of gaps where some gaps exist in the middle of a fairly long record.

Table 1. Evaluation of Benchmark Methods

The implemented evaluation method is based on the comparison between omitted values and the predicted values by each of the methods. This highlights another limitation and potential misuse of the evaluated methods. All methods should only be used to fill gaps in available records. No extrapolation should be used to estimate daily rainfall before or after the record exists at any

gauge. The evaluation data set did not include any data to allow the evaluation of interpolation methods outside the limits of the available record.

In summary, the results underline the selected method as a two-step methodology. In the first step the CCWM is used to estimate daily rainfall at all gauges on the missing days. It must be noted that the optimal value of 4.5 for the exponent k in equation 2 is an empirically obtained value for the evaluated data set. The theoretical basis for this particular value is thoroughly evaluated. For different applications, this value should be determined for the available data whenever possible. In the second step, the LWOM is implemented using stepwise regression, with the CCWM-predicted values used to fill any gap in the explanatory variable matrix. Again, the number of gauges used as input should be evaluated for different applications. The presented results clearly show that the LWOM-predicted daily precipitation values can be used for water resources evaluation purposes where accurate water budgets are required. The use of interpolated rainfall values is not recommended for event-based hydrologic simulation modeling. For these applications, the modeler is encouraged to search the record for the longest possible windows of time where no data gaps exist. However, if no such windows exist, the LWOM can be used to fill only a small number of gaps, relative to the size of the utilized data sets. Results must still be interpreted with careful reference to the underlying precipitation values. The use of a classification method can greatly improve the accuracy of the modeling state (rain vs. no rain). Results show that the SBC (with a small search radius) is preferred to the SVM classifier for its superior performance as well as its simplicity. However, application of this classifier is not recommended for water budget applications as it introduces some bias into the estimated values.

Conclusions

The study reported in this paper has evaluated four improvised interpolation methods to fill gaps in the daily precipitation records at 53 rain gauges in areas of interest to the Southwest and South Florida Water Management Districts. The evaluated methods include four methods and three benchmark methods, with implementation variations for each. Benchmark methods were selected to provide a basis against which the evaluated methods performance could be quantified and compared. The four evaluated methods include variations of the Inverse Distance Weighting Method (IDWM), Correlation Coefficient Weighting Method (CCWM), Linear Weight Optimization Method (LWOM), and Artificial Neural Networks (ANNs). The benchmark methods are variations of the Single Best Estimate (SBE) method and gauge and climatological mean estimators (GME and CME). In addition, two classification methods were evaluated in combination with the estimation methods in an attempt to separate zero and non-zero precipitation estimates. The evaluated classifiers are Support Vector Machine (SVM) and variations of a Single Best Classifier (SBC). Results showed that a reasonable performance can be achieved using a two step procedure which implements stepwise regression to provide the final estimates. Two classifiers were evaluated in conjunction with the interpolation methods, the Single Best Classifier (SBC) and Support Vector Machines (SVM). Results showed that the SBC, with a search radius set to 2 gauges, provides the most accurate determination of state (rain Vs no rain). However, this introduces additional bias into the estimated daily precipitation values. Results in this study show enough support for the LWOM for the evaluated data sets and is recommended for infilling precipitation records.

ABSTRACT

The accuracy of discharge measurements using velocity meters and the velocity-area method is typically assessed based on empirical studies that may not correspond to conditions encountered in practice. In this paper, a statistical approach for assessing uncertainty based on interpolated variance estimation (IVE) is introduced. The IVE method quantifies all sources of random uncertainty in the measured data. This paper presents results employing data from sites where substantial over-sampling allowed for the comparison of IVE-estimated uncertainty and observed variability among repeated measurements. These results suggest that the IVE approach can provide approximate estimates of measurement uncertainty. The use of IVE to estimate the uncertainty of a discharge measurement would provide the hydrographer an immediate determination of uncertainty and help determine whether there is a need for additional sampling in problematic river cross sections.

INTRODUCTION

Tens of thousands of discharge measurements are made annually by the U.S. Geological Survey (USGS), other government agencies, and private entities to quantify the flow in rivers and streams. These measurements are used for design of hydraulic infrastructure, water supply management and planning, or other water resources needs and the ability to assess the uncertainty of the measured flow is useful for many purposes. This paper presents uncertainty estimates using the Interpolated Variance Estimator (IVE), a newly developed method for estimating uncertainty in discharge measurements made using the traditional velocity-area measurement technique.

The discharge of a channel is equal to the flux integral of the flow velocity over the flow area. The conventional USGS velocity-area method of discharge measurement approximates this calculation by measuring the width, depth, and velocity at a minimum of 24 discrete points along the channel cross section. The total discharge in a channel is estimated by summing the discharge estimated for *m* vertical subsections, which together span the width of the channel:

$$Q = \sum_{i=1}^{m} b_i d_i v_i \tag{1}$$

where Q is the discharge, b_i is the width, d_i is the depth, and v_i is the velocity in vertical subsection i.

Within the velocity-area method, the USGS uses the mid-section method to define discharge in the vertical subsections. The subsection associated with each depth and velocity measurement extends half the distance to the location of the preceding and following measurements. The measured depth and velocity are assumed to represent the average depth and average velocity throughout the vertical subsection. This assumption is valid only if an adequate number of subsections are used, such that the measured depth and velocity profiles vary approximately linearly.

To estimate the average velocity in each vertical subsection, velocity is typically measured at 1, 2, or 3 points in each vertical column, depending on the total depth and the apparent velocity profile for the vertical. The average velocity at these points is used to estimate the mean velocity of the entire vertical subsection. In the USGS, the flow velocity is measured either by using mechanical flow meter or by acoustic velocity meter. Additional details on discharge measurement techniques used by USGS are described by Rantz and others (1982).

Traditional methods of estimating the uncertainty in discharge measurements include hydrographer estimates (Rantz and others, 1982) and statistical error propagation techniques (International Standards Organization, 2007; Sauer and Meyer, 1992; Herschy 1971). The statistical error propagation techniques estimate the total uncertainty in a discharge measurement as a function of the uncertainty in individual components of the discharge measurement:

$$u(Q) = \pm\sqrt{u_m^2 + u_s^2 + \frac{\sum_{i=1}^{m}[(b_i d_i v_i)^2 (u_{bi}^2 + u_{di}^2 + u_{vi}^2)]}{(\sum_{i=1}^{m} b_i d_i v_i)^2}} \tag{2}$$

where

$u(Q)$ = Relative uncertainty in discharge (fraction)
u_b = Relative uncertainty in width of a vertical subsection(fraction)
u_d = Relative uncertainty in average depth of a vertical subsection (fraction)
u_v = Relative uncertainty in average velocity of a vertical subsection (fraction)
u_m = Relative uncertainty in discharge measurement due to approximation of integral using limited verticals (fraction)
u_s = Relative uncertainty in discharge measurement due to calibration errors and other systematic errors (fraction)

Estimates of the various components of the total uncertainty are derived from empirical and laboratory studies and are generally insensitive to the site-specific measurement and flow conditions. Pelletier (1988) provided an overview of these studies. The uncertainty in velocity is attributed to various causes such as uncertainty due to pulsation in the flow, uncertainty due to the accuracy of the instrument, and uncertainty due to approximation of average velocity using only 1 to 3 points in the vertical (Pelletier, 1988; Herschy 1975; Carter and Anderson 1963).

Estimation of uncertainty using these methods is most likely to yield accurate estimates of discharge measurement uncertainty if the measurement conditions are similar to those experienced in the empirical or laboratory studies. The IVE method applies the same statistical error propagation techniques, but also takes advantage of the many measurements of depth and velocity in a cross section so that the estimated uncertainty of these components reflects the site-specific measurement and flow conditions.

INTERPOLATED VARIANCE ESTIMATOR (IVE): METHOD

As applied using the mid-section method, the discharge measurement equation (equation 1) is an approximation that assumes that the depth or velocity measured at the midpoint of each vertical subsection adequately represents the true *average* depth or velocity for the entire subsection. In reality, the midpoint measurement is imperfect as a measure of the average, and using depth as an example, this can be expressed as:

$d_i = D_i + \varepsilon_i$	(3)

where D is the true average depth and ε represents random error. These random errors may arise from measurement error or because the midpoint value, even if measured perfectly, is just an approximation of the average value. The midpoint is only a good approximation if depth and velocity vary linearly. With an adequate number of verticals, the depth and velocity profiles will vary approximately linearly.

The IVE method uses adjacent vertical subsections to interpolate a second estimate of the mean depth (or velocity) for each vertical. This estimate is compared to the measured depth or velocity. The difference between these two estimates is treated as a random variable, Δ (see Figure 1):

$$\Delta_{i,d} = d_i - d_{i,est} \tag{4}$$

where $d_{i,est}$ is the depth interpolated from the adjacent verticals. If depth and velocity vary linearly (as assumed by the mid-section method), the expected value of Δ is zero. Δ is assumed to have the same distribution for all verticals. For equally spaced verticals, the expression for Δ can also be expanded to:

$$\Delta_{i,d} = D_i + \epsilon_i - \frac{1}{2}(D_{i-1} + \epsilon_{i-1}) - \frac{1}{2}(D_{i+1} + \epsilon_{i+1}) \tag{5}$$

To employ IVE, it is also necessary to assume that the errors, ε, in estimating the average depth or velocity are independent and random and that the distribution of the errors is the same at each vertical, with variance u_d^2 or u_v^2. Then, for equally spaced verticals, the variance of Δ can be expressed analytically as:

$$\begin{aligned} Var[\Delta_{i,d}] &= Var\left[D(x_i) + \epsilon_i - \frac{1}{2}(D(x_{i-1}) + \epsilon_{i-1}) + \frac{1}{2}(D(x_{i+1}) + \epsilon_{i+1})\right] \\ &= Var\left[\epsilon_i - \frac{1}{2}\epsilon_{i-1} + \frac{1}{2}\epsilon_{i+1}\right] \\ &= Var[\epsilon_i] + \frac{1}{2}^2 Var[\epsilon_{i-1}] + \frac{1}{2}^2 Var[\epsilon_{i+1}] \\ &= u_d^2 + \frac{1}{2}^2 u_d^2 + \frac{1}{2}^2 u_d^2 \\ &= (1 + \frac{1}{4} + \frac{1}{4})u_d^2 \\ &= \frac{3}{2}u_d^2 \end{aligned} \quad (6)$$

The variance of Δ can also be estimated as the sample variance:

$$Var[\Delta_{i,d}] = \frac{1}{(m-4)-1}\sum_{i=3}^{m-2}(\Delta_{i,d} - E[\Delta_{i,d}])^2 \quad (7)$$

Note that verticals at the edges of the measurement are omitted from this calculation. Using the two expressions for the variance in Δ(equations 6 and 7), and assuming that the expected value of Δ equals zero, the variance of the depth measurement can be derived as:

$$\hat{u}_d^2 = \left(\frac{1}{m-5}\right)\sum_{i=3}^{m-2}\frac{2}{3}(\Delta_{i,d})^2 \quad (8)$$

An analogous calculation can be used to estimate the velocity uncertainty as:

$$\hat{u}_v^2 = \left(\frac{1}{m-5}\right)\sum_{i=3}^{m-2}\frac{2}{3}(\Delta_{i,v})^2 \quad (9)$$

These equations can be generalized for the case of non-equally spaced verticals. All of the random sources of uncertainty are accounted for using IVE, eliminating the need to enumerate, quantify, and sum the many possible sources of random error.

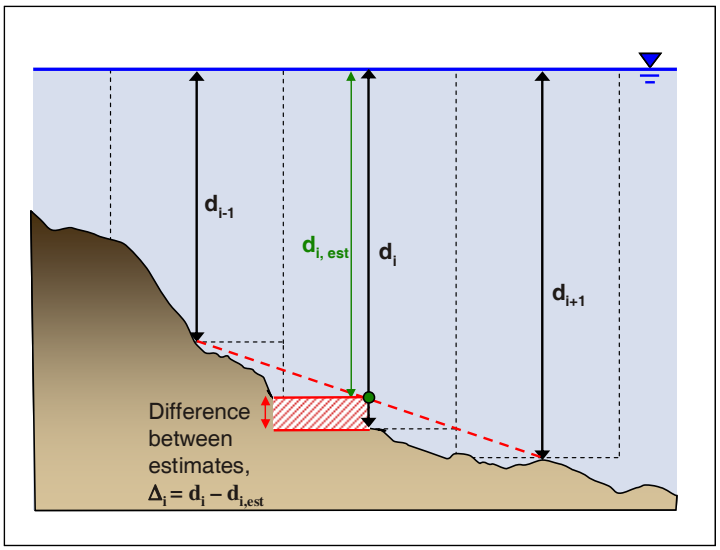

Figure 1. Illustration of Δ, the difference between two estimates of flow depth. The first estimate, d_i, is the measured depth at a vertical. The second estimate, $d_{i,est}$, is the depth estimated by linear interpolation between two adjacent verticals.

Measurement error will tend to increase Δ as well as the estimate of u_d and u_v. In addition, if the depth or velocity profiles do not vary linearly from subsection to subsection, Δ (u_d and u_v) will tend to be large, as the linear interpolation will not provide a good estimate of the variable.

The u_d and u_v estimated using IVE are substituted into equation 2 to calculate total uncertainty in the discharge measurement. The uncertainty due to the limited number of verticals is considered part of the random uncertainty estimated by u_d and u_v and so is not included as a separate term. It is important to note that the IVE method cannot account for systematic uncertainty due to instrument miscalibration, improper use of the streamgaging equipment, or other factors. The systematic uncertainty, u_s, as well as uncertainty in the width measurement, u_w, must still be estimated using other means, such as empirical or laboratory studies.

INTERPOLATED VARIANCE ESTIMATOR (IVE): RESULTS

The IVE method was tested at 11 locations in which multiple discharge measurements were made during steady flow conditions (Table 1). For example, 21 discharge measurements were made on the Watauga River at Sugar Grove, NC (USGS Station ID 03479000) on October 22, 1991. Assuming that each discharge measurement had the same uncertainty and that discharge remained relatively constant, the "true" uncertainty of an individual discharge measurement was estimated as the standard deviation of this set of measurements. As shown in Table 1, the Watauga dataset is unusual for the large number of measurements available. In all other cases, 10 or fewer measurements were available, and particularly for the very small sets, the sample estimate of the standard deviation may not be as reliable as for the Watauga dataset. In addition, these sets of measurements were taken for

different reasons, including for training purposes or comparison of different types of current meters. Thus, a mix of experienced and inexperienced hydrographers and a mix of different instruments were often used to collect the measurements.

For estimates of uncertainty using the IVE method, the width uncertainty was assumed to be 0.5 percent, and the systematic uncertainty was assumed to be 1 percent, consistent with suggestions by the International Standards Organization (2007). Figure 2 plots the "true" uncertainty versus the IVE-estimated uncertainty. As can be seen, the IVE method does seem to give a reasonable indication of measurement quality. There is a significant positive correlation between the two estimates of uncertainty, with an R^2 (coefficient of determination) value of 0.6. Although the IVE estimates appear to be biased somewhat low in these examples, this could be due to mis-specification of the systematic uncertainty of these measurements. Additional testing will provide more information to better evaluate the suitability of the IVE method for routine use.

Table 1. Discharge measurement datasets

Station ID	Site name	Date	Mean flow, ft^3/s	# of meas.
06187950	Soda Butte Creek near Lamar Ranger Station, WY	8-13-93	155	10
06190540	Hot (Boiling) River near Mammoth, WY	8-15-93	29	8
06232600	Popo Agie river at Hudson Siding near Lander, WY	8-16-93	205	4
06037000	Gibbon River near West Yellowstone, WY	8-14-93	136	10
06721500	St Vrain Creek near Allenspark, CO (set A)	8-17-93	67	8
06721500	St Vrain Creek near Allenspark, CO (set B)	8-18-93	65	7

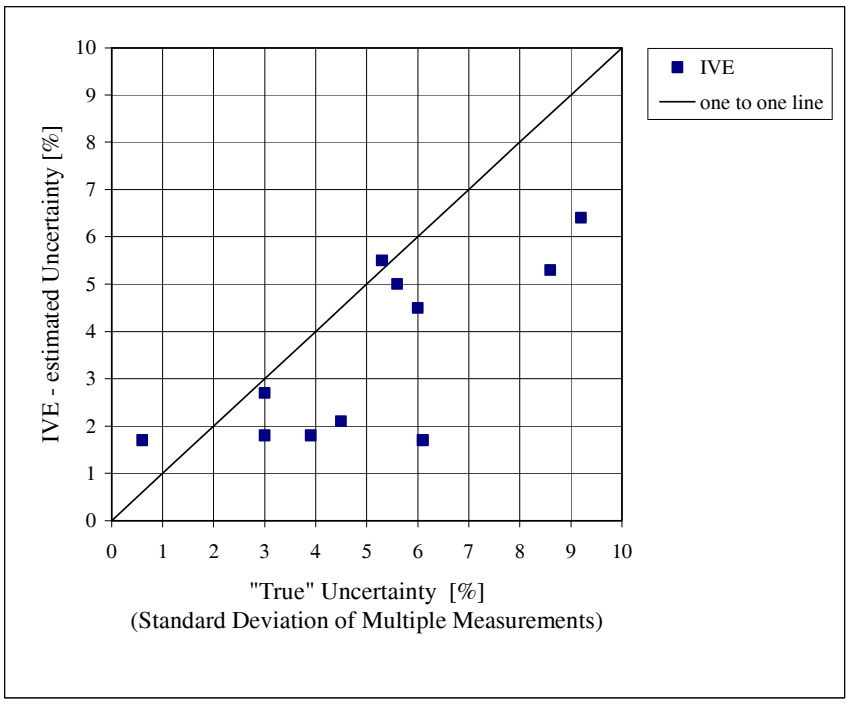

Figure 2. Uncertainty of discharge measurements. "True" measurement uncertainty, calculated as the standard deviation of multiple measurements during steady flow conditions, is compared to estimated uncertainty derived from the IVE method.

CONCLUSIONS

The analysis of measurement datasets with repeat observations suggests that the IVE method has promise as a method for quantifying the uncertainty that arises from random errors in a discharge measurement. The IVE method has the advantage of being an objective measure of uncertainty that is based on the actual channel and flow conditions experienced during the discharge measurement. It can easily be programmed into a computer, providing the hydrographer with immediate assessment of the measurement uncertainty. A large uncertainty may indicate the need for additional measurements, or the need to find a more suitable cross section.

The IVE method is also being tested using Monte Carlo simulations of discharge measurements. Preliminary results indicate that the method provides a good assessment of measurement uncertainty. Further testing of the IVE method will include additional field measurements.

ACKNOWLEDGEMENTS

Data for this study were provided by USGS hydrologists Janice Fulford, Dennis Risser, Ron Shields, Anthony Tallman, and Ron Shields (retired). Greg Schwarz and Phil Turnipseed, also of USGS, provided helpful reviews of an early manuscript.

1 Introduction

The conceptual or computational procedure for numerically simulating a process(s) which occur in a watershed is generally called hydrologic modeling. Modeling is commonly used to estimate runoff from a watershed, which is one of the most important aspects of any hydraulic and hydrologic design project. One of the widely used applications of these estimates is to determine the design or flood discharge of a watershed. While useful, any simulation model is a simplification of the real world processes and parameters. Because of these simplifications, there is a range of suitable problems for which models can be applied.

Traditionally, hydrologic simulation modeling systems have been classified as 1) Lumped parameters, 2) Quasi-distributed parameter or 3) Distributed systems. In terms of spatial discretization/ resolution, we can organize these hydrologic model categories on an ascending scale of sophistication beginning with lumped models to the physically based distributed model. The lumped models treat the complete basin as a single homogeneous element and develop a single outflow hydrograph (Jones, 1997). The quasi-distributed models discretize the watershed into homogeneous sub-areas or sub-basins based on the topography or drainage area. The infiltration or rainfall parameters are treated as homogeneous within each sub-basin and the flow is determined (Gan, 2001). The physically based fully distributed models divide the entire basin into elementary unit areas such as grid cells and flows are passed/routed from one grid cell to another as water drains through the basin (Jones, 1997). These three model categories are presented graphically in Figure 1. This allows the heterogeneity of the watershed to be incorporated on the scale of a grid cell. Grid resolution is generally chosen so that each grid cell will be fine enough to represent the spatial variation of all the input parameters such as rainfall, infiltration/loss parameters etc (Vazquez, 2002).

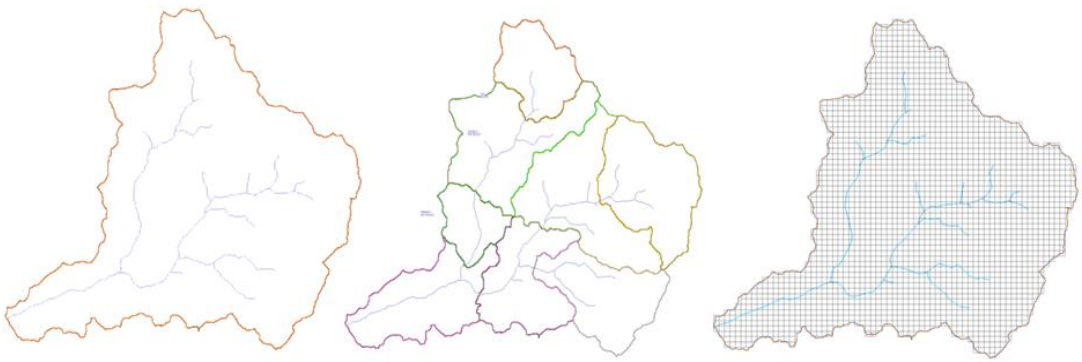

Figure 1: Graphic representation of lumped, quasi-distributed and distributed models

The majority of the modeling systems used in practice today are the simple lumped parameter models (Butts, 2004). This can be attributed to the fact that these models require a fewer number of parameters or data to be defined/calibrated for their operation (Butts, 2004). Despite many significant simplifications in these models, many of them have proven to be quite successful in simulating an observed flow hydrograph. The major benefit of using such simplified models is the ease in their calibration as smaller number of control parameters is used and it is easy to establish some pattern in their variation to produce desired watershed response.

An important shortcoming of simple lumped parameter models is that their parameters are not directly related to the physical characteristics of the catchment (Zhang et al, 2004). In general, their applicability is limited to gauged watersheds where the expected conditions are within the historic data used for calibration and no significant change in catchment conditions has occurred (Zhang et al, 2004).

The relationship between rainfall and runoff is a complicated process which is defined by numerous parameters each with inherent uncertainties. If these uncertainties are modeled using a stochastic, or even a statistical deterministic approach, it results in significant computational requirements (Jones, 1997). To better incorporate the variations and uncertainties involved in defining a watershed response to the rainfall, a physically based distributed model is always preferable (Kalin & Hantush, 2006). Distributed models can simulate both spatial and temporal variability of the watershed characteristics. These models, because of the larger computational requirements, add a massive computational burden. Historically, these computational resources were not available to general practitioners. With the advent of powerful computers, numerous quasi-distributed and distributed hydrologic models are emerging and many claim to be the best model, or at least capable of solving a wide variety of problems (Sui & Maggio, 1999). Because each model intrinsically has various limitations and assumptions, it can be concluded that model selection has always been a difficult problem for practicing engineers. Selection is not only limited by the accuracy of simulated results, but also includes the ability, knowledge and efforts to correctly develop a model from available data sources.

2 Models and tool selection

The USACE has played a vital role in the development and application of hydrologic models in the Unites States. It is the agency which establishes the modeling standards and guidelines and has developed a series of hydrologic, hydraulic and environmental models since the early 1960's. USACE models are extensively used throughout the world and they included such pioneering models as HEC-1, HEC-2, HEC-HMS, HEC-RAS, and GSSHA. Two of their models HEC-HMS and GSSHA will be used as the tools for this research. As a straightforward and well established standard model, HEC-HMS is widely used in the US and worldwide. GSSHA is a more sophisticated physically-based research model that the USACE is promoting as a model capable of simulating more complicated hydrologic/hydraulic situations such as the levee

failures in New Orleans and sediment and nutrient transport within a watershed (reference). Both models are commonly used and are promising, with many applications in peer-reviewed literature. GSSHA is supported by the US Army Engineer Research and Development Center and is embedded into the Watershed Modeling System (WMS) (Nelson, 2006). Moreover, this research is promoted and funded by the USACE to test and establish the reliability of their models so that the broader engineering community can take advantage of such models.

HEC-HMS, GSSHA, and WMS are the hydrologic models and tools used in this research. The following sections talk in brief about these tools and Models.

2.1 HEC-HMS

The USACE model, Hydrologic Modeling System (HEC-HMS) is designed to simulate the precipitation-runoff processes of dendritic watershed systems (HEC-HMS, 2000). HMS is widely used in a broad range of hydrologic problems varying from the analysis of large river basin water supply and flood hydrology to the study of small urban or natural watershed runoff. HEC-HMS has been used for studies of water availability, urban drainage, flow forecasting, future urbanization impact, reservoir spillway design, flood damage reduction, floodplain regulation, and systems operation (HEC-HMS, 2000).

HEC-HMS is popular for its simple and relatively easy approach, and it has been shown to perform excellently for certain problems, but the general perception (largely because of familiarity) is that it can be applied for almost all problems, even for complex scenarios. The capability of HEC-HMS to analyze the watershed hydrology in both lumped and quasi-distributed (HEC-HMS ModClark Method) fashion is its strength.

2.2 GSSHA

The Gridded Surface Subsurface Hydrologic Analysis (GSSHA) model is a reformulation and enhancement of the distributed runoff model CASC2D (Ogden, 2000). GSSHA is a physically based, two-dimensional model in which the watershed is discretized into uniform raster grids of any size. It is capable of both long-term and single event simulation, sediment and nutrient transport, ground water surface interaction, wet land simulation, lumped and distributed rainfall etc. by solving the finite difference equations. The model solves transport equations using finite difference and finite volume techniques and includes 2-D diffusive-wave overland flow routing and 1-D diffusive-wave channel routing (Downer, 2006). GSSHA is a process-based model with an option to select the specific processes to be modeled for a particular application. Among the processes that can be simulated are precipitation distribution, snowfall accumulation and melting, precipitation interception by vegetation, surface water retention, infiltration, overland flow runoff, overland erosion and deposition, channel routing of water, channel routing of sediments, channel routing of conservative contaminants, unsaturated groundwater flow (Vadose

zone modeling), saturated groundwater flow, stream recharge/discharge to groundwater, exfiltration of groundwater to land surface, and evapo-transpiration (ET) (S. Hunter et al, **19xx)**.

2.3 WMS 8.2

The interface for developing the input files from the geo-spatial information using the GIS based platform are available in Watershed Modeling System (WMS 8.1) for both GSSHA and HEC-HMS (Nelson, 2006). WMS has GIS based user interface and is capable of both pre and post processing the data necessary for hydrologic modeling.

3 Methodology

The discretization of watershed is done to consider the spatial variations in the watershed. The discretization might be in the form of sub basins or in the form of grids. Most of the times, the watershed boundaries within the watershed are taken as the sub basin boundaries and the hydrologic parameters are assumed to be same over such sub basins. This helps in incorporating the distinct variation in the watershed parameters during hydrologic modeling. Another approach is to divide the watershed into grid cells of uniform size and allocate the watershed properties to each such cell. This will help consider the spatial variability of the parameters in greater detail and with higher resolution. Each grid cell in some way is a small sub basin where all the computations are done to determine the abstractions and losses.

3.1 Lumped Vs Quasi-distributed models in HEC-HMS:

In the lumped model, the entire basin is assumed as a single unit and the hydrologic computations are done. As seen in Figure 2, the watershed is not further divided into sub basins or grids. For the quasi–distributed approach, three different cases were analyzed, one with 2, next with 4 and the last with 8 sub basins. This comparison was done to see how these different discretizatins affect the watershed response. SCS curve number method was used for loss methods and SCS equation was used to determine the lag time for Clark transformation methods. A uniform precipitation of 2.5 inches with SCS type-II 24 hour distribution resulted in the following (see **Figure 4**) outflow hydrograph.

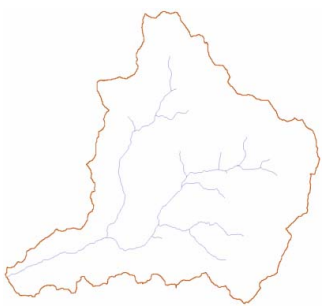

Figure 2: Lumped Model

Figure 3: Quasi-distributed Model (2 sub basins)

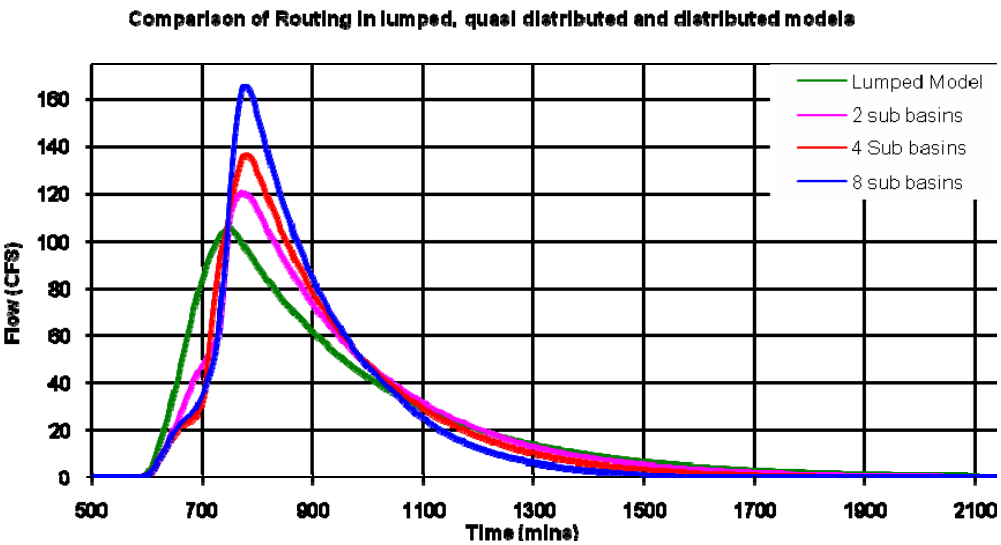

Figure 4: Results from Lumped and Quasi-distributed models

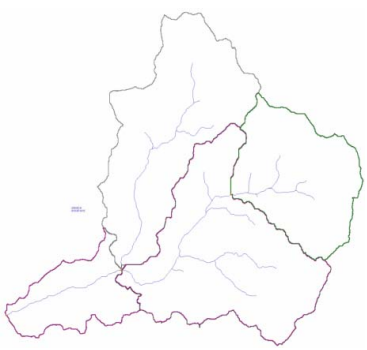

Figure 5: Quasi-distributed Model (4 sub basins)

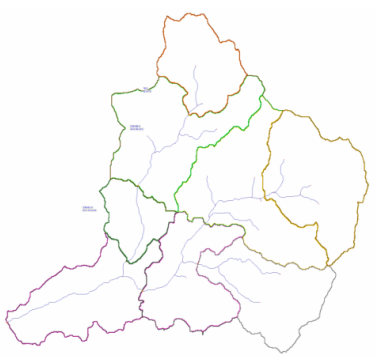

Figure 6: Quasi-distributed Model (8 sub basins)

Muskingum routing method was used to transfer the outflow hydrograph from intermediate outlet points in the quasi-distributed models to the final basin outlet. The parameters required for routing were extracted using WMS. The results show (Figure 4) that the lumped model gives smaller peak under the same conditions as compared to the quasi-distributed models. The increasing number of sub basins shows the increase in the peak flow.

This leads us to believe that the quasi-distributed models give conservative results as compared to the lumped models and the higher the resolution of discretization the sub basins; the more conservative is the result.

3.2 Lumped Vs distributed models in HEC-HMS:

In another part of this research, a comparison was made between lumped and distributed HEC-HMS models. Two test watersheds were studied and the comparison of the two methods is done.

The lumped model uses SCS CN loss method with Clark transformation method. Similarly, the distributed model uses gridded CN method with ModClark transformation method. A uniform rainfall of 2.5inches with SCS type-II 24 hour distribution resulted in the following outflow hydrograph (Figure 7).

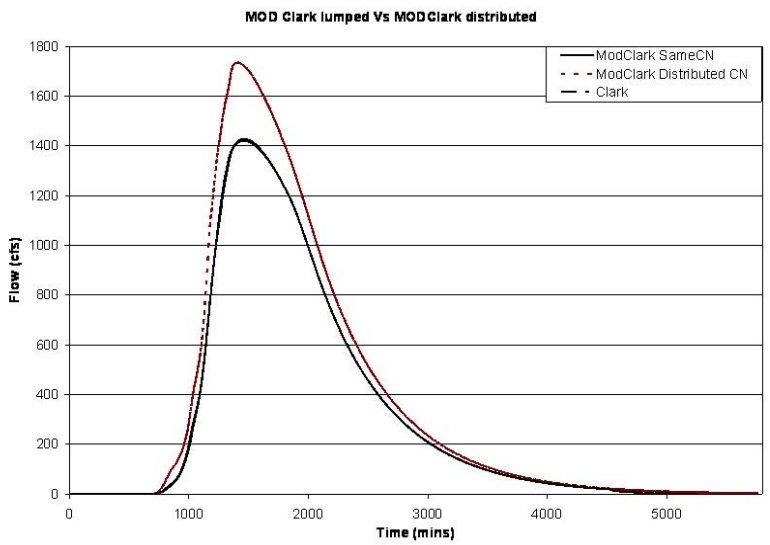

Figure 7: Hydrograph Comparison from Clark and ModClark methods

The hydrograph from the Clark method results in a smaller peak as compared to that from the ModClark method. This means that further distributing the watershed parameters such as the curve number results in a higher and thus more conservative response.

3.3 Distributed models in GSSHA

Although the ModClark method in HEC-HMS is distributed as compared to the lumped and the quasi-distributed models, it is not a physically based model. It uses unit hydrograph approach for the transformation. Because of this there are several problems which cannot be solved by the

ModClark method. To deal with such issues, the USACE has developed GSSHA which is a fully distributed physically based hydrologic model.

GSSHA is capable of solving a wide range of hydrologic problems varying from simple problems that can be modeled using a lumped model to much complex scenarios. Further, it is capable of handling other important ecological processes such as wetland simulation, sediment and nutrient transport etc. (Downer, 2006).

GSSHA itself is not a standalone program because it does not have the graphical user interface (GUI) but it has been developed in WMS. Advanced pre and post processing tools for analyzing the geospatial data are developed in WMS to facilitate the distributed modeling with GSSHA. WMS also provides the post processer which is very useful in result visualization as well as calibration of the GSSHA models.

3.4 Analysis of land use change scenario in GSSHA

Because of rapid change in the human needs, the engineering practice is also facing new problems and design requirements. Change of land usage and its effects on the watershed response has been studied for a long time and it is one of very important aspect of land development studies. GSSHA is capable of simulating the effects of the land use changes.

A research has been carried out with an experimental watershed (See

Figure 8) to see how well GSSHA can simulate the land use change scenario. Such a generic watershed is used for this study instead of using a real world watershed because the parameters can be controlled easily and there are smaller numbers of factors that affect the outflow.

The land use is changed at various locations of the watershed such as near and away from the stream, near and away from the outlet, on steep and mild slope etc. The main goal of this study is establish the fact that GSSHA can simulate the scenarios as intuitively such changes are expected to act.

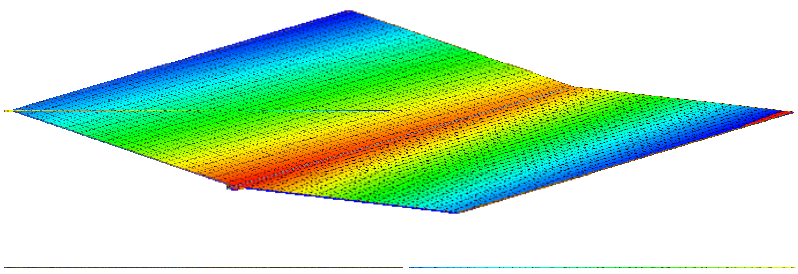

Figure 8: Experimental watershed to analyze land use change scenario

Nine different locations of the changed land use and its effect on the outflow hydrograph are studied. Similarly, a lumped model is created in HEC-HMS and the same scenarios are analyzed. But in case of the lumped model, the location of changed land use does not matter significantly because it is represented by the percentage of the watershed area that is impervious. The following figure (see Figure 9) shows some of the preliminary results of this research.

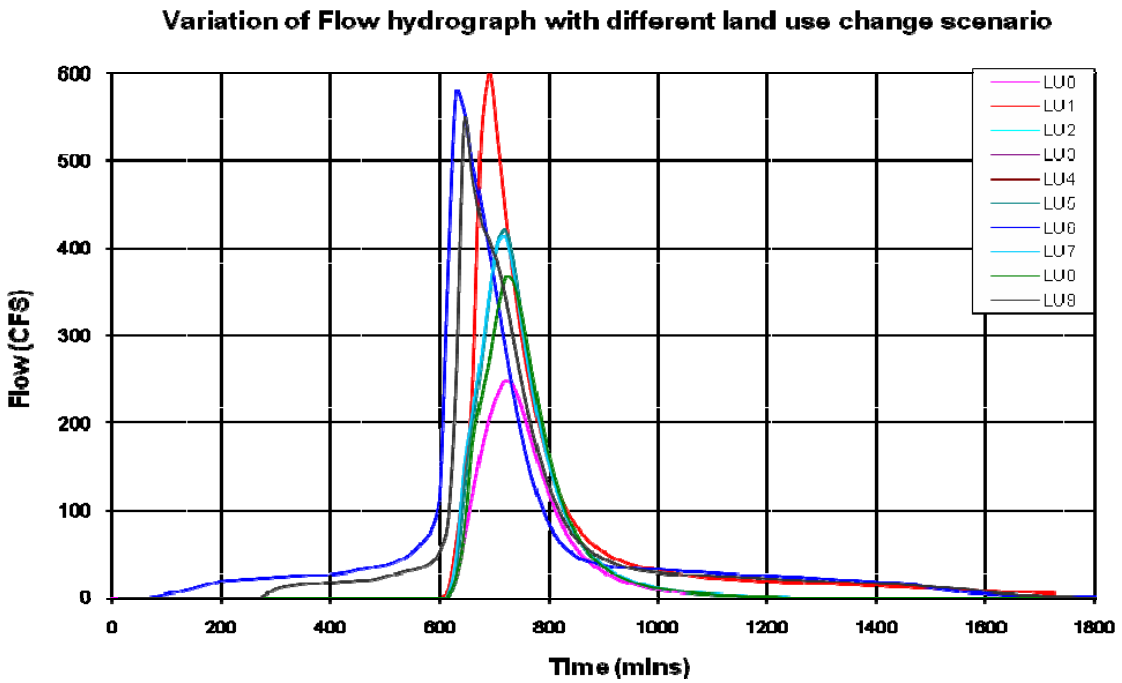

Figure 9: Results from land use change scenario simulation

In the figure (see Figure 9), the smallest hydrograph represents the outflow from the watershed when there is no land use change and all other cases are under different location of the changed land use. This research is still ongoing and a lot of other facts are yet to be analyzed. The results from this research will be validated with the real world watershed to establish that GSHSA is usable in solving such problems.

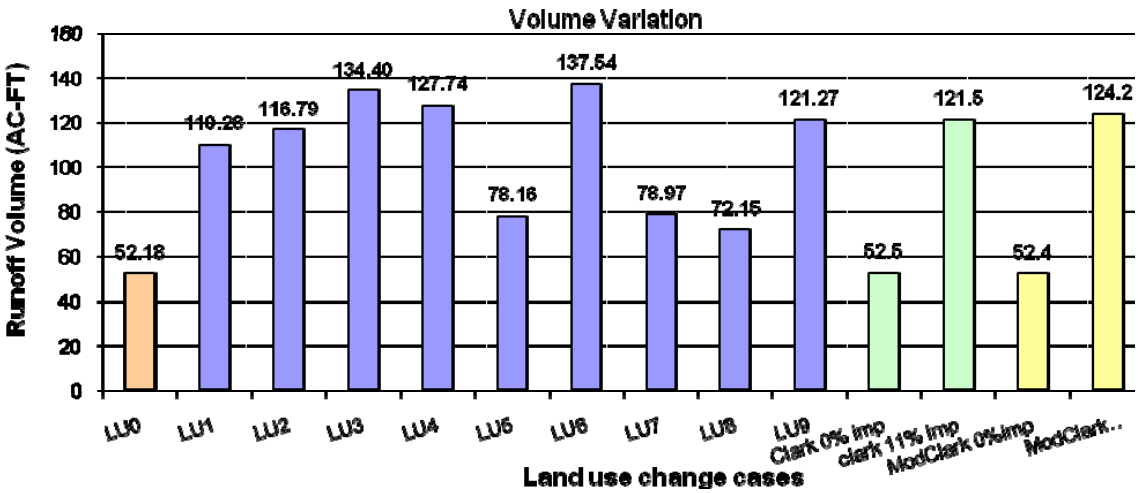

Figure 10: Runoff volumes in land use change scenario analysis

As seen in the above figure (see Figure 10), the results from a lumped model (HEC-HMS simulations) are the same for all different land use locations and it does not represent the actual responses of such changes. From this observation, it can be inferred that it is not always safe to use the lumped models and there are very good models like GSSHA for such cases.

4 Discussion and conclusion

Various research components discussed above are a part of bigger project in which the assessment of the distributed models in terms of the usability, accuracy and necessity has been done. As already been stated, this project is funded by the USACE to see how well their models perform for all these different hydrologic problems and scenarios.

The use of distributed hydrologic models by the engineering community is still limited. Different literatures discuss about the reasons behind the problems and complications in using such models. This study is mainly focused on finding such hurdles and suggesting the solutions to overcome them. It is evident that the physically based distributed models are data hungry and a lot of high resolution spatial data is necessary. The tools to process such data is another concern because it consumes a lot of time and resources and at the same time it is the vital part of modeling as the parameters for the model are derived from them.

At present, the GIS data are available for majority of areas and are easily accessible. There are tools like WMS which facilitate the pre and post processing of the data. In this study, we are evaluating the ease of modeling GSSHA and HEC-HMS models using WMS interface. This evaluation includes all different aspects from data collection, processing, parameterization,

visualization to calibration of the models. It has been a continuous process and a lot of improvement has been made in WMS interface for GSSHA and HEC-HMS.

With such effective tools, the distributed models are now as easy as the lumped models to develop and they can be applied to solve a wider of range of problems than that can be done with the lumped models. The only problem that such models are facing is the prevailing perception that these are difficult to develop and calibrate. We expect that the outcomes of this research help changing such perception and encourage people to start using these tools. Summary and conclusion

Abstract

Land use change and urbanization can have significant impacts on hydrologic processes within watershed systems. Monitoring data, however, are rarely sufficient to fully understand the spatial and temporal factors that contribute to the change in streamflows. This paper presents a modeling framework to evaluate changes in flow regimes at various spatial scales as a result of rapid urbanization in the Eagle Creek watershed in the Midwestern United States. We also aim to determine which components of land use change and preexisting conditions (previous land use and hydrologic soil group) have greater impacts on changes in the flow regime. The Soil and Water Assessment Tool (SWAT) model was used to simulate 50 years of streamflows for the 273 km^2 watershed under the land use conditions of the years 2000 and 2004, as defined by the National Agricultural Statistics Service (NASS) and National Land Cover Data (NLCD) geospatial datasets. Flow duration curves (FDCs) were constructed for 230 subbasins within the watershed under the 2000 and 2004 land use conditions. A two sample Kolmogorov-Smirnov test (KS test) was used to quantify the significance of the difference between the FDCs corresponding to the year 2000 versus 2004 land use scenarios for each subbasin. A multivariate regression analysis indicated that change in urban area, change in forest area, and coverage by hydrologic soil group A have the greatest impact on the change in streamflows associated with land use change.

Introduction

The significance of the impact of urbanization upon the nation's surface waters has long been recognized by several monitoring programs. As early as the 1960's, the United States Geographical Survey (USGS; Leopold, 1968) began alerting planners to the increased dangers of flooding and lost groundwater storage that may occur as the area occupied by roads, parking areas, and other impervious structures expanded. Recent studies have brought to light that the intensity and spatial distribution of urban development are key factors in the generation and timing of surplus runoff (Burges, 1998). It is well understood that with urbanization comes increasing imperviousness and disruption of the natural hydrologic cycle. But, the role of other watershed characteristics in conjunction with land use change has not been fully investigated. For example, will urbanizing pastureland have the same hydrologic impact as urbanizing cropland or forest areas? Will land use/land cover change in areas with predominantly permeable soils have similar impacts on runoff generation and streamflows as areas with poorly drained soils?

Past efforts to understand the impacts of urbanization have typically involved monitoring and/or hydrologic modeling at the watershed outlet. At the watershed scale, it would be rare to find geospatial homogeneity. If a watershed contains clustered areas of urban, crop, and forest, for example, an analysis based on the watershed outlet will provide results which are an amalgamation of effects due to the varying land uses throughout the watershed. This averages or 'washes out' the effects of individual components within the watershed. It seems that monitoring solely at the watershed outlet is inadequate to understand the impacts of urbanization and land use change on hydrologic regimes within the watershed.

A portion of the Upper White River Watershed located in the Midwestern United States has been selected for a study of the impacts of urbanization, prior land use conditions, and soil characteristics on a changing streamflow regime. The watershed was selected due to two of the receiving streams within the watershed, Eagle Creek and Fishback Creek, having witnessed rapid expansion of surrounding urban areas during the previous decade. The availability of long records of precipitation data, flow measurements and yearly land use data over the period of rapid urbanization make this watershed an ideal candidate for the analysis.

There are two main objectives of this study. The first objective is to determine the long-term change in streamflow regimes under observed conditions at various spatial scales within the watershed. The second objective is to determine other important factors that may have an impact on changes in the flow regime.

The Study Watershed

The 368.5 km^2 Eagle Creek Watershed spreads across Boone, Hamilton, Hendricks, and Marion Counties in central Indiana, as seen in Figure 1. The area is composed of the catchments draining into Fishback and Eagle Creek before they empty into the Eagle Creek Reservoir, a large recreational lake that also provides direct intake for the T.W. Moses water treatment plant (Tedesco et al., 2003). For a fuller description of the watershed characteristics, including the results of several water quality studies, refer to Tedesco et al. (2003) and Tedesco et al. (2005).

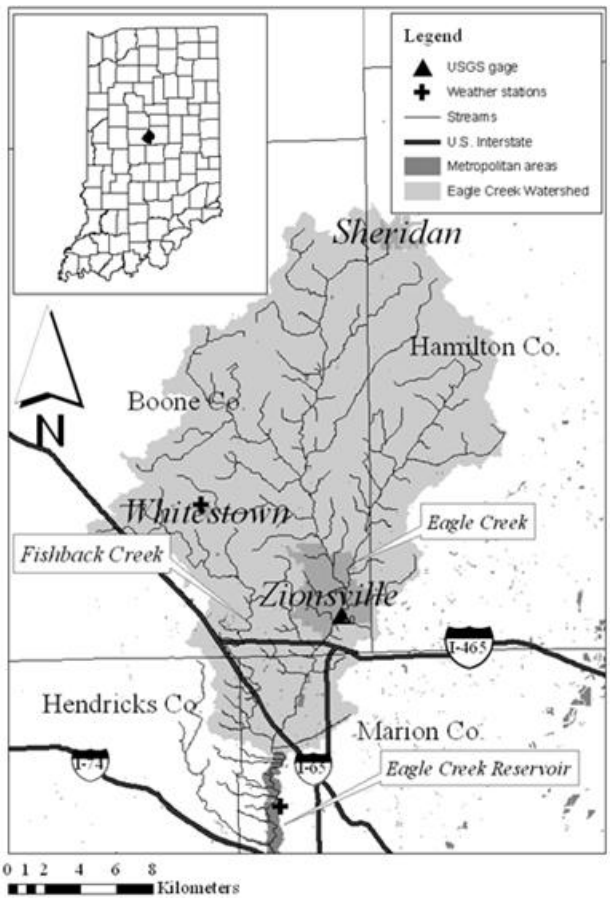

Figure 1. The Eagle Creek Watershed and its location in central Indiana (inset)

The watershed has traditionally been under extensive agricultural production. Land use data from the USDA's National Agricultural Statistics Survey (NASS) documenting the years 2000 and 2004 (Table 1) shows row crops (corn and soybeans) occupying 50.1 and 51.3% of the total area. Over the same period, urban area increased from 4.2% in 2000 to 12.7% in 2004. The increase of urban space led to a significant loss of pasture, as over 60% of the newly developed areas had been pasture in 2000, while another 13% had been under agricultural production.

Table 1. Land use of Eagle Creek Watershed in years 2000 and 2004

Year	% Corn	% Soybeans	% Pasture	% Forest	% Urban	% Water
2000	23.2	26.9	38.9	6.2	4.2	0.6
2004	27.8	23.6	27.4	8.1	12.7	0.4

The SWAT Model

The Soil and Water Assessment Tool (SWAT; Neitsch et al., 2001a,b) was chosen to investigate the long-term effects of land use change under observed conditions based on the insights it has provided into the hydrology of predominantly agricultural watersheds (Borah and Bera, 2003). SWAT is a process-based, semi-distributed model specifically designed with the intent of simulating the effects of land management decisions for continuous, multi-year periods at a daily time-step (Arnold

et al., 1998). Previous studies utilized the model for assessment of watersheds throughout the Midwest, including Illinois (Arnold and Allen, 1996), Kentucky (Spruill et al., 2000), and Indiana (Smithers and Engel, 1996; Arabi et al., 2006). Like Eagle Creek Watershed, the watersheds modeled in those studies were predominantly under row crop production. Fohrer et al. (2001) suggest that the semi-spatially distributed approach taken by SWAT is invaluable for studying relatively small (< 20% of total watershed area) shifts in land use.

SWAT employs a process-based model to simulate watershed hydrology. A two-stage procedure routes runoff from precipitation first overland and then through the stream network. Runoff generation begins at the hydrological response unit (HRU), a unique combination of soil type, land use, and management procedure within a subbasin. For each HRU, SWAT determines a curve number value based on the land cover, the hydraulic properties of the soil, and the antecedent moisture condition. The total generated runoff is summed for the subwatershed and is routed overland using a kinematic model and a modified Manning's equation to determine the time required for the entire subbasin to be contributing runoff (Neitsch, et al., 2001b). The total volume is then routed downstream through the channel network.

Methods

SWAT required three basic inputs to represent the physical characteristics of Eagle Creek Watershed: a digital elevation map (USGS 30 m resolution digital elevation map), a land use dataset (NASS 2000, 2004), and a soil dataset (Soil Survey Geographic Database, SSURGO). In the hopes to make the representation of land management more realistic, default crop schedules were replaced with observed management practices, and tile drains were added to poorly drained soils. Recorded precipitation and temperature data from National Climate Data Center station ID# 129557 and #124249 were used for each simulation. The watershed was divided into 230 subbasins and 4177 HRUs. This detailed watershed subdivision scheme provided the basis for examination of long-term (50-year) changes in flow regimes at various spatial scales.

Calibration & Validation

Three indices were used to evaluate model performance during calibration and validation: the coefficient of determination (R^2), the Nash-Sutcliffe model efficiency coefficient (E_{NS}), and the relative error (percent total difference). The study area for model calibration and validation was determined by the drainage area contributing into the USGS gage (#03533200) at Zionsville (see figure 1). The corresponding drainage area is contained within the Eagle Creek Watershed and has an area of 273 km^2, or roughly 75% of the Eagle Creek Watershed. Calibration of SWAT was accomplished by using both a genetic algorithm-based automatic calibration program and a manual calibration procedure (Arabi, 2005). SWAT was calibrated for the years 1995-1999 using the 2000 NASS dataset. Validation of the calibrated model was performed with the observed flow data for 2000-2004 using NASS datasets corresponding to the respective years.

Flow duration curves

The calibrated SWAT model was used to simulate 50-year periods of daily streamflows in the Eagle Creek Watershed under two land use scenarios. The two scenarios included the observed land use conditions of the years 2000 and 2004, during which the watershed underwent change in land uses. All other factors such as soil type and climatic inputs were left unchanged between the two scenarios.

Flow duration curves (FDCs) were constructed for each of the 230 subbasins from the simulation data. To understand the changes in flow regime at a given outlet, several comparisons were made between the FDCs from land use conditions of 2000 and 2004. The overall average flow change and the flow change over selected exceedance intervals (0-10%, 10-90%, and 90-100% flows) were calculated as flow change indices. In order to assess the significance of the flow regime change, a two-sample Kolmogorov–Smirnov test (KS tests) was implemented on each of the flow change indices. Two-sided tests were used to assess if there was significant increase or decrease in the flow regime. One-sided tests assessed if there was significant increases in the flow regime.

Multiple regression models

It was desired to understand if land use change alone was the primary factor which caused a change in the flow regime or if there were other factors which might predispose an area to more significant change in the flow regime. Regression models were used to understand which factors had the greatest impact on flow regime change.

The regression models were broken up into groups by the response variables to be predicted. Each group of models predicted average flow change over the aforementioned flow change indices. The first group of models predicted average flow change (i.e., =[change in streamflows]). The second group predicted the absolute value of average flow change (i.e., =|[change in streamflows]|). The models used various combinations of land use change, soil type, and interactions thereof as predictors. The coefficient of determination, adjusted for number of predictors (R_a^2), was used as the measure of goodness of fit and a t-test was used to assess the significance of each predictor.

Results & Discussion

Performance indices for the SWAT model were sufficient for the entire calibration period (E_{NS} = 0.67, R^2 = 0.70) and validation period (E_{NS} =0.59, R^2=0.63). The KS test results yielded that 2004-FDCs corresponding to 178 out of the 230 subbasins were significantly different from 2000-FDCs at a 0.05 significance level.

A comparison of FDCs for numerous subbasins suggested that changes in the flow regimes at the subbasin level were not solely a product of urbanization. Table 2, below, compares the land use and flow regime change experienced by subbasins 166 and 209. From the table, it can be seen that the subbasins are similar in size (0.89 and

1.23 sq km) and experience similar amount of average flow change (23.42% and 23.01% increase in flows). However, the land use change experienced by the two subbasins is different. Subbasin 166 experiences 18.26% urban area increase and a 19.82% decrease in pasture area. The flow increase is likely attributed to the urbanization of pasture area. Subbasin 209 experiences a 13.65% increase in crop area and a 12.01% decrease in forest area. The increased flows in subbasin 209 are likely caused by forest area being converted to croplands.

Table 2. Land use change, soil group, and flow change for subbasins 166 and 209

Subbasin	Area	Flow change	Land use change (%)				Soil group (%)		
(#)	(km^2)	(%)	Urban	Crop	Pasture	Forest	Soil A	Soil B	Soil C
166	0.89	23.42	18.26	2.64	-19.82	-2.64	0.00	100.00	0.00
209	1.23	23.01	-1.10	13.65	2.81	-12.01	26.69	64.67	8.64

Figure 2 shows the FDCs for subbasins 166 and 209. Although the average flow rates from the subbasins experienced a similar increase, it can be seen that different parts of the flow duration curves are affected. Subbasin 166 has a greater increase in the larger magnitude, lower probability flows. Subbasin 209 experienced a greater increase in the mid range of exceedance probabilities and mid range of flows.

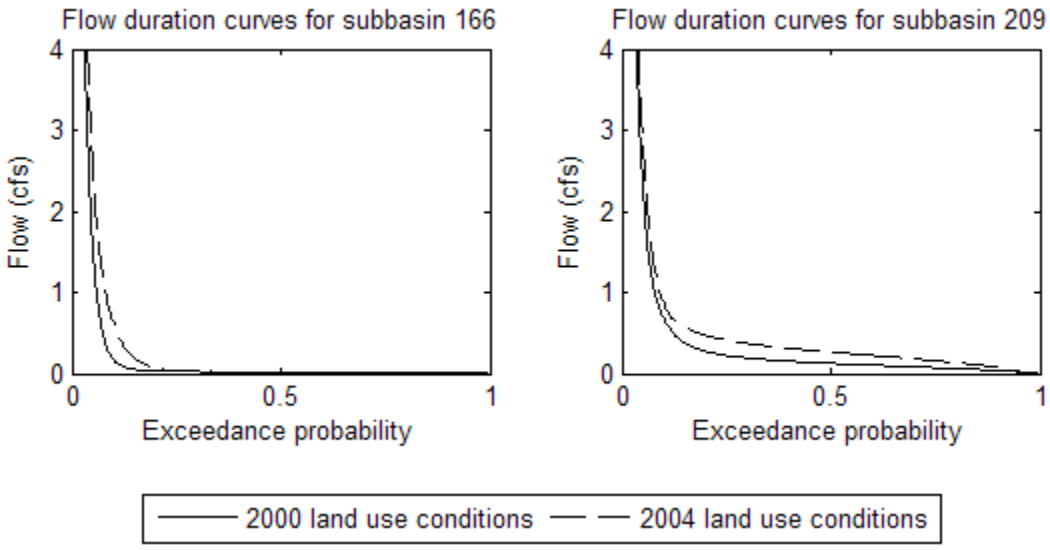

Figure 2. Flow duration curves for subbasins 166 and 209 for land use conditions 2000 and 2004

Table 3 compares the land use and flow regime change experienced by subbasins 166 and 72. The two subbasins are similar in size and experience nearly identical land use changes. Subbasins 166 and 72 both experience a reduction of pasture areas and an increase in urban areas. Yet, subbasin 166 experiences a much larger flow increase of 23.42% whereas the flows in subbasin 72 increase by only 7.33%.

Table 3. Land use change, soil group, and flow change for subbasins 166 and 72

Subbasin	Area	Flow change	Land use change (%)				Soil group (%)		
(#)	(km^2)	(%)	Urban	Crop	Pasture	Forest	Soil A	Soil B	Soil C
166	0.89	23.42	18.26	2.64	-19.82	-2.64	0.00	100.00	0.00
72	0.62	7.33	16.35	1.85	-16.85	-1.70	0.00	48.57	51.43

The primary difference between the two subbasins is the hydrologic soil group composition. Subbasin 166 is completely covered by NRCS hydrologic soil group B, which is a soil with a moderate infiltration rate. The majority of subbasin 72 is covered by soil group C, which has a lower infiltration rate and a higher runoff potential than soil group B.

One of the main ways urbanization increases runoff is by increasing imperviousness which reduces infiltration. Covered by a soil with a lower inflation rate, subbasin 72 would be predisposed to producing more runoff even before urbanization, as compared to subbasin 166. So, the increased imperviousness associated with urbanization may not have as drastic an impact on runoff and streamflows, which is supported by Table 3. A much more drastic change in the FDCs of subbasin 166 than the change in FDCs of subbasin 72 can be seen in Figure 3, below. These results suggest that soil type is an important factor in predicting flow changes with changing land use.

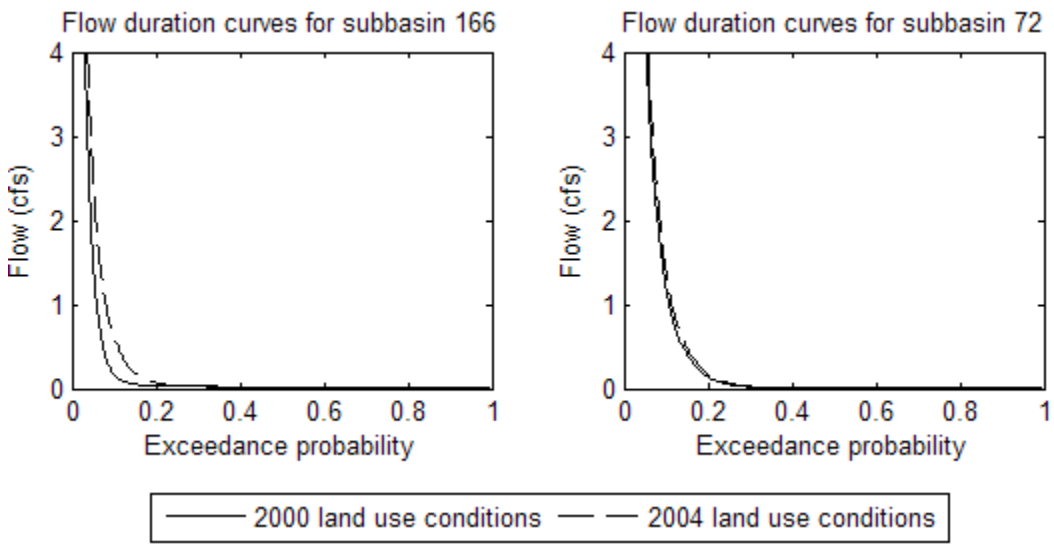

Figure 3. Flow duration curves for subbasins 166 and 72 for land use conditions 2000 and 2004

Multiple regression models

The regression models varied greatly in their ability to predict the change in flows associated with the changing land use conditions of 2000 and 2004. The R_a^2 of the models ranged from as high as 0.91 to as low as 0.14, as seen in Table 4, below. The models with the best fit were consistently the models which predicted the low exceedance probability (0-10%) high level flows and the models which predicted the overall average flow change. Further, it was the models which included all predictors that were found to have the greatest R_a^2.

Table 4. Goodness of fit of regression models prediction of flow change

	Absolute value models				Actual value models			
Flows predicted	**0-100%**	**0-10%**	**10-90%**	**90-100%**	**0-100%**	**0-10%**	**10-90%**	**90-100%**
Lowest Ra^2	0.216	0.258	0.160	0.175	0.216	0.203	0.141	0.162
Highest Ra^2	0.761	0.846	0.591	0.595	0.839	0.913	0.597	0.594

Although many combinations of predictors were explored, a model was chosen for further analysis which has a reasonable fit (R_a^2 = 0.77), a manageable number of predictors and several notable features. The chosen model defined in Table 5, below. Since each predictor is in terms of percent land use change or percent coverage by hydrologic soil group, the coefficients are able to be compared to one another. This comparison allows for determination of which predictor has greater impact on flow change by which coefficient is larger in magnitude.

Table 5. Selected regression model which predicts average flow change

Predictor	Estimate of Coefficient	Std. Error	t value	Pr(>|t|)
(Intercept)	-3.971	1.888	-2.103	0.037
Urban change (%)	0.352	0.778	0.452	0.652
Crop change (%)	0.206	0.727	0.283	0.777
Pasture change (%)	-0.195	0.725	-0.269	0.788
Forest change (%)	-0.533	0.745	-0.715	0.475
Soil A (%)	0.408	0.043	9.425	< 2e-16
Soil B (%)	0.061	0.035	1.760	0.080
(Urban change)(Soil A)	0.004	0.009	0.458	0.647
(Urban change)(Soil B)	0.016	0.015	1.103	0.271
(Crop change)(Soil A)	0.016	0.009	1.704	0.090
(Crop change)(Soil B)	0.019	0.014	1.355	0.177
(Pasture change)(Soil A)	0.024	0.008	2.861	0.005
(Pasture change)(Soil B)	0.015	0.014	1.067	0.287
(Forest change)(Soil A)	0.025	0.009	2.849	0.005
(Forest change)(Soil B)	0.010	0.014	0.731	0.465

From Table 5, it can be seen that the predictors with the greatest impact on flow change are forest area change, coverage by soil group A, urban area change, crop area

change, and pasture area change, ordered from largest impact to smallest impact. All other predictors have coefficients of nearly one order of magnitude less than the aforementioned factors. The direction of impact is also important for these predictors; increased urban and crop areas, decreased pasture and forest areas, as well as coverage by soil group A are all predicted to increase flows. Coverage by soil group A is also the most significant predictor in the model, as determined by the high t-value. Additionally, the coefficient of percent cover by soil group A is roughly an order of magnitude greater than the coefficient of coverage by soil group B. This supports the earlier suggestion that more permeable soils could predispose land use change to increasing flows since soil group A is more permeable than soil group B.

There are also a number of disagreements in the model. All of the interaction terms have positive coefficients. Although this agrees with the predictions of urban and crop area change and coverage by soil groups A and B, it predicts an opposite flow change as a result of forest and pasture area change. It is worth noting that the interaction terms also have a much lesser impact on flow change than the other predictors in the model since their coefficients are an order of magnitude lesser in most cases.

Conclusions

The goals of this study were to determine the influence of land use change on streamflow regimes within the watershed and to determine the other important factors that may have an impact on changes in the flow regimes. The KS test showed there was significant change in the 50-year daily flow simulations under observed land use conditions 2000 and 2004 in the majority of the subbasins. An examination of the FDCs showed that similar flow regime change is not solely a product of urbanization. In fact, similar amounts of land use change and urbanization resulted in different amounts of flow regime change. It was found that preexisting conditions (i.e., prior land use and soil type) can influence flow regime change in conjunction with land use change and urbanization. Further, when lands covered by more permeable soils (soil groups A and B) are urbanized, they are prone to more drastic changes in flow regime than urbanizing an area covered by less permeable soils. Finally, multivariate regression analyses suggested that the amount of urban change, amount of forest change, and coverage by hydrologic soil group A have the greatest impact on flow regime changes associated with land use change.

ABSTRACT

Implementation of conservation measures do not always result in an immediate and measurable sediment yield reduction at the outlet of large watersheds. In this study, instantaneous suspended sediment and discharge measurements, taken in 1943-1948 and again in 2004-2008, in the Fort Cobb Reservoir watershed were used to estimate the downstream cumulative effects of 60 years of conservation practices on sediment yield. The analysis showed a substantial reduction in mean annual sediment yield between 1943-1948 and 2004-2008. This reduction was attributed to the gradual implementation of land use conversion and broad range of conservation measures over a 60- year time span.

INTRODUCTION

Soil and water conservation measures are highly effective at reducing overland soil erosion and sediment delivery from hillside to adjacent channels (Berg et al., 1988; McGregor et al., 1990). However, in large watersheds, the effectiveness of upland conservation measures, as well as channel stabilization efforts, does not necessarily lead to an immediate measurable sediment yield reduction at the watershed outlet (Trimble, 1999; Shields, 2008). The apparent disconnect or lag in response between upstream conservation measures and downstream sediment yield reduction, can be attributed to a variety of confounding factors, such as protracted implementation of conservation measures; spatial and seasonal variability of soil erodibility (especially in agricultural settings); timing of runoff producing storms in relation to agronomic activities; highly variable rainfall (amount, intensity) and resulting runoff with storm event; and potential shifting of sediment sources resulting from changing land use and management over time. Furthermore, in large watersheds, a lag in sediment yield response to upstream

conservation measures can be anticipated due to the slower propagation of sediments through the channel network and effects of sediment storage and subsequent remobilization. These factors and their complex interactions contribute to the notoriously large variability of watershed runoff and sediment yield, and frustrate efforts to identify the timing and magnitude of impacts of upstream conservation measures on sediment yield at the outlet of large watersheds (Pearson et al., 2006; Walling, 1999; Vente et al., 2007).

In this study, the effectiveness of upstream conservation measures to reduce sediment yield at the outlet of a watershed is determined by comparing historic and recent discharge and suspended sediment observations on a mixed agricultural watershed in west central Oklahoma. Discharge and suspended sediment were measured in the 1940s and again in 2004-2008 at several U.S. Geological Survey (USGS) gauging stations within the watershed which offered the opportunity to estimate changes in watershed sediment yield as a result of extensive conservation effort over the span of 60 years between the two measurement periods. Findings are interpreted in terms of land use conversion, conservation practices, urban development, and variations in climate.

WATERSHED DESCRIPTION

The Fort Cobb Reservoir watershed is a 787 km^2 agricultural watershed consisting primarily of crop and range/pasture land. Thirty event-based suspended-sediment and discharge measurements were taken by the USGS at the Cobb Creek gauging station near Fort Cobb during 1943-1948 (Figure 1; Table 1). In 1959 the Fort Cobb Dam was constructed. Subsequently, in 2004-2008 a total of 133 suspended-sediment and discharge measurements were taken at four gauging stations on the three major streams discharging into the reservoir (Figure 1; Table 1). The gauging station names were: Lake Creek near Sickles; Lake Creek near Eakly; Willow Creek near Albert; and Cobb Creek near Eakly (Figure 1).

LAND USE AND CONSERVATION PRACTICES

1943-1948. Historical crop data and land use distribution information were used to estimate land use for the 1940-1957 period (Storm et al., 2007). About 72% of the watershed area was in production agriculture, about 25% in pasture and range, and the remaining 3% in forest, roads, and urban areas. For the purposes of this study, these land use estimates were assumed to adequately represent the 1943-1948 time period. The extent of implemented conservation practices in the watershed during the 1940s was very limited and assumed to be of little practical relevance.

* Not a permanent suspended-sediment collection site; only one measurement available.
** After 1959, discharge below the dam is gate controlled.

2004-2008. Land use for the 2004-2008 period was estimated based on three separate remote sensing studies conducted in 2003, 2005 and 2006. The average land use from these three studies was assumed to adequately represent the land use conditions for the 2004-2008 timeframe. About 52% of the watershed was in production agriculture, 36% in grass/pasture lands, and the remaining area in forest (9%), water (2%) and roads/urban (1%). Soils in the central and eastern portion of the watershed (about 70% of the watershed area) are sandy, fertile, extensively cultivated and vulnerable to erosion, whereas soils in the far western portion of the watershed are more stable and not as extensively cultivated.

Over the last 50 years, about 80% to 90% of cropland that needs terraces has been terraced, and over the last 10 years about 50% of the cropland was in conservation tillage, minimum disturbance tillage, or no-till. Cost-sharing conservation programs supported some reshaping of gullies and installation of grade stabilization structures, and further conservation treatments were installed without cost-sharing assistance. In addition, small impoundments and flood retarding structures were constructed in the late 1950s and early 1960s, and more recently selected unstable stream bank sections were stabilized. Despite these efforts, a geomorphic assessment in 2007 identified several long unstable channel reaches (Simon and Klimetz, 2008), and controlling soil erosion continues to be a priority to protect fragile and erosion prone soils the watershed.

SEDIMENT RATING CURVES

1943-1948. Thirty instantaneous suspended-sediment and discharge measurements were taken by the USGS at the Cobb Creek gauge near Fort Cobb during 1943-1948 (Table 1; station A in Figure 1). To facilitate subsequent data comparison between gauging stations and across time periods, the sediment and discharge data were reformulated on a unit area basis, and a second-order regression was fitted to the data (Figure 2). The resulting sediment-discharge rating curve represent land use and management conditions that prevailed during the 1940s and 1950s and is referred to as the pre-conservation rating curve.

2004-2008. Another 133 sediment and discharge measurements were taken at four USGS gauging stations during 2004-2008 (Table 1; stations B, C, D and E in Figure 1). Again, the data were expressed on a unit area basis and displayed in a scatter diagram (Figure 3). The high degree of similarity and overlap in the data from the four gauging stations led to the assumption that a single second-order regression curve would adequately represent the sediment and discharge relationships at the four gauging stations. This rating curve represented the land use and management conditions that prevailed in 2004-2008 (post-conservation conditions) and embodied the broad range of conservation practices that were implemented in the second half of the 20th century.

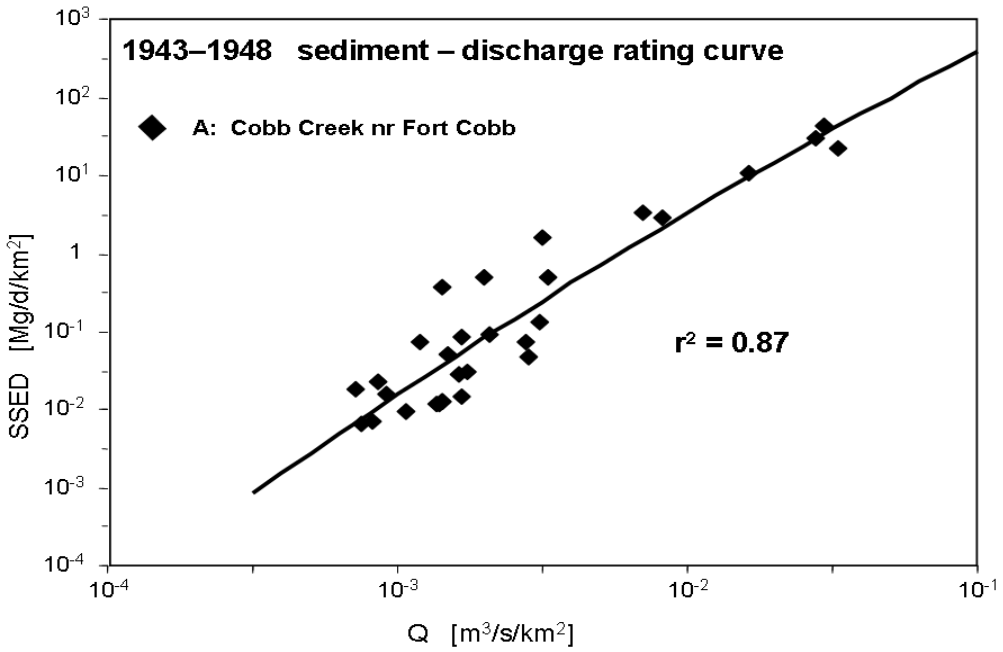

Figure 2. Instantaneous suspended sediment (SSED) – discharge (Q) rating curve at Cobb Creek near Fort Cobb, representing the 1943-1948 land use and management conditions.

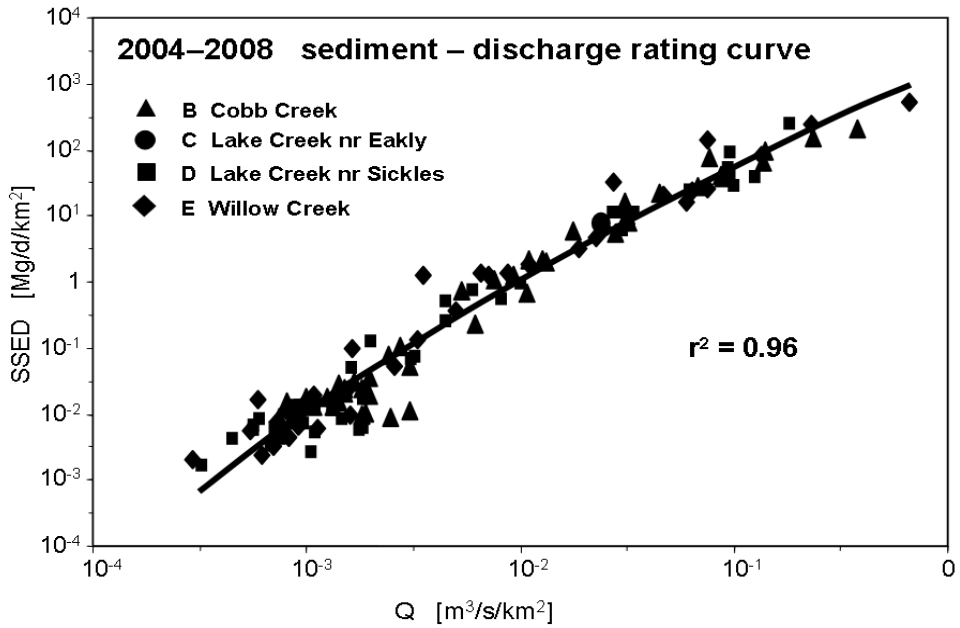

Figure 3. Instantaneous suspended sediment (SSED) – discharge (Q) rating curve at Cobb Creek near Fort Cobb, representing the land use, management and conservation conditions that were in place during 2004-2008.

The implication that a single sediment-discharge rating curve applied for gauging stations with upstream drainage area ranging from 49 to 342 km^2, suggested that the rating curve was to a large extent independent of drainage area and applicable throughout the watershed for drainage areas within the range defined by the gauging stations. It was also noted that topographic, soil and land use characteristics immediately below the four gauging stations was very similar to those above the stations. Thus, the absence of any change in physiographic watershed characteristics and the independence of the rating curves on drainage area, led to the assumption that the rating curve for the 2004-2008 land use and management conditions for the four stations (representing 70% of the watershed area) was also representative of the one that would have existed at the Cobb Creek gauging station near Fort Cobb, provided the reservoir had not been constructed in 1959. This sediment-discharge rating curve was referred to is the post-conservation rating curve.

SEDIMENT YIELD

Annual suspended sediment yield at the Cobb Creek gauging station near Fort Cobb was calculated by summing daily sediment yield obtained from the sediment rating curve for given daily discharge values. Sediment yield for the pre-conservation time period was estimated by evaluating the pre-conservation rating curve with 18 years of observed daily discharge values at the Cobb Creek gauging station near Fort Cobb. The average annual sediment yield for pre-conservation land use and management conditions was estimated to be 740 [$Mg/yr/km^2$]. Sediment yield for post-conservation time period was estimated for the same 18 years of observed daily discharge, except that the post-conservation rating curve was used. The average annual sediment yield for post-conservation land use and management conditions was estimated to be 115 [$Mg/yr/km^2$]. This represented an 85% reduction from the pre-conservation sediment yield and was attributed primarily to conversion of cropland to grassland and implementation of a broad range of conservation practices during the second half of the 20^{th} century.

DISCUSSION

Urbanization was not a leading factor affecting watershed sediment yield, because the two small rural communities in the watershed have not grown very much over time. Influences of climate variations were largely avoided by using the same 18-year daily discharge record for estimating sediment yield. And, effects of climate variability on the sediment-discharge rating curves were also minimal because instantaneous sediment and discharge measurements were taken at various times and seasons during the year, and for high and low flow conditions, irrespective of any variations in climatic conditions.

Land use conversion and conservation measures implemented in the second half of the 20^{th} century were the most likely reason for the identified sediment yield reduction. While conversion of cropland to grassland greatly reduced sediment delivery to the channel, terraces and conservation tillage were also important contributors to the sediment yield reduction from cropland. Further impediments to sediment movement towards the

watershed outlet were provided by small flood control reservoirs which effectively trap sediments. However, many existing gullies, long incised channels, unstable banks and head cuts provide for an ample source of sediments. Incised channel are difficult to remediate because the damage is rarely reversible and comprehensive solutions along the entire channel length are difficult, costly and involve agreement and cooperation of all land owners along the water course.

SUMMARY AND CONCLUSIONS

Efforts to measure a reduction in sediment yield at the outlet of large watersheds as a result of upstream conservation measures are often frustrated by the high variability of discharge and sediment load and lag in watershed response that result from complex interactions between rainfall, runoff, soil erosion, sediment transport, sediment storage and subsequently remobilization, and gradual implementation of conservation measures. In this study, effects of conservation practices on watershed sediment yield were investigated for the Fort Cobb Reservoir watershed. Instantaneous suspended sediment and discharge data were obtained from the USGS and watershed sediment yield was estimated based on sediment-discharge rating curves and daily discharge records. The rating curve based on sediment and discharge data from 1943-1948 reflected land use and management conditions prevailing in that era (i.e. no conservation practices). The rating curve based on 2004-2008 data reflected land use and conservation conditions prevailing during these years and embodied the cumulative and integrated effects of extensive conservation practices implemented in the second half of the 20th century. Average annual sediment yield was estimated to be 740 [Mg/yr/km^2] for the 1943-1948 pre-conservation period, and 115 [Mg/yr/km^2] for the 2004-2008 land use and conservation conditions.

The substantial reduction in annual sediment yield between 1943-1948 and 2004-2008 was related to conversion of land use and implementation of conservation practices. The gradual implementation and cumulative effects of land use conversion and broad range of conservation measures over a 60- to 70-year time span was likely the cause of the reduction in today's watershed sediment yield over that from the 1940s. While it may be difficult to identify beneficial impacts of conservation practices on sediment yield at the watershed outlet during the short time span of a conservation project (up to 5 years), this study demonstrated that targeted, widespread and sustained conservation efforts can lead, with some delay, to sizable reduction in sediment yield at the watershed outlet, as was the case for the Fort Cobb reservoir watershed.

ABSTRACT

The central part of the San Diego Creek Watershed was historically occupied by an extensive swamp that was drained in the late 19th century to accommodate the expansion of ranching and agriculture. Stable isotopes (δ^{34}S-SO_4, δ^{15}N-NO_3, δ^{18}O-NO_3, and $\delta^{82/76}$Se) are used to examine the link between denitrification of fertilizer-derived nitrate and sulfide/selenide oxidation along three discrete groundwater flowpaths that begin at the inferred outer boundary of the historic marsh and terminate at or near a surface water boundary. Isotopes along one flowpath strongly suggest a link between denitrification and sulfide oxidation: both δ^{15}N-NO_3 and δ^{18}O-NO_3 increase from upgradient values of 6.8‰ and 6.8‰ to downgradient values of 19‰ and 14.3‰ respectively while δ^{34}S-SO_4 becomes more negative from an upgradient value of 0.1‰ to a downgradient value of -12.7‰. The other two flowpaths show little to no isotopic evidence of denitrification and δ^{34}S-SO_4 signatures do not change dramatically, suggesting that, in the vicinity of these flowpaths, oxidation may not be the primary mechanism mobilizing sulfate and selenium from more reduced forms. Selenium isotopes do not directly demonstrate a link between denitrification and oxidation of reduced forms of selenium, but rather preserve information about the redox gradient in the historic marsh. The data do not rule out the possibility of nitrate acting as an electron acceptor in the oxidation of reduced forms of selenium. This hypothesis is further supported by results from soil slurry experiments where nitrate-rich water was more effective than oxygenated artificial rainwater in mobilizing selenium in select soil samples.

INTRODUCTION

The San Diego Creek Watershed covers approximately 291 square kilometers in Orange County, California. Historically, a wetland known as the "Swamp of the Frogs" marsh occupied the central, low-lying part of the watershed. This marsh was drained in the late 1800s to make way for the expansion of ranching and agriculture. Today the area is undergoing rapid urbanization. The water table in the wetland

system existed at land surface, creating a reducing environment in which redox sensitive elements such as sulfur and selenium were sequestered in marsh sediments (Hibbs and Lee, 2000). After channels were dredged to drain the marsh, the water table was permanently lowered to a few feet below land surface. This change in hydrology induced a geochemical shift from a reducing environment to an oxidizing environment that now acts as a source of sulfur and selenium by permitting the oxidation and remobilization of the reduced forms that had been sequestered in the marsh. Fertilizer associated with historic agriculture supplies nitrate to the shallow aquifer, which can oxidize sulfides and selenides. Groundwaters, enriched in nitrate and selenium, feed surface streams. This scenario could potentially have adverse impacts on wildlife that depend on these streams and the receiving water body, Upper Newport Bay, which is an ecological preserve.

METHODS

Three groundwater flowpaths were investigated to understand the evolution of groundwater chemistry within the boundaries of the historic "Swamp of the Frogs" Marsh (Figure 1). Historical soil maps were consulted to characterize matrix properties and water table maps were used to estimate the direction of groundwater flow along the three flowpaths. Fifteen groundwater seeps were sampled: four along the El Modena flowpath (EM), five along the Valencia flowpath (V) and six along the Edinger flowpath (E). All seeps span marginal and interior reaches of the historic swamp. Water samples were analyzed for nitrate, dissolved selenium, selenium speciation and a suite of stable isotopes (δ^{34}S-SO_4, δ^{15}N-NO_3, δ^{18}O-NO_3, and $\delta^{82/76}$Se). The EM flowpath was also sampled for δ^{13}C-DIC. Selenium speciation data were used in the Nernst equation to compute redox potentials. Two of the three flowpaths were also sampled for dissolved iron and manganese to further aid in the characterization of redox potential.

Four soil samples were collected for soil leaching experiments. Two clays were collected from a fresh trench *within the boundary of the historic swamp*. The "upper" clay was collected approximately three meters below land surface from the unsaturated zone. De-watering associated with local construction permitted the collection of the "blue" clay, which normally resides below stream head in the saturated zone, from approximately six meters below land surface. Two soil samples were also collected from the dry streambeds of upland basins (HC and RC), *well outside the boundary of the historic swamp*. Soils collected from both within and outside the boundaries of the historic swamp were subjected to leaching experiments in order to quantify the amount of leachable selenium contained therein (modified from Black et al., 1965). Soils were subjected to leaching by two types of water: artificial rainwater, which was made to mimic the composition of rainwater native to southern California; and nitrate-rich water, which was mixed to approximate the average nitrate concentration found in the shallow aquifer (11 mg/L NO_3-N). Two soil-water slurries were prepared for each soil by mixing 250 mL of one of the leaching agents with 125 g of dried soil in a 1000 mL HDPE bottle, which were shaken via wrist-action shaker for one hour. Leachate was immediately filtered after shaking and aliquots were set aside for dissolved selenium and anion analysis. The

clay soils were too viscous to filter directly and were "diluted" with an additional 250 mL of ultra-pure water following the period of shaking. They were then centrifuged at 5000 rpm for 10 minutes and the supernatant filtered for analysis. Several complementary analyses were run on these soils to support the leaching experiment including total selenium and selenium speciation.

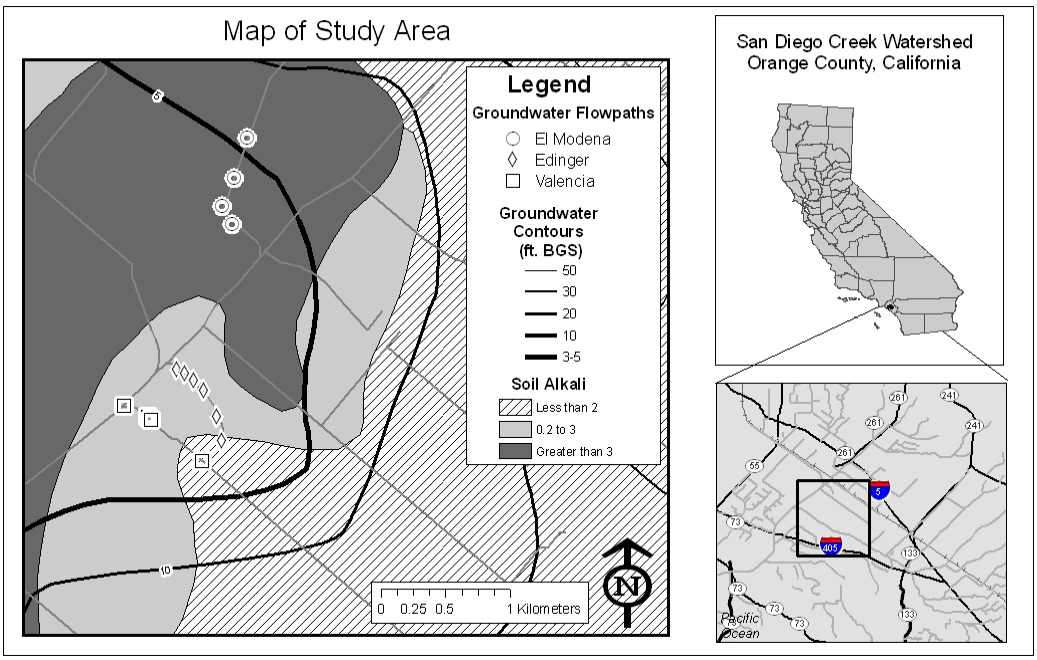

Figure 1. Map showing three groundwater flowpaths, depth to groundwater contours in feet below ground surface, and soil alkali contours.

RESULTS AND DISCUSSION

Soils in the study area have properties that are consistent with deposition in a shallow marsh environment. They are composed of fine-grained material with moderate to high alkali (Figure 1 and Table 1). Finer-grained material and higher soils alkali (> 3%) comprise the matrix through which the EM waters flow, while the matrix for the V and E flowpaths are comprised of a greater proportion of sand with only moderate alkali (0.2 to 0.4%; USDA, 1901).

Background concentrations of *total* selenium in typical soils (i.e. those that are not impacted by selenium) are on the order of 0.4 mg/kg, while soils derived from Cretaceous rocks have higher *total* selenium content on the order of 5 mg/kg (Thomas et al., 1998). Selenium data show that total selenium levels in the upland soils as well as in the "upper" clay are comparable to those found in unimpacted soils (Table 2). Speciation data show that selenium oxyanions (Se^{6+} and Se^{4+}) comprise about 40% of total selenium in the soils collected from within the boundary of the historic swamp. The dominant form of selenium in the "upper" clay is selenate (Se^{6+}), whereas there is more than twice as much selenite (Se^{4+}) as selenate (Se^{6+}) in the

"blue" clay. This indicates that selenium in these soils exists in readily leachable forms.

Results of the leaching experiments are shown in Table 2. As expected, the clay soils from within the boundary of the historic swamp contain more leachable selenium than the soils collected from the upstream basins. Leachable selenium in the upstream soils as well as the "upper" clay is less than typical background concentrations of *total* selenium. The "blue" clay contains elevated levels of leachable selenium on the order of 7 mg/kg, which agrees reasonably well with the total selenium in these soils. The artificial rainwater and nitrate-rich water were equally effective at leaching selenium from all soils except the "blue" clay. The nitrate-rich water leached 21.6% more selenium from the "blue" clay than artificial rainwater did. This result suggests that nitrate may have acted to oxidize the more reduced selenite (Se^{4+}) in the "blue" clay to selenate (Se^{6+}).

Selenium speciation data show that groundwaters are oxic to suboxic, with redox potentials ranging from 0.44 to 0.51 mV with respect to the Se^{4+}/Se^{6+} redox couple (Table 1). Negligible concentrations of dissolved iron and manganese support calculations of positive redox potentials. The down-gradient seeps along two of the three flowpaths (EM and E) show some evidence of more suboxic conditions, which may affect the mobility of contaminants like nitrate and selenium in the shallow aquifer.

Selenium is positioned just below sulfur in the periodic table of the elements and behaves in similar ways. It is proposed that sulfides (FeS_2), metal selenides (Se^{2-}), elemental selenium (Se^0), and adsorbed selenite (Se^{4+}) distributed in soils of the historic marsh are being oxidized by nitrate to sulfate and selenate (Se^{6+}), the most mobile species, by a process similar to the reactions in Equations 1 and 2 below, which describe processes that prevail in systems with positive redox potentials (Steinberg et al., 1992; Masscheleyn, 1990). Soil leaching experiments support these conclusions.

$$5FeS_2 + 14NO_3^- + 4H^+ \rightarrow 7N_2 + SO_4^{2-} + 5Fe^{2+} + 2H_2O \qquad \text{Equation 1}$$

$$5FeSe_2 + 14NO_3^- + 4H^+ \rightarrow 7N_2 + SeO_4^{2-} + 5Fe^{2+} + 2H_2O \qquad \text{Equation 2}$$

Stable isotopes of the redox sensitive elements sulfur and nitrogen have been used to track oxidation-reduction processes in a variety of natural settings (Bohlke and Denver, 1995; Bottcher et al., 1990). This is possible because of microbial and/or kinetic fractionation processes that tend to segregate the "lighter" isotopes in the products. Research has shown that as denitrification proceeds in the presence of reduced forms of sulfur (such as pyrite), that the sulfide will be oxidized and that stable isotopes could be used as viable tracers of this process (Bottcher et al., 1992 *in Matthess*).

Stable isotopes of sulfur ($\delta^{34}S\text{-}SO_4$) provide evidence of sulfide oxidation along the EM flowpath, with signatures becoming progressively lighter in the down-gradient direction. Lighter values of $\delta^{34}S\text{-}SO_4$ are consistent with the biologically-mediated oxidation of reduced forms of sulfur (Clark and Fritz, 1997). A concomitant

**SJBA: San Joaquin Black Adobe, FSA: Fullerton Sandy Adobe (USDA, 1901)*

increase in the isotopic signature of nitrate (δ^{15}N-NO_3 and δ^{18}O-NO_3) is observed along this flowpath, indicating a trend of denitrification as water flows down the hydraulic gradient (Figure 2). Denitrification often proceeds via the oxidation of organic carbon. Data from these springs show a minimal enrichment of δ^{13}C-[DIC] along the flowpath (from an upgradient value of -14‰ to a down-gradient value of -11‰), which is inconsistent with denitrification via the oxidation of organic carbon as the dominant electron donor. The isotopic signature of DIC suggests it originated from atmospheric CO_2 with possibly some contribution from carbonate cement disseminated in soils. Isotopic data strongly support a model of sulfur oxidation by nitrate along the EM flowpath. Nitrate associated with historic fertilizer application in upgradient orchards acts as an electron acceptor for metal sulfides (such as pyrite) disseminated in soils. Ferrous iron (Fe^{2+}) released in this way may be subsequently removed from solution via oxidation by nitrate and/or oxygen (Clark and Fritz, 1997).

Table 2. Soil Selenium Content with Speciation and Leaching Data

	Se-speciation (mg/kg)		Total Se (mg/kg)	Leachable Se (mg/kg)	
	Se (IV)	Se(VI)		Artificial Rainwater	Nitrate-rich water
Blue clay	2.98	1.27	10.4	6.54	7.95
Upper clay	< 0.02	0.155	0.383	0.088	0.087
RC streambed	ND (< 0.02)	ND (< 0.046)	0.360	0.003	0.004
HC Streambed	ND (< 0.02)	ND (< 0.046)	0.198	0.01	0.009

Along the EM flowpath, the isotopic signature of selenium ($\delta^{82/76}$Se) varied from an observed upgradient value of about 1.0‰ at the outer boundary of the historic marsh, decreasing to approximately -1.0‰ as groundwater moves slightly inside the marsh interior. From there, $\delta^{82/76}$Se increases to nearly 3‰ toward the end of the flowpath, well inside of the interior of the historic marsh. A discernable fractionation has been shown to accompany reduction of selenate (Se^{6+}) to selenite (Se^{4+}) and in the reduction of these oxyanions to less mobile forms (Johnson et al., 1999). This is similar to the isotope fractionation that accompanies the reduction of sulfur species. Minimal isotope fractionation observed in the oxidation of elemental and organically-bound selenium (Johnson et al., 1999) and the fact that selenium is a trace element may explain the observed evolution of selenium isotopes and the differences of the patterns observed for δ^{34}S-SO_4.

Because of the chemical similarities between sulfur and selenium, it was expected that, like sulfur, selenium would grow isotopically lighter. However, two factors contribute to a different pattern emerging from the selenium isotope data. First, recent research suggests that, contrary to the fractionation observed in redox transformations of sulfur, selenium undergoes significant fractionation only during reduction, but not upon re-oxidation (Johnson et al., 1999). Therefore, its historic isotopic signature is preserved as it is re-oxidized to a mobile, aqueous phase. Second, because selenium is a trace element it is not as abundant as sulfur and therefore cannot be expected to show a similar isotopic pattern. As a trace element, selenium has the potential to be completely removed and immobilized in the reducing sediments of the historic marsh, whereas sulfur is much more abundant, which limits

its potential for complete removal from the aqueous system. Regional patterns of selenium concentrations support this interpretation where higher levels of selenium are observed in the outer fringes of the historic marsh and much lower concentrations deep within its interior.

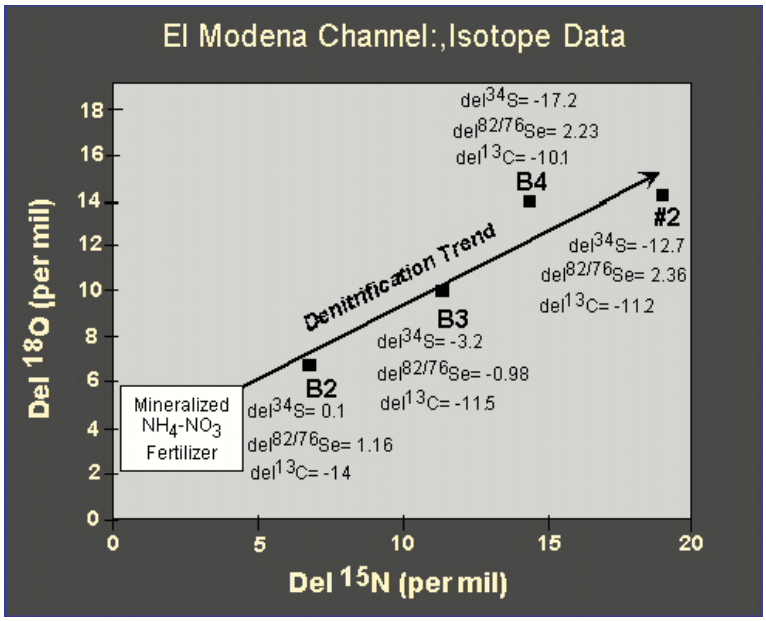

Figure 2. Denitrification trend along the El Modena flowpath with complementary stable isotope values supporting sulfide/selenium oxidation.

A scenario based on a closed system Rayleigh fractionation model may explain the observed isotopic pattern for selenium along the EM flowpath. Selenium enters the marsh with a natural "above marsh" isotopic signature of approximately 1.0‰. As it flows into the reducing waters of the marsh, it undergoes partial (~50%) reduction and isotopic fractionation, which imparts a "lighter" (-1.0‰) signature to the reduced fraction, leaving the mobile phase with an isotopically enriched signature (~3‰). This "heavy" signature is found toward the interior of the historic swamp where strong reducing conditions would have prevailed, resulting in complete removal of the residual dissolved selenium. These signatures are retained upon re-oxidation of the reduced forms of selenium from the marsh sediments after drainage of the marsh. Upstream surface water samples collected from upland tributaries reveal the source end-member isotopic signature of selenium to be ~1.6‰, which is consistent with these interpretations.

Along the V flowpath, stable isotopes of redox sensitive elements show minimal variation: δ^{34}S-SO_4 varies less than one per mille; δ^{15}N-NO_3 varies from 9.6‰ to 10.6‰; δ^{18}O-NO_3 varies from 3.9‰ to 11.3‰; and $\delta^{82/76}$Se varies less than 0.1 ‰. These variations are small enough to discount the role of redox processes that would mobilize reduced forms of sulfur and selenium in the subsurface, such as those observed along the EM flowpath. Another mechanism is proposed to explain the observed data along this flowpath. Previous work has shown that this flowpath coincides with high silica concentrations, which may indicate excess phytoplankton

activity in the shallow waters of the fringes of the "Swamp of the Frogs" (Meixner et al., 2004). It is possible that, due to abundant organic matter, a more homogenized reducing environment existed in the vicinity of the V flowpath, which would have prevented sulfate and selenium in these waters from migrating further into the marsh interior. Thus, uniform isotopic signatures of $\delta^{34}S\text{-}SO_4^{2-}$ and $\delta^{82/76}Se$ are preserved along this flowpath.

Stable isotopes of sulfur and selenium along the E flowpath, exhibit a similar trend to that observed along the EM flowpath. Stable isotopes of sulfur decreases steadily as water flows down the hydraulic gradient from 2.0‰ to -2.3‰. This increasingly negative isotopic signature is consistent with sulfide oxidation. Selenium isotopes exhibit an up-gradient $\delta^{82/76}Se$ signature of 0.91‰, becomes marginally depleted as waters move down-gradient, then, toward the end of the flowpath, $\delta^{82/76}Se$ becomes isotopically heavier (~1.7‰). This pattern is not as dramatic along the E flowpath as it is along the EM flowpath. It is difficult to say whether this pattern is indicative of the historic redox gradient in the historic marsh (as described along the EM flowpath) or if it instead is a reflection of present-day redox patterns. A substantial fractionation (3 to 12‰) of selenium isotopes has been observed during the reduction of Se^{6+} to Se^{4+} (Johnson et.al., 1999). Trace element data for the redox sensitive species iron and manganese suggest intermediate redox conditions presently exist along the down-gradient portion of the flowpath (Table 1). Thus the conversion of selenate to selenite in these down-gradient waters may explain the observed isotopic enrichment of selenium toward the end of the flowpath.

Analysis of $\delta^{15}N\text{-}NO_3$ and $\delta^{18}O\text{-}NO_3$ along the E flowpath was complicated by excess concentration of sulfate in these waters. Therefore $\delta^{18}O\text{-}NO_3$ values must be interpreted with caution (Jack Liu, Isotech Labs, personal communication). Generally $\delta^{15}N\text{-}NO_3$ and $\delta^{18}O\text{-}NO_3$ both grow isotopically enriched as waters flow down-gradient, suggesting an overall trend of denitrification, which may be linked to sulfide and selenium oxidation. Upgradient waters have concentrations of ~14 mg/L NO_3-N while down-gradient waters have concentrations of ~2.7 mg/L NO_3-N. This represents an 86% reduction in the concentration of NO_3-N. If denitrification alone explained the reduced concentration of NO_3-N observed in down-gradient waters, we would expect $\delta^{15}N\text{-}NO_3$ to show enrichment in excess of approximately 10‰ along the flowpath (Bottcher et.al., 1990). However, a maximum enrichment of only 5‰ in $\delta^{15}N\text{-}NO_3$ is observed along the flowpath. When plotting $\delta^{18}O\text{-}NO_3$ versus $\delta^{15}N\text{-}NO_3$, these waters cluster in two distinct groups (Figure 2). The upgradient sites exhibit a slight enrichment of both $\delta^{15}N\text{-}NO_3$ and $\delta^{18}O\text{-}NO_3$, suggesting that denitrification is occurring in these waters to a small extent. The upgradient waters possess a relatively lighter isotopic signature with little evidence of denitrification along this portion of the flowpath, suggesting that there may be a combination of factors operating to produce the observed results (i.e. mixing of multiple sources of nitrate along this flowpath, dilution by waters with low nitrate concentrations). Based on the available data, denitrification alone is insufficient to explain the decrease in nitrate concentration observed in downgradient waters.

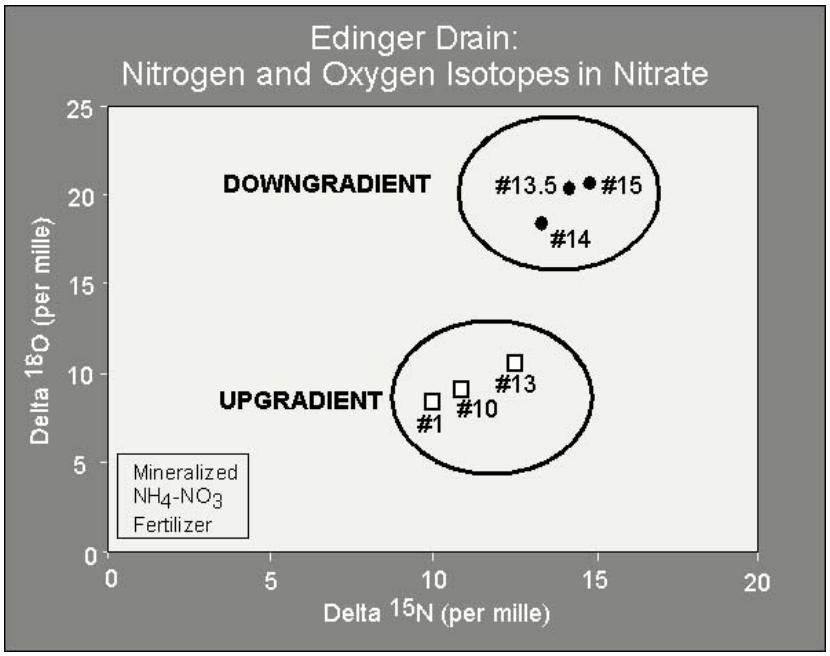

Figure 3. Stable isotopes of nitrate along the Edinger flowpath.

CONCLUSIONS

Groundwaters of the shallow aquifer can be largely characterized as oxidizing, though areas exhibiting intermediate redox conditions have been identified. Isotopic data support a model of sulfur oxidation by nitrate along the EM and E flowpaths. Along the V flowpath, stable isotopes show no evidence for groundwater evolution via the redox processes that appear to operate along the other two, but may be explained by more homogeneous redox conditions that prevailed in the historic marsh due to abundant organic matter.

The observed pattern of selenium isotopes along the EM and E flowpaths may be explained by two possible scenarios. It may reflect the reduction of selenium along the historic redox gradient that existed locally in the fringe of the historic swamp, whereby selenium becomes progressively lighter along the upgradient part of the flowpath (along the margin of the historic marsh) and then becomes markedly heavier toward the end of the flowpath (within the interior of the marsh). Alternatively, along the E flowpath, it may reflect the present-day redox gradient that controls the mobility of selenium along these flowpaths, where selenium concentrations are reduced and partially removed via sorption and/or precipitation in the more suboxic waters toward the end of these flowpaths. Nevertheless, isotopic data do not rule out the possibility that nitrate acts to oxidize reduced forms of selenium from the soil matrix within the boundary of the historic swamp.

Long Term Effect of a Stream Restoration Plan on Water Quality

Yuan Cheng[1], Ph.D., P.E.

[1]Senior Civil Engineer, Benatec, a Division of Century Engineering, Inc., 200 Airport Road, New Cumberland, PA 17070; PH (717)-901-7055; FAX (717)-901-7059; email ycheng@centuryeng.com

ABSTRACT

A stream restoration plan near the headwaters of the Swatara Creek was implemented to reduce the acidity and dissolved metals associated with coal mine drainage. The plan has been in effect since 1995, though various components of the plan have been phased in over several years, the last of which was installed in 2002. Specific stream restoration components included limestone channels and diversion wells, anoxic and oxic limestone drains and constructed wetlands. The stream data selected for the analysis includes: daily mean flow, daily pH value, daily specific conductance, and daily water temperature. Low flow and high flow are predicted to have significant effects on acidity reduction. An autoregressive model is used to study trends associated with daily specific conductance and daily pH values. The prediction model, based on current effectiveness derived from available data, can provide future benefit to those responsible for the development or refinement of similar restoration plans.

INTRODUCTION

This study evaluates the long term effect on stream water quality after the stream restoration plan has been installed. Daily data can be converted into a time series model containing water quality characteristics such as pH value, specific conductance measured at 25^{o}C, and water temperature. Stream flow is the driving force that carries the elevated acidity and high level metals downstream. Thus, the correlation between stream flow and pH value, as well as the other water quality parameters such as specific conductance and stream water temperature, are developed. In using the correlated values, the daily data (stream flow, pH value, specific conductance, and temperature) are not treated as independent and random. Therefore, an autoregressive model is applied to work with the correlated values. Since the restoration plan was implemented in phases over several years, the time-series record has been affected by plan maturation. Thus, the recorded daily data should become a non-stationary time-series. For this non-stationary time series, an unsteady term is included in the autoregressive model.

STUDY SITE

Northern Swatara Creek is a perennial stream and one of the headwaters for the Swatara Creek in eastern central Pennsylvania. The Northern Swatara Creek watershed has a contributory area of 43 square miles. The land use in the Northern Swatara Creek watershed is comprised of large forest, small townships, some spread farms, and extensive areas of abandoned coal mining. In the watershed, coal mine drainage from abandoned mines was the primary cause of stream pollution. From 1995 to 2002, a stream restoration project (PADEP, 2002) has been implemented in phases. At that time, USGS gauge stations were installed and monitored to record stream flow and stream water quality data. Some data records were discontinued after 2003, but some records continued until 2007. The data from two USGS gauge stations was used in this study. One USGS gauge station is at Site C3, which is gauge USGS 0157155014 (USGS web site, 2008) in Newtown, Schuylkill County. The other gauge station is at Ravine (USGS web site, 2008), which is gauge USGS 01571820 in Ravine, Schuylkill County. Site C3 is approximately 6 miles upstream from Ravine.

The Northern Swatara Creek has been contaminated with high levels of metals and elevated acidity due to coal mine drainage. Since 1995, several components of the stream restoration plan, including limestone channels, limestone diversion wells, anoxic limestone drains, oxic limestone drains, and constructed wetlands, have been implemented within the watershed. The project was completed in 2002.

GRAPHICAL VIEW ON THE SELECTED DATA FOR THE STUDY

The selected records, shown on Figure 1 and Figure 2 for Site C3, as well as Figure 3 and Figure 4 for Ravine, are used to study the change in stream water quality. The maximum time span represented by the available data through the implemented phases is about 10 years. The 1996-1997 dataset is the earliest result available. The 2002-2003 dataset represents implementation of the final phase for the plan and a point when some water quality data collection at Site C3 was discontinued. The 2006-2007 dataset represents the last available records for the gauge station at Ravine.

By visual inspection of Figure 1, the record shows that the pH value at the troughs is synchronous with the stream flow at the peaks. This relationship means the acidity is elevated when the flow increases. Also according to Figure 1, the specific conductance increases when the stream flow decreases but is synchronous with the increased pH value. The stream water temperature cycles with the seasonal weather, but it does not rhythmically change with the stream flow. A similar phenomenon occurs with the datasets from 2002-2003 and 2006-2007 (see Figures 2, 3, and 4 in the next pages).

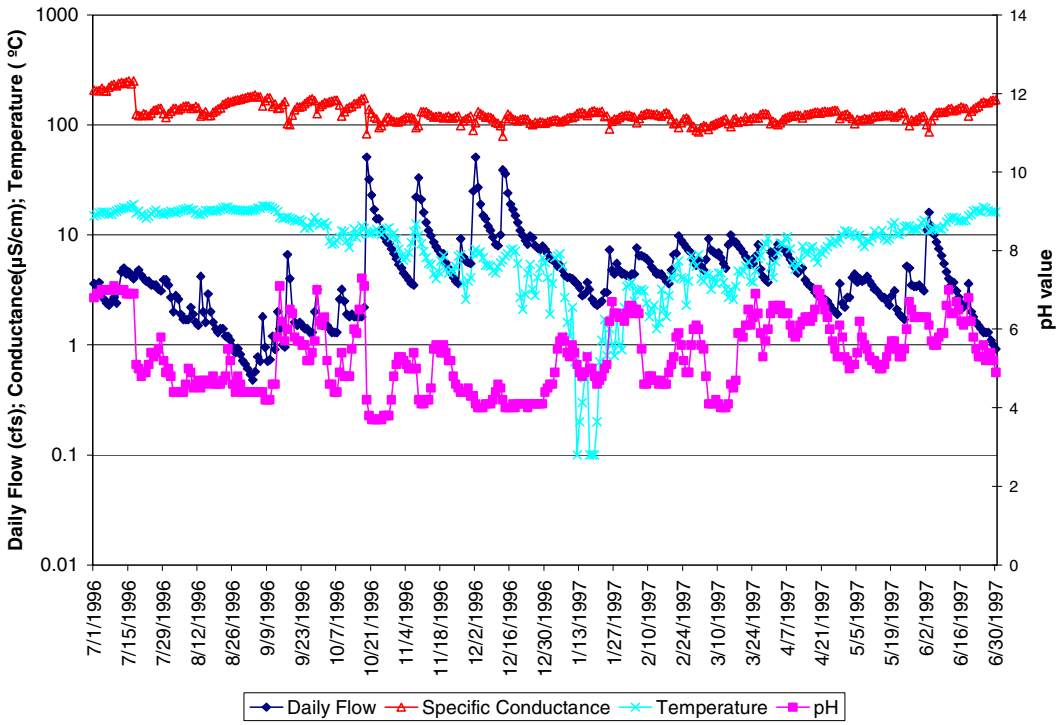

Figure 1 Daily data of Site C3 from July 1, 1996 to June 30, 1997

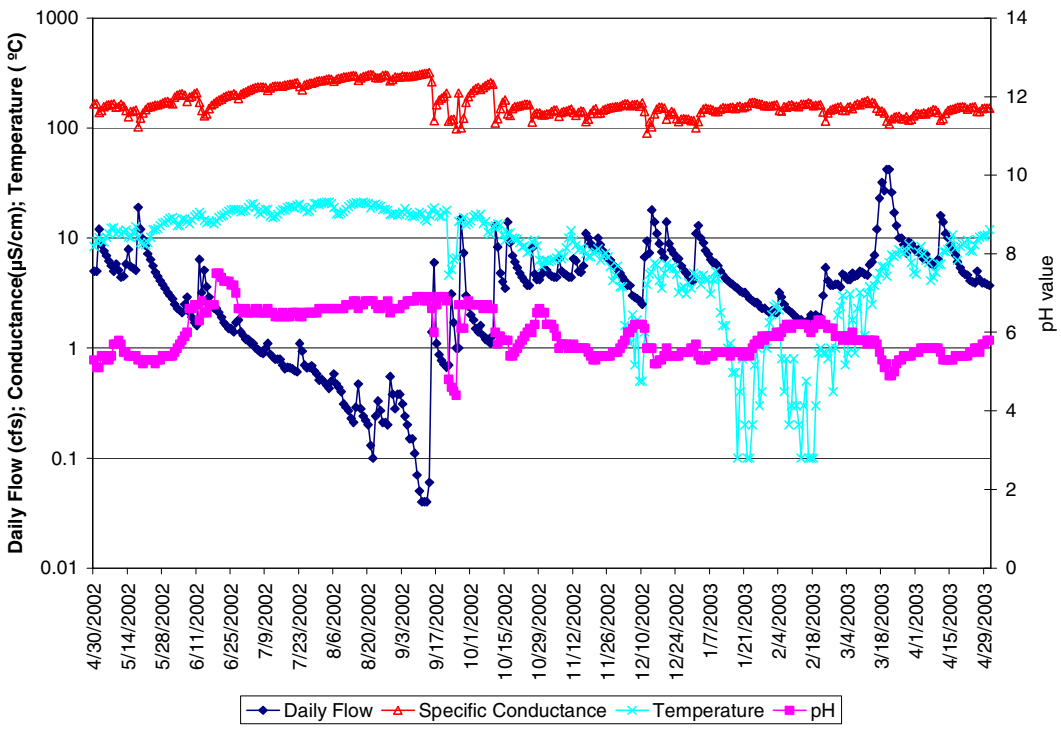

Figure 2 Daily data of Site C3 from April 30, 2002 to May 1, 2003

For Site C3, it is graphically indicated that the variation in pH values for 2002-2003 shown in Figure 2 are less than the variation for 1996-1997 shown in Figure 1. That means the plan has been working well to stabilize the pH value in the

stream although the stream flow exhibited greater fluctuation in 2002-2003. The draught season in the summer of 2002 sustained a long period of low flow, so the pH values only varied within a small range from 6.5 to 6.8 (see Figure 2).

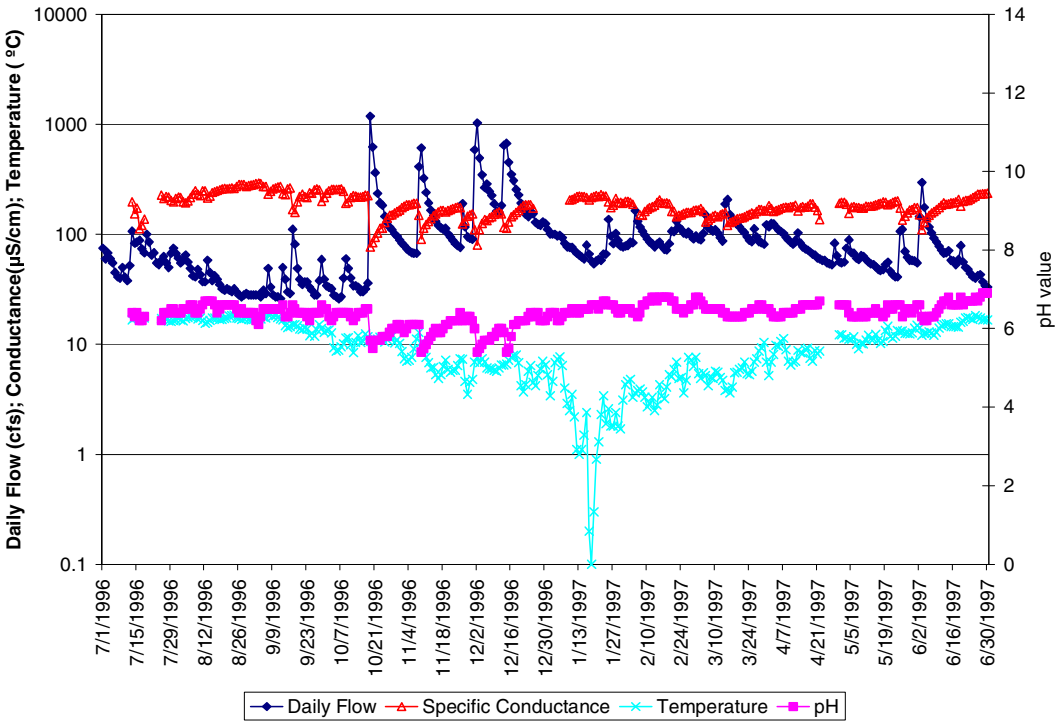

Figure 3 Daily data of Ravine from July 1, 1996 to June 30, 1997

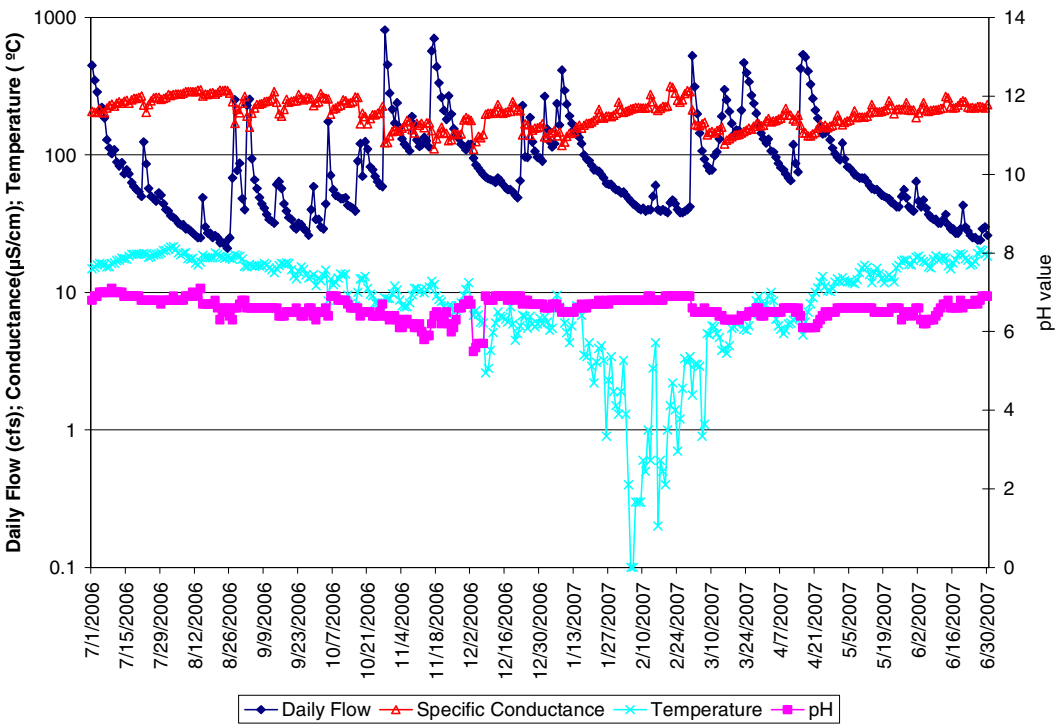

Figure 4 Daily data of Ravine from July 1, 2006 to June 30, 2007

For the site at Ravine, it is graphically indicated that the pH values shown on Figure 4 exhibit less variation when compared with the pH values shown on Figure 3. This observation regarding pH value is similar to what is seen at Site C3. However, the specific conductance shown on Figure 4 is larger than the one shown on Figure 3, which is a similar observation for the specific conductance shown on Figures 1 and Figure 2.

CROSS-CORRELATION COEFFICIENTS

The cross-correlation coefficient is used to assess if two time-series models are correlated to some extent which describes the dependence of one set of data on the other. In this study, the cross-correlation coefficient is defined as

$$R_{xy} = \frac{C_{xy}}{S_x S_y} \quad \text{(EQ.1)}$$

In EQ.1 S_x and S_y are the estimated standard deviations of the X_t and Y_t time-series, respectively. The cross-covariance is $C_{xy} = \frac{1}{N}\sum_{t=1}^{N}(X_t - \overline{X})(Y_t - \overline{Y})$. The variable X_t is the daily flow and the variable Y_t is one of the water quality parameters, such as pH value or specific conductance (SC). The mean value for each time-series X_t and Y_t is $\overline{X}$ and $\overline{Y}$, respectively. Based on EQ.1, the cross-correlation coefficients are computed and summarized in Table 1.

Table 1. Cross-correlation Coefficients for Flow and pH, as well as for Flow and SC

Gauge Name	Site C3		Ravine		
Period	1996-1997	2002-2003	1996-1997	2002-2003	2006-2007
$R_{\text{Flow pH}}$	-0.19	-0.75	-0.82	-0.65	-0.37
$R_{\text{Flow SC}}$	-0.57	-0.92	-0.93	-0.88	-0.79

The negative cross-correlation coefficients shown in Table 1 indicate that an increased daily flow will have both decreased pH value and specific conductance on the same day. The negative cross-correlations also verify the flow peaks and the pH troughs occurred at the same time.

TIME-SERIES AND STOCHASTIC ANALYSIS

The set of stream gauge records consists of a series of observations for the stream quality after stream restoration plan components were implemented. The observed data was modeled and the study results were successful in quantifying the improvement of the stream quality. Also, the developed stochastic model based on

actual data can be used to predict improvement or impairment of the stream water quality.

The daily data was not treated as independently random but rather as auto-correlated. Thus, a time-series analysis was appropriately applied in this study in order to consider the autocorrelation between the individual daily data. To predict the change in water quality due to the plan, an autoregressive model with a non-stationary term *kt* was introduced as follows.

$$X_t = m + kt + \{\ [\sum_{i=1}^{p} a_i X_{t-i}] + e_t\ \}\ \text{(EQ.2)}$$

In EQ.2, X_t is the observed data at the time t, X_{t-i} is the observed data at the previous time t-i, m is a constant, k is the time rate change, a_i are autoregression coefficients of AR (p), and e_t is the random error with zero mean and constant variance. For this study, the order p of the autoregressive model AR (p) is limited to 2 although a higher order p can be used. The e_t in EQ.2 represents randomness and uncertainty as a part of the series data.

Three different sets of the coefficients of EQ.2 are determined by the Least Squares Method to fit the USGS daily record within 1996-1997, 2002-2003, and 2006-2007, respectively.

COMPUTED COEFFICIENTS OF THE MODEL

The stream restoration plan is expected to have effectively changed the stream water quality. The changes can be detected if the coefficients in EQ.2 are significantly changed during the years. Using the stochastic model, EQ.2, the validated coefficient changes can be used to quantify the improvement of the water quality. Then the EQ.2 with the fitted coefficients is used as a stochastic model to predict the trend of water quality in the stream channel. The computed coefficients are summarized in Table 2 for the pH time-series and in Table 3 for the specific conductance (SC) time-series in different years.

Table 2. Computed Coefficients Based on Time-Series Data of the pH

Gauge Name	Site C3				Ravine			
Coefficients	m	k	a_1	a_2	m	k	a_1	a_2
1996-1997	0.55	2.7E-4	1.14	-0.25	0.63	9.7E-5	1.01	-0.11
2002-2003	0.56	-2.4E-4	0.892	0.02	0.71	-4.0E-5	0.86	0.04
2006-2007	No data	No data	No data	No data	0.95	-4.9E-5	0.88	-0.03

For $AR(2)$ coefficients, a_1 and a_2 are constrained so that $-1 < a_2 < 1$, $a_1 + a_2 < 1$, and $a_2 - a_1 < 1$.

Table 3. Computed Coefficients Based on Time-Series Data of the SC

Gauge Name	Site C3				Ravine			
Coefficients	m	k	a_1	a_2	m	k	a_1	a_2
1996-1997	15.1	-8.2E-3	0.80	0.09	23.6	-0.019	0.97	-0.08
2002-2003	15.3	-0.018	0.87	0.06	16.6	-0.015	1.02	-0.09
2006-2007	No Data	No Data	No Data	No Data	23.6	-0.014	0.90	5.6E-4

For $AR(2)$ coefficients, a_1 and a_2 are constrained so that $-1< a_2<1$, $a_1+ a_2 <1$, and $a_2- a_1<1$.

As an example, the coefficients of m, k, and AR (2) of Site C3 shown in Table 3 are used to simulate the daily specific conductance. The results are shown in Figure 5 and Figure 6, respectively and compared to the 1996-1997 and 2002-2003 records of Site C3.

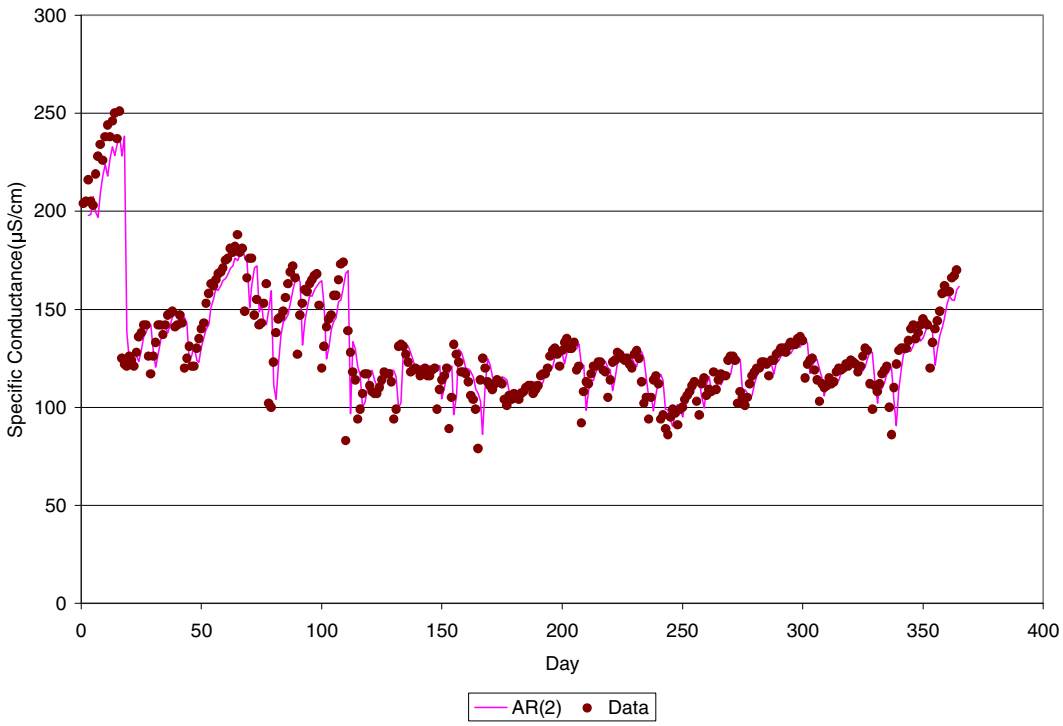

Figure 5 Simulation Result of the Daily Specific Conductance at Site C3 for 1996-1997

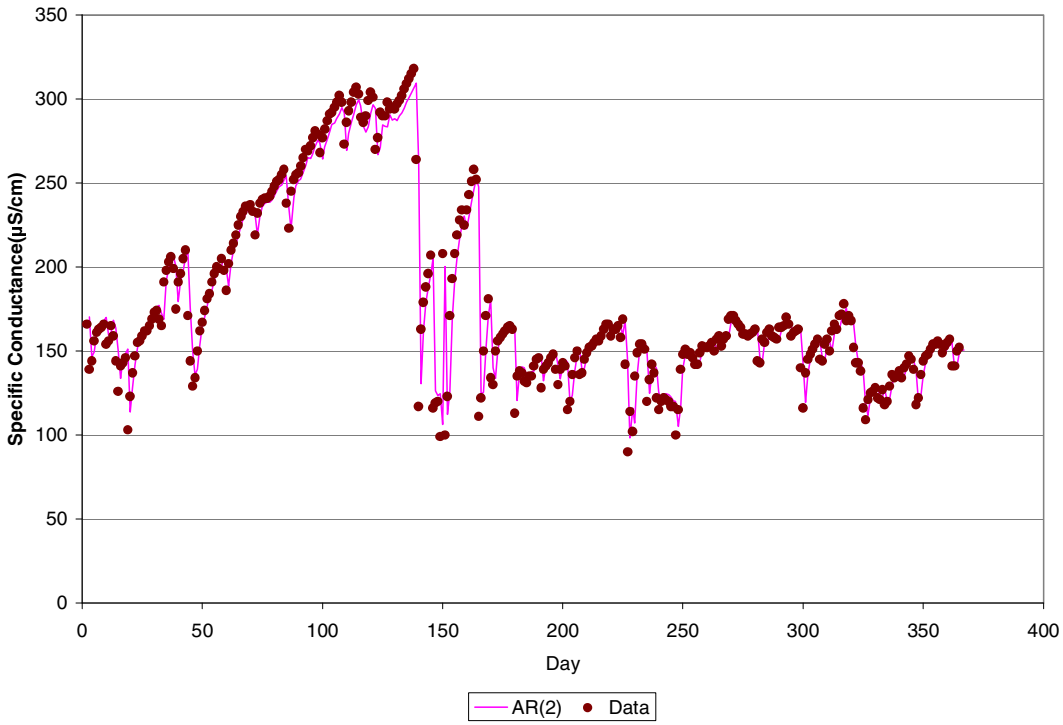

Figure 6 Simulation Result of the Daily Specific Conductance at Site C3 for 2002-2003

Based on the results shown on Figure 5 and Figure 6, it is concluded that the model coefficients in the simulation represent the stream specific conductance very well.

THE EXPECTED TREND OF THE WATER QUALITY IMPROVEMENT

A further mathematical operation on EQ.2 is shown as follows to compute the steady state *K* values, which are statistically expected trend coefficients. Let

$$E[X_t] = M + Kt \text{ , EQ.3,}$$

where *M* is the expected initial constant at the time *t*=0 for a specific year, and E [ ] stands for "Expected Value of [ ]". Then, apply the operator E[ ] on EQ.2 to get EQ.4.

$$E[X_t] = m + kt + \sum a_i E[X_{t-i}] = m + kt + \sum a_i (M + K(t-i)) \quad \text{EQ.4}$$

Rearranging the coefficients for 1 and *t* in EQ.4 and equating EQ.3 to EQ.4, the coefficients of *M* and *K* are solved as follows:

$$M = \frac{m - K\left(\sum i a_i\right)}{1 - \sum a_i} \qquad K = \frac{k}{1 - \sum a_i} \quad \text{EQ.5}$$

Using EQ.5 and the values shown in Table 2 and Table 3, the expected trend coefficient *K* for different years and different gauges are computed and shown in Table 4 and Table 5.

Table 4. The Expected Constant *M* and Trend *K* for pH

Gauge Name	Site C3		Ravine	
Expected Coefficient	*M* for pH	*K* (1/day)for pH	*M* for pH	*K* (1/day)for pH
1996-1997	4.81	2.4E-3	6.23	9.6E-4
2002-2003	6.54	-2.8E-3	7.05	-4.0E-4
2006-2007	No data	No data	6.65	-3.4E-4

Table 5. The Expected Constant *M* and Trend *K* for SC

Gauge Name	Site C3		Ravine	
Expected Coefficient	*M* (μS/cm) for SC	*K* (μS/cm-day)for SC	*M* (μS/cm) for SC	*K*(μS/cm-day) for SC
1996-1997	144	-0.078	219	-0.171
2002-2003	231	-0.267	269	-0.235
2006-2007	No data	No data	231	-0.138

For Site C3 and Ravine, the expected trend coefficient *K* of the time-series in different years is presented in the third and last column of Table 4 and Table 5. A negative value for *K* indicates that the expected trend is downward. A trend showing a decreasing pH value is indicated by the negative *K* values in 2002-2003 and 2006-2007 (see the third and last column of Table 4), but it has a positive trend in 1996-1997. The decreased pH value means that acidity will be elevated in the coming years. Thus, the cause for this prediction can be investigated by inspecting the installed components of the restoration plan. The non-functioning components may need to be replaced; for example, a new limestone channel may need to be installed, or the constructed wetlands and ponds may need to be cleaned out by removing the build up of sediment.

CONCLUSIONS

The negative cross-correlation coefficients show that an increase in daily flow can elevate the acidity of the stream. Conversely, a decrease in daily flow can reduce the stream's acidity.
