The purpose of this study was to examine a series of stormwater wetlands and (1) evaluate the performance of undersized practices typical of retrofits and (2) document any marginal improvements in pollutant removal provided by wetlands in series.

Site Description

The Dye Branch Stormwater Wetlands were located in the Piedmont of North Carolina in the Town of Mooresville and were constructed between the Fall of 2005 and the Spring of 2006. Complications with one of the outlet structures left the system only in partial operation until December 2006. The wetlands serviced a watershed with an estimated area of 12.5 ha (31 acres), 60% of which was impervious. This does not include the local watershed draining directly to the BMP, which was estimated to be approximately 1.3 ha

(3.3 acres) excluding the BMPs themselves. This adjoining watershed was primarily forested or grassed, and likely only produced a small percentage of the total runoff that the wetlands received during most storm events. The composite curve number for the watershed was estimated to be 87.5. Soils in the watershed were primarily Cecil fine sandy loam.

Stormwater runoff from the watershed drained into a large concrete diversion structure where a 15.2-cm (6-inch) orifice routes stormwater flows up to 133.1 l/s (4.7 cfs) to the wetland (Figure 1). Using a rational method analysis on the watershed, this corresponded to an estimated rainfall intensity of approximately 0.5 cm/hr (0.2 in/hr) (Kuichling 1889, Lloyd-Davies 1906, Mulvaney 1851). During storms which produced flows higher than this value, a concrete bypass weir was overtopped and excess runoff proceeded down an unnamed tributary and in to Dye Branch; the additional hydraulic head on the diversion orifice during overtopping events resulted in increased flow to the wetlands. Debris accumulation in the diversion structure resulted in a minor reduction of pollutants, particularly sediment, entering the wetlands.

Figure 1: Orifice Plate in Diversion Structure Used to Route Flow to Wetlands

Due to topographical and space limitations, the BMP was designed as a treatment train of three wetland cells (Figure 2). The cells had a combined area of approximately 0.33 ha (0.81 acres). The estimated runoff volume during the 2.54-cm (1-inch) storm was estimated by the discrete curve number method (NRCS 2004) to be approximately 1416 m^3 (50,000 cf). Based on the final BMP design, only 575 m^3 (20,300 cf) was expected to be retained by the wetlands. The cells were hydraulically separate, which allowed individualized flow monitoring.

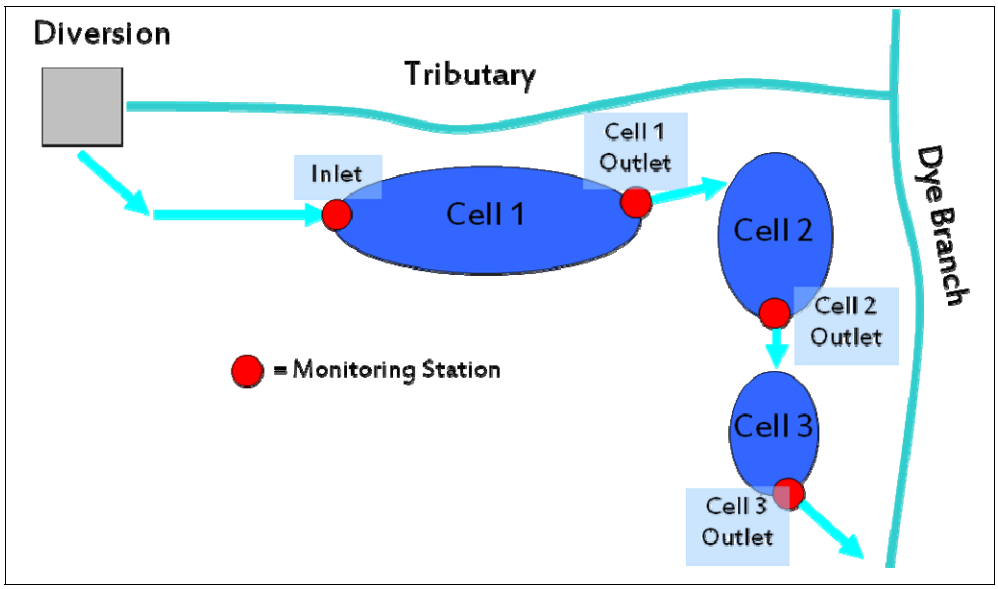

Figure 2: Schematic of Dye Branch Wetlands

Wetland cell 1 was the largest of the three cells (0.19 ha (0.48 acres)). The design included a large forebay (0.02 ha (0.05 acres)). A flashboard riser was used as the outlet of the cell, with two 5.08-cm (2-inch) orifices controlling the normal pool and a 1.16 m (3.8 ft) weir bypassing excess inflow volumes to cell 2. Approximately 23.5 cm (9.25 inches) of freeboard were present between the normal pool and the bypass weir, allowing a design storage volume of 382 m^3 (13,500 cf). However, due to the subsoils of the wetland infiltrating more water than expected, the actual pool of the wetland was frequently lower than the design normal pool, providing more volume storage than anticipated.

Wetland cell 2 was approximately 0.07 ha (0.18 acres), with a forebay which covered 0.01 ha (0.02 acres) of the surface area of the wetland. A flashboard riser was used as the outlet of the cell, with two 5.08-cm (2-inch) orifices controlling the normal pool and a 1.16 m (3.8 ft) weir bypassing excess runoff volumes. Approximately 30.5 cm (1 foot) of freeboard was present between the normal pool and bypass weir, allowing a design storage volume of 193 m^3 (6800 cf). Inter-event infiltration resulted in additional storage in this wetland as well.

Wetland cell 3 was approximately 0.06 ha (0.15 acres), with a 0.004-ha (0.01-acre) forebay. A flashboard riser was used as the outlet of the cell. No detention was present in the cell, as flow was controlled by a 1.16 m (3.8 ft) weir with no drawdown orifice. The normal pool was consistently below the control weir, resulting in some storage occurring during events. A set of three sediment baffles were installed during the construction of the system to be removed after the site had stabilized. Although the site was sufficiently stabilized, these baffles were in place at the start of the monitoring study, and were left in place as to not disturb the cells during the study.

Monitoring Description

Flow monitoring

Flow was measured at the inlet of cell 1 and the outlet of all three wetland cells (Figure 2). After passing through the diversion structure, stormwater runoff was routed into a large concrete structure outfitted with a 120 degree v-notch weir. An ISCO 730 bubbler module was used to measure the hydraulic head on the weir. Standard equations were used to calculate flow using these measurements. Stage-discharge relationships were generated for the orifice / weir combinations at the flashboard riser outlets of wetland cells. ISCO 730 bubbler modules were used to calculate the stage at each riser during storm events, these measurements were used to calculate flow. Due to some questionable flow data, volume and load calculations were not made. However, water quality analyses aided by these data were deemed valid as hydrographs from each location were consistent with the operation of the system.

Water Quality Monitoring

Water quality samples were taken at each flow monitoring point, where monitored hydrographs were adequate to trigger flow weighted samples. A sample was only considered for analysis if at least 5 aliquots were taken during a given event. Samples were collected using ISCO Avalanche™ refrigerated, automatic samplers and were normally collected within 24 hours of a rain event at the inlet and at the outlet of the wetland cells which had substantially drained. For wetland cells which had not substantially drained after 24 hours, a return visit was made to retrieve the samples. During some events, it was necessary to collect the samples prior to the event completely passing through the system due to sample hold times. Samples were preserved as necessary and shipped to an NCDWQ laboratory where they were analyzed for turbidity, total suspended solids (TSS), total Kjeldahl nitrogen (TKN), total ammoniacal nitrogen (TAN), nitrate – nitrite (NO_2-NO_3), and total phosphorus (TP). Total nitrogen (TN) was calculated by adding the concentrations of TKN and NO_2-NO_3. Organic nitrogen (ON) was calculated by subtracting TAN from TKN.

Statistical Analysis

Overall, 27 storm events were monitored at the site; however, sampler power failures and inadequate volumes for analyzing all constituents were sometimes experienced. Further, to provide balanced analysis of the system, only storms where samples were collected from all monitoring points were used for data analysis. Between 10 and 15 paired samples with at least 5 aliquots were collected for each pollutant across the seasons (Table 1).

Prior to in-depth statistical analysis, the data were checked for normality using the Kolmogorov-Smirnov test (REFERENCE). The results of this analysis were verified using box plots and histograms of the data. The data were found to have various distributions. Most data were normally distributed; however, some required log transformation and some could not be matched to any distribution. To maintain consistency in the analyses, and due to the small number of paired samples taken for each pollutant, a non-parametric Wilcoxon signed-rank test (WSR) was chosen to determine the statistical significance of the comparisons being made. Using this non-parametric

analysis allowed evaluation without concerns over the distribution of the data. Efficiency ratios were used as a metric for the amount of pollutant removal provided by each wetland cell. Since flow paced samples were collected, each pollutant measurement from a given sample event was considered to be an event mean concentration (EMC). The following equation was used to determine the efficiency ratio:

$$ER = 1 - (\frac{Average_Outlet_EMC}{Average_Inlet_EMC})$$

Results and Discussion

Performance of Undersized Wetland

As retrofit BMPs are commonly constrained by space in urban environments, data evaluating the performance of undersized BMPs such as wetlands are desirable for use in watershed management. Wetland cell 1 was sized to capture approximately 27% of the volume that would leave the treatment watershed during a 2.54-cm (1-inch) water quality rain event. The actual volume captured was somewhat larger because of frequent periods where the water level in the wetland dropped below the normal pool. This is common in some constructed wetlands (Lenhart and Hunt (in review), Line et al. 2008) and likely improves hydraulic performance beyond the design.

Table 2 shows the influent and effluent EMCs for the water quality parameters at wetland cell 1. To provide some comparison for water quality performance analysis, these values are compared to stormwater wetland median effluent concentrations from the ISBD (GCWWE 2008). Although influent concentrations were similar to those exiting stormwater wetlands in the ISBD (GCWWE 2008), effluent values were lower than influent values for each parameter, resulting in significant reductions ($p<0.05$) and ERs of at least 0.39 for each. Further, mean influent concentrations of TKN, NO_2-NO_3, TN, and TP were similar to those determined for eight parking lots in North Carolina by Passeport and Hunt (2009). Although relatively low influent concentrations can result in artificially low efficiency ratios, the undersized wetland cell 1 still performed well. Effluent concentrations at cell 1 were less than those in the ISBD (GCWWE 2008) for each pollutant, indicating good performance relative to other stormwater wetlands. These data indicate that undersized wetlands may provide water quality improvements when space is limited in retrofit designs and may be beneficial in watershed management plans in urban watersheds.

Table 2: Wetland Cell 1 Efficiency Comparisons

Pollutant	Median Effluent EMCs of Wetland Basins in the ISBD – mg/L (reference)	Median Inlet Concentration (mg/L)	Median Cell 1 Outlet Concentration (mg/L)	Efficiency Ratio
TSS	19	80.5	13.5	0.83
TKN	1.09	1.25	0.765	0.39
NO_2-NO_3	0.2	0.4	0.14	0.65
TN	1.21	1.68	0.865	0.49
TP	0.58	0.26	0.11	0.58

Performance of Wetlands in Series

The sampling scheme at the Dye Branch Stormwater Wetlands allowed an analysis of wetlands in series by comparing EMCs and efficiency ratios for the three wetland cells. Table 3 shows the EMCs of pollutants at each monitoring point. Pollutant concentrations decreased at each sequential monitoring point for most pollutants, although slight increases were noted between the wetland cell 2 outlet and the wetland cell 3 outlet for ON and TKN. The EMCs from each cell were lower than concentrations presented in the ISBD (GCWWE 2008). It should be noted that EMCs for ON at the outlet of each wetland cell were very similar at 0.68, 0.63, and 0.64 mg/L for wetland cells 1, 2, and 3, respectively.

Table 3: Pollutant EMCs for Each Monitoring Point at DBW

Pollutant	Inlet	Cell 1 Outlet	Cell 2 Outlet	Cell 3 Outlet
TSS	77	12	11	9
TP	0.31	0.12	0.12	0.10
TN	1.74	0.84	0.74	0.72
ON	1.00	0.68	0.63	0.64
TAN	0.28	0.04	0.03	0.03
TKN	1.30	0.73	0.66	0.67
NO_2-NO_3	0.44	0.14	0.08	0.07
Turbidity	39	15	14	10

Differences in wetland cell performance can be further explored with the efficiency ratios shown in Table 4. These data reemphasize data in Table 3, as efficiency ratios are positive for most pollutants in each wetland cell; however, from wetland cell 2 to wetland cell 3, there are minor increases in ON and TKN. Pollutant efficiency ratios generally experience diminishing returns as stormwater passes through each wetland cell, although efficiency ratios for TSS, TP, and turbidity increased in wetland cell 3. This is potentially due to the sediment baffles still in place in wetland cell 3, which could impact the concentrations of these particle associated pollutants. It should be noted that none of these increases in wetland cell 3 were statistically significant ($p<0.05$). Further, only wetland cell 1 provided statistically significant reductions ($p<0.05$) for all pollutants.

Only nitrogen species were significantly reduced between the outlet of cell 1 and the outlet of cell 2.

Table 4: Efficiency Ratios for Each Wetland Cell

Pollutant	Inlet to Cell 1 Outlet	Cell 1 Outlet to Cell 2 Outlet	Cell 2 Outlet to Cell 3 Outlet
TSS	***0.84***[1]	0.11	0.18
TP	***0.62***	0.03	0.11
TN	***0.52***	***0.12***	0.03
ON	***0.32***	***0.07***	-0.02
TAN	***0.85***	0.26	0.13
TKN	***0.44***	***0.09***	-0.01
NO_2-NO_3	***0.67***	***0.47***	0.12
Turbidity	***0.62***	0.09	0.24

[1]: Significant Differences are italicized and bolded

A number of processes in wetlands affect nitrogen species, resulting in a complex cycle. Microbial transformations change ON to TAN, TAN to NO_2-NO_3, and NO_2-NO_3 to nitrogen-based gasses, including N_2. Simultaneously, various nitrogen species are taken up by plants and microorganisms, becoming organic biomass. Uptake is not considered a permanent removal mechanism, as plant and microbe die-off can lead to a reintroduction of nutrients into the water column (Kadlec and Knight 1996). These processes were likely exhibited in Table 4 above, as wetland processes in each cell continued to remove TAN and NO_2-NO_3 as evidenced by positive ERs for each wetland cell for these nitrogen species. However, reduced or negative ERs were noted for ON and TKN (which includes ON) as stormwater passed through the system. Similar observations were made by Lenhart and Hunt (in review) in a study of a stormwater wetland in the coastal plain of North Carolina.

Conclusions

A system of three wetland cells in series was monitored in this study. Data from the first wetland cell showed that both sediment and nutrients were significantly removed ($p < 0.05$) by a wetland sized only to hold 27% of the 2.54-cm (1-inch) design storm volume. This study indicates that undersized wetlands are able to improve water quality in urban watersheds, which is important when assessing the benefit of installing retrofit stormwater BMPs where space is limited.

The marginal benefit of stormwater BMPs in series was also evaluated in this study. At least 80% of the total concentration change for a given pollutant occurred within the first wetland cell. Further, only the first wetland cell significantly ($p<0.05$) reduced all pollutants tested in the study. Diminishing returns were generally observed in the system, but the ERs associated with nitrogen species continually declined through the wetland cells. TSS, TP, and turbidity showed a minimal, non-significant ($p<0.05$) increase in removal efficiency in wetland cell 3. Based on this study and supporting assertions by others (USEPA 2002, ASCE – WEF 1998, NCDENR 2007), placing BMPs of a similar type in series is not a beneficial management strategy when using effluent concentrations or efficiency ratios as a metric. Percent removal is not constant from BMP to BMP in a

series. While calculations of percent removal may be simple to understand, they should not be exclusively used to evaluate stormwater BMP performance. This is especially the case for systems which have low influent pollutant concentrations, such as the subsequent stormwater wetlands in series

ABSTRACT

The dynamics of the urban landscape are ever changing. As the population grows, urban sprawl gathers momentum and the path for a drop of rainfall changes complexion. The physical processes involved from when rain falls until when it reaches a treatment plant or waterway are highly non-linear. In larger urban catchments, these non-linearities have largely been ignored and linearized through development of lumped or semi-distributed models. This linearization is often used to overcome the sheer size and complexity of the urban catchments. The answer to the question of how much network complexity should be included in a model has been pre-empted by the application of conduit skeletonization and subcatchment aggregation. These simplification techniques are not without their dangers and may introduce bias into the predicted hydrographs. This paper provides a review of modeling approaches that are typically undertaken in modeling large urban catchments, highlighting their advantages and disadvantages. The majority of the approaches involve the application of hydrologic models that require calibration and significant knowledge of hydrologic inputs. In many cases the assessment of existing urban hydrologic systems is hindered by the absence of input data and/or calibration data. With this in mind, an innovative approach to modeling large urban hydrologic systems is presented. This approach builds on the fundamentals of the geomorphologic instantaneous unit hydrograph (GIUH) that was developed by Rodriguez-Iturbe and Valdes in 1979, which has been successfully applied to natural watersheds over the past three decades. Application of GIUH has evolved such that it can be applied to ungauged natural watersheds with knowledge of as little as the watershed area and layout of the stream network. The approach proposed in this research, in a similar manner, uses the morphology of the sewer system to route flow through the network. Excess rainfall is determined using the Green and Ampt method based on the physical characteristics of the underlying soils. The kinematic wave approach is used, in conjunction with stochastically generated parameters describing relevant subcatchment and sewer characteristics to establish probability distribution functions (PDF) for overland (both pervious and impervious) and sewer travel times. The PDF's of the travel time and excess rainfall are convoluted to generate an outflow hydrograph. This approach maintains the non-linearity of the physical processes in highly urbanized catchments and allows model development in the

absence of detailed input and calibration data. Through application of this approach an improved understanding of the physical process can be achieved.

INTRODUCTION

The dynamics of the urban landscape are ever changing. Development has seen swamp lands turn into pastures, pastures into corn fields, and corn fields into concrete. As the population grows, urban sprawl gathers momentum and what was once pervious may inevitably become impervious. So as the ground beneath our feet changes complexion so does the path for a drop of rainfall. In order to be able to trace this path it is imperative that the physical processes associated with its travel be better understood. The primary objective of this research is to improve the understanding and representation of the physical processes in highly urbanized catchments.

Urbanized catchments have changed complexion significantly over the past 20 years and will continue to do so into the future. At the simplest level urban consolidation and urban sprawl have seen the imperviousness of urban catchments increase. More complex landscapes are being developed to cater to low impact development and include stormwater best management practices. Sewer systems built in the 20th century often have insufficient capacity to carry post-development flows and are constantly being retrofitted or replaced. Combined sewer systems are seldom built in preference to separated stormwater and sanitary sewer systems. Existing CSO systems that cannot be easily replaced are being intercepted by complex deeper tunnel systems in order to prevent overflows polluting adjacent rivers and waterways in large storm events. All of these changes are unique in their own way but each impacts the behavior of water as it travels through the urban landscape. The question is how one represents the intricate physical processes that are associated with modern urban landscapes?

In order to be able to represent the physical processes one must first understand their high degree of non-linearity. As rain falls, runs off a roof, down a gutter, through a rain garden, onto the street, along a gutter, into an inlet connected to a storm sewer, through that sewer and eventually to a treatment plant or water way, one does not render such a process to be linear. However, traditional approaches to representing such behavior have done exactly that ignoring this obvious non-linearity in the physical processes. In this research the approach that is presented maintains this non-linearity, ensuring a sound fundamental representation of the physical processes.

Since the advent of computer technology the representation of urban catchments has fallen on computer models. Representation has evolved from simple back-of-the-envelope rational-method calculations to more sophisticated DOS based models like ILLUDAS to complex Windows based models capable of solving the full St. Venant equations like InfoSWMM. There are now a plethora of hydrologic simulation packages (including SWMM, HEC-HMS, MOUSE, InfoWorks, etc) that are capable of modeling urban stormwater and combined sewer overflow systems and these are commonly used in practice. Although these models are capable of modeling these systems, there are two key factors that hinder their use in modeling large urban systems. The first problem is that each of the models mentioned require calibration,

and for the most part calibration data are not available. Secondly, the large amount of input data required for these models are often unavailable and are uncertain when they are available. The input data required for the commercially available hydrologic models mentioned above includes:

- Subcatchment data: area, percent imperviousness, slope, length, roughness, soil characteristics, depression storage etc.
- Inlet data: type, size, rating curve etc.
- Pipe data: size, length, roughness, upstream and downstream invert, etc.
- Junction data: surface elevation, invert etc.

For many large urban catchments in densely populated areas, sanitary and storm sewer infrastructure was installed over 50 years ago when documentation was not what it is today. As such this critical input information simple does not exist. In some cases, the only available information is the layout of the sewers themselves. Typically, engineers make simplifying assumptions so that the commercially available simulation packages may be used to model the network. Cantone and Schmidt (2008) explored a number of the commonly employed simplification techniques, including subcatchment aggregation and conduit skeletonization. Tests on a simple CSO network showed that such simplification techniques introduce error in the calculated outflow hydrograph and hence caution must be used in applying them.

Given that the existing models are unable to overcome the problems at hand; this research provides the opportunity to develop a hydrologic model that can be applied in ungauged urbanized watersheds where limited input data are available.

LITERATURE REVIEW

The challenges involved in deriving such a method were met head on by Rodriguez-Iturbe and Valdes (1979) and Gupta et al (1980) when they developed the geomorphologic instantaneous unit hydrograph (GIUH) for natural watersheds. Subsequent development of the GIUH approach has allowed this model to be applied to not only ungauged watersheds, but also to watersheds lacking detailed geomorphologic information (Yen and Lee 1997). In the GIUH approach, rainfall excess is assumed to follow different paths on overland areas and in channels of different stream orders; these different paths can be described probabilistically, according to the drainage pattern to reach the watershed outlet (Yen and Lee 1997).

GIUH applied to watersheds has been the subject of much research since its inception, however little of this research has focused on its application to urban watersheds. Many papers propose different representations for the travel time of the rainfall excess, ranging from exponential (Rodriguez-Iturbe and Valdes 1979), uniform (Gupta et al 1980) and gamma (Jin 1992) distributions to those involving kinematic-wave theories (Lee and Yen 1997). Of particular relevance to this research is a paper published by Yen and Lee (1997) that showed that knowing as little as the watershed area and stream order of each reach a representative unit hydrograph for a

watershed could be obtained using other data acquired from large-region averaged values.

The application of the GIUH concept to urban concepts has not been studied exhaustively. Rodriguez et al (2003, 2005) have published a body of work that utilizes GIUH in the urban setting. Rodriguez et al 2003 showed that the plethora of information contained in Urban DataBanks (UDB) could be used in combination with the GIUH concept to derive Urban Unit Hydrographs (URBS-UHs) for three urban catchments in France with surface areas ranging from 18 to 180 ha. In their formulation Rodriguez et al (2003) make a number of key assumptions:

- Water flows over impervious surfaces and in sewer networks dominate the rapid response of urban catchments. In this way only impervious areas are modeled, pervious areas are ignored.
- UDB's contain enough geometric information to allow the path for the propagation of runoff to be modeled and identified.
- The flow velocity field is a spatial variable depending on the considered flow conditions and available UDB information.
- Flow can be considered a monotonic response to a rain impulse.
- Downstream segments can reasonably be considered to accept the outflow of upstream segments.
- The entire area is assumed to be covered by cadastral parcels and street surfaces. Flow is parameterized over each parcel.
- Street flooding and sewage system overflow is not allowed.
- Street gutter flow is supposed to reach a priori the sewer system at each street network intersection.
- Hydraulic behavior of inlets has been ignored.
- Street gutters are modeled as small-sized pipes (250 mm diameter).
- Hydraulic dispersion along the flow path is ignored.

The approach presented by Rodriguez et al (2003) is highly dependent on the quality and quantity of the information in the UDB. As previously mentioned this type of information is simply not available in many urban catchments. Secondly, Rodriguez et al (2003) ignore runoff from pervious areas. Runoff from pervious areas particularly for wet antecedent moisture conditions can be significant in shaping the surface runoff hydrograph.

In their 2005 paper Rodriguez et al compare the method they developed in 2003 with two other methods usually applied in natural catchments (H2U and FDTF). The three unit hydrograph determination methods make use of varying degrees of the description of drainage network morphology and their combined application requires rainfall and runoff data collected from hydrological recording devices.

Lhomme et al (2004) applied a GIS-based geomorphological routing model to the urban catchment El Batan in the city of Quito, Ecuador. Despite being described as an urban catchment the area of the catchment is some 52 km^2 and a significant portion of the network is made up of natural streams. The formulation presented by the authors

of this paper is reliant on a detailed GIS database of input information and the model is calibrated using hydrologic rainfall and runoff data.

Few researchers have formulated models utilizing morphologic approaches for developing unit hydrographs in urban areas. The model developed by Rodriguez et al (2003) is heavily reliant on detailed catchment description provided through UDB's and utilizes a number of simplifying of assumptions that distinguish it from the approach proposed herein. Similarly, the later work by Rodriguez et al (2005) and Lhomme et al (2004) present approaches that incorporate GIUH but are dependent on rainfall and runoff data and/or detailed catchment description. The approach presented in this paper is not dependant on detailed catchment parameters nor does it require the catchment to be gauged. In addition the approach presented is adaptable and potentially will be able to incorporate important hydrologic processes associated with inlets, lot scale BMP's and runoff over pervious surfaces that are not accounted for in the aforementioned approaches presented in the literature.

METHODOLOGY

The model proposed in this research simplifies the complex hydrologic processes of an urban catchment by initially considering overland surface runoff and conduit flow only. For any given rainfall hyetograph, depression storage in both the pervious and impervious areas is accounted for. For pervious areas, infiltration losses are derived using the Green-Ampt method (as described below). The overland flow for all subcatchments is sub-divided into a pervious and impervious portion with water flowing from pervious to impervious areas by default. By subtracting the depression storage and infiltration losses from the precipitation, the excess rainfall falling on the overland plane is derived for both the pervious and impervious areas. Excess rainfall along with subcatchment parameters are used to determine the overland flow travel time for a given subcatchment using the kinematic wave approach (Yen and Lee 1997).

Green-Ampt Method

Green and Ampt (1911) proposed a physically based approximation to Richard's equation that has an exact analytical solution in order to derive infiltration losses. This approach is well documented in the literature (Chow et al 1988) and so the details are not presented here. Using the infiltration rate calculated using the Green and Ampt equations, and having already subtracted depression storage, the excess rainfall for both the impervious and pervious areas may be determined using:

$$q_{L,perv}(t) = i(t) - f(t) \quad (1)$$

$$q_{L,imp}(t) = i(t) \quad (2)$$

One of the shortcomings of the Green-Ampt model is readily accessible accurate estimates of the Green-Ampt parameters such as the porosity, effective porosity, wetting front soil suction head and hydraulic conductivity. Rawls et al (1983) analyzed approximately 5000 soil horizons throughout the United States and determined average and standard deviation values of the Green-Ampt parameters for

different soil classes (sand, loamy sand, silt loam, etc.). The model presented in this paper only utilizes the expected value of the Green-Ampt parameters, however in the future the model will be adapted to account for the variability in these parameters. The variance in the Green-Ampt parameters will be utilized in a first order second moment (FOSM) analysis to determine the variance in the excess rainfall, which will in turn be used to determine a variance in the overland and conduit travel times. This will allow a more sophisticated probability-density-function, utilizing the mean and variance, to be used in Equation (28).

Travel Time Estimation

Overland Flow

Using the kinematic-wave approach it is possible to simulate the surface-runoff process using the shape, length, slope and surface condition of a subcatchment (Lee an Yen 1997). Implicit to this approach is the assumption that backwater effects are not important and that there is slope on the plane of flow.

Consider an *i*th order basin in the watershed as consisting of two rectangular overland planes as shown in Figure 1. One plane classified as pervious and the other as impervious. Assume that both planes contribute a lateral discharge into a conduit of constant cross-section and slope.

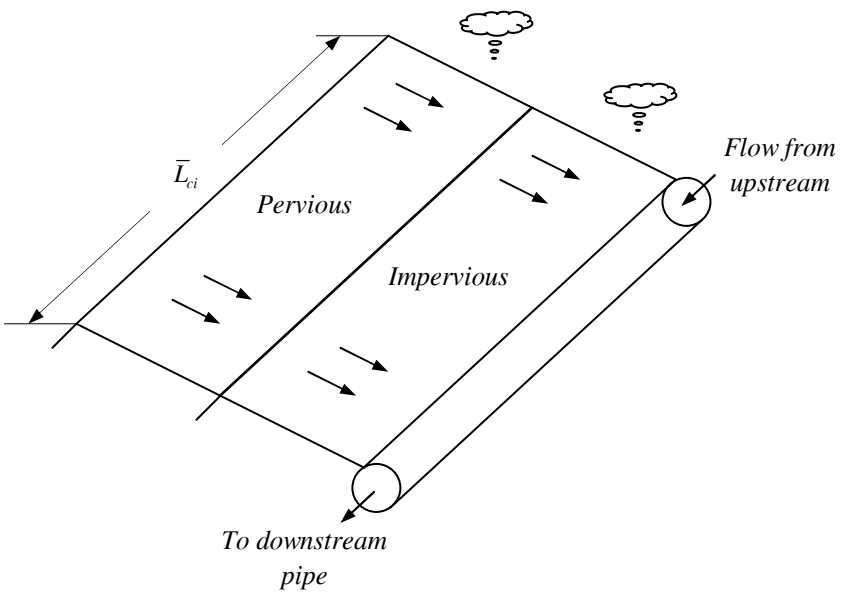

Figure 1 Schematic of surface runoff model

According to Lee and Yen (1997) the mean length of the *i*th order v-shape overflow plane can be estimated by:

$$\bar{L}_{oi} = \frac{AP_{OAi}}{2N_i \bar{L}_{ci}} \tag{3}$$

where P_{OAi} is the probability that a drop of rainfall excess will fall on an *i*th order overland flow region, A is the total area of the catchment, N_i is the number of conduits in the *i*th order, and $\overline{L}_{ci}$ is the average length of the *i*th order conduit.

This formula can be applied to both the pervious and impervious planes shown in Figure 1 using the following equations:

$$\overline{L}_{oi,perv} = \frac{AP_{OAi}}{2N_i\overline{L}_{ci}} \times (1 - \overline{imp}_i) \tag{4}$$

$$\overline{L}_{oi,imp} = \frac{AP_{OAi}}{2N_i\overline{L}_{ci}} \times \overline{imp}_i \tag{5}$$

where $\overline{imp}_i$ is the average fraction of impervious area in the *i*th order catchment.

Lee and Yen (1997) showed that the continuity equation and simplified momentum equation for the kinematic wave overland flow plane may be written:

$$\frac{\partial h_{oi}}{\partial t} + \frac{\partial q_{oi}}{\partial x} = q_L \tag{6}$$

$$q_{oi} = \alpha_{oi} h_{oi}^{\ m} \tag{7}$$

where t is time, x is the flow direction, q_{oi} is the ith order overland flow discharge per unit width, m is a constant, α_{oi} is a parameter reflecting the hydraulic characteristics of the overland flow, h_{oi} is the overland flow depth in ith order plane, and q_L is the lateral flow rate joining the main conduit. For a rectangular plane the constant m can be recognized as 5/3 and the coefficient α_o may be derived from Manning's equation:

$$\alpha_{oi} = \frac{\overline{S}_{oi}^{\ 1/2}}{n_o} \tag{8}$$

where $\overline{S}_{oi}$ is the mean ith order overland slope and n_o is the Manning's roughness coefficient for the overland plane.

Flow over the plane will increase until equilibrium is reached and the longest time for a raindrop to travel through the ith overland plane, T_{xoi}, is the time to reach equilibrium (Wooding 1965):

$$T_{xoi} = \left(\frac{n_o \overline{L}_{oi}}{\overline{S}_{oi}^{\ 1/2} q_L^{\ m-1}} \right)^{1/m} \tag{9}$$

Equation (9) applies for a single overland plane. In this model, flow from the pervious area flows over the impervious area before reaching the conduit. Consequently the longest time for a rain drop to travel is a function of where the rain drop falls. For rain that fall on the impervious portion of the overland flow plane directly, the travel time

is given by Eq.(9) with n_o, $L_{oi\,i}, S_{oi}$ and q_L equal to $n_{o,imp}$, $L_{oi,imp\,i}, S_{oi,imp}$ and $q_{L,imp}$, respectively.

For a rain drop that falls on a pervious area there is a travel time associated with flow over the pervious plane itself as well as the impervious plane. For flow over the pervious plane, travel time is given by Eq. (9) with n_o, $L_{oi\,i}, S_{oi}$ and q_L equal to $n_{o,perv}$, $L_{oi,perv\,i}, S_{oi,perv}$ and $q_{L,perv}$, respectively.

The time for flow from the pervious area over the impervious area is given by:

$$T_{xoi,pervimp}(t) = \left(\frac{n_{o,imp}\overline{L}_{oi,imp}}{\overline{S}_{oi}^{\,1/2}\left(\frac{1-imp_i}{imp_i}q_{L,perv}(t)\right)^{m-1}} \right)^{1/m} \tag{10}$$

Conduit Flow

The total discharge entering an *i*th order pipe from the average *i*th-order overland area includes flow from both the pervious and impervious overland flow planes and is given by:

$$q_{LTi}(t) = q_{L,perv}(t)\overline{L}_{oi,perv} + q_{L,imp}(t)\overline{L}_{oi,imp} \tag{11}$$

Therefore the continuity and simplified momentum equation for the conduit flow are:

$$\frac{\partial A_i}{\partial t} + \frac{\partial Q_{ci}(t)}{\partial x} = q_{LTi}(t) \tag{12}$$

$$Q_{ci}(t) = \alpha_{ci} h_{ci}^{\,m}(t) \tag{13}$$

where Q_{ci} is the ith order conduit discharge, m is a constant, α_{ci} is a parameter reflecting the hydraulic characteristics of the conduit flow, and h_{ci} is the flow depth in the ith order conduit,. For a circular conduit, Wong and Zhou (2003) found that the constant m can be taken as 5/4 and the coefficient α_c may be derived from Manning's equation:

$$\alpha_{ci} = 0.744\frac{\overline{D}_i^{\,1/6}\overline{S}_{ci}^{\,1/2}}{n_c} \tag{14}$$

where $\overline{D}_i$ is the mean ith order conduit diameter, $\overline{S}_{oi}$ is the mean ith order conduit slope and n_c is the manning's roughness coefficient for the conduit.

For a first order channel flow is only conveyed from the overland flow planes and as such the flow depth in the channel, h_{cs1}, is given by:

$$h_{cs1}(t) = \left(\frac{q_{LT1}(t)\overline{L}_{c1}}{\alpha_{c1}} \right)^{1/m} \tag{15}$$

Unlike the open channel flow in natural channels, there is good possibility that the closed conduits encountered in urban conduits will become pressurized. If a conduit becomes pressurized, i.e. $h_{csi} > \bar{D}_i$, then the travel time in a first order conduit is given by:

$$T_{xci}(t) = \frac{\pi \bar{D}_i 2}{4 q_{LTi}(t)} \tag{16}$$

If the conduit does not become pressurized then the travel time in the first-order conduit is given by Wooding (1965):

$$T_{xc1}(t) = \frac{B_1(t) h_{cs1}(t)}{q_{LT1}(t)} \tag{17}$$

For circular conduits, $B_i(t)$ is given by:

$$B_i(t) = \frac{\bar{D}_i}{2} \frac{\left(1 - \cos 2 \arccos\left(1 - \frac{2h_{ci}(t)}{\bar{D}_i}\right)\right)}{\sqrt{1 - \left(1 - \frac{2h_{ci}(t)}{\bar{D}_i}\right)^2}} \tag{18}$$

For higher order channels, the discharge from upstream conduits must be considered. Yen and Lee (1997) found that the water depth at the entrance of an ith (i>1) order conduit is given by:

$$h_{coi}(t) = \left(\frac{q_L^*(t)\left(N_i \bar{A}_i - A P_{OAi}\right)}{\alpha_{c1} N_i} \right)^{1/m} \tag{19}$$

In an urban catchment with overland flow comprising both pervious and impervious flow plains, q_L^* in Eq. (19) is given by:

$$q_L^*(t) = q_{L,perv}(t)\, imp_i + q_{L,imp}(t)\left(1 - imp_i\right) \tag{20}$$

If the flow in the conduit becomes pressurized, i.e. $h_{coi} > \bar{D}_i$, then the travel time in the conduit for an ith order conduit, $T_{xci}(t)$, is given by Eq. (16), where $q_{LTi}(t)$ is given by:

$$q_{LTi}(t) = \frac{\alpha_{ci} {h_{coi}}^m(t)}{\bar{L}_{ci}} \tag{21}$$

If the conduit does not become pressurized then the travel time in the conduit for an ith order conduit, $T_{xci}(t)$, is given by Yen and Lee (1997):

$$T_{xci}(t) = \frac{B_i(t)}{q_{LTi}(t)} \left[\left({h_{coi}}^m(t) + \frac{q_{LTi}(t) \bar{L}_{ci}}{\alpha_{ci}} \right)^{1/m} - h_{coi}(t) \right] \tag{22}$$

Structure of Geomorphic Instantaneous Unit Hydrograph

In an urban watershed rainfall excess occurs randomly over the watershed following a path through an overland flow region to subsequent conduits and eventually to an outlet. As such, an integration of the rainfall excess along all the possible paths in the watershed will yield the outflow hydrograph. The GIUH concept, as originally defined by Rodriguez-Iturbe and Valdes (1979) is reliant on the watershed being ordered according to the Strahler ordering procedure:

1. Channels that originate at a source are defined to be first order channels.
2. When two channels of order *i* join, a channel of order *i+1* is created.
3. When two channels of different order join, the channel segment immediately downstream has the higher of the orders of the two combining channels.

An example of a 3rd order Strahler urban network of conduits is provided in Figure 2. Based on such an ordering scheme a watershed of order Ω can be divided into different states. Overland flow regions are denoted by x_{oi} and conduits by x_{ci}, where $i = 1, 2, ..., \Omega$. Each raindrop (of excess rainfall) falling within the catchment will first fall on an overland region. The order of the region is defined by the order of the conduit receiving the runoff from the overland region. Within this overland region, the rain may fall on either a pervious or impervious overland flow region. If the raindrop falls on an impervious region it is assumed to then pass directly into a conduit, whereas if the raindrop falls on a pervious region it is assumed to travel onto an impervious overland region of the same order before entering the conduit. This unique representation allows for a probabilistic representation of the network geometry by its channel order rather than simulating the overland surfaces and channels individually according to their actual geometry, which is what is done in deterministic modeling.

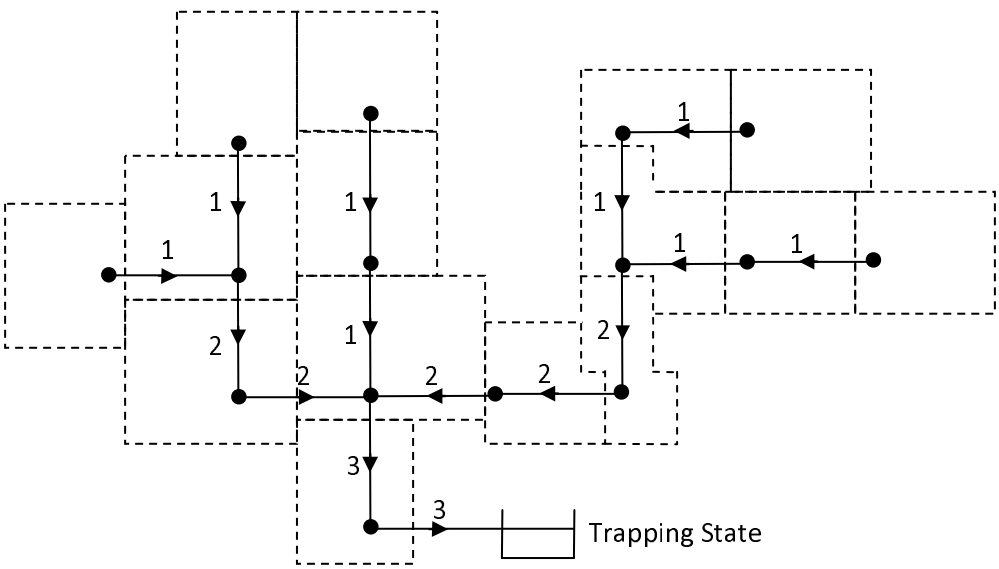

Figure 2 Third order network with Strahler ordering system.

According to the original formation of the GIUH by Rodriguez-Iturbe and Valdes (1979), the travel of a drop is governed by the following rules; (i) when the drop is still in the overland phase, the state is the order of the stream to which the land drains directly; (ii) the only possible transitions out of a state are to a state of a higher order. Under such a formulation the possibility of a rain drop traveling from a pervious region to impervious region is ignored, as is the possibility of a raindrop flowing from one first order channel into another first order channel. Unlike natural catchments the likelihood of a raindrop flowing from a first order conduit into another first order conduit of a different geometry is relatively high and as such must be accounted for. Thus if w denotes a specified path $x_{oi,perv} \rightarrow x_{oi,pervimp} \rightarrow x_i \rightarrow x_j \rightarrow ... \rightarrow x_\Omega$, the probability for a raindrop adopting this path can be expressed as:

$$P(w) = P_{OAi} \cdot P_{x_{oi,perv}x_{oi,imp}} \cdot P_{x_{oi}x_{ci}} \cdot P_{x_{ci}x_{cj}} \cdots P_{x_{ci}x_{c\Omega}} \tag{23}$$

where $i = 1, 2, ..., \Omega$ and $i \le j \le \Omega$, P_{OAi} is probability that a drop of excess rainfall will fall on an ith-order overland region (initial state probability), $P_{x_{oi,perv}x_{oi,imp}}$ is the transitional probability of a raindrop traveling from a pervious region to an impervious region which is equal to the perviousness of the *i*th order overland region, $P_{x_{oi}x_{ci}}$ is the transition probability of a raindrop moving from an ith order overland region to an ith order channel and is equal to unity, and $P_{x_{ci}x_{cj}}$ is the transition probability of a raindrop moving from an *i*th-order conduit to a *j*th-order conduit.

In the literature (Lee and Yen 1997, Kirshen and Bras 1982, etc.) formulations exist for determining intital state probability and transition probability based on the number of channels in each order, N_i, and the average area contributing to an ith-order channel, $\overline{A}_i$. As part of this investigation it was determined that such formulations could not be so readily applied in urban catchments. As such these terms were derived from their physical meanings using an algorithm developed in ArcGIS:

$$P_{OAi} = \frac{\left(\text{total area draining directly into conduits of order i}\right)}{\left(\text{total basin area}\right)} \tag{24}$$

$$P_{x_{ci}x_{cj}} = \frac{\left(\text{number of conduits of order i draining into conduits of order j}\right)}{\left(\text{total number of conduits of order i}\right)} \tag{25}$$

To the best of the authors' knowledge, no study has attempted to apply the GIUH to catchments where the possibility of pipes transitioning from an *i*th-order pipe into another *i*th order pipe is significant. When transitions from an *i*th-order pipe into another *i*th order pipe are not accounted for the number of possible paths for a given order is discrete. For example, in a 5th order catchment there would be 16 (32 if you account for the transition from pervious to impervious overland flow) different possible flow paths that a raindrop could take. However, if you account for the possibility of a raindrop transitioning within a given order, the number of possible flow paths increases dramatically. A Monte-Carlo simulation was performed on a 5th order urban catchment in Chicago (as described in the Results section below) and it was found that the number of possible flow paths exceeded 50,000. This number is

highly dependant on the layout of the network itself. In that particular catchment it was possible for a raindrop to flow through 10 successive 1st order pipes, 13 successive 2nd order pipes, 20 successive 3rd order pipes, 43 successive 4th order pipes, and 10 successive 5th order pipes. To account for each of the 50,000 or more possible flow paths within the model would be intractable. As such the distribution of possible successive flow paths within an order *i* was used to generate a scaling factor for the travel time within the *i*th-order conduit. The scaling factor was taken to be the expected value from the distribution of the number of ith order pipes downstream of an ith order conduit. For example, in the catchment used in the example application of this method there are 472 first order pipes, of which 166 flow directly into conduits of higher order, 119 flow through two first order pipes before transitioning into a higher order conduit, 71 flow through three first order pipes before transitioning into a higher order conduit, etc. It was found that the expected value for the number of first order pipes through which a raindrop would travel before transitioning to a higher order conduit was 2.62. Accordingly then the travel time calculated from Equation (16) or (17) for a first-order conduit would be multiplied by 2.62, effectively lengthening the first order pipe to account for the possibility of a raindrop flowing through multiple first order pipes successively.

In Equations (9), (10), (16), (17),) and (22) above, the travel times for the different states in any path w were defined. Thus the total travel time of a raindrop moving through path w to the watershed outlet, $T_w(t)$, is given by:

$$T_w(t) = T_{x_{oi,perv}} + T_{x_{oi,pervimp}} + a_i T_{x_{ci}} + a_j T_{x_{cj}} + ... + a_\Omega T_{x_{c\Omega}} \quad (26)$$

where $a_i, a_j, ...a_\Omega$ represent the scaling factors accounting for transitions with a given order.

Unlike in deterministic modeling, where it is necessary to find the component travel times for every path in the watershed, the GIUH formulation estimates the travel time collectively and probabilistically for each state by assuming the travel times of different states in the watershed are statistically independent and $f_{x_k}(t)$ is the travel time probability-density-function in state x_k, with a mean value T_{x_k} (Yen and Lee 1997). Using these assumptions Equations (23) and (26) can be combined, for an instantaneous unit input, to yield the instantaneous unit hydrograph (IUH) of the watershed (Rodriguez-Iturbe and Valdes 1979):

$$u(t) = \sum_{w \in W} \left[f_{x_{oi,perv}}(t) * f_{x_{oi,pervimp}}(t) * f_{x_{ci}}(t) * f_{x_{cj}}(t) * ... * f_{x_{c\Omega}}(t) \right] \cdot P(w) \quad (27)$$

where $*$ denotes a convolution integral, and $w \in W$, W being the path space $W = \left\langle x_{oi,perv}, x_{oi,pervimp}, x_i, x_j, ..., x_\Omega \right\rangle$, $(i = 1, 2, ..., \Omega)$.

Many different forms of the travel time probability density function have been explored over the years by researchers. The two most commonly adopted distributions are the exponential and uniform distributions. In this model the travel time for both overland flow and conduit flow was assumed to follow an exponential

distribution with a mean travel time T_{x_k}. In this way the watershed is conceptualized as linear reservoirs in series and/or parallel (Gupta et al. 1980) and is written:

$$f_{x_k}(t) = \frac{1}{T_{x_k}} \exp\left(\frac{-t}{T_{x_k}}\right);\ \forall t \tag{28}$$

EXAMPLE APPLICATION OF MODEL

To demonstrate the application of the model to produce the runoff hydrograph of a given event for an urban catchment and to verify the model by comparison with observed data, a selected rainstorm for the CDS-51 catchment in the Village of Dolton, a southern suburb of Chicago, is presented as an example. This catchment captures storm and sanitary flows for the 341 ha service area contributing to drop shaft CDS51, which feeds the Calumet Tunnel and Reservoir Plan (TARP) system. This catchment was divided into 773 subcatchments collecting inflow from in excess of 800 inlets and feeding a pipe network of 775 pipes ranging in size from 150 mm (6") to 2150 mm (84"). Characteristics (diameter, pipe length, upstream and downstream invert) of the combined sewer network in CDS51 were obtained from the Village of Dolton sewer atlas developed in 1977. Subcatchments were delineated using contours developed from Cook County's LiDAR data, aerial photography and engineering judgment. Imperviousness, infiltration parameters and slope were all obtained from the high resolution synthetic urban watershed developed by Crosa (2008). Manning's roughness for the pervious and impervious overland flow regions were taken to be 0.015 and 0.20 respectively, while a value of 0.014 was used for the conduits. The Green-Ampt infiltration parameters were taken to be homogeneous for the catchment and were derived by taking the weighted average of the parameters throughout the catchment.

CDS-51 is a 5th order catchment and has the geomorphic parameters detailed in Table 1. For this catchment the majority of the required subcatchment and conduit data were available and as such the geomorphic parameters were obtained using all the available data. However, it is not necessary to use all of these data if they are not available. The parameters required for the model could be generated using a subset of the data or perhaps even parameters derived from nearby watersheds were such data available. This is one of the key advantages of this method and these hypotheses will be tested as research continues.

Table 1 Geomorphic data for CDS-51 catchment

Channel Order	N_i	A_i (ha)	L_{oi} (m)	S_{oi}	P_{OAi}	L_{ci} (m)	S_{ci}	D_i (mm)	a_i
1	472	1.04	34	0.0112	0.57	61	0.0061	326	2.62
2	176	4.75	42	0.0115	0.26	60	0.0039	438	5.12
3	60	14.98	27	0.0129	0.07	73	0.0020	704	5.68
4	51	95.90	41	0.0099	0.08	64	0.0014	1179	19.25
5	10	316.10	42	0.0107	0.02	85	0.0056	2073	5.50

The rainstorm used was generated by combining data from four nearby Illinois State Water Survey (ISWS) raingages and NEXRAD data from three nearby radars. The data were combined using a technique developed by Cello et al (2008). The rain storm occurred on the 25th April 2007 and resulting hourly rainfall hyetograph is presented in Figure 3. For brevity, tests of other rainstorms are not reported here.

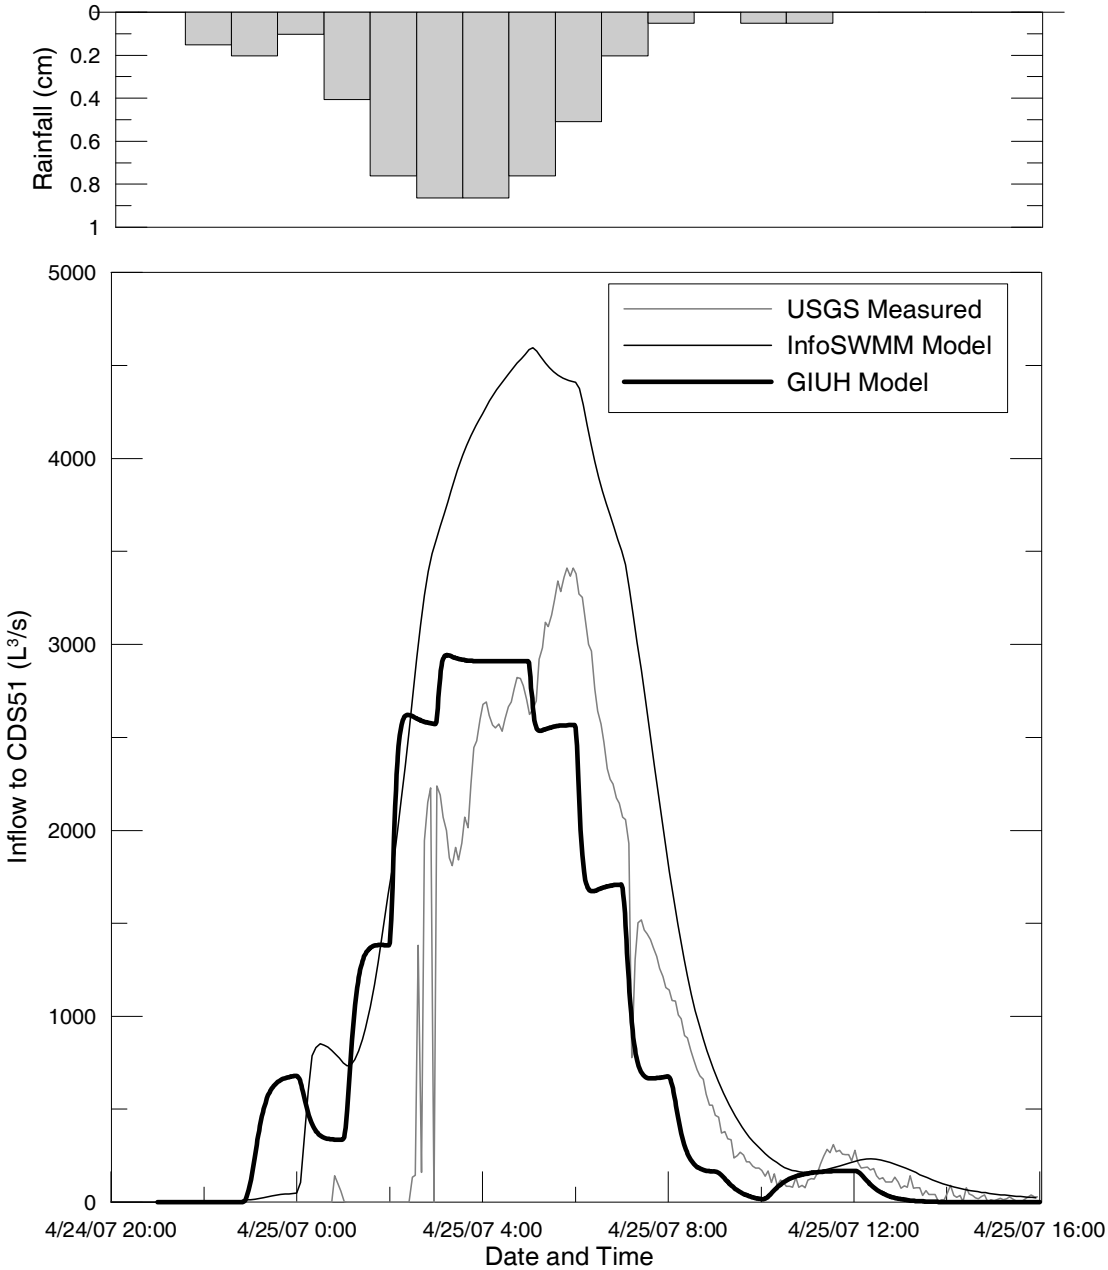

Figure 3 Hydrologic response of CDS-51 to 25th April 2007 storm

Using the input data described above the model was run for the 25th April 2007 storm and the resulting runoff hydrograph is presented in Figure 3. The hydrograph is compared to observed data collected by the USGS at the inflow pipe to drop shaft CDS-51 in the Calumet TARP system. In addition the hydrograph is compared to an

all-pipe InfoSWMM model that was analyzed by Cantone and Schmidt (1008). This model utilizes all of the input parameters available for each of the 773 subcatchments and 775 pipes in the watershed.

Figure 3 highlights that GIUH model is capable of reproducing the observed hydrologic response of CDS-51. The GIUH model predicts a similar volume of runoff, a peak runoff within 10% of the observed peak and shape that mirrors the observed.

CONCLUSIONS

A model, based on conduit ordering and the kinematic wave approximation for estimation of rainwater travel time, has been presented and shown capable of predicting hydrologic response in large urban catchments. This model calculates pervious excess rainfall using the physically based Green-Ampt method and computes travel time in both pervious and impervious overland flow regions, allowing flow to move from pervious to impervious regions prior to reaching a conduit. The model makes use of the known layout of the sewer network and utilizes geomorphic parameters to calculate rainwater travel time through circular conduits under free-surface and pressurized flow conditions. The estimation of travel time through conduits on any given path, allows for the possibility of successive travel in conduits of identical order. The methodology presented does not require runoff and rainfall data for calibration and has the potential to operate without a complete set of conduit and subcatchment input parameters. This work builds on GIUH concept developed by Rodriguez-Iturbe and Valdes (1979) representing the hydrologic response by convoluting a series of probability density functions of travel time.

The model proposed in this paper has large scope for improvement. First, the variability in Green-Ampt infiltration parameters as well as in geomorphic parameters must be explored. This variability can be used to explore different probability density functions for travel time and will account for the uncertainty in the hydrologic inputs. Second, this method must be tested to determine its applicability to catchments where input data are even more limited. This may include the use of only a sub-sample of data or, at the extreme, use of geomorphic parameters from an adjacent or similar urban watershed. Third, the present model only allows for overland flow from pervious to impervious regions but in the future could be adapted to allow flow from impervious to pervious areas. This flexibility would be particularly useful in simulating stormwater BMP's such as rain gardens. Finally, it is necessary to explore the impact of inlet structures on the hydrologic response of the catchment.

ACKNOWLEDGEMENTS

This research would not have been possible without ongoing funding and support from the Metropolitan Water Reclamation District of Greater Chicago as part of the University's work on Chicago's Tunnel and Reservoir Plan.

Analysis of Bioretention Media Specifications and Relationships to Overall Performance

Sean W. O'Neill[1] and Allen P. Davis[1]

[1]Department of Civil and Environmental Engineering, University of Maryland, College Park, MD 20742; PH (301) 405-1958; FAX (301) 405-2585; email: apdavis@umd.edu

Abstract

Bioretention performance specifications differ greatly among jurisdictions. Selected specifications from Prince George's County, MD; MDE; Fairfax County, VA; VDCR; and DNREC are compared for hydrologic management effectiveness, pollutant removal efficiency, construction and maintenance costs, and constructability. Optimal construction and performance requirements are summarized, with the necessity of variable criteria for differing pollutants acknowledged. Specification recommendations are tailored accordingly. Shallow cells with a surface mulch layer are recommended for removal of metals and particulate pollutants. Deeper cells having thick vegetative cover instead of top dressing are recommended for nutrient removal. Additionally, aluminum water treatment residual as a media amendment for phosphorus removal is recommended. This combined with an anoxic saturated zone for nitrogen removal may prove ideal for combined nitrogen and phosphorus removal.

Introduction

Non-point source pollution continues today to be a challenge that needs addressing by engineers, scientists, and regulators. As development continues and the size of urban conurbations continues to increase, so do the associated impervious areas such as roads, parking lots, and roofs. Urban stormwater runoff and the concomitant flux of pollutants to surface water bodies is an especially pressing issue that requires attention. One technology, which also happens to be an EPA Best Management Practice (BMP), that is implemented as a means to reduce runoff pollution discharges is bioretention. Also known as biofiltration or rain gardens, these facilities are effectively shallow depressions filled with sandy media into which runoff is directed. This interception of runoff prevents direct stormwater migration to surface waterways, increases groundwater infiltration, and improves water quality.

Construction and performance specifications for bioretention cells vary markedly depending on the municipal body from which the standard originates. In this project the performance designs from five municipalities were evaluated: Maryland Department of the Environment (MDE); Prince George's County, Maryland Department of Environmental Resources (PGDER); Delaware Department of Natural Resources and Environmental Control (DNREC); Virginia Department of Conservation and Recreation (VDCR); and Fairfax County, Virginia Department of

Public Works and Environmental Services (DPWES). Parameters within the varying standards are compared to show their inconsistencies, as well as highlight optimal criteria leading to performance success as it relates to water quantity management, water quality improvement, reduced construction and maintenance costs, and constructability.

Literature Review

Bioretention has been shown to be a vibrant and viable technology with regard to its use as a means of mitigating stormwater pollution. The technology has been proven both in the field and the laboratory to efficiently mitigate peak flows, minimize surface discharge volumes, and effectively remove stormwater contaminants including heavy metals and nutrients, especially particulate bound.

Maintaining or returning a site's hydrology to a predevelopment state is one of the technology's major advantages. A high media hydraulic conductivity is integral to meeting this goal (Hsieh and Davis, 2005). Even in the harsh environment of the field, bioretention has shown marked improvement of site hydrology (Davis, 2008).

Excellent removal of particulate pollutants has also been shown, including total suspended solids (TSS); metals such as Pb, Cu, Zn, and Cd; and particulate phosphorus (P). In fact, work has shown that effective removal of particulates takes place in approximately the top 20 cm (8 in) of the bioretention media (Li and Davis, 2008a; 2008b). TSS is stopped via filtration mechanisms of the soil and mulch, as are particulate metals. In dissolved form, they will bind to organic matter (OM) such as the mulch top dressing and organics within the bioretention media (Davis et al., 2001).

The majority of P in stormwater is found in particulate form (MWCOG, 1983; Bratieres et al., 2008), which is removed by filtration just as other particulates. However, dissolved P (and nitrogen) is often leached from bioretention cells because of degradation of OM (Davis et al., 2006; Hsieh et al., 2007a; 2007b; Bratieres et al., 2008). Effective removal of nutrients has been observed through proper vegetative coverage (Bratieres et al., 2008; Read et al., 2008), as well as the establishment of an anoxic zone in the media for nitrogen (N) removal via denitrification (Kim et al., 2003; Hunt et al., 2006).

Specifications

Specifications for the design and construction of bioretention systems are inconsistent around the country. The focus of this study is on the Mid-Atlantic States of Maryland, Delaware, and Virginia. It should be noted that with regard to the hydrologic standards reviewed here, the criteria are performance criteria and not design criteria.

An originator for bioretention specifications, Prince George's County, Maryland developed the initial framework on which others built. A summary of relevant county performance guidelines may be found in Table 1. Minimum infiltration rate is 5.1 cm/hr (2 in/hr). Cell media depth is recommended as 76 cm (2.5 ft.); but may be reduced to 46 cm (1.5 ft.) if only shallow rooted plants are used, or increased up to 1.2 m (4 ft.) if trees and/or shrubs are planted. The surface mulch layer may be no more than 7.6 cm (3 in.) deep. The topsoil in the bioretention soil

mixture (BSM); although rated as a loam, sandy loam, or loamy sand (L/SL/LS) per USDA textural classification; must contain 5% or less of clay. The leaf compost component of the BSM is aged leaf mulch.

The Maryland Department of the Environment (MDE) specifies a facility infiltration rate of 1.3 cm/hr (0.52 in/hr) Facilities which cannot meet this requirement are mandated to have an underdrain; once having an underdrain installed, facilities become exempt of the minimum infiltration rate requirement. The BSM for MDE may be rated as a L/SL/LS per USDA; or SM, ML, or SC by the Unified Soil Classification System (USCS). BSM depth must be maintained between 76 and 122 cm (2.5 - 4 ft), with a surface mulch layer of 5.1 – 7.6 cm (3 - 4 in.) thickness. In addition to BSM textural requirements, the ambient soil in which the bioretention cell is situated must contain less than 20% clay and less than 40% silt and clay, which can severely limit siting. A summary of MDE bioretention specifications is found in Table 1.

Table 2 elucidates select bioretention specifications for Virginia facilities. They are required to have an infiltration rate between 1.3 and 21 cm/hr (0.52 - 8.3 in/hr). Media depth must be at least 76 cm (2.5 ft), and the completed facility should have a surface mulch layer of 5.1 to 7.6 cm (2 - 3 in) depth. Alternatively, 70-80% herbaceous plant ground cover may be used instead of a surface mulch layer.

Fairfax County, Virginia, maintains the VDCR infiltration rates, but has augmented drain time requirements as seen in Table 2. Interestingly, underdrains are required on all facilities except those situated on lots containing only single family homes that are not part of a subdivision. The BSM must have a depth of at least 76 cm (2.5 ft), although this is increased to 1.22 m (4 ft) when large trees and/or shrubs are planted. The BSM composition calls for organic compost, which has strict specifications, including: having 50-60% organic matter, a moisture content of 40-50%, and stability as measured by CO_2 evolution of 0-4 mg CO_2-C per g organic matter per day.

The DNREC has promulgated design standards for the state of Delaware, as seen in Table 3. They stipulate a minimum infiltration rate of at least 2.6 cm/hr (1.0 in/hr). Media depth needs to be between 91 and 122 cm (3 - 4 ft). The mulch surface layer is optional in DNREC specifications, but if applied is designated to be between 5.1 and 7.6 cm (3 - 4 in) in depth.

Criteria for Success & Universal BSM

The ultimate goal of any bioretention construction and performance specification is to stipulate limiting requirements needing to be met, which will provide for proper and optimal performance of the structure while minimizing all associated costs. With this in mind, the primary recommendation herein is to accommodate variable construction requirements for the removal of target pollutants. While ideally all contaminants will be removed with a single design, to achieve maximum efficiency this is not practical.

Optimal drain times and infiltration rates for water quantity management and quality improvement are best determined on a situational basis based on local conditions and pollutants of concern. Current standards, however, set limits for facilities which are reasonable, ascertainable, and ultimately lead to rapid water throughput. This allows for runoff control and increased groundwater infiltration, as

well as preventing standing water which may attract disease vectors such as mosquitoes.

Many jurisdictions allow for bioretention cells to be constructed with underdrains which connect directly to municipal stormwater sewers. These devices can reduce the infiltration benefits of bioretention, and add to construction costs. However, underdrains also allow for increased flow rates and drawdown times, and are oftentimes required, such as the MDE requirement when the minimum infiltration rate of 1.3 cm/hr (0.52 in/hr) cannot be attained. Prince George's and Fairfax Counties also require underdrains on facilities situated in certain land use areas: the former on residential plots and sites with infiltration rates less than 2.5 cm/hr (1.0 in/hr); the latter on all sites except single family homes not part of a neighborhood development. This is meant to safeguard against possible flooding which may cause property damage, and has nothing to do with improving facility performance.

The majority of regulations require a media depth of approximately 76 cm (2.5 ft). However, some of the specifications allow for alterations to this range depending on the plantings in the facility. Prince George's County allows the depth to be reduced to 46 cm (1.5 ft) in the event of shallow plants. And both Prince George's and Fairfax Counties increase their minimum to 1.2 m (4 ft) when trees or shrubs are planted. Regulators may want to extrapolate this concept to allow installation of more shallow facilities in areas where dissolved contaminants are not of concern. Evidence suggests that the removal of particulate contaminants including TSS and metals occurs in only the top 10 to 20 cm (8 – 16 in) of media (Li and Davis 2008). Ultimately, a depth of 46 to 91 cm (1.5 - 3 ft) will provide for toxics/metals removal while minimizing construction cost.

Resent research shows that greater infiltration and evapotranspiration for bioretention facilities occurs with increasing maximum depth of cells, especially over 0.9 m (3 feet; Li et al., 2009). Considering this, bioretention facility designers must compromise between the reduced cost of shallow facilities and the improved infiltration and hydraulic performance of deeper ones.

Additionally, a mulch layer on the surface may be ideal to further sorb metals and prevent media clogging by particulates. Minimal OM is necessary in the BSM, as the top dressing and filtration action of the media should be sufficient for metals removal. To provide for plant growth, OM content of 1.5-4% in the final mixture should be sufficient while minimizing nutrient leaching. Additionally, some metals (i.e., Cu) may strongly bind to OM which may become dissolved, leading to leaching from the facility (Li and Davis, 2008). This provides for additional reasoning to reduce unnecessary OM addition to the BSM.

The surface mulch layer provides moisture retention in the BSM, necessary to support plant growth in such sandy media during prolonged dry periods. However, it is detrimental to nutrient removal. Therefore, for nutrient removal cells the top dressing may be replaced with vigorous herbaceous plant growth, such as that specified in the Virginia state specifications. This will not only remove a source of nutrient leaching, but sufficiently thick plant growth will provide adequate shade to retain media moisture, much the same as the top dressing. Additionally, the plants will act as a sink for N and P, contributing to the efficiency of the cell.

Concerning media depth with regard to nutrient removal, sufficient vegetative plant coverage will lead to increased nutrient uptake through plant roots. In fact, while plant coverage is vitally important to effective bioretention N and P removal, it is also strongly affected by variations in plant species (Read et al., 2008; Bratieres et al., 2008). Also, nutrient reduction in bioretention is thought to be best modeled by a first order kinetic decay model, where with increasing travel time or distance through the cell the concentration moves towards a background concentration (Bratieres et al., 2008). Hence, increased media depth will result in concurrent increased nutrient removal. Therefore, the predominant design recommendations in such instances should be vigorous vegetative coverage and sufficient media depth counterbalanced by construction cost.

Consideration should also be given to the installation of upturned underdrains for subrhizomal N treatment anoxic zones (Kim et al., 2003; Dietz and Clausen, 2006; Hunt et al., 2006). This will add to the cost of the facility, but is a viable means of N removal. It should be noted that when utilizing the technology in bioretention facilities, OM as a carbon source for microbes will be needed in the BSM. Ideally, this will be a material which has a high carbon to nutrient ratio (C:N:P). In this way, microbes will utilize the carbon from the OM amendment and the nutrients from the inflowing stormwater, and the nutrient removal capacity of the cell will not be sacrificed. To date, only limited inclusion of this option into specifications has occurred.

In the case of particulate or nutrient removal, the issue of ideal BSM must be addressed. As increased infiltration relative to native soil is of primary concern in most cases, a large proportion of sand is necessary to impart a large hydraulic conductivity and act as a filtering media. Topsoil is necessary to provide nutrients and other qualities for plant growth. Clay and silt content should be kept low, as they limit the ability of water to infiltrate freely. OM, while beneficial for both plant growth and metal sorption, can lead to nutrient leaching.

Ultimately, a final BSM will ideally contain approximately 50-60% construction sand and 40-50% L/SL/LS topsoil on a per volume basis. Clay content of the BSM must be minimized to maintain proper cell hydrology, ideally less than 5-8%. As mentioned above, no additional OM will be necessary in either of the targeted pollutant cases (metals and particulates vis-à-vis nutrients) with the exception of N removal by means of an upturned underdrain. One may note that the mixture ratio of sand and soil is designated on a per volume basis. While many jurisdictions specify mixture on a per weight basis, this is impractical in the field and leads to increased costs. Mixing of the final BSM on a per volume basis allows this activity to occur on site by contractors, providing for increased constructability and therefore reduced cost through fewer labor hours.

Lastly is the consideration of BSM soil amendments for pollutant removal. This has been touched on slightly in consideration of OM as a component of the BSM, and deemed unnecessary for metal removal but essential for N removal via the biological nitrification/denitrification pathway. Consideration has been given as well to P fixation with soil amendments. Coal combustion fly ash has been used in bioretention to immobilize P and has shown excellent removal (Zhang et al., 2008). However, such fly ash is highly alkaline and is not expected to perform optimally

over the long term. It is believed that, given the acidic nature of soils and stormwater on the east coast of the United States, aluminum-based drinking water treatment residual (Al-WTR) is a more viable option. The active component, aluminum (hydr)oxide, is expected to work ideally in the pH range encountered in eastern bioretention facilities, and will remain insoluble and bind P even under reducing conditions found in anoxic environments. Al-WTR utilized as an amendment in conjunction with an anoxic denitrification zone is hypothesized to be an ideal combination for effective and versatile nutrient removal in bioretention facilities.

Abstract

Protecting biological diversity of a stream system while supporting development and growth is critical to sustainability. To this end, the City of Lenexa, Kansas has embarked on the Eastern Lenexa Detention Study. The study focuses on 1017 acres (1.6 sq. mi.) of Little Mill Creek watershed in Lenexa, Kansas, a Kansas City suburb. Little Mill Creek drains to Mill Creek, which is listed as an impaired water body under section 303(d) of the Clean Water Act. Water quality impairment parameters include chloride, fecal coliform bacteria, and biology.

This study examined whether modifying 16 existing detention basins to capture and detain smaller storm events would significantly increase biological diversity and reduce erosion potential within Little Mill Creek. The study used biological data and discharge measurements collected at 11 sites within and near Little Mill Creek to develop linkages among hydrologic and biologic metrics.

Computer modeling showed that retrofit of the study area basins, which control only 30% of the watershed, did not change the hydrology in the stream reach sufficiently to expect an increase in biological diversity. Although not quantified by this study, pollutant removal from retrofit implementation is expected to have a positive impact on biological diversity. Controlling a larger percentage of the watershed is expected to show more significant increases in biologic diversity.

Introduction

Protecting biological diversity of a stream, while supporting development and growth, is critical to sustainability. To this end, the City of Lenexa, Kansas has embarked on the Eastern Lenexa Detention Study. The study focuses on 1017 acres (1.6 sq. mi.) of Little Mill Creek Watershed in Lenexa, Kansas, a Kansas City suburb. The Little Mill Creek Watershed is nearly 90 percent developed. Eleven percent of the study area has commercial/institutional land use; 56 percent is in residential use;

the remainder has mixed land use. Little Mill Creek drains to Mill Creek; the Kansas Department of Health and Environment lists Mill Creek as an impaired water body on the Clean Water Act 303(d) list. Chloride, fecal coliform bacteria, and biology have been identified as water quality impairment parameters in the Mill Creek watershed.

The study examined whether modifying 16 existing detention basins controlling 30 percent of the drainage area to capture and detain smaller storm events would increase biological integrity and reduce erosion potential along Little Mill Creek. To make this determination, a continuous simulation model of the watershed was created using the Environmental Protection Agency's (EPA) Stormwater Management Model (SWMM 5). The model was calibrated using rainfall and continuous stream stage information within the watershed. After calibration, the detention basin retrofit projects were incorporated into the model to simulate the impacts on in-stream flows. The resulting changes in in-stream flows were used to infer changes in stream biodiversity.

Methods

Using 2007 Water Environment Research Foundation (WERF) Protocols for Studying Wet Weather Impacts and Urbanization Patterns (Pomeroy *et al.*, 2008) as a guide, macro-invertebrate and discharge data were used to develop linkages among hydrologic and biologic metrics specific to Little Mill Creek watershed. Macro-invertebrate samples were collected at five locations within Johnson County, Kansas, and three locations within Little Mill Creek watershed (Figure 1). Samples were compared to hydrologic metrics derived from measured discharge values for United States Geological Survey (USGS) gage locations outside Little Mill Creek Watershed. Simulated discharge values from the Little Mill Creek SWMM model were used to develop hydrologic metrics for Little Mill Creek and compare them to the biologic metrics at the same location. The SWMM model was then used to simulate the retrofit of 16 detention basins within the study area to include a 40-hour drawdown of the water quality volume (WQv). The results of the proposed SWMM analysis were used to estimate the impact of the retrofits on in-stream biology.

Watershed Characteristics and Hydrologic Modeling

The study area is located in Lenexa, Kansas. It is a sub-basin within Little Mill Creek watershed. Average annual precipitation is 38.5 inches. The following scenarios were examined in this study:

- **Existing without Detention**: In this scenario all sub-basins in the pilot study area are developed with existing land use. Existing detention basins were not modeled in this scenario.

- **Existing with Detention**: Existing detention basins with existing land use are included in this scenario.

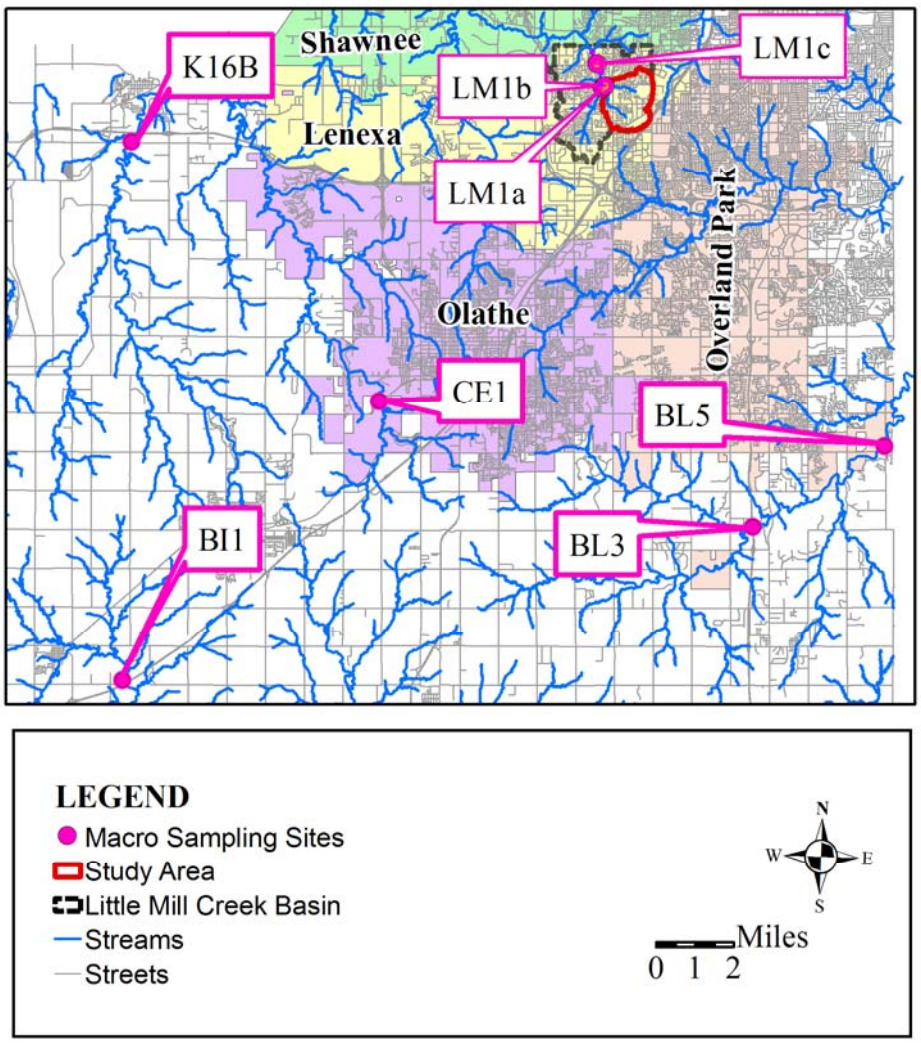

Figure 1 - ELDS Sampling Locations

- **Proposed**: In this scenario retrofits of 16 existing detention basins within the study area are simulated. The retrofit projects incorporate the control of the WQv released over 40-hours. All retrofits were designed to maintain flood control performance for the one percent annual chance event that is achieved in the previous detention scenario.

In Lenexa, Kansas, the WQv is computed as the product of the 90 percent rainfall depth and a runoff factor based on percent imperviousness. The WQv was calculated using the method described in the Manual for Best Management Practices for Stormwater Quality (MARC/APWA 2008) using the following equation:

$$WQv = P*Rv$$

Where WQv = water quality volume (computed as inches across the watershed, the volume is then determined by multiplying the result of this equation by the watershed

area); P = depth of rainfall event for the Kansas City area (1.37 inches) and the Rv (volumetric runoff coefficient) is defined using

$Rv = 0.05 + 0.009*I$

Where I is percent imperviousness.

Computation of Hydrologic Metrics

Studies have shown that the $T_{0.5}$ hydrologic metric is a strong predictor of biotic richness (Booth et al., 2004; Pomeroy et al., 2008). The $T_{0.5}$ metric is the percent of time that the flow is greater than the peak flow of the 0.5-year storm, and is an indicator of stream flashiness. A higher $T_{0.5}$ value indicates that a stream is less flashy than a stream with a lower $T_{0.5}$ value because the length of time the discharge is above the peak flow of the 0.5-year storm is longer. The 0.5-year storm is defined from a partial duration series of flows. By plotting the $T_{0.5}$ and the biologic metric at particular location, a relationship can be drawn between in-stream hydrology and biologic richness.

$T_{0.5}$ was calculated for the locations where macroinvertebrate sampling was performed (Table 3). Measured flow data were used where available. For locations without measured flow data, results from a calibrated continuous simulation hydrologic model were used to estimate the $T_{0.5}$.

The period of flow record from October 2003 to September 2005 was used to calculate $T_{0.5}$ for sites BI1, CE1, BL5, BL3 and K16b. The continuous SWMM model was run for the same period using the existing with-detention scenario and the resulting flows were analyzed to generate $T_{0.5}$ at LM1c, LM1a, LM1b.

Computation of Biologic Metrics

Macro-invertebrate samples were collected during spring and summer 2007 by USGS at eight locations within and near the study area (Figure 1). Data analysis included computations of the Kansas Biotic Index (KBI; Huggins and Moffett, 1988). KBI is a pollution tolerance index used to categorize the macroinvertebrate assemblage's tolerance to organic pollution. Using taxa-specific tolerance values, this index evaluates the tolerance of the macroinvertebrate assemblage to the effects of nutrient and oxygen demanding pollutants. A higher index indicates a community more tolerant of organic pollution exerting oxygen demands in the stream setting.

Tolerance values for the KBI analysis were primarily derived from Table D-1 of *Procedures for Sampling Macroinvertebrates as part of the City of Lenexa Stream Monitoring Plan* (Watershed Institute, Inc.). For a few taxa (*Prostoma*, *Crangonyx*, and *Hyallela*) tolerance values were developed using average regional values from Appendix B of the EPA document, *Rapid Bioassessment Protocols for Use in Streams and Wadeable Rivers: Periphyton, Benthic Macroinvertebrates, and Fish*, Second Edition (2003). Within the family Chironomidae, it was assumed that all taxa would be classified as "non-red," except the genus *Chironomus*.

KBI classifies macroinvertebrate assemblages using the rating scale provided in Table 2.

The formula used to calculate KBI is:

$$\mathbf{KBI = \Sigma(x_i * t_i)/n}$$

x_i = number of individuals within the taxon
t_i = tolerance value of the taxon
n = total number of organisms in the sample

The KBI analyses yielded consistent results. The three Little Mill Creek sampling sites have ratings of "Moderate Impact" (KBI scores of 2.8 – 2.9) from nutrient and oxygen demanding pollutants (Table 3).

Table 2. KBI rating scale

KBI RATING SCALE[1]	
KBI Score	**Rating[2]**
≤ 1.50	No Impact
1.51 – 2.50	Slight Impact
2.51 – 3.50	Moderate Impact
≥ 3.51	High Impact

[1] Adapted from Table 10, Huggins and Moffett (1988)
[2] Impact from nutrient and oxygen demanding pollutants

Table 3 KBI for Macro Sampling Sites

Site ID	Site Name	KBI
BI1	Big Bull C Nr Edgerton, KS	2.2
CE1	Cedar C at Hwy 56 at Olathe, KS	2.3
MI4	Mill C at 87th St Nr Lenexa, KS	3.0
BL5	Blue R at Kenneth Rd, Overland Park, KS	2.0
BL3	Blue R Nr Stanley, KS	2.1
K16b	Kill C at 95th St Nr Desoto, KS	2.4
LM1c	Little Mill C at 79th Street	3.0
LM1a	Little Mill C at 84th Street	3.0
LM1b	Little Mill Trib at 83rd Street	2.9

Results

Linear regression can be used to correlate $T_{0.5}$ and KBI. Figure 2 shows the linear regression of the KBI and $T_{0.5}$ hydrologic metrics. The data show good correlation between $T_{0.5}$ and KBI with an r-squared of 0.78. The regression line in Figure 2 can be used to estimate the response to biologic diversity with changes in stream hydrology. The $T_{0.5}$ at location LM1b Little Mill Tributary at 83rd Street for the proposed conditions scenario was plotted in Figure 2 to indicate the biologic response to changes in hydrology. The proposed conditions $T_{0.5}$ did not change significantly from the existing with detention scenario $T_{0.5}$.

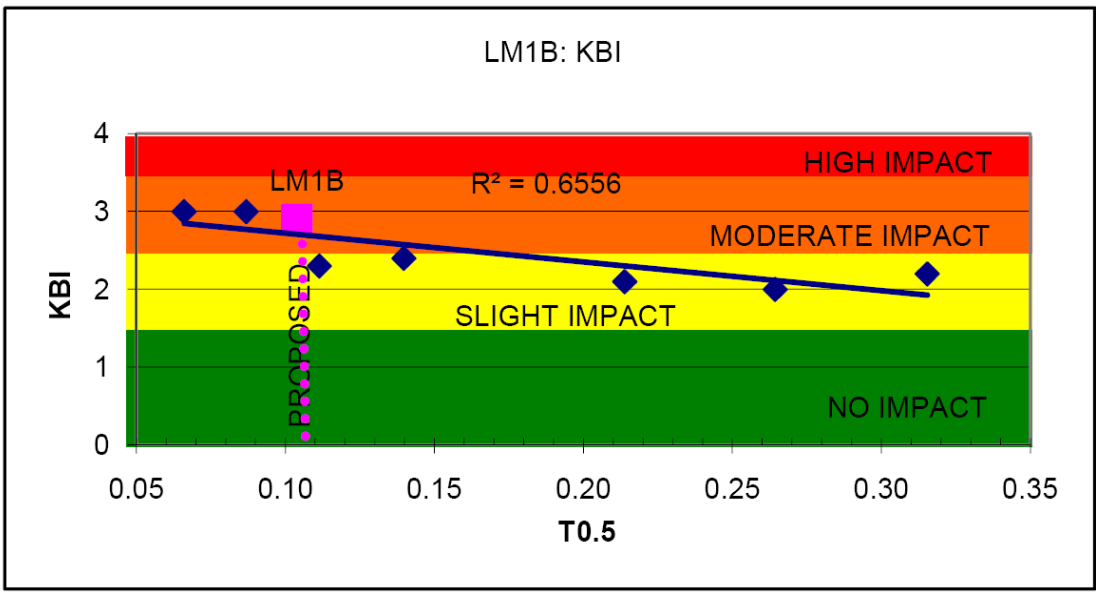

Figure 2 $T_{0.5}$ versus KBI

Conclusions

Regression equations were used to estimate the impact of in-stream biological diversity with changing flow regimes. An increase in $T_{0.5}$ is related to an increase in biological diversity. Many other factors besides hydrology can affect biologic diversity in a stream system, including pollutants and stream bed substrate. Therefore, even if a desired $T_{0.5}$ is reached, biologic diversity may still not be present due to these other factors.

The proposed $T_{0.5}$ showed little change from the existing value, indicating the proposed retrofit projects are not expected to make a large impact on the stream biology from a hydrologic perspective. However, capturing the water quality volume and releasing it between 24 and 48 hours has been reported to remove total suspended solid loads by as much as 80 percent (Debo and Reese, 2003). Therefore, the proposed retrofits should reduce pollutant loads to the stream, improving stream ecology and the aquatic environment.

One possible reason for the small response to hydrology is that only 30% of the area tributary to the reach analyzed is controlled by retrofits. If a larger percentage of the tributary area were controlled to the same degree, a larger positive impact to the $T_{0.5}$ would be expected. The extent of watershed control needed to produce the desired results is not known.

ABSTRACT

This paper presents empirically derived estimates of the Rational C runoff coefficient for rural watersheds in Kansas. The C values vary with location (there is an east-west trend) and recurrence interval. The C values derived for western Kansas are in line with values commonly assumed for rural watersheds. However, the C values computed for eastern Kansas are much higher than the values found in many hydrology textbooks and design guidelines. The median Rational C values for the watersheds in eastern Kansas are 0.32, 0.63, and 0.97 for the 2-, 10-, and 100-year recurrence intervals.

INTRODUCTION

Over 150 years since its original description, the Rational equation is still widely used by engineers to size drainage structures. Although its use is typically restricted to small watersheds, the Rational method has been used to design billions of dollars worth of drainage infrastructure including storm sewer systems, culverts, and small bridges. The fact that the Rational method has endured as a design methodology caused Yen (1992) to question whether the method persists because it is fundamentally sound, or because the field of hydrology has simply not progressed.

A companion paper in these proceedings (Young et al. 2009) compares the accuracy of the Rational method with regional flood frequency equations. Regional flood frequency equations are often favored over the Rational method for larger, ungaged watersheds. Young et al. (2009) demonstrate that the Rational equation outperforms USGS-style regional flood frequency equations for watersheds up to 30 mi^2 – as long as appropriate values of the Rational C are selected.

The real question, then, is what Rational C values are appropriate? An informal review of hydrology textbooks and design guidelines reveals that most published Rational C values can be traced back to a 1969 sanitary and stormwater sewer design manual produced jointly by ASCE and the Water Pollution Control Federation

(WPCF 1969). Interestingly, the WPCF (1969) manual does not provide justification for the Rational C values selected.

There have been a few research studies that have estimated Rational C values for watersheds. Schaake et al. (1967) used data for twenty small watersheds in the Baltimore, Maryland area to estimate Rational C values. These watersheds were all small (less than 150 acres) and urban in nature. French et al. (1974) carried out a large study of Rational C values in New South Wales, Australia. Rational C values were estimated for 37 watersheds, ranging in size up to 250 km^2. Hotchkiss and Provaznik (1995) estimated Rational C values for 24 rural watersheds in south-central Nebraska. The results for these three studies are discussed along with the findings of this study.

The objective of this study was to establish appropriate Rational C values for rural watersheds in Kansas with drainage areas up to 30 mi^2. A dataset consisting of 72 gaged, rural watersheds was used to compute Rational C values for various recurrence intervals.

Data and Methodology

The Rational equation is commonly written as

$$Q_T = C \cdot i \cdot A \tag{1}$$

where Q_T is the peak discharge for recurrence interval T, C is the Rational runoff coefficient, i is the rainfall intensity, and A is the watershed area. The rainfall intensity is selected for the recurrence interval of interest and for a duration equal to the watershed time of concentration, t_c. The time of concentration is defined as the length of time it would take for water to travel from the most remote point in the watershed to the watershed outlet.

Once Q_T, i, and A are known for a particular watershed, the Rational C value for a particular recurrence interval can be backed out of Eq. 1 using the following relation:

$$C = \frac{Q_T}{i \cdot A} \tag{2}$$

The objective of this study was to determine Rational C values appropriate for rural watersheds in Kansas. As such, a dataset of Q_T, i, and A values was established for 72 gaged, rural watersheds. Figure 1 shows the location of the watersheds used for this study, along with contours of mean annual precipitation (MAP). The watersheds selected for this study all have drainage areas less than 30 mi^2 and streamgage records longer than 20 years.

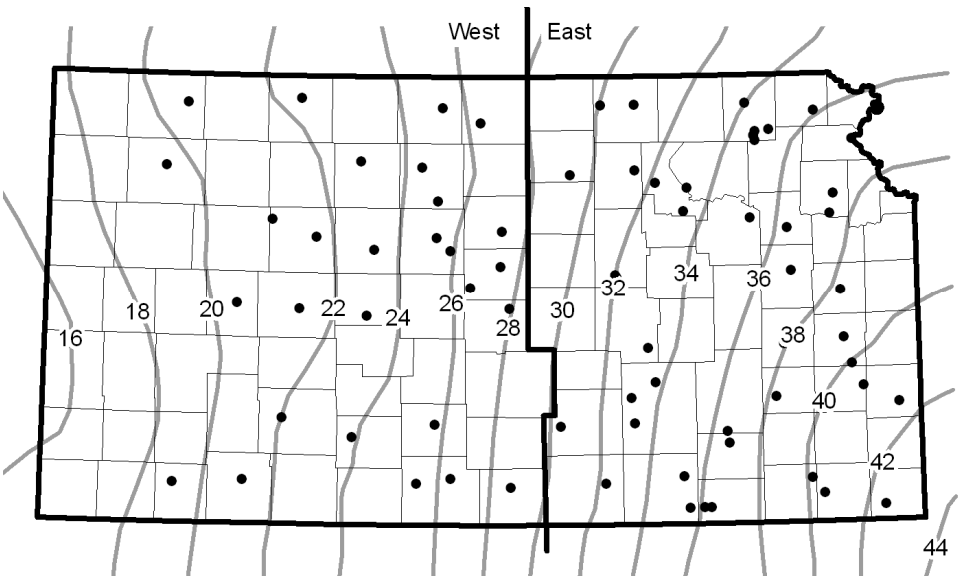

Figure 1. Watershed Locations and Mean Annual Precipitation (in)

Flood frequency analysis was performed according to Bulletin 17B methods for each of the 72 gage records to estimate the flood quantiles (Q_T) for each watershed (Flynn et al. 2006). The drainage areas for each location were determined from digital versions of the USGS 7.5-minute topographic maps. The time of concentration for each watershed was estimated using the following equation for rural streams in Kansas:

$$t_C = 0.0368\left(\frac{L}{\sqrt{S}}\right)^{0.66} \tag{3}$$

where L is the length of the main channel from the outlet to the draingage divide (in ft), and S is the slope of the main channel (in ft/ft) measured between points that are 10% and 85% of the way upstream from the outlet, and t_c is in minutes. This equation for t_c was developed using observed rainfall and streamflow data for nineteen small rural watersheds in Kansas (McEnroe and Zhao 1999). The channel lengths and slopes were measured for each watershed from USGS topographic maps.

Point rainfall intensities for each of the watersheds were selected from the KDOT rainfall tables, which were compiled using data from the National Weather Service (NWS) *Technical Memorandum HYDRO-35* (Frederick et al. 1977) for durations less than or equal to one hour, and from the U.S. Weather Bureau's *Technical Paper No. 40* (Hershfield 1961) for durations in excess of one hour. The point rainfall intensities were extracted for recurrence intervals of 2, 5, 10, 25, 50, and 100 years. These rainfall values were converted to area-rainfall intensities using the point-to-area conversion employed in the U. S. Army Corps of Engineers hydrologic modeling software (Hydrologic Engineering Center 1998).

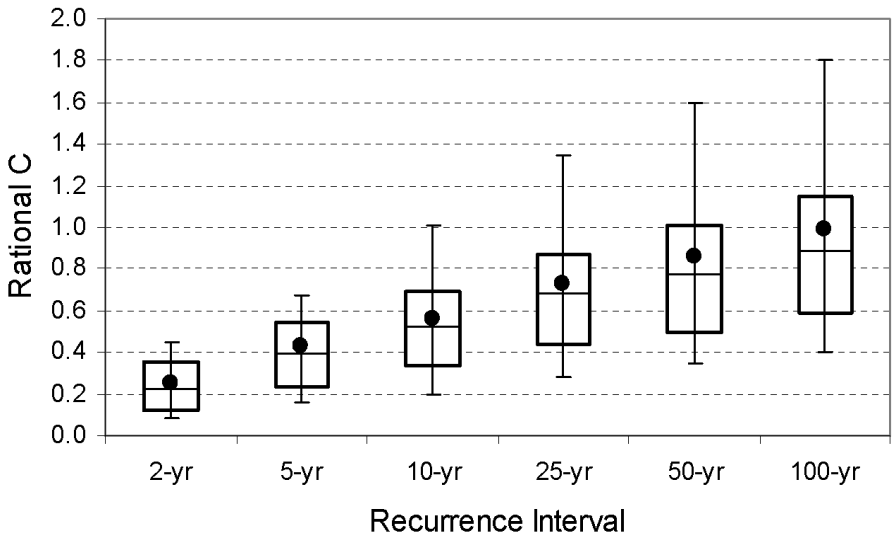

Figure 2. Distribution of Rational C Values for the 72 Watersheds.

RESULTS

Equation 2 was used to compute Rational C values for each watershed for recurrence intervals of 2, 5, 10, 25, 50, and 100 years. Figure 2 presents box-and-whisker plots of the Rational C values plotted versus recurrence interval. The boxes in Figure 2 mark the 25th, 50th, and 75th percentiles, the whiskers mark the 10th and 90th percentiles, and the dots mark the average Rational C value for the 72 watersheds. Table 1 presents summary statistics for the Rational C values.

Table 1. Summary Statistics for Rational C Values for All 72 Stations

Recurrence Interval (years)	Mean	Median	Standard Deviation
2	0.25	0.23	0.15
5	0.43	0.39	0.24
10	0.56	0.53	0.31
25	0.73	0.68	0.42
50	0.86	0.77	0.52
100	0.99	0.89	0.62

It is clear that there is tremendous variability in the Rational C values estimated in this study. Some of this variability is due to uncertainty in the estimate of C for each watershed and recurrence interval, and some of the variability likely results from differences in watershed characteristics.

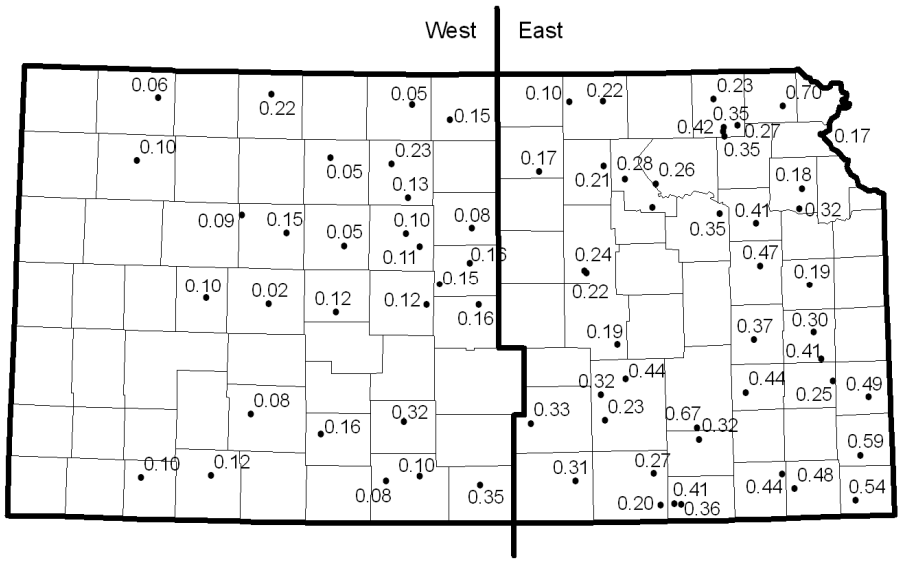

Figure 3. Rational C Values for 2-Year Recurrence Interval

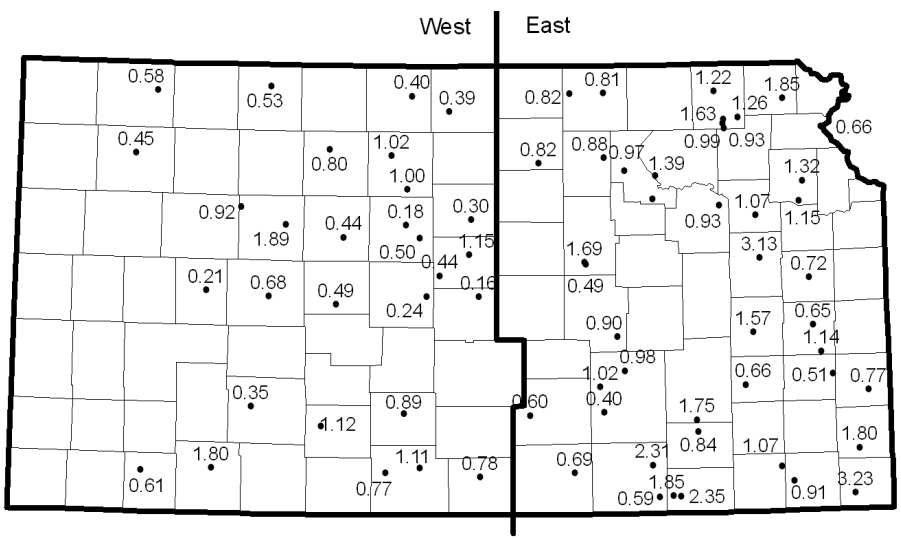

Figure 4. Rational C Values for 100-Year Recurrence Interval

Figures 3 and 4 map out the 2- and 100-year Rational C values. These two figures show a noticeable east-west trend in the Rational C values. In general, Rational C values are higher in eastern Kansas and lower in the western regions of the state. This is likely caused by two main factors. Figure 1 shows the pattern of mean annual precipitation for the state. Rainfall ranges from less than 16 in/yr at the western edge of the state up to nearly 44 in/yr in the southeastern corner. Soil permeability also varies across the state. The eastern half of the state has a mix of NRCS hydrologic soil types B, C, and D. The western half of the state is predominantly hydrologic soil

type B. As such, the eastern portion of the state experiences more rainfall, with lower soil infiltration rates, while western Kansas has higher soil permeability and less rainfall.

Figure 5 shows the median Rational C values for the entire 72-watershed dataset, along with the median values for eastern and western Kansas. As noted in previous studies, the Rational C values increase with recurrence interval.

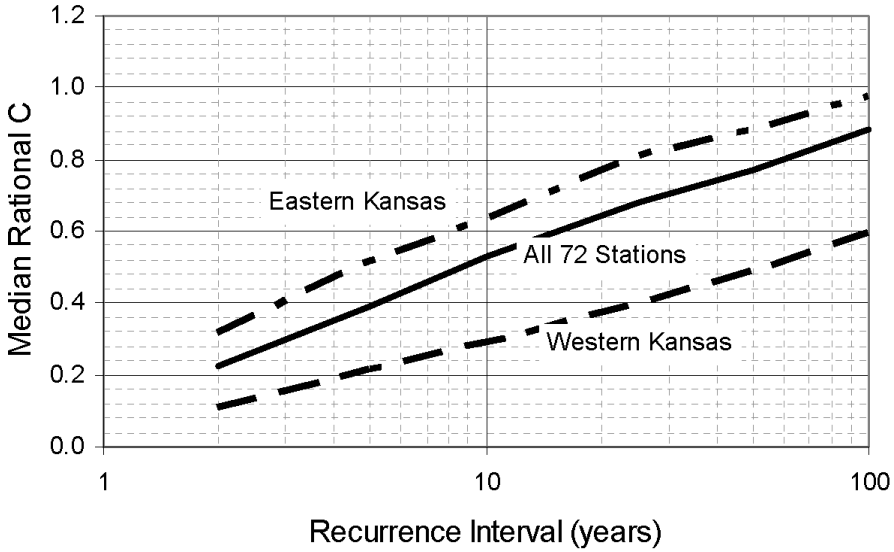

Figure 5. Median Rational C Values vs. Recurrence Interval

DISCUSSION AND CONCLUSIONS

Many modern hydrology textbooks and design guidelines present the Rational C values originally published in WPCF (1969). For unimproved (rural) watersheds, WPCF (1969) recommends a C value of 0.1 for the 2-year recurrence interval and a C value of 0.3 for the 10-year recurrence interval. Based on the results of this study, the C values published in WPCF (1969) appear to be appropriate for western Kansas, but are much too small for use in eastern Kansas. In fact, the Rational C values for eastern Kansas are more than double those recommended in WPCF (1969).

The Rational C values established in this research exhibit greater dependence on the recurrence interval than typically assumed. The ratio of the 100-year to the 10-year C value is 1.68 for all 72 stations, 2.07 for western Kansas, and 1.54 for eastern Kansas. In contrast, Gupta (2001) recommends a ratio of 1.25 for these two recurrence interval.

The findings of this research raise the question of whether the Rational C values currently used for design are too low. This study found the median C value for the 100-year discharge in eastern Kansas to be 0.97. Very few design engineers would

use a Rational C value near 1.0 for a rural watershed – no matter what the recurrence interval.

Other studies have also found Rational C values higher than typically assumed. French (1974) mapped out Rational C values for rural watersheds in New South Wales, Australia. Their findings, reproduced in the *Handbook of Hydrology* (Pilgrim 1993), show Rational C values of over 1.0 for the 10-year recurrence interval on the eastern edge of the study area. C values for the more arid inland areas trend down to 0.1 for the 10-year storm. Hotchkiss and Provaznik (1995) computed Rational C values for 24 rural watersheds in south-central Nebraska. Their C values for the 10-year recurrence interval ranged from about 0.2 to 0.8, with mean C values approximately 20% higher than the WPCF (1969) value.

The Rational C values presented in this paper are based on the analysis of a large number of rural watersheds in Kansas. The results should not be applied to urban watersheds, or to watersheds outside of the study area. However, the findings indicate that conventional wisdom regarding Rational C values may be wrong, and may lead to undersized hydraulic structure. It is critical that engineers examine the basis for Rational C values used in design. Further research should be carried out to establish appropriate values for other areas in the United States. Particular attention should be paid to urban watersheds, where the Rational method is most commonly applied.

ACKNOWLEDGEMENTS

This work was funded by the Kansas Department of Transportation under K-TRAN grant KU-06-4. James Richardson, P.E., of KDOT served as project monitor. This gratefully acknowledged.

Abstract
Underground hydrodynamic separators are widely used in urban areas for removal of suspended solids and floatables from stormwater due to limited land availability for the installation of above ground stormwater best management practices (BMPs). Hydrodynamic separators are sized for applications based on design runoff from the drainage basins that they serve. However, during less frequent storm events, device maximum treatment rates are exceeded and previously captured sediments can be scoured and washed out of these devices. A methodology has been developed to assess sediment retention in hydrodynamic separators under water flow rates exceeding their maximum design treatment rates. This new testing protocol has been used in controlled field and laboratory tests on full-scale commercial devices under high water flow conditions to determine sediment retention performance. Application of this work is primarily to establish the frequency of required cleaning for installed devices.

Background

Hydrodynamic separators are used as best management practices (BMPs) in urban areas for removing contaminants from stormwater. These underground devices are attractive in areas where land is at a premium because of their small footprint. Hydrodynamic separators are flow-through devices used as pre-treatment in a multi-BMP treatment train or as stand-alone BMPs. Water either enters these devices tangentially, thus creating a swirl, or plunges into the main sump. Hydrodynamic separators may be single or multiple sump devices. They have no moving parts and rely on flowing water as their source of energy, so they require no power. Hydrodynamic separators principally function as enhanced settling devices and commonly include a mechanism for capture of floatable solids and liquids. This paper addresses non-floatable solid capture and retention in hydrodynamic separators.

There are two important criteria to consider when determining the overall performance of hydrodynamic separators: 1) their efficiency in removing contaminants under treatment flow conditions and 2) their ability to retain accumulated solids under high flow conditions. Hydrodynamic separators are sized based on the runoff from the drainage basins they serve. As most rainfall events result in flow rates less than the maximum treatment rates for the installed devices, removal efficiency under treatment rates is an important parameter for assessing the performance of these devices. However, during less frequent storm events, maximum design treatment rates are exceeded, and previously captured solids can be subject to scouring, resuspension and washout from these devices.

Historically, monitoring programs have been used to assess the performance of hydrodynamic separators. Monitoring offers the advantage of assessing the performance of BMPs under a wide range of actual hydraulic and pollutant loading conditions for a given drainage basin (Wilson *et al.,* 2009). However, monitoring is limited by the accuracy of sample collection strategies as well as the magnitude and frequency of storm events. In addition, due to the many uncontrolled variables in actual runoff events, it is difficult to use the results of a monitoring study to estimate a device's performance under different flow and sediment particle size conditions than were tested. As a result, new protocols for testing the performance and sediment retention of hydrodynamic separators utilizing controlled field and laboratory testing have been developed.

Performance Testing

Controlled field testing was performed on four commercial devices (Wilson *et al.*, 2009) and laboratory testing was performed on three devices (Carlson et al., 2006; Mohseni and Fyten, 2008; Fyten and Mohseni, 2009) using a range of flow rates and sediment sizes to determine suspended sediment removal efficiencies and develop non-dimensional performance functions. Test procedures, analysis and results from performance testing can be found in the references.

Sediment Retention Testing

The net removal of contaminants by hydrodynamic separators is a function of their performance at capturing pollutants under design storm events and their ability to retain previously captured sediments during high flow events. In hydrodynamic separators two processes cause the wash out of deposited sediments: 1) scouring and resuspension of deposited sediments and 2) turbulence in the sump which overcomes the resettling of resuspended sediments, dispersing them upward to the outlet of the device.

A new methodology has been developed to assess sediment resuspension and washout in hydrodynamic separators under flow rates exceeding their design maximum design treatment rates. The test methodology follows as Procedure 1.

Procedure 1: Sediment Retention Testing Procedure

Procedure:

1) Drain and clean the device
2) Pre-load the device with sediments of known particle sizes
3) Measure the amount of sediments in the device
4) Flow water for a set time duration at rates above device maximum design treatment rates
5) Measure the amount of sediments remaining in the device
6) Determine the sediments washed out via mass balance

Procedure 1 has been applied in the testing of three full scale commercial devices: 1) an Environment21 V2B1 Model 4 in the field and in the laboratory by the authors, 2) a Stormceptor STC 1200 in the laboratory by the authors and 3) an ecoStorm Model 3 in the laboratory (Mohseni and Fyten, 2008).

Environment21 V2B1 – Field Testing

An in-service Environment 21 V2B1 Model 4 was tested in the field in 2007 using Procedure 1. Before and after water flow, a trowel was used to flatten and level the surface of the deposit and a 2 foot level was used to check if the deposit was truly level. After leveling, two methods were used to determine the amount of the sediment in the V2B1 device: 1) A ruler measuring the depth of the sediment to the floor of the device and 2) A laser range finder measuring the distance between the top of the sediment and the ceiling of the device.

Method 1: A standard metal ruler stick was used to measure the depth of the sediment at 18 locations in the device. The same 18 locations were used for each sediment level measurement, and the 18 readings were averaged to obtain average sediment depths.

Method 2: A Hilti Model PD 30 laser range finder was used to measure the distance from the top of the sediment to the ceiling of the device. This laser range finder device has a published accuracy of $\pm 1/16^{th}$ inch over its entire measurement range of 660 feet. A custom bracket was fabricated, and the laser range finder was securely

fastened in the bracket. The bracket incorporates a bubble level. Figure 1 shows the laser range finder with the attached bracket and level.

Figure 1: Laser range finder with bracket and level

The laser range finder was used to measure the distances between the top of the sediment and the ceiling of the device at 28 marked locations. To take a reading, the laser range finder bracket was placed on top of the sediment and positioned until the bracket was level and the laser beam was on target on the mark on the ceiling for the respective reading. Prior to the first test, readings were taken when the device was empty to determine the distances between the floor of the device and the ceiling of the device at each of the 28 points. The depth of sediment at each point was determined by subtracting the distance between the top of the sediment and the ceiling from the distance between the floor and the ceiling of the device. The 28 sediment depths were averaged to obtain the average sediment depth.

The two sediment measurement methods had an average variation in sediment reading of 0.23 cm, a maximum variation of 1.0 cm and a standard deviation of 0.40 cm.

Six tests were conducted in the summer (“Initial Tests”), followed by six duplicate tests in the fall (“Repeat Tests”). These first twelve tests utilized US Silica F110

gradation and two final tests were conducted using AGSCO 70-100 gradation. US Silica F110 and AGSCO 70-100 are commercial silica sand gradations with specific gravities of 2.5. US Silica F110 has a d_{50} of 120 µm, a d_{15} of 80µm and a d_{85} of 170µm. AGSCO 70-100 has a d_{50} of 200 µm, a d_{15} of 120 µm and a d_{85} of 280 µm. Sediment was added to the device prior to each test so that the starting sediment level was approximately six inches. The tests were conducted with water supplied from a fire hydrant, which had water temperatures ranging from 14 to 18 degrees Celsius. The test durations ranged from 30 to 120 minutes. The results of the fourteen retention tests are shown in Figure 2.

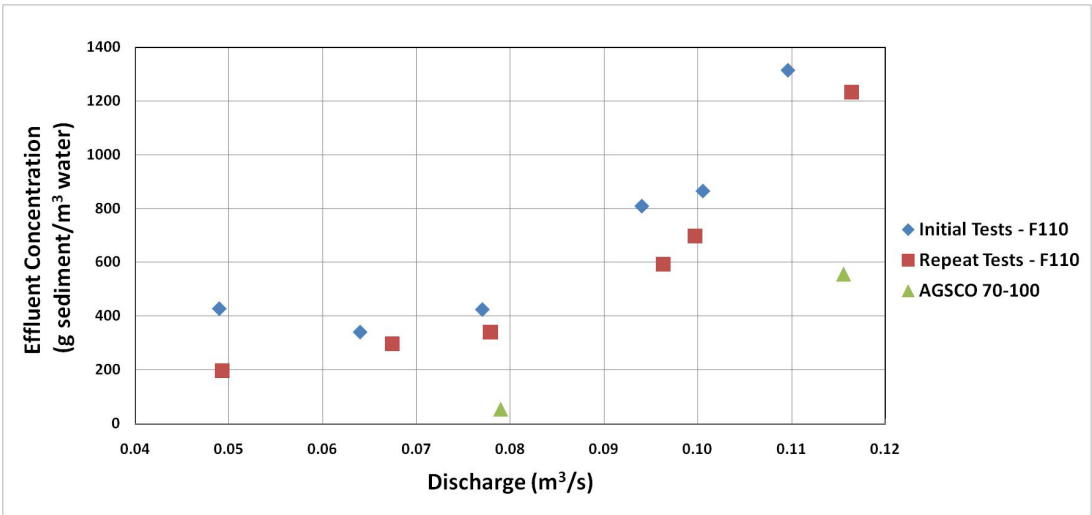

Figure 2: Sediment retention field testing – Environment 21 V2B1 Model 4 (Saddoris et al., 2009)

As anticipated, the larger AGSCO 70:100 sand was better retained than the US Silica F110. Larger particles are less likely to scour, and the larger particles that have been resuspended are more likely to resettle due to their higher settling velocities.

The F110 repeat tests, which were conducted later in the year with lower temperature water, demonstrated higher sediment retention. As water temperature drops its viscosity increases. The effect of water temperature and viscosity on sediment retention in hydrodynamic separators is not yet fully understood.

Environment21 V2B1 – Laboratory Testing

An Environment 21 V2B1 Model 4 was tested in the laboratory in 2008 following Procedure 1. The experimental setup utilized a fiberglass manhole and the Environment21 V2B1 piping placement and baffle wall proprietary design. The device tested in the laboratory in 2008 had a smaller outlet pipe from the first chamber to the second chamber than the device tested in the field in 2007. In addition, a different sediment measurement technique was used for laboratory testing than was used for field testing.

For laboratory testing the entire full-scale device was placed on a frame, which was placed on Tovey Engineering Model FR10 load cells. These load cells have a published non-repeatability of 0.01% of their rated capacity. Numerous tests were conducted on the setup to confirm that load cell measurement drift and non-repeatability were minimized.

The amount of sediment washed out during a test was determined by measuring the weight change of the entire device from the start of the test to the end of the test. Prior to a test, the system was disconnected from the piping and weighted using the load cells, and the water level was recorded. The piping was then connected and a test was conducted at the specified flow rate for the specified duration. At the conclusion of the test the suspended sediment was allowed to settle, and then water was drained from the device to approximately the pre-test water level. The piping was disconnected, and the final weight and water level were recorded. At the end of every test an adjustment was made to the weight to compensate for the difference in water height, and the amount of sediment washed out was calculated based on the weight change of the device and the densities of the sediment and water.

Twelve tests were conducted utilizing US Silica F110 gradation, and five tests were conducted using AGSCO 70-100 gradation. The pre-test sediment level for each test was approximately five inches. The tests were conducted with water supplied from the Mississippi River, which had temperatures ranging from 0 to 2 degrees Celsius. The test durations ranged from 45 to 180 minutes. The results of the retention testing for the V2B21 in the laboratory are included as Figure 3.

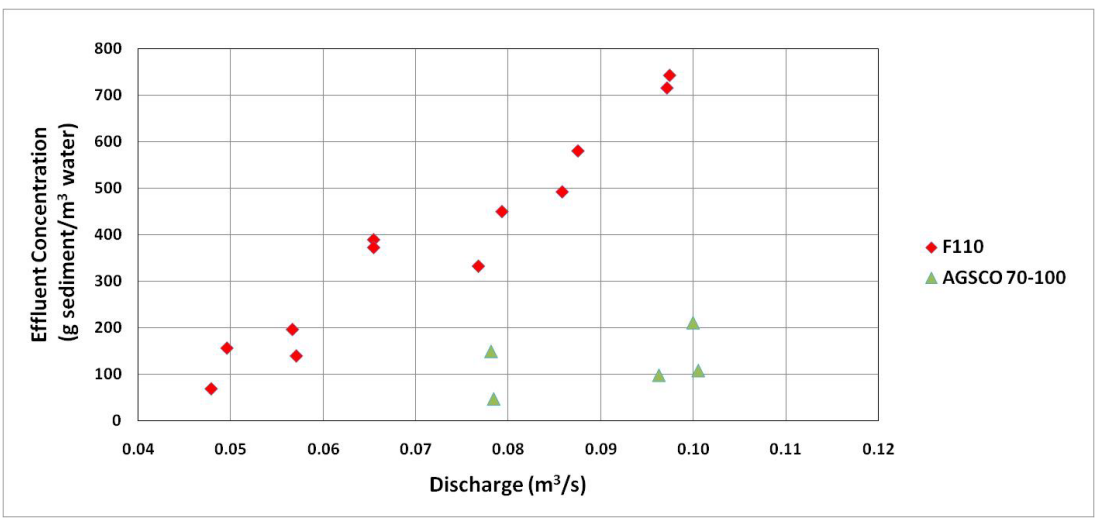

Figure 3: Sediment retention laboratory testing – Environment 21 V2B1 Model 4

As witnessed during field testing of the Environment21 V2B1 in 2007, the larger AGSCO 70-100 sediment was better retained in the device.

Stormceptor STC 1200 – Laboratory Testing

A Stormceptor STC 1200 was tested in the laboratory in 2008 following Procedure 1. The experimental setup utilized a fiberglass manhole and an insert of standard design provided by Stormceptor. Load cells were used for sediment measurement following the same protocol as used for the Environment21 V2B1 laboratory testing (see above). The tests were conducted with water supplied from the Mississippi River, which had temperatures ranging from 0 to 1 degree Celsius. The test durations ranged from 60 to 120 minutes.

Prior to the first test, approximately six inches of US Silica F110 gradation was charged to the sump of the Stormceptor device. Sediment retention tests were conducted at discharges of 0.014 m^3/s (0.5 ft^3/s), 0.085 m^3/s (3 ft^3/s) and 0.14 m^3/s (5 ft^3/s). Measurable sediment removal did not occur during any of these tests, as evidenced by:

1) The weight change of the system was not significant
2) There was no visual appearance of sediment in the discharge water during the tests
3) Sediment did not settle in the outlet channel or on top of the Stormceptor insert after the water flow was stopped
4) As observed through the outside of the fiberglass manhole, the sediment level at the perimeter of the device did not change

Following the F110 tests, approximately 2-1/2" of SCS250 sediment was added to the sump and allowed to settle overnight on top of the F110 sediment. SCS250 is a commercial silica sand gradation with a specific gravity of 2.6. SCS250 has a d_{50} of 28 µm, a d_{15} of 3 µm and a d_{85} of 80 µm. Sediment retention tests were conducted at discharges of 0.014 m^3/s (0.5 ft^3/s), 0.14 m^3/s (5 ft^3/s) and 0.25 m^3/s (9 ft^3/s). After a small initial washout of suspended small solids during the first test, measurable sediment removal did not occur during the SCS250 sediment retention tests.

Sediment retention testing of a Stormceptor STC 1200 at St. Anthony Falls Laboratory indicated there was no measurable scouring and washout of sediments under high water flow conditions.

Scale Model Testing

A 1:10 scale model of a ten foot diameter separator with a swirling flow and two concentric cylinders was built at St. Anthony Falls Laboratory to advance the understanding of the principal processes which govern sediment scouring, resuspension and washout. Velocity measurements were taken in the model under a variety of flow conditions using a 3-dimensional Acoustic Doppler Velocimeter (ADV). Figure 4 shows the model with the ADV setup.

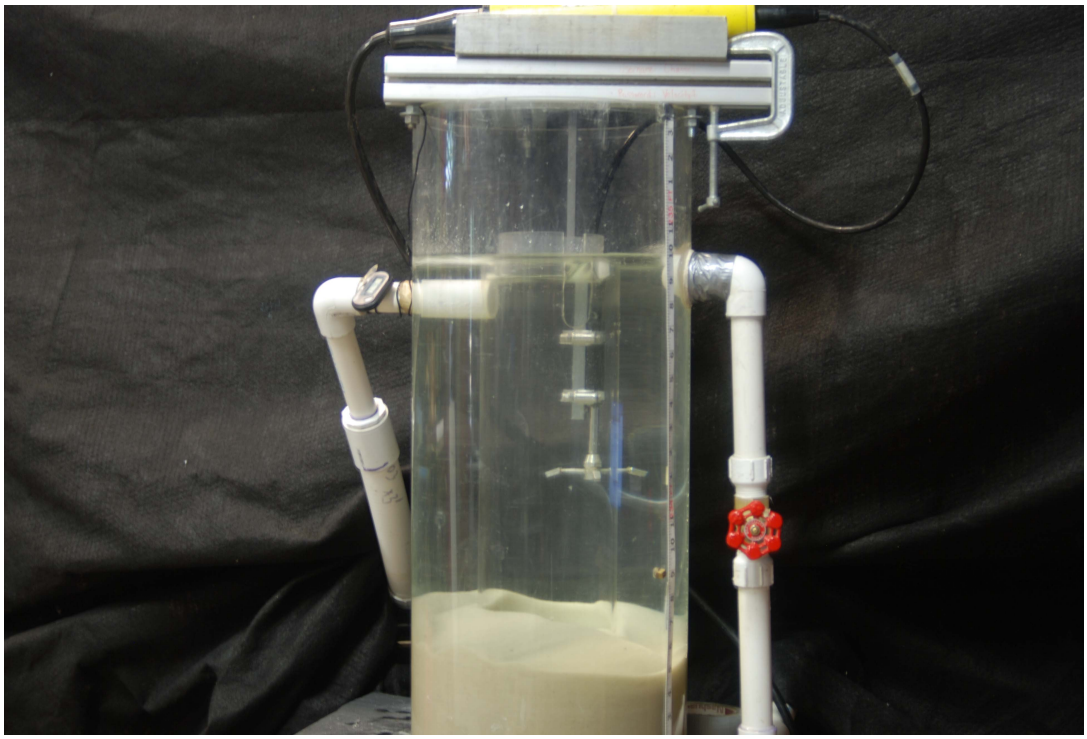

Figure 4: Model hydrodynamic separator with ADV setup (Saddoris et al., 2009)

Vertical velocity profiles were measured at one quarter of the circle downstream of the inlet pipe (1/4 Position in Figures 5 and 6) and at three quarters of the circle downstream of the inlet pipe (3/4 Position in Figures 5 and 6). The velocity readings were taken at a position halfway between the outer cylinder and the inner cylinder of the device. The x-direction was tangential to the radius in the horizontal plane. A variety of discharges were tested, and the results at 0.27 liters per second and 0.92 liters per second discharge are included as Figures 5 and 6, respectively. In Figures 5 and 6, the horizontal axis is the x-direction velocity divided by the average of the x-direction velocity for the position. The vertical axis is the reading height above the sediment bed divided by the height of the water column for the given discharge.

The velocity measurements taken in the model and shown in Figures 5 and 6 indicate:

1) There can be high flow velocities near the bed (3/4 position in Figures 5-7) and therefore substantial energy available for scouring
2) The velocity profiles can be dramatically different at different positions in the device
3) Velocities may be lower near the device outlet, potentially reducing the number of scoured particles that are washed out
4) Flow patterns in swirl flow devices can be complex

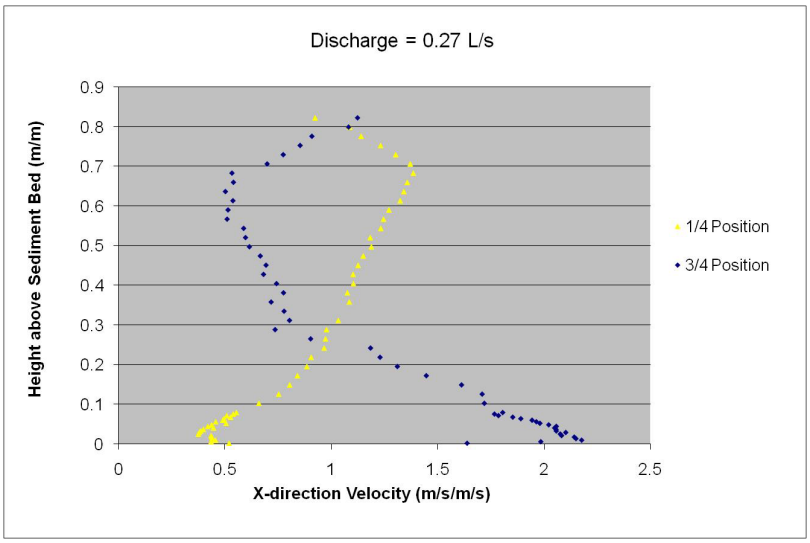

Figure 5: Scale model ADV testing at 0.27 L/s discharge

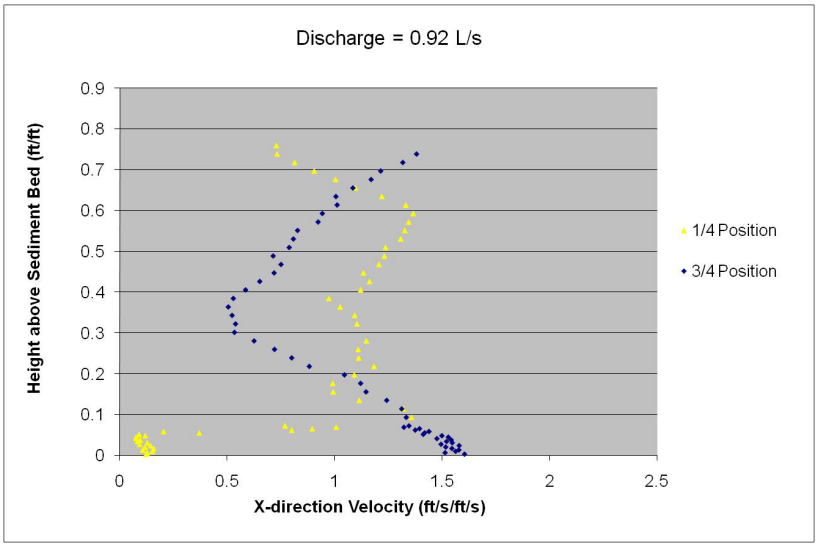

Figure 6: Scale model ADV testing at 0.92 L/s discharge

Further testing and data analysis is required to understand and predict flow patterns in swirl flow devices, which will lend to understanding of scouring, resuspension and washout of deposited sediments.

Maintenance

Future maintenance demands are an important consideration when evaluating hydrodynamic separators as a stormwater treatment option, since full life-cycle costs can be dramatically impacted by maintenance needs.

The primary maintenance activity required with hydrodynamic separators is cleaning of deposited sediments. These devices have design sediment capacities, and sediments must be occasionally removed to minimize resuspension and washout of accumulated sediments. Cleanout is typically accomplished utilizing a vacuum truck,

which is a reasonably costly procedure, so accurate prediction of required cleanout frequency would provide vital information on total life-cycle costs for hydrodynamic separators. However, many variables affect the accumulation of sediments, including watershed hydrology, suspended solids particle size distributions and densities in stormwater runoff, device performance efficiencies and device sediment retention capabilities. Therefore, accurate prediction of net sediment accumulations in a specific device in a specific drainage basin is challenging.

Typically, manufacturers recommend frequent inspections of sediment accumulations for the first one to two years of service so that sediment accumulation rates and cleanout schedules can be predicted. This procedure is time consuming and subject to inaccuracies, as rainfall conditions can vary significantly from year to year, and the results cannot be applied to different devices in different watersheds. If crucial variables affecting net sediment accumulation were well understood, models could be developed to predict cleanout frequencies and better estimate total suspended solids removals for regulatory compliance.

Summary

Solids removal performance, sediment retention and maintenance demands are all important considerations when selecting and sizing hydrodynamic separators for use as an urban stormwater best management practice (BMP).

Field and laboratory sediment retention testing has been completed on an Environment21 V2B1. Sediment compaction and shielding can influence sediment retention under actual operating conditions, so the idealized results obtained cannot be directly adopted as sediment retention rates for in-service devices. However, these results can be applied to help understand the impact of varying conditions on sediment retention, providing information for device design and maintenance. Further work is required to develop non-dimensional retention functions for the Environment21 V2B1 device, so the results so can be applied to a wider range of flow rates, suspended solids sizes and densities and water temperatures.

Laboratory testing has also been completed on a Stormceptor STC 1200. Measurable scouring and washout of sediments under high water flow conditions was not observed for this device.

In one test of a scale model swirl flow hydrodynamic separator the velocity profiles were complex, but could provide important indicators for understanding scouring and sediment washout. Sediment retention in hydrodynamic separators is specific to each design, so additional work is required to test devices and develop retention functions.

With adequate knowledge of drainage area runoff characteristics, suspended solids properties in runoff, device removal efficiencies and sediment retention capabilities, hydrodynamic separators could be accurately selected and maintenance schedules could be optimized to achieve sediment removal targets while minimizing costs.

Abstract

Although proprietary devices for the treatment of stormwater are used in many urban areas as best management practices (BMPs), their cost has prompted the Minnesota Department of Transportation (DOT) to consider the use of standard sumps to meet stormwater quality goals. However, no data on the effectiveness of sediment removal and proper operation of the sumps exist. Such data is necessary for standard sumps to be considered as a stormwater pretreatment device in Storm Water Pollution Prevention Program regulations.

To determine whether standard sumps remove suspended sediment from stormwater runoff, a sump was tested in a laboratory setting. The removal efficiencies under low flow conditions as well as the flushing effluent concentrations under high flow conditions were determined. In the low flow removal efficiency tests, sediments of specific size and concentration were fed into the influent pipe. At the conclusion of the test, the sediments removed by the sump were collected, dried and weighed. In the high flow condition tests, a predetermined sediment mix was placed inside the sump and the quantity of sediments remaining after the sump had been flushed by high flows for a period of time, was determined.

Sump removal efficiency functions have been developed, and an uncertainty analysis has been conducted as part of the data interpretation.

Background

The standard sump (manhole) has been a key component in stormwater infrastructure. In addition to providing a location for pipe junctions and storm sewer maintenance access, the sump's detention time provides for removal of some particulate and trash. In recent decades, proprietary devices for the treatment of stormwater have become increasingly popular to aid communities in meeting stormwater quality regulations. These regulations are a response to the 1987 amendments to the Clean Water Act (Smith 2001). While these proprietary devices have proven effective as a pre-treatment device that removes inorganic particles larger than silt, their expense has led the Minnesota DOT to seek other avenues to reach their stormwater pretreatment goals.

From 2005 to 2007, a team from St. Anthony Falls Laboratory at the University of Minnesota provided an in-depth laboratory and field performance analyses of several proprietary devices. The focus of these studies was to assess the removal of various sediment sizes from the influent. It was decided to follow the same testing procedure in the evaluation of standard sumps. The results would then be easily compared to that of the proprietary devices and the cost effectiveness of the standard sump can then be determined. In addition to the evaluation of the sump as a sediment capturing device, scour tests have been conducted to determine what flows will cause removal of the previously captured sediment. Guidelines for proper cleaning schedules can be produced with the latter data.

Theory

It is common practice to use monitoring for the evaluation of performance of stormwater best management practices (BMPs). Unfortunately, the use of samplers for monitoring influent and effluent has proven unreliable for the collection of some sediment particle sizes (Wilson et al., 2007). Therefore, in this study a mass balance approach was adopted to assess the performance of standard sumps.

The analysis of sediment removal efficiency will use the Peclet number (Wilson et al. 2009) because it provides a common non-dimensional ground to compare various devices. In this case the Peclet number is directly proportional to the particle settling velocity, device diameter, and depth. It is also inversely proportional to the device flow rate, thus

$$Pe = \frac{Vs * h * d}{Q} \tag{1}$$

When the Peclet number is plotted versus a particle size's measured removal efficiency, a performance function for a specific stormwater treatment device can be developed (Wilson et al., 2009). This performance function is described by the relationship shown in equation 2.

$$\eta = \left[\frac{1}{R^b} + \frac{1}{(a\ Pe)^b} \right]^{-\frac{1}{b}} \tag{2}$$

In equation 2, R, a, and b are fitted parameters, Pe is the Peclet number and η is the corresponding particle's measured removal efficiency. The measurement of η requires the addition of known masses of several particle sizes to the influent in the experiment, and subsequent drying, sieving and weighing of the captured sediment, as described in the next section.

A similar relationship has not yet been developed for the high flow scour tests, so they will be reported as a percent of the initial mass in the sump that is removed by the corresponding high flow.

Experiment Setup

A full scale fiberglass sump was constructed for testing by a local fiberglass manufacturer and placed on a test stand in the St. Anthony Falls Laboratory (SAFL) of the University of Minnesota in Minneapolis, Minnesota. The sump was then connected to the SAFL plumbing system and flow was measured using a pre-calibrated circular weir downstream of the model. The sump was 4 feet in diameter and 4 feet deep (the height of the inlet pipe from the sump bed), and had 15" inlet and outlet pipes at 0 and 180 degrees respectively. There was a one percent drop between the inlet and outlet pipes. Sediment was piped as a slurry from a sediment feeder into the inlet pipe approximately one foot upstream of the sump. The transverse velocity of the slurry allows for proper penetration into the flow within a short development length. The short development length eliminates loss of sediment in the inlet pipe. A manometer is connected to the device for the recording of water surface elevations in the inlet pipe, the sump, and the outlet pipe. Figure 1 is a picture of the fiberglass sump on the test stand.

Figure 1. Sump and Test Stand

Testing Procedure

Flow rates

The flow rates used in testing were determined by first calculating the 80% pipefull discharge using Manning's equation and assuming that this flow would be the design for a 10-year runoff event. Given this flow, the rational equation could be used to develop a representative urban watershed. The maximum flow rate for treatment assessment (MFRT) was then defined as the 1-year storm and calculated.

Performance Testing

Performance testing involves feeding of a known quantity and concentration of sediment with a known particle size to the inflow. A sediment mix was created from three median sediment sizes, 545 μm, 335.5 μm, and 107 μm. This mix was sieved so that particle overlap is not an issue and all three sizes are added to the flow in equal parts with a concentration of 200mg/L for all tests. Twelve tests were conducted with flow rates of 100%, 75%, 50%, and 25% of MTR in triplicate. These flow rates were 2.4 cfs, 1.8 cfs, 1.2 cfs, and 0.6 cfs. Three additional tests were conducted at 0.8 cfs and twice at 0.9 cfs with the 545 μm particle size only. Thus, with the three particle sizes, 39 different Peclet numbers and removal efficiencies could be calculated and fit to the model. Each test involved the addition of 10-15kg of the three part mix of sediment to flow. The amount of sediment added depended on the flow, i.e. low flows had smaller amounts of sediment input. The test duration was varied so the influent concentration remained the same

with lower flowrates having longer durations. Following each test the sediment was collected from the sump, dried, sieved, and weighed.

Scour Testing

Scour testing involved the placement of a predetermined amount of sediment into the sump before flows above the MFRT were applied, and the amount of sediment lost from the sump was recorded. This test involved the use of straight US Silica Sand F-110 which has a median particle diameter of 110 μm. The flow rates used were 100%, 75%, and 50% of the value for the 10 year storm as described above. These flow rates were 5.5 cfs, 4.2 cfs, and 2.8 cfs. All tests had a duration of one hour. After the initial placement of the known mass of sediment before the test, and after the termination of the test, sediment depth measurements were taken to determine the amount of sediment removed from the sump. The average effluent concentration could then be determined. In addition, tests were conducted to determine a mean bulk density of 107 lb/ft^3 for the US Silica Sand F-110.

Model Uncertainty

While the performance function has proven to fit the data nicely, no model or measurement is completely accurate (Kline, 1985). In order to evaluate the model fit it is necessary to evaluate the uncertainty of the model. Quantifying the uncertainty of this model involves the distribution of the residuals. As can be seen in Figure 2, the model residuals are not normally distributed. To deal with this issue, it was decided to use bootstrap resampling method to create pointwise confidence intervals to quantify the error in the fit of the model. Carpenter et al. (2000) provides an overview of the bootstrap method and its application.

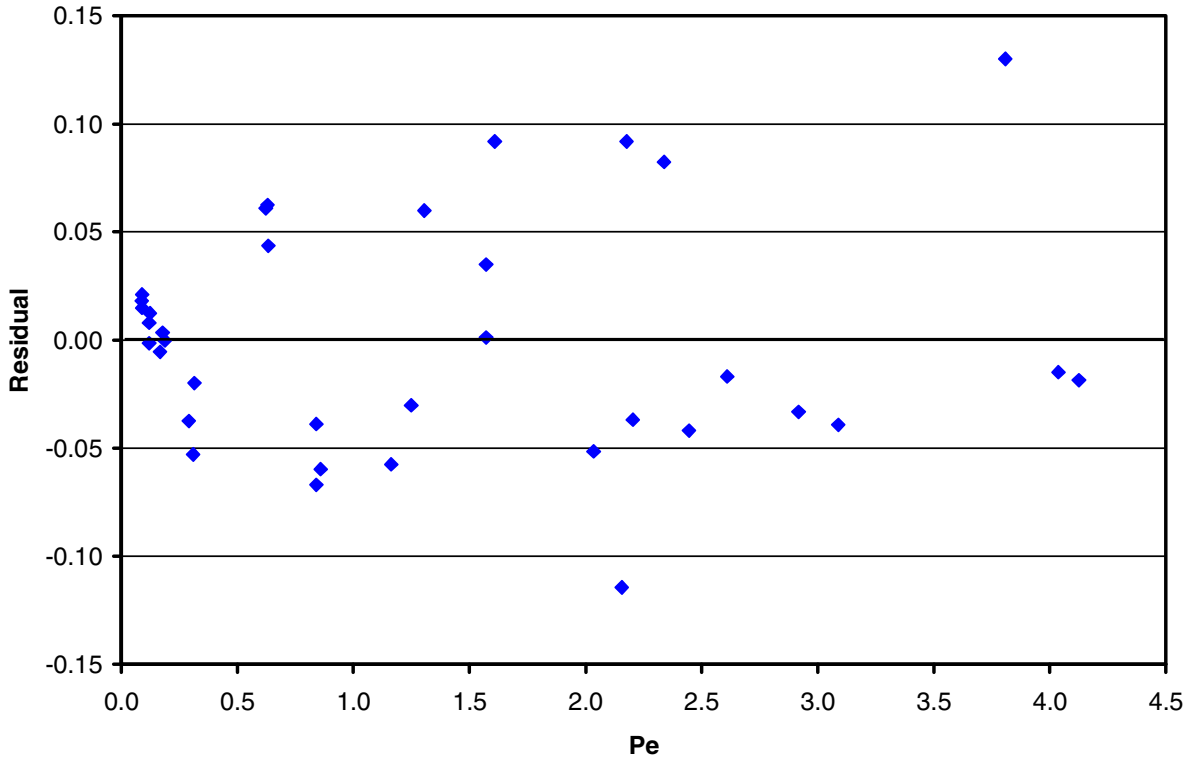

Figure 2. MN/DOT Sump Performance Curve Residuals

Results

Performance Results

Figure 3 shows the results of the performance test as well as the model fit to the data. The results from the performance tests of the standard 4 ft diameter sump indicate that the sump is effective in removing sediment from stormwater. As would be expected, the sump is more effective at higher Peclet numbers, which indicates either low flow rate or larger particle size. The three parameter model also fits the data well with a Nash-Sutcliff Coefficient of 0.97. With this model, it will be possible for designers to predict the removal efficiencies based on particle size, particle density, water temperature and flow. In addition, one can compare the results to various proprietary devices. Figure 4 shows results of a field test on a Stormceptor (Wilson et al., 2009), and of the standard sump. The performance of the two is close up to a Peclet number of two, where they begin to differ. The sump chosen can be expected to remove approximately 75% of the sediment, while the Stormceptor may remove up to 97% of particles. Even though the two performance functions seem to be very similar, it is important to note that dimensionless function was obtained from a Stormceptor with very large dimensions and thus to obtain the Stormceptor removal efficiency for a certain particle size and density, the standard sump flow rate should be significantly smaller than the Stormceptor. If the removal efficiency of standard sumps with different dimensions follow the function showed in Figure 4 for standard sumps, then up to a

Peclet number of about 2, using a standard sump for stormwater treatment is more cost effective than a Stormceptor.

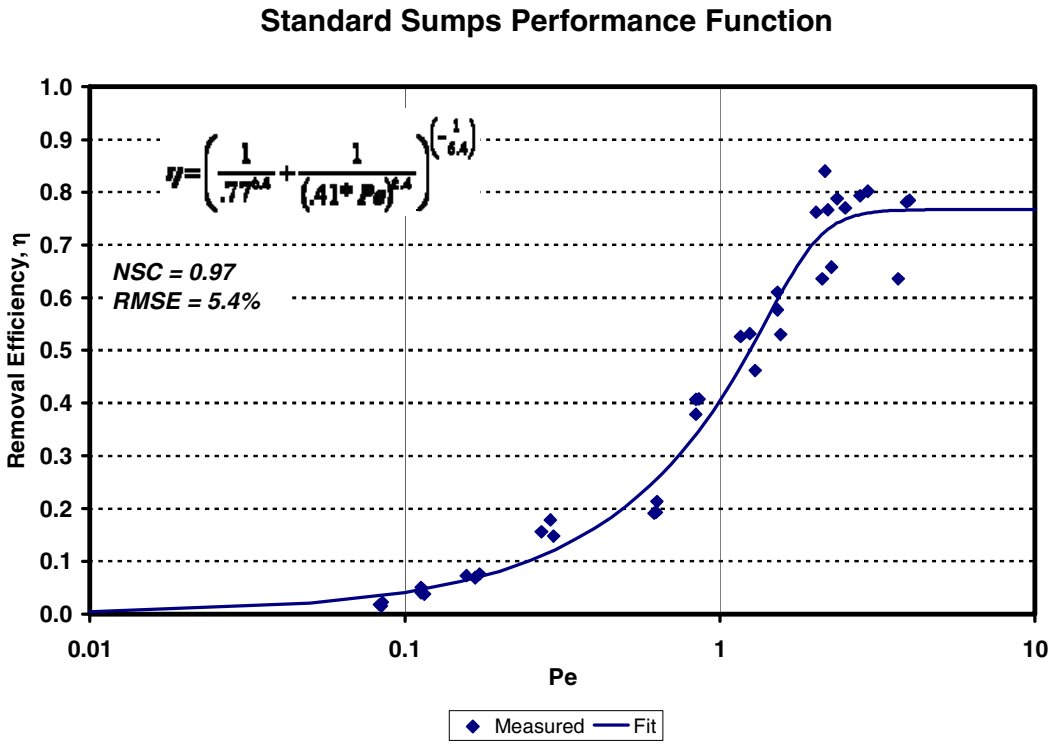

Figure 3. MN/DOT Sump Performance Function

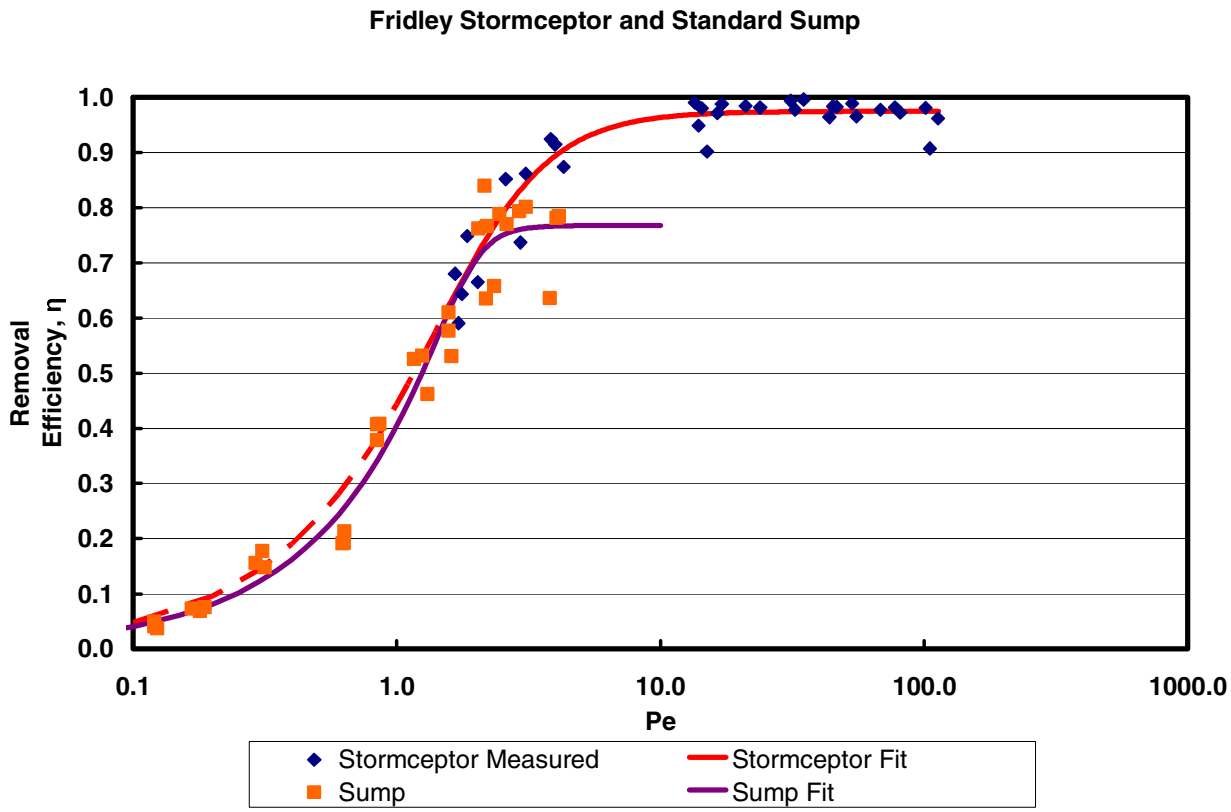

Figure 4. A 10-ft Stormceptor and a 4-ft Standard Sump

Scour Results

The results from the scour tests indicate a discrepancy between measurements and what is expected (Table 2). It would be expected that the higher the flow rate, the more scour would occur. The tests show little scour at the lowest flow rate, then a large increase for the intermediate flow, and finally decreased scour for the highest flow rate. A repeat test of the intermediate flow rate was conducted and showed a lower percent removal, however it was still high when compared to the values for the highest flow rates. On the whole, however, the amount of sediment removed remained low with values not exceeding 30% removal.

Table 2. Scour Test Results

Flow rate (cfs)	Depth Removed (m)	Mass Removed (kg)	Effluent Concentration. (mg/L)	Removed amount (%)
2.69	0.0000	6.21	0.38	1.97
2.88	0.0087	14.93	0.85	4.88
4.17	0.0502	86.04	3.37	27.38
4.17	0.0464	79.47	3.12	24.61
5.7	0.0288	49.28	1.41	14.08
5.41	0.0297	50.88	1.54	13.93
3.92	0.0213	36.53	1.52	12.85

Model Uncertainty Results

The results of the uncertainty analysis provide insight into the quality of the model fit. The uncertainty analysis gives the uncertainty of the model fitting, not the uncertainty in the data. In other words, for a 95% confidence interval 95 out 100 fitted lines will lie within these bounds. Figure 5 shows the fitted model with its 95% confidence bounds.

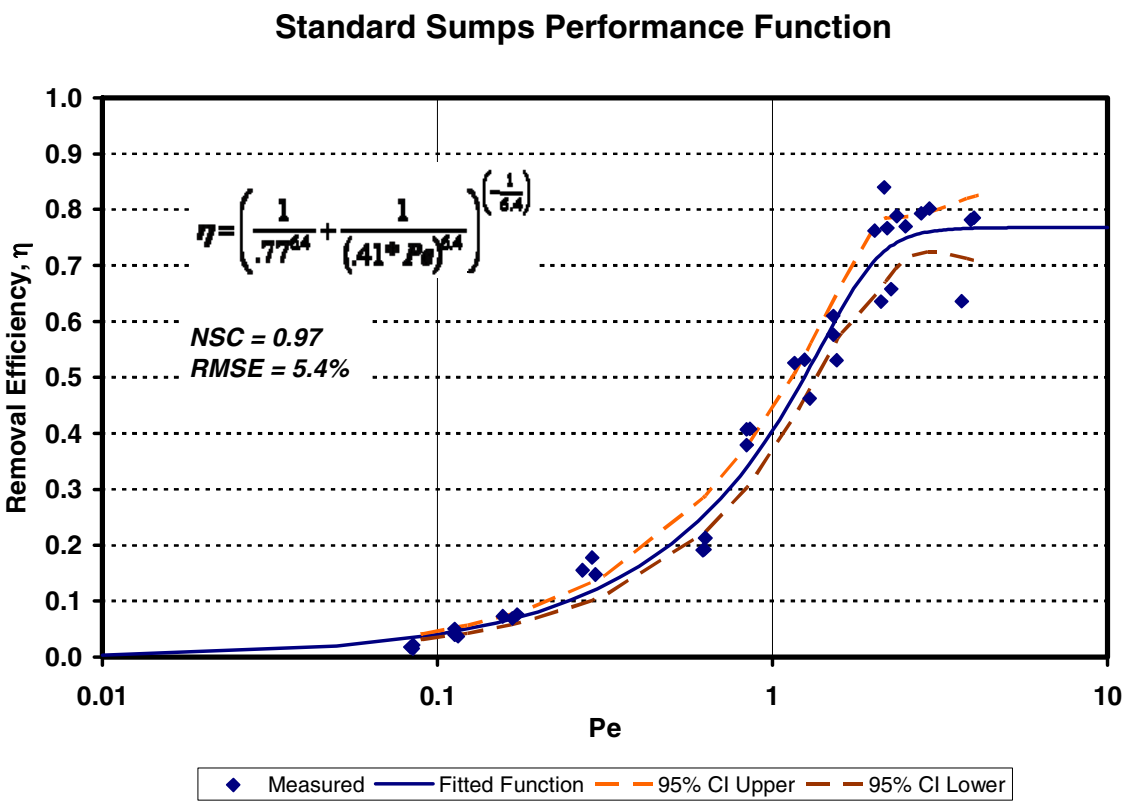

Figure 5. MN/DOT Sump Performance Function With Confidence Intervals

Future Research

The testing of the 4ft diameter sump is the first in a series of tests sponsored by the Minnesota DOT. Future research includes tests on a 4-ft diameter shallow sump and a 6-ft diameter deep and shallow sump. In addition, 90 degree outlets have been constructed on the test sumps to model flows through sumps with different outlet configurations. Acoustic Doppler Velocimeter tests will also be completed to provide information on the flow characteristics.

Conclusion

The performance of a standard sump for stormwater BMP has been assessed in this project. While the sump cannot attain the high removal efficiencies for typical flow rates and sediment particles seen by the proprietary devices, it could prove effective under some conditions. Communities which would expect higher removal efficiencies may find that a standard sump can reach their stormwater pretreatment goals. In these cases the sump would be a good option because of its simplicity and low costs. In addition, scour remains low at flow rates slightly higher than the MFRT. This ensures that captured particles will remain in the sump as long as the municipality follows a regular cleaning schedule.

Acknowledgements

We would like to thank the Minnesota Department of Transportation for providing funding for this project. In addition, thanks is due to Julia Molony of the University of Minnesota Statistical Clinic for her help with the uncertainty analysis. Also Andrew Sander, Teigan Gulliver, Benjamin Plante, and Andrew Fyten at the St. Anthony Falls Laboratory provided great help and support through the setup and testing process.

Abstract

A Bayesian load duration curve approach is developed to estimate indicator bacterial load reductions for a small, urban watershed with stormwater and animal inputs. The Bayesian load duration curve approach uses the truncated bivariate normal probability distribution to predict flow, in-stream bacterial concentration, and the resulting load for a specified number of flow conditions. Using non-informative priors, the Bayesian approach propagates the uncertainty resulting from the natural variability in observed concentrations through to the predicted in-stream indicator bacterial concentration and load. Using the best estimate 90th percentile in-stream loads, the Bayesian method predicts indicator bacterial load reductions ranging between 68% for low flows and 99.9% for high flows. The predicted distributions of in-stream bacterial concentration are then compared pre- and post-implementation of stormwater filtration. The pre-implementation distribution of in-stream indicator bacterial concentration demonstrates that the stream exceeds the standard of 235 cfu/100ml *E. coli* 76.1% of the time during the recreational season with a 95% credible interval CI(74.6, 78.0). The post-implementation distribution of indicator bacterial concentration predicts that the concentration of indicator bacteria exceeds the limit set by the water quality standard 72.4% CI(70.6, 74.3). Alternatively, the Bayesian model is then used to predict in-stream concentration post-implementation of an aggressive ultra-violet disinfection process.

Introduction

The formulation of water quality management plans in the United States is driven by the US Environmental Protection Agency (US EPA) rules and guidance for the determination of Total Maximum Daily Loads (TMDLs) (NRC 2001). As required by section 303(d) of the Clean Water Act (1987), each state must identify the waters within its borders that are not in attainment of water quality standards, not protecting a balanced wildlife population, or not supporting their designated use. There are over 60,000 listed impairments for waterbodies on the US EPA 2004 303(d) list of impaired waters. For these impaired waters, the TMDL program general guidance requires a base level of analysis (EPA 2005): (1) the identification of pollutants causing impairment; (2) the wasteload allocations from point sources, the load

allocations from nonpoint sources, and natural background conditions necessary to implement the applicable water quality standard; and (3) a margin of safety (MOS) and a consideration of seasonal variations. Beyond the base level of analysis, the program remains flexible in terms of the methodology used to accomplish 2 and 3. The benefit of this flexibility is the variety of methodologies possible for addressing the overwhelming number of impaired waterbodies.

The objective of the work is to demonstrate and apply the use of a new Bayesian water quality model for TMDL application when the impairment source is presumed to be pathogen contamination (as measured by indicator organisms). Further, we will demonstrate this model's predictive power given alternative control strategies for stormwater. The new model is designed to increase TMDL progress by relaxing the data requirements inherent to existing models while adding the capability to model control strategies. In addition, the new model incorporates uncertainty analysis by treating the model parameters and predictions probabilistically. The new TMDL method is based on the traditional load duration curve approach, but with added capability to predict control strategy performance under uncertainty.

The new Bayesian load duration curve approach is presented and then applied to an urban case study with non-point source bacterial contamination to calculate the required load reductions and evaluate alternative control strategies. The following section provides background on the Bayesian process; the recommended methods for TMDL bacterial analysis, including the traditional load duration curve approach; and each model's ability to formulate control strategies.

Background

Alternative TMDL Bacterial Models

The TMDL program is flexible in the methodology allowed for load allocations and reductions. EPA technical documents (EPA 2001; EPA 2007) as well as research (Donigian and Huber 1991; Wilkinson, Jenkins et al. 1995; Borah and Bera 2003; Borah and Bera 2004; Horn, Rueda et al. 2004; Benham, Baffaut et al. 2006) summarize the strengths and weaknesses of the recommended and popular methodologies for bacterial TMDLs. These reviews categorize the models into many different types including dilution models, continuous dynamic models, and empirical models. Dilution models, primarily used for point source allocation, specify the maximum load for the critical low-flow period (EPA 2001). To model both non-point and point sources, continuous or empirical models are employed.

Continuous models include QUAL2E, WASP, and HSPF, which provide time-series estimates of concentration based on point and non-point source loading. Of the three, only HSPF also allows certain Best Management Practices (BMPs) to be modeled using a constant percent load reduction. QUAL2E was developed to examine waste load allocations under steady flow conditions with limited non-point source representation (Shanahan, Henze et al. 1998). WASP and HSPF are dynamic models with the ability to model both point and non-point source loading; WASP requires

non-point source loading inputs while HSPF allows a "buildup and washoff" sub-routine (Donigian and Huber 1991; EPA 2001). These tools simulate the variation in in-stream concentration over long periods of time at multiple locations to allow identification of critical conditions and locations. These tools also allow simulation of changes to source loading to identify viable load reduction alternatives. Although useful for exploring alternative loading scenarios, the dynamic models require numerous types of data for model formation and comprehensive datasets for calibration (Donigian and Huber 1991; EPA 2001; Borah and Bera 2003). In addition, the large number of model parameters prevents a thorough uncertainty analysis. An alternative to the data-intensive continuous, dynamic models for specifying both point and non-point source allocation is the load duration curve approach.

In guidance provided by the US EPA Office of Water, the load duration curve (LDC) TMDL approach is recommended over difficult to construct and run dynamic models when the primary driver of contamination is flow (EPA 2007). A load duration curve is an empirical method that plots the percent of time that an observable quantity of interest is exceeded. In other words, a duration curve is the complement of the cumulative distribution function F(y) for a quantity of interest y:

$$DC(y) = 1 - F(y) = P(Y \geq y)$$

Duration curves have been used in water resources planning to communicate the variability of water quality and quantity characteristics and to evaluate the impact of management options on those characteristics (Vogel and Fennessey 1995). In TMDL applications, the quantity of interest is the in-stream allowable contaminant load, W. A load duration curve DC(W) can be constructed to estimate a TMDL for a waterbody from the flow duration curve DC(Q) given an in-stream water quality target concentration, S:

$$DC(W) = DC(Q) * S$$

where the $DC(Q)$ is created from a long-term record of average hourly or daily flow measures (Searcy 1963). The load duration curve specifies the allowable in-stream load over the range of possible flow conditions and can be used as the base for the TMDL allocation process. The TMDL for each flow condition is the minimum allowable in-stream load for that flow condition as specified by the $DC(W)$. Load reductions can be specified by comparing the $DC(W)$ to the 90^{th} percentile observed in-stream load under each flow condition (2007).

Although the traditional LDC approach is sufficient for meeting the minimal TMDL requirements, using the approach, it is difficult to map loads to specific sources. Bonta and Cleland (2003) suggest that source tracking techniques be paired with the LDC approach to identify differences in source between flow conditions. In addition, the traditional LDC approach can not facilitate the prediction of water quality or BMP effect on water quality. To facilitate prediction, Bonta and Cleland (2003) present a

load duration curve method that predicts water quality for flow conditions with no observed samples using ordinary least squares regression (OLS). The Bayesian approach outlined in the present work is similar to the regression approach in that it extends the observations in a monitoring record to predict in-stream load for any given flow, but the process proposed here assumes a statistical model for both flow and concentration that allows prediction of future in-stream concentration given a control strategy.

Bayesian Basics

Bayesian data analysis is the process of making inferences from data using probability models for observed quantities as well as unobservable quantities of interest (Gelman, Carlin et al. 2004). For example, given an observable quantity of interest *y*, Bayesian data analysis can estimate an unobservable quantity θ, such as population parameters for *y,* if the two quantities can be expressed as a joint distribution function,

$$p(\theta, y) = p(\theta)p(y \mid \theta)$$

where p(θ) is the prior distribution of the unobservable quantity, which is designed to represent the uncertainty about θ, and p($y|\theta$) is the sampling distribution of the observed quantity. All inferences about θ are based on Bayes rule which estimates a posterior distribution for the unobservable quantity p($\theta|y$) from the joint distribution function by conditioning on the known value of observable quantity *y,*

$$p(\theta \mid y) = \frac{p(\theta)p(y \mid \theta)}{\int p(\theta)p(y \mid \theta)d\theta}$$

In addition to making inferences about θ by formulating the posterior distribution p($\theta|$y), Bayes rule can be used to make inferences about future observations of the observable quantity $\tilde{y}$ through the posterior predictive distribution p*($\tilde{y}|y$),

$$p*(\tilde{y} \mid y) = \int p(\tilde{y} \mid \theta)p(\theta \mid y)d\theta$$

The posterior predictive distribution is expressed as an average of the conditional predictions over the posterior distribution of θ. In this way, Bayesian analysis propagates the uncertainty from model parameters through to the final prediction. The qualities of Bayesian data analysis, including the probabilistic representation of quantities of interest and propagation of uncertainty, makes it a powerful tool for water quality planning (Hobbs 1997).

Bayesian Model

The Bayesian model predicts the distribution of in-stream indicator bacterial concentration over the recreational season using a bivariate likelihood model relating the natural log of indicator bacterial concentrations *y* to the natural log of flow *x* for

different flow conditions *c*. By dividing the flow into conditions, each with equal probability *P*, the joint distribution for each condition $f_{T,c}(x, y)$ is a singly truncated bivariate normal distribution, expressed here as the product of the marginal distribution of *x* and the conditional distribution of *y*,

$$f_{T,c}(x,y) = \frac{1}{\sigma_x P\sqrt{2\pi}} \exp\left\{-\frac{1}{2}\left[\frac{x-\mu_x}{\sigma_x}\right]^2\right\} \times \frac{1}{\sigma_{y|x,c}\sqrt{2\pi}} \exp\left\{-\frac{1}{2}\left[\frac{y-\mu_{y|x,c}}{\sigma_{y|x,c}}\right]^2\right\}$$

where

$$u_{y|x,c} = \alpha_c + \beta_c(x - \bar{x}_c)$$

$$\beta_c = \frac{\rho_c \sigma_{y,c}}{\sigma_x}$$

$$\sigma^2_{y|x,c} = \sigma^2_{y,c}(1 - \rho^2_c)$$

$$\alpha_c = \mu_{y,c} - \beta_c(\mu_x - \bar{x}_c)$$

and for a given sample of *n* specimens in the truncated section, $\bar{x} = \sum_1^n \frac{x_i}{n}$. In this form, the conditional distribution of *y* is normally distributed with a standard deviation $\sigma_{y|x,c}$ and mean $u_{y|x,c}$. The conditional expected value $u_{y|x,c}$ is equivalent to an OLS regression between *x* and *y* in each flow condition.

The Bayesian model creates posterior estimates of the parameters of *y* for the truncated bivariate normal distribution $\theta_{y,c} = (\mu_{y,c}, \sigma_{y,c}, \rho_c, \mu_{y|x,ci}, \sigma_{y|x,c})$ for each flow condition (i.e. low, normal, and high) using Markov chain Monte Carlo (MCMC) samples implemented through the WinBUGs program (Spiegelhalter, Thomas et al. 1999). Non-informative priors are used to reduce the influence of the model structure on the predicted results. Three chains of 40,000 iterations with over dispersed starting points were used for posterior inference. The burn-in period was 20,000 iterations and was identified when the Rubin Diagnostic $\hat{R}$ (Gelman and Rubin 1992) converged to 1.

To calculate the load reduction for a particular flow value x_i, the posterior MCMC samples of parameter estimates are used to generate samples of the posterior predictive 90th percentile in-stream load for flow x_i. To do this, one sample of concentration is generated from each MCMC sample of mean and standard deviation of conditional concentration $(\mu_{y|x,ci}, \sigma_{y|x,c})$ for the select flow x_i. These samples make up the posterior predictive distribution of concentration at flow x_i. The posterior predictive concentration samples are then used to generate a series of loads for flow x_i from which the 90th percentile load is estimated. This process is repeated 1000 times for each flow x_i to create a 95% credible interval of 90th percentile load. The percent

reduction is found by taking the difference between the selected confidence of the 90th percentile in-stream load and the allowable in-stream load specified by the load duration curve *DC(W)*.

To evaluate model performance, posterior predictive checks were generated for the parameters $\theta_{y,c} = (\mu_{y,c}, \sigma_{y,c})$ using the MCMC samples and sample data. The posterior predictive distributions of $\theta_{y,c} = (\mu_{y,c}, \sigma_{y,c})$ are compared to the maximum likelihood parameter estimates using the data:

$$\hat{\mu}_{y,c} = \bar{y}_c + \bar{r}_c \left(\frac{\bar{s}_{y,c}}{\bar{s}_{x,c}}\right)(\bar{x}_c - u_{x,c})$$

$$\hat{\sigma}_{y,c} = \bar{s}_{y,c} \sqrt{\frac{1 - (1 - \frac{\bar{s}_{x,c}^2}{\sigma_{x,c}^2})(1 - \bar{r}_c^{\,2})}{(1 - (1 - \frac{\bar{s}_{x,c}^2}{\sigma_{x,c}^2}))}}$$

where r_c is the sample correlation coefficient and bars over the parameters indicate that only observed data from within the condition are used in estimation (Cohen 1955).

Site

Panther Hollow Stream is located within a 115 acre watershed encompassing Pittsburgh's central park, Schenley Park, and the surrounding urban neighborhood. The stream feeds a small lake created for recreational purposes in the early 1900s. Panther Hollow Stream contributes large loads of indicator bacteria from stormwater runoff, wildlife, and pets that presently prevent recreational activity. The Bayesian LCD analysis is used to predict bacterial concentrations at the outlet of the stream during the recreational season to determine the load reductions necessary to meet the recreational grab sample standard of 235 cfu/100ml *E. coli* as well as evaluate alternative control strategies.

Flow and *E. coli* concentration were monitored in Panther Hollow Stream over the recreational season of May-August in 2006 and 2007. Weekly samples were collected at the outlet of Panther Hollow Stream in order to assess compliance with the federal recreational water quality standard. Water samples were collected using sterilized and sealed 500 ml Nalgene bottles. Samples were transported on ice and refrigerated (4°C) until processing, which occurred within six hours of collection. All laboratory tests were run in duplicate and a blank was run for 10% of the samples. EPA Method 1603 (modified mTEC) and EPA approved ColiQuant Membrane Filtration methods were used to determine the concentration of *E. coli* (cfu/100ml) in the samples. Flow (cfs) at the time of sampling was estimated using a FP101-FP201

Global Flow Probe to measure stream velocity at mid-stream and the estimated stream cross-sectional area.

The scatterplot in Figure 1 shows the range of observed in-stream $\log_{10}$ concentration and flow for Panther Hollow Stream. The figure shows that as flow increases, the observed in-stream concentration increases above the maximum grab sample standard of 235 cfu/100ml *E. coli*, shown as a dashed line. Figure 1 also shows the equal probability flow conditions, roughly matching the observed weather conditions of dry weather and raining. As evidence in support of the structural assumption of normality, Figure 2 shows histograms of $\log_{10}$ concentration for each of the three flow conditions along with normal Q-Q plots, where alignment with the straight diagonal line indicates a normal probability distribution.

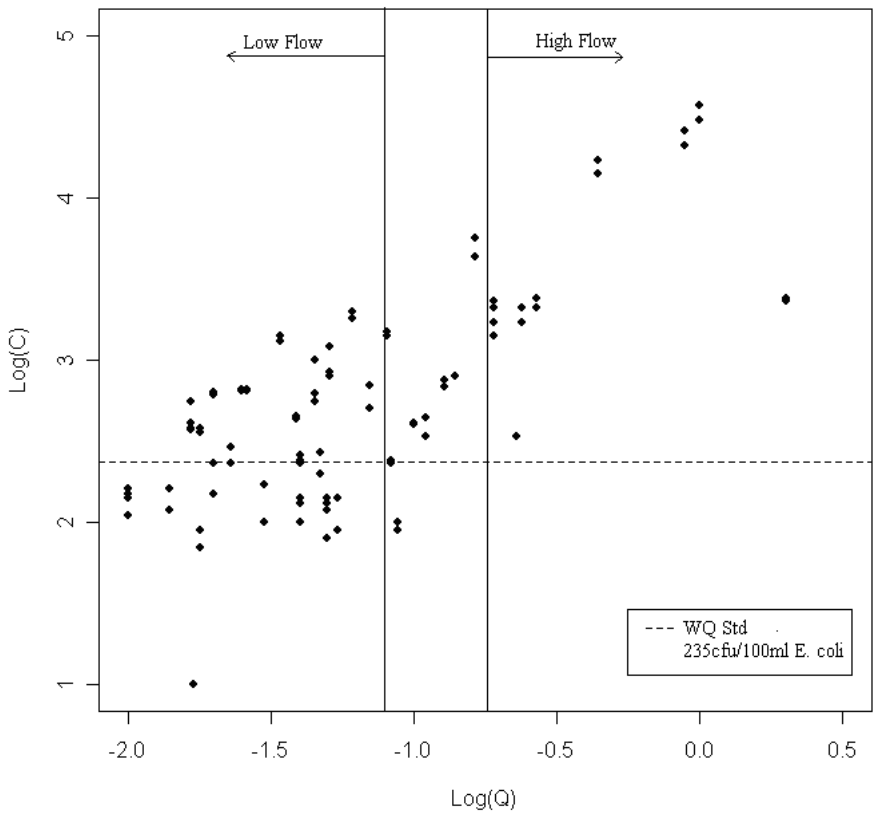

Figure 1. Scatterplot of E. *coli* Concentration and Flow for the 2006 and 2007 Recreational Seasons. The vertical lines show the divisions between low, normal, and high flow conditions.

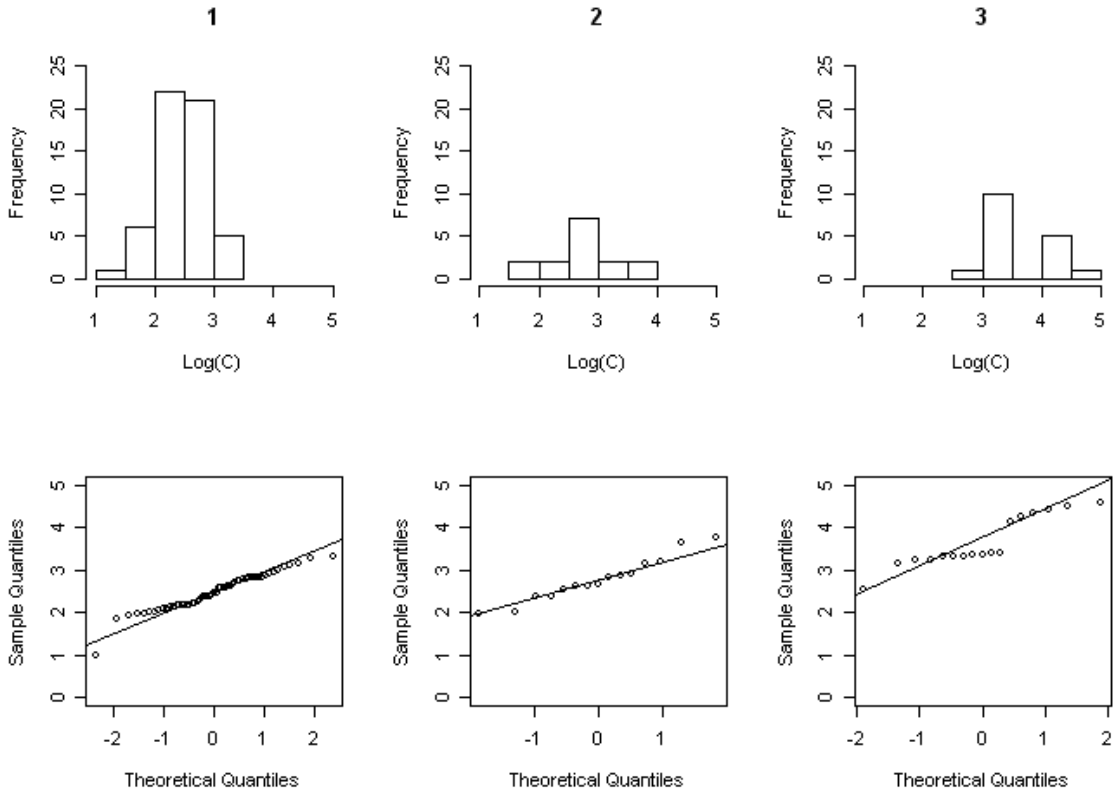

Figure 2. Histograms and normal Q-Q Plots of Recreational Season E. *coli* Concentration for Each Flow Condition. Histograms for the low, normal, and high flow conditions (i.e. 1,2,3) show the sample distribution of $\log_{10}$ *E. coli* concentration. The normal Q-Q plots show fit to the normal model represented by the diagonal line.

Flow Model

The LDC methodology requires a long-term, continuous flow record. Since no streamflow gauge is located in the watershed to provide this type of data, a dynamic watershed model was built in Hydrological Simulation Program-Fortran (HSPF) to simulate hourly flows for Panther Hollow Stream over the recreational seasons 2001-2007. The series of average hourly flows were used to estimate the empirical period-of-record *DC(Q)* as well as parameterize the truncated bivariate normal model.

HSPF models unidirectional flow through completely mixed streams segments using a storage-routing method (Bicknell, Imhoff et al. 2001). Input into the model includes information about the stream segments, watershed, and meteorological conditions. The watershed characteristics are used to estimate overland and subsurface wet weather flows. The Panther Hollow Stream watershed is approximately 115 acres (10% impermeable and 90% permeable) with slopes ranging between 0.1 and 0.6. The calibrated hourly precipitation for years 2001-2007 is

provided at a 1km x 1km resolution for the city of Pittsburgh using NEXRAD radar and a 30 rain gage network by Three Rivers Wet Weather (2007).

The main parameters in the flow calibration process include nominal soil moisture storage and infiltration capacity. The infiltration capacity was initially set within the range common of SCS Hydrologic Soil Group C with moderate to high runoff potential. Soil moisture storage was initially set at 25% of the annual average rainfall. These key parameters were then adjusted in the calibration process to achieve good model performance using the 2006 sample season data. Model performance was evaluated by two measures. The reliability index *RI* (Leggett and Williams 1981) quantifies the average factor by which simulated hourly flows differ from the observations. The modeling efficiency (MEF) measures how well the model predicts the observed values relative to the average of the observations. A MEF value near one indicates a close match between observations and model predictions (Stow, Roessler et al. 2003). A value of zero indicates that the model predicts no better than the average of the observations, and a value less than zero indicates that the average predicts better than the model. The MEF at the stream outlet is 0.76, indicating a close match between observations and model predictions. The RI at the stream outlet is 2.0, indicating that a model predicts the observations within a multiplicative factor of two, on average.

Control Strategies

Two alternative control strategies are compared for achieving the recreational water quality standard: a stormwater sand-filtration best management practice and an ultraviolet (UV) disinfection process. The two alternatives represent the two extremes of commonly implemented stormwater control strategies; the BMPs are generally less expensive but have uncertain performance, while the UV disinfection process has well documented performance at a great expense (Perdek, Arnone et al. 2003). The posterior predictive distributions of concentration in each flow condition are used to compare the percent of time that the waterbody is in compliance with the recreational standard pre- and post- control strategy implementation.

The first control strategy, the stormwater BMP is a sand-filtration sock or box that fits into the stormwater culverts and filters only the collected stormwater. The BMP performance was estimated by Hipp *et. al.* using benchscale testing with bacterial suspensions ranging between 10,000-80,000 cfu/100ml at a flow rate of 0.1 cfs (2006). The BMP performance is incorporated into the model using three alternative approaches; all three approaches assume that all stormwater is treated without bypass. The first is a constant load reduction approach, similar to what is assumed in HSPF. The constant load reduction is set at 46.0% as reported from the benchscale removal efficiency by Hipp *et. al.* (2006). This constant load reduction is applied to the posterior predictive distribution of load for the high flow condition.

The aggregated data on stormwater Best Management Practices (BMP) performance in the National Pollutant Removal Performance Database (Winer 2000) and the

International Stormwater BMP Database (Wright Water Engineers 2007) indicate that there is significant variability in the performance of BMPs. Therefore, the second two techniques incorporate uncertainty in load reduction performance. A lognormal distribution with parameters estimated using the method of moments, a sample mean of 46.0%, and sample standard deviation based on the benchscale performance at 36.0% is used to represent variability in the BMP performance. In addition, a uniform distribution is compared with lower and upper limits set at 9.0% and 92.0% to match the mean performance and standard deviation. Each method is applied to the posterior predictive distribution of load for the high flow condition through Monte Carlo sampling of percent reduction.

The BMP performance is compared to a more aggressive control strategy, an ultraviolet (UV) disinfection process using low-pressure mercury lamps with a wavelength of 25.7 nm. The performance of the UV disinfection process is measured as a rate of inactivation. The natural log of the rate of inactivation is assumed to follow the first-order reaction (Droste 1997):

$$\log(\frac{N}{N_0}) = -KD$$

where
N and N_0 are the concentration of bacteria at time t and initially (cfu/100ml)
K is an inactivation coefficient (cm^2/J)
D is radiation dose (mW/cm^2)

The radiation dose D is a function of the initial intensity of radiation and the time to which the organism is exposed to radiation:

$$D = (I_0 e^{-kd})t$$

where
I_0 is the initial intensity of radiation (mW/cm^2)
k is the absorbance coefficient (base e) (cm^{-1})
d is the depth of water (cm)
t is the exposure time (s)

The radiation dose is affected by flow in two ways. The time of exposure and intensity of radiation decreases as flow increases, decreasing the radiation dose. Here, the depth is assumed to increase proportional to the flow rate while time decreases proportional to the flow rate. In this way, the performance of the UV process changes based on the flow conditions.

To model UV performance, the absorbance coefficient k is set at 0.125 cm^{-1} to represent natural waters and the model is parameterized to achieve a 0.01 rate of inactivation for the 90th percentile stormwater flow rate of 0.25 cfs. The linear relationship between log inactivation and radiation dose is then used to solve for the

rate of inactivation given an observed flow and concentration from the posterior predictive distribution. This process is repeated for the 80th percentile flow of 0.15 cfs. In contrast to the stormwater BMP, the UV disinfection process treats the in-stream bacterial loads under all flow conditions.

Results

The Bayesian LDC results include the posterior predicted distribution of in-stream *E. coli* concentration during the recreational season for the outlet of Panther Hollow Stream, the estimated load reductions necessary to meet the recreational water quality standard, and the predicted distribution of bacterial concentration post-implementation of the various control strategies. All results are based on the posterior distributions of the truncated bivariate normal parameter estimates.

Table 1 shows the mean posterior parameter estimates $\theta_{y,c} = (\mu_{y,c}, \sigma_{y,c}, \rho_c, \sigma_{y|x,c})$ along with 95% credible intervals (CI). The mean posterior parameter estimates of bacterial concentration, standard deviation, and conditional standard deviation for the high flow condition are larger than those of the low flow condition. This suggests that during periods of high flows, the concentration of indicator bacteria is higher and more variable than during periods of lower flow; however, there is overlap in the 95% CI among parameter estimates for the different conditions. Looking at the correlation coefficients, the high and low flow conditions have strong positive relationships between flow and concentration. The differences in parameter estimates among the flow categories are displayed in Figure 3. The posterior predictive checks in Figure 3 show the posterior predictive distributions, observed maximum likelihood parameter estimates, and Bayesian p-values for the mean and standard deviation of concentration for each flow condition, $\mu_{y,c}$ and $\sigma_{y,c}$. The Bayesian p-value range between 0.21 and 0.62 indicates that the observed data are plausible under the posterior predictive distributions.

Table 1. MCMC Parameter Estimates. Parameter estimates for concentration are shown in $\log_{10}$ units for low, normal and high flow conditions (1,2,3). Mean estimates are shown in the first row and the 95% CIs are shown in parenthesis.

	Condition		
Parameter	**1**	**2**	**3**
$\mu_{y,c}$	2.792	2.655	3.172
	(2.391,3.003)	(2.413, 2.879)	(2.669, 3.670)
$\sigma_{y,c}$	0.500	0.673	0.700
	(0.364, 0.708)	(0.370, 1.384)	(0.482, 1.013)
ρ_c	0.490	0.240	0.564
	(-0.050, 0.813)	(-0.846, 0.931)	(0.033, 0.839)
$\sigma_{y\|x,c}$	0.409	0.476	0.544
	(0.337, 0.502)	(0.336, 0.702)	(0.383, 0.769)

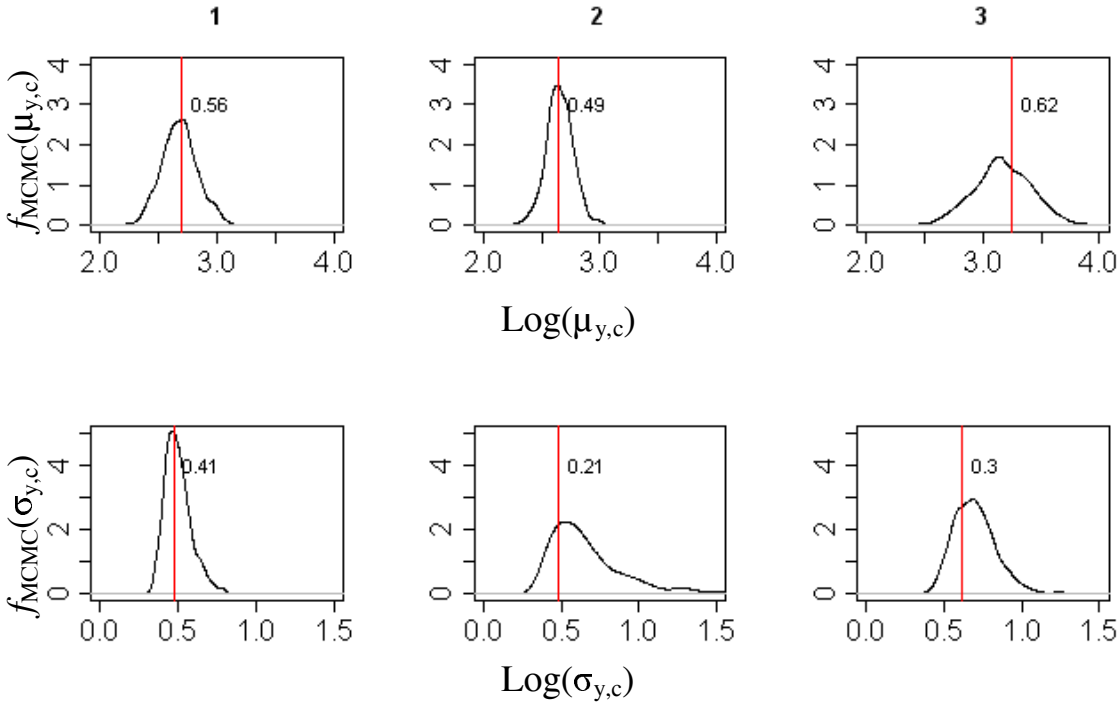

Figure 3. Posterior Predictive Check. The posterior predictive distributions, observed maximum likelihood estimates, and Bayesian p-values for $\mu_{y,c}$ and $\sigma_{y,c}$ are shown for $\log_{10}$ transformed variables with the flow conditions increasing in magnitude from left to right.

The resulting posterior predictive cumulative distribution function (CDF) of recreational season concentration at the stream outlet is shown in Figure 4. In Figure 4, the CDF for bacterial concentration is represented as a bold line with the allowable in-stream *E. coli* concentration set by the standard (235 cfu/100ml) shown as a vertical line. The posterior predictive CDF predicts that the in-stream indicator bacterial concentration exceeds the limit 73.4% of the time during the recreational season with a 95% credible interval CI(71.9%, 74.8%). Figure 4 also shows the CDFs for each flow condition, with exceedance probabilities 57.4% CI(54.2%, 60.1%), 73.5% CI(70.7%, 76.0%), and 97.8% CI(96.9%, 98.6%). Since each flow condition has a unique posterior predictive CDF, the load reductions required to meet the water quality standard vary for each flow condition.

The estimated load reductions necessary to meet the recreational water quality standard for Panther Hollow Stream are shown in Figure 5. Figure 5 displays the components of the traditional LDC approach necessary for a TMDL analysis: the flow CDF (the complement to the *DC(Q)*), represented as a dashed line; the CDF of the allowable in-stream bacteria load for the recreational season (the complement of *DC(W)*), represented a solid line; and estimates of the 90th percentile in-stream bacterial load, represented as closed circles. The x-axis of Figure 5 measures flow

$\log_{10}(Q)$ (cfs) and in-stream bacteria load $\log_{10}(W)$ (cfu/s), and the y-axis measures density values. Unlike the traditional approach, the Bayesian LDC displays the expected posterior predictive estimate of the 90th percentile in-stream load E[90th[log[W]|log[Q]]] for six representative flows. The black bars show the 95% CI for the predicted 90th percentile loads. All of the Bayesian model predictions of expected 90th percentile load are to the right of the allowable in-stream load, indicating that load reductions are necessary. The Bayesian percent load reductions (*PRB*) for each flow are presented using the mean of the posterior predictive 90th percentile loads.

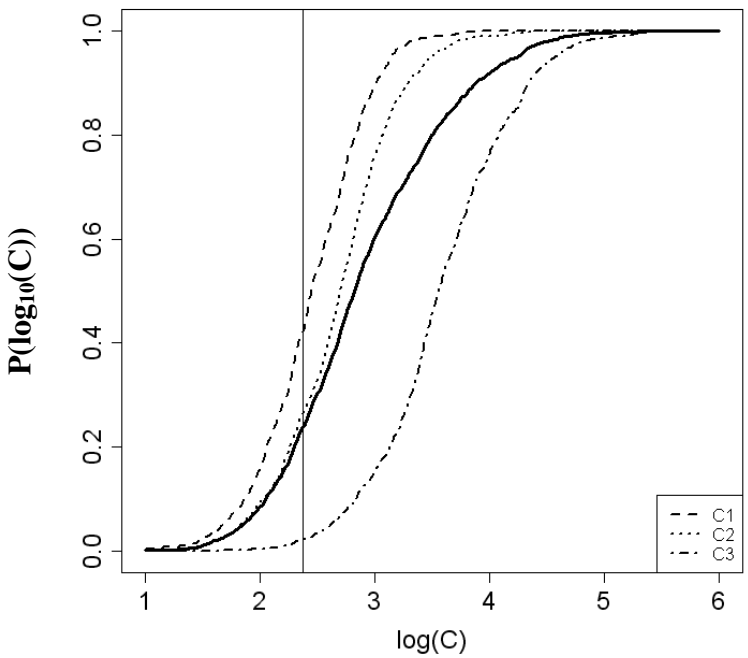

Figure 4. Posterior Predictive Recreational Season Cumulative Distribution of Concentration. The CDF for $\log_{10}(C)$ (boldface) is compared to the recreational standard of 235 cfu/100ml *E. coli*. The posterior predictive CDFs for each flow condition are also shown (C1, C2, and C3).

Looking at the *PRB* estimates, the lower flows with $P(\log_{10}(Q))\leq 0.1$ have the lowest percent reductions with a best estimate of 68%, respectively. As flow increases, the load reduction also increases so that at high flows ($0.9<P(\log_{10}(Q))\leq 1.0$) a 99.9% reduction in load is required to meet the water quality standard. These results are consistent with the bacterial load reductions estimated for other urban streams under high flow conditions; for example, the bacterial load reductions during periods of high flow estimated in the US EPA technical guidance are 99% for Muddy Creek, VA; 93% for Pee Dee River, SC; and 92% for Waldo Creek, MI (EPA 2001, 2007).

The posterior predictive cumulative distribution of recreational season concentration for Panther Hollow watershed incorporating the control strategy reduction in load is

displayed in Figures 6 and 7. Figure 6 presents the predicted concentration distributions for the BMP control strategy and Figure 7 presents the results for the UV disinfection process. Both figures display the CDF for the no-control strategy for comparison. Figure 6 also displays the CDFs for the high flow condition to illustrate the effect of BMP performance uncertainty on predicted exceedances. The low and normal flow conditions' CDFs are not displayed and remain the same as the no-control strategy for the stormwater BMP control strategy and are reduced to zero cfu/100ml for the UV disinfection process.

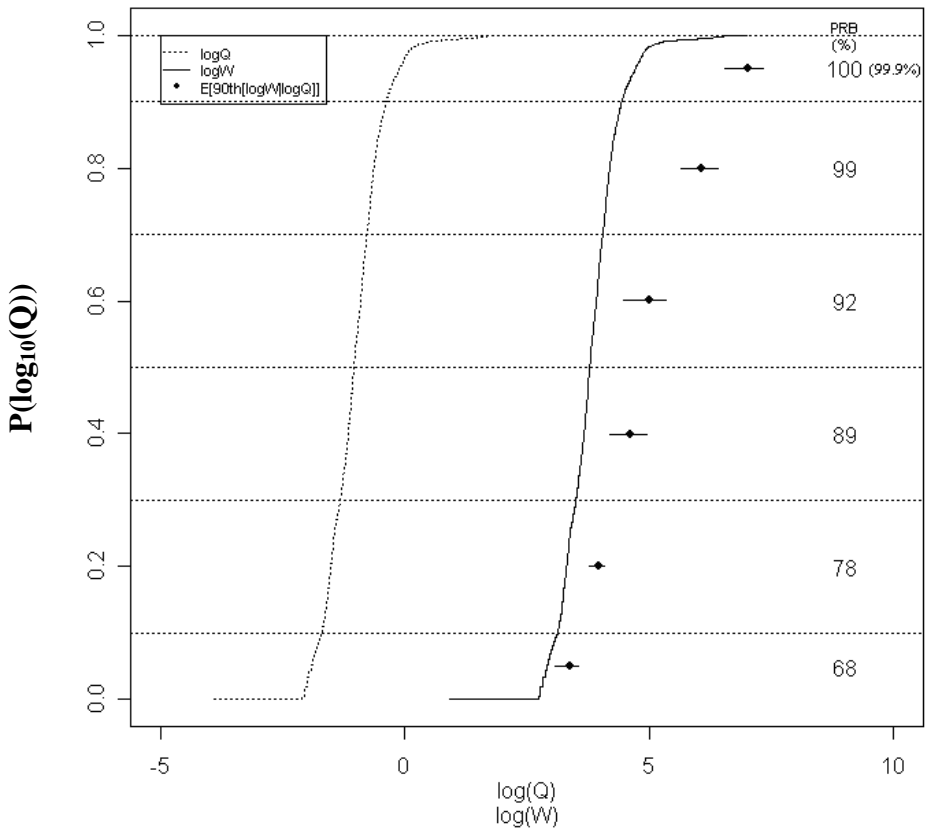

Figure 5. Cumulative Distribution Function of Allowable Load for the Recreational Season with 90th Percentile In-Stream Load Predictions. The figure displays the CDF for flow along with the CDF of the allowable in-stream bacteria load for the recreational season. The x-axis measures flow, $\log_{10}(Q)$ (cfs), and in-stream bacteria load, $\log_{10}(W)$ (cfu/s), and the y-axis measures density values. The Bayesian model predictions of expected 90th percentile load, E[90th[log[W]|log[Q]]], for six representative flows are shown as dots. The black bars show the 95% CI for the Bayesian predicted loads. The Bayesian percent load reductions *PRB* for each percentile are presented using the best estimate 90th percentile loads at each flow.

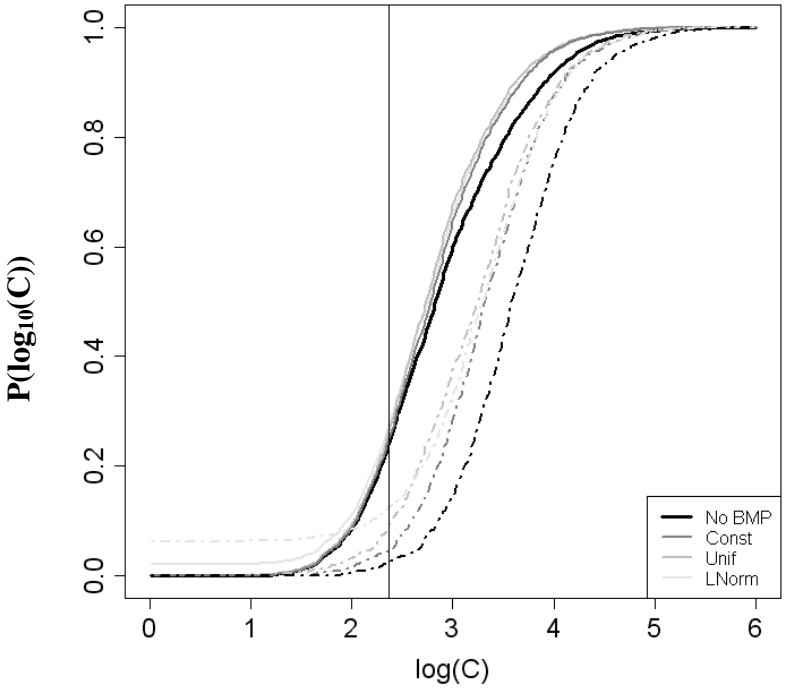

Figure 6. Posterior Predictive Cumulative Distribution of Recreation Season Concentration with BMP Percent Reduction. The overall CDF for $\log_{10}(C)$ with and without BMP load reduction is compared to the standard of 235 cfu/100ml *E. coli*. The high flow condition CDF is shown as dashed type for comparison.

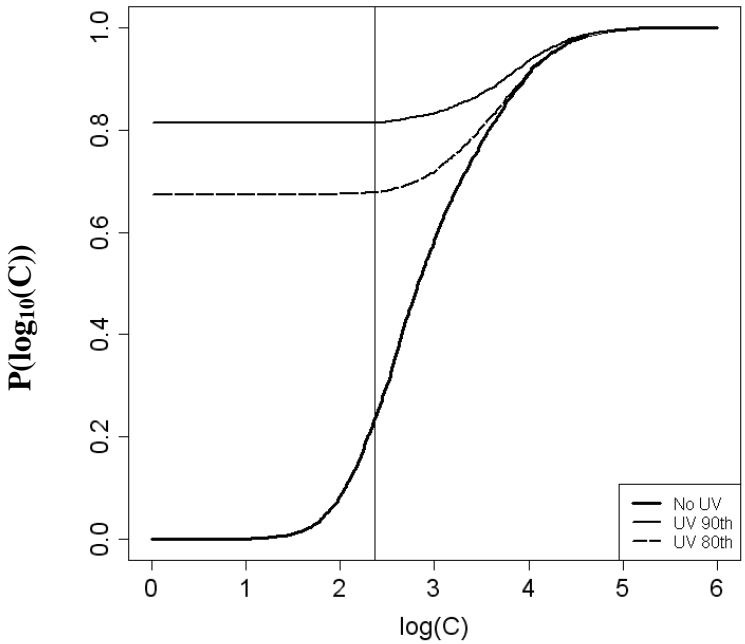

Figure 7. Posterior Predictive Cumulative Distribution of Recreation Season Concentration with UV Disinfection. The overall CDF for $\log_{10}(C)$ with and without UV disinfection is compared to the standard of 235 cfu/100ml *E. coli*.

In the high flow condition, the constant 46.0% load reduction *Const* and the uniform representation of load reduction *Uniform* predict percent exceedances not significantly different from the no-control strategy simulation *None* for the high flow condition, 94.4% CI(92.7, 95.9) and 93.7% CI(92.1, 95.2). Table 2 lists the percent exceedances for each control strategy along with the 95% CI. The percent of time that the outlet of Panther Hollow Stream is above the maximum water quality limit is listed for the stormwater BMP control strategy and the ultraviolet disinfection process designed for the 80th and 90th percentile flows. The percent exceedances for alternative methods of representing the performance measure of the stormwater BMP are compared. The alternative methods include no-control strategy implementation, a constant 46% load reduction, a uniform distribution for load reduction, and a lognormal distribution for load reduction.

Table 2. Percent Exceedances for Each Flow Condition Under Alternative Control Strategies.

C	*None*	*Const*	*Uniform*	*LNormal*	*UV 80th*	*UV 90th*
1	57.4 (54.2,60.1)				0 (0,0)	0 (0,0)
2	73.5 (70.7,76.0)				0 (0,0)	0 (0,0)
3	97.8 (96.9,98.6)	94.4 (92.9,95.6)	90.3 (88.6,92.2)	87.1 (84.7,89.3)	95.0 (93.6,96.4)	54.3 (51.5,56.7)
Overall	76.1 (74.6,77.3)	75.1 (73.5,76.4)	73.8 (72.0,75.8)	72.7 (71.1,74.9)	31.1 (31.2,32.2)	18.1 (17.1,18.9)

*95%CI in parenthesis

Similar to the high flow condition, the *Const* and *Uniform* overall percent exceedances are not significantly different from the no-control strategy. The predictions using the lognormal representation of the BMP performance *LNormal* for the overall and high flow conditions are significantly lower than that of the no-control strategy. The lognormal representation of percent load reduction with mean 46.0% and standard deviation 32.0% predicts that the high flow condition exceeds the standard 86.5% CI(84.7, 88.7) of the time during the recreational season with an overall exceedance of 72.4% CI(70.6, 74.3). Overall, the stormwater BMP shows minimal improvement in indicator bacterial concentration from the no-control strategy.

The water quality after the UV disinfection process, displayed in Figure 7, shows dramatic reductions in in-stream *E. coli* concentration. In Figure 7, the CDF of concentration with no intervention is compared to the CDFs given a UV process designed to eliminate 99% of the organisms at the 90th and 80th percentile flows. As expected, the percent exceedance of the water quality standard drops to 18.1% CI(17.1, 18.9) and 31.1% CI(31.2, 32.2) using the aggressive UV disinfection process. Still, the variability in UV disinfection performance due to changes in dilution and exposure time results in in-stream bacterial concentrations in exceedance of the recreational water quality standard during extreme flow events.

Discussion

The motivation for this work is the need for a TMDL model that will increase TMDL development and implementation progress. The Bayesian model is able to utilize sparse, diffuse data to increase TMDL progress while explicitly communicating uncertainty in load reduction results. The new TMDL model also enables the prediction of water quality given a specific control strategy performance and its associated performance uncertainty. In the Panther Hollow TMDL demonstration, the Bayesian water quality model is used to predict water quality pre- and post-implementation of alternative control strategies. The post-implementation predictions using a sand-filter BMP and aggressive disinfection process demonstrate that it is not possible to bring the waterbody into compliance without aggressive, potentially expensive controls. However, as pointed out by the TMDL program reviews, an evaluation of the control strategy is not part of the minimal TMDL requirements (EPA 2002). Without this evaluation, the implementation of BMPs is likely to have minimal effect on the overall water quality of urban streams with high levels of bacterial contamination.

The structure of the model presented here allows for evaluation of alternative control strategies and the propagation of uncertainty in control strategy performance through to the predicted distribution of post-implementation indicator bacterial concentration. The US EPA has identified the lack of knowledge about BMP performance as a crucial research gap (EPA 2002). Here, the predicted distribution of bacterial concentration for a sand-filter stormwater BMP using a constant percent load removal assumption has a percent exceedance statistically different than that of a variable load removal. Although the predicted water quality may be sensitive to the uncertainty in BMP performance, the representation of control strategy performance uncertainty in existing models is limited and is difficult to incorporate given the lack of field performance data.

The presented Bayesian Load Duration Curve model is a potentially powerful approach for creating management plans for watersheds with limited data. Still, progress in TMDL implementation will continue to be limited until evaluation of the control strategy is mandatory as part of the minimal TMDL requirements, and additional research provides more detailed performance measures for Best Management Practices.

Abstract

Researchers in Maryland, North Carolina, and Pennsylvania have been conducting parallel bioretention/bioinfiltration research since fall 2007. Various designs have been tested including those that rely on underdrains, have internal water storage (IWS) layers, or are underdrain-free. The cells provide a range of watershed practice size ratios and employ a variety of land covers. Researchers are pooling water quantity and quality data to help create new design standards. Initial results from the shared data will be presented, with specific attention to bioretention design parameters that control flow modification and water quality improvement.

Two bioretention cells of varying vegetative cover are being monitored in Rocky Mount, NC. This site is located in the upper coastal plain with sandy in-situ soils. These cells were designed with a 0.9 m media depth and a 0.6 m deep internal water storage (IWS) layer. Another bioretention cell is being monitored in Silver Spring, MD. It was constructed with a 0.9 m media depth and a 0.3 m pooling depth. Finally, there are two bioinfiltration cells being monitored in Villanova, PA. The first is the "Traffic Island" bioinfiltration cell, which has been monitored since 2003. The bowl is only designed for 1.2 cm over the impervious surface, yet overflow rarely occurs for events less than 5.1 cm. The site had groundwater wells installed in 2007 and is the subject of an ongoing study on the groundwater effects. The second site has only been monitored for approximately six months.

Cumulatively, the four bioretention cells extensively examined have dramatically reduced outflow volumes, completely assimilating all events less than 1.2 cm – and in some designs much greater events. By aggregating the data, runoff reduction by bioretention can be profound.

Keywords: Bioretention; bioinfiltration; low impact development; hydrology; pollutant removal; and nutrients.

Introduction

Stormwater managers are faced with controlling increased flooding, altered hydrology, and high pollutant loads associated with impermeable and reduced permeability surfaces (USEPA, 1983). Streets and parking lots generate a large proportion of urban runoff, and these areas derive most of their pollutant loads from automobiles (Barrett et al., 1998). Atmospheric deposition also contributes a substantial amount of certain pollutant loads (Wu et al., 1998). As part of the National Water Quality Inventory, 32% of estuaries and 47% of lakes/reservoirs that were assessed were identified as impaired. Nutrients were the main cause of impairment, and urban stormwater runoff was the number three source (U.S.EPA, 2007). Regionally, two of the most productive estuaries in the U.S. are the Pamlico and Albemarle Sounds in North Carolina (NCDWQ, 2003) and the Chesapeake Bay in the Middle Atlantic States (Chesapeake Bay Program, 2008).

To reduce the negative effects caused by urbanization and to meet the new stormwater rules, strategies such as stormwater Best Management Practices (BMPs) or Low Impact Development (LID) technologies are used. The goal of LID is to develop a site that preserves or meets target hydrologic conditions (Davis, 2008). Bioretention is a very common LID practice, as it serves three major functions: (1) hydrologic, (2) water quality, and (3) aesthetic.

Bioretention combines a natural and engineered system to manage stormwater from developed areas. One design goal is treating the "first flush" runoff (Davis et al., 2009). Bioretention removes pollutants from runoff through adsorption, biological decomposition, filtration, and sedimentation. Metals are removed in the mulch layer through its high capacity for binding metals (Davis et al., 2001). Evapotranspiration (ET) and exfiltration play major roles in volume reduction in a bioretention cell, which are important for pollutant load reduction (Heasom et al., 2006; Hunt et al., 2006; and Li et al., 2009).

Previous bioretention research shows good removal rates and low effluent concentrations for total nitrogen (TN), total Kejhdhal nitrogen (TKN), heavy metals, oil/grease, and total suspended solids (TSS) in both field (Dietz and Clausen, 2006; Davis et al., 2006; Hunt et al., 2006; and Hunt et al., 2008) and laboratory studies (Davis et al., 2001; Hsieh and Davis, 2005; and Davis et al., 2006).

Kim et al. (2003) proposed including an overdrain to create a continuously submerged anoxic zone to promote denitrification. The results from pilot-scale bioretention studies were 70 to 80% mass removal rates of nitrate plus nitrite ($NO_{2,3}$-N). Despite these positive laboratory results, later field studies by Hunt et al. (2006) and Dietz and Clausen (2006) were inconclusive about adding a saturated layer (Figure 1) to create anaerobic conditions required to convert nitrate into nitrogen gas. A field study by Davis (2007) had limited data, but it showed high removal rates of nitrate. Passeport et al. (2009) also had promising field results. Two grassed bioretention cells with different in-situ soils were studied. The study showed significant reduction in nitrate for one of two cells examined. Passeport et al. (2009) believed this was due to the longer saturation period maintained in the one cell surrounded by tight clay, but recommended that the role of in-situ soils be further explored in future studies.

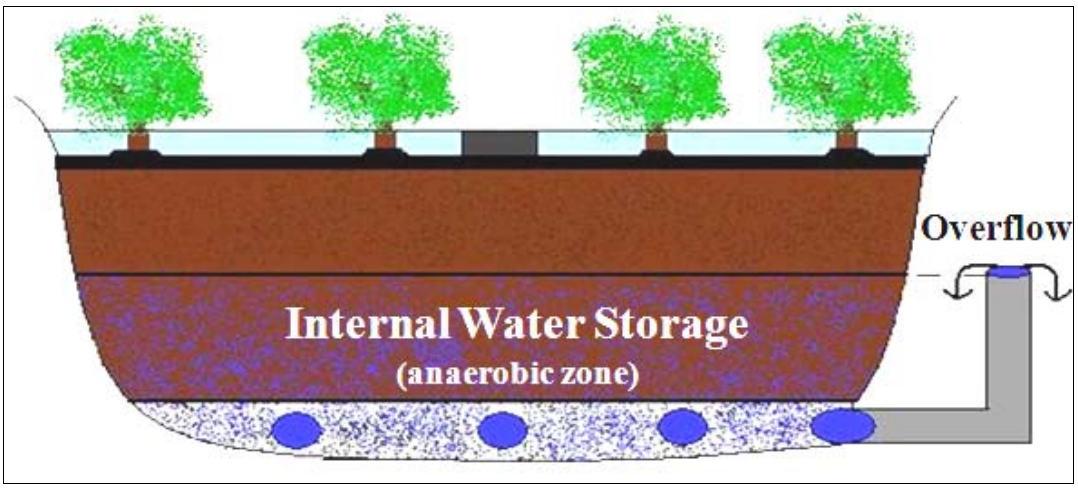

Figure 1. Schematic of bioretention cell with internal water storage (IWS) zone.

Site Descriptions

Rocky Mount, North Carolina

Two bioretention cells are situated in the parking lot for the Imperial Centre in downtown Rocky Mount. They were constructed in the winter of 2005/2006. Current monitoring began in September 2007. There are two bioretention cells at this site (Figure 2). One was planted with shrubs, perennials, and trees (mulch/shrub cell) and the other with centipede turf (grassed cell). Both cells were designed with a 0.6 m (2 ft) deep IWS zone. The IWS zone was created by attaching a 90 degree PVC elbow to the underdrain. The fill media is 0.9 m (3 ft) deep for both cells. In January 2009, the IWS layer was reduced to 0.3 m (1 ft) deep to characterize performance with a shallower IWS zone. Data presented herein are only for the 0.6 m IWS condition.

The range of the P-Index (Hardy et al., 2007) in both cells was low (6-15). Particle size analyses on the fill media were measured using the hydrometer method and determined the fill media was 98% sand and 2% fines (silt & clay). The sand content in the fill media at this site is greater than the sand content (85-88%) recommended in the North Carolina bioretention design guidelines (NCDWQ, 2007). A summary of the site characteristics are found in Table 1.

Table 1. Rocky Mount bioretention watershed and cell characteristic summary.

Actual Characteristics	**Grassed Cell**	**Mulch/Shrub Cell**
Bioretention Cell Area	146 m^2 (1575 ft^2)	142 m^2 (1530 ft^2)
Watershed Area	2200 m^2 (0.54 ac)	2450 m^2 (0.61 ac)
Watershed % Impervious	76%	72%
Fill Media Depth	0.9 m (3 ft)	
IWS Depth (2007-2008)	0.6 m (2 ft)[1]	
IWS Depth (2009-current)	0.3 m (1 ft)	
P-Index of Fill Media	6-15 (Low)	

[1]Only data from this design configuration are presented

Figure 2. Bioretention cell images: mulch/shrub (left) and grassed (right).

Silver Spring, Maryland

Located at the base of the Dennis Avenue Health Center parking lot, the Silver Spring cell was constructed in 2005. Current monitoring began in May 2008. Shrubs and trees were planted in a top layer of mulch. Below the mulch is a permeable soil layer, followed by a sand layer, and finally a gravel layer. The design for the media required a minimum of 10% clay, 30-55% silt, and 35-60% sand. In the gravel layer, 15.2 cm (6 in) perforated PVC pipes were installed to conventionally drain the cell to the existing stormwater network. A summary of the site characteristics is given in Table 2. Images of the bioretention cell and an aerial view of the entire site appear in Figure 3. In the aerial view, the cell is outlined in red.

Figure 3. Silver Spring bioretention cell (left) with aerial view of the site (right).

Table 2. Silver Spring bioretention cell characteristic summary.

Characteristic	**Values**
Bioretention Cell Area	102 m^2 (1096 ft^2)
Watershed Area	4500 m^2 (1.11 ac)
Watershed % Impervious	85%
Fill Media Depth	0.9 m (3 ft)

Villanova Pennsylvania

The bio-infiltration BMP is located in a grassy traffic island in the parking lot of Villanova's West Campus. The West Campus parking lot serves a dormitory complex and a recreation area. The traffic island was retrofitted into the shape of a shallow bowl, allowing the inflow of water to accumulate within. Constructed in 2001, the site has been monitored for water flow since 2003 and for quality in 2004. Bio-infiltration is accomplished by using a combination of porous soils and vegetation. The media consists of a 4-foot layer of sand mixed with the existing soil located at the traffic island. The species of vegetation planted at the site can survive in both dry and wet conditions over long periods of time. The area also has a grass buffer zone extending from the curb to the fill media. Outflow is through a bypass weir utilizing the original culvert system or by infiltration. The traffic island has no underdrains. A summary of the site characteristics is given in Table 3. Images of the cell along with a close up during a storm event are shown in Figure 4.

Table 3. Villanova bioinfiltration characteristic summary.

Characteristic	**Values**
Cell Area (Bottom)	149 m^2 (1600 ft^2)
Post Rainfall Bowl Recession Rate	0.5 to 2.5 cm/hr (0.2 ~ 1 in/hr)
Watershed Area	5261 m^2 (1.3 ac)
Watershed % Impervious	50%
Bowl Storage (Watershed cm)	1.5 cm (0.59 in)
Fill Media Depth	1.22 m (4 ft)

Figure 4. Villanova bioinfiltration cell (left) and close up during storm event (right).

Methods

Rocky Mount, North Carolina

The monitoring equipment used at both sites include: ISCO 6712 Automated Portable Samplers to monitor hydrology and collect flow-weighted composite samples, ISCO 730 Bubbler Flow Modules in combination with 30^o weirboxes to measure outflow at both sites, and ISCO 674 Rain Gauges to measure rainfall. The Soil Conservation Service - Curve Number (SCS-CN) discrete method was used to estimate runoff volumes at Rocky Mount. Runoff enters the cells as diffuse flow from all angles, so a collection trough was installed to collect a representative sample of

runoff. Rainfall (0.51 mm in 15 min) triggers the sampler to enable, and once enough liquid has ponded in the trough, the sampler pulls a sample. Flow-weighted composite samples were analyzed for nutrients and TSS. The nutrient species being analyzed include: Ortho-P, TP, NH_3, $NO_{2,3}$-N, TKN, and TN.

Silver Spring, Maryland

A concrete channel conveys runoff from the parking lot through a 23-cm Parshall flume into the cell. A bubbler meter connected to an ISCO 6712FR Refrigerated Sampler monitoring station records the water level every two minutes. A rain gage placed on top of this inflow station also monitors rain depth. After the runoff infiltrates through the cell, it enters the underdrain and passes through a 15-cm ThelMar plug-in weir connected to a second ISCO 6712FR Refrigerated Sampler, which records the outflow water level at two-minute increments. Based on the dimensions of the flume and weir, set equations were employed to determine the corresponding inflows and outflows. The inflow and outflow volumes are also estimated by using the trapezoidal rule with the inflow and outflow values.

Water samples have not yet been analyzed for water quality values. However, TSS, phosphorous, and other tests will be run in the near future to examine water quality improvement in water exiting the cell compared to the runoff entering it.

Villanova University

A level detector is used to measure the rate of infiltration from the surface bowl, and outflow, which is solely overflow at this site, is measured using a weir in the culvert leaving the site. Soil moisture meters and lysimeters have been placed under and within the cell. Water samples for quality analysis are taken from the water bowl above the fill material. As considerable removal in the stone beds leading to this BMP has been observed, "first flush" flow samplers have been installed to better represent the inflows to the site. These devices are installed to capture water samples where the runoff enters the site through curb cuts. Vadose zone water quality (outflow) is measured using lysimeters located at the bottom of fill material (multiple depths and locations). Surface water outflow (only large storms) grab samples are taken from the bowl. A well was added to the site in 2006 to learn more about the site interaction with the groundwater. In 2007 several more were drilled, and pressure transducers with conductivity meters were added to allow for study of the groundwater hydrology from both the hydrology and environmental perspective.

Results and Discussion

Rocky Mount, North Carolina

Data were collected at Rocky Mount under the 0.6 m deep IWS zone configuration from September 15, 2007, through January 7, 2009. Sixty-eight runoff producing events were monitored for hydrology. The mean and median event sizes were 17.9 and 13.7 mm, respectively. Four events generated outflow from each cell. The magnitude of the events that produced outflow in the grassed cell were 83.3, 65.3, 53.1, and 49.3 mm (3.28, 2.57, 2.09, and 1.94 in). Of these four events, only the 65.3 mm event also produced outflow in the mulch/shrub cell because the other events were of much longer duration and lower intensity. It appeared that the

mulch/shrub cell had higher exfiltration because outflow was not generated by these events. The mulch/shrub cell's runoff was generated by three smaller depth events (38.3, 25.4, and 22.8 mm; 1.51, 1.00, and 0.90 in). Two of these had durations under one hour, so these events were characterized by short duration and high intensity.

Outflow volume vs. runoff volume relationships for the grassed cell and mulch/shrub cell are displayed in Figures 5 and 6, respectively. From field visits during the larger storms, it was observed that runoff entered the emergency overflow for the mulch/shrub cell twice, but it did more frequently for the grassed cell due to a less permeable layer in the surface from a clay layer underlying the centipede turf. Based on survey data, a 19.1 mm (0.75 in) event would generate enough influent volume to produce overflow, assuming no "in storm" infiltration occurred. All of the events that did not produce overflow or outflow had pollutant load removals from the stormwater network of 100%. This site had excellent pollutant removal ability because of its sandy in-situ soils coupled with the internal water storage zone.

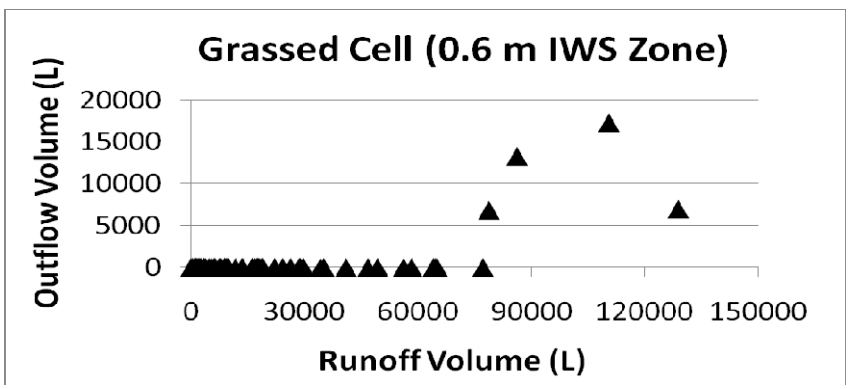

Figure 5. Outflow volume vs. runoff volume for grassed cell in Rocky Mount.

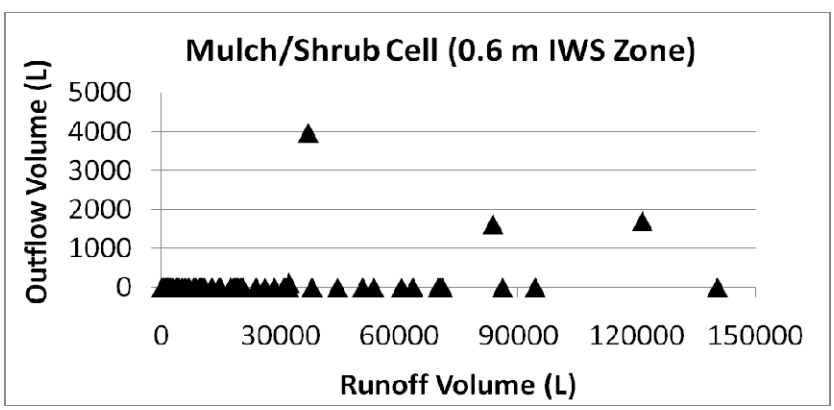

Figure 6. Outflow volume vs. runoff volume for mulch/shrub cell in Rocky Mount.

In January 2008, once it was realized that outflow would not be a regular occurrence due to the presence of the IWS zone, grab samples were taken from the underdrains within 24 to 48 hours after an event. Seventeen events with influent and effluent samples from the grassed cell have been analyzed for all water quality constituents, except for TSS, which has had 14 events analyzed. The grassed cell had a TN, TP, and TSS reductions of 81%, 67%, and 93%, respectively. The water quality results are displayed in Table 4.

Table 4. Preliminary water quality concentration results at Rocky Mount grassed bioretention cell.

	TKN	**$NO_{2,3}$-N**	**TN**	**NH_3-N**	**TP**	**Ortho P**	**TSS**

N	17	17	17	17	17	17	14

Forty-two ambient water quality samples were taken from 1997 to 2002 at the Tar River by NC-97 in Rocky Mount, which is less than 1.2 km (0.75 mi) from the Rocky Mount bioretention site (NCDWQ, 2003). The results indicate the parking lot runoff is a lot dirtier than the water in the Tar River, exceeding the 90th percentile sample for all constituents. The runoff treated by the grassed cell was cleaner than or comparable to ambient conditions in the Tar River. TKN, $NO_{2,3}$-N, and TN were all below the 25th percentile, and NH_3-N and TP were nearly the 50th percentile. The results from TN were especially profound, with inflow exceeding the 90th percentile and outflow similar to the 10th percentile.

Silver Spring, Maryland

Inflow and outflow data have been recorded from 76 events. All storms have shown a reduction in both volume and flow rate from inflow to outflow, and 41 of the events had no outflow. Figure 7 shows the relationship between inflow volume and outflow volume, which has a reduction of volume of 36%. Events with higher inflow produced more outflow. The volumetric capacity of the cell, which is the minimum inflow volume that produces outflow, is estimated to be approximately 16,700 liters or the equivalent of 0.37-cm of rain over the drainage area.

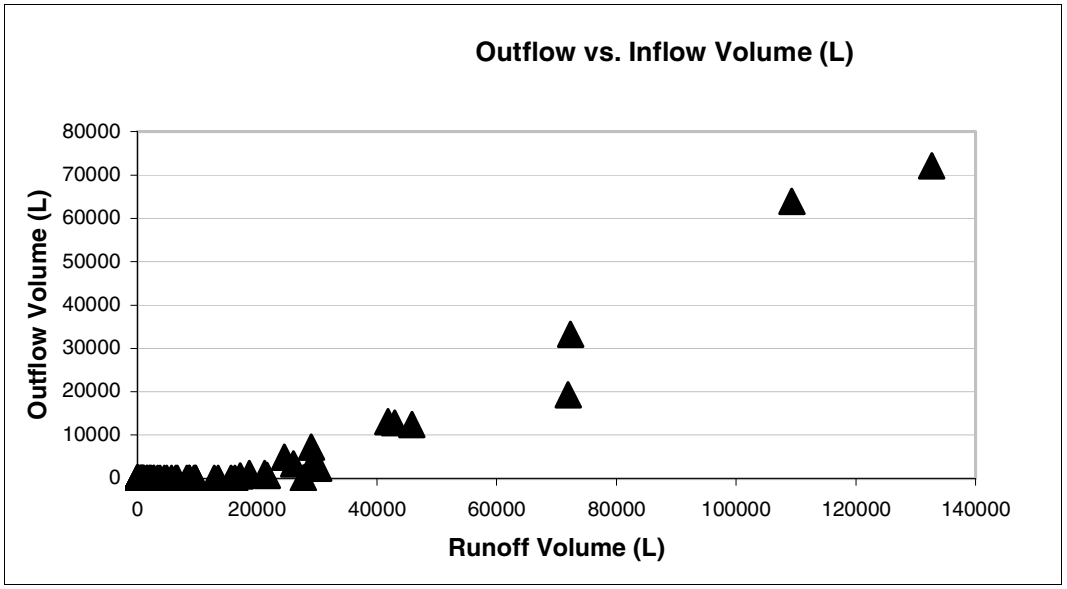

Figure 7. Outflow volume vs. inflow volume at Silver Spring bioretention cell.

Villanova, Pennsylvania

Inflow and outflow data have been recorded from a multitude of events since 2003. Routinely 70 – 85% of the yearly rainfall is captured and infiltrated. Repeating the lessons from Maryland and North Carolina, Volume is reduced for all storms, and a considerable number of events have no outflow (Figure 8).

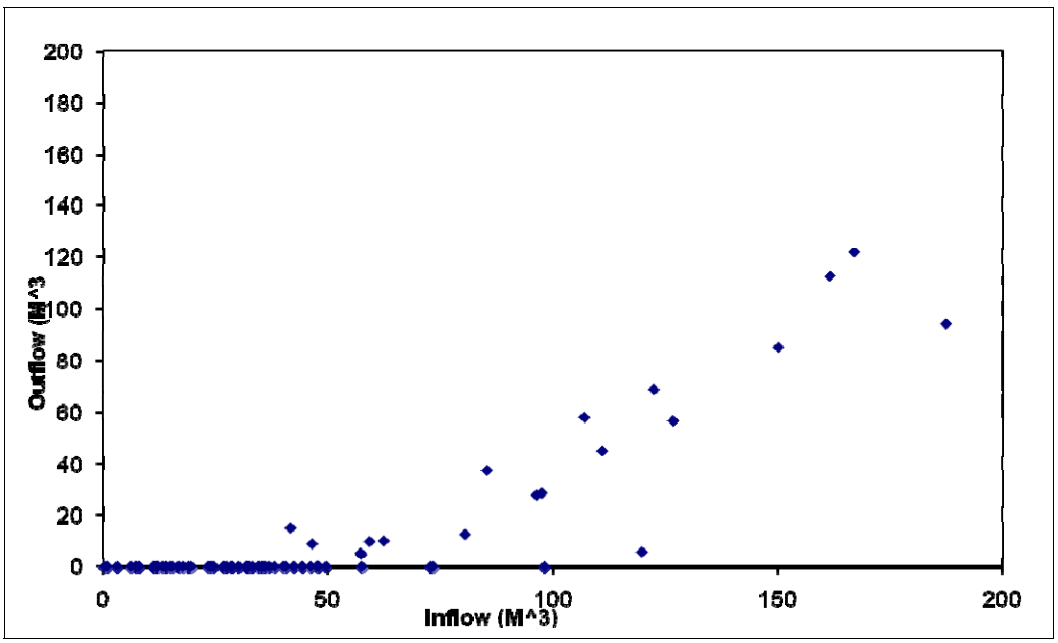

Figure 8. Outflow volume vs. inflow volume at Villanova, PA.

Conclusions and Design Recommendations

- Cumulatively, all four bioretention cells presented have dramatically reduced outflow volumes, often eliminating outflow altogether. All cells completely assimilated events less than 1.2 cm, with some design configurations assimilating even larger events.
- One specific design configuration that was very successful incorporated an internal water storage (IWS) zone at a site with sandy in-situ soils. In Rocky Mount, only four events out of 68 generated outflow in both the grassed and mulch/shrub cell under this design.
- Large flow reduction can have a great effect on pollutant load reduction.
- In a new way to quantify bioretention performance, Rocky Mount bioretention cell data were compared to ambient conditions in the nearby Tar River. The data from this site showed the parking lot runoff was much dirtier than ambient conditions (exceeded the 90th percentile of ambient conditions), while the water treated by the Rocky Mount grassed bioretention cell was cleaner than or comparable to median ambient conditions.

Acknowledgements

Breaking Down the Barriers to Low Impact Development in Colorado

By Andrew Earles, Ph.D.[1], P.E., D.WRE, Derek Rapp, P.E., CPESC[2], Jane Clary, CPESC[3] and Janice Lopitz[4]

The Keep it Clean Partnership (KICP) is a group of municipalities including Boulder, Erie, Longmont, Louisville and Superior and Boulder County in the Boulder and St. Vrain watersheds that are permittees under the Phase II Stormwater National Pollutant Discharge Elimination System (NPDES) Program. Recognizing that infiltration-based best management practices (BMPs) are often not planned and implemented in situations where they potentially could be successfully used, KICP initiated a study to identify barriers to implementation of Low Impact Development (LID) practices in their watersheds. Barriers identified are broad and include physical, institutional, technical, social and economic factors, some perceived and some real, which act as impediments to more widespread implementation of LID.

The KICP study has included development of a questionnaire that has been circulated to municipal staff, engineers, developers and other parties involved in the development review and approval process. As a part of the study, KICP has developed a checklist for use by developers and by municipal staff reviewing plans to identify potential opportunities for LID and to be sure that the relevant factors that can lead to success or failure of a LID approach are considered in the development review process. Checklists were applied to several proposed development projects to refine the checklists and to identify additional barriers to LID based on "real world" projects. This paper presents the results of the KICP study. Major components of the study discussed in this paper included the following:

1. Identification of potential barriers to design and implementation of LID practices. This was accomplished through a series of several meetings in which participants identified barriers they had encountered and through interviews with planners, engineers and developers.

[3] Project Coordinator, Wright Water Engineers, Inc., 2490 West 26th Avenue Suite 100A, Denver, Colorado 80211. Ph: (303) 480-1700, email: clary@wrightwater.com.

[4] KICP Coordinator, Boulder County Public Health , 3450 Broadway, Boulder, CO 80304. Ph: 303-441-1439, email: jlopitz@bouldercounty.org.

2. Development of questionnaire based on barriers identified by the group. The questionnaire was distributed to municipal staff involved in KICP as well as to engineers and developers working in the KICP watersheds. The Homebuilders Association (HBA) of Metropolitan Denver also distributed the questionnaire to members of its water quality committee.

3. Identification of conceptual level strategies to address barriers identified as a part of the study.

The following sections provide an overview of LID and discuss the primary components of the project.

What is LID?

The Low Impact Development Center provides the following definition for LID:

> *Low Impact Development (LID) is an innovative stormwater management approach with a basic principle that is modeled after nature: manage rainfall at the source using uniformly distributed decentralized micro-scale controls. LID's goal is to mimic a site's predevelopment hydrology by using design techniques that infiltrate, filter, store, evaporate, and detain runoff close to its source. Techniques are based on the premise that stormwater management should not be seen as stormwater disposal. Instead of conveying and managing/treating stormwater in large, costly end-of-pipe facilities located at the bottom of drainage areas, LID addresses stormwater through small, cost-effective landscape features located at the lot level. These landscape features, known as Integrated Management Practices (IMPs), are the building blocks of LID. Almost all components of the urban environment have the potential to serve as an IMP. This includes not only open space, but also rooftops, streetscapes, parking lots, sidewalks, and medians. LID is a versatile approach that can be applied equally well to new development, urban retrofits, and redevelopment/ revitalization projects. (http://www.lid-stormwater.net).*

LID is currently included in the water quality guidance published by the Denver Urban Drainage and Flood Control District (UDFCD), a reference used by many municipalities in the area. The LID concept of runoff volume reduction is the first step in the "Four Step Process" for design of best management practices in Volume 3 of the UDFCD Urban Storm Drainage Criteria Manual. LID practices currently included in Volume 3 are planning, minimization of directly connected impervious area, infiltration practices, porous landscape detention, grassed swales and buffers and pervious pavement practices. UDFCD is currently in the process of updating Volume 3 of the USDCM to place more emphasis on volume reduction/LID practices.

Identification of Potential Barriers to LID

Through meetings with KICP, discussions with nationally recognized experts who are members of the American Society of Civil Engineers (ASCE) Environmental and Water Resources Institute (EWRI) Urban Water Resources Research Council (UWRRC), discussions with local municipal reviewers, engineers and developers, the following were identified as potential barriers to implementation of LID in the Front Range of Colorado:

- Fear of liability (engineers, owners, reviewers approving design)
- Reluctance to try something new/lack of demonstration projects
- Lack of education and training
- Lack of common nomenclature (rain garden versus porous landscape detention)
- Limited design examples/good technical documentation
- Costs—design, construction, operation and maintenance, life cycle
- Safety concerns
- Public perception
- LID not integrated early in planning process
- Guidance versus requirements
- Compatibility with existing developments
- Water rights
- Potential for mixed messages from government (different departments)
- No clear economic incentive for using LID
- Difficulty in measuring benefits of LID
- Semi-arid area hydrology
- Maintenance and durability
- Long term ownership/maintenance
- Standing water “nuisance” problems
- Fear of lengthening review process
- Conflicts with municipal code requirements
- American Disabilities Act considerations
- Poorly drained soils and/or high groundwater table
- Expansive soils and construction defect lawsuits
- Other alternatives are “easier”

- LID does not altogether eliminate need for other types of BMPs and drainage infrastructure
- HOA or covenant restrictions (i.e. requirement for irrigated blue grass versus xeriscaped bioretention area)
- Different guidance/criteria from different groups (Center for Watershed Protection [CWP] versus UDFCD versus others)
- Examples of LID failures
- Conflicts with landscaping requirements (i.e. sensitivity of some types of plants to periodic inundation)
- Confusing ordinances
- Iterative versus linear process in coordination with landscapers, planners and others
- Criteria for individual LID BMPs versus overall LID design philosophy
- Requires specialized construction techniques

Many of these barriers were identified as a part of an initial set of workshops with input from KICP and participants from the development community, and others emerged as a part of the development review case studies. For example, in the review of the Redstone Ranch development in Erie a suggested opportunity for improving implementation of LID was limiting sidewalks to one side of the street in selected areas to reduce the overall site imperviousness. Participants in the design review indicated that this would not likely be feasible because a goal of municipal officials and an expectation of the public was to have an easily accessible integrated trail system for pedestrians and cyclists, while minimizing street crossings to get from one trail to another to avoid conflicts with motorized traffic.

Questionnaire

To assess the relative importance of each of these barriers, the project team created a questionnaire to gage participants' experience level with LID and to examine the relative importance of each of these barriers. The questionnaire also requested that participants note their role in the development process (municipal, engineer, developer, etc.) and to rank the significance of barriers on a scale of 1 to 5, with 1 corresponding to a minor barrier and 5 corresponding to a significant barrier. Overall, there were 33 responses to the one page questionnaire, predominantly municipal respondents, but with good representation (more than 25%) from the development community as well. Table 1 shows the overall results of the questionnaire.

Questionnaire results in Table 1 are sorted from those identified as most significant barriers to least significant barriers. In addition, the table shows the number of "1" and "5" responses for each barrier to illustrate which barriers received the most extreme ratings.

Conceptual Strategies for Addressing Barriers

Although the scope of work for the KICP Barriers Identification project was limited to identification of barriers, development of the checklist and conducting design reviews using the checklist, the project team developed conceptual approaches for beginning to address barriers. Conceptual strategies are listed in Table 2.

Table 2. Conceptual Strategies for Addressing LID Barriers

Identified Barriers	Conceptual Strategies
Perceived design, construction, maintenance costs	Examples of successful LID pilot studies in the Rocky Mountain Region including economic analysis and long-term performance monitoring and documentation of maintenance.
"Mixed messages" from different governmental departments (planning versus engineering versus open space versus street maintenance)	Development of improved regional guidance (Volume 3), model ordinances and criteria, better coordination between engineering, planning, parks and recreation, etc.
Maintenance and durability concerns	Long-term performance monitoring and documentation of maintenance activities for existing LID installations.
No clear economic incentive for using LID	Develop incentives for LID implementation (reduced storage requirements for water quality event and potentially larger events) to provide credit. Consider expedited variances to shorten review process for proven methods. Documentation of savings on LID projects in region.
LID not integrated early enough in planning process	Checklist at pre-application meeting to identify opportunities for LID.
Other types of BMPs and drainage infrastructure may still be required even with LID	Examine potential reduced sizing of other "traditional" BMPs when LID measures are adopted.
LID "recommended" in guidance rather than "required"	Evaluate ordinances and requirements in other communities where LID has been more widely adopted.
Lack of successful demonstration projects in area	Consider municipal demonstration projects to "showcase" LID.
Concerns with swelling soils	Better coordination with geotechnical engineers and consideration of soil treatment and amendments.
Specialized construction techniques may be required	Examine construction techniques used for successful LID projects and construction techniques that have contributed to LID failures. Consider contractor education programs and/or certification.
Other water quality alternatives are "easier" to design, construct and maintain	Emphasize importance of "Step 1--Volume Reduction" from UDFCD Manual. Provide updated design details, specifications.
Long term ownership (private versus publicly owned and maintained)	Evaluate need for easements, deed restrictions, public authority to maintain/repair LID BMPs on private property and back-charge owners. Public education for property owners.
Difficulty in measuring benefits of LID	Increased monitoring of LID hydrologic and water quality benefits on individual BMP and site scales (local data). Develop tools for quantifying effects of LID on sizing of other drainage facilities.
Reluctance to try something new	Municipal examples to lead the way. Publicity of successful implementation of LID.
Limited technical design guidance	Updated criteria and focus on planning and volume reduction. Development of detailed specifications templates. More involvement of engineers for construction observation/clarifications during construction.
Poorly drained soils/low infiltration capacity	Better coordination with geotechnical engineers and consideration of soil treatment and amendments. Understand there are some circumstances where LID is not feasible.

Table 2. Conceptual Strategies for Addressing LID Barriers (Continued)

Identified Barriers	Conceptual Strategies
Conflicts with municipal code requirements (i.e. curb and gutter required)	Consider expedited variance requirements where LID features are desired and conflict with standard code requirements.
Different or conflicting LID guidance or criteria from different groups (UDFCD versus Center for Watershed Protection versus others)	Develop LID criteria specific to semi-arid region and incorporate into regional guidance (UDFCD Manual).
Semi-arid climate (i.e. difficulty in supporting green rain gardens)	Use drought tolerant species. Do not expect "green" rain gardens. More emphasis on xeriscaping coupled with infiltration.
Iterative coordination process with planners, designers, landscapers and others is required	Early coordination between developers, engineer and municipal staff from multiple departments to define LID approach for project and identify specific barriers.
Confusing or unclear ordinances related to LID and/or disconnected impervious area	Improved model ordinances and criteria.
Education and training do not provide skills to design and implement LID	Expanded training courses through municipalities and professional organizations. Consider webinars, field tours, symposia.
Potentially longer review process	Integrate LID concepts as early as feasible in planning process. Improved familiarity of municipal reviewers with LID concepts and methods.
Fear of liability (engineers, owners, reviewers)	More local examples of successful LID implementation, Consider in municipal projects to set example for private development community.
Standing water nuisance problems	Include underdrains in designs. Clearly define maintenance requirements. Avoid grading plans that specify very mild (unconstructable slopes).
Public perception (temporary ponding on lots, standing water, mosquitoes and other factors)	Public education on benefits of LID. Better LID design can reduce nuisance water.
High groundwater table	Require submittal of geotechnical information including groundwater levels early in review process. Recognize that LID may not be feasible in all situations.
Water rights considerations	Avoid storage/harvesting of runoff for beneficial use. Directing downspouts from roof to pervious areas is not a problem for water rights (incidental use), but collecting runoff from downspouts, storing it (i.e. rain barrels, then beneficially applying the collected water is not legal.
Confusing nomenclature--lack of consistent names for practices (rain gardens versus porous landscape detention versus bioretention)	Develop glossary of LID terminology as a part of regional guidance.
Compatibility with existing developments that do not use LID practices	Involvement of Landscape Architects and Planners to better define "community identity and character."
Examples of LID failures	Forensic investigation of LID failures. Identify specific factors leading to unsuccessful applications and learn from mistakes.
Conflicts with landscaping requirements and ordinance requirements	Better coordination with Landscape Architects.
Safety considerations	Generally not considered a major barrier, but evaluate safety, especially in areas where the general public will be in close physical proximity to LID BMPs (e.g. Drop off into infiltration swale between sidewalk and street in areas where street parking is likely).
Americans with Disabilities Act considerations	Provide alternate surfaces for disabled access if there is potential for pervious surface to impede mobility.

Conclusion

The results of this project demonstrate that there are many significant barriers to implementation of LID in the Front Range of Colorado, some very real and some largely perceived. Identification of these barriers is an important first step in encouraging wider use of LID practices in this region, because once barriers are identified, strategies can be developed to overcome the barriers. Strategies may include improved communication between municipal departments (engineering, planning, parks and recreation, etc.), updated design guidance and details for developers and engineers, increased public education efforts and other outreach programs. Communities' will also need to determine how LID supports their development and water quality goals - as any new standards will need to be approved by policy boards (councils, advisory boards, etc.)

Fortunately in Colorado, there are a number of organizations ranging from watershed groups to Colorado AWARE (Addressing Water and Natural Resources Education) to municipal permittees such as KICP and governmental organizations such as UDFCD and the Colorado Department of Public Health and Environment that are keenly interested in encouraging the use of LID. Additional efforts by these groups, potentially in collaboration with one another, has great potential to overcome many of the barriers identified in this study.

Challenges in Attaining Recreational Stream Standards for Bacteria: Setting Realistic Expectations for Management Policies and BMPs

ABSTRACT

Attainment of U.S. Environmental Protection Agency (EPA) recreational water quality criteria and state water quality standards for bacteria presents significant challenges to water resource managers in communities throughout the U.S. From a regulatory perspective, many communities are faced with Total Maximum Daily Loads (TMDLs) for bacteria, typically for either *E. coli* or fecal coliform. For local governments responsible for National Pollutant Discharge Elimination System (NPDES) Municipal Separate Stormwater (MS4) permits, this issue can be particularly challenging and many questions arise with regard to whether stormwater best management practices (BMPs) can reduce bacteria in stormwater runoff. Many valid questions exist regarding how attainable current stream standards are and what measures are truly meaningful in reducing bacteria in streams and in development of meaningful TMDLs.

This paper provides a synopsis of Best Management Practice (BMP) performance data provided for bacteria in the International Stormwater BMP Database and discusses implications of these findings for stormwater managers. Findings from analysis of these data are used to provide some recommendations regarding the types of efforts that are expected to provide meaningful results in terms of water quality management policy and bacteria reduction in stormwater and receiving waters. Implications for development of TMDLs with the potential to provide real improvement of water quality is also discussed.

INTRODUCTION

Attainment of U.S. Environmental Protection Agency (EPA) recreational water quality criteria and state water quality standards for bacteria presents significant challenges to water resource managers in communities throughout the U.S. As one example, in some watersheds, largely uncontrollable natural sources of bacteria can cause or contribute to the exceedance of bacteria standards. When natural sources are comingled with controllable anthropogenic sources, it can be extremely difficult to establish realistic and meaningful strategies for attaining bacteria standards. As a result, draconian measures are sometimes implemented (e.g., prohibiting human use of recreational trails along waterways) or considered.

From a regulatory perspective, many communities are faced with Total Maximum Daily Loads (TMDLs) for bacteria, typically for either *E. coli* or fecal coliform. For local governments responsible for National Pollutant Discharge Elimination System (NPDES) Municipal Separate Stormwater (MS4) permits, this issue can be particularly challenging and many questions arise with regard to whether stormwater best management practices (BMPs) can reduce bacteria in stormwater runoff. Many valid questions exist regarding how attainable current stream standards are and what measures are truly meaningful in reducing bacteria in streams and in development of meaningful TMDLs. The International Stormwater BMP Database provides data that can

begin to help communities answer some of these questions. A summary of bacteria data in the BMP Database follows, along with findings and recommendations based on these data.

STORMWATER BMP MONITORING RESULTS FOR BACTERIA IN INTERNATIONAL STORMWATER BMP DATABASE

The International Stormwater BMP Database contains nearly 500 paired fecal coliform monitoring events at 61 sites (Table 1) and over 100 paired *E. coli* monitoring events at 12 sites (Table 2). The majority of the *E. coli* data sets are in Portland, Oregon and are from sites with Low Impact Development BMPs such as bioswales and green roofs. The fecal coliform data set is more geographically diverse with studies in California, Florida, Virginia, Ontario, New York, Texas, Georgia, North Carolina and Oregon. A few caveats related to this data set include:

- Although a few event mean concentration (EMC) data sets for bacteria exist in the Database, the majority of samples are grab samples, typically because a six hour maximum holding time is specified for bacterial analysis, making it inconvenient and difficult to collect samples for a representative hydrograph using automated samplers and to deliver the samples to the laboratory within this timeframe. Thus, the limitations of grab samples, which are well documented in the technical literature, apply. Additionally, some monitored storm events in the database are based on a single pair of grab samples of the influent and effluent, whereas others are based on arithmetic averages of several grab samples, and some are flow-weighted averages.
- The number of events sampled for studies presented in Tables 1 and 2 varies. For the E. coli data set, an average of 10 storms per BMP was monitored. For fecal coliform, an average of eight storms per BMP was monitored; however, six of the studies (10 percent of the studies) had fewer than three sampling events, resulting in their exclusion from subsequent analysis.
- Prior to 2008, the water quality data entered into the Database were based on "Legacy STORET" nomenclature, which many people found confusing. (The new Water Quality Exchange (WQX) format developed by the U.S. Environmental Protection Agency (USEPA) is more intuitive and has been adopted in 2007 updates to the Database). The authors have assumed that the reported data with various STORET codes fall into these three categories: fecal coliform, *E. coli* and fecal strep.
- A complicating issue when evaluating *E. coli* data from multiple sources is that unlike most conventional chemical and physical parameters, bacteria has an upper quantitation limit that can vary by orders of magnitude between studies, or sometimes even within studies. The upper quantitation limit is influenced by the dilution of the sample during analysis. As a result, statistical analysis of lumped data sets can be problematic and it may be necessary to examine the performance of each BMP individually.

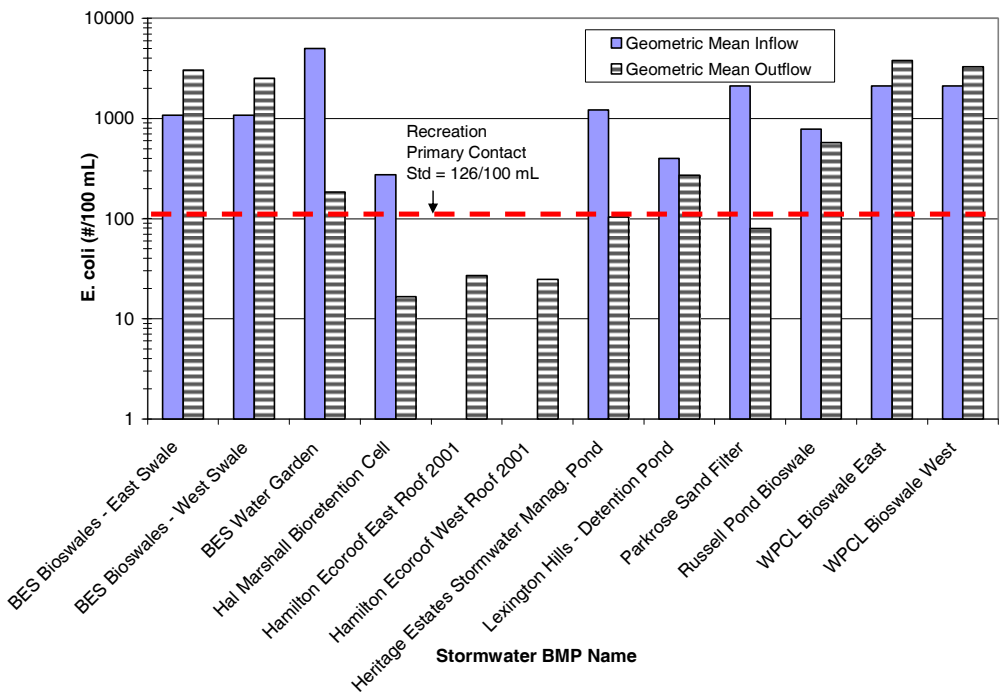
[1] Refers to vegetation types planted in bioswales.

In addition to review of the tabulated data, graphical presentation of the data is useful in identifying potential trends. The International Stormwater BMP Database analysis protocols (Geosyntec and WWE 2007) used for conventional water chemistry analysis focus on the effluent concentrations achieved by various BMPs (e.g., is the BMP helping to protect receiving water quality?) and whether there is a statistically significant reduction between influent and effluent concentrations (e.g., is the reduction in reported means real?). Several other factors such as changes in runoff volumes are also considered. In keeping with this approach, Figure 1 provides notched box and whisker plots of the fecal coliform data according to BMP type for several categories of BMPs. The geometric mean is used as a benchmark in these plots because attainment of stream standards is based on the geometric mean of the bacteria data. The USEPA promulgated instream standard for primary contact recreation is currently 126/100 mL for *E. coli* and was 200/100 mL for fecal coliform prior to USEPA's adoption of *E. coli* as a pathogen indicator. Figure 1 indicates that swales (GS) and detention basins (DB) do not appear to effectively reduce bacteria in effluent concentrations and may possibly increase bacteria concentrations. Although the effluent values are still above primary contact recreation standards, media filters and retention ponds show potential promise in reducing bacteria counts, based on statistically significant differences between the influent and effluent medians (i.e., the 95th percentile confidence limits for the medians of the influent and effluent data sets do not overlap). Data sets for wetlands and manufactured devices are not of adequate size to draw meaningful conclusions.

Figure 1. Notched Box and Whisker Plots Summarizing Paired Fecal Coliform BMP Monitoring Results (Source: International Stormwater BMP Database 2007)



Key:

Inflow (Red)
Outflow (Blue)

DB= Detention Basin
GS= Grass Swales
HD=Manufactured Devices
MF= Media Filters
RP= Retention Ponds
WC=Wetland Channels

It is also worthwhile to evaluate the performance of individual BMPs. Bar charts presenting the geometric mean concentrations for the influent and effluent for each study were prepared. Figure 2 provides the geometric mean influent and effluent concentrations for *E. coli* studies in the database. A series of similar plots for fecal coliform were also prepared according to BMP type (Clary et al. 2008) based on the data summarized in Table 1, but are not reproduced in this paper due to space limitations.

Figure 2. Comparison of Geometric Mean E. coli Data for Stormwater BMPs in International Stormwater BMP Database

FINDINGS AND IMPLICATIONS FOR STORMWATER MANAGERS

Findings and implications for stormwater managers based on a review of the bacteria data in the International Stormwater BMP Database include:

- Bacteria concentrations in untreated runoff were consistently high for the majority of the BMP study sites, with the influent concentrations varying substantially. The variation may be due to both site-specific conditions as well as the upper quantitation limit for the study.
- The ability of structural BMPs to reduce bacteria varies widely within BMP categories. No single BMP type appears to be able to consistently reduce bacteria in surface effluent to levels below instream primary contact recreation standards. As a result, stormwater managers, permit writers and TMDL participants should not assume that structural BMPs can meet numeric effluent limits for bacteria for all storms and under all conditions. This is consistent with 2006 findings from a Storm Water Panel Recommendations to the California State Water Resources Control Board regarding the feasibility of numeric effluent limits for stormwater in general (CSWRCB 2006).
- Computer modeling of bacteria in stormwater should incorporate significant variability in both untreated runoff (influent) and BMP effluent and should be undertaken with caution. Feedback from some environmental engineers and consultants who apply common models to pathogen and fecal indicator transport suggests that the models provide highly uncertain predictions for pathogen and indicator concentrations and fluxes (USEPA 2007, based on input from Ali Boehm, Stanford University). Additionally, modeling assumptions related to microbe association with particles are typically not well developed (Characklis and Camper 2009). Models should be kept simple, with results not reported in unrealistically precise terms. TMDLs should acknowledge this variability and incorporate terms of compliance based on real-world monitoring data.
- BMP categories that appear to have potential for bacteria reduction in effluent include retention ponds and media filters and bioretention practices, with these considerations:
    - Retention ponds may be well suited for development with significant land area and adequate water rights (typically a challenge in semi-arid and arid states such as Colorado) or abundant rainfall. In ultra-urban areas, infill development, and arid/semi-arid climates, retention ponds are often impractical. Another potential disadvantage with retention ponds if bacteria removal is an objective is that they can attract waterfowl and wildlife, which can increase bacterial levels. Research related to unit treatment processes that are potentially effective for retention ponds is needed. For example, Characklis and Camper (2009) are conducting ongoing research related to microbe association with particles. This is important because the degree to which microbes in the water column associate with settleable particles has important implications for microbial removal via sedimentation-based BMPs.
    - Media filters and bioretention cells show promise in removing bacteria at the site-level. These findings are consistent with recent research by Hathaway and Hunt (2008) in North Carolina. For new developments based on Low Impact Development techniques, the use of bioretention cells or rain gardens is becoming more common in some part of United States. The key unit treatment process (filtration) associated with media filters is well proven in the drinking water arena, so it is not surprising that these BMPs would reduce bacteria, provided that the facilities are properly maintained. For existing developments, some targeted retrofitting in bacteria "hot

spot" areas could be possible, but costs of watershed-wide retrofits with many media filters will likely be cost prohibitive. One of the important aspects of long-term functioning of distributed controls such as bioretention cells is ensuring that these facilities are maintained and continue to function as designed in perpetuity. In many cases, local governments are already stretched to ensure maintenance of regional stormwater facilities, so although these practices may hold promise, "ensuring" their continued function may be administratively challenging.

- Swale and extended detention (dry) pond BMPs appear to have low effectiveness in reducing bacteria and in some cases have the potential for exporting bacteria. The authors hypothesize that potential causes could include that fact that these types of BMPs tend to attract geese, wildlife and domestic pets, which may contribute to bacteria loading. Regardless, these BMPs can still be effective at reducing pollutant concentrations such as total suspended solids (TSS), total metals, and other constituents, as demonstrated in the 2007 analysis of the International Stormwater BMP Database (Geosyntec and Wright Water Engineers 2007), and are valuable components of stormwater management programs. Some infiltration may also occur in these facilities, as well.
- Several BMP categories have data sets too small to warrant interpretation; these include the wetland, porous pavement and manufactured device categories. However, one could anticipate how some of these BMPs may perform by evaluating BMPs with similar unit processes. For example, properly designed porous pavements, such as those with a sand layer above the sub-surface underdrains, could potentially perform similarly to media filters.
- In addition to the ability of a BMP to reduce concentrations of bacteria, it is also important to consider whether the BMP reduces the volume of stormwater runoff and the frequency of discharges. BMPs such as bioretention, vegetated biofilters, and, in some cases, dry-extended detention basins have shown the ability to reduce runoff volumes via infiltration and/or evapotranspiration losses. These factors should also be considered in BMP selection.

As part of the data analysis, the authors also compared the conclusions based on International Stormwater BMP Database to previous findings reported by others such as Pitt (2004) and Schueler and Holland (2000). A few representative excerpts from previous findings include:

- *A natural outcome of discussions after examining microorganism levels in urban waters focuses on their potential control. Unfortunately, there does not appear to be an easy (inexpensive) solution to reduce the often-times very high indicator bacteria levels found in stormwater…The most basic control program would incorporate the required inappropriate discharge detection and elimination program…included in the NPDES stormwater permit program, and dog feces controls. These can be highly effective and of low to moderate (or higher) cost… Dog feces control programs are a basic public health and aesthetic benefit and should also be implemented (including enforcement)…the remaining indicator bacteria, although possibly still quite high in comparison to the current criteria, would indicate minimal risks, as they should mostly originate from urban wildlife…In order to reduce the bacteria levels to criteria levels, much more costly control programs will be needed. These should only be implemented after a local risk-assessment is conducted and actual human health impairments are identified* (Pitt 2004).
- *Concentrations of bacteria in urban stormwater are notoriously variable on a site-specific basis, even for similar land use types and even at the same sampling location. Due to the*

wide variability of bacterial data, it is difficult to make accurate estimates of expected pollutant loading and pollutant removal that are transferable from site-to-site with any degree of confidence. Even with the significant variability, all of the databases and literature sources agree that bacteria concentrations in untreated urban stormwater are very high (estimates range from 15,000/100 mL to over 50,000/100 mL for fecal coliform) and difficult to reduce to instream standards (Schueler and Holland 2000).

CONCLUSIONS AND RECOMMENDATIONS FOR ADDITIONAL RESEARCH

The International Stormwater BMP Database provides a relatively large and growing bacterial data set that is useful in evaluating the effectiveness of various structural BMPs with regard to bacteria removal. Media filters and retention ponds were most effective based on the current data set; however, effluent concentrations for these BMPs remained above primary contact recreation standards in many cases. Although several BMP types such as extended detention basins and grass swales did not appear to be effective at reducing bacteria concentrations, these BMPs can be effective at removing other pollutants such as TSS and total metals and may help to reduce runoff volumes and frequencies (thereby reducing bacteria loading). The bacteria-related findings reinforce earlier research by investigators such as Pitt (2004) and Schueler and Holland (2000). Recommendations for additional research include:

- Analysis of site specific conditions at BMP studies may help to identify factors such as exposure to sunlight, meteorological conditions, natural (non-human) contributions of bacteria associated with the BMP, and other factors that help to explain why some BMPs perform better than others. A more refined level of statistical analysis may also be valuable (e.g., hypothesis testing to determine statistically significant differences between influent and effluent concentrations, along with other techniques).
- Continued submittal of bacteria monitoring data for BMPs to the International Stormwater BMP Database is needed to continue to refine these findings and enable more statistically robust conclusions. Even though the overall number of paired storm events is fairly large, the number of studies per BMP category remains relatively small, as does the number of storm events monitored for some BMP studies. It is essential that evaluation of BMP performance related to bacteria include geometric mean effluent concentrations due to the fact that even when large percentage removals are present (and the BMP appears to be "doing something"), the effluent concentrations still typically exceed primary contact stream standards. This is critical for realistic expectations in BMP-based stormwater permits.
- Continued national data-based dialogue and research regarding bacteria levels in stormwater runoff relative to instream recreational water quality criteria is needed, in keeping with USEPA's expert workshop and critical path science plan for revising recreational water quality criteria (USEPA 2007) that acknowledges that many unanswered questions exist regarding recreational standards for bacteria. Near-term "critical path" research identified as part of the USEPA (2007) workshop includes addressing issues such as the significance of natural versus human-induced sources of bacteria, determination of acceptable risk levels, and other factors. This is critically important research to ensure that time and effort expended by regulators and MS4 permit holders is meaningful in terms of protection of human health. As an example, recent microbial risk assessment conducted for the Chicago Waterways Project (Petropolou et al. 2008) showed relatively low risk to human health due to secondary contact recreation in waters, despite elevated bacteria concentrations. Ideally, EPA would also support bacteria-related monitoring for BMPs so that a national baseline

expectation regarding the ability of structural BMPs to effectively treat bacteria could be developed.

- From a practical standpoint, state and federal regulators should carefully consider whether appropriate recreational use classifications are assigned to streams. Assigning primary contact recreation standards to streams that are not truly used for primary contact recreation can result in unnecessary 303(d) listing of streams and costly TMDL efforts that may result in BMP-based requirement to treat bacteria in MS4 permits. These situations do not provide meaningful increases in protection of human health and can be costly, diverting resources away from other real water quality issues. Aside from source control BMPs such as pet waste ordinances and illicit discharge detection and removal, MS4 permit holders may find themselves with unachievable permit requirements. This situation can also result in dilemmas for state regulators who may ultimately find themselves unable to issue a permit that contributes to an exceedance of a water quality standard. Some states (e.g., Kansas and Texas) have recently worked to develop more detailed recreational use standards that focus on streams where true primary contact recreation is occurring.
- Development of cost-benefit data for stormwater BMPs relative to bacteria reduction for municipal stormwater managers is important. Most local governments need this type of information for decision-making when determining how to best allocate limited resources.

ABSTRACT

Water inputs to Santa Monica Mountains National Recreation Area (SMMNRA) watersheds include local precipitation, runoff of imported water and treated wastewater derived from imported water. Imported water from northern California is isotopically distinct from southern California precipitation. This contrast allows source flow differentiation.

To determine the relative contributions of water sources to creeks and streams in the SMMNRA, stable water isotopes [δ18O, δD] are used.

Sampling of rainwater, stream water, tap water and treated wastewater was done from January through December 2008. Analysis includes a focused study of McCoy Creek.

Results show tap water and treated wastewater to be fairly reliable end members and local precipitation to be unreliable as an end member. The isotopic signatures of McCoy Creek samples appear to be affected either by evaporation or changes in imported waters' isotopic signatures.

SMMNRA STUDY AREA

Land Use and Hydrology. The [SMMNRA] covers a gross area of 153,250 acres with various land use designations: urban, residential, commercial, agricultural, parks & recreation and natural preservation (National Park Service 2007.) Local precipitation, runoff of imported water and treated wastewater derived from imported water are all potential water inputs to SMMNRA watersheds.

In many creeks, groundwater baseflow accounts for much of the dry season stream flow (Hibbs and Andrus 2007.) Shallow groundwater in SMMNRA watersheds may be sourced from recharge by local precipitation or from recharge by imported water applied to irrigated landscapes.

Other studies on Las Virgenes Creek, a major tributary to Malibu Creek, indicate that Las Virgenes Creek is fed mainly by groundwater baseflow. Baseflow feeding into Las Virgenes Creek is derived primarily from local precipitation, not from recharge of imported water. These results were obtained during the dry season (Hibbs and Andrus 2007.)

This is a key observation because Las Virgenes Creek flows through the City of Calabasas before entering state park lands. Urban runoff (from residential and

municipal application of imported water) was only a small percentage of the flows in Las Virgenes Creek (Hibbs and Andrus 2007.)

Climate and Topography. The study area has a Mediterranean climate. The rainy season is from November to April. The dry season is from May to October. Precipitation is not constant during the rainy season but limited to rain events or occasional snow. Average yearly rainfall is roughly 15 inches along the coast, 22 to 27 inches along inland ridges (Dale, Brown and Thomas 2009.)

The Santa Monica Mountains form a 72 km long, west-trending coastal range that drains south from the Simi Hills (Dibblee 1987.) Elevations are mostly between 1000 feet and 2000 feet. Sandstone Peak, close to the western end, is 3111 feet high. Water flow has cut deeply into the mountains; gorges cut by the Topanga and Malibu Creeks are hundreds of feet deep (Dale, Brown and Thomas 2009.)

MCCOY CREEK

McCoy Creek is located in the City of Calabasas. Most of the creek is south of the Ventura Freeway between Las Virgenes Road and Old Topanga Canyon Road. The creek's watershed begins in the New Millennium development at the very western end of Parkway Calabasas (City of Calabasas Public Works Department 2006.) Its general direction of flow is toward the northeast. From head to mouth, much of McCoy Creek is adjacent to land developed for residential or recreational purposes. Consequently, McCoy Creek is ideal for observing imported water's effects on local water chemistry.

East of the New Millennium development, McCoy Creek emerges from an underground cement culvert below Parkway Calabasas. McCoy Creek then flows through a natural channel in an area with native vegetation before entering the Calabasas Golf Course and Country Club. The golf course flanks both sides of the creek for 0.6 mile (City of Calabasas Public Works Department 2006.)

After McCoy Creek exits the golf course, a tributary flows into McCoy Creek from the south by crossing underneath Parkway Calabasas. The confluence is concrete-lined (City of Calabasas Public Works Department 2006.)

McCoy Creek then flows beneath Parkway Calabasas via two box culverts before emptying onto property owned by Countrywide Financial. There, the property is maintained as a park (City of Calabasas Public Works Department 2006.)

McCoy Creek leaves Countrywide Financial's property by flowing under a road named Park Capri and into the park next to Lake Calabasas. In the park's western area, high-density residential land borders the creek to the north. The natural southern bank has oak woodland vegetation, which gives way to turf grass by the lake. A concrete overflow structure drains the lake into McCoy Creek "south of the Calabasas Tennis and Swim Center" (City of Calabasas Public Works Department 2006.)

By Calabasas' northern boundary, McCoy Creek flows under Calabasas Road in Old Town Calabasas. The creek then crosses under the Ventura Freeway before joining Dry Canyon "Creek to form Calabasas Creek" (City of Calabasas Public Works Department 2006.)

Five sites for observing McCoy Creek were selected: two upstream near the New Millennium housing development [Gate Upper and Gate Middle,] one site just after McCoy Creek enters the Calabasas Country Club and Golf Course [Golf Course Site 1,] one site just before McCoy Creek exits the golf course [Golf Course Site 5] and one site at the Calabasas Tennis and Swim Center [23400 Park Sorrento] (see Figure 1). Sampling took place about every 6 weeks beginning in July 2008.

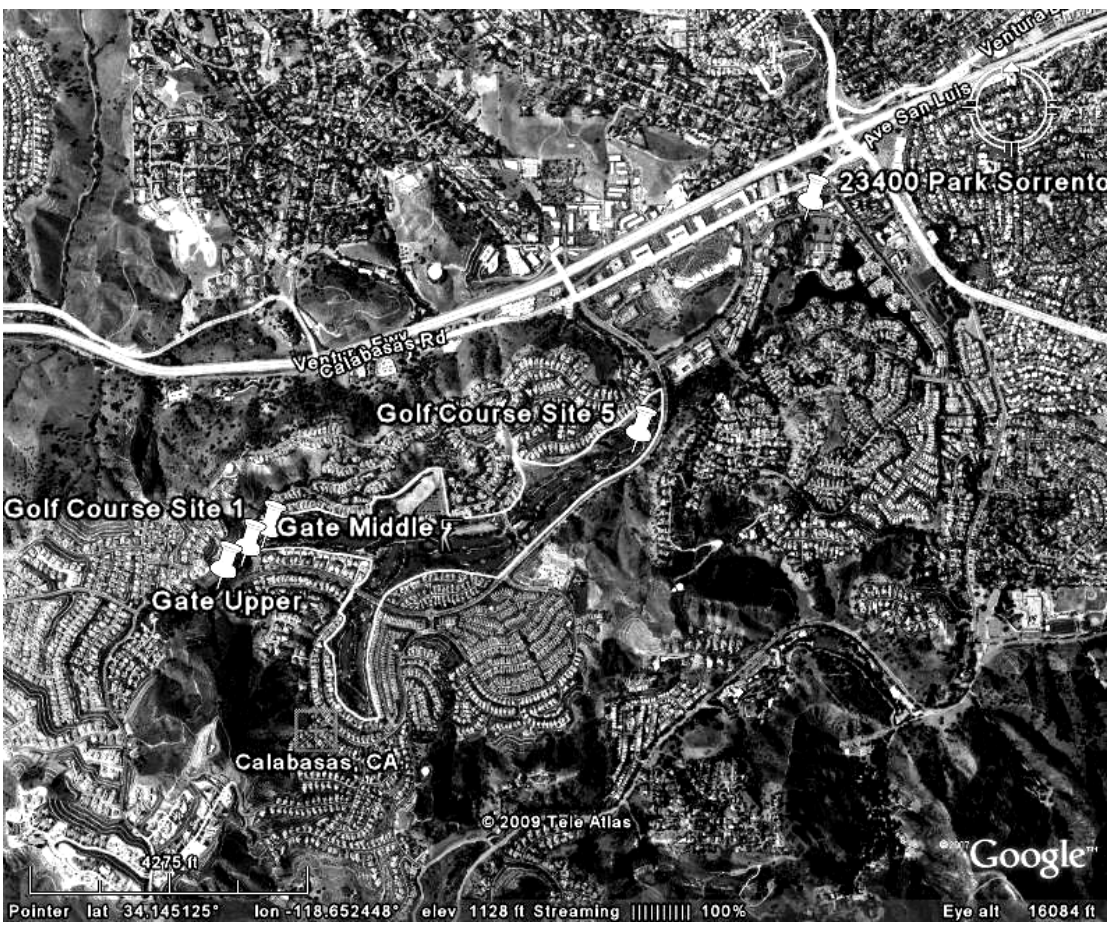

Figure 1. McCoy Creek sampling sites indicated by virtual tacks (Google Earth 2007.)

METHODS: STABLE WATER ISOTOPES

Unpreserved samples were collected in LDPE bottles. In each instance, containers were filled to the rim to minimize headspace. Minimizing headspace is necessary to prevent isotopic fractionation caused by evaporation, which could produce inaccurate results.

Stable isotopes of water, δ18O and δD, were measured in per mille [‰]. Mass spectrometry analysis for δ18O and δD was at the Environmental Isotope Laboratory at the University of Arizona's Geosciences Department. Analytical precision was 0.08‰ or better for δ18O and 0.9‰ or better for δD based on repeated internal standards. Standardization was based on Vienna Standard Mean Ocean

Water [VSMOW] & Standard Light Antarctic Precipitation [SLAP] (Christopher J. Eastoe, Lab Director, personal correspondence, January 12, 2009.)

Measurements of δ18O and δD were taken with a Finnigan Delta S gas-source isotope ratio mass spectrometer. To test hydrogen isotopes, samples were reacted with Cr metal at 750 degrees Celsius "using a Finnigan H/Device coupled to the mass spectrometer" (Christopher J. Eastoe, Lab Director, personal correspondence, January 12, 2009.) To test oxygen isotopes, samples were equilibrated with carbon dioxide gas at about 15 degrees Celsius "in an automated equilibration device coupled to the mass spectrometer" (Christopher J. Eastoe, Lab Director, personal correspondence, January 12, 2009.)

RESULTS & DISCUSSION

SMMNRA Study Area. Stable water isotopic signatures of all samples gathered January 2008 through December 2008 are plotted in relation to the Global Meteoric Water Line (see Figure 2).

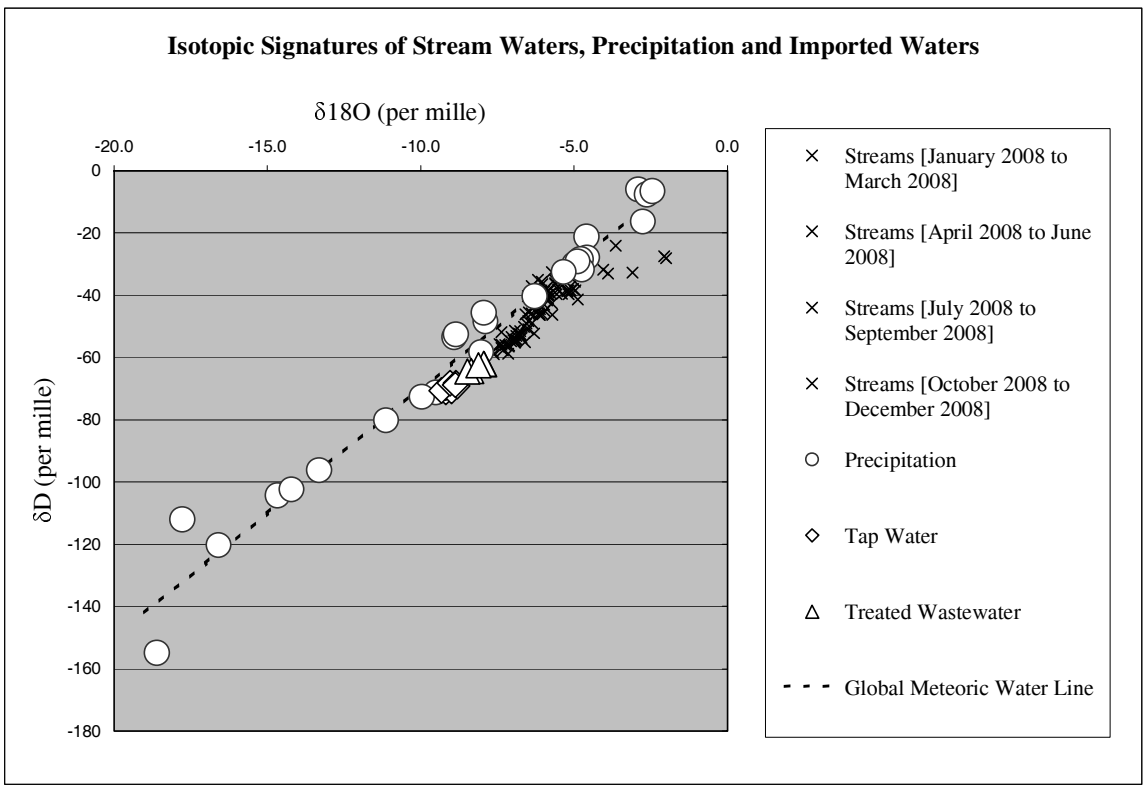

Figure 2. Isotopic signatures of stream waters, precipitation and imported waters relative to the Global Meteoric Water Line.

The isotopic signatures of tap water and treated wastewater remain fairly regular, which indicates that tap water and treated wastewater are reliable end members. Treated wastewater is isotopically heavier than tap water due to 1) evaporation of treated wastewater during reservoir storage and 2) infiltration of isotopically heavier groundwaters into pipes transporting untreated sewage.

Precipitation samples' isotopic signatures vary widely. There are a number of possible causes for this variation: orographic effects as a storm moves inland and higher in elevation, weather patterns such as whether a storm comes from the north or the south, how long a storm event had been occurring at the time of sampling, etc. Due to rainwater's wide-ranging isotopic signatures, precipitation is not reliable as an end member for analysis.

Stream waters also vary greatly in their isotopic signatures. None are isotopically lighter than tap water and treated wastewater, however. Also, stream samples appear to plot between imported water and most precipitation samples in terms of isotopic enrichment or lightness. Therefore, it seems likely that most stream waters are composed of different proportions of imported waters and local precipitation.

McCoy Creek. Stable water isotopic signatures of McCoy Creek sites and end members are plotted in relation to the Global Meteoric Water Line (see Figure 3). From upstream to downstream, the McCoy Creek sampling sites were Gate Upper, Gate Middle, Golf Course Site 1, Golf Course Site 5 and 23400 Park Sorrento. Because no rainwater was collected in the immediate vicinity of McCoy Creek, isotopic signatures from the nearest precipitation samples are shown. These samples' locations are the Las Virgenes Municipal Water District [LVMWD] in the southwest and Gates Canyon Park in the northwest.

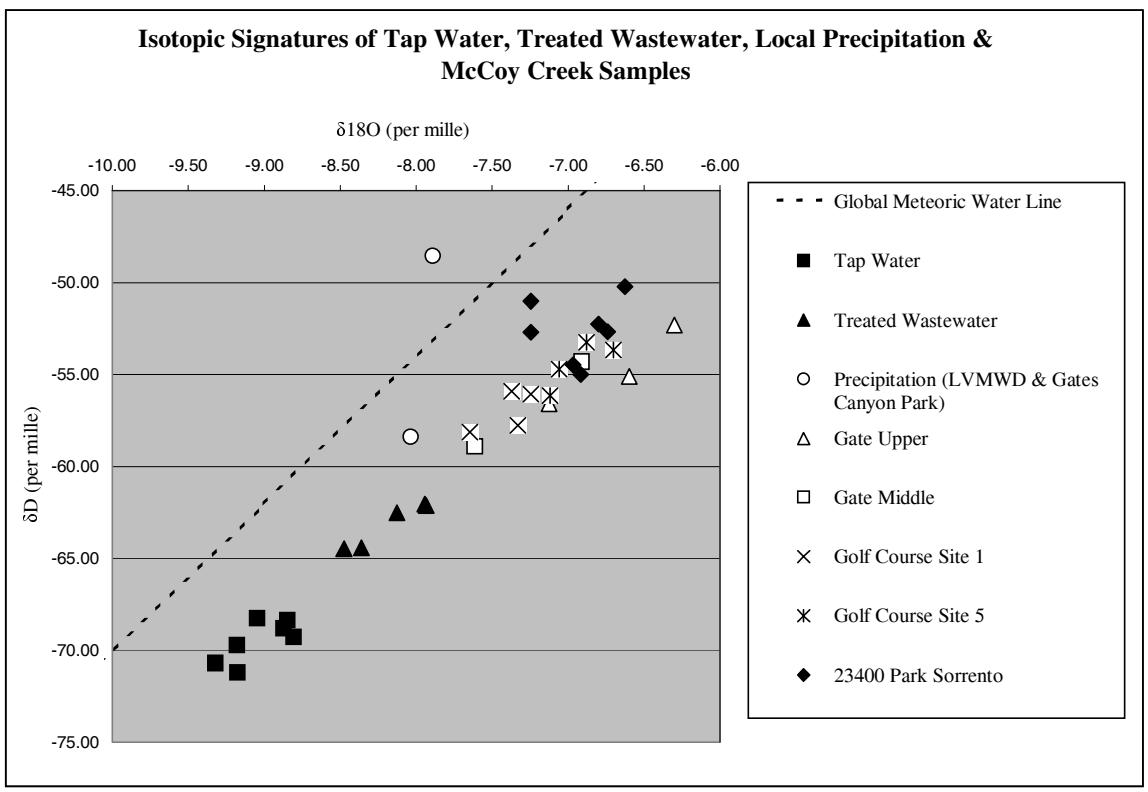

Figure 3. Isotopic signatures of imported waters, precipitation and McCoy Creek samples relative to the Global Meteoric Water Line.

Isotopic signatures at Gate Middle are usually lighter than at Gate Upper. Golf Course Site 1 samples plot between Gate Middle samples. Isotopic signatures at Golf Course Site 5 are heavier than at Golf Course Site 1 and heavier at 23400 Park Sorrento than at Golf Course Site 5.

There appears to be a significant contribution of isotopically lighter imported water to McCoy Creek as it flows from the New Millennium development into the golf course. Although the golf course and 23400 Park Sorrento water their lawns with treated wastewater that is isotopically lighter than stream water, McCoy Creek's water leaves the Calabasas Country Club and Golf Course more isotopically enriched than when it arrived. Also, McCoy Creek is more isotopically enriched at 23400 Park Sorrento than at the Calabasas Country Club and Golf Course.

An explanation for McCoy Creek's heavier isotopic signature at sites with potential inputs of isotopically light imported water could be that conservative watering practices result in most treated wastewater being taken up by plants. With input of treated wastewater to McCoy Creek thus minimized, the isotopic signature of the stream water could become enriched by evaporation or rainfall.

Isotopic signatures of imported waters and McCoy Creek waters monitored over time suggest that the creek waters' isotopic signatures might vary due to local evaporation or due to influence by fluctuations in imported waters' isotopic signatures (see Figures 4 and 5).

The isotopic signatures of both tap water and treated wastewater were relatively light from mid-spring to midsummer. They then became heavier from mid-summer through late September. After late September, the isotopic signatures of tap water and treated wastewater began to become isotopically lighter.

Fluctuations of isotopic signatures of McCoy Creek water at 23400 Park Sorrento closely follow fluctuations of imported waters' isotopic signatures. δD at the other sites appears to mimic fluctuation of δD in imported waters, but with a delay that affects all these sites. $\delta 18O$ results at these sites have a similar-looking delay in fluctuation relative to imported waters' $\delta 18O$ results, but the delay in fluctuations of $\delta 18O$ does not occur consistently.

CONCLUSION

Because the stable water isotope signatures of tap water and treated wastewater remain fairly stable, they are useful end members for analyzing relative contributions to stream flow in the SMMNRA. Precipitation, however, varies greatly in isotopic signature for multiple possible reasons, so rainwater is not reliable as an end member.

Fluctuations of isotopic signatures in tap water and treated wastewater appear to be reflected in the isotopic signatures of McCoy Creek samples. Inputs of treated wastewater to McCoy Creek may be limited by plant uptake.

Possible explanations for stream waters' different isotopic compositions in relation to imported waters include evaporation as well as the quantity of input by imported waters to stream flow.

Results from samples collected in January 2009 and February 2009 may reveal clearer patterns regarding imported waters' effects on stream waters by extending the time over which isotopic signatures are observed.

ABSTRACT

The Las Vegas Valley represents an extreme hydrologic condition in that its high density population must manage discrete but very heavy rainfall events in an erstwhile arid climate. The runoff from these events is routed by way of an elaborate existing and proposed flood control facility system which is composed of washes, channels, storm drains and detention basins. First developed in 1986, the CCRFCD Master Plan has been an excellent planning document for major flood control facilities within the Las Vegas Valley. Currently, the CCRFCD uses a periodic (every 5 years) stormwater infrastructure master plan update process, which requires hydrologic modeling to understand system response to major storm events. Over time, the Master Plan Update (MPU) has evolved into a technical tool for guiding local governmental agencies and private consultants in the development of both public and private property.

This paper will describe the design and on-going development of an Arc Hydro based GIS database for the Las Vegas Valley. This database will provide the geographic and technological foundation for regional hydrologic modeling, efficient permitting, and emergency response modeling. Benefits of moving to this standard include 1) an in-built geometric network that can be used for delineation of drainage area and stream tracing, 2) the integration of existing CCRFCD GIS and hydrologic modeling data into a single database, and 3) making accessible the broad variety of tools that already exist for the Arc Hydro platform.

The development of the database focuses on the workflow of converting existing stormwater GIS coverages into the Arc Hydro database schema. Existing HEC-1 stormwater models are also used in the workflow to 1) describe the catchment-to-catchment connectivity as prescribed by the current master plan models, and 2) to populate the database with information necessary for hydrologic modeling in the future. An ESRI ArcMAP extension called CCRFCD Arc Hydro Tools has been built to facilitate the database development process. To enhance user friendliness and power, this toolset introduces some novel concepts, such as in-built workflow accounting, intelligent map interaction, and environmentally driven network

construction. The design process for this extension, plus some examples of its use, will be described.

INTRODUCTION

The Las Vegas Valley represents an extreme hydrologic condition in that its high density population must manage discrete but very heavy rainfall events in an erstwhile rain-less climate. The runoff from these events is planned to be routed by way of an elaborate, and evolving, flood control facility system which is composed of washes, channels, storm drains and detention basins. The Clark County Regional Flood Control District (CCRFCD), in which the Las Vegas Valley lies, is responsible for planning out regional scale development of this system. First developed in 1986, the CCRFCD Master Plan has been an excellent planning document for major flood control facilities within the Las Vegas Valley. Currently, the CCRFCD uses a periodic (every 5 years) stormwater infrastructure master plan update process, which requires hydrologic modeling to understand system response to major storm events. Over time, the Master Plan Update (MPU) has evolved into a technical tool for guiding local governmental agencies, private developers and engineering consultants in the development of both public and private property.

The next step in the evolution of the MPU process will be to move to an on-going update process, where the stormwater drainage system will be modeled in a GIS-based framework. Through a maintenance tool, used each time a new development is constructed, the system model will be continually updated as new construction occurs within the Las Vegas Valley. To get started on this evolutionary step, CCRFCD plans on converting their existing stock of model data – which includes Arc Info coverages of facilities and HEC-1 model input files – into a fully functional Arc Hydro database.

This paper will describe the planning and development of the CCRFCD Arc Hydro solution. Topics covered will include a discussion of the value of on-going stormwater master planning, a description of the CCRFCD Arc Hydro technological solution including the powerful set of tools developed to help automate the process of converting CCRFCD's existing stock of ArcInfo coverages using HEC-1 hydrologic modeling files into the new Arc Hydro geodatabase, and extensions to the Arc Hydro database design necessary for modeling the stormwater system in Las Vegas Valley.

THE NEED FOR ON-GOING STORMWATER MASTER PLANNING

Like many communities around the country, CCRFCD conducts a periodic master planning process to set the direction of stormwater system enhancement. Every five years, a new MPU plan is produced that specifies the set of stormwater facilities that will be built/maintained over the next five years and quantifies how the entire system will perform with the new set of facilities in place. This quantification is accomplished through a comprehensive hydrologic modeling processing, which traditionally has used the Hydraulic Engineering Center (HEC), HEC-1 model.

At each five year MPU, the most up-to-date model input data available is used. This data includes 1) geo-spatial information about the stormwater facilities, their connectivity and hydraulic properties, 2) updated landuse data that reflects ultimate future development, and 3) updated characterizations of regional storms that occur in the region. This data is collected and formatted to form model input at each master plan update – the data collection effort typically represents the largest task in the MPU development process because it requires collecting data from hundreds of new developments via public entities, and others.

The result of the MPU process is an accurate and reliable characterization of the Las Vegas Valley ultimate condition stormwater system. With extremely high rates of new development – motivated by a high rate of regional population growth – it is becoming clear that an opportunity for improvement of the master planning effort is to continually update the hydrologic models as information about new development becomes available.

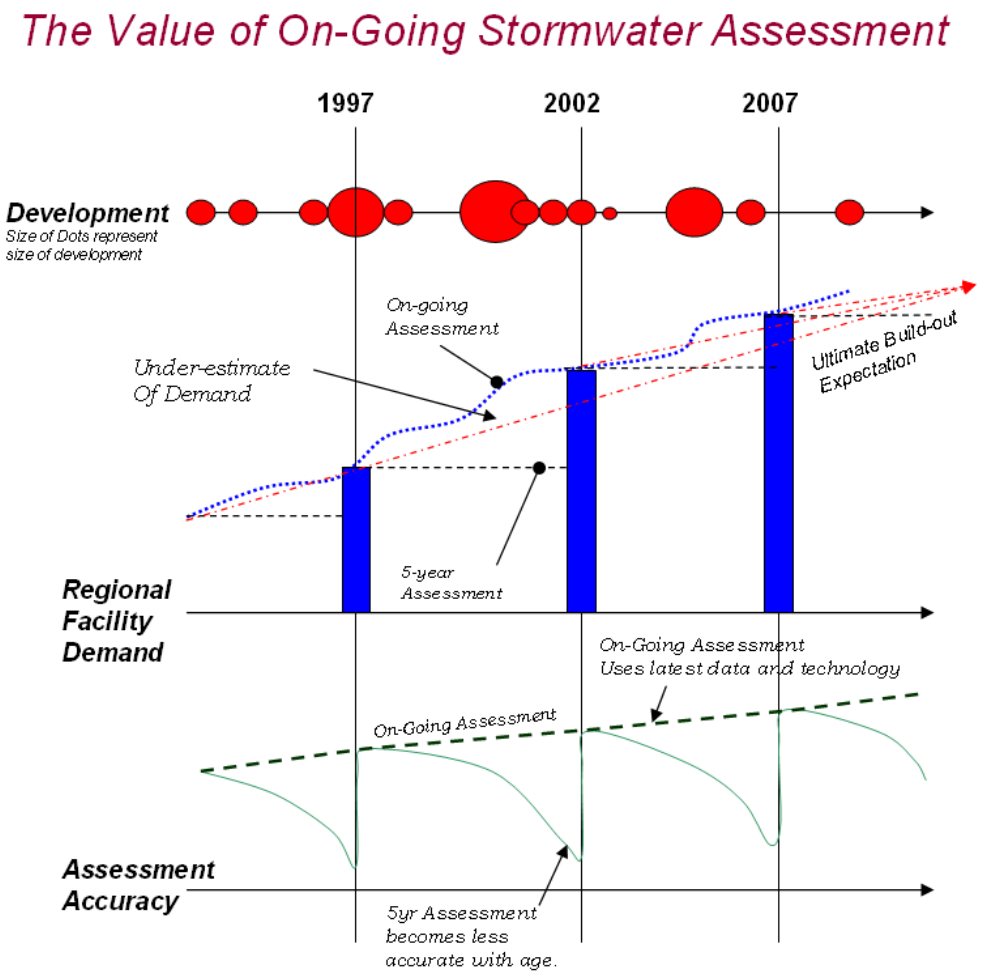

Figure 1. Schematic illustrating the value of an on-going stormwater assessment process.

Figure 1 shows a schematic of the value of such an on-going stormwater assessment process. The top panel in the figure represents new development. The red dots each represent a new development, with the size of the dot representing the size of the development. The middle panel shows the effect of new development on facility demand. As each new development is built, demand on the stormwater facilities increases. A periodic update will capture an accurate estimate of demand at the time of the preparation of the master plan model. The periodic plan will also estimate growth in demand based on perhaps linear interpolation to an ultimate build-out situation that occurs several decades in the future. As time passes, the estimate of growth of demand will become less accurate as unanticipated high growth occurs. The lower panel in the figure shows the accuracy of the estimates of facility demand. In general, accuracy will increase over time due to improved hydrologic modeling methods, but the accuracy will decrease over time in a five year cycle as the time since the last master plan update increases.

Figure 1 provides a good illustration of the value of continuous update of the master plan. If a continuous update occurs, new developments will be captured in the models as they occur. As a result, the accuracy of the modeling effort will remain high, as illustrated by the dashed line in the lower panel of the figure.

THE CCRFCD ARC HYDRO SOFTWARE SOLUTION

The need for on-going stormwater assessment establishes a need for an information solution capable of assimilating new data about land use, hydrologic parameters, and regional stormwater facilities in a relatively automated way. Moreover, the information solution should be able to generate input for hydrologic modeling and organize the output of the models into a useful product for interpretation and reporting. Ideally, the solution will be able to facilitate the entire modeling process in a seamless, single user interface, process.

These needs point to an information solution that is centered on a digital depiction of the real physical stormwater system. This digital depiction should also contain data about terrain and geology – which may be required for understanding the topography and to determine the initial abstraction – and data on the man-made and interpreted environment – which may include roads, rail lines, utility information, landuse data, census information, political boundaries, and parcel definitions. We refer to this digital depiction of reality as the digital watershed (Hampson et.al. 2008).

Figure 2 illustrates the CCRFCD Arc Hydro information solution. The digital watershed database will be composed of an extended Arc Hydro that represents 1) the hydrologic system, 2) the geologic system including soils and land cover, and 3) the man-made environment including land use and political boundaries, etc. The Arc Hydro database design is the natural choice for the CCRFCD solution as it has been developed over many years by a national community of experts in hydrology (Maidment, 2002). Arc Hydro works on the Environmental Systems Research

Institute (ESRI) ArcGIS platform, which is the platform used at CCRFCD and around the country. There is a large body of examples of application of the Arc Hydro system, an ESRI-supported suite of tools for working with Arc Hydro geodatabases, and a national community of Arc Hydro users. The Arc Hydro design has pre-existing feature classes for each part of the stormwater system. Several modifications of the design are necessary to facilitate the modeling of man-made water conveyances – as opposed to natural river systems for which the Arc Hydro design was originally conceived. Specific modifications will be covered in a later section.

A suite of applications will work with the digital watershed database to facilitate 1) exploration of data and model inventory, 2) maintenance of the system through check in/out of new models reflecting new development, 3) hydrologic modeling with newly received input data, 4) automated production of master planning analysis products, and 5) compliance with federal and state regulatory processes. The applications will be built as extensions to the ESRI ArcMap application, which is already in use at CCRFCD as the primary GIS application.

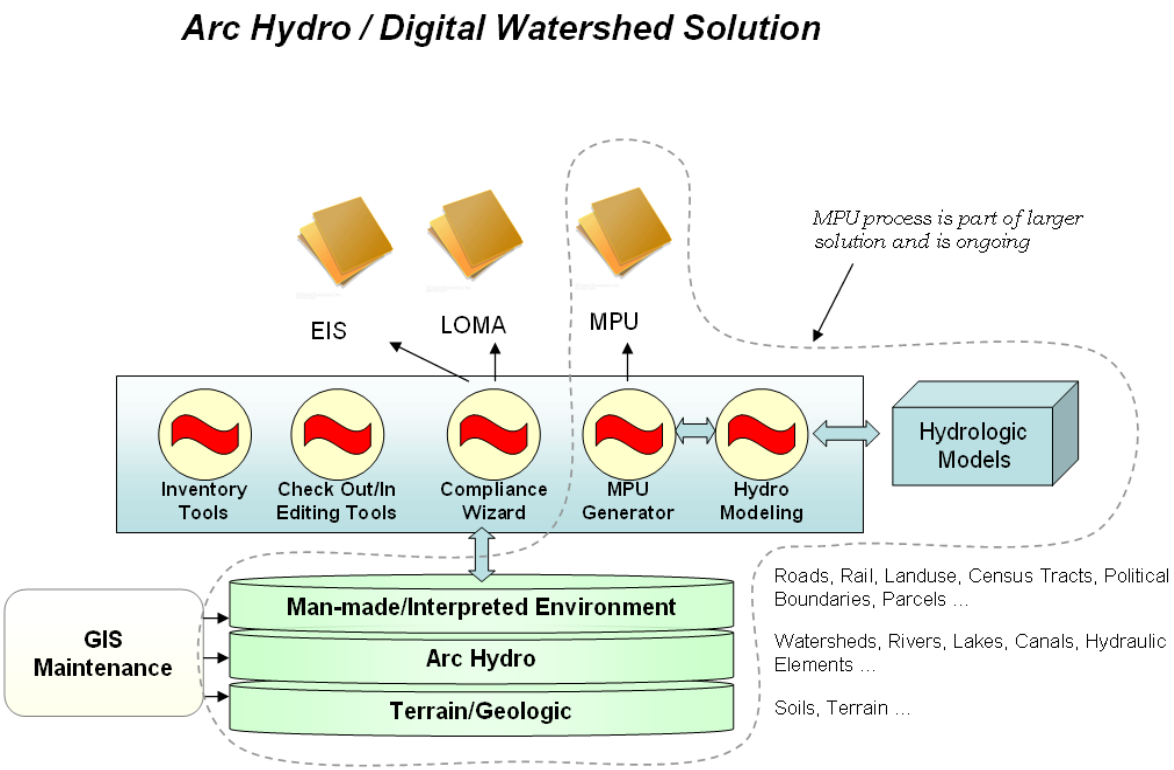

Figure 2. Conceptual Architecture of the CCRFCD Arc Hydro Solution.

MODIFICATIONS TO THE ARC HYDRO DESIGN TO ACCOUNT FOR DESERT ENVIRONMENT STORMWATER INFRASTRUCTURE

The Arc Hydro geodatabase has been created using 1) a set of basic GIS shape files depicting the stormwater channels and detention basins, and the catchments draining

to them, and 2) a set of HEC-1 model input files used to understand the connectivity from the catchments to the stormwater infrastructure and the connectivity of infrastructure itself. A tool was developed to automatically import this data and infer from it a proposed Arc Hydro database.

Modifications to Arc Hydro Connectivity Feature Classes

We found it necessary to modify the basic Arc Hydro design during this process to accommodate the stormwater infrastructure system, which essentially replaces the dendritic natural stream system that is the heart of the Arc Hydro design. Specifically, for the HydroEdge feature class, we added sever subtypes of hydroedge including:

- ***Regional Facilities****: These included the stormwater channels and other mand-made conveyances and natural washes that convey water.*
- ***Schematic Links:*** *A Family of schematic link types was created to establish full connectivity of the system while maintaining the exact shape and dimension of the regional facility features – as the length and size of the regional facilities is used in applications like maintenance cost estimation. The schematic link types include:*
    - ***Catchment Links****: Catchments were linked to the conveyance system via a set of phantom hydroedges called catchment links. These linked the centroid of the catchment directly to the point in the stormwater infrastructure where the catchment is considered to drain.*
    - ***Detention Basin Flow Line****: Stormwater channels drain to detention basins in several locations in the system. Schematic links were created to establish connectivity through the detention basins. Schematic links were used, as opposed to extending the facility hydroedges through the detention basin, so as to preserve the exact shape of the facilities and the associated attributes like length, which are used in stormwater system maintenance cost estimation.*
    - ***Diversions****: In HEC-1 modeling, a diversion can be created that diverts flow from one location to another.*
    - ***Floodway Centerline****: Natural washes exist in Las Vegas, which are wide and full during flooding. Connectivity through these washes was established through using Floodway Centerlines.*
    - ***Route****: A route in the hydrologic model (HEC-1) is used when the hydrograph needs to be routed from one location to another. These routes impact the shape and timing of the hydrograph due flow attenuation and translation. The routes used in the model either represent the regional conveyance system or other local flood conveyances.*

For the HydroJunction feature class, we also added several sub types to accommodate HEC-1 type hydrologic modeling. They included:

- ***CPoint****: These junctions are known as combination points. They represent the hydrojunctions where flows from two or more separate sources join.*
- ***Catchment:*** *These junctions represent the centroid of catchments*
- ***Detention Basin:*** *These junctions represent the centorid of detention basins*
- ***MultiNode:*** *These junctions represent locations where the modeler may want to partition the incoming flows to a hydrojunction simply for modeling purposes. For example, two channels may drain to a single hydrojunction. The local catchment may drain to the only one of the channels. Given this situation, the modeler will want to add the flow from the catchment plus the flow in the channel from upstream catchments to get the total flow in the channel. For the other channel, the flow will be defined as only that flow from the upstream catchment. In this case, the modeler will need to specify one channel flows to one hydrojunction with one HydroID and the other channel flows to another hydrojunction with another HydroID, despite the fact that the channels are actually flowing to a single physical location. To avoid duplication of hydrojunctions in the same location, the multinode has the ability to have up to 5 separate HydroIDs. The multimode, of course, introduces some extra complexity to the Arc Hydro design, as it conflicts with the rule that geographic features should have only one HydroID, but its elegance and respect for the physical nature of the system was deemed worth it. Upstream and downstream path queries were created in the CCRFCD Arc Hydro tools to enable searching through the multi-nodes as a result.*

Finally, the waterbody feature class was used to model the detention basins within the system and the catchment feature class was used to model catchments. With the exception of adding CCRFCD indexing and naming fields, few structural changes were made to these tables. They included:

Extensions to the Arc Hydro Geodatabase Schema for Non-Hydrologic Components

As the CCRFCD Arc Hydro geodatabase will be used eventually for hydrologic modeling, the database was extended to included data for soils, land use, and a working layer for calculating curve numbers.

A TOOL FOR MAINTAINING THE ARC HYDRO DATABASE

Currently under development is a maintenance tool for the CCRFCD Arc Hydro database. This tool will allow developers and engineers to extract portions of the enterprise SDE geodatabase as personal geodatabases. The developers will then be able to modify the facilities, and modeling parameters of that portion of the database according to planned development, or simply to improve the accuracy of GIS-data and modeling data. Then, the developer will be able to submit the personal geodatabase back to CCRFCD, where it will first be quality controlled to ensure acceptability, and then checked back into the CCRFCD enterprise geodatabase, thereby updating the enterprise geodatabase with the most recent data.

Through continuous use of the maintenance tool, the enterprise geodatabase, on which master planning updates are founded, will be continually maintained. The need for data collection at the next MPU, will be diminished drastically. The maintenance extends only to the geodatabase for the current MPU period (2008 – 2013). In 2013, when the MPU is conducted again, a valley-wide modeling effort will be required. Eventually, both the new GIS-data and the model will be run on each new submission of data, so that both the geodatabase update and the model update happen continuously, and there is no need for a periodic update.

CONCLUSIONS

The Clark County Regional Flood Control District (CCRFCD) has made a substantial move toward facilitating on-going stormwater master planning. An Arc Hydro database has been created that contains the entire stormwater infrastructure system and understands connectivity from the catchment to the stormwater conveyance system, through the detention basins, and eventually to the Las Vegas Wash and Lake Mead. Moreover, the features and attributes within the Arc Hydro database will contain sufficient data to re-create the hydrologic models that make up the master plan update model set. Currently a maintenance tool is being created to keep the Arc Hydro database up-to-date over time. As CCRFCD moves into the future, on-going modeling updates will soon be achievable, and the value of on-going master planning will be realized.

ACKNOWLEDGEMENTS

The authors would like to thank Clark County Regional Flood Control District for its support during the development of this project. We would also like to thank Gale Fraser, Stan Clawson, and Michael Moore of CCRFCD, and Matt Baird and Jack Hampson of PBS&J for their support and advice.

ABSTRACT

Healthy streams have the physical characteristics and chemical water quality to support healthy and diverse populations of organisms. The Codorus Creek, a tributary to the Susquehanna River, which eventually drains to the Chesapeake Bay, is being restored in several locations. Penn State University (York and Harrisburg campuses) is evaluating the effectiveness of the state-funded restoration activities. We examine the current pollutant loadings of two branches of this stream in conjunction with land use practices, particularly agriculture and wastewater treatment plants. Fish, macroinvertebrates, and periphyton are routinely sampled. Streamwater sampling for water chemistry analyses occurs during both baseflow and storm event conditions. Restored sites are being compared to both impaired and control sites to determine whether restoration has any significant reduction in a pollutant's load. Preliminary results indicate that the southern branch has greater impairment than the eastern branch. The southern branch impaired site showed greater annual mean loads of total nitrogen and total phosphorus, a macroinvertebrate community dominated by pollution tolerant organisms, and a greater number of fish with parasitic diseases. All sources contributing to the total nitrogen load to Codorus Creek have not been identified. Although restoration activities may decrease pollutant loads, such as as suspended solids, restoration is not believed to be effective in decreasing nitrogen loads. Nitrogen is found more readily in the aqueous phase (streamwater) rather than adsorbed to sediment particles. Therefore, more effective ways to remove nitrogen in water is to decrease or eliminate the source or to treat the streamwater directly. Further monitoring and comparison of restored sites to control and impaired sites are

needed. In addition, future work on the toxicity of the legacy sediments has been proposed.

INTRODUCTION

The Chesapeake Bay has pollutant concentrations that affect the fisheries, tourist, and recreational industries. The main pollutants of concern are nutrients and suspended sediment. Large increases in nutrients cause eutrophication. Suspended sediment affects aquatic organisms such as shellfish populations by smothering the shellfish and degrading or eliminating its habitat. Because many of Pennsylvania's streams eventually enter the Chesapeake Bay, it is prudent to control the pollutant sources upstream if the Bay is to recover. Agriculture, a dominant land use in Pennsylvania, is the leading source of both suspended sediment and nutrient contributions to streams and rivers. However, erosion from streambanks is a source for suspended sediment as well.

Historically, the dominant land use in the South-central Pennsylvania area was agriculture. Up until the early industrial revolution (mid-1800s) this agriculture depended on a large number of mills, most of which were powered by the hydro-mechanical forces of small streams. During colonial times, there were in excess of three hundred mills and their associated mill dams in some counties (Natural Streams Project 2008, Lloyd 2007). These dams collected sediment over the years, including any contaminants present. When most of these mills were eventually abandoned, their respective dams breached or eroded away. The collected sediments, or legacy sediments, began eroding and washing downstream. Walter and Merritts (2008) recognized legacy sediments as a source of suspended sediments and nutrients in South-central PA. These sediments are still problematic as erosion continues into the present.

The Codorus Creek empties into the Susquehanna River, which then flows into the Chesapeake Bay. Historically, forty-five mills were located along the three branches of this stream, (Natural Streams Project 2008). Suspended solids and nutrients from the remaining legacy sediments and the erosion of surrounding farmland contribute to the stream's pollutant loads. Restoration of the Codorus Creek is a high priority and several restoration projects are being planned or recently have been initiated on both the Eastern and Southern branches of the creek. This study, under a Pennsylvania Department of Environmental Protection's Growing Greener Grant (#SC30462), examines the loadings of pollutants in Codorus Creek along with biological metrics to determine the health of the stream at reference, restoration, and impaired sites.

Restoration activities were slated for specific portions of the stream. To date, restoration has been completed at several study sites on both the eastern and southern branches. The intent of the study was to determine what effect restoration has in improving stream health. The working hypothesis of this research proposes that natural stream channel restoration will initiate a cascade of shifts in the physical,

chemical, and biological characteristics of the stream, ultimately leading to greater ecosystem health.

SITE DESCRIPTION

Located in South-central Pennsylvania, Codorus Creek flows through York County. The mainstem of Codorus Creek originates in West Manheim Township, Maryland and empties into the Susquehanna River (near Saginaw, Pennsylvania) (Pennsylvania Department of Natural Resources [PA DCNR] 2002). Three branches of this creek (east, south, west) join the mainstem before it empties into the Susquehanna River. Considered a trout stream and warm water fishery, the stream flows in the northeast direction, including two manmade lakes that serve as reservoirs. The drainage area is 720km^2 (278mi^2) (PA DCNR 2002). Primary land use is cropland, followed by woodland. Urban areas (*e.g.*, the city of York) comprise of a lesser percentage of land use in the Codorus watershed (Smith 2003). Nonetheless, these urban areas impact Codorus Creek.

The initial phase of the project focused on pre-restoration characterization of the East and South Branches of the creek. A reference site (upstream of the proposed restoration), impaired, and proposed restoration sites (both downstream of the reference site) were monitored for both branches of the creek. A total of nine sites were sampled on the two branches, five on the eastern branch and four on the southern branch.

METHODOLOGY

Physical/Chemical Parameters

Baseflow and storm event samples are taken throughout the study period for nutrient (total phosphorus and total nitrogen) and suspended sediment analysis. Precipitation data was obtained from the WeatherBug® network. Average values for stations in each watershed were used in modeling storm-event volume and loads for suspended solids, total nitrogen (TN) and total phosphorus (TP). Suspended solids (SS) was determined by gravimetric analysis of particles collected on Whatman GF/F filters (American Public Health Association [APHA], American Water Works Association [AWWA], and Water Environment Federation [WEF] 1996). Total nitrogen and total phosphorus were determined using the alkaline persulfate thermal digestion and subsequent analysis of phosphate and nitrate ions (Valderrama 1981). One multiparameter sonde (YSI model 6600M) was placed on each branch at an impaired site. The sondes continually measured sonde depth, turbidity, specific conductivity, dissolved oxygen, pH, and water temperature.

Biological Parameters

Habitat assessments for each study site were made using the U.S. EPA Rapid Bioassessment Protocol III for wadable streams (Barbour *et al.* 1999). Periphyton samples were collected at approximately bimonthly intervals. The exact timing of the periphyton sampling depended on stream discharge; periphyton samples were only collected after at least ten days without a scouring precipitation event. Samples were collected and analyzed for chlorophyll *a* (chl*a*), dry mass, and ash-free dry mass (AFDM) (Steinman, Lamberti, and Leavitt 2006). Macroinvertebrates were collected twice a year (spring and autumn) using a proportionate habitat approach (Barbour *et al.* 1999). Biological metrics for macroinvertebrates was determined by using macroinvertebrate abundance data which, in turn, allowed for the calculation of the index of biotic integrity for macroinvertebrates (IBI_M) (PADEP 2007; Stribling *et al.* 1998). Fish were surveyed once a year (summer) using an electrofishing approach recommended by Barbour *et al.* (1999). Data from the electrofishing was used to determine an index of biological integrity for fish (IBI_F) (Roth *et al.* 2000).

RESULTS AND DISCUSSION

Physical/Chemical parameters

Suspended sediment: Both branches showed greater concentrations at the impaired sites during baseflow conditions. Storm events created conditions where more sediment was available for transport than at baseflow conditions. SS at the Reference sites on both the Eastern and Southern Branch were significantly lower ($p < 0.05$) than at the impaired sites throughout the year. There were no significant differences when the reference sites on both branches or the impaired sites on the branches were compared to each other (Hoch 2007).

Nutrients: Total nitrogen concentrations were similar for both branches at baseflow conditions. Seasonality was not a factor and concentrations were not significantly different for either total phosphorus or total nitrogen between reference and impaired sites on the eastern branch. Total phosphorus concentrations at the southern impaired site were greater than those found at the reference site. During stormflows, total phosphorus concentrations were higher on the eastern branch than the southern branch. Total nitrogen concentrations appeared to be dependent on storm intensity and stream branch. Greater releases of total nitrogen occurred in storms of 1 – 4cm on the southern branch. On the eastern branch, storms of the same size or greater released more total nitrogen than the smaller storms (Hoch 2007).

SS concentration was a poor predictor of TN concentrations in both watersheds supporting the possibility that erosion of legacy sediments are not the dominant source of TN to downstream areas. In contrast, the TN, TP concentration was positively related to SS concentrations, indicating that the bulk of the input of the

phosphorus to the stream was particle-bound and associated with erosion (Hoch 2007).

Biological Parameters

Periphyton – chlorophyll α: Chlorophyll *a* was used to assess the biomass of primary producers in the stream. In both reaches, pool samples tended to contain lower chlorophyll α than riffle samples. In addition to differences between habitats, seasonal differences were found with greater concentrations in winter and the lowest in summer months. The highest chlorophyll *a* concentration was found at the impaired site in the South Branch. This site is downstream of the discharge of the New Freedom Wastewater Treatment Plant. Not surprisingly, the concentration of TP at this site was significantly higher at this site than at any of the other sites (Hoch 2007).

Periphyton – ash free dry weight: Greatest dry weight concentrations were found in pools. However, mineral content was greater than organic content. This higher mineral content was due to the silt found in the stream. Little differences were observed between sites on each branch and between the branches themselves (Hoch 2007).

Macroinvertebrates: Macroinvertebrate data indicated no consistent differences overall between the control and impaired sites in the overall density of macroinvertebrates, although the seasonal variability makes it difficult to detect differences when yearly averages are compared. Macroinvertebrate diversity was always greater at the Southern branch reference site than at the impaired site on this branch. On the East Branch, diversity at the reference site was only greater than the impaired site for 4 of the 7 total samples obtained. In addition, the average IBI_M scores for each watershed were significantly higher ($p < 0.05$) at reference reaches compared to impaired reaches. There were no differences in the IBI_M scores between the reference sites on the two watersheds while the scores for the East branch impaired site was generally higher than that for the South Branch.

Fish: Twenty-two species of fish were observed in the surveys. Interestingly, a greater number of species were found at the impaired sites rather than the reference sites. Black nose dace was the dominant species at reference sites and the long nose dace was dominant at the impaired sites. Biomass was dominated by two other species. All sites, except the southern branch reference site, were dominated by the white sucker. The southern branch reference site was dominated by brown trout. Although the eastern branch demonstrated more diversity, there was no significant difference between the two branches. Some captured fish showed disease anomalies: black spot parasite or parasitic flatworms. Using the index of biological integrity for Maryland streams (Roth *et al.* 2000), all sites were in the poor range except for the reference site on the southern branch. This site was considered fair (Hoch 2007).

Overall, the southern branch is more impaired than the eastern branch. Data are still being collected and analyzed. Three sites are proposed to be restored in summer 2009 (R.L. Irwin, personal communication 2009).

ABSTRACT

Numerous efforts to improve storm water quality on a watershed-wide basis have lacked a reproducible, transparent, methodical approach to optimize the selection and implementation of structural Best Management Practices (BMPs) to meet receiving water quality goals. For urban stormwater retrofit projects, structural BMPs are primarily selected in an opportunistic, site-specific fashion, focusing on one or a few pollutants, stakeholder inputs, or local funding availability. As geographic information systems (GIS) technologies improve, computing power increases, and pollutant loading and treatment efficiency datasets become more robust there is an opportunity to improve watershed-based implementation planning efforts.

The authors have developed methods to prioritize water quality improvement needs and identify structural BMP opportunities on a watershed scale to maximize the return on investment for improved water quality. Opportunity evaluation considers property ownership and the potential for retrofitting to achieve multiple benefits, such as water quality, aesthetics, recreation, and habitat. It is recognized that different types of land parcels typically have different types of opportunities and constraints. BMP opportunities can be regional or distributed in nature depending on the land use, size, and location of the public parcel, among other things. By utilizing GIS-based parcel and land use information in the context of water quality need, potential opportunities, and constraints, as well as BMP unit processes and performance data, watershed-wide benefits of BMP implementation can be assessed.

An analysis tool has been developed in the ArcGIS™ environment that automates many of these spatial prioritization and identification processes, while allowing for stakeholders and decisions-makers to provide meaningful input that supports BMP implementation decisions. Once candidate BMPs have been identified for a high priority area, the tool can estimate the potential pollutant load reductions and planning level costs associated with site-specific implementation. Example studies are provided to illustrate the concepts and GIS methods employed.

INTRODUCTION AND PURPOSE

Agencies in Southern California, like many others throughout the United States, are facing a number of challenges and opportunities with respect to stormwater quality. The challenges lie in the implementation of TMDLs and planning for future MS4 Permits while considering limited space, aging infrastructure, and numerous other constraints. Opportunities lie in funding opportunities such as successful local ballot propositions, Integrated Regional Water Management Planning efforts, and coordinated redevelopment and urban retrofit projects.

With the advent of geographic information systems (GIS), watershed-wide stormwater BMP implementation planning and prioritization efforts have the potential to significantly improve. However, the general approach with many efforts is to identify opportunities based on limited spatial analyses and stakeholder inputs without considering *a priori* the spatial distribution of relative water quality improvement need. The prioritization of potential opportunities, if conducted, often lacks a reproducible, updateable and methodical approach that considers both the relative need for water quality improvement and the constraints of BMP implementation.

Once opportunities have been prioritized, the selection of candidate BMPs must consider site-specific constraints and the potential for improving water quality. Quantifying water quality improvements can be particularly challenging given uncertainties in rainfall, hydrologic response, water quality loading, and BMP effectiveness. By combining long-term hydrologic simulations with stochastic water quality modeling methods, the storm-to-storm variability of loads and load reductions can be quantified for selected site-specific scenarios. This quantification of uncertainty provides a more realistic estimate of the confidence in model predictions and the range of potential improvement to water quality. Site-specific scenario model results can then be extrapolated to inform watershed-wide water quality improvement planning.

The purpose of this paper is to present some of the approaches and considerations for identifying opportunities and assessing potential benefits of watershed-wide BMP planning and implementation efforts. The Structural BMP Prioritization and Assessment Tool (SBPAT; Geosyntec 2008) is then introduced and used to demonstrate these methods and illustrate how site-specific modeling can be used to assess various watershed-wide BMP implementation scenarios.

WATERSHED WIDE PRIORITIZATION APPROACHES

The identification and prioritization of stormwater BMP retrofit projects should consider water quality improvement needs and BMP implementation opportunities. Water quality improvement need may be quantified by estimating runoff volumes, pollutant loads, and stressors by analyzing land use, imperviousness, receiving water impairments, and local monitoring data. BMP implementation opportunities may be identified by considering parcel attributes such as size, ownership, land use, and distance to storm drains. Depending on the specific goals of the watershed

prioritization additional spatial data sets may also be included. As examples, two different watershed-wide prioritization approaches are described below.

Los Angeles County Structural BMP Prioritization Methodology (Methodology). The BMP Prioritization Methodology (Geosyntec 2006) provides a four step procedure for prioritizing catchments by water quality need and BMP implementation potential and then ranking BMP types based on relative cost, effectiveness, implementability, and other benefits. The four steps of the Methodology are shown in Figure 1.

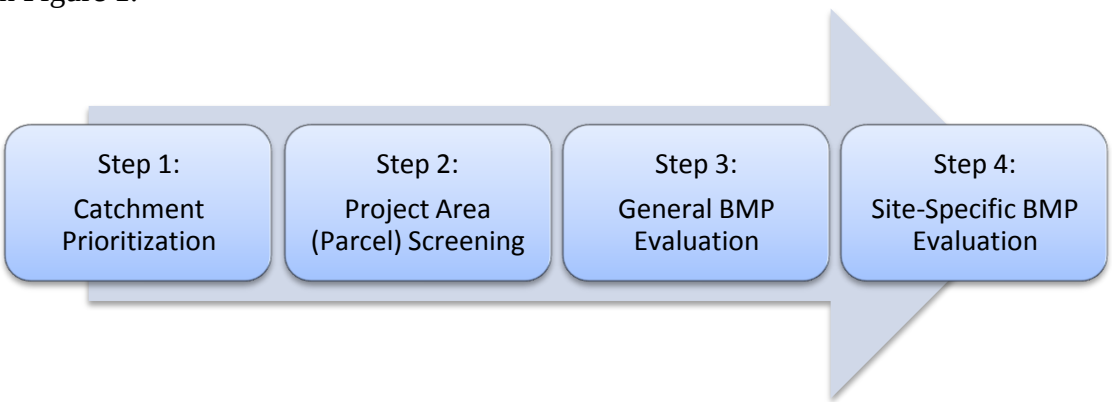

Figure 1. Overall Methodology flowchart.

During Catchment Prioritization (Step 1), the relative need for retrofitting a catchment within a watershed is quantified by developing a Catchment Prioritization Index (CPI) and a Nodal CPI. The CPI is calculated by estimating normalized pollutant loads or concentrations for every catchment and weighting each pollutant according to downstream receiving water impairments and TMDLs. Downstream receiving water impairments are determined using a defined catchment network where every catchment has a unique identifier and a unique downstream catchment identifier. The Nodal CPI is calculated as the area-weighted average of the CPI values from all upstream tributary catchments. The CPI provides a relative measure of the need to address pollutants of concern generated directly from the catchment. A Nodal CPI provides a measure of the need to address pollutants of concern generated upstream from the catchment. Both the CPI and Nodal CPI serve as the basis for prioritization of catchments for BMP implementation.

Project Area Screening (Step 2) identifies parcels in or downstream of high-priority catchments that provide the greatest opportunities for structural BMP implementation. Two different types of structural BMPs are explicitly considered:

- Regional/subregional BMPs: centralized stormwater facilities, typically placed near the outlet of a catchment or subwatershed (a group of catchments) ,designed to treat stormwater from larger drainage areas (order of magnitude:100-200 acres).

- Distributed/onsite BMPs: stormwater devices and landscaping practices dispersed throughout a catchment and typically serving smaller drainage areas (order of

magnitude: <10 acres), such as a large single parcel, rooftop, or section of roadway.

If a catchment is identified as having a high water quality improvement need but regional and distributed structural BMP opportunities are limited, then non-structural or institutional BMPs must be considered.

Potential BMP opportunities are determined by calculating distributed and regional BMP scores for every catchment. The BMP scores are determined by first calculating parcel scores according to their size, ownership, land use, and distance from major storm drains. An area-weighted parcel score is then calculated for every catchment. An overlay analysis compares the distributed BMP scores to the CPI values and the regional BMP scores to the nodal CPI values. Catchments with high BMP scores and high CPI values are considered high priority catchments for retrofit BMP implementation. Figure 2 provides examples of regional and distributed BMP priority and opportunity maps generated for the Ballona Creek watershed in Los Angeles, California. These maps represent the final products of Steps 1 and 2 of the Methodology.

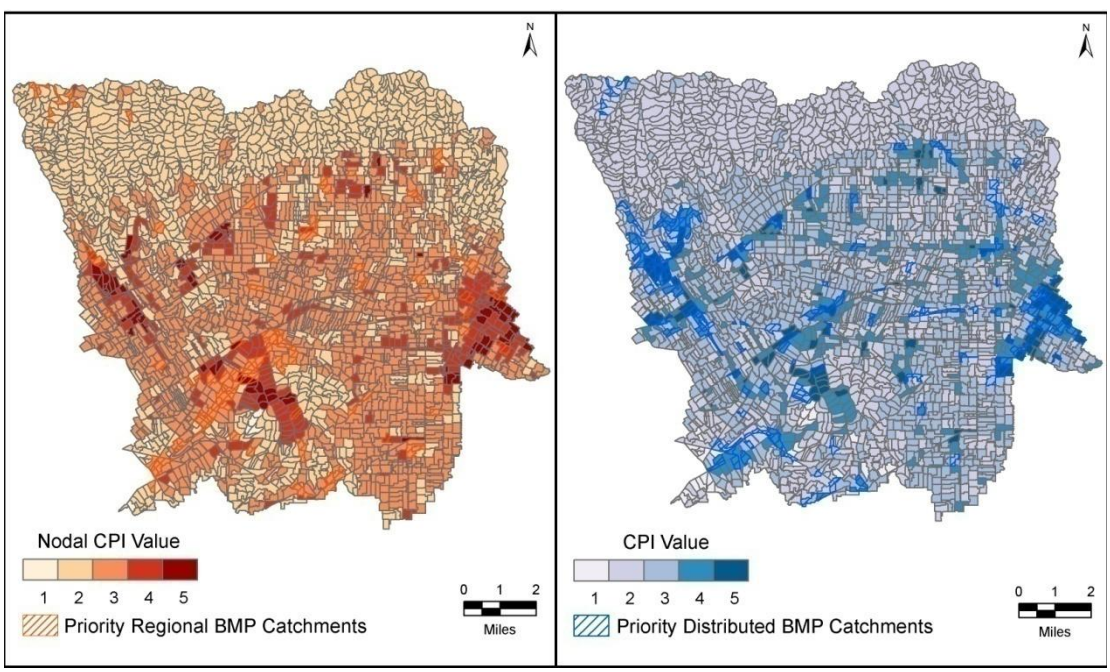

Figure 2. Example Regional (left) and Distributed (right) BMP Priority and Opportunity Maps.

Once regional and distributed BMP priority catchments are identified, during Steps 3 and 4 of the Methodology BMP comparison matrices are produced using user-defined weights of the relative importance of various BMP implementation factors, such as cost, effectiveness, site-specific constraints, and other benefits. These matrices can then be used to identify which BMPs should be further evaluated for specific priority catchments.

The Green Solutions Project. Similar to the BMP Prioritization Methodology, the Green Solutions Project (Geosyntec and GreenInfo, 2008) involved watershed-wide assessment of water quality improvement need and potential BMP implementation opportunities. However this project focused was on multi-use, multi-benefit "green" BMPs that can be implemented on publicly owned parcels. The overall purpose of the Green Solutions Project was to quantify the number of acres needed and the amount of existing public lands suitable for stormwater quality retrofit projects to effectively treat runoff while also providing new park, recreation, natural habitat or other green open space lands.

Water quality treatment needs and BMP implementation opportunities were identified for each major watershed in the County (Figure 3) by applying various assumptions regarding treatment areas, BMP design, parcel and land use suitability, treatable areas, and water quality priorities.

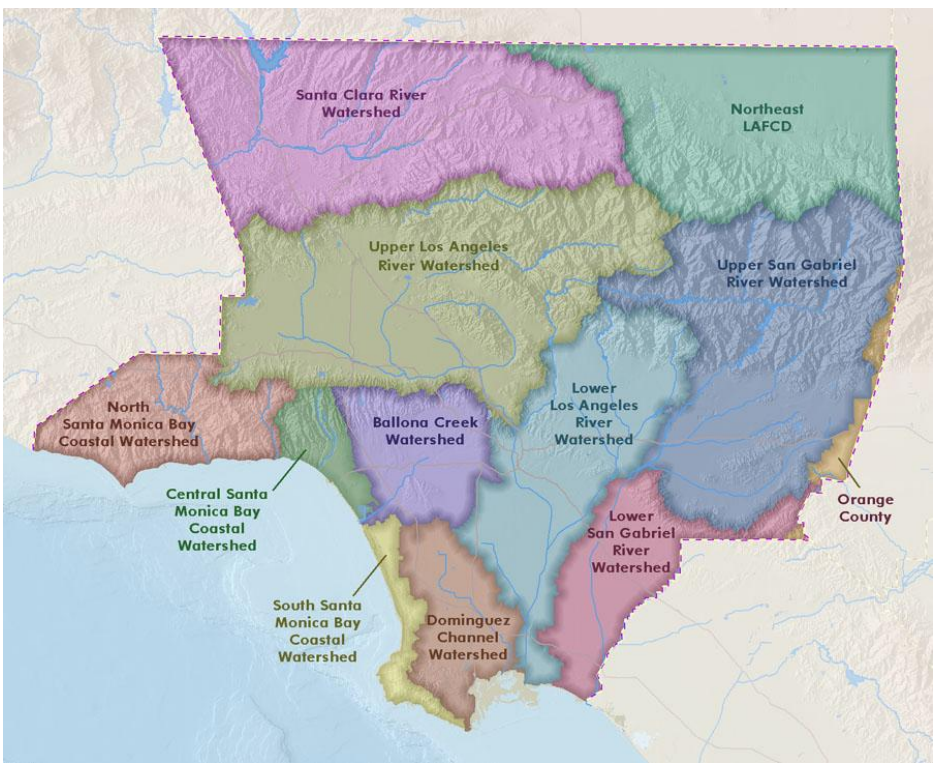

Figure 3. Los Angeles County Watersheds (Geosyntec and GreenInfo 2008).

Effective drainage areas, or area contributing to direct runoff, were estimated for each subwatershed based on Los Angeles County's runoff coefficient equation:

$$A_E = (0.9 \times A_T \times Imp) + [0.1 \times A_T \times (1 - Imp)]$$

Where: A_E = Effective Drainage Area (acres)
A_T = Total Drainage Area (acres)
Imp = Proportion Impervious (0 to 1)

By applying typical BMP design assumptions and analyzing runoff capture efficiencies from long-term hydrologic simulations of historical Los Angeles area rainfall, treatment area ratios (TARs), or the ratio of BMP footprint to the effective tributary area (Figure 4), were estimated to range between 5-10%. This range was then used to estimate a range of potential land needed to capture 80% of the average annual runoff volume from the effective drainage areas.

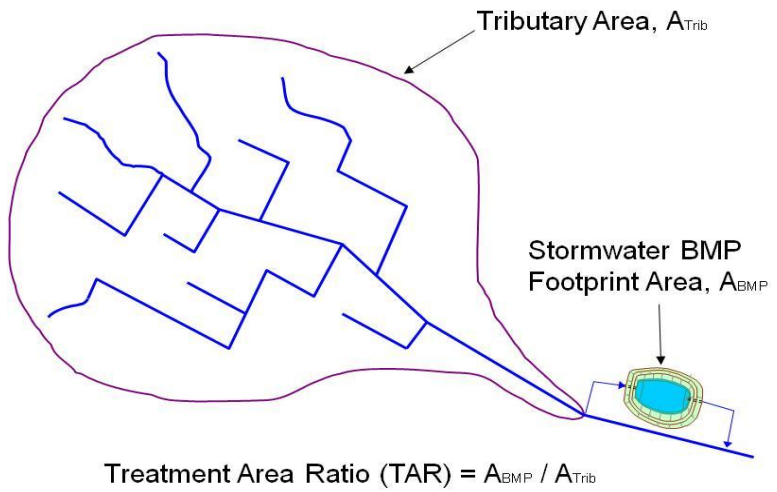

Figure 4. Conceptual Illustration of the Treatment Area Ratio (TAR) (Geosyntec and GreenInfo, 2008).

Suitable acres of publicly owned land for BMP implementation were then estimated by evaluating aerial photographs of a subset of parcels for each major land use category. Ranges of suitable acres were then assigned to all public parcels by land use. Public parcels greater than 100 acres were evaluated and assigned suitable acreages individually. A range of total suitable acres for each subwatershed was then computed by summing the values assigned to all public parcels.

Finally, comparisons of needed BMP footprint areas to suitable acres were then used to identify subwatersheds with adequate or deficient public land to meet stormwater treatment goals. Figure 5 summarizes the estimated BMP acres suitable as a percentage of the needed acres for all watersheds in Los Angeles County. The wide range illustrates the high level of uncertainty associated with this planning level analysis, but clearly indicates which watersheds have few or many opportunities for water quality improvement through the retrofit of public lands. Figure 6 shows the average percent suitable acreages by subwatershed for each L.A. County watershed. The catchment prioritization index (CPI) from the BMP Prioritization Methodology has also been overlain to illustrate which watersheds have the most pressing needs.

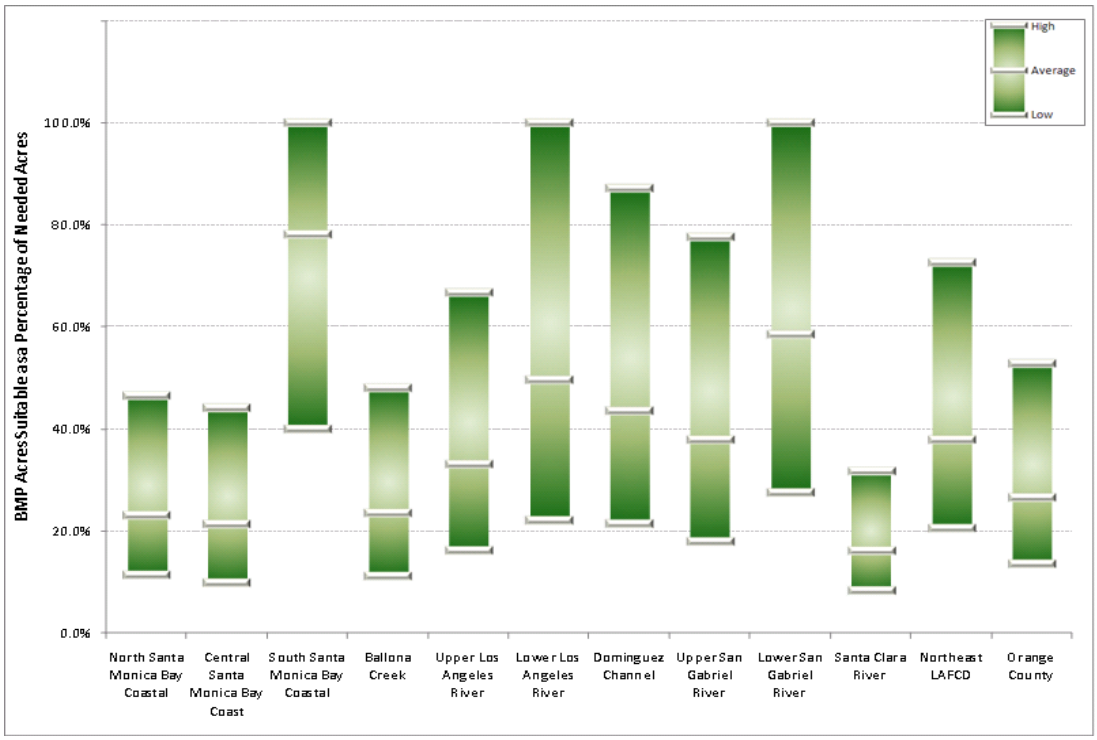

Figure 5. Percent of BMP Area Needs Potential Met by Suitable Public Lands (Geosyntec and GreenInfo, 2008).

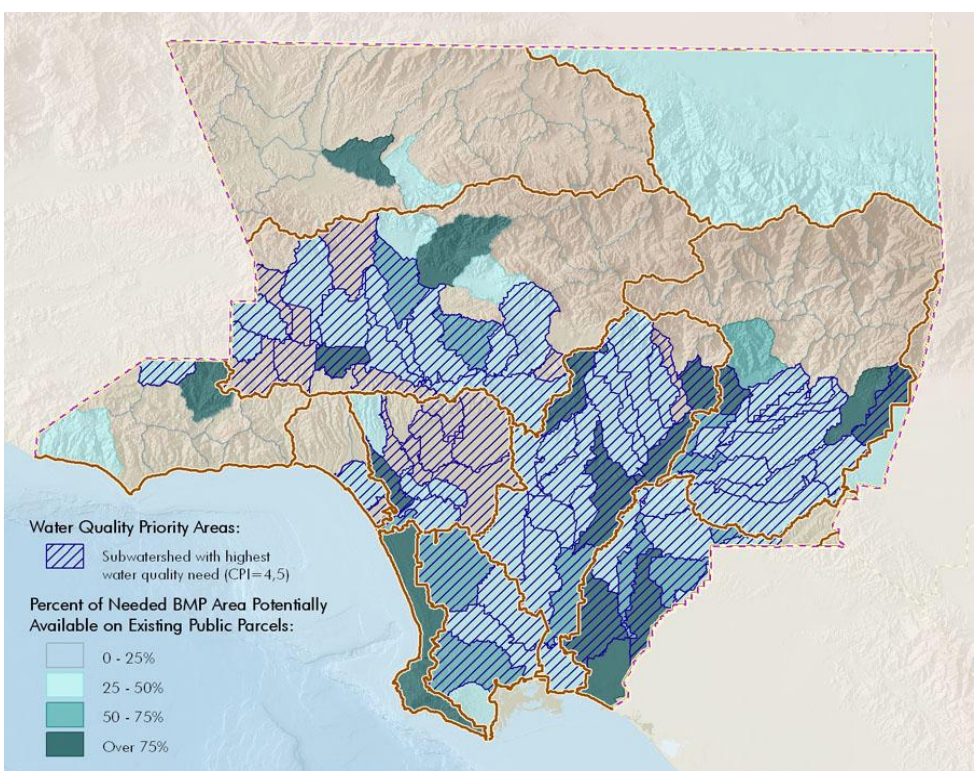

Figure 6. Average BMP Area Needs Potentially Met versus Water Quality Improvement Priority (Geosyntec and GreenInfo, 2008).

STRUCTURAL BMP PRIORITIZATION AND ANALYSIS TOOL (SBPAT)

The Structural BMP Prioritization and Analysis Tool (SBPAT) is a GIS-based decision support tool that has been developed as an ArcGIS™ extension (Geosyntec, 2008). SBPAT includes two primary elements: a Prioritization component and a Modeling component. The Prioritization component implements the Los Angeles County Structural BMP Prioritization Methodology, as described above. The Modeling component is intended to help evaluate the costs and benefits of implementing specific BMP types within prioritized catchments by modeling the hydrology and quality of runoff before and after BMP implementation. It utilizes a modified U.S. EPA Storm Water Management Model (SWMM) and a Monte Carlo water quality model to estimate average annual runoff volumes and loads and average storm EMCs before and after BMP implementation. The predicted uncertainty of these estimates and planning-level capital and O&M costs are also provided to assist in risk-based decision making regarding BMP implementation.

Primary inputs for SBPAT include spatial and non-spatial data sets. A pre-populated geodatabase includes many of the necessary inputs including catchments, slopes, soils characteristics, land uses, imperviousness, long-term rainfall records, land use EMCs, and BMP effluent concentrations. Land use EMCs were estimated using Los Angeles County data (LACDWP, 2001 & 2002) and BMP effluent concentrations were estimated using data from the International BMP Database (WWE and Geosyntec, 2008). The primary user inputs are catchment prioritization parameters and site-specific information such as extent of BMP implementation and BMP design parameters. Figure 7 illustrates the primary inputs and components of SBPAT.

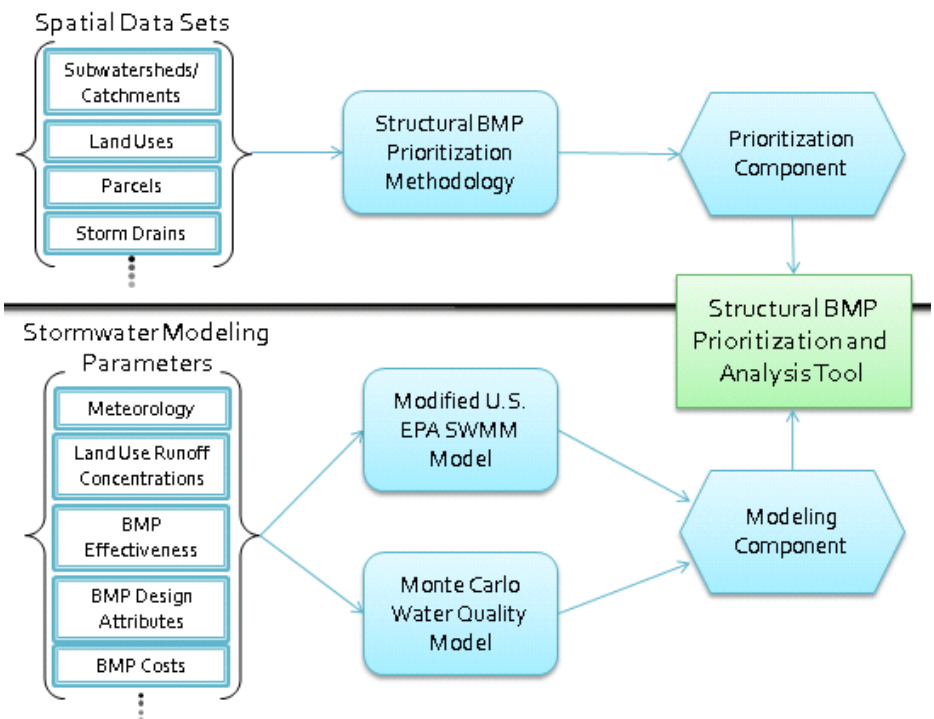

Figure 7. Primary Inputs and Components of SBPAT.

SBPAT DEMONSTRATION OF BMP MODELING ANALYSIS

The catchments of the Ballona Creek watershed were prioritized using the Prioritization Component of SBPAT. A 238-acre, 85% impervious study area was selected by choosing a high priority group of catchments as shown in Figure 8.

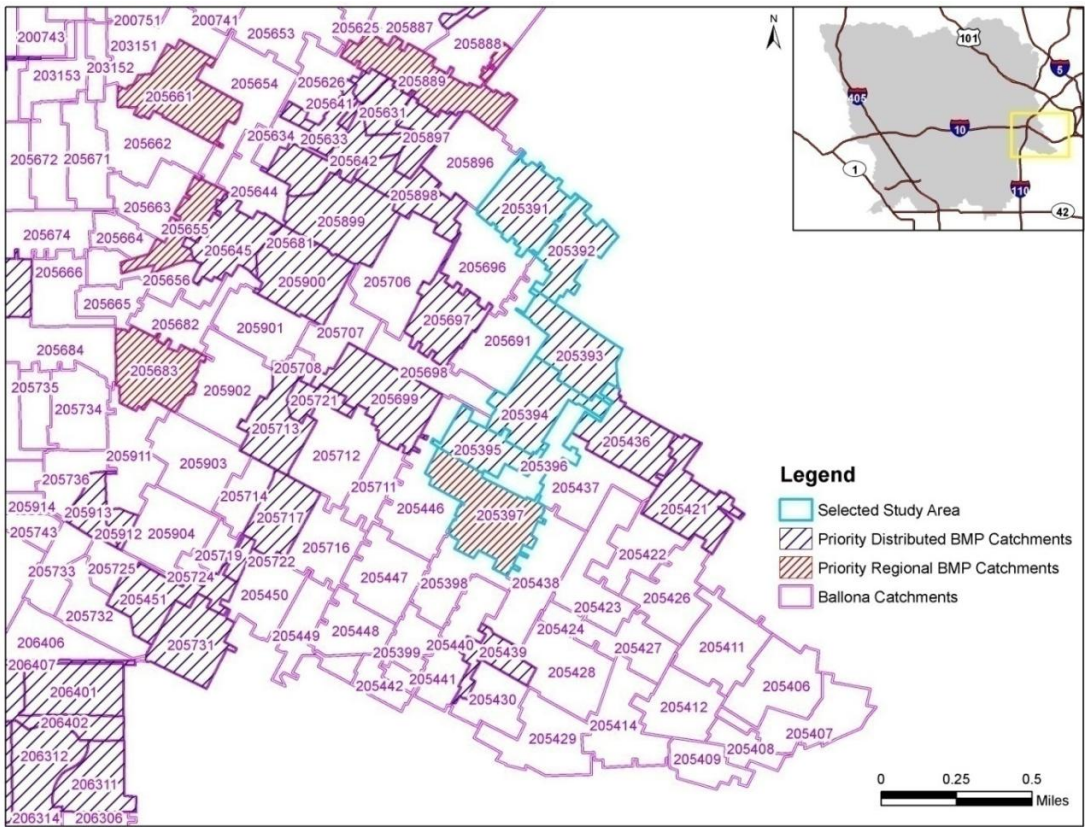

Figure 8. Selected Study Area and Priority Catchments.

BMP Implementation Scenarios. Due to a Metals TMDL (LARWQCB, 2007), BMP types were selected for this example that would likely reduce loads or concentrations of metals based on fundamental unit treatment processes (Strecker et al., 2005). Within SBPAT, the user identifies distributed BMPs by land use (in terms of percent implementation). Regional BMPs are assumed to be placed at the downstream end of the study area and will treat runoff from the entire area. The BMP design capacities determine the quantity of runoff that is treated over the simulation period.

Four different BMP modeling scenarios were simulated as follows:

- Scenario 1: Distributed BMPs only with the land use-based percent implementation strategy described below.
- Scenario 2: A regional extended detention basin sized to fit within a 0.75-acre playfield of a City-owned park; estimated design volume of 4.5 ac-ft.
- Scenario 3: A regional hydrodynamic separator sized to treat 0.2 in/hr design intensity for the entire study area; estimated design flow rate 39 cfs.

- Scenario 4: A regional subsurface flow wetland sized to fit beneath the 0.75-acre playfield in the City-owned park (design flow rate of 1.4 cfs), including an equalization basin designed to capture a 0.2-inch storm from the entire study area.

For Scenario 1, aerial photographs were examined to estimate available areas for distributed BMP implementation within each land use type. Distributed BMP assignments (Table 1) were based on estimated available areas and the following target treatment levels:

- Since metals are priority pollutants, industrial, commercial, and transportation land uses should be highest priority; target level of distributed BMP implementation was set to 80%.
- Multifamily and educational land uses are generally lower priority; target level of distributed BMP implementation was set to 50%.

Table 1. Distributed BMP Assignments by Land Use.

Land Use	*Cisterns*	*Bioretention*	*Perm. Pvmt*	Media Filters
Commercial	0%	0%	30%	50%
Education	20%	30%	0%	0%
Industrial	0%	0%	20%	60%
MF Residential	30%	20%	0%	0%
Transportation	0%	0%	5%	75%
Vacant	0%	0%	0%	0%

Default sizing parameters for each BMP type were not changed; distributed BMPs would be sized to capture and treat the Los Angeles County Standard Urban Storm Water Mitigation Plan (SUSMP) design storm criteria (LACDPW, 2002).

The three regional BMP scenarios (Scenarios 2-4) were an extended detention (ED) basin, hydrodynamic separator (HD separator), or a subsurface flow (SSF wetland). The ED basin and SSF wetland were limited to available space within the City-owned park, but it the hydrodynamic separator was sized to meet a BMP design criteria of 0.2 in/hr (the device can be placed underground and in-line with a major storm drain).

Summary of Results. Table 2 summarizes the total influent volume and the percent captured (reduced or treated) and untreated for each individual BMP. Scenarios 1 and 3 capture the largest total volume of runoff as these BMPs were sized using the SUSMP size criteria and default design assumptions. The ED Basin (Scenario 2) and SSF wetland (Scenario 4) were sized according to the estimated available space for implementation and therefore resulted in much smaller percent captures.

Table 2. Average Annual Percent Reduction, Treated, and Untreated Volumes.

BMPs	*Influent Vol (ac-ft)*	*% Reduced*	*% Treated*	*% Untreated*
Cisterns	10	46%	0%	54%
Bioretention Areas	8.7	52%	0%	48%
Permeable Pvmt	40	88%	0%	12%
Media Filters	106	0%	87%	13%
Total Dist. BMPs (Scenario 1)	164	20%	42%	38%
ED Basin (Scenario 2)	220	0%	30%	70%
HD Separator (Scenario 3)	220	0%	86%	14%
SSF Wetland (Scenario 4)	220	1%	16%	83%

Figure 9 graphically compares the average annual metal load and average storm EMC reductions between the scenarios. As indicated in the figure, Scenarios 1 and 3 produce the highest load reductions for total copper (TCu), total lead (TPb), and total zinc (TZn). However, despite the small percent volume capture for the SSF wetland (18%), it outperforms the HD separator for dissolved metals load reductions and outperforms both the distributed BMPs and the HD separator for dissolved metals concentrations reductions. The SSF wetland also does nearly as well for total metal concentration reduction. The high load reductions for all constituents for the distributed BMP scenario can be largely attributed to the 20% volume reduction.

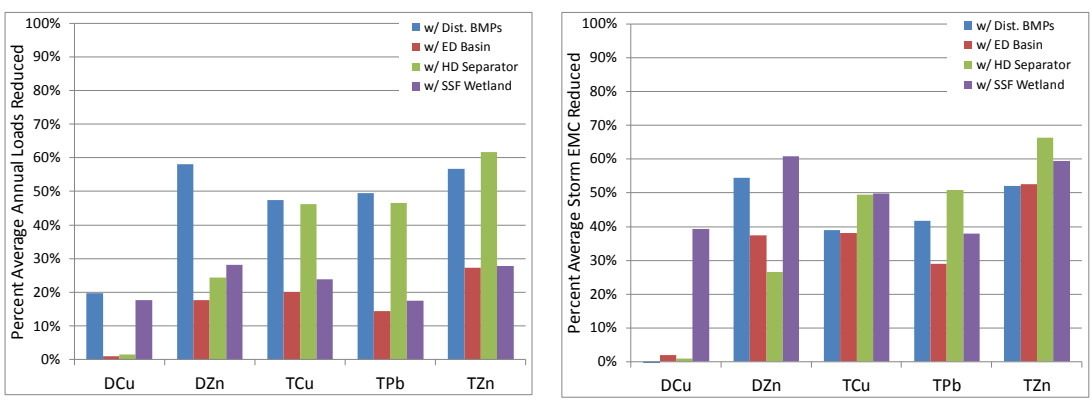

Figure 9. Scenario Comparison of Percent Average Annual Volume and Load Reductions.

In addition to evaluating relative changes in volumes, loads, and concentrations with the implementation of BMPs, a comparison to in-stream numeric water quality objectives was evaluated. The Ballona Creek Metals TMDL (LARWQCB, 2007) lists the wet-weather water quality objectives shown Table 3.

Table 3. Wet-weather Numeric Targets for Ballona Creek.

	Dissolved(µg/L)	*Total Recoverable (µg/L)*
Copper	11	18
Lead	49	59
Zinc	94	119

Table 4 summarizes the storm event exceedance probabilities with and without BMPs for several constituents. As shown in the table, the exceedance probabilities for all total metals are expected to be reduced significantly by the distributed and regional BMP implementation scenarios. Only the SSF wetland is predicted to reduce the exceedance probabilities of dissolved copper or fecal coliform. The distributed BMP scenario and the SSF wetland scenario are predicted to reduce exceedance probabilities of dissolved zinc, but the other two regional BMP scenarios are not predicted to have an effect. Dissolved copper exceedances are expected to increase slightly for the distributed BMP scenario due to volume losses from land uses with lower average dissolved copper EMCs.

Table 4. Storm Event Exceedance Probabilities Before and After BMP Implementation.

Pollutant	*DCu (ug/L)*	*DZn (ug/L)*	*TCu (ug/L)*	*TPb (ug/L)*	*TZn (ug/L)*
Threshold	11	94	14	59	119
Pre-BMP	62%	90%	91%	3%	96%
Dist. BMPs (Scenario 1)	65%	55%	66%	0%	66%
ED Basin (Scenario 2)	62%	90%	64%	1%	58%
HD Separator (Scenario 3)	62%	90%	51%	0%	39%
SSF Wetland (Scenario 4)	24%	38%	46%	1%	46%

SBPAT provides planning level estimates of capital and annual maintenance for each modeled BMP type. Capital costs do not account for engineering, design, or permitting, but a default of 25% is added to all capital and maintenance costs to account for contingencies. Figure 10 compares life-cycle costs for the four modeled scenarios assuming all BMP types have the same life span (30-years) and annual discount rate of 2%. The much higher costs for distributed BMP is due high capital costs for permeable pavements and high annual maintenance costs for media filters.

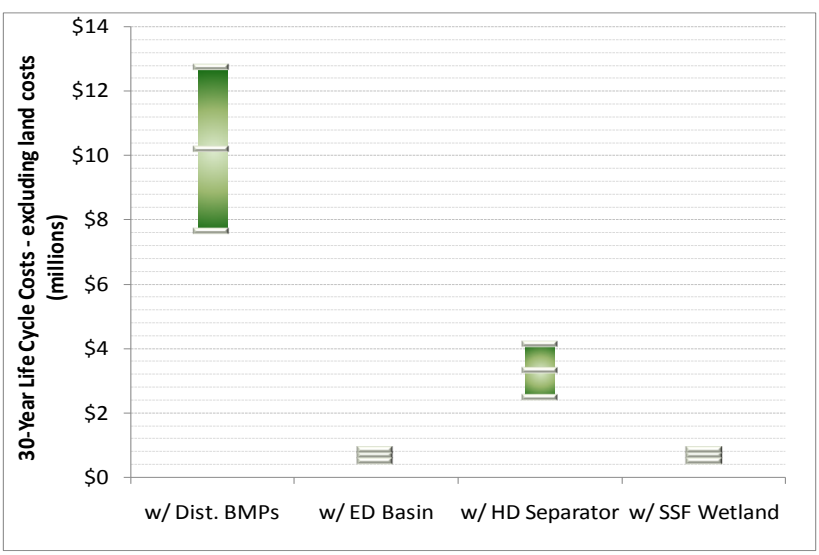

Figure 10. Life-Cycle Cost Comparisons between the Modeled Scenarios.

After several example study areas of various sizes and land use distributions are simulated, it may be possible to extrapolate the results from this site-specific simulation to the larger watershed. Care must be taken not to over-generalize BMP implementation feasibility, especially for regional BMPs where site-specific constraints can be more limiting than for distributed BMPs. Due to the generally small number of regional BMP retrofit opportunities in urbanized watersheds, it may be feasible to evaluate all of these individually. The extrapolation of distributed BMP results is more appropriate since these BMP types are not as dependent on the routing of concentrated flows and it may be possible to generalize BMP implementation based on land use and parcel ownership.

SUMMARY AND CONCLUSIONS

Various methods are available for identifying and prioritizing water quality improvement projects within a watershed. A GIS provides a framework for assimilating many spatial datasets at the watershed scale so that multiple objectives and constraints can be simultaneously considered. The Structural BMP Prioritization Methodology is a transparent, reproducible method for prioritizing BMP retrofit projects at a catchment scale that accounts for both water quality improvement need and BMP implementation opportunities. The Green Solutions Project provides an alternative method that identifies potential opportunities at a subwatershed scale for implementing multi-use, multi-benefit BMPs on public lands and identifies where there is a lack of suitable public lands to address water quality concerns. SBPAT is an ArcGIS™ extension that automates the Prioritization Methodology and allows users to model BMP implementation scenarios within priority catchments. Planning level costs and benefits of the scenarios can then be compared against water quality objectives. Site-specific assessments can be extrapolated across an entire watershed to assist with the development of strategic water quality implementation plans.

ABSTRACT

Infiltration as a Best Management Practice (BMP) is strongly encouraged by many who are focused on water quality, water resources, and regulatory compliance. It is often considered the ideal solution that solves multiple problems. Many practicing engineers, designers, and project approvers however, are concerned about the widespread implementation of infiltration measures, and have initiated restrictive conditions that significantly limit their use. This paper discusses benefits and considerations that should be made when proposing infiltration BMPs, offers potential methods to meet what can be limiting site conditions, and discusses recent applied research/design efforts that been initiated in southern California.

Infiltration has numerous potential benefits, particularly in urbanized watersheds. Infiltration BMPs when implemented properly can lead to a) restoration of natural hydrologic cycles; b) mitigation of the degradation of creeks; c) management of water resources; and d) comprehensive watershed-wide water quality improvement.

There are, however, numerous design considerations that should be evaluated when proposing infiltration BMPs. These include a) soil type/infiltration capacity; b) groundwater;, c) pre-existing contamination; d) design and hydraulic issues; e) long-term issues such as groundwater mounding and ground settlement; f) introduction of geological hazards such as landsliding, soil liquefaction and their impacts; and i) other issues such as mold and waterproofing that may result from the presence of wet soil. While many of these considerations can be fatal flaws, in some cases innovative engineering approaches can be implemented to increase the viability of infiltration, particularly where choice of satisfactory alternatives is limited. This paper explores some of these methods and impacts related to implementation of these methods. In addition, some recently initiated projects that are expected to contribute to the body of knowledge regarding infiltration concerns and opportunities, and are worthy of further examination and tracking are outlined.

INTRODUCTION

Infiltration (through infiltration basins, infiltration trenches, bioretention, and/or drywells) as a Best Management Practice (BMP) is strongly encouraged by many who are focused on water quality and water resources. It is often considered an ideal solution to stormwater quality mitigation that solves multiple problems. Many practicing engineers, designers, and project approvers however, are concerned about the widespread implementation of infiltration measures, and have initiated restrictive conditions that significantly limit their use. This paper discusses benefits and considerations that should be made when proposing infiltration BMPs, offers potential methods to meet what can be limiting site conditions, and discusses recent applied research/design efforts that been initiated in southern California.

Infiltration has numerous potential benefits, particularly in urbanized watersheds. Infiltration BMPs when implemented properly can lead to restoration of natural hydrologic cycles, through the introduction of subsurface and groundwater flows to shallow aquifers would have been effectively sealed off by urbanization. Infiltration contributes to the restoration of natural hydrological cycles and can assist or mitigate the degradation of creeks (hydromodification effect), by reducing the increased volumes, durations, frequencies, and erosive power of post-urban stormwater. Infiltration, in areas where groundwater is a resource, can help encourage integrated water resources practices, and in doing so can support comprehensive watershed-wide water quality improvement. Large scale infiltration practices may assist with infrastructure requirements, potentially reducing required capacities and frequency of use of drainage systems.

The authors have observed that some documented criteria relating to infiltration can be qualitative or oversimplified, and as such, may not provide specific details or may not necessarily providing a consistent factor of safety. The following is a list of some more quantitative design limitations found in various sources (EPA 2004, CASQA 2003, MassDEP 2008, Stormwater Center and others):

- May not be appropriate where spills may occur.
- The maximum contributing area to an individual infiltration practice should generally be less than 5 acres.
- Infiltration basins require a minimum soil infiltration rate of (range varies 0.15 to 0.5) inches/hour, not appropriate at sites with Hydrologic Soil Types C and D.
- If infiltration rates exceed 2.4 inches/hour, then the runoff should be fully treated prior to infiltration to protect groundwater quality.
- Not suitable on fill sites or steep slopes.
- Risk of groundwater contamination in very coarse soils.
- Upstream drainage area must be completely stabilized before construction.
- Provide significant separation distance (2-feet to 10-feet, depending on standard cited) from the bottom of infiltration basin.
- Provide pretreatment.

The authors recommend caution implementing generic criteria/limitations, and present some evaluation considerations that should be examined on a site specific basis. This paper presents a general discussion only, and provides suggestions on analyses that might be appropriate with the confirmation of the project's geotechnical engineers and geologists.

ENGINEERING MITIGATION / DESIGN CONSIDERATIONS

Infiltration BMPs are simple in principle; however, there are a number of key elements that need to be considered in the feasibility and design stages to achieve the desired performance. These elements include the soil and geology, groundwater, pollutant accumulation, and a wide variety of geotechnical considerations that could affect neighboring structures, slopes, and groundwater conditions.

SOIL AND GEOLOGIC CONDITIONS

The critical success factor for infiltration BMPs is the capacity of the soil to convey the storm water. The basic principles governing flow in a porous media was formulated by Henri Darcy. Darcy's law describes a steady-state flow in the form of $Q = kiA$, where k = the hydraulic conductivity, i = gradient (dh/dl) and A = area of flow. As illustrated in Darcy's equation, the capacity for soil to convey water is a function of three basic components hydraulic conductivity, head, and the area available for infiltration. Ideal soil conditions are primarily granular materials consisting of sand, gravel, or a combination. Coarse-grained soil has a greater hydraulic conductivity than fine grained materials (silt and clay) and therefore can convey water more readily. Most storm water infiltration facilities that have failed are the result of poor or marginal soil conditions that are inconsistent with infiltration demand. Soil having a hydraulic conductivity greater than approximately 1×10^{-3} cm/s is generally considered to be excellent for infiltration. Hydraulic conductivity between 1×10^{-3} and 5×10^{-4} cm/s are good, and below 5×10^{-4} cm/s are marginal.

Marginal soils have a much higher propensity to clog from sediment accumulation and biofouling. Regardless of the soil conditions, reductions in flow capacity due to clogging is addressed by lowering the design hydraulic conductivity by a half or full-order of magnitude. Infiltration characteristics can be maintained over the long-term by adequate pre-treatment, such as fore bays or basins, to remove trash, sand, and silt sized particles that could restrict the flow of water into the soil.

A thorough geotechnical field exploration program should be performed to evaluate the soil and geologic conditions. The investigation should include soil borings to permit direct observation and sampling of the soil. Cone Penetration Test (CPT) soundings will provide detailed stratification and an indirect indication of density, hydraulic conductivity, and material type, but should not be used without conventional soil sampling. Groundwater observation or vadose zone monitoring probes installed in the borings provides a means to perform the in-situ testing of hydraulic conductivity and observation of groundwater elevations. The groundwater surface elevation should be monitored over a wet season to understand the seasonal fluctuations. The grain-size distribution and density are the two soil parameters that

indicate whether the planned site is appropriate for infiltration. Of greatest importance is the presence of fine-grained materials such as silt and clay, as small fraction of these materials can result in a substantial reduction in permeability. For example, the addition of just two percent of minus #100 standard US sieve material can reduce the hydraulic conductivity of the sand by one or two orders of magnitude (Cedergren, 1989).

In addition to identifying the subsurface stratigraphy, the investigation must include an evaluation of the permeability in the vadose zone. One of the greatest shortcomings of vadoze zone permeability testing is the attempt to measure saturated hydraulic conductivity of unsaturated materials. Saturated conductivities are generally lower than their unsaturated counterparts. Generally, an evaluation of the in-situ hydraulic conductivity for free-draining soil requires ground saturation. As such, a large volume, constant-head test such as USBR Test Method 7300-89, is likely to yield results that are more representative of conditions that the infiltration facility will experience during operation (USBR, 1990). The standard of practice is to measure the hydraulic conductivity using in-situ methods rather than laboratory testing. Urbonas and Sathre (1993) suggest that at least three measurements of in-situ hydraulic conductivity be made both within and down gradient of the infiltration area. The hydraulic conductivity selected for design is sometimes selected as the lowest recorded measurement, or as the values that are most representative of the proposed infiltration zone characteristics. Hydraulic conductivity may also be tested in geotechnical laboratory, but this testing should not substitute for the high-volume in-situ measurements.

DESIGN CONSIDERATIONS

Marginal sites

If a site is underlain at depth by fine grained soil, then infiltration should not be considered. Typically sedimentary materials are horizontally stratified as materials have been sorted naturally according to the depositional energy. This sorting often results in near horizontal beds of sand, silt, or clay, of variable lateral extent. So, it is possible to have a site that has clays near the ground surface, but sand or granular materials at a greater depth. In these cases, if a hydraulic connection is made between the two strata, then it is possible to direct the storm water to a zone that is more conducive for infiltration. Engineering controls such as large-diameter gravel-filled borings can be placed in the bottom of the basin to provide the hydraulic link to the deeper highly permeable soil.

Aside from the soil conditions, there are urbanized settings that may be inappropriate for infiltration. Heavy industrial sites may have constituents that would be problematic if introduced into the soil and groundwater. It is absolutely imperative that the designer understand the groundwater basin plans and the constituents in the industrial storm water effluent, so that the infiltrated storm water is consistent with the basin plan.

Groundwater

As previously mentioned, many infiltration BMPs have failed by attempting to force infiltration in sites having marginal hydraulic conductivity. The presence of shallow groundwater has also caused basins to fail through a reduction in transmissitivity due to groundwater mounding. Mounding occurs when the volume of water entering the basin is too great to be timely conveyed away from the basin through the soil. In general, the infiltration capacity increases as the separation from groundwater increases. There are numerous literature guidance documents that provide hydraulic, soil, and performance criteria. For example, the recommended minimum separation from groundwater ranges from 2 to 10 feet, (EPA, 2004). In some cases these minimum amounts may be insufficient to infiltrate the desired flow volume, particularly if the soil has marginal infiltration characteristics. The recent Water Augmentation Study in the Los Angeles Basin (LASGRWC) (Los Angeles and San Gabriel Rivers Watershed Council, 2005), indicated that the separation guidelines are not only based on the physical ability for water to move through the soil, but also to allow time for sufficient biological activity before reaching groundwater.

Unfortunately, the greatest infiltration capacity is needed during the wet season, when groundwater is often at its highest levels. For this reason, it is important to understand the sequence of storm events that the infiltration BMP will be required to accommodate. Steady-state seepage analyses may be appropriate for small-footprint, low volume infiltration BMPs. Larger, high-volume BMPs will likely require transient modeling to understand the complex behavior of unsaturated / saturated, time dependent scenarios. Using these models, the designer can model the anticipated storm water impulse flow and its gradual infiltration into the soil. These models also allow for a long-term evaluation of ground water mounding and can identify the seasonal decay in the ground water mound at the infiltration point and at selected distances away from the infiltration point. Understanding the lateral development of a groundwater mound is helpful in the geotechnical analyses of potential collateral impacts (e.g., settlement, expansion, and/or soil liquefaction). An example of a transient analysis for a large infiltration facility is presented in Figure 1. This example depicts the seasonal rise and fall of the groundwater mound at various distances from the center of the infiltration facility over a 10-year time-frame and the corresponding storm water inflows.

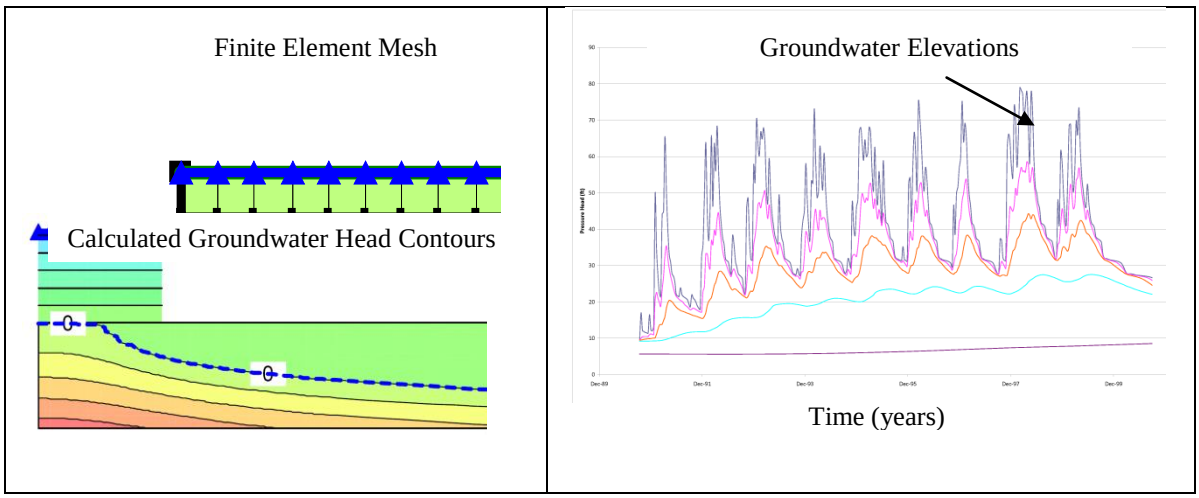

FIGURE 1. A) FINITE ELEMENT MESH AND CALCULATED PRESSURE HEAD CONTOURS DURING INFILTRATION; B) PLOT ILLUSTRATING GROUNDWATER MOUND DEVELOPMENT OVER A 10 YEAR PERIOD.

Modeling the development of groundwater mounding also provides an indication of where the infiltration water will migrate and to what extent the vadose zone will become saturated. These changes not only have geotechnical implications, but also may affect existing pollutant plumes in groundwater or mobilize constituents in the vadose zone. During the basin feasibility stage, it is important to identify known release areas near the infiltration facility.

VOLUME OF WATER/MODELED RAINFALL

The volume of water to be infiltrated is governed by the design storm event and the tributary area. This event may be regulatory driven or may be derived from a hydrological / statistical evaluation of historical precipitation to arrive at a "capture" ratio. The 90th percentile year is commonly utilized for the basis of design. In the example presented above, hydrological records were available for many decades, and the decade of the 1990s represented the 90th percentile decade in this example. An appropriate capture ratio is dependent upon a large number of factors such as watershed area, constituents of concern and their variation in concentrations throughout the wet season, receiving waters, groundwater basin plans, or on regulatory mandated reductions in constituent concentrations.

Where infiltration BMPs are proposed as subregional facilities, the tributary area can be 10 to over 100 times the infiltration area. This results in a significant concentration of flow, well above natural infiltrative conditions.

POLLUTANT ACCUMULATION

One consideration for infiltration as a stormwater BMP is the quality of the influent. While pre-treatment is a design requirement, it often is focused on the removal of gross solids and sediment to prevent clogging. Table 1, below presents an analysis of potential pollutant accumulation loading rates calculated for a hypothetical site in

Southern California. Key constituents in this hypothetical example are analyzed per land use (e.g., copper for transportation land use), and accumulation rates are compared to various disposal thresholds. Figure 2 illustrates that, based on the typical event mean concentrations and land uses, regular maintenance can help avoid significant pollutant accumulation, but that even with some deferred maintenance, under normal circumstances high concentration levels may accumulate for a number of years before becoming problematic.

Example Mass Balance: Metal Accumulation in Bioretention BMPs

Input	Copper	Lead	Zinc	Cadmium
Land Use with Highest Concentration	Transportation	High Density Single Family Residential	Light Industrial	Transportation / Commercial
Rate of Accumulation in Media, R_{accum}, mg/kg/yr	**4.2**	**0.59**	**40**	**0.054**
Human Health Thresholds[5], mg/kg	3,000	150	23,000	1.7 (Res) 7.5 (Com/Ind)
Time to Human Health Thresholds, years	**709**	**256**	**579**	**31 (Res)** **139 (Com/Ind)**
TTLC, mg/kg	2,500	1,000	5,000	100
Time to TTLC, mg/kg	**590**	**1706**	**126**	**1842**

FIGURE 2. EXAMPLE (SOUTHERN CALIFORNIA) OF POLLUTANT ACCUMULATION VS. VARIOUS THRESHOLDS

GEOTECHNICAL CONSTRAINTS OF INFILTRATION

General

The introduction of surface water into the ground through infiltration can result in a variety of issues related to characteristics of certain deposits, such as settlement through collapsible soil, expansive soil movement, slope instability, and increased soil liquefaction potential. However, in most deposits, these issues are, constrained to relative proximity of the infiltration facility and hence readily identifiable and mitigated.

In order to mitigate infiltration impacts, a geotechnical investigation should be performed prior to (preferably conceptual) design of the infiltration facility. Potential geotechnical issues due to infiltration should be considered along with other relevant issues affecting the design and, if necessary, design should be enhanced and/or modified.

Relevant, infiltration-induced geotechnical issues and related evaluation requirements are discussed in the balance of this section. Mitigation measures are just hinted as numerous possibilities exist, yet their implementation is dictated by the size and importance of the project, severity of impact, and many other parameters that are beyond the scope of this paper.

Slope Stability

Stability of native and man-made slopes near the infiltration facility can be affected even by a temporary rise in groundwater elevations and/or by change in groundwater flow direction. Therefore, geotechnical investigation coupled with a groundwater mounding analysis should be performed to assess changed conditions within and around the infiltration facility. If significant change in groundwater elevations is evaluated and/or downslope groundwater flow is anticipated, formal slope stability evaluation is required. This evaluation may trigger supplemental geotechnical investigation to better define slope stratification, saturation, and material properties. Mitigation measures, if any, will depend on the continuation and duration of the elevated groundwater levels, assessed potential for concurrence of infiltration and seasonal increases in groundwater regime, and slope face inclination, keying and drainage, to name a few.

Soil Liquefaction and its Impacts

Soil liquefaction is a phenomenon in which loose to medium dense, saturated granular materials partially or entirely lose its strength when subjected to ground shaking. Soil liquefaction may also occur in fine-grained materials such as some low-plasticity silts and clays and can affect deposits in excess of 100 ft. Partial or complete loss of soil strength due to liquefaction can have a range of consequences on buildings and their foundations, but also on slopes and even on nearly-level ground. Severe consequences of soil liquefaction, commonly referred as the soil liquefaction impacts, include liquefaction-induced total and differential settlements, cracking of ground surface, lateral spreading of mild to nearly-horizontal slopes, soil liquefaction-induced downdrag on pile foundations, and impact of liquefied soils on shape of acceleration response spectra used for structural design.

Storm water infiltration may cause increase of ground water elevation and hence, indirectly, in increased soil liquefaction potential in not only infiltration-saturated layers, but also in layers below. Therefore, a groundwater mounding analysis should be conducted along with assessment of the duration of mounding. The assessment of duration is especially important as it is not likely that the maximum (design) earthquake coincides with the highest mounding that may exist only briefly during rainy season. If long-term impacts of stormwater infiltration are found likely, mitigation of increased soil liquefaction potential and impacts should be considered.

Expansive Soils

Expansive soil is generally defined as soil or rock material that has a potential for shrinking or swelling under changing moisture conditions. These soils, commonly present in coastal areas, typically contain clay minerals that expand in volume when water is introduced and shrink when the water is removed or the material is dried. When expansive soil is present near the ground surface, even a temporary change in moisture conditions from either direct infiltration or indirectly from rise in groundwater elevation cause these soils to swell. Conversely, as soils dry or the

groundwater surface falls after infiltration, these soils will shrink in response to the loss of moisture in its structure.

The effects of expansive soil movement (swelling and shrinking) is typically greatest near ground surface and affects near surface structures such as shallow foundations, roadways, rail lines, and concrete pavements. Basements or below-grade parking structures can also be effected as additional loads are applied to the basement walls from potentially large swelling pressure generated by soil expansion. The geotechnical investigation should identify if these materials are present near the proposed infiltration facility, and if so, geotechnical engineers should evaluate soil expansion potential on a site-specific basis and assess if the surface water infiltration will, through shrinkage and swelling cycles, induced damage to nearby and/or planned structures.

Collapsible Soils

Typically, collapsible soils are most commonly observed in sediments that are loosely deposited, separated by coatings or particles of clay or carbonate. When saturated, these soils may collapse and thus induce damage to foundations, structures and slopes.

Infiltration of stormwater may result in a temporary flooding of collapsible soils. Similarly, even temporary rise in groundwater elevations could change the soil structure by dissolving or deteriorating the intergranular contacts between particles of certain soils, resulting in a sudden collapse referred to as "hydrocollapse." This hydrocollapse phenomenon generally occurs during the first saturation episode of natural deposits, i.e., repeated cycles of saturation are not likely to result in additional collapse. The magnitude of hydrocollapse is proportional to the thickness of the soil column where infiltration is occurring.

It is important to evaluate the hydrocollapse potential of soils during the geotechnical investigation. However, in many cases, this is difficult, if possible task. Luckily, at most instances, the magnitude of hydrocollapse is small and hence not likely to cause significant damage at the ground surface. When hydrocollapse is suspected, but not demonstrated, network of surface settlement monuments is typically installed around the infiltration site, adjacent roadways, and in the neighboring developments. These monuments are typically monitored prior to completion of infiltration facility, after the first infiltration event, and periodically thereafter. If settlement-sensitive structures are present at or in the vicinity of the site, mitigation measures may be required.

SUMMARY

Both the benefits and considerations of infiltration BMPs have been presented. Infiltration has numerous potential benefits, particularly in urbanized watersheds. The locations of these urban BMPs often require numerous design considerations that need to be evaluated when proposing infiltration BMPs. These considerations may identify fatal flaws or may require the necessity for innovative engineering solutions,

particularly where choice of satisfactory alternatives is limited. Current advancements on projects in southern California have identified the need for more careful examination of the design approach and considerations of the BMP impacts on existing structures

ABSTRACT

Bioretention cell are gaining popularity as a stormwater best management practice (BMP). This can be largely attributed to the fact that they present a broad range of potential benefits such as decreased runoff, thermal attenuation, aesthetics and improved water quality through various physical, chemical and biological processes. Ten prototype cells were constructed in Oklahoma as part of an ongoing demonstration project. The cells ranged in size from 19 m^3 to 435 m^3, and the filter media incorporated fly ash to enhance phosphorus and heavy metal retention. Eight of the cells were installed in Grove, Oklahoma by a contractor, while the other two were constructed in Stillwater by the authors. This paper discusses engineering considerations, general design procedures, cell specifications, construction costs and issues that arose during construction.

INTRODUCTION

Non-point source pollution from urban runoff is a major concern in many watersheds. Nutrients, heavy metals, and organic chemicals and pathogens contained in non-point source pollution, while at low concentrations, negatively impact water quality due to the large volumes and widespread nature of flow. Bioretention cells (BRC) are gaining popularity as a stormwater BMP and are in essence "functional landscaping." They are landscaped areas that treat storm water runoff and present a broad range of potential benefits including decreased runoff; improved water quality through various physical, chemical, and biological processes; thermal attenuation; and aesthetics for a limited drainage area (Hunt and White, 2001).

Ten BRC have been constructed in Oklahoma, in a variety of land use settings, as part of an ongoing study to demonstrate the effectiveness of this technology. Eight are located in Grove, and two are located in Stillwater. Of the ten cells, two are residential properties, six are public or municipal properties, and two are commercial properties.

This paper provides an overview of the engineering considerations, general design procedures, site parameters, construction specifications, construction costs, lessons learned during construction, and initial water quality analysis.

CELL DESIGN

In general, the designs for this project are consistent with the BRC guidelines set by Prince George's County (2002), Hunt, et al (2001 and 2005), and the LID Center (2003). Figure 1 depicts a typical section of the BRC design for this project. Variations from the references cited include a 1:1 side slope for improved safety during construction, sand plugs for adequate infiltration through the top soil layer, the addition of a blend of sand and fly ash as a filter medium, and vegetation criteria suitable for eastern Oklahoma. Construction for this project was formally bid through the Oklahoma Department of Central Services, requiring a complete Plans, Specifications, and Estimate (PS&E) package.

It was arbitrarily decided that the cell would catch the first ½ inch of runoff from any storm event in the designated ponding area. There is an expectation that the majority of the pollutants will be present in that first flush. However, there is little supporting data for that assumption. Given the drainage area from the site survey, the volume of the first flush, V_R (ft^3) is,

$$V_R = \frac{0.5}{12} A_D$$

The filter layer consisted of a blend of sand and 5 percent fly ash by weight. As with the ponding area, the water storage volume of the filter was arbitrarily set to equal ½ inch of runoff from the drainage area. The volume of this layer, V_F (ft^3), is based on a porosity, φ, of 0.30.

One cell was constructed with a biozone. The biozone was designated as an anaerobic layer within the BRC to encourage denitrification. An inverted siphon was used to create the anaerobic condition by increasing the amount of head necessary for water to leave the system, thereby maintaining a constant saturated zone. This layer consisted of sand with a specification to contain no more than 5 percent fines. The volume of the biozone was again arbitrarily set to accommodate ½ inch of runoff

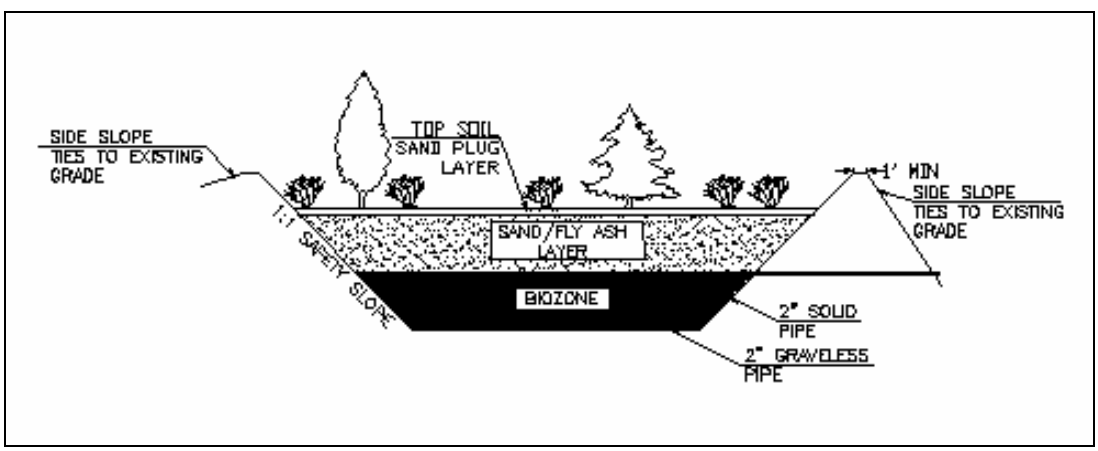

Figure 1. Bioretention cell typical section

from the drainage area. Volume and depth of this layer were calculated based on a porosity of 0.39, which is a typical value for a clean, uniform sand (Holtz and Kovacs, 1981).

Inlet channel dimensions were calculated using a combination of the rational method for surface flow and Manning's equation. An overflow bypass was designed as a broad-crested weir on the back end of the cell.

The topsoil available in Grove, Oklahoma is a silty loam, with a hydraulic conductivity much less than 1 in/hr. The Stillwater site had a deep clay loam. Even blending equal parts sand and topsoil did not provide adequate hydraulic conductivity to ensure infiltration into the filter layer. Sand plugs were introduced as a solution for increased infiltration into the cell, and were designed for ease of construction. Sand plugs were randomly placed, such that no two plugs touch each other, as shown in Figure 2 below.

Since BRC are usually in landscaped areas, plantings should be aesthetically pleasing. With that requirement in mind, the horticultural planting list was developed using the following criteria: plants had to be wet and dry tolerant, not N fixers, noninvasive species, low-maintenance requirements, offer color variety, plants had to be easily attainable and replaceable, and include trees, shrubs, flowering perennials, ornamental grasses, and rock accents. A conscious effort was made to include native species in the cell vegetation. To maintain landscaping aesthetics and to help retain moisture for the vegetation, a 2 inch hardwood mulch layer was applied over the top soil / sand plug layer after planting the vegetation. Hardwood was used to minimize mulch floating out of the cell.

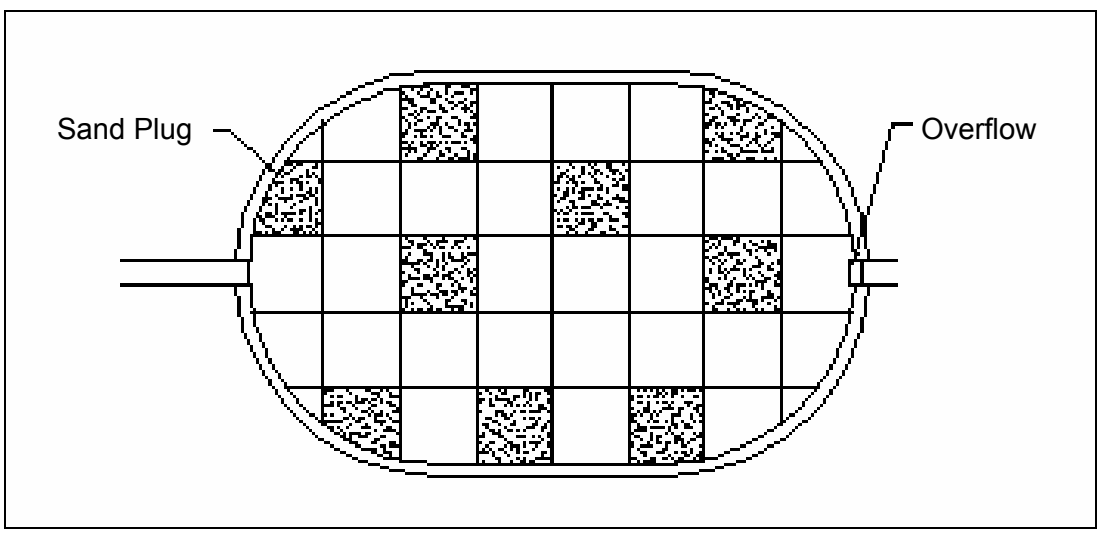

Figure 2. Example of sand plug layout.

FILTER MEDIA SELECTION

Phosphorus removal in BRC has been highly variable in previous research (Hsieh and Davis, 2003; Hunt, 2003). As phosphorus is a contaminant of concern in the Grand Lake watershed, it was necessary to find a means to improve phosphorus removal in BRC. Zhang. (2006) conducted a series of experiments to find a cost effective filter medium with both a high phosphorus sorption capacity and an

adequate hydraulic conductivity to improve the removal of phosphorus in BRC, and concluded Class C fly ash was suitable.

Sorption isotherms and desorption experiments were conducted to characterize phosphorus sorption and desorption of Dougherty sand and various mixtures with fly ash. The fly ash exhibited a high phosphorus sorption predominantly due to calcium phosphate precipitation. With the addition of 5% fly ash, the distribution coefficient, K_d, of Dougherty sand was elevated from 2.08 mL/g to 398 mL/g (5.77 to 1100 in^3/lb), and phosphorus removal increased from 9.4% to 94.2%. Desorption results indicated that Dougherty sand released a large amount of phosphorus, averaging 42% of the initially sorbed phosphorus. However, Dougherty sand with 5% fly ash released negligible amounts of phosphorus, even when the initial phosphorus concentrations were increased. The end result of the study was that, in a hypothetical scenario, the sand/fly ash infiltration layer provides satisfactory phosphorus removal over a long period and enhances phosphorus retention significantly.

The infiltration capacity of filter media is an important parameter for BRC. It is not recommended to leave water in the ponding area of BRC for longer than four days because it restricts the use of water-intolerant plants and encourages the breeding of mosquitoes and other insects (USEPA, 1999). PGDER (2002) recommends that the infiltration rate should be greater than 2.54 cm/hr (1 in/hr) in a BRC intended for runoff infiltration. The infiltration rate may be directly calculated with the hydraulic conductivity by Darcy's law and the hydraulic gradient. In the limiting case of a saturated medium with no ponding, the hydraulic gradient is equal to one, and the infiltration rate is equal to the hydraulic conductivity. Hunt (2003) suggested that the desired range of hydraulic conductivity in BRC is 1.26 cm/hr to 5.04 cm/hr (0.5 to 2.0 in/hr). However, the hydraulic conductivity requirement depends on the BRC design.

A falling head permeameter (McWhorter and Sunada, 1977) was used to determine the saturated hydraulic conductivity (K_s) of Dougherty sand (Thermic Arenic Haplustalf), and the mixtures of the sand with various levels of fly ash. The hydraulic conductivity (K_s) of Dougherty sand was 34 cm/hr (13 in/hr). Fly ash had an extremely low hydraulic conductivity, which could not be measured by the procedure used. The hydraulic conductivity of Dougherty sand and its mixtures with various levels of fly ash are presented in Figure 3. The hydraulic conductivity dropped exponentially with increasing fly ash content. To keep the hydraulic conductivity of amended soils higher than 2.54 cm/hr (1 in/hr), the incorporation rate of fly ash should be less than 6% calculated from the exponential relationship (Figure 3).

Due to the pozzolanic nature of fly ash and hydration reactions, the hydraulic conductivity of the sand/fly ash mixtures may decrease with an extended saturation period. To assess the effect of saturation period on the hydraulic conductivity of the sand/fly ash mixtures, Dougherty sand, D+2.5%F, and D+5%F were kept in saturation in the testing columns for 28 days and the hydraulic conductivity measured periodically. Dougherty sand was examined for comparison in this case.

The change of hydraulic conductivity over the extended saturation period for Dougherty sand, D+2.5%F, and D+5%F is shown in Figure 4. The trends were

different for Dougherty sand and the sand/fly ash mixtures. Hydraulic conductivity of Dougherty sand dropped slightly first, and then recovered to the previous level. This behavior was probably due to movement of the fines through the column. However, the hydraulic conductivity of D+2.5%F and D+5%F decreased rapidly during the first 24 hours, and then stabilized after 14 days. Because of the pozzolanic

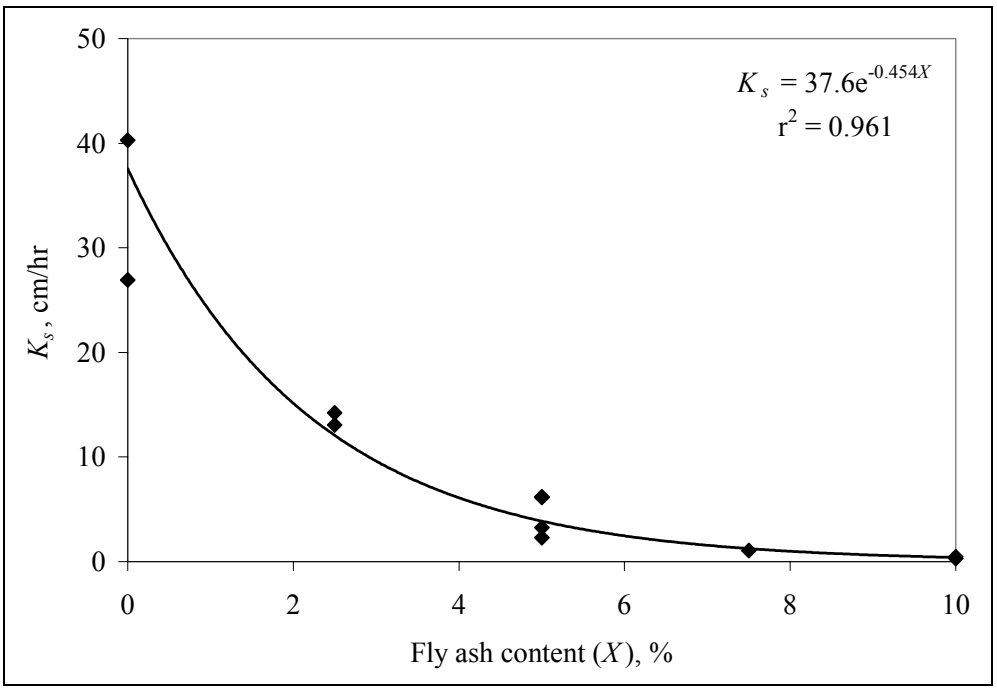

Figure 3. Effect of the fly ash addition on hydraulic conductivity of Dougherty sand.

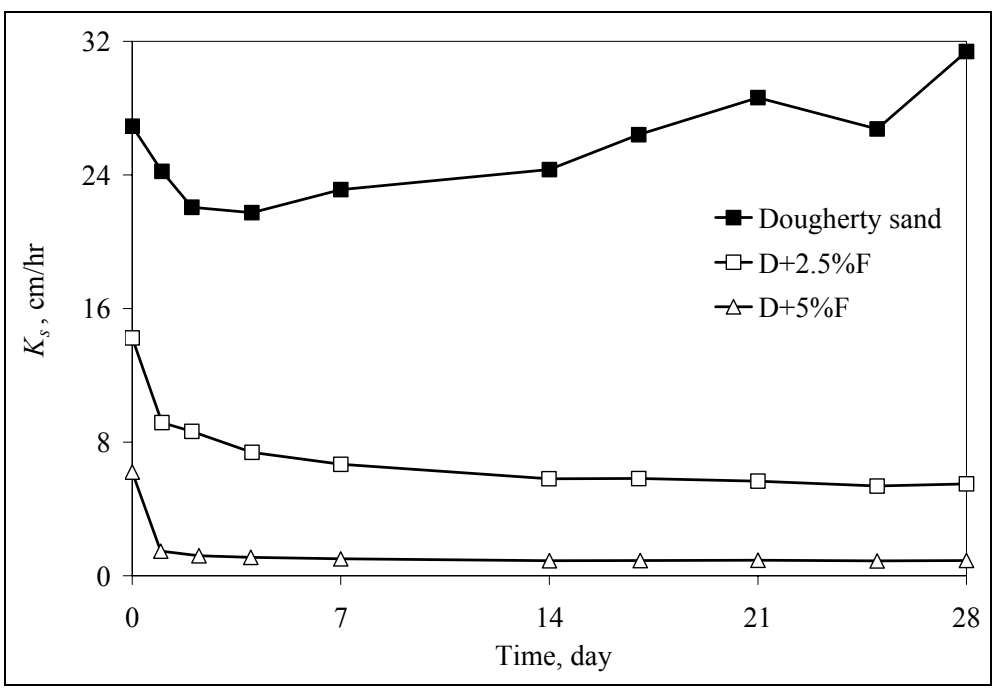

Figure 4. Effect of extended saturation period on saturated hydraulic conductivity of Dougherty sand, D+2.5%F, and D+5%F.

reactions that occurred in the water-saturated sand/fly ash mixtures, the permeability of D+2.5%F and D+5%F was decreased. The stabilization of hydraulic conductivity after 14 days indicated the end of the pozzolanic reactions. At the end of the 28-day experiments, the hydraulic conductivity of D+2.5%F and D+5%F was 5.50 cm/hr and 0.91 cm/hr (2.2 and 0.36 in/hr). This characteristic of the sand/fly ash mixtures implies that their 4-day or 7-day hydraulic conductivity should be evaluated to ensure the adequate infiltration. With the final hydraulic conductivity of 0.91 cm/hr (0.36 in/hr), D+5%F still possesses an adequate hydraulic conductivity to drain 30 cm (1 ft) ponding water within 33 hours.

Installation of the filter medium consisted of 6 inch lifts to keep the mixture as consistent as possible and to prevent preferential flow through this layer of the BRC. The sand specified in the design was a clean sand with less than 5% fines. Fly ash utilized was Class C, obtained from the Chouteau power plant for the Grove sites and from the Sooner power plant for the Stillwater site.

Combining the sand and the fly ash in the field was accomplished in two ways. The first method involved mixing with heavy equipment before placement in the cell. A load of sand was deposited near the cell site and the appropriate amount of fly ash was then mixed into the sand by repeatedly filling the bucket of a front end loader and pouring it back over the pile containing the sand and fly ash, until an even blend was achieved. The second method entailed using a roto-tiller to mix media in lifts inside the cell. A 6 inch lift of sand was placed into the cell. The appropriate amount of fly ash was then evenly distributed on top and tilled into the sand.

CONSTRUCTION COSTS

Sites were chosen based on grade, location, drainage area, visibility, and access. Of the sites chosen, two are commercial properties, two are residential, and six are public. Land use includes both paved and grass. There is one site where the paved surface and the grass surface are approximately equal and one where the runoff is intercepted primarily from a roof surface. Drainage areas vary from 0.11 acre to 1.90 acres, with all but one being less than one acre.

The first eight sites listed in Table 1 were constructed by a contractor selected through a formal state bidding process. All eight sites are located in Grove, Oklahoma. Cost was bid on a volume basis and includes mulch but not vegetation. Cell cost ranged from $7,368 at the Clark residence, which is the second smallest cell with a volume of 27 m^3 (35 yd^3), to $29,172 at the Grand Lake Association, which had a volume of 435 m^3 (569 yd^3). The cell at Lendonwood Gardens was the smallest, but cost more to construct because of site conditions requiring tree removal and traffic control.

The two BRC (Cell A and Cell B) constructed at the Oklahoma State University Botanical Gardens in Stillwater, Oklahoma are also listed in Table 1. These cells were constructed primarily “in house.” Excavation was professionally contracted, though not through a bidding process as were the cells listed in Table 1. Final costs for both Cell A and Cell B were $4,753 and $11,479, respectively.

Table 1. Bioretention cell area, volume and cost as constructed by a contractor in Grove, Oklahoma and by Oklahoma State University in Stillwater, Oklahoma

Location	Drainage Area (Acres)	Land Use	Area (m^2)	Volume (m^3)	Final Cost
Elm Creek Plaza 36°34'47" N, 94°46'08"W	0.62	Paved	63	128	$12,496
Lendonwood Gardens 36°34'59" N, 94°47'13"W	0.54	Turf	23	19	$8,847
Grove High School 36°37'19" N, 94°44'50"W	0.65	Paved	149	161	$17,071
Grand Lake Association 36°36'39" N, 94°48'14"W	1.90	Paved/Turf	172	435	$29,173
Cherokee Queen Riverboats 36°38'05" N, 94°48'54"W	0.45	Paved	116	108	$13,796
Early Childhood Development Center 36°35'12" N, 94°46'57"W	0.11	Paved (Roof only)	48	70	$10,715
Spicer Residence 36°38'59" N, 94°46'08"W	0.39	Turf	101	93	$13,271
Clark Residence 36°35'18" N, 94°49'36"W	0.18	Turf	30	27	$7368
Cell A 36°07'00" N, 97°06'01"W	0.32	Paved	28	66	$4,753
Cell B 36°07'01" N, 97°06'01"W	0.90	Paved	160	208	$11,479

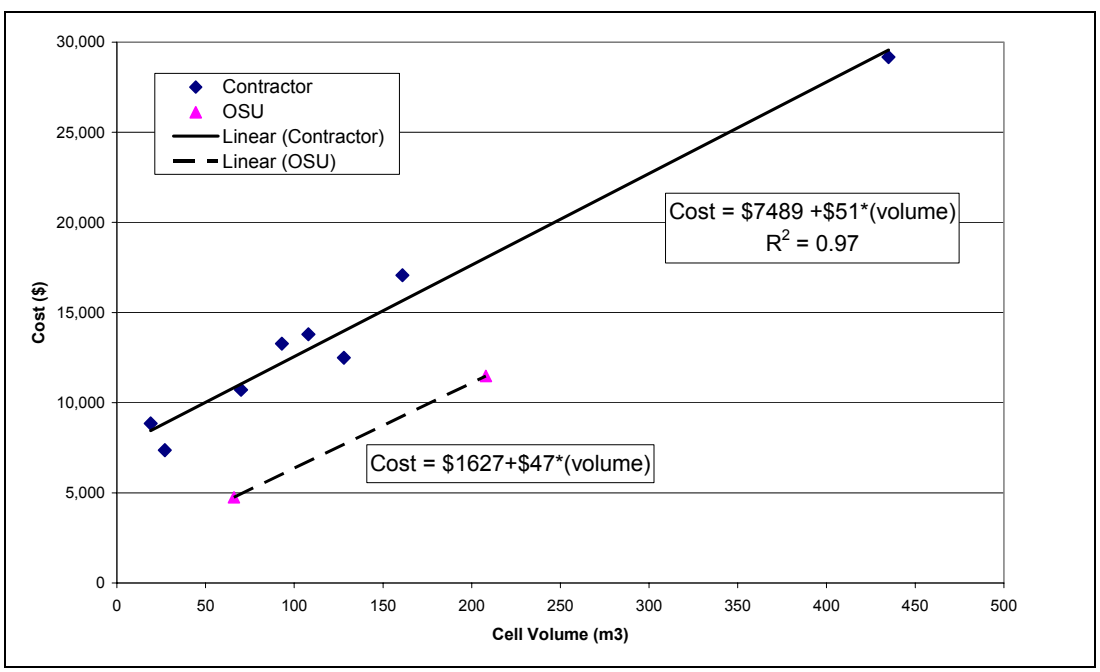

Figure 5. Comparison of Bioretention Cell costs; contractor versus OSU constructed cells

A linear regression equation was fit to cell cost as a function of volume for both contractor and in-house constructed cells in Figure 5. There is a difference of approximately $6,000 between contractor and in-house construction costs for cells of comparable sizes. However, the price difference may decrease as BRC technology becomes more common in the region and contractors learn more about what cell construction entails. Competition may also contribute to a decrease in the cost of contractor constructed projects.

MONITORING

Monitoring of the cells in Stillwater began in July 2008. Cell B is divided into two hydraulically separate regions. One region contains the sand/ fly ash media blend for the filter layer, and the second contains only sand in the filter layer. This was done in an effort to observe the effectiveness of the fly ash in a quantifiable manner.

Nitrate and phosphorus contents were measured in the effluent of the cell, as exhibited in Table 2. Effluent pH values were lower for the sand only side of Cell B than for the fly ash side. Alkalinity was lower in the effluent samples taken from the fly ash side of Cell B, than for the sand only side of Cell B. NO_3-N was lower in the effluent collected from the sand only side of Cell B. However, Ortho-P content measured in the effluent from the fly ash side of Cell B were lower than that measured in the effluent from the sand only side of the same cell.

Metal contents were also measured in the effluents as listed in Table 2. Marked differences are visible in the Fe contents when comparing both sides of Cell B. The effluent from the fly ash side of Cell B had lower Fe contents, ranging from 0.06 ppm to 0.19 ppm, than the sand only side which had contents ranging from 0.10 ppm to 5.81 ppm.

Table 2. Effluent pH, nutrients, alkalinity, and metal content by cell.

Cell	Sample #	pH	NO3_N (ppm)	Alkalinity (ppm)	Ortho - P	Fe (ppm)	Cu (ppm)	Pb (ppm)
Cell B-South - No Fly Ash	2	7.9	4.53	226	0.16	0.10	<.02	<.02
	5	8.1	3.61	223	0.1	0.13	<.02	<.02
	7	8.1	3.88	263	0.18	0.35	0.03	<.02
	10	7.6	6.78	342	0.13	0.44	<.02	<.02
	12	7.3	6.6	365	0.14	0.11	<.02	<.02
	15	7.3	0.71	206	0.06	5.77	<.02	<.02
	18	7.5	0.51	219	0.07	5.60	<.02	<.02
	21	6.8	0.93	190	0.08	5.81	<.02	<.02
Cell B-North - Fly Ash	1	10.4	3.59	158	0.07	0.06	0.03	<.02
	4	9.7	2.85	92	0.07	0.13	0.02	0.05

	14	9.3	8.73	106	0.05	0.14	0.02	<.02
	17	9.3	8.73	106	0.06	0.08	0.02	<.02
	20	10	8.68	148	0.06	0.13	0.02	<.02

LESSONS LEARNED

Overall, the design process translated well to the construction of the BRC for this project. However, lessons were learned in the field.

Mixing fly ash in the field presented a challenge and was approached using the two previously described methods. The challenge arose in ensuring an adequately mixed medium on such a large scale, and neither method was considered adequate Samples were taken during placement and the variability is being quantified now and will be reported at a later date.

Fly ash storage is an issue that needs to be addressed. During the construction phase of this project, Oklahoma experienced significant rain. Fly ash exhibits pozzolanic characteristics when exposed to even small amounts of moisture. Clots of fly ash are formed and it is difficult to sift through the large quantities of fly ash to effectively remove them. This poses many issues of concern such as effective sorption capacity, preferential flow within a non-uniform medium, and achieving an even blend of sand and fly ash. The contractor stored the fly ash underground in a pit and covered it with a tarp. A similar method was used for short term storage at the Stillwater site. Under typical climate conditions this would be appropriate. However, a better solution would be to store the fly ash in weather proof/resistant vessel such as a trailer.

Another point of interest is to observe the differences in capabilities and costs when comparing construction by a contractor versus construction in-house. On average, the contractor was able to complete a cell within four days, with three people, a backhoe and a bobcat. The cells constructed by OSU averaged six days, using five people, two tractors, a dingo, and a roto-tiller. Most of the additional time required for the in-house construction was during the backfilling process. The contractor was able to use heavy equipment with a greater capacity for moving soil than the process employed by the in-house team, which relied more on man-power and smaller, more readily available equipment. It costs approximately $6,000 more to have a contractor build a cell. However, it takes half the time and considerably less man power and equipment. Differences in cost and labor are attributed to the issues surrounding man versus machine and in-house versus contractor labor.

There were two cell failures. The first was at Elm Creek Plaza, where the cell receives runoff from a parking lot and sits on a stream bank. Berm failure occurred due to fugitive water from a neighboring property during a 50 year storm, providing roughly twice the design flow. The flow destroyed the overflow weir that was poorly placed on the streambank. The cell was repaired and reinforced, and the overflow was moved to a different location to alleviate the possibility of a repeated failure. The property owner also had the channel between the two properties cleaned out and deepened. One positive outcome is that immediate benefits with regard to erosion have been observed at this site. During construction it was necessary to rebuild the bank as it had eroded substantially in the time between the design and construction phases, and the cell would not have fit as designed.

The second failure was at the Spicer residence. The cell is located near the lakefront, above the GRDA takeline and the U.S. Army Corps of Engineer's regulation line. Excessive rains after a long period of drought have caused the lake to rise to unusually high elevations. The shore effects at the high lake elevations

caused erosion of the cell berm. Repairs commenced once the water receded. The berm was repaired and reinforced. High water levels around the lake area also delayed construction and submerged the Cherokee Queen cell, but caused no significant damage.

CONCLUSION

The constructed cells appear to be operating as intended. Planned future monitoring will define actual performance. Bioretention cells designs are evolving and reflecting the need to attenuate specific contaminants based on land use. This is an important development that will make bioretention more effective and more attractive as a BMP. Costs associated with this technology will be better understood with time and experience, and may also decrease as designs and construction processes become more efficient. Overall, bioretention cells will be most effective in mass quantities, and could have a significant impact on water quality in Oklahoma.

ABSTRACT

The stormwater community has a critical need for evaluating the life-cycle costs of Low-Impact Development (LID) Best Management Practices (BMPs) as part of encouraging communities to incorporate LID. Great effort has gone towards demonstrating that LID BMP techniques can mediate negative stormwater effects including increased discharge volume from impervious surfaces and pollution loading as water travels through urban settings. However, LID BMPs must be proven to be cost effective as well as technically functional.

The current suite of cost tools available through the Water Environment Research Federation (WERF) is being expanded to include vegetative roofs, rainwater catchment systems, and bioretention facilities. These tools provide a detailed framework to facilitate cost estimation for capital costs, operation and maintenance costs, and life-cycle net present value. The tools can serve as a format for cost reporting for past, current and future projects, and also provide users with planning-level cost estimates.

The cost tool includes both a parametric cost estimation to demonstrate approximate cost per drainage area, and a line-itemized engineer's cost estimation tool. The line-item engineer's estimate allows the user to customize their project, while exposing the user to an extensive list of potential costs and opportunities to maximize stormwater management value. The use of this cost tool will enable consistent reporting of cost data on LID BMPs, so that users will be able determine the cost of each component of the project, both in materials and in planning and design. The standard format will also improve the ease of preparing cost estimates, since the necessary line items are broken out for consideration. Creating an understanding of the life-cycle cost benefits of LID will lead to more use of LID and green infrastructure in development and redevelopment.

INTRODUCTION:

A set of whole life cost (WLC) models designed to assist in planning-level cost estimation of various stormwater Best management Practices (BMPs) has been

expanded to include single-site, decentralized low impact development (LID) stormwater management practices. Included in this new set of tools are WLC estimating models for green roofs, residential rain gardens, parking-lot scale curb contained bioretention, in-curb planter vaults, and cisterns collecting runoff from commercial buildings. In addition to providing a general cost estimate based on drainage area, the tool synthesizes basic design concepts and parameters from multiple BMP and LID references in order to clearly describe the type of facility for which cost estimates are generated.

Each spreadsheet estimates capital costs as well as operation and maintenance costs to provide the user a WLC estimate for a selected LID facility. Default capital costs as well as operational and maintenance costs are provided, however, the model allows the user to enter known site-specific costs through all aspects of the model in order to produce a more accurate cost estimate for any specific project. For each facility type, two cost estimation methods are presented: a parametric estimate based on assumed default values; or an engineer's estimate with an extensive list of project-specific line items for which the user can enter known costs. The model combines either capital cost method with whole life operation and maintenance costs to estimate the WLC of the facility.

Currently, cost information on LID BMP infrastructure development is limited, and expanding this information is a critical part of the campaign to encourage LID development around the country. Managers around the country are hesitant to adopt LID practices because the cost factor is not well known. In addition to predicting costs, the model is designed to be used as a cost-reporting tool. The provided format can be used to enter costs of a completed project so that LID cost information can be shared and the model may be improved in the future.

BACKGROUND:

In 2005, the Water Environment Research Foundation (WERF), in collaboration with the United Kingdom Water Industry Research (UKWIR) and with funding support from the Environmental Protection Agency (EPA), released a cost estimation spreadsheet tool as part of a report titled, "Performance and Whole Life Cost of Best Management Practices and Sustainable Urban Drainage Systems" (Lampe, et al 2005). These spreadsheets include tools for costing traditional stormwater BMPs: retention ponds, planted swales, and extended detention basins. Permeable pavement, a source control BMP, is also included in the tool set. Capital costs for these BMPs are based on parametric equations derived from costs reported by agencies that had completed projects fitting the descriptions of each model. Capital, maintenance, and operating costs are separated into line items to provide the user details of each cost component for individual BMP installations.

The EPA has determined that providing better cost information to land owners and agencies should encourage expansion of LID and BMP approaches to stormwater management. As part of an effort to encourage agencies to adopt LID and BMP

approaches to stormwater management, the EPA has decided to expand the WERF cost estimation tool.

WLC MODELS:

The first spreadsheet in the WLC models requires a user to specify a series of design guidelines and system characteristics, such as drainage area, project size, and/or the primary objectives of the project. Each model requires the user to answer a different series of questions relative to that specific model. For example, the design options in the Cisterns model are shown in Figure 1.

Design & Maintenance Options

STORAGE REQUIREMENTS	Unit	Model Default	User	Chosen Option
Drainage Area, DA (often roof area)	sq ft	5,000		5,000
Max Design Rainfall Event	in	2		2
Precipitation Volume Generated per Event	gallons	6,233		6,233
Total Storage Needed	gallons	6,300		6,300

SYSTEM CHARACTERISTICS	Unit	Model Default	User	Chosen Option
Type of Tank Desired (*P=Plastic, M=Metal, F=Fiberglass, C=Concrete. See sizing suggestions below*)	-	C		C
Primary Use (*I = Indoor, Non-potable O = Outdoor Irrigation*)	-	O		O
Height of Building (Used to calculate 'Indoor' Use costs)	story	3		3
Number of Fixtures per Floor (toilets, used to calculate 'Indoor' Use costs)	ea	10		10

DESIGN & MAINTENANCE OPTIONS	Unit	Model Default	User	Chosen Option
Choose Level of Maintenance, Irrigation (*"H"=high; "M"=medium; "L"=low*)	-	M		M

Figure 1: Design and Maintenance Options from the Cisterns WLC model.

Each design option and system characteristic controls a major cost component used to calculate the simple cost estimate on the "Capital Costs" page. As in the example above, the user enters "Drainage Area" and the desired "Max Design Rainfall Event" to calculate storage size needed for the facility. This storage volume is then used to estimate the appropriate tank size and tank cost. In the "System Characteristics" box, the "Type of Tank Desired" tells the model which cost curve to use in estimating the cost of the tank, and the "Primary Use" option tells the model which equation to use to most appropriately size the distribution pump.

The user may also select a level of maintenance they estimate to be appropriate for their project in the "Maintenance Options" window on the first spreadsheet. Each level of maintenance assumes a different maintenance cost structure, explained on the "Maintenance Cost" page of each model.

Figure 2 shows the "Capital Cost Option A", or simple cost estimation, from the Cisterns model. This page estimates costs based on the information entered in the "Design Options" page, displays default costs, and allows the user to adjust the cost

of each item as appropriate. Totals entered in the "User" column are read in the "Chosen Options" column, allowing the user to adjust some cost values and rely on the model defaults for others. Advanced users may use this function to compare two separate sets of design options or system characteristics. In Figure 2, the user has specified that a one horsepower motor is needed instead of a 0.5 horsepower motor, and the costs in the "Chosen Option" column have re-calculated a separate user-chosen cost estimate. This "Chosen Option" cost is the cost used to calculate the WLC through the rest of the model.

Cistern

CAPITAL COSTS

Site Name:
Site Location:

Implementation Date:

Choose Capital Costing Option

A	Total Facility Cost	$ 17,920

"A" - Simple Cost based on Drainage Area
"B" - User-Entered Engineer's Estimate

C	User entered 'Concrete' for Tank Material in Design Options
O	User entered 'Outdoor' as Primary Use Option in Design Options

Method A: Simple Cost Based on Tank Volume*

Cost Based on Drainage Area	Cost per Acre of DA Treated		Chosen Option
	Model Default	User	
Tank Size	6,300		6,300
Tank Costs per Gallon	$ 1.66		$ 1.66
Estimated Tank Cost	$ 10,458		$ 10,458
Installation Cost	$ 6,275		$ 6,275
Pump Size Needed (horsepower)	0.5	1.0	1.0
Pump Cost	$ 599		$ 1,188
Culinary Re-Supply	$ -		$ -
Tank Installation Base Cost	$ 17,332		$ 17,920
System Design Cost	$ 1,387		$ 1,434
Total Facility Cost	**$ 17,332**		**$ 17,920**

Figure 2. Capital Cost Option A from Cisterns WLC tool.

On the "Capital Costs" page, "Cost Option B" is an engineer's estimate outline for each project type. "Cost Option B" is designed to serve three functions: 1) provide a user the opportunity to incorporate their own project-specific costs into the WLC model; 2) to provide an extensive list of anticipated cost items to the user to assist with planning; and 3) to serve as a form for record keeping and cost reporting so that agencies may share LID BMP cost information in a useful and efficient way. If "Cost Option B" is selected as the capital costing option, the engineer's estimate is used to estimate the WLC for the project.

Maintenance costs are calculated on the third worksheet in the model. Similar to the "Capital Cost" page, the model makes literature-based assumptions where available (or Best Professional Judgment if literature values are not available), and the user may adjust these assumptions to their needs. Maintenance costs are calculated by estimating hours per service event, hourly cost of labor, hourly cost of equipment, and cost of any materials used. Maintenance costs are divided into two types in the model: routine and corrective or infrequent. The user may control the schedule of these activities, which affects the WLC calculations. In the models representing smaller-scale projects, the costs of equipment and materials (such as a weed trimmer

or garbage bags for litter removal) is included in the hourly labor cost. Two tables are shown on this page, as shown in Figure 3. The top table is used to estimate labor costs per service event. The lower table is the reference table that shows the costs that the upper table uses to calculate cost, based on the user-chosen level of maintenance. The user may change maintenance costs in two locations, either in the look-up table or in the "user" columns in the upper cost-calculating table.

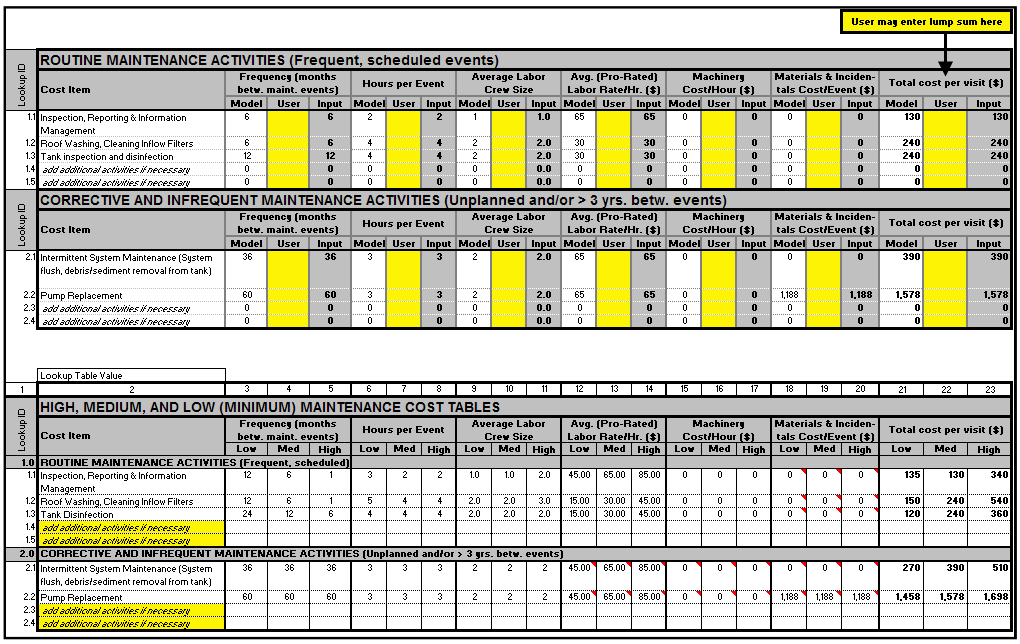

Figure 3. Maintenance Cost Worksheet from Cisterns WLC Model

After capital and maintenance costs have been estimated, each WLC model compiles all costs into an estimate on the "Cost Summary" page (Figure 4). This page summarizes annual costs for routine maintenance, corrective or infrequent maintenance, and capital costs. From this summary, the model builds a 50-year lifetime cost estimate for the facility (shown in the "Whole Life Costs" page) including a discount rate that the user may adjust on the "Design and Maintenance Options" page, and is then graphed to show the user a year-by-year facility cost for planning. Three graphs are presented: Present Value of Costs over 50 years (Figure 5), a Cumulative Discounted Costs over 50 years, and a Discounted Costs per Time.

Cost variability of LID BMP infrastructure across the United States is significant, as is climate variability which drives LID objectives. Because of this, the WLC models are designed to produce a default planning level cost estimate and allow the user to enter more specific cost values for every component tracked by the model. The existing WLC tools were designed to provide cost estimations for stormwater agencies in the United States and the United Kingdom. This expanded suite of WLC tools is targeted more towards single-lot scale LID stormwater controls because of the scale of projects addressed. This likely will increase variability in actual costs because the agencies available to construct the LID facilities are greatly increased. In

some instances, this includes opportunities for land owners to provide their own labor and sources for materials with the potential to drastically decrease whole life cost. Although many of the practices addressed by the tool are more applicable to smaller land areas, municipalities and regional management agencies can use these tools to examine future policy change options to shift a large-project, regional management paradigm of conveyance to a decentralized paradigm of many smaller projects that address catching the rain where it lands.

CAPITAL COSTS	Included in WLC Calculation			Total Cost
	Model	User	Chosen Option	
Tank Costs	$ 10,458		$ 10,458	$ 10,458
Total Associated Capital Costs (Install, pump, ect)	$ 7,463		$ 7,463	$ 7,463
Capital Costs				$17,921

REGULAR MAINTENANCE ACTIVITIES	Months Between Events	Cost per Event	Total Cost per Year	Included in WLC Calculation		
				Model	User	Chosen option
Inspection, Reporting & Information Management	6	$ 130	$ 780	$ 780		$ 780
Roof Washing, Cleaning Inflow Filters	6	$ 240	$ 1,440	$ 1,440		$ 1,440
Tank Disinfection	12	$ 240	$ 2,880	$ 2,880		$ 2,880
add additional activities if necessary	0	$ -	$ -	$ -		$ -
add additional activities if necessary	0	$ -	$ -	$ -		$ -
Totals, Regular Maintenance Activities				$5,100		$5,100

CORRECTIVE AND INFREQUENT MAINTENANCE ACTIVITIES (Unplanned and/or >3yrs. betw. events)	Years Between Events	Cost per Event	Total Cost per Year	Included in WLC Calculation		
				Model	User	Chosen option
Intermittent System Maintenance (System flush, debris/sediment removal from tank)	3	$ 390	$ 130	$ 130		$ 130
Pump Replacement	5	$ 1,578	$ 316	$ 316		$ 316
add additional activities if necessary	0	$0	$0	$0		0
add additional activities if necessary	0	$0	$0	$0		0
Totals, Corrective & Infrequent Maintenance Activities				$446		$446

Figure 4. Cost Summary Spreadsheet for the Cisterns WLC model

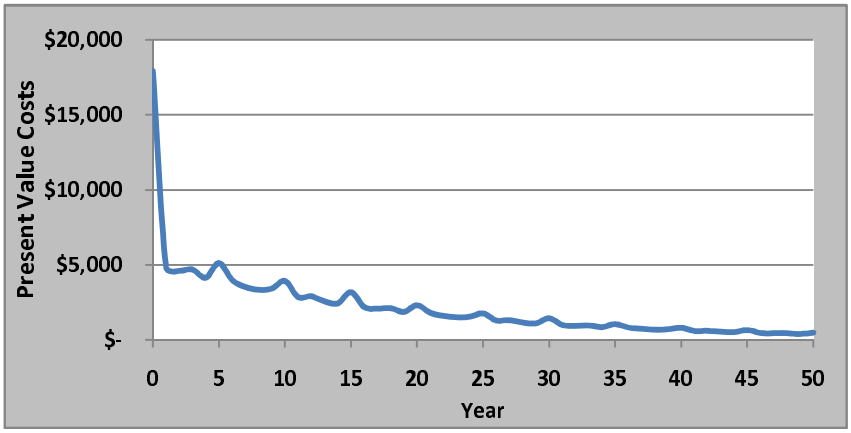

Figure 5. Whole Life Cost Presented as a Present Value of Costs Graph for the Cisterns WLC tool.

Capital and maintenance default costs used in the tool are generated from literature available in the public domain. In some instances, sufficient data were not available, or reported cost information was not sufficiently transparent to ensure appropriate cost comparisons. In such cases, design guidelines for each respective facility were summarized from multiple sources and, based on these design guidelines, cost estimates were constructed from component cost in the RS Means 100 and from national providers. In the parametric estimate, efforts have been made to present the

model as transparently as possible in order to both display how costs are generated and to allow the user to adjust many of the cost components in each model to improve the accuracy of the cost estimate generated for the user's specific scenario. For each facility type, different methods to establish default costs are used based on the availability of information in the public domain. These methods are discussed specifically for each WLC model below.

Green Roofs

Green Roofs evaluated by this model are "extensive" roofs, which are defined as having shallow soils and low plant cover, with limited roof access. "Extensive" roofs were evaluated because they minimize the need for structural reinforcements that may be required for "intensive", or deeper soil roofs, which would further complicate cost estimation. Many green roof arrangements evaluated by this model will weigh around 35 lb/ft^2; the most basic configuration may weigh as little as 20 lb/ft^2 and the more elaborate configuration can weigh over 50 lb/ft^2 (Roofscapes, 2008). The model can automatically generate two cost estimates based on roof area, building height, and roof function: one cost based on a pre-manufactured modular style installation ("Option A" on "Capital Costs") and a custom installation consisting of a root boundary layer, vegetative cover, and if elected, engineered soils ("Option B" on "Capital Costs"). A template is also provided for a user-entered engineer's estimate.

All costs are assumed to be in addition to the cost of a traditional roof covering. Green roof designs are not intended to be used as a substitute for a traditional roof covering. Instead, green roofs are designed to be installed on top of a conventional roof. One suggested benefit of green roofs is the increased lifespan of a conventional roof membrane due to the shading and insulating effects of the green roof installation. Conventional roofs have a typical life span of approximately 25 years; installation of a green roof on top of the conventional roof has been reported to prolong the life of the conventional roof two-fold (Toronto and Region Conservation, 2005).

A literature review suggests that the driving factor in the cost of green roof installations is the selection of landscaping options. In the development of the green roof cost tool, roof size and final cost were obtained for 48 buildings from the City of Portland (2005), the Chesapeake Bay Foundation (2008), and the Toronto and Region Conservation (2005). However, developing a parametric cost equation from the available literature was not feasible due to a combination of inconstancies in cost reporting and variations in design. This WLC model assumes the most basic type of installation, and allows the user to create a more elaborate installation including botanical upgrades, walkways, and irrigation. In order to account for the high variability in design options, the user may include or omit many green roof components and/or over-ride all default costs on the "Capital Costs" and "Maintenance Costs" pages. This model is designed to estimate costs for extensive roofs, however, it can be used to estimate costs for intensive roofs by increasing the soil depth and increasing the vegetative costs. This will substantially increase the weight of the roof, which may require structural reinforcements as noted previously.

Residential Rain Gardens

Design guidelines and general cost information for residential rain gardens are readily available in the public forum. Many community water quality-focused organizations and municipalities encourage the installation of rain gardens on residential properties because of the efficiency of rain gardens in reducing runoff volume, the relatively low expense of installation and maintenance, and limited regulations of landscaping practices on residential lots (Edgewood College, 2003; Kassulke, 2003; Belan and Otto, 2004; City of Lincoln, 2008; EPA, 2008; James City County, 2008; Maryland Department of the Environment, 2000). Unlike other larger scale stormwater management approaches, single home owners have access to the equipment and technology required to install a rain garden in their yards. Because this access is so broad, designs and costs of installments are also broad.

Based on the literature surveyed, two sets of cost information are reported for this tool. The first cost set includes estimates for land owners installing and managing residential rain gardens with labor provided at no cost, i.e. their own labor or volunteer labor. This cost set includes only costs of materials from local nurseries and hardware stores averaging $4.40 (normalized to 2008 US$) per square foot of garden installed. The second cost set includes rain gardens installed and managed by professional landscapers and averages $16.00 per square foot of garden installed (Edgewood College, 2003; Kassulke, 2003; City of Lincoln, 2008; EPA, 2008; James City County, 2008).

Labor, plants, and mulch costs drive the capital cost of most residential rain garden installations. EPA (2008) discusses the advantages of a developer installing multiple rain gardens during the initial development stage of large sub-divisions; this tool includes a cost-adjustment for this installation approach. However, this WLC model is best suited to provide planning-level WLC estimates for small-parcel land owners and managers interested in installing small rain gardens and comparing different cost options.

Curb-contained Bioretention

Many bioretention concepts take advantage of different ecological processes; however, they are often similar in construction approaches, design, and function. This WLC model is designed to incorporate bioretention concepts that can be contained by curbing and are designed to mitigate stormwater runoff from the surrounding pavement. Specifically, the model is designed to produce a planning-level cost estimate for a series of smaller basins that are back-filled with highly porous media and planted with vegetation that encourages infiltration and/or evapotranspiration and reduces stormwater peak runoff from expansively paved areas. These depressions are typically surrounded by curbing to maximize storage during large events, and to prevent drive-over in vehicle areas, and often include an overflow outlet or underdrain to conventional stormwater systems. The RS Means cost estimate

provided does include cost of demolition in the case of a retrofit. In the “Design and Maintenance Options”, the user may select “New” construction or “Retrofit” construction. If “Retrofit” is selected, a cost adjustment of 16% of the estimated base facility cost is added to the total cost estimate (Clar et al, 2004). Costs for this type of installation throughout the literature reviewed may be higher than current practice, as this is a relatively new technology. It is expected that as familiarity with the design concepts increases, cost should decrease.

The need for underdrains is dependent on soil type and overflow drain options, and underdrains represent a major percentage of the total project cost. Because of this, the WLC model includes the option for the installation of underdrains as part of the bioretention cells. If the user does not feel that this model fits their design criteria, the user should refer to the first suite of WLC models designed for large-scale LID installations such as extended detention basins, retention ponds, or swales.

In-curb Planter Vaults

Runoff reduction for small events with small drainage areas may be accomplished with in-curb planter vaults, defined as sub-grade storage vaults built into curbs to allow road or parking lot drainage to enter the vault's planter. In addition to reducing runoff volume, the planter facilitates passive precipitation storage to provide for urban vegetation in traffic islands or sidewalks. The vaults are filled with engineered structural soils to facilitate root growth, maximize porosity/water storage capacity, and support the load of the sidewalks and streets above them. These vaults can be capped by a normal sidewalk or street, and include a planted opening (often planted with a shrub or small tree).

The user can choose between two installation options in this model. The first installation option is a pre-cast vault, supplied by a manufacturer. In a review of available literature, for sources that reported costs for pre-cast vaults (EPA, 2005; Fairfax County, 2005; Unified Facilities Criteria, 2005; Calkins, 2008) the vaults were supplied by the same manufacturer. Differences in cost were functions of local construction and transportation costs; these values were averaged to create a per-pre-fabricated box installed cost estimate. Pre-fabricated vaults are substantially less expensive than vaults that are formed and poured in-situ and often include installation and service contracts to minimize inconvenience to the developer/manager.

The second installation option is vaults that are formed and poured in-situ. In-situ installations allow greater flexibility in all aspects of the design implemented, including water quality volume and landscaping components. In-situ installations include increased design, engineering and construction management costs in addition to a longer construction phase. Only the City of Portland (2005) reported costs for this type of installation. Instead of reporting this cost directly in the model, the Portland-style installation costs are averaged with an RS Means-based cost estimate of a similar project. This reduces the cost reported in the WLC model compared to Portland’s reported costs, which should be representative of future projects. Portland

noted that their installations, which were pilot in nature, included a number of unexpected costs that could be reduced in the future as the practices become more routinely implemented.

Cisterns for Commercial Buildings

In this model cisterns are defined as water catchment systems that channel rainwater from impervious surfaces into a storage tank for later use. This model is designed to estimate the cost of cistern systems for commercial buildings. Components included in this cost estimation model are the water tank, tank installation, and a re-distribution pump. The costs in the model were derived from a combination of literature review (CFM, 2008; Hicks, 2008; Miller, 2008; Nicklas, 2008; Ohio State Extension, 2008), component cost analysis, and an RS Means-based estimate of standard pump, tank, and installation costs.

The model allows the choice of two re-use options to more accurately estimate component costs. These options are “Outdoor Use”, assumed to be an automated spray irrigation system, or “Indoor Use”, assumed to use the collected water for toilet flushing. Indoor use is assumed to require a larger distribution pump in order to lift water to the upper stories of a building. The parametric cost estimate model does not include any costs of irrigation systems or double-plumbing that may be necessary depending on local regulations. Also, the model assumes that any gutters or internal conveyance systems from the roof to a storm drain are required components of a conventionally drained building. Although conventional storm water conveyance systems and cistern conveyance systems will differ in design (for example the downspouts will need to be directed into the cistern instead of a gutter or storm drain and more screening may be required), the model assumes that the cost difference is negligible. This model assumes minimal screening as the only method of treatment for stored water and intends for water supplied by the cistern not to be used as a potable source. Depending on the project location, different levels of treatment may be required by the local health department before the water can be used inside a building.

Summary and Conclusions

The expanded set of WLC models for LID BMP infrastructure provides planning-level estimates, describes system design approaches, and provides a standardized cost reporting form for agencies and developers to record and share development cost information. Many projects described in these models will vary greatly in design and cost based on the specific project goal and location. Flexibility has been built into the model to allow a user to compensate for design aspects specific to their project based on climate, regulatory environment, or other factors, as well as general regional cost differences in materials and labor.

The scale of any given project will also likely affect the final cost of the project. Every effort has been made to scale costs appropriately according to the size of the

project (related to, for example, drainage area, garden area or roof area); however, many of the cost models are based on limited cost data, and a limited number of varying project sizes. Economies of scale may not be entirely captured in these cost models. The scale of the project may also affect sourcing of materials and labor. Single-lot owners and managers may have many sourcing options for materials and labor for costs ranging from volunteer labor to more expensive labor, depending on quality or skill level required for the project. On larger -scale projects, a manager working for a municipality may be limited in their sourcing options for labor and materials.

To minimize the effects of the above-mentioned issues, each cost model was designed independently. Cost estimating approaches varied greatly from one model to another because the required infrastructure varied. For example, many sources are available on the internet to assist a home owner in designing, installing, and estimating the cost of a residential rain garden. Based on this information, the derivation of a per-garden size cost formula was direct. However, the cost reporting for green roofs was too unspecific to ensure that appropriate comparisons were made between sources and even within the same source. Most information sources reviewed (Toronto and Region Conservation, 2005, Peck and Kuhn, 2008) suggest that as roof area increases, the cost per square foot of an installation decreases. However, when comparing reported costs, the larger roof areas tended to be much more elaborate in design, and therefore, more expensive per square foot. Deriving a per-roof area cost proved unreliable. To overcome this, the two approaches described in the green roofs section above were created (one based on a modular green roof supplier's estimate and one based on component cost analysis) instead of one literature-based cost equation. In all instances, if the area-based estimate is insufficient for a particular project, a form is included in the cost tool to allow the user to create an engineer's estimate for a green roof project.

Regional LID BMP design considerations vary greatly, and therefore, so does infrastructure cost. The WLC models described here allows a user to modify cost information sufficiently to compensate for these variations and provide adequate planning-level cost estimations. In addition to providing cost estimates, the design concepts presented in each model provide factors to consider during the planning stages of an LID project. The model's function as a cost reporting tool will help agencies record and share cost information. These three model components will help to fill the lack of LID BMP cost information available to managers, thus encouraging the expansion of the use of LID BMP practices.

Data Reporting Guidelines for Certification of Manufactured Stormwater BMPs: Part II

CE Database: Stormwater management, best management practice, performance characteristics, water quality, certification

Authors: Robert M. Roseen M.ASCE[1], Ernie Carrasco[2], Yuan Cheng[3], Bill Hunt[4], Charlene Johnston[5], Jim Mailloux[6], Walt Stein[7], Tim Williams[8]

Abstract

Data Reporting guidelines presented here were developed as part of the ASCE/EWRI Task Committee on Guidelines for Certification of Manufactured Stormwater BMPs. This work is the collaboration of the Stormwater Infrastructure Committee of EWRI's Water, Wastewater, and Stormwater Council (WWSC) and the Wet Weather Flow Technology Committee of the Urban Water Resources Research Council (UWRRC). These guidelines were developed by review of the major manufactured treatment device certification protocol requirements drawing primarily from the Technology Assessment Protocol-Ecology (TAPE) and the Technology Assessment Reciprocity Partnership (TARP). These reporting guidelines have been broadened to support the International Stormwater Best Management Practices (BMP) Database. With the increasing need for the field testing of proprietary devices comes the importance of consistent data reporting guidelines to be used when reporting to regulatory agencies or designers. The need for standardized reporting is underscored by the tremendous impact the range of testing factors can have upon testing results. These factors include the testing environment, experimental design, testing methodologies, statistical analysis, and data presentation. The need for consistency is underscored by the complex influence these factors have upon performance results. A clear and consistent data reporting approach can ensure that these biases are minimized, well understood, and that representative field testing can be effectively evaluated by the regulatory agency. A consistent reporting format is also needed to aid vendors to efficiently navigate the complicated application process for device certification. Finally, an independent third-party is needed to either conduct or review the testing to ensure testing impartiality. The committee membership includes stakeholders from the regulatory, academic, manufacturing, and design communities.

Introduction

The need for a strict coherent approach to the testing of manufactured treatment devices (MTD) for stormwater management is ever increasing. MTD abound in the marketplace; however, there is limited information about system performance by third-party verification, and third-party verification protocol is not consistent This makes it difficult for consumers and stormwater managers to make informed decisions. A few states are making progress on this front, but there is no recognized consensus in the approach. To address this issue, both prescriptive testing protocols for laboratory and field conditions are required. The data acquired through those processes requires detailed reporting. The certification process itself can arguably be as difficult as the device testing process. Because of a lack of reporting guidance for the dominant testing protocol, vendors are left to discover the reporting requirements. This can lead to an inefficient, incomplete, and multi-stepped review process that can take years to negotiate effectively.

The ASCE/EWRI Task Committee on Guidelines for Certification of Manufactured Stormwater BMPs was convened in 2007 and is comprised of a range of stakeholders from academics, industry, and regulatory communities. By the end of 2009, the subcommittee on Data Reporting is responsible for preparation of the reporting guidelines for the presentation of testing results, so the data can be readily interpreted by the regulatory community.

The result of effective data reporting is a System Performance Evaluation Report that presents sufficient information to determine if an MTD meets the requisite performance standards within a reasonable level of statistical confidence. The System Performance Evaluation Report includes both summary data and sufficient experimental data to provide a detailed review of system performance. A critical review of leading testing protocols was performed and used as the basis for these guidelines. The first and only approved certification report for a MTD was also included. These reporting guidelines may need to be further adapted based on the synthesis of the subcommittee's products on both Field Testing and Data Analyses.

Background

Prescriptive testing protocols are needed because the range of influences upon testing and performance data is wide and not always well understood. Influences include watershed characteristics, storm event characteristics, maintenance requirements, system sizing, and testing methodologies. A testing protocol that does not dictate methods introduces biases that are challenging to account for.. In addition for performance characteristics to be compared across a range of different MTDs similar analytical methods and monitoring strategies must be used. The function of existing protocols is often to provide both a uniform testing environment and an accelerated review process that aids in the acceptance of stormwater technologies. Arguably, the current protocols have mixed success as measured by the existence of very few approved technologies despite programs existence for over 7 years.

If the testing protocol adequately addresses these issues, the testing results must be presented in order that a committee of scientists is not necessary to synthesize and interpret the results. This last point is significant, because the staff of the many regulatory agencies that reviewing the test results can not be expected to decipher the range of factors influencing system performance. As such, reporting results require sufficient information ranging from detailed appendices of experimental data to summary data indicating whether the systems met requisite performance standards within a reasonable level of statistical confidence.

A consistent reporting format does not currently exist; this leads to an , which has lead to a non-transparent and inefficient application and review process. Consistent and thorough data reporting requirements will aid regulatory review and vendor application alike.

The technology protocols and reports reviewed as part of this effort included:

- TARP Tier II Guidance Document: Protocol for Stormwater Best Management Practice Demonstrations. (NJCAT, 2003).
- New Jersey Tier II Stormwater Test Requirements - Amendments to Tarp Tier II Protocol. (NJCAT, 2006).
- TARP (Technology Acceptance Reciprocity Partnership) Tier I Guidance Document. TARP. (2001).
- NJCAT Technology Verification: Stormwater Management Stormfilter (CONTECH Stormwater Solutions, Inc. 2007).
- ETV Verification Protocol Stormwater Source Area Treatment Technologies. US EPA Environmental Technology Verification Program, Washington DC. (USEPA, 2002).
- Technology Assessment Protocol- Ecology's (TAPE) by the State of Washington, Department of Ecology. (WADOE, 2002).
- Improved Protocol for Classification and Analysis of Stormwater-Borne Solids. Water Environment Research Foundation, Alexandria, Virginia. (WERF, 2007)
- Urban Stormwater BMP Performance Monitoring. (USEPA and ASCE 2002)
- International Stormwater BMP Database. (ASCE et al, 1996))

International Stormwater BMP Database

The reporting framework was broadened to include data reporting criteria that will also meet the requirements for inclusion in the International Stormwater BMP database (BMPDB). The purpose of the BMPDB is to provide scientifically sound information for improved the design selection, and performance of stormwater management strategies. Continued population of the database and assessment of its data will lead to a better understanding of factors influencing BMP performance and help to promote improvements in BMP design, selection, and implementation. Statistical performance reporting requirements consistent with those used in the BMPDB are proposed as part of the MTD reporting framework. The database is only as valuable as the information that is included in it. The breadth and depth of the testing that will be done for MTD certification are ideal for inclusion in the BMPDB.

Work Plan

The subcommittee work plan for year one was to develop a consensus on a Reporting Framework. This was accomplished by the review of existing protocols, literature, and technology evaluation reports. Next, the framework was to be developed in the form of an annotated outline and sample mock-up. By year two, final input from the subcommittee will be completed. The next stage is for the draft Reporting Framework to be circulated amongst the full committee. The Final Data Reporting Guidelines will be completed in 2009. At which point, the full committee guidelines will be presented at the EWRI Annual Meeting.

DRAFT Reporting Framework

The reporting framework includes information ranging from the testing location, MTD specific information, test methods and procedures, and testing and sampling conditions. The test methods section will be determined largely from the subcommittee on Field Testing Methodology. The performance results and discussion are presented from two perspectives: 1) complete testing summary statistics and 2) on an individual event basis. Overall system performance is needed to determine the basic MTD performance. The summary statistics reflect largely the BMPDB (ASCE, 1996). The individual storm reports (ISR) on system performance enables understanding of the system variability with respect to storm event characteristics. This section has been adapted largely from existing reporting protocols for TAPE (2008).

The framework is listed below.

1. Summary: Executive Summary with rated performance rating, Study Summary, Data Collection Summary
2. Definitions
3. Site Conditions: longitude, latitude, land cover type, land use activities, site conditions, site elevations and slopes, location of sampling equipment, location of on-site stormwater collection system, and a description of any upstream BMPs
4. Technology Description:
   a) The specific device used (model number, size)
   b) Functionality of treatment mechanisms including pretreatment and bypass requirements
   c) Physical description: engineering plans, site installation requirements
   d) Cost of system and installation
   e) Sizing methodology: flows, volumes, etc.
   f) Maintenance procedures
5. Test Methods and Procedures
   a) Particle size for influent, effluent, and residuals, mass based, concentration based
   b) Water quality parameters monitored
   c) Data Quality Objectives (DQO), QA methods, and measurement accuracy for the observations
   d) Measuring instruments, sampling frequency, and sampling program information
   e) Sampling Locations and Peak Concentration Timing
6. Testing and Sampling Event Characteristics:
   a) Storm date, depth, antecedent dry period, intensity, duration, season, type of runoff (precipitation, snowmelt, groundwater, etc.)
   b) Number of influent and effluent aliquots; storm volume, % storm treated influent, effluent, peak flow rate, calculation of peak reduction and lag coefficients, number of storms exceeding design criteria.
   c) Comparisons with Data Quality Objectives
7. MTD Performance Results and Discussion:
   a) Event mean concentrations for influent and effluent with summary statistics (N, mean, median, coefficient of variation, standard deviation, one –tailed sign t-test)
   b) Detection limits and confidence intervals
   c) Performance metrics: removal efficiency, efficiency ratio

d) Statistical Evaluation: time series plot, box and whisker with confidence intervals, effluent probability method, linear regression . Statistical analyses should be consistent with the International BMP Database (bmpdatabase.org).
e) Solids characterization: influent, effluent, residuals particle size analysis
f) Accumulated mass reductions
g) Individual Storm Reports with event characteristics (6a and 6b), combination event hydrograph and hyetograph with sample times; system performance characteristics (7a-c), monitoring details
h) Quality Assurance, rejection criteria and rejection summary.
i) Maintenance findings: discussion on recommended maintenance schedules

8. Conclusions, Performance Claims, and Limitations
9. Appendices: Raw data and credentials
10. Third Party Review. The testing and reporting, if not performed by an independent professional third party, must be reviewed. The independent review should include a review summary and observation of at least one monitoring event.
11. Appendices

Conclusions

Guidelines produced by the Data Reporting subcommittee will be completed in 2009. The Committee's intentions are to facilitate a rapid review, so emerging technologies can be brought to market with the confidence of both third-party verification and regulatory approval. To accomplish this, a thorough and effective System Performance Evaluation Report reviewed by an independent third party is needed. The challenge is to balance the complex science of technology verification with the need for thorough review and a clear presentation of results. The collaboration of stakeholders from the regulatory, academic, manufacturing, and design communities will ensure an appropriate balance is achieved.

Design of Integrated Bioinfiltration-Detention Urban Retrofits with Continuous Simulation Methods

William C. Lucas, S.M. ASCE

Griffith University, Nathan Campus, Brisbane Australia Bill.Lucas@Student.Grifith.edu.au, wlucas@integratedland.com

ABSTRACT

This paper presents the elements involved in the design of a bioretention planter/trench infiltration-detention system as an urban retrofit project. The system was designed to intercept all of the runoff from a synthetic 5.08mm 24-hr rainfall event. Diverted flows were conveyed into bioretention planter for treatment. The bioretention systems were fingerprinted into areas comprising 0.8% of the contributory drainage areas, with an associated stone trench comprising another 3.4%. The system was modeled using SWMM 5.0.014 continuous simulation (CS) software. Under existing conditions, over 80% of annual runoff exceeded the 3.50 L-s^{-1}-ha^{-1} (0.05 cfs-ac^{-1}) threshold for initiation of combined sewer overflows (CSOs). Nearly all runoff was intercepted by the planter/trench infiltration system, and even with a soil infiltration rate of only 2.54 mm-h^{-1}, nearly 46% was infiltrated, and less than 8% was discharged at rates that could initiate CSOs. The number of CSO events was reduced from 74 to 4, a reduction of 95%. The volume of flows exceeding the threshold decreased by over 91%.

KEYWORDS: Bioretention; Infiltration; Routing; Modeling; Continuous Simulation; SWMM

INTRODUCTION

Because it determines runoff capture performance for a given area, infiltration is one of the most important processes in bioretention systems. However, infiltration is an element that remains poorly understood, let alone effectively addressed in their design. As such, computational approaches that realistically address infiltration are urgently needed. The Green-Ampt formulation can be quite precise if its parameters are properly determined. It has the ability to account for head, and the resulting changes in infiltration rates according to Darcy's Law. These aspects of the Green-Ampt formulation make it very attractive for modeling.

Many biological processes also affect infiltration properties. The beneficial effects of native plants on infiltration rates persist even in depositional situations where sediments accumulate (Rachman et al, 2004). Plant movement in the wind tugs at the soil surface, breaking clogging mats, and cracking through deposits. Ponded rainfall can then more easily penetrate clogged surface layers, increasing infiltration rates. Root turnover promotes the formation of macropores. These processes associated with vegetation are remarkably effective in restoring and/or enhancing infiltration rates. Field infiltration rates in native grass hedges are much higher than found in adjacent croplands (Rachman et al, 2004; Blanco-Canqui et al, 2004a,

2004b; Seobi et al, 2005). In bioretention columns, Culbertson and Hutchinson (2004) have documented that switchgrass (Panicum virgatum.) increased infiltration rates in bare soils from 0.5 cm-h-1 to 128 cm-h-1, an increase well over two orders of magnitude. The presence of vegetation can result in infiltration rates several orders of magnitude higher than predicted by underlying soil properties (Ralston, 2004). Therefore, the presence of vegetation can play as much of a role in determining the infiltration and percolation response as the underlying soil texture composition. It is only recently that the literature has begun to address how media properties such as texture and organic matter interact with soil structure and vegetation to affect the matrix infiltration and percolation response (*e.g.*, Sharma et al, 2006).

In addition to the complexity of infiltration responses, there are several different compartments through which runoff flows in bioretention systems. There is a surface pool compartment that infiltrates into the media compartment, but also has the capability of bypassing surface flow in excess of storage. Flows initially pass slowly from the media into a stone layer as unsaturated flow, which increases in rate until saturated. Flows from the stone layer infiltrate into the surrounding soil which typically controls system capture because media flow rates are typically much faster than that of the surrounding soils. As such, the hydraulic gradient is initially rapid, but eventually decays to the rates determined by the surrounding soil. Where soils have very low infiltration rates, an underdrain can be installed to permit more flow to be captured and treated by the media. A key aspect of this arrangement is the fact that flows under saturated conditions are driven by hydraulic gradients, so backwater created by any of these nodes will control system response.

Given the complexity of this system, there is still uncertainty about how to properly model infiltration processes in bioretention systems. A method that mimics the Green-Ampt initial infiltration response needs to be combined with standard level pool routing that takes into account hydraulic gradients. This paper presents the elements involved in the hydraulic routing of bioretention systems as part of an urban retrofit project in Columbus Square, Philadelphia, Pennsylvania.

METHODS

System Design

Two bioretention planters linked by a stone trench were designed to provide storage of at least 25.4 mm (1") of runoff from the surrounding impervious areas. These systems are intended to not only intercept runoff from frequent events, but also to infiltrate as much of it as possible. The balance that doesn't infiltrate is released through a small orifice to reduce flows below the 3.50 $L\text{-}s^{-1}\text{-}ha^{-1}$ CSO threshold. Each planter comprises a 5.08cm long by 91cm wide (16.67' by 3.0') cast in place concrete cell. The planter media is placed at a depth of 81cm (32"), with the top being 41cm (16") below the lip of the planter. This results in the media being 10cm (4") below street elevation. Runoff from the street is intercepted by a 91cm wide curb cut, with a sump 91cm deep. It is covered with a metal cover to permit access to remove coarse debris. Collected runoff then flows through a 91cm wide slot that is 10cm high, placed 5cm above the media to prevent backwash of mulch from the planter. The planters are placed upon a stone bed of AASHTO no. 57 stone with a compacted void percentage of at least 40%. Figure 1 displays the planter section.

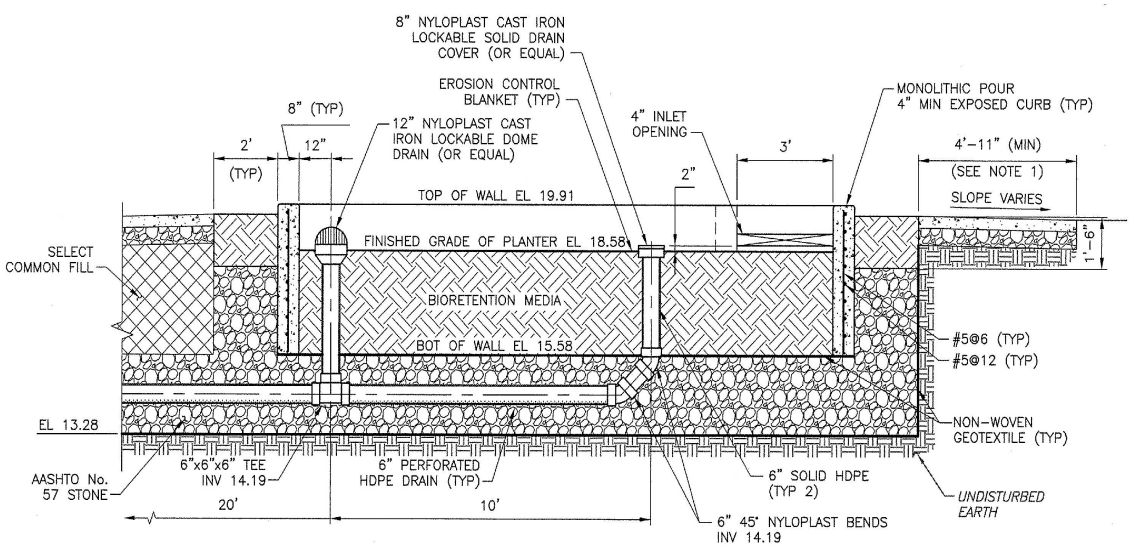

Figure 1: Section View of Typical Planter System (Courtesy of CDM and PWD)

Runoff collected in the planters initially passes through the planting media, and once ponding depths exceed 5cm, also pass through an 46cm circular inlet and then into an 20cm (8") distribution manifold into the underlying stone. Given this internal bypass arrangement, these systems are capable of intercepting runoff very effectively in even large events, while treating the smaller events as flow through the media for better treatment performance. Between the planters, there is a 23.9m long by 1.5m wide (78.5' by 5') infiltration trench 152cm deep, with its bottom set this distance below street elevation. This trench is also filled with no. 57 stone. Runoff accumulated in the stone system is collected by a perforated underdrain which discharges into a control structure comprising a 13mm (0.52'') circular orifice at the underdrain invert, and a 61cm (24") wide overflow compound v-notch weir 122cm (48") higher. Although infiltration tests at the locations of the planters indicated negligible infiltration, the extent of the area exposed by the trench is likely to encounter areas of some infiltration. As a result, the nominal infiltration rate of the soil surrounding the trench was projected at 2.54 mm-h^{-1} (0.10 in-h^{-1}) per hour.

Routing Setup

To represent the system, it is necessary to disaggregate the various components so they can be modeled discretely. As shown in the routing diagram in Figure 2, this is accomplished through modeling the contributing subareas individually. Each bioretention/surround system is then subdivided into three nodes: an Inlet node, a Planter Pond node, and a Media node. The Planter Trench node is filled by flows through the media and bypass flows from the surface pond of each planter. The inlet orifices are modeled explicitly to ensure that they do not constrain flows. Overflows down the street represent bypass flow to surface inlet node that is not intercepted by the planters.

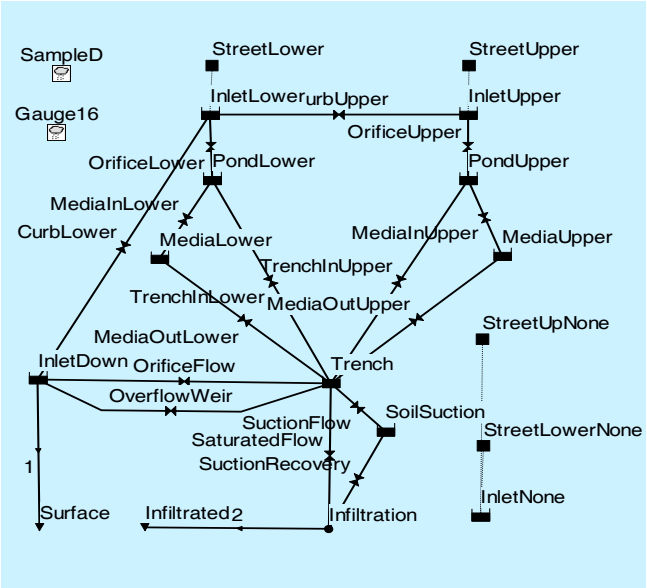

Figure 2: SWMM 5.0.14 Model Routing Diagram

To route flows into the media, an alternative approach is needed to reproduce such vertical flow dynamics. One approach is to model the flows into the media and as if it was routed through an orifice. This obviously does not replicate the complexity of unsaturated flow dynamics into and through a complex media/soil system of several layers. Furthermore, orifices increase flow at the half power of head, while Darcy's Law through media of a uniform length bears a linear relationship to head. Therefore orifice responses will be only an approximation at best. However, because the ponding depths that increase flows into media are so shallow, allocating an orifice several inches below the surface is an effective method to mimic inflows into the media. Flows are initially higher than stabilized rates until head in the media rises, thus mimicking Green-Ampt response, while the orifice will then respond to the hydraulic gradient when the media is saturated.

For flow through the media, SWMM5 now offers a flow routing option that permits flows through elevation-dependent rating curves that reflect the difference in head between nodes. With this option, the rating curve flow declines once there is less effective head. This often occurs when outflow is controlled by infiltration into the surrounding soils. In this manner, the outflows can respond according to the limiting condition. To do this, the hydraulic grade line must be carried upward from the surrounding soils through the media into the pond, and even back out the inlet in extreme events. As a result, there can be minimal flow into or through the media once the surrounding stone is filled up and outflows are restricted by its discharge response. This method can provide quite a reasonable representation of flows into and through the media when it is saturated.

Because the planter area of the systems is only 0.8% of the effective source area, even relatively small events will exceed the infiltration rates into the media, resulting in surface ponding. Once the surface ponding exceeds the bypass inlet grate set 5cm higher, the resulting flows are also routed through the bypass inlet into the stone surround and trench system as primary flows. Accumulated runoff into the combined surround and trench stone system is collected by a perforated underdrain which discharges into a control structure comprising an orifice and the compound v-notch overflow weir. Because infiltration rates are so low, this system is designed to release accumulated runoff at low rates into the InletDown node.

Flows passing through the trench node infiltrate into the surrounding soil at a K_{sat} projected to be 2.54 mm-h^{-1}. Outflows from this node can be allocated by rating curves computed according to the corresponding wetted area and K_{sat}. However, in

addition to saturated flows, it is necessary to mimic the response of capillary suction response of the surrounding soil. This is accomplished by creating a dummy SoilSuction node created 444cm (13.55') below the bottom of the trench. This dummy node area is sized according to the projected capillary suction volume divided by this depth. Flows enter the node through an orifice at the bottom sized to represent the initial rate, which is based on the ratio of capillary suction to K_{sat}, divided by a peak factor.

Given this configuration, flow rates into this node are initially rapid due to the high head across the orifice, and then decline as the SoilSuction node fills up (saturates) and the effective head differential declines. To replicate recovery, flows leave this soil node at the initial K_{sat} applied to the bottom of the trench, divided by a recovery factor. This is applied as a constant rating curve. In this manner, there will be minimal suction flow for events that occur when the SoilSuction node is full (wet), while events that occur when it has drained will have more of a suction response. The recovery rate is subtracted from the K_{sat} applied to the surrounding soils as a function of wetted area. In essence, this SoilSuction node operates as a sponge with the capacity representing the suction head volume, designed in a manner that accelerates the same infiltrated volume that would be encountered with a constant K_{sat}. While these artifices vastly oversimplify the actual processes involved, the system response throughout an event is quite similar that expected from a more physically process-based model, while requiring considerably fewer computational resources.

SWMM used a CS time series rainfall file to project annual responses. This distribution is the 2005 "synthetic year" distribution developed by Camp Dresser and McKee (CDM) based on 26 years of rainfall records. This design year was selected as being hydrologically representative of annual rainfall distributions, subject to including a range of larger events to address flooding design. An uncontrolled system without the SMPs (InletNone) was established for comparison purposes. The model was then used to compare flow distributions of the uncontrolled system to the Planter-Trench LID system in terms of reducing overall runoff, and in particular, reducing combined sewer overflows (CSOs). A threshold of 3.50 L-s^{-1}-ha-1 (0.50 cfs-ac-1) was set as the runoff rate at which CSOs are likely to occur. This disaggregated routing results in unexpected behavior during events as the various compartments fill and empty at different rates.

RESULTS AND DISCUSSION

Figure 3 displays the response for two events in January 2005. The upper row displays the response for the upper and lower media, the middle row displays the relative elevations of the Media, Trench and SoilSuction nodes, while the bottom row shows both the surface and exfiltration outflows from the Trench. In this case, the first event is 12 mm precipitation over 8 hours, while the second is a 43.4 mm event that occurs over 14 hours. This latter event is the fourth largest event in the 2005 rainfall time series.

In the first event, initial orifice controlled inflow rates into the media are as high as inflow rates into the pond until the media approaches saturation, after which and inflows are then controlled by the system based on Darcy's Law. There is relatively rapid drainage from both the upper and lower media. Because soils are

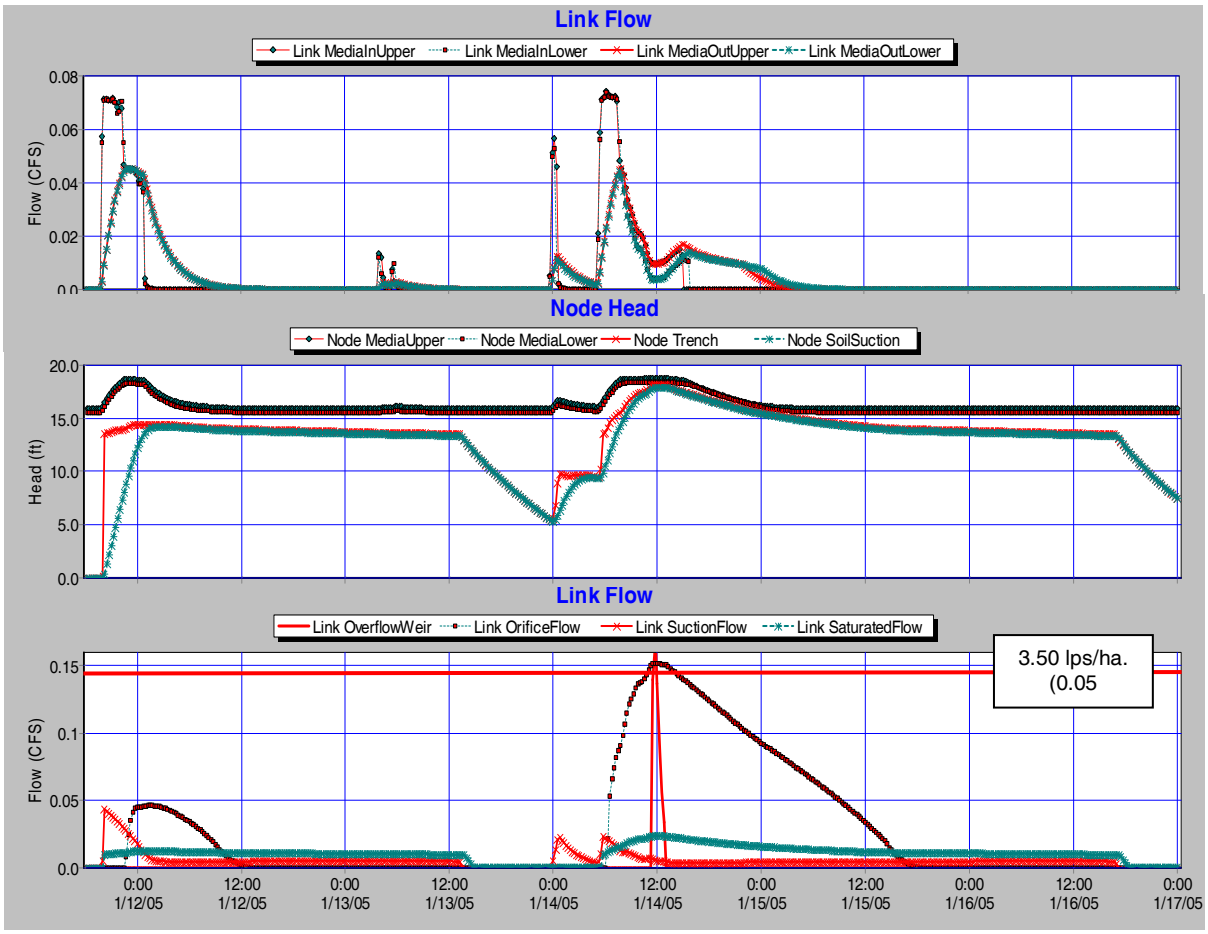

Figure 3: Flow Rates and Node Depths, Jan 12 and January 14, 2005 Events. Top Row displays Flow into and out from Media, Middle Row displays Media Trench and Suction Node Elevations, while Bottom Row displays Trench Outflow into Surrounding Soil via Suction and Saturated Flows, as well as Flows through Orifice and Overflow Weir.

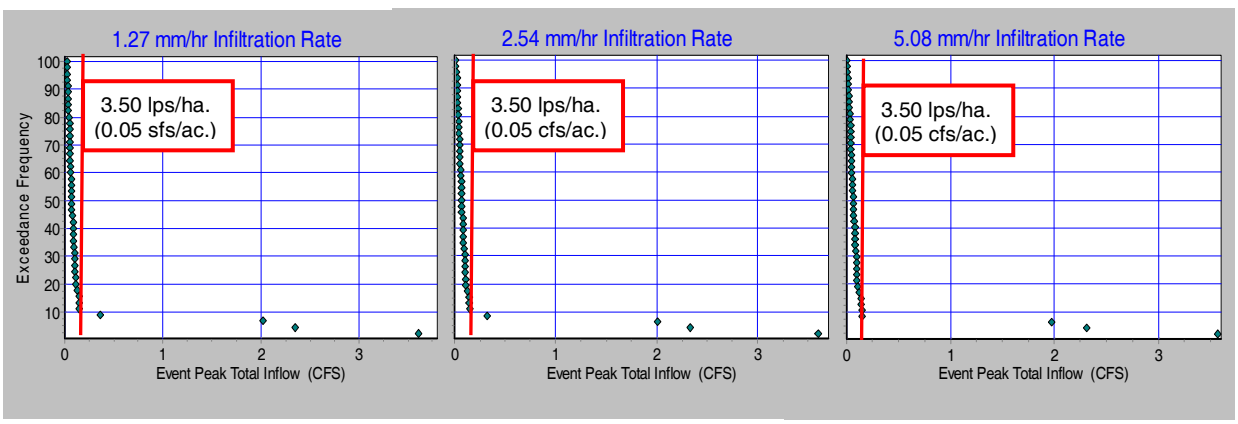
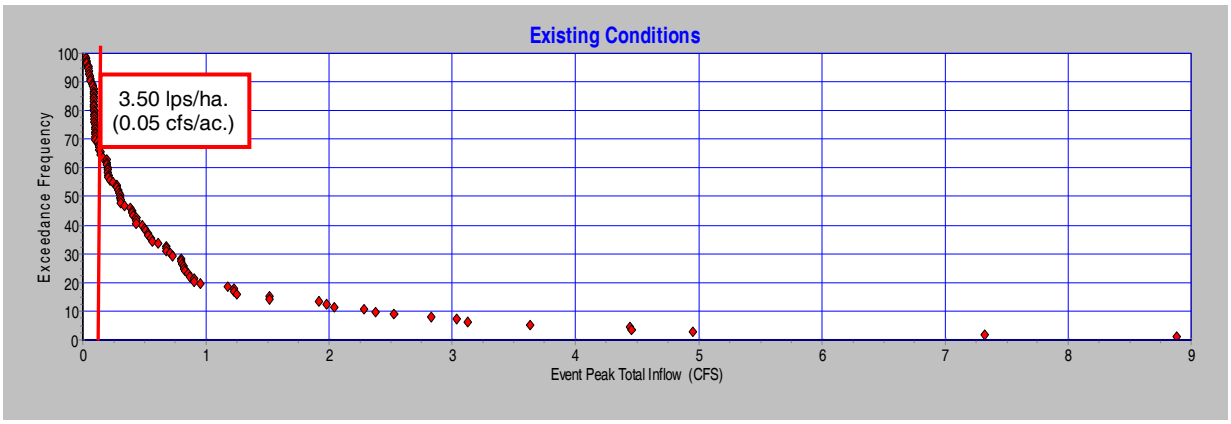


initially dry, the elevation of the trench in the middle row is initially much higher than SoilSuction, resulting in a corresponding peak in the SuctionFlow response shown in the bottom row. Note how OrificeFlow discharge is delayed well after media outflows, and is well under the 3.50 L-s^{-1}-ha-1 threshold for CSOs.

The response of the latter event is similar to the first in terms of media inflows. However, during peak runoff, there is a characteristic double peak in the media response, in which the dip is matched by a corresponding peak in the overflow weir flow. The dip between the peaks occurs as the trench elevation approaches that of the media. There were two precipitation pulses in this event, in which the SoilSuction node had not fully recovered from the first event. This resulted in two SuctionFlow responses, of which neither was as pronounced as the first event. There was a slight CSO exceedance as shown in the OverflowWeir discharge.



The preceding events were examined in detail to present the dynamic interactions between the various nodes so as to get a better of the overall system response. The entire 2005 design year was then run to evaluate the cumulative annual performance of the system. The full dynamic wave option was used, with a time step

of 6 seconds to avoid instabilities. The annual flow routing continuity error was 0.06%. To examine sensitivity of the system to underlying infiltration rates, runs were also made with the nominal rate of 2.54 mm-h^{-1} doubled to 5.08 mm-h^{-1}, and halved to 1.27 mm-h^{-1}.

Figure 4 displays the resulting distribution of CSO exceedances, and their magnitude. Table 1 presents the resulting runoff and infiltration volumes, as well as the number of CSO exceedances and their total volume. The total runoff from the uncontrolled system was 1175 cu.m., representing an effective depth of 1.13 m. This comprised 113 different runoff events, of which 73 exceeded the CSO threshold. With the SMP systems at the lowest infiltration rate 1.27 mm-h^{-1}, the runoff volume was reduced by 40.8% to 680 cu.m. While this is a substantial reduction in annual runoff, the number of CSO exceedances declined to only 4 events, a decrease of 95%. Likewise, the volume of exceedances was reduced from 947 to 103 cu.m, a reduction of 89%. This emphasizes just how effective the SMP system can be due even when constrained by very low infiltration rates into the surrounding soil. This is due to the effective interception and retardance of flows.

(a) (b) (c)

d)

Figure 4: Peak Flow Exceedance Frequencies: (a) Planter-Trench LID, Infiltration Rate at 1.27 mm-h^{-1} (0.05 in.-h^{-1}); (b) Planter-Trench LID, Infiltration Rate at 2.54 mm-h^{-1} (0.10 in.-h^{-1}); (c) Planter-Trench LID, Infiltration Rate at 5.08 mm-h^{-1} (0.20 in.-h^{-1}); (d) No LID Inlet Flows.

Table 1: SWMM Routing Results, 2005 Design Year, Uncontrolled Runoff Compared to Planter Trench LID System, Infiltration Rates at 1.27-, 2.54- and 5.08-mm-h^{-1}

Scenario	Uncontrolled Runoff	LID Planter Trench Controlled Inlet		
		1.27 mm-h^{-1}	2.54 mm-h^{-1}	5.08 mm-h^{-1}
Runoff Volume (cu.m.)	1175	680	637	535
Infiltrated Volume (cu.m.)	0.0	479	538	640
Infiltrated Depth (m.)	0.00	0.46	0.52	0.62
Percentage Infiltrated	0.0%	40.8%	45.8%	54.5%
Treated Volume (cu.m.)	0.00	512	513	514
Percentage Treated	0.0%	43.6%	43.6%	43.8%
Number of CSO Exceedances	74	4	4	3
CSO Exceedance Volume (cu.m.)	947	103	91	81
CSO Percentage Exceedance	80.6%	8.8%	7.7%	6.9%

When the infiltration rate was set at 2.54 mm-h^{-1}, the percentage infiltrated increased to 45.8%, with 538 cu.m. infiltrated. The number of exceedances was the same. The volume of exceedances was reduced to 91 cu.m., a reduction of 90%. With the infiltration rate increased to 5.08 mm-h-1, 54.5% of the inflow volume was infiltrated, representing 640 cu.m. The number of exceedances further declined to 3, a reduction of 96%, and the volume of exceedances was reduced to 81 cu.m., a reduction of 92%. Note that these latter results were obtained at infiltration rates that are still quite low. Table 3 also presents the extent of flows that are treated by the media. In all three scenarios, the percent treated is nearly 44%, a remarkable proportion for a SMP with a surface area of only 0.8% percent of the source area. While the remaining runoff volume may not be treated by the media, it represents less polluted flows that occur after the first flush, which flows are both filtered by passing through the planter vegetation and then through the stone.

Figure 5 graphically displays how the resulting annual flows are distributed. This graph uses the typical percent exceedance display as shown on the upper abscissa. However, flows are not only altered in terms of their distribution, they are also reduced in terms of total volume and duration. Therefore, comparisons of normalized cumulative frequencies can be misleading in terms of seeing what the actual effect may be. To better display the comparison of the LID scenario to the uncontrolled scenario, the data is plotted on the bottom abscissa in terms of 15 minute flow intervals. While this method shows very similar trends in flow distributions, their origins are different. In the exceedance distribution, flows are apportioned across the entire range of percentages, because they are normalized in terms of total flow. On the other hand, because the cumulative flows are not normalized against themselves, they represent the true comparison between treatments with different flow volumes and durations.

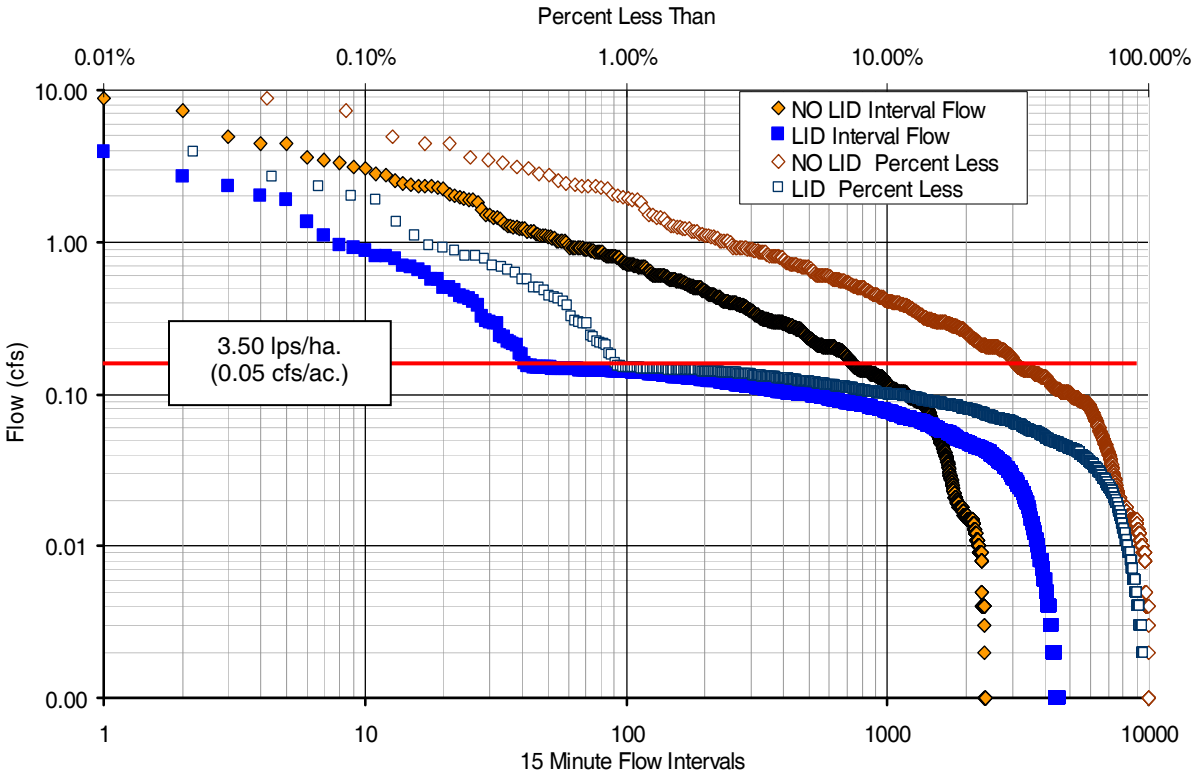


Figure 5: Flow Exceedance Frequency and Cumulative Flow Distribution: Uncontrolled Runoff Compared to Planter-Trench LID System, 2.54 mm-h^{-1} (0.10 in.-h^{-1}) Infiltration Rate.

Without SMP controls, flows exceed the CSO threshold over 20% of the time. With the SMP system at the nominal infiltration rate, the percent of time that flows exceed the CSO threshold then declines to 1% of total runoff duration. However, because total flow volumes and durations are different between these scenarios, it is difficult to determine what this difference in percentage really means.

In contrast, the interval flow plots show a more comprehensive picture. In the No LID scenario, there are 800 flow intervals over the CSO threshold, with the remaining 1600 or so intervals less than the threshold. In contrast, there are only 40 intervals over the threshold in the LID scenario, while there are some 3400 flow intervals are below the threshold. So even though there are many more flow intervals in the LID scenario, their flow rates are relatively low. In essence, these low flows are meant to make up for the low infiltration rates. This type of observation is not so readily apparent from the percentage graphs. Furthermore, it can be seen that the few flows that are over the threshold in the LID scenario are much lower than the corresponding uncontrolled flows. This is partly because the low flow outflow from the orifice releases so much more runoff at rates below the threshold. This restores storage volume so that even large peaks can be reduced.

CONCLUSIONS

Flows in bioretention systems should be represented vertically in addition to the horizontal routing approaches typically used in conventional stormwater design. By judicious selection of orifice parameters and properties allocated to the dummy

node for surrounding soils, it is possible to realistically model the dynamics of the system using the power of a CS model. With this discrete routing approach, the benefits of urban retrofits can thus be better documented. Given the computational efficiency of this method of analysis, it can be applied to many discrete subcatchments to address specific outfall discharge criteria in a comprehensive manner, and under many scenarios.

Based on this comprehensive approach at the street scale, the combined planter-trench system is capable of transforming the runoff response from urban source areas into a runoff response more typically found in pervious areas. Where infiltration rates are favorable, the resulting runoff response could approach that of a forested condition. This is accomplished with only 0.8% of the contributory source area used for the surface facility, in association with an underground trench system comprising an additional 3.4% of the source area. These possibilities make integrated bioretention-infiltration systems a viable approach to contribute materially to Philadelphia's Long Term Control Plan to reduce Combined Sewer Overflows.

ABSTRACT

Typically, the sizing of hydrodynamic separators (HDS) for stormwater treatment is based on two factors. The first factor is the ability to remove a designated fraction of a particle size distribution, usually with a d_{50} of 100 μm or greater. The second factor designates the magnitude of flow that needs to be treated from a given site.

The techniques for determining the magnitude of flow vary, but two basic methods dominate. The first is a fairly simplistic method that requires the HDS to be sized to remove a target percentage of a specified particle size at a defined flow rate. The flow rate can be determined using a specified rainfall intensity and storm return period with a hydrologic model output, such as the Santa Barbara Urban Hydrograph. The second method, sometimes called the average annual load method, is based on calculations which use the storm depth (or intensity) frequency distributions converted to flows through a unit, which are then used to predict the removal performance. The removal performance prediction is based on laboratory studies of specific gradations of silica sediment, which have been tested to create a performance graph. These graphs often show plots of removal performance to the point where zero removal is achieved. These flows at zero removal are sometimes termed the "peak treatment flow".

This paper provides a perspective on this methodology and an approach to how sizing methods can be changed to optimize the total load reduction of a system by throttling the flow to a rate that is less the "peak treatment flow".

As a simple example, if a system's performance graph demonstrates that the HDS is 0% efficient at 5 cubic feet per second (CFS), then when that "peak treatment flow" reaches the system, no removal will occur. However, if the system is operated at a lower operating rate by bypassing a portion of the "peak treatment flow", this would result in some degree of treatment for a portion of the flow, and would therefore be more efficient overall. Say, in the example above, the system is designed to bypass at 4 CFS to get a 20% removal for the 4 CFS portion of the flow and a zero percent removal for the 1 CFS bypass flow. The total efficiency would be 16% (20%

removal for 80% of the flow) as compared to a total efficiency of 0%, resulting from no bypass at all.

The question becomes: Given the characteristic curve of an HDS system, at what point is it best to bypass the system to optimize removal on a total flow basis? This paper presents a method to accomplish this task.

BACKGROUND

Hydrodynamic separators (HDS) are compact water treatment devices that are effective for the treatment of coarse and gross solids. (WERF, 2008) Since they rely principally on the physics of settling governed by Stokes Law, the devices become less efficient with increasing surface loading or volumetric flow rates. However, based on system geometry and the management of the hydraulic grade line, some systems are more efficient at a given flow rate for a set particle size gradation of coarse solids. Hence, performance curves, plotted as flow rate vs. removal efficiency, are used to design these systems. The curves are typically generated in a laboratory setting using known gradations of silica sand at concentrations typically found in stormwater runoff (NJDEP, 2006). These curves typically show the removal efficiency range from 100% to 0% removal. The flows at zero removal are sometimes termed the "peak treatment flow".

To meet jurisdictional design requirements for coarse solids removal, two basic methods dominate. The first is a fairly simplistic method that requires the HDS to be sized to remove a target percentage of a specified particle size at a defined flow rate. For example, the design flow rate is determined using a specified rainfall intensity and storm return period with a hydrologic model output, such as the Santa Barbara Urban Hydrograph. Then the system must be sized to remove 80% of a specified particle at that design flow rate.

The second method, sometimes called the average annual load method (CONTECH, 2006), is based on the notion that a jurisdiction needs to remove 80% of the designated solids on an average annual load basis. Since flow, relative removal efficiency, and mass load, through the unit are dependent on rainfall, calculations which use the storm depth (or intensity) frequency distributions converted to flows are used to "model" the overall annual removal performance. However, this approach should be considered more of a method than a model since critical factors such as particle size and load are assumed constant, when in reality they vary with storm depth, and intensity. This method and others utilize the entire efficiency curve such that bypass around the unit does not occur until the peak treatment flow (0% efficiency) is reached.

TOTAL FLOW OPTIMIZATION

This approach raises the question: Would the overall annual removal increase by bypassing the flow sooner? At first, this may seem counter-intuitive but if one

considers the peak treatment flow rate it becomes clearer. Given a total inflow into the system that results in 0% removal, it would be better to bypass a portion of that flow and achieve some removal efficiency of that portion such that there would be some removal at the total flow.

The question then becomes: Given the characteristic curve of an HDS system, at what point is it best to bypass the system to optimize removal on a total flow basis?

METHOD TO OPTIMIZE HDS OPERATION

Figure 1 below shows a general schematic of an HDS configured with a bypass. Typically the bypass is configured to operate when the total inflow (Q_{TOTAL}) exceeds the 0% efficiency flow rate of the HDS and scouring and resuspension of solids would occur.

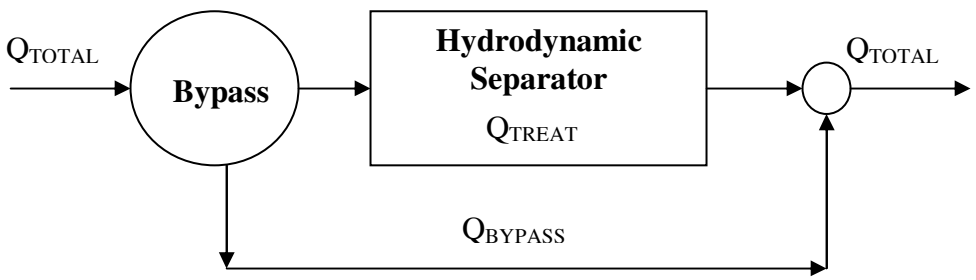

Figure 1: A schematic of an HDS with a high flow bypass.

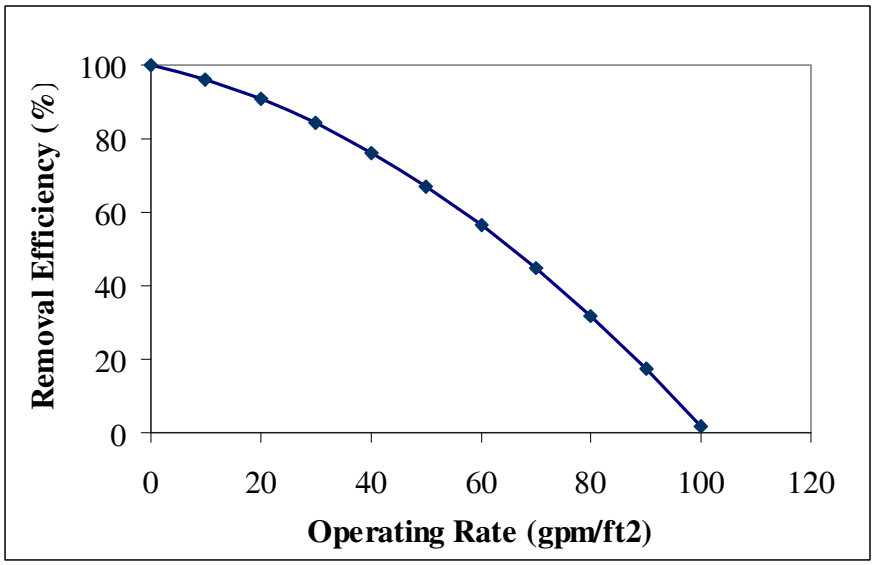
Given Figure 1, the following relationships can be established:

$$\text{Eqn 1:} \quad Q_{TOTAL} = Q_{TREAT} + Q_{BYPASS}$$



$$\text{Eqn 2:} \quad E_{BYPASS} = 0$$

Let's assume that the removal efficiency (E) for any of the bypass flow is 0% and the HDS has some characteristic removal efficiency curve resulting from laboratory testing. For the demonstration purposes of this paper a hypothetical HDS curve is created. The hypothetical functional relationship between the flow and efficiency is:

Eqn 3:

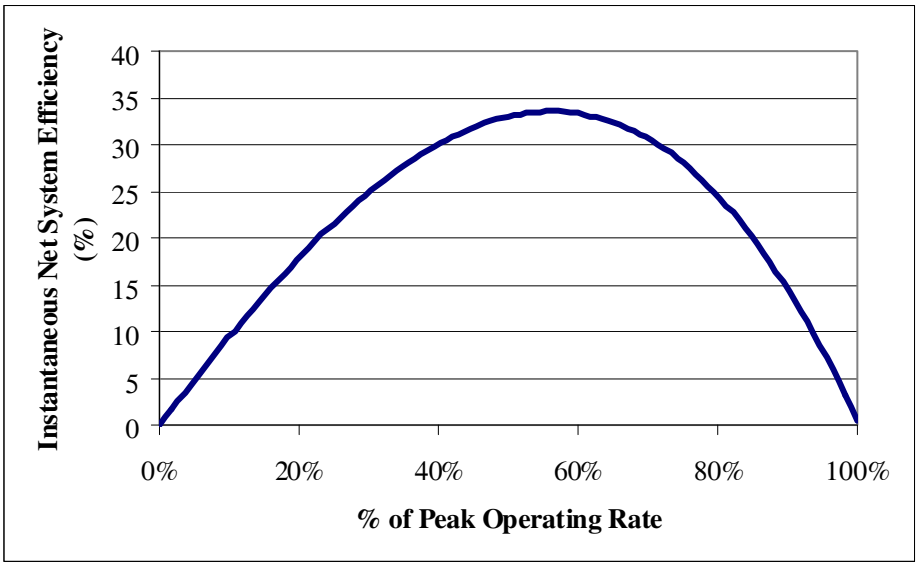
$$E_{TREAT} = -0.0065\ Q_{TREAT}^2 - 0.3338\ Q_{TREAT} + 100$$

Graph 1 is a plot of the efficiency curve given by equation 3.

Graph 1: An efficiency plot for a hypothetical hydrodynamic separator.

The total system treatment efficiency can then be calculated using Equation 4:

$$\text{Eqn 4:} \quad E_{TOTAL} = [(E_{TREAT} \times Q_{TREAT}) + (E_{BYPASS} \times Q_{BYPASS})]/[Q_{TOTAL}]$$



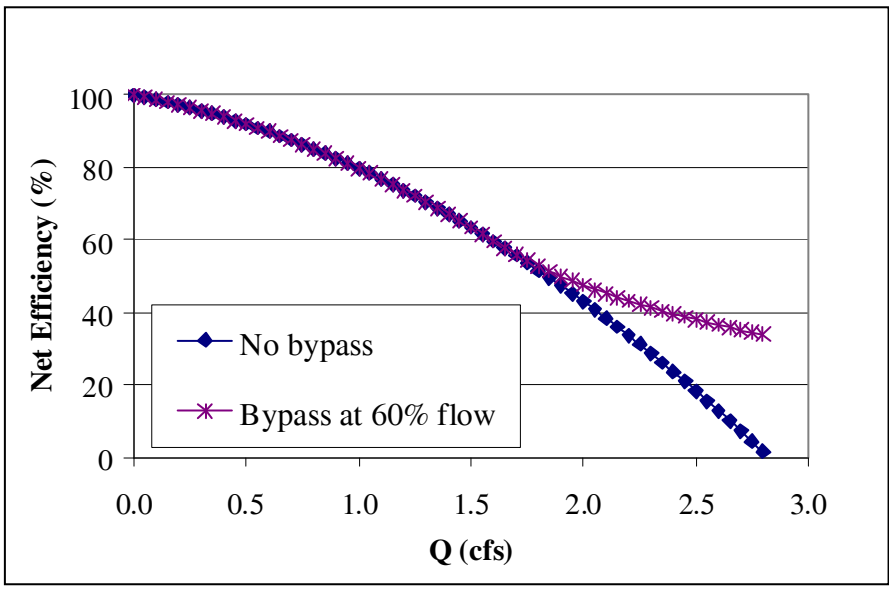
Since $E_{BYPASS} = 0$, then

$$\text{Eqn 5:} \quad E_{TOTAL} = [(E_{TREAT} \times Q_{TREAT})/[Q_{TOTAL}]$$

Equation 5 can be used to solve for the most optimal system operating rate. Equation 3 can be substituted into equation 5 and differentiated with respect to Q. The first differential can then be set to zero and solved for a value of Q with corresponds to the maximum E_{TOTAL}. However a numerical solution is very easy to calculate with a spreadsheet. Given the equations above, a spreadsheet was created to calculate the E_{TOTAL} for the entire operating range of the separator. The spreadsheet calculations are shown in Table 1. In this example, the peak treatment rate is 2.8 CFS and therefore the total flow (Q_{TOTAL}) is set to 2.8 CFS. Column 1 is the flow through the HDS and the removal efficiency (column 2) is calculated using Equation 3 (E_{TREAT}), Q_{BYPASS} (column 3) is calculated from Equation 1 and the total efficiency (column 4) is calculated from Equation 5. The percent peak operating rate (column 5) is simply the ratio of the Q_{TREAT} to Q_{TOTAL}. Graph 2 below is a plot of the results.

Table 1: Numerical Total Efficiency Model of Hypothetical Hydrodynamic Separator.

Q_{TREAT} (cfs)	Removal Efficiency (%)	Q_{BYPASS} (cfs)	Total Efficiency (%)	% of Peak Operating Rate
0.00	100.0	2.80	0.000	0%
0.10	98.7	2.70	3.490	4%
0.20	97.3	2.60	6.877	7%
0.30	95.7	2.50	10.144	11%
0.40	93.9	2.40	13.272	14%
0.50	92.0	2.30	16.243	18%
0.60	89.9	2.20	19.041	21%
0.70	87.6	2.10	21.646	25%
0.80	85.1	2.00	24.042	29%
0.90	82.5	1.90	26.211	32%
1.00	79.8	1.80	28.134	36%
1.10	76.8	1.70	29.794	39%
1.20	73.7	1.60	31.174	43%
1.30	70.5	1.50	32.254	46%
1.40	67.0	1.40	33.019	50%
1.50	63.4	1.30	33.449	54%
1.60	59.7	1.20	33.528	57%
1.70	55.7	1.10	33.237	61%
1.80	51.6	1.00	32.558	64%
1.90	47.4	0.90	31.474	68%
2.00	43.0	0.80	29.967	71%
2.10	38.4	0.70	28.019	75%
2.20	33.6	0.60	25.612	79%
2.30	28.7	0.50	22.730	82%
2.40	23.6	0.40	19.352	86%
2.50	18.3	0.30	15.463	89%
2.60	12.9	0.20	11.045	93%
2.70	7.3	0.10	6.078	96%
2.80	1.5	0.00	0.547	100%



Graph 2: Determination of the optimum operating rate.

Observing this graph, it is clear there is an optimal operating rate, which for this characteristic curve is about the 55% operating rate. This rate corresponds to a treatment efficiency of about 62% (Graph 1). In other words, if a flow rate of say 5,000 gpm (11 CFS) was to be treated, the unit would be sized such that the maximum flow rate would occur at 11 CFS and flows in excess of 6 CFS should be bypassed. Graph 3 represents an overall performance curve for the hypothetical separator for the flow range from 0 to the maximum operating rate (2.8 CFS), considering the case of no bypass as well as bypassing at 60% of the maximum operating rate.

DISCUSS AND CONCLUSIONS

From this analysis it can be concluded that operating hydrodynamic separators to the point of zero efficiency is not the most efficient use of their operational characteristics when looking at the entire flow regime. One thing that may appear surprising about this example is that the instantaneous net system efficiency was 34% and one may say that this is the absolute best the average annual load reduction the unit could achieve. What this model does not address is that frequency distribution of the incident runoff, which is heavily weighted toward small storms and which may result in higher efficiencies. In addition this model is really applicable to a total flow at or less than the peak operating rate. Flows less than those bypassed will be removed at the efficiency of the separator.

Graph 3: Combined efficiency curve showing two bypass conditions (bypass at 60% of peak treatment rate and no bypass)

ABSTRACT

A thorough understanding of the hydrology of a constructed stormwater wetland (CSW) is essential to develop a water budget; that is a comprehensive view of all inputs and outputs in the system. Two of the principal functions of a CSW are to 1) reduce peak flows and 2) improve water quality. The latter is achieved through biological, chemical, and physical processes that are ultimately governed by the hydraulics and hydrology of the system. As these built systems populate the watershed management landscape, it is necessary to account for all flows that pass through the CSW to ensure that it is providing a benefit and does not have any deleterious effects on the watershed. One of the most significant and least understood aspects of a CSW is the groundwater-surface water exchange. This exchange is difficult to quantify, but is deserving of consideration because of the potential impact this exchange has on groundwater and surface water quantity and quality in a CSW system. Therefore, the goals of this study are to 1) use hydraulic and hydrologic computer models to create a water budget of the CSW, with a focus on quantifying groundwater-surface water fluxes, and 2) discuss the implications of how hydraulic and hydrologic processes affect the water quality within a CSW.

1 INTRODUCTION

A growing amount of research is dedicated to identifying the conditions necessary for the successful construction of treatment wetlands. Items commonly cited for a successful design are hydrologic analysis, water source and quality, site selection criteria, plant material selection, soil and geologic conditions, buffer zone placement, and maintenance procedures (Kusler and Kentula 1996). Hydrology has commonly been cited as one of the primary factors in controlling wetland functions (Hammer 1989, Owen 1995). Wetland hydrology has a bearing on the soils and nutrients in the wetland, and therefore has an influence on the character of the ecosystem. The flows and storage volume dictate the retention time of the wetland, and thus, the opportunity for interactions between waterborne substances and the wetland ecosystem. Therefore, the design of a treatment wetland attention must emphasize the system hydrology since treatment efficiency is dependent upon the extent of water-biota interactions and the proximity of waterborne substances to sites of biological and physical activity. (Kadlec & Knight, 1996)

The hydrologic characteristics of constructed stormwater wetlands (CSW) are usually described through development and analysis of a water budget. The water budget is a way to describe the processes through which water is introduced, temporarily stored, and

removed from the CSW. Water is introduced to a CSW through direct precipitation, overland flow, overbank flow, and groundwater discharge. Temporary storage includes channel, overbank, basin, and groundwater storage. Water is lost from the CSW through evaporation, plant transpiration, channel, overland flow, and groundwater recharge (WRP, 1993).

Water budgets are essential for understanding the fluxes of constituents between the hydrologic, biochemical, and ecological systems of a CSW. They also provide information regarding the relationship of the CSW to the surrounding terrain (Dexler et al., 1999). However, there has been very few water budgets compiled for CSW, or wetland systems in general. The development of water budgets for wetlands is hindered by the need for long term monitoring, the difficulty in estimating certain hydrologic components (e.g. the groundwater – surface water exchange), and the laborious nature of data collection (Dexler et al., 1999). The purpose of this research is to develop a water balance for the Villanova CSW that can aid future research in understanding the fate of pollutants within the system, the mechanisms that result in high pollutant removal efficiencies, and the possibility that the CSW is functioning as a volume-reducing BMP. In the present study, an integrated hydraulic and hydrologic model of the CSW is developed using the Danish Hydraulic Institute's (DHI) MIKE 11 and MIKE SHE modeling software. The MIKE SHE software has a water balance tool that will be used to develop a water budget for the Villanova CSW.

2 SITE DESCRIPTION

The Villanova CSW is a mature wetland system that is located on Villanova University's campus in Villanova, Pennsylvania (Figure 1). The CSW was originally a detention basin that was retrofitted in 1999. It was noticed that the soils in some areas of the detention basin were perpetually saturated and thus it seemed an eligible site for a CSW; however, a formal evaluation of the water budget was never conducted. Water is primarily introduced to the system from two pipes that drain part of Villanova University's campus. The total drainage area is approximately 23 hectares, and of this area, 57%, 31%, and 12% of the surfaces are impervious, semipervious, and pervious respectively.

Since 2003, the Villanova CSW has been monitored for quantity and quality performance (Rea 2004; Woodruff 2005; Flynn 2008). During 2007, approximately 20% more water entered the system than exited for the entire year (Unpublished data). Due to infrequent calibration, however, the quality of historical quantity data must be interpreted with caution. According to past research, during base flow conditions average removal efficiencies of total phosphorous and total nitrogen were 60% and 80%, respectively (Rea 2004).

3 MIKE SHE AND MIKE 11 MODELING SYSTEMS

To model the Villanova CSW, the Danish Hydraulic Institute's (DHI) MIKE SHE and MIKE 11 modeling systems were used. MIKE SHE is capable of modeling all processes of the land phase of the hydrologic cycle; these include: precipitation, evapotranspiration, overland flow, channel flow, unsaturated subsurface flow, and saturated groundwater flow. Furthermore, MIKE SHE is capable of simulating interactions between the

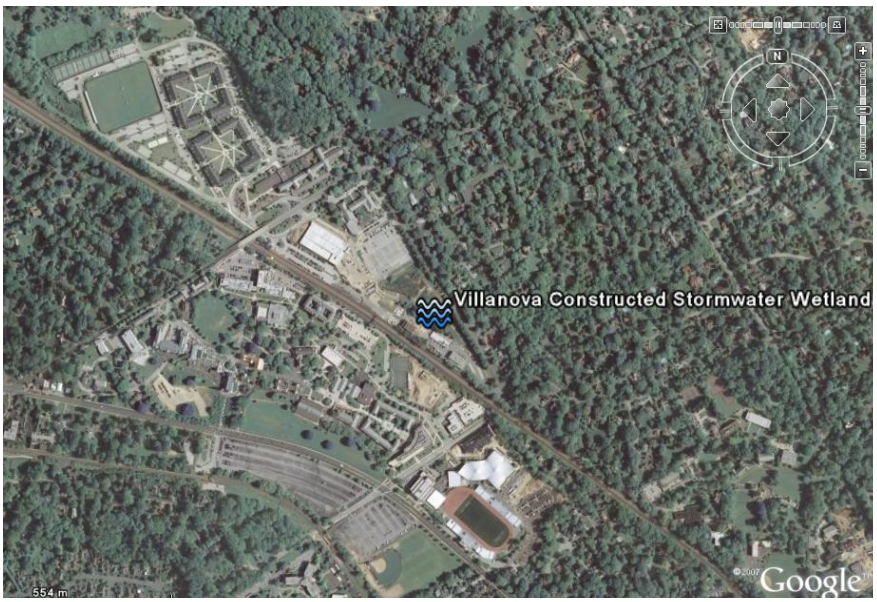

Figure 1. Aerial photograph of Villanova University and the Villanova University Constructed Stormwater Wetland

groundwater and surface water. Geotechnical investigations of the area surrounding the Villanova CSW indicate that the groundwater table may be at or above the bottom of the CSW.

MIKE 11 is a one-dimensional modeling system for rivers and channels. MIKE 11 generates a one-dimensional (1D) simulation of river flows and water levels using the fully dynamic Saint-Venant Equations. It is also able to simulate a wide range of hydraulic control structures, such as weirs, gates, and culverts. The model is based upon user-defined network geometry, cross-sections, resistance, and boundary conditions. MIKE 11 is ideal for modeling the CSW as flow is approximately 1D with some backwater conditions that can be mathematically described by the Saint-Venant Equations.

MIKE 11 and MIKE SHE can be integrated to model overland flow to and from the MIKE 11 river network and to model surface and sub-surface flow processes between the two. The ability to dynamically integrate the channel and overland flow is crucial to the modeling of the CSW since it is essentially a main channel with a wide, heavily vegetated floodplain. The interactions between the river channel and overland flow are modeled using the "overbank spilling option," which treats the river bank as a weir. When the overland flow water level or the river water level is above the left or right bank elevation, then water will spill across the bank based on the standard weir formula:

$$Q = \Delta x \cdot C \cdot (H_{us} - H_w)^k \cdot \left[1 - \left(\frac{H_{ds} - H_w}{H_{us} - H_w} \right)^k \right]^{0.385}$$

where Q is the flow across the weir, Δx is the cell width, C is the weir coefficient, H_{us} and H_{ds} refer to the height of water on the upstream side and downstream side of the weir respectively, H_w is the height of the weir, and k is a head exponent. If the water levels are such that water is flowing to the river, then the overland flow to the river is added to

MIKE 11 as lateral inflow. If the water level in the river is higher than the level of ponded water, then the river water will spill onto the MIKE SHE cell and become part of the overland flow.

4 MODEL DEVELOPMENT

4.1 Field data

The Villanova CSW is a highly monitored research site. As such, a greater than normal amount of input data is available for model compilation. For example, precipitation, inflow, and outflow are measured continuously at five minute intervals. The field data used in compiling the MIKE 11 and MIKE SHE models is discussed in this section.

The flow from the contributing drainage area is conveyed through a storm sewer system and is accounted for as an upstream boundary condition in the MIKE 11 simulation. The flows entering the CSW from the inlet pipes are monitored using Sigma 950 area/velocity bubbler probes. Measurements are taken every five minutes and the equipment is calibrated monthly.

Precipitation is measured at the CSW using a "tipping bucket" rain gauge (American Sigma Model 2149) that is connected to the Sigma 950 located at the inlet. Readings are taken continuously in five minute intervals. This measured rainfall data was input to the model as a uniform distribution over the entire catchment. Based upon the small area of the catchment it is assumed that any variation within the catchment would be negligible.

Kadlec & Knight (1996) recommend that wetland evapotranspiration can be estimated as 80 percent of the evaporation from a Class A evaporation pan. The website for the Pennsylvania State Climatologist posts average daily Class A evaporation pan data for south east Pennsylvania and it is assumed that this data is representative of the CSW. To verify this assumption two plastic containers, approximately 0.7m x 0.45m x 0.25m in size, were filled with water and placed at the CSW. During August, September, and October 2008 daily evaporative losses were recorded on a random basis. The observed losses correlated well with those reported by the Pennsylvania State Climatologist. The Pennsylvania State Climatologist evaporation pan values were multiplied by 0.8 and input into the model as reference evapotranspiration rates.

In 2006, David Blackmore and Associates, Inc. completed a geotechnical investigation of the area adjacent to the CSW. Their investigation consisted of 40 borings and a laboratory soil analysis. The report indicates three layers in the soil profile. Based upon the elevation of the CSW and the elevations of the soil strata described in the report, it was assumed that the soil in the CSW is similar to the soil layer that the geotechnical report refers to as "Stratum III." Stratum III is described as "an orange brown, brown, tan, and gray decomposed/weathered gneiss. The upper portion of this stratum is considered medium dense to dense. The lower portion of this stratum is considered dense to very dense". The soils in Stratum III were classified by Blackmore (2006) as SM soils. The assumption that the CSW soils were similar was visually verified by soil samples taken within the CSW in fall 2008 and near the CSW when wells were drilled in January 2009.

Soil samples collected from the CSW were analyzed in the laboratory to determine the saturated hydraulic conductivity. A flexible wall falling head permeameter test indicated a saturated hydraulic conductivity of 3.55×10^{-6} m/day (0.0014 in/day) and a constant head permeater test indicated a value of 0.23 m/day (9.20 in/day). For compacted SM

soils, published values for saturated hydraulic conductivity range from 0.048 – 0.28 m/day (1.90-10.90 in/day) (Johnsen and Jensen 2001). The saturated hydraulic conductivity in the vertical direction was set to 0.051 m/day (2.0 in/day) because it falls within the range of values and is a conservative estimate. The DHI user manual (2007) states that the horizontal hydraulic conductivity is typically five to ten times greater than the vertical hydraulic conductivity. Therefore, the horizontal hydraulic conductivity was set to 0.382 m/day (15 in/day), 7.5 times the vertical hydraulic conductivity.

In order to model flow between the groundwater and surface water in the CSW the groundwater table must be defined in the model. Since the elevation of the groundwater table is not known explicitly, the water table in the CSW was approximated using a linear regression model between four points at which the water table was known: three boring wells and Mill Creek, the downstream receiving water body. The water table between the three wells and Mill Creek formed a near perfect linear relationship ($y = -0.0184x + 419.44$ ft, $y = -0.0184x + 127.87$m, $R^2 = 0.9999$, Figure 2). Based upon this linear regression, a groundwater table was defined and entered in the MIKE SHE model.

The bedrock constitutes the lower boundary of the model. Blackmore (2006) reports that gneiss bedrock was encountered in four of the test borings. The maximum elevation at which bedrock was encountered was 417.92 feet. However, one of the boring was extended to 50 feet without encountering bedrock. For this model, the bedrock elevation was estimated to exist at an elevation of 375 ft.

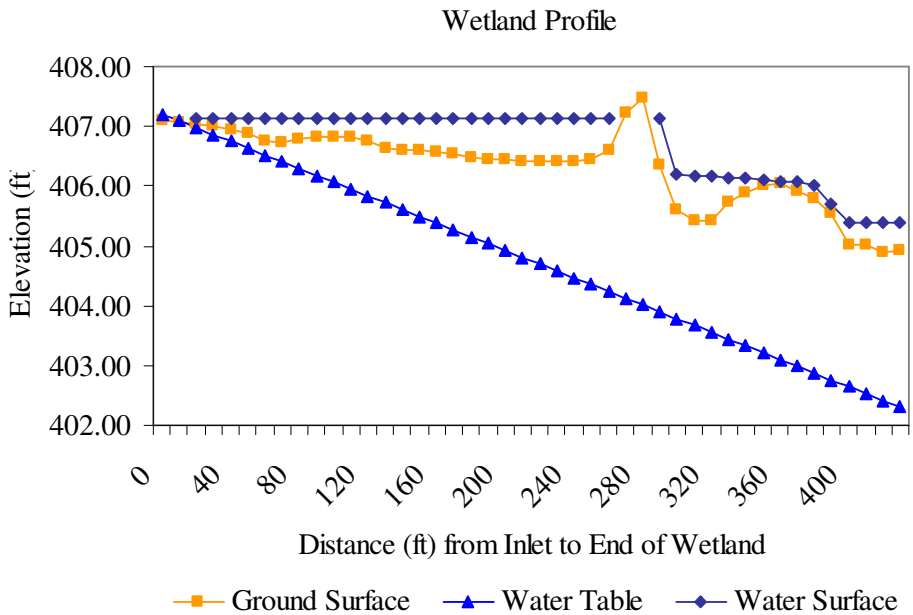

Figure 2. Estimated Surface Water, Ground Surface, and Groundwater Profiles

4.2 MIKE SHE

The first step in developing a MIKE SHE model is setting the simulation specifications. This includes the simulation period, time step controls, and computational control parameters. All the phases of the hydrologic cycle were selected, including overland flow, rivers and lakes (channel flow), unsaturated flow, evapotranspiration, and saturated flow. The simulation period for this model is May 1, 2007 to May 31, 2007. The time

steps are set to the recommended default values as per the MIKE SHE User Manual (2007).

The second step in developing a MIKE SHE model is defining the model domain and grid. The domain is defined as the perimeter of the CSW. A topographic survey of the CSW from the summer of 2007 was used to delineate this area. This topography was also used to define the ground surface in MIKE SHE and the cross-sections in the MIKE 11 simulation. The grid size was set to one meter by one meter on a 200 meter by 250 meter grid.

The overland flow in MIKE SHE is simulated using an explicit numerical solution of the diffusive wave approximation. The input data required for the calculation of overland flow are the Manning's number, detention storage, and the initial water depth on the ground surface. A Manning's number of 0.08 was used based upon recommended values for a floodplain with medium to dense brush (Chow, 1959). The detention storage is used to limit the amount of water that can flow over the ground surface and is equivalent to the trapping of surface water in small ponds or depressions within a grid cell. The detention storage was set to 0.25 millimeters. The surface area of the CSW having an initial water depth (standing water) was delineated using aerial photographs of the CSW and ArcMap 9.2.

The soil information gathered from the geotechnical report and laboratory analyses was used to define the soil properties in the unsaturated and saturated zones. The vertical flow in the unsaturated zone is calculated using a simple two-layer water balance, which is suggested in the DHI User Manual (2007) when there is a shallow water table, such as in the CSW. The main purpose of this method is to calculate evapotranspiration and the amount of water that recharges the saturated zone. The model assumes that if sufficient water is available in the root zone, the water will be available for evapotranspiration. The output is an estimate of the actual evapotranspiration and the groundwater recharge.

In the saturated zone, spatial and temporal variation of the hydraulic head are described mathematically by the three-dimensional Darcy equation and solved numerically by an iterative implicit finite difference technique. The saturated zone component interacts with the other components of the MIKE SHE model by using the boundary flows from other components implicitly or explicitly as sources and sinks.

4.3 MIKE 11

As previously mentioned, MIKE 11 is a one-dimensional hydrodynamic software package based on the complete dynamic wave formulation of the Saint Venant equations for open-channel flow. It was used to simulate flow and water level through Villanova's CSW and is integrated with MIKE SHE as part of SHE's Rivers and Lakes module. Cross-sections were created approximately every 20 meters along the main channel. The cross-section geometry is based upon the topographic survey from 2007. The upstream boundary condition is the inflow from the inlet pipes. As previously described, this inflow is continuously monitored using Sigma 950 area/velocity bubbler probes. The model was run several times with varying Manning's numbers to see which value generated an outflow hydrograph most similar to the actual, measured outflow hydrograph.

4.4 WATER BALANCE

After developing and running an integrated MIKE11/MIKESHE model, the output is used by the water balance editor to generate a water balance for the simulation. As described in the MIKE SHE User Manual (2007), the water balance editor is "a post processing tool which provides a clear, unambiguous summary of flow and storage changes for the individual model components as well as for the entire model." It also provides an "analysis of errors occurring in the model due to input data or numerical instabilities." The compilation of a water balance for the CSW is the primary goal of this study.

5 RESULTS

Before attempting to integrate the MIKE SHE and MIKE 11 models, each model was run separately to verify the simulations. Outflow hydrographs created by the MIKE 11 hydraulic model of Villanova's CSW are only moderately correlated with actual measured hydrographs ($r = +0.70$). Figure 3 depicts the actual measured outflow hydrograph as well as outflow hydrographs generated by MIKE 11 based upon Manning's numbers of 0.04 and 0.12. Although the modeled inflow exactly mirrors the actual inflow of the CSW, the hydraulic models consistently overestimate the volume of water exiting the system. MIKE 11 consistently overestimates the volume of outflow by 32%, indicating that nearly a third of the total volume is unaccounted for. There is also a distinct spike at the beginning of the actual hydrograph that has not been replicated by MIKE 11.

As a free-standing model, MIKE SHE has been run successfully. Without being linked to MIKE 11, direct precipitation on the wetland is the only input to the system. The majority of flows introduced to the system come from the inlet pipes. These flows are introduced to the wetland system via MIKE 11, and cannot be simulated in MIKE SHE until it is integrated with MIKE 11. The current conditions simulated in MIKE SHE are considered unrepresentative of the CSW and as such the results from MIKE SHE are extraneous. However, the model was pre-processed and a water movement simulation was run without errors or warnings, indicating that it will be capable of simulating the system when integration occurs.

Both models are properly functioning independently, however, MIKE 11 and MIKE SHE have not been successfully integrated yet. The main technical problem with integrating the two models is the geo-referencing. The world is properly represented as a three dimensional object; however, maps can only represent two of those dimensions. Frequently, designs are created in abstract space without any geographic reference point. The 2007 topographic survey of the CSW was created in abstract space. The input files for MIKE 11 were generated from this survey, while the input files used for MIKE SHE were generated from spatially referenced data. A spatial reference point can be applied to non-referenced data, such as the CSW survey. By providing the CSW survey with a spatial reference the input files for both MIKE 11 and MIKE SHE can be created in the same geo-spatial data frame. After correcting the spatial referencing it will be possible to integrated the models and generate a preliminary water budget of this CSW.

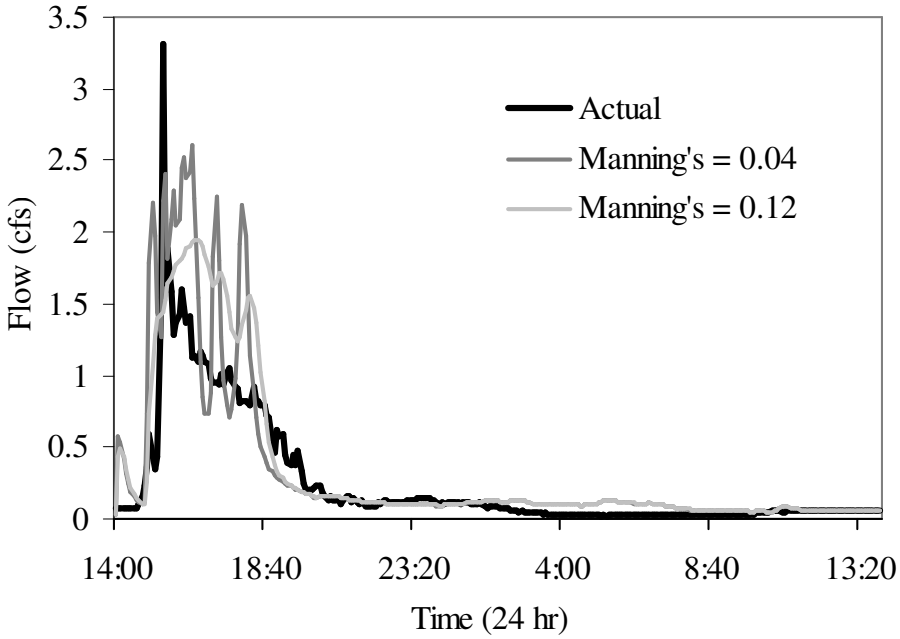

Fig 3. Actual Outflow Hydrograph and MIKE11 Model Outflow Hydrographs for a Manning's numbers of 0.04 and 0.12

6 Discussion & Future Work

The MIKE11 model has consistently overestimated the volume of water leaving the wetland when compared with the measured outflow volume. This overestimation has occurred in several trials with varying values of Manning's number. A possible reason for this overestimation is that there are real losses that are not accounted for in the MIKE 11 model alone, such as infiltration, evaporation and transpiration. It is anticipated that this discrepancy in outflow volume will be resolved by incorporating the MIKE11 model with the MIKE SHE model since the SHE model can account for system losses such as infiltration, evaporation, and transpiration.

Furthermore, the MIKE11 model has been unable to replicate the spike observed at the beginning of the actual hydrograph. This initial spike in outflow is most likely due to direct overland flow and precipitation on the CSW. MIKE SHE is capable of simulating precipitation and overland flow, and when integrated with MIKE 11 will account for this spike.

When completed, the integrated model of the CSW is expected to be a useful tool for discerning the movement of water and waterborne constituents through the system. However, the output generated by the model must be interpreted with caution. The input data used to compile this model is based predominantly on approximations and assumptions. If actual conditions in the CSW vary from the conditions specified in the model than the output may be misleading. For example, it is commonly recognized that a great deal of spatial variation may exist when considering hydraulic conductivity and other soil properties. Thus, continued calibration, verification and collection of monitored data will continue to build an exhaustive dataset of varied CSW conditions. In addition, current research is focused on investigating the effects of temperature on water viscosity and thus on the infiltrative capacity of soils (Emerson, 2008). It is

recommended that future models be designed to investigate the impact of such variations as opposed to using a single value to represent the entirety of the system, as was done in this study.

This model also utilizes water table elevations that were estimated based upon a geotechnical investigation completed over 18 months prior to the simulation period of the model. The water table elevation is susceptible to fluctuations based upon antecedent dry or wet weather. Therefore, the available groundwater data may not be representative of the groundwater elevations occurring for the specified time duration of the model. Wells were installed around the CSW in January 2009 and will be equipped with monitoring data to continuously record the water table elevation.

There is also uncertainty surrounding the estimated evapotranspiration rates. Although the regional evaporation pan data was reduced by 20% to estimate evapotranspiration, as per Kadlec and Knight (1996), this technique is merely a general rule of thumb. Furthermore, the location of the reference evaporation pan was approximately 75 miles from the CSW. Variations in solar radiation, temperature, wind speed, and humidity between the two locations could cause error in the estimated evapotranspiration values. A parallel study at Villanova is examining evaporation; this data can be used in the future for localized rates.

Although there may be inherent error in the model, uncertainty in assumptions can be reduced by continuing to build the library of data for the CSW. The model serves as a valuable tool for understanding the hydrology of the CSW and provides the research team with a preliminary water balance. The development of a water balance clarifies the significance of each component of the budget on the CSW's functions. Additionally, the budget is the first step towards understanding the fate of nutrients and other contaminants in the CSW system on a unit process scale.

Abstract

Bioretention is a principal low impact development (LID) practice. This paper examines two critical questions associated with bioretention design and construction. First, fill media is perhaps the major cost in constructing bioretention cells, so shallower media depths would be preferred, were they to work as well as deeper media systems. Two sets of bioretention cells of varying media depths in the upper coastal plain of North Carolina have been monitored since April 2008. They treat an impervious asphalt parking lot watershed in Nashville, NC. The bioretention cells were constructed with media depths of 0.6 and 0.9 m. Performance is being measured with respect to hydrology and water quality. Data show the deeper media depths meet the LID hydrology goal of volume reduction more frequently (35% compared to 9% of 45 events monitored).

The second question examines how bioretention cells are excavated. Two excavation techniques, the conventional "scoop" method which purposefully smears the underlying soil surface and the "rake" method which uses the teeth of an excavator's bucket to scarify the underlying soil surface, were tested. Field tests were conducted on three soil types (sand, loamy sand, and clay) and under a variety of antecedent soil moisture conditions. Saturated hydraulic conductivity, surface infiltration, and soil compaction were measured for each excavated condition. In all cases, the rake method of excavation yielded more permeable, less compacted soils than the scoop method. The difference of infiltration and hydraulic conductivity between the two excavation techniques was statistically significant ($p<0.05$) when tests were conducted in wet soil conditions. Also, the infiltration rate at the clay site was significantly lower ($p<0.05$), and the hydraulic conductivity at the sandy site was significantly lower ($p<0.05$), when the scoop methodology was used. Based on results of this experiment and because there is essentially no extra cost associated with the rake method of excavating bioretention cells, the rake method of excavation is recommended over the conventional scoop method. The use of the rake method is expected to increase long term exfiltration from bioretention cells.

Keywords: bioretention; low impact development; media depth; exfiltration; construction impacts; stormwater runoff.

Introduction:

As part of the National Water Quality Inventory, 32% of assessed estuaries and 47% of assessed lakes/reservoirs were identified as impaired. The main cause for impairment was nutrients. Urban stormwater runoff was among the top three sources

for the impairment in these water bodies (USEPA, 2007). Historically, flooding had been the primary concern related to urban runoff because of reduced pervious land surfaces to infiltrate water. Newer concerns of water quality issues have arisen because of excess amounts of nitrogen, phosphorus, and heavy metals found in urban stormwater (USEPA, 1983).

In order to minimize the negative effects caused by urbanization and to meet the new stormwater rules, strategies, such as Low Impact Development (LID), that employ infiltration are increasingly adapted. The goal of LID is to plan and construct a site so that the hydrology and water quality mimic that of the initial undeveloped site (Davis, 2008). Bioretention is a very common LID practice, which meets several design goals: (1) hydrologic, (2) water quality, and (3) aesthetic.

Bioretention combines a natural and engineered system to manage stormwater from developed areas. They are designed to at least treat the water quality volume of runoff. Bioretention removes runoff pollutants through adsorption, biological decomposition, filtration, and sedimentation. Evapotranspiration (ET) and exfiltration play major roles in volume reduction in a bioretention cell, which are important for pollutant load reduction (Hunt et al., 2006 and Li et al., 2009).

Previous field (Dietz and Clausen, 2006; Davis et al., 2006; Hunt et al., 2006; and Hunt et al., 2008) and laboratory studies (Davis et al., 2001; Hsieh and Davis, 2005; and Davis et al., 2006) have shown that bioretention has good removal rates of and low effluent concentrations for total nitrogen (TN), total Kejhdhal nitrogen (TKN), heavy metals, oil/grease, and total suspended solids (TSS). However, removal of nitrate has been poor in conventionally drained systems.

In NC, media depth requirement is based on vegetation. The minimum media depth is 0.6 m for cells vegetated with grass or shallow rooted plants and 0.9 m for cells vegetated with shrubs or trees (NCDWQ, 2007). In comparing six bioretention cells in NC and MD, Li et al. (2009) showed that deeper media depths appeared to promote more infiltration and ET and that the deeper media depths more closely mimicked pre-development hydrology. They concluded that media depth may be a controlling design parameter to meet target hydrologic performance goals.

With all of the research published on bioretention, limited data exist on how construction activity impacts their performance. One study by Tyner et al. (2009) studied innovative construction techniques to improve exfiltration from permeable pavement, in regions with clay in-soil. They treated the subgrade with boreholes, a subsoil ripper, and trenches. Disturbing the compacted bottom layer created a significant increase in exfiltration compared to the undisturbed control plot (Tyner et al., 2009). If construction processes are optimized to promote higher exfiltration rates from the bottom layer of bioretention cells, outflow volume will decrease, which will consequently decrease pollutant loads released to the storm drain network.

Compaction has an important influence on soil hydraulic properties, including soil water retention, soil water diffusivity, and hydraulic conductivity. All of which govern infiltration rates (Horton et al., 1994). Natural infiltration is negatively affected by removal of surface soils and exposure of subsurface soils. Earth moving equipment can compact the soil, which decreases subsoil permeability (Gregory et al., 2006). Also, rainfall on exposed subsoil has also been shown to cause surface sealing, which will decrease infiltration rates (Gimenez et al. 1992).

Gregory et al. (2006) examined the effects of compaction on infiltration at urban construction sites in North Central Florida. Infiltration was measured in non-compacted and compacted soils from three land types. Overall, construction activity reduced infiltration rates 70 to 99% at all sites. Pitt et al. (2008) showed results similar to Gregory et al. (2006): typical compaction considerably reduced infiltration rates. Tests on both clay and sandy soils showed that infiltration rates were significantly reduced in compacted soils, and clay soils were less able to withstand low levels of compaction compared to sandy soils.

One way bioretention cells function to remove pollutants is by reducing the ratio of outflow to influent runoff (Hunt et al., 2006; and Li et al., 2009). Promoting more exfiltration from the bottom layer of the bioretention cell will improve pollutant removal capabilities of bioretention. This can be accomplished through varying construction techniques and conditions to minimize compaction and promote exfiltration. Understanding hydraulic properties of the in-situ soil are important to estimate bioretention performance and its ability to enhance groundwater recharge (Shuster et al., 2007).

Media Depth

In answering the first of the two critical questions associated with bioretention design and construction, the effects of bioretention performance were examined based on fill media depth. Fill media is perhaps the major cost in constructing bioretention cells, so shallower media depths would be preferred if they to work as well as deeper media systems.

Site Description

The field site is located in the parking lot of a Wal-Mart Supercenter in Nashville, NC. The store was constructed from June 2007 to February 2008, and monitoring began on April 12, 2008. There are seven bioretention cells that treat runoff from the front half of the Wal-Mart parking lot. Three are connected to one outlet drain, and the other four are connected to another outlet drain. The set of three cells have a media depth of 0.9 m, and the set of four cells have a media depth of 0.6 m. Due to backwater constraints, the last cell in each set was not monitored. All the cells are designed to capture and treat the 2.5 cm storm. The bioretention cells were covered by mulch, shrubs, perennials, and trees, and these cells were designed with conventional drainage. The asphalt parking lot, which drains to the bioretention cells, experiences heavy use.

After several months of data collection, it was realized that the bioretention cells were undersized. The actual ponding depth and surface storage area of the bioretention cells were much less than the design specifications. The actual surface storage volume is only 38% and 45% of the designed surface storage volume for the 0.6 m and 0.9 m media depth cells, respectively. Monitoring of this configuration will continue through March 2009. All data presented herein were collected from these "undersized" cells. In April 2009, the surface storage volume will be increased to be closer to the design volume. Monitoring will continue for 12 more months to compare the difference in performance of undersized cells to those designed to treat the water quality event. A summary of the site characteristics are given in Table 1.

Table 1. Summary of characteristics for monitored bioretention cells in Nashville.

Design Characteristics	**0.6 m Media Depth**	**0.9 m Media Depth**
Number of Cells Monitored	3	2
Drainage Area	6580 m^2 (1.62 ac)	4310 m^2 (1.06 ac)
Impervious Area	79%	94%
Design Cell Storage Volume	97 m^3 (3430 ft^3)	69 m^3 (2440 ft^3)
Actual Cell Storage Volume	37 m^3 (1300 ft^3)	31 m^3 (1110 ft^3)
Actual Storage Capacity Compared to Design	**38%**	**45%**
P-Index (Fill Media)	11-18 (Low)	
Fill Media Composition	86-89% Sand & 11-14% Fines	

Methods

The monitoring equipment used include: ISCO 6712 Automated Portable Samplers to monitor hydrology and collect flow-weighted composite samples, ISCO 730 Bubbler Flow Modules in combination with weirs to measure outflow, and ISCO 674 Rain Gauge to measure rainfall. In Nashville, runoff enters each bioretention cell at two curb cuts. A rectangular weir with end contractions was installed at one of the curb cuts to collect a representative sample of the entire parking lot. Initial abstraction values of 2.0 mm (0.08 in) for the impervious asphalt parking lot (CN = 98) and 13.5 mm (0.53 in) for impervious surfaces (CN = 79) were subtracted from rainfall to calculate runoff volumes.

Flow-weighted composite samples were analyzed for nutrients and TSS. The nutrient species being analyzed include: Ortho-P, TP, NH_3, $NO_{2,3}$-N, TKN, and TN. Samples are collected and taken to the NCSU Center for Applied Aquatic Ecology laboratory within 24 hours (EPA-certified laboratory).

Results and Discussion

In Nashville, forty-five runoff producing events were monitored for hydrology, since monitoring began on April 12, 2008. Of these events, the mean and median rainfalls were 19.4 mm and 13.3 mm, respectively. Hydrology performance was analyzed by examining the 24 hour volume reduction – a LID hydrology goal first proposed in Davis (2008). With this performance measure, it was found that the bioretention cells with 0.9 m deep media met the LID hydrology goals more frequently (35%) compared to the 0.6 m deep cells (9%). Davis (2008) proposed that if the inflow volume is reduced by two-thirds, the site will meet the LID hydrology goal of 24 hour volume reduction. The 24 hour time period was selected because outflow from bioretention occurs for long periods of time at very low rates. Two-thirds reduction was chosen because the rational method C coefficient of a highly pervious surface is about 0.9, and it is about 0.3 for an undeveloped area (Davis, 2008). This is represented by the dashed line in Figure 1. In comparing these results to the six sites of varying media depths presented in Li et al. (2009), the 0.6 m media depth cells performed worse than all six sites. It even performed worse than the lined cell with 0.5-0.6 m media depth in Louisburg, NC, and this was the only site that the 0.9 m media depth cells performed better than.

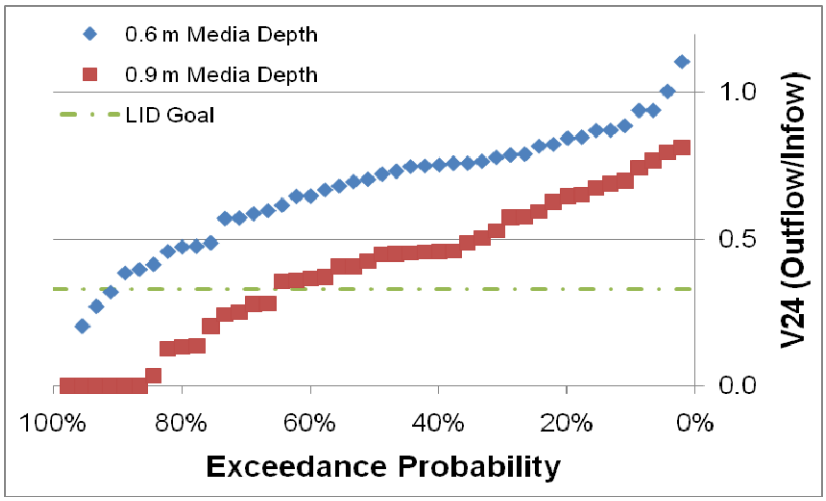

Figure 1. Exceedance of 24 hour volume reduction in Nashville bioretention cells.

Combined underdrain and overflow are being monitored in the outflow. Runoff not measured in the outflow has been lost through exfiltration and ET. Since the cells have the similar surface areas and vegetation, it is assumed that the difference in ET between the two cells is small. In the 0.9 m media depth cells, 38% of runoff is lost through ET and exfiltration compared to 23% for the 0.6 m media depth. This supports Li et al. (2009), in that deeper cells promote more exfiltration. In comparing the overflow, the 0.9 m media depth has 37% of the influent water leaving as overflow, where the 0.6 m media depth has 41% as overflow. The reason for the 0.6 m media depth having slightly more overflow is that it has a smaller surface storage volume compared to the 0.9 m media depth. The remaining flow is released by the underdrains, as seen in the water balance in Figure 2.

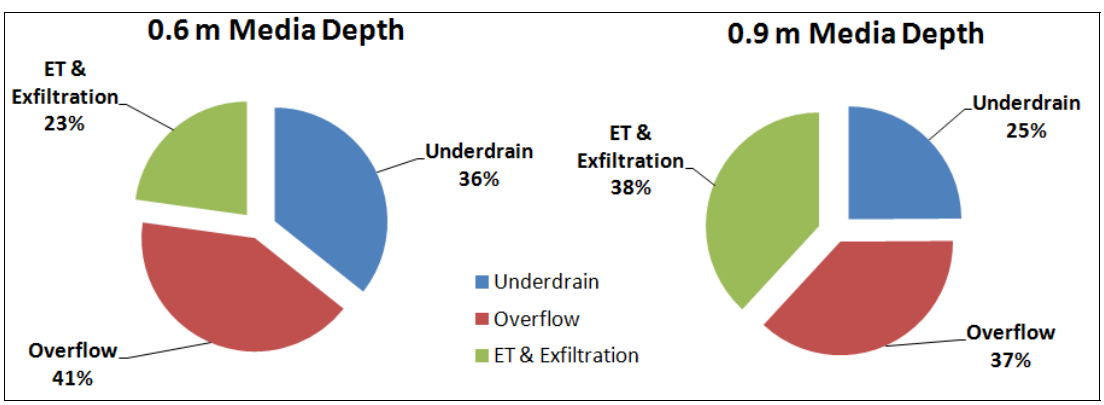

Figure 2. Fate of runoff in Nashville bioretention cells.

Out of the 45 monitored events, ten have been greater than the design storm (2.5 cm), so there should have been at most ten events producing overflow. However, due to the reduced surface storage, 29 and 26 events produced overflow in the 0.6 m and 0.9 m deep cells, respectively. For properly constructed cells, better performance would be expected. However, the data still show that the deeper media cells are performing better with respect to meeting the hydrologic goal of volume reduction than the shallower media cells.

Construction Impacts Study

The second critical question associated with bioretention design was to find ways to improve exfiltration through the bottom of bioretention cells during construction. Excavation technique, soil moisture condition, and soil type were all examined to find ways to improve exfiltration to the in-situ soil.

Construction Description:

Bioretention cells were constructed in an area of clay soil, representative of the Piedmont region of NC (NCSU Lake Wheeler Field Research Facility in Raleigh), and in an area of sandy soil, representative of the upper coastal plain of NC (Nash County Agricultural Center in Nashville). In order to be consistent with typical bioretention construction, a fill media depth of 0.6-0.9 m was used.

The excavation techniques used were a "rake" versus a "scoop" approach. Examples of the two methods can be seen in Figure 3. The "rake" approach used the teeth of the backhoe bucket to scarify and till the surface, where the "scoop" technique had more smearing and compaction associated with it. The "scoop" technique is consistent with sewer and utility line placement, where the surface is smoothed and compacted to minimize shifting and settling. Due to the maximum compaction levels occurring between 20 to 30 cm during construction, emphasis was placed on using consistency in technique for excavating the final 30 cm of soil (Gregory et al., 2006).

Figure 3. Demonstration of excavation – rake method (left) vs. scoop method (right).

Another method was excavating in different soil moisture conditions – wet soil versus dry soil. In order to test the difference of these conditions, excavation in dry soil took place after several consecutive dry, warm days. To test for excavation in wet soil, the cell was manually irrigated overnight to saturate the soil. One cell was randomly selected as the "wet" cell and the other was designated as the "dry" cell, and each of these was randomly divided into two roughly equal sized sections to test the different excavation techniques.

Monitoring Methods:

After excavation was complete, field testing took place. The order of testing was as follows: (1) soil samples were weighed on site to test for gravimetric soil moisture content at the time of construction, (2) double ring infiltrometers and soil cores were placed at test sites to avoid foot traffic, (3) soil was tested for compaction, and (4) infiltration tests were run and soil cores were taken. For each combination of

excavation technique, soil type, and antecedent moisture condition, there were two soil samples collected for measuring gravimetric soil moisture content; six soil cores to test for hydraulic conductivity, bulk density, and porosity; three infiltration tests; and fifteen soil compaction measurements. A summary of the methods and devices used to determine the soil properties are in Table 2.

Table 2. Summary of devices and methods to determine soil properties.

Soil Property	Testing Device	Method	Notes
Permeability	Amoozemeter	Amoozegar, 2006	Pre-excavation
Gravimetric soil moisture content	Scale	ASTM D 2216 (ASTM, 2005)	Field
Infiltration	Double ring infiltrometer	Bean et al., 2007	Field, 30 and 61 cm diameter rings
Soil compaction	Spectrum Field Scout SC-900 hand cone penetrometer		Field, five tests per infil. test (Gregory et al., 2006)
Sat. hydraulic conductivity	Constant head test	Klute, 1986	Laboratory, 7.6 cm diameter cores
Dry bulk density	Weigh oven-dry core		Laboratory, bulk density = mass solids / total volume
Particle size analysis	Hydrometer method	Gee and Bauder, 1986	Laboratory

The pooled dataset of infiltration and saturated hydraulic conductivity were not normally distributed. A Box-Cox transformation was applied to the infiltration and saturated hydraulic conductivity data, with shift parameters of 0.22 and 0.44, respectively (Box and Cox, 1964). Box-Cox transformation was used because it provided the most consistent variances, and Levene's test (homogeneity of variance test) showed it was the best method of transformation. Once the transformed dataset was normally distributed, ANOVA was run using SAS version 9.1.3

Results:

Nashville (Sandy Soil Site):

Bioretention cell construction at the Nash County Agricultural Center took place from August 2-3, 2008. The antecedent weather conditions for the two weeks prior to construction were hot and dry. Despite being separated by 1.5 m, the soil texture differed between the two test plots. The soil texture, as classified by the USDA, was loamy-sand for the "dry" test plot and sand for the "wet" test plot.

For both soil conditions tested, infiltration and saturated hydraulic conductivity decreased when the scoop method was used. This was due to increased soil compaction associated with more scoop method bucket contact, which consequently increased the bulk density. As the compaction and bulk density increased, water movement through the soil slows down (Horton et al., 1994).

Plotting the residuals of hydraulic conductivity versus the residuals of bulk density and taking into account the effects of excavation technique and soil moisture

condition, there was a statistically significant negative association of hydraulic conductivity to bulk density (p-value = 0.017). As bulk density increases, hydraulic conductivity is reduced, which was seen for soil samples from the "scoop" method.

Raleigh (Clay Soil Site):

Bioretention cell construction at Lake Wheeler Field Labs, in Raleigh, took place from October 10-12, 2008. The antecedent weather conditions for nine days prior to construction were warm and dry. Similar to the results from the Nashville site, infiltration and saturated hydraulic conductivity were lower when the scoop method was used. This was due to increased soil compaction associated with more bucket contact from the scoop method. Based on particle size analysis and the USDA classification, the soil texture for the "dry" cell was sandy-loam for the rake method and clay for the scoop method, and the soil texture of the "wet" cell was clay.

Combined Results:

The datasets were pooled to test the impacts that excavation technique, antecedent moisture condition, soil type, and interactions among the three had on infiltration and saturated hydraulic conductivity. P-values for the combinations based on soil condition are presented in Table 3. Analyzing the data based on soil condition showed there was a significant impact of excavation technique on infiltration and saturated hydraulic conductivity for the wet condition (p-values = 0.036 and 0.005, respectively), but no significant impact existed for the dry condition.

Table 3. Effects of soil condition on infiltration and hydraulic conductivity (p-values)

Factor (Soil Condition – dry vs. wet)	Excavation Technique	Excavation Technique & Soil Type
Infiltration (dry)	0.153	0.932
K_{Sat} (dry)	0.508	0.573
Infiltration (wet)	**0.036**	0.499
K_{Sat} (wet)	**0.005**	0.623

P-values for the combinations based on soil type are presented in Table 4. There was a significant impact of excavation technique on hydraulic conductivity in sandy soil (p-value = 0.024) and infiltration rate in clay soil (p-value = 0.047), but no significant impact existed for infiltration rate in sandy soil or hydraulic conductivity in clay soil. There was no effect on soil condition in the clay site, but there was a significant impact on infiltration and saturated hydraulic conductivity at the sandy site. This was due to the "dry" cell having loamy-sand in-situ soil, compared to sand.

Table 4. Effects of soil type on infiltration and hydraulic conductivity (p-values).

Factor (Soil Type – clay vs. sand)	Excavation Technique	Soil Condition (dry vs. wet)	Excavation Tech. & Soil Condition
Infiltration (clay)	**0.047**	0.511	0.629
K_{Sat} (clay)	0.173	0.952	0.202
Infiltration (sand)	0.148	**<0.0001**	0.845
K_{Sat} (sand)	**0.024**	**0.030**	0.222

Conclusions

The Nashville bioretention cell data are similar to those found in the literature. Deeper media depths meet the LID hydrology goal of volume reduction more frequently than the shallower media depths (35% compared to 9% of 45 monitored events). This is because the cells with deeper media depths are exfiltrating more water. For properly constructed cells, better performance would be expected. Despite the relatively poor performance, the results still show that deeper media cells perform much better with respect to meeting the hydrologic goal of volume reduction.

Using the teeth on the bucket to rake the final 30 cm of soil, instead of scooping the soil improved the soil properties that govern infiltration. The rake method scarified the bottom layer in the bioretention cell. This increased the soil's ability to exfiltrate water from bioretention cells to the underlying soils. Using the scoop method reduced the potential for exfiltration because it compacted the soils to a greater extent, as evidenced by higher bulk densities and compaction measurements.

In particular, when excavating in wet conditions, the hydraulic conductivity and infiltration rate associated with the rake method were significantly more than that of the scoop method (p-values = 0.005 and 0.036, respectively). The hydraulic conductivity associated with the rake method of excavation were significantly more at the sandy soil sites (p-value = 0.024), and the infiltration rate associated with the rake method of excavation were significantly more at the clay soil sites (p-value = 0.047). Based on the results of this study and because there is no extra cost associated with the rake method, it is recommended to use the rake excavation technique in preference to the "conventional" scoop method for future bioretention or other infiltration BMP projects to decrease outflow volume and pollutant loads.

Acknowledgements:

The authors would like to acknowledge the Cooperative Institute for Coastal and Estuarine Environmental Technology (CICEET) and NC Department of Environment and Natural Resources (NCDENR) for funding this project. Thanks to NCSU faculty, Dr. Aziz Amoozegar, Dr. Greg Jennings, and Dr. Jason Osborne. The authors sincerely appreciate Joe Wright for his help in excavating the bioretention cells exactly how they needed to be. Thanks to everyone involved with this project at the Lake Wheeler Research Facility and Nash County Ag. Center for their cooperation, in particular Mike Wilder, Bill Lord, Joni Tanner, and Ken Snyder. Also thanks to NCSU-BAE staff and students for their assistance.

ABSTRACT

Erosion is an important consideration in remediation strategies of slopes at contaminated sites such as mine tailings. Pelletized waste materials offer the dual advantages of waste utilization and soil erosion prevention at such sites. These materials could be designed to reduce stormwater runoff by optimizing their infiltration capacities, to trap the eroded soil particles and pollutants before they get to the nearby lakes and streams, and store sufficient moisture for supporting vegetation. In this paper, we present the results of our study that focused on flow, erosion, and filtration through an erosion control blanket built with three different particle size ranges of pelletized waste materials. The finest gradation is used on the upper portion of the slope, and the medium and coarse gradations are used in the lower portions to act as graded filters for the upper portion. The density, gradation, and erodibility properties of the waste materials are used for calculating the flow, internal erosion, filtration, and moisture retention in the erosion control blanket. The model is intended to aid in the engineering design of erosion-resistant blankets on slopes. It optimizes the physicochemical and hydraulic characteristics of the pelletized waste materials to fulfill diverse functions of an erosion blanket, viz., erosion resistance, runoff inhibition, moisture retention to support vegetation, and controlled infiltration.

INTRODUCTION

Soil erosion is a world-wide problem that is causing early deterioration of public infrastructure, and pollution of surface and ground waters. As compared to vegetated landscapes, exposed soil slopes of earth structures and waste disposal sites experience

higher levels of erosion due to rainfall. Engineering suitable methods to prevent erosion for protecting environment is now a statutory requirement in many countries. In the United States of America (USA), the Clean Water Act (CWA) and the National Pollutant Discharge Elimination System (NPDES) are being enforced to prevent pollution of surface and ground waters from point and non-point sources of pollution.

In the United States, the annual soil loss due to erosion is estimated at 4 billion tons. Soil erosion results in loss of fertility, leaching of nutrients and pesticides, increased sedimentation of drainage systems and water bodies, and increased cost of drinking water treatment. In USA, the estimated annual economic loss considering these costs is put at 44 billion dollars (Brady and Weil, 2004). As per NPDES Phase II, that is in force from 2003 in USA, any activity disturbing soil on areas measuring 1 acre or over must have an approved storm water pollution prevention plan (SWPPP).

Faucette et al (2005, 2007), and Osorio and Ona (2006) studied the suitability of compost for preventing soil erosion and compared the stormwater quality with other options for erosion control. Gyasi-Agyei (2004, 2005) described the use of compost for preventing erosion and establishment of grass on slopes.

In this paper, we have presented the results of our recent studies on the performance of erosion control blankets composed of pelletized waste materials. Several waste materials, including compost, can be pelletized to result in particle aggregates of desired properties and gradations. Successful erosion control blankets can be designed based on the properties and gradations of pelletized waste considering their resistance to erosion, self-filtration potential, and capacity to retain moisture and nutrients for promoting growth of vegetation.

WASTE MATERIALS IN EROSION CONTROL

Utilization of waste materials in erosion control reduces the need for disposing them in landfills, which are becoming increasingly expensive due to cost of urban lands. The treated wastes for erosion control should have low self-erodibility characteristics, long-term chemical stability, and capacity to retain moisture and nutrients for supporting vegetation. Pelletization of compost and similar materials increases their particle sizes, and improves their resistance to degradation and self-erosion.

In USA, the Environmental Protection Agency (EPA), the Composting Council Research and Education Foundation (CCREF), the U.S. Composting Council (USCC), and the federal and state Departments of Transportation (DOTs) have started to advocate and regulate the use of compost for preventing soil erosion. Similar efforts are underway to utilize pelletized inorganic industrial wastes in pollution prevention applications. However, the use of pelletized waste as erosion control blankets is hindered due to lack of understanding of their mechanism, design methods, and performance histories.

In this study, we are developing a mathematical model that considers the flow through different sections of an erosion control blanket, erodibility of waste pellets, and migration and filtration of eroded particles. Fig. 1 shows the schematic of a three-section erosion control blanket. The gradation of pellets is finer in the top section, medium in the middle section, and coarser in the bottom section. This variation is chosen to allow the water to flow freely inside the blanket without emerging on the slope. It is also meant for filtering and retaining any soil particles and contaminants that are getting eroded in the upper sections.

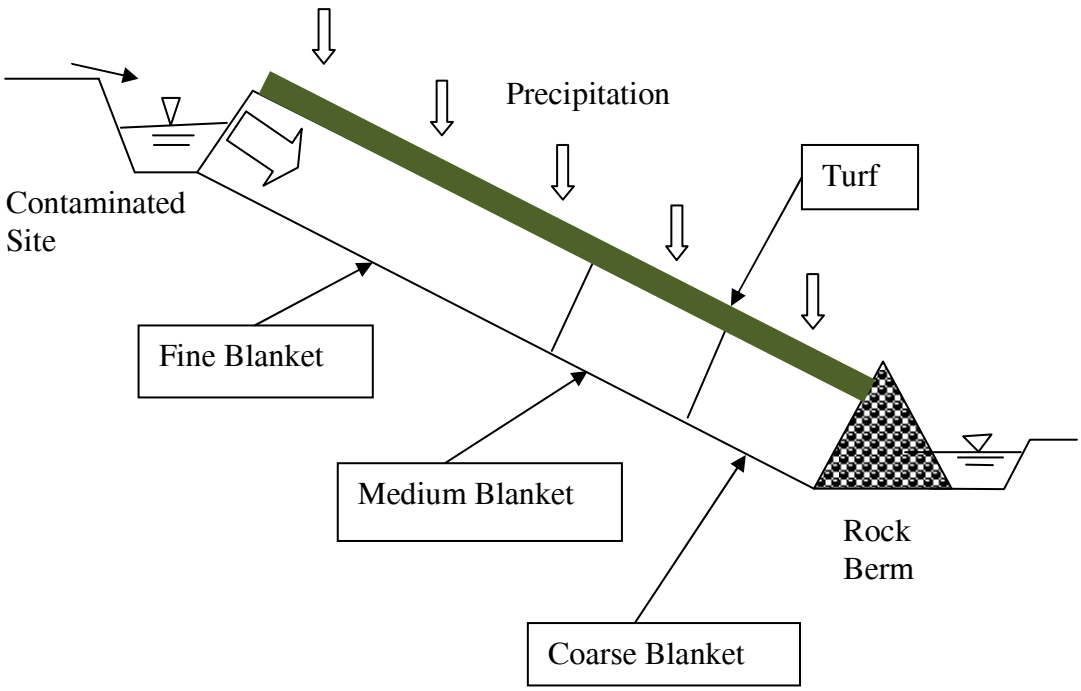

Fig. 1. Schematic of a three-section erosion control blanket of pelletized waste

As shown in Fig.1, the top ditch collects all the discharge from the contaminated site and facilitates flow of that influent through the erosion control blanket. The turf prevents erosion of blanket due to rainfall, but allows some infiltration. The thickness of the erosion control blanket shall be sufficient to safely conduct the inflow entering at the top and rainfall infiltration, without seepage emerging on the top of the blanket. Also, the blanket shall have suitable particle gradation for retaining moisture to support vegetation during dry seasons. The gradation of medium blanket and coarse blankets shall satisfy the filtration criteria with respect to their upper section so that the seepage would not result in soil loss or pollution.

INTERNAL & SURFACE EROSION AND MOISTURE RETENTION

The success of an erosion control blanket depends on the design choices of particle gradations and section thicknesses. Such a design exercise shall consider possible surface erosion (before and after establishment of vegetation), the internal erosion

and filtration processes, and moisture retention. The hydraulic conductivities of any particulate material can be estimated for initial and life-cycle stages by considering void ratio, particle characteristics, and particle gradation. These parameters change during the life cycle due to erosion, and escape/entrapment of particles due seepage.

Surface Erosion

The Revised Universal Soil Loss Equation (RUSLE), Renard et al (1997), is a widely used method for estimating annual soil losses due to surface erosion. It is given as:

$$\mathbf{A = RKLSCP} \qquad \mathbf{(1)}$$

where A is the long-term annual average soil loss, R is the rainfall-runoff erosivity factor, K is the soil erodibility factor, L is the slope length factor, C is the crop and cover management factor, and P is the support practice factor. Kinnell (2007) reported that RUSLE over estimates small event soil losses and under estimates large event soil losses. Alternative advanced models of rainfall induced surface erosion were described by Tayfur (2001), Lie et al (2005), Liu et al (2005), Raff and Ramirez (2005), Visser et al (2005), and Walter et al (2007).

Internal Erosion

The internal erosion of the finer blanket can be estimated by idealizing its pore space as a bundle of capillary tubes and calculating the shear stresses causing erosion. The model reported by Kakuturu and Reddi (2006) can re-written in this context as:

$$\mathbf{m_{er} = E\{\tau(t) - \tau_{cr}\}p\Delta t} \qquad \mathbf{(2)}$$

where m_{er} = the mass eroded in time interval Δt,

E = erodibility rate expressed as mass eroded per shear stress difference, area

$\tau(t)$ = the shear stress on the walls of that idealized pore tube at any given time

τ_{cr} = the critical shear stress of the material, and

p = the surface area of that idealized pore tube

The shear stress, $\tau(t)$, can be estimated using the discharge as:

$$\mathbf{\tau(t) = 4\eta Q(t)/(\Pi\, r_{cc}^3)} \qquad \mathbf{(3)}$$

where η = dynamic viscosity of the seeping water,

Q(t) = the flow rate at any time t, and

r_{cc} = the radius of the idealized pore tube.

The internal erosion and subsequent partial re-deposition of eroded particles gradually reduces the hydraulic conductivities of medium and coarse sections during the life-cycle. Therefore, the design objective is to ensure that their hydraulic conductivities remain more that the desired values even at the end of life cycle. Reddi et al (2000) reported a model for estimating permeability reduction due to the entrapment of eroded particles in pore spaces.

Moisture Retention

The variation of gradation along the different parts of such a blanket configuration results in differences in the moisture retention capacity. This impacts the growth of vegetation and surface erodibility. Moreover, internal erosion of finer blanket may, over several years, reduce the moisture retention capacity of finer blanket. On the other hand, entrapment of eroded particles may increase the moisture in lower parts.

EXPERIMENTAL INVESTIGATIONS

For verifying the potential of pelletized compost blankets to resist erosion, a series of laboratory experiments were conducted at the Kansas State University, Manhattan, KS (USA). As shown in Fig. 2, a laboratory model of compost erosion control blanket was tested by simulating the precipitation using a rainfall simulator.

Fig 2. Erosion testing of a 3-section compost blanket using a rainfall simulator

Pelletized compost (patent pending) manufactured by Earth Solutions, LLC, was used in our study. Two configurations were tested: (1) Mixed compost, with same gradation throughout, which was a mixture of three particle size ranges viz., fine, medium, and coarse; (2) Filtered compost, a 3-section blanket with fine, medium, and coarse size ranges arranged in separate sections from top to bottom, respectively. The compost sections were filled up in the test box (914 mm x 305 mm x 178 mm). The test box was placed at a slope of 1:3 (V:H), a typical value of slopes where erosion control is critical.

Six repeated rainfalls at an average intensity of 63.5 mm/hour were created for 1-hour duration each time. Six tests on each configuration were first conducted without vegetation. Four tests were repeated after establishing vegetation by embedding grass seeds between the base soil and compost blanket. In all the tests, the eroded material

was collected and weighed for obtaining erodibility rate. The results of the tests on un-vegetated and vegetated blankets are presented in Fig. 3 and Fig. 4, respectively.

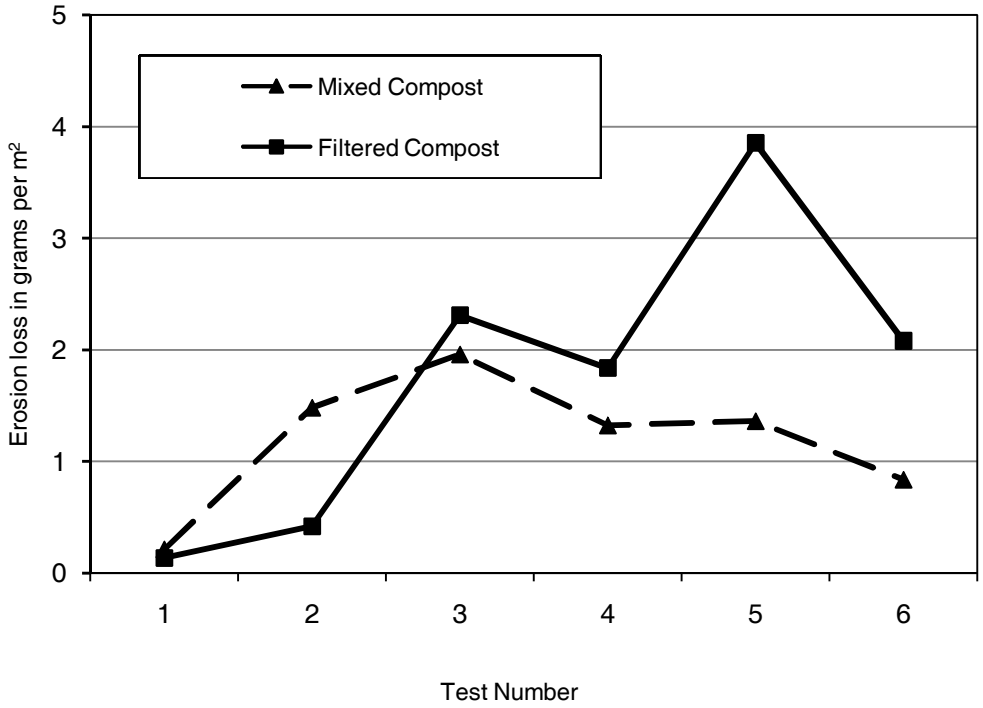

Fig. 3. Comparison of surface erosion losses of compost blankets (without vegetation)

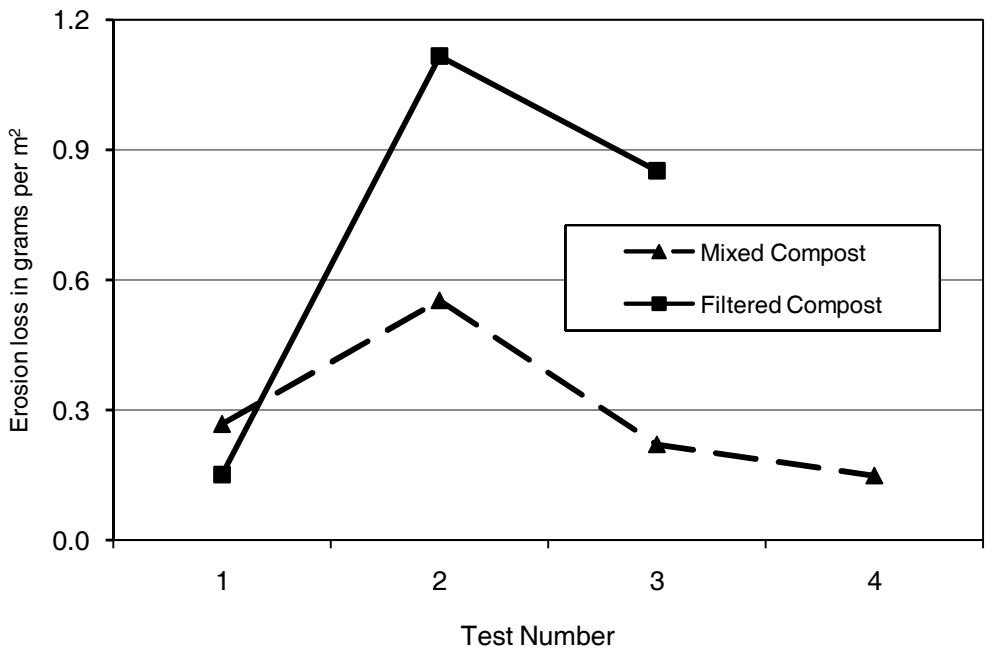

Fig. 4. Comparison of surface erosion losses of compost blankets (without vegetation)

DISCUSSION AND CONCLUSIONS

It is seen from the experimental results that the mixed compost resulted in lower values of surface erosion losses compared with filtered compost. These results suggest that mixed compost, that is very well graded, has more resistance to surface erosion than filtered compost whose sections are not well graded. The surface erosion losses were smaller with vegetation than without vegetation. These results suggest that vegetation substantially reduces surface erosion of compost blankets.

Until now, the experimental part of our study was focused on surface erosion caused by precipitation on the slope. However, it is also needed to study the base flow (as shown in Fig.1) for considering erosion and filtration within the blanket. A comprehensive approach considering all the surface and internal phenomena could result in better mechanistic understanding of erosion control blankets.

Acknowledgments

The authors wish to thank Kansas Livestock Association and Agri Beef Co. who have supported some of the research reported in this paper. We are also thankful to David Suhling, Research Technologist in the Department of Civil Engineering at Kansas State University, for his important role in the design and construction of the experimental apparatus. The authors greatly appreciate the contributions of Joshua Howard, Alice Devine, and Rick R. Stott to this research.

ABSTRACT

Rain gardens effectively remove some stressors from stormwater, but in most cases they show much smaller removal rates of nitrate, likely due to the media's high sand and low organic matter content that inhibit nitrate removal by denitrification. EPA's pilot-scale research explores the use of shredded, unprinted newspaper as a carbon source to fuel denitrification. A bench-scale experiment was conducted to test the drainage capability of media containing shredded newspaper layers. Stormwater was introduced at low and high rates to bins containing zero, one, and two layers of newspaper at varying depths. While there were differences in effluent flow rates between control and newspaper treatments, surface ponding occurred in all three treatments, suggesting that some other factor besides the newspaper had an effect on drainage properties. Grain size and clay mineralogy analyses indicated that migration of finer particles into the deeper soils could have inhibited drainage.

Key words: rain gardens, bioretention, low-impact development, urban stormwater, nitrate, denitrification, soil media, carbon amendment, newspaper

INTRODUCTION

Excess nitrogen (N) is among the most widespread and pervasive pollutants in surface waters throughout the United States (USGS, 1999). The U.S. Geological Survey's National Water Quality Assessment program findings show that elevated

nitrate (NO_3^-) in streams and groundwater is as common in urban areas as in agricultural areas (USGS 1999). In urban watersheds, stormwater runoff from impervious surfaces carries an associated N load to storm drains that empty into receiving waters (Klein, 1979; Lee et al., 2004). Some practitioners are championing low-impact development practices, such as rain gardens, as a more sustainable approach than conventional stormwater management approaches for mitigating the hydrologic flows and environmental stressor loads associated with urban stormwater (Walsh et al., 2005; Dietz, 2007). Rain gardens have been shown to be particularly effective in removing total suspended solids, heavy metals, phosphorus, and some N species (Davis et al., 2001; Davis et al., 2003; Dietz and Clausen, 2005; Davis et al., 2006; Dietz and Clausen, 2006; Hunt et al., 2006; Davis, 2007; and Hsieh et al., 2007).

Practitioners currently specify rain garden media with high sand content and low organic matter content to promote infiltration and sorption of heavy metals and phosphorus (Dietz, 2007). However, this design inhibits denitrification, the biological transformation of NO_3^- to nitrogen gas (N_2) that is released to the atmosphere. Denitrification requires anaerobic conditions and organic carbon as an energy source to drive the reaction. The few NO_3^- removal studies in laboratory, pilot-scale, and field-scale rain gardens have mostly shown low rates of NO_3^- removal (Davis et al., 2001; Kim et al., 2003; Dietz and Clausen, 2005; Hsieh and Davis, 2005; Davis, 2007) and in some cases, NO_3^- production (Davis et al., 2001; Barrett, 2003; Davis et al., 2006). However, Dietz and Clausen (2006) did find reasonable rates of nitrate removal in another study.

Through the manipulation of soil media, vegetation, and rain garden size, pilot-scale rain garden mesocosms at the Urban Watershed Research Facility (UWRF) in Edison, New Jersey, will be designed to facilitate denitrification and NO_3^- removal by providing organic matter hotspots, soil media saturation at depth, plant uptake, and larger media volume and depth. The pilot-scale test adds shredded, unprinted newspaper, a recalcitrant organic carbon source, to the rain garden media. Newspaper's high lignin and cellulose content and ability to retain moisture may allow it to act as a hotspot for denitrification in rain garden systems over the long term (McClain et al., 2003). In a column study Kim et al. (2003) demonstrated that adding shredded newspaper to rain garden media increased NO_3^- removal rates more than other carbon sources tested, including wood chips, wheat straw, leaf mulch compost, sawdust, and alfalfa.

In Kim et al.'s (2003) column study the shredded newspaper was mixed homogeneously with the sandy media. While feasible in small-scale applications, this becomes more difficult for full-scale rain gardens because it requires mixing large volumes of media and shredded newspaper. In the UWRF pilot-scale rain gardens the shredded newspaper will be added into the media in layers rather than mixed homogeneously; however, there are concerns that this layered approach may make the newspaper act like a boundary layer. Consequently, a bench-scale test of the system is necessary to ensure that the shredded newspaper layers do not impede stormwater infiltration and drainage and thus result in saturated or ponded conditions for an unacceptable period.

The primary objectives of this study are to 1) test the ability of bench-scale

rain gardens to drain stormwater through sandy media containing layers of shredded newspaper, and 2) isolate the components of the bench-scale system which may impede drainage. Drainage capability will be tested using sandy media only, sandy media plus one-newspaper layer, and sandy media plus two-newspaper layer treatments. This paper presents the results of the completed bench-scale study; the pilot-scale study will be initiated in the spring of 2009.

METHODS

Experimental Apparatus

The bench-scale test system consisted of three 90-cm long x 60-cm wide x 60-cm deep plastic bins raised 90 cm above the floor on cinder blocks in a greenhouse. The bins were elevated to enable gravity drainage to cylindrical containers (55.9 cm diameter, 85.1 cm deep). All three bins contained a horizontal, 3.75-cm slotted PVC pipe 2 cm from the bottom that routed water through the wall of the bin and to the collection container. The slotted pipes were wrapped in nonwoven, permeable, polypropylene geotextile fabric (US Fabrics Inc., Cincinnati, OH, model 115NW) to prevent clogging and media loss.

The first bin, which served as a control treatment, was filled with a sand-clay soil mix used for baseball infields in New Jersey (NJ Gravel and Sand, Wall, NJ). State infield mixes are commonly used in rain garden applications. Media characteristics are presented in Table 1.

Table 1. Characteristics of Bench-Scale Study Media

Soil Characteristic	Value
% Passing Sieve # 270	10-20%
% Sand	81%
% Silt	9%
% Clay	10%
Compacted Bulk Density	1.80-1.86 g cm^{-3}
Organic Matter Content	1.56%

Note: Sieve data and compacted bulk density were specified by the manufacturer. Organic matter content was measured at EPA's laboratory facility. All other parameters were measured at the Rutgers University Soil Testing Laboratory.

A freeboard of 5 cm was maintained above the media during installation; this was true in all three bins. The media was added as gently as possible to reduce compaction, and it settled about 2 cm before, and an additional 2 cm following, stormwater introductions. The second bin, which served as the one-newspaper layer treatment, was filled with media and included one 2.5-cm layer of shredded, unprinted newspaper (American Veterans Group, Riva, MD) 11 cm from the top of the bin. Newspaper was also added gently by hand to reduce compaction during initial installation. The third bin, which served as the two-newspaper layer treatment, was filled with media and contained two 2.5-cm layers of shredded newspaper 48 and 11 cm from the top of the bin. Newspaper was shredded using a conventional office cross-cut shredder which produces confetti-type shred with dimensions of 3.125 cm x

0.125 cm.

Stormwater Additions

Urban stormwater runoff from a 9.75-acre area of an adjacent community college parking lot and high-density residential development was collected from an outfall at the UWRF and stored on site in an 11-m^3 holding tank in the greenhouse. Mixed stormwater was introduced to the bins at a set rate using a spray bar secured slightly above the media surface.

During the low-flow test, 40 L of stormwater were introduced to each bin during a two-hour interval, a rate equivalent to 333 mL min^{-1}. Bins were run one at a time, once per day, for two work weeks (i.e., 10 runs in each bin) during June 2008. The order in which the bins were run was changed daily. During the subsequent high-flow test, 100 L of stormwater were introduced to each bin during a two-hour interval, again, once per day, for two weeks during July 2008. This rate of introduction is equivalent to 833 mL min^{-1}. Both the high- and low-flow rates are relatively low (both are two orders of magnitude lower than one gallon min^{-1} ft^{-2}).

The cylindrical drainage containers were placed under the drain in each of the three bins to collect all effluent. Each drainage container was instrumented with a water level logger (Global Water model WL16) to measure effluent depth at six-minute intervals. The rate of change of the measured effluent depth was used as a surrogate for effluent flow rate.

Media Analysis

Following the hydraulic experiments, tests were performed on the media to quantify grain size and soil characteristics. One soil core was taken in the center of each bin to the bottom of the bin using a ¾ inch-diameter Oakfield corer. Cores were separated into 3-cm profile segments and stored at 4°C until analysis. The number of profile segments varied from four to six among bins due to varying amounts of media settling and compaction during coring. Samples were prepared and analyzed for particle size distribution on a Coulter counter model LS 230 (Beckman Coulter, Inc., Fullerton, CA). A sample of the original, uncompacted media used to fill the bins was sent to the Rutgers University Soil Testing Laboratory for texture analysis. Approximately 10 g of the original air-dried media were sent to EPA's AWBERC Laboratory for clay mineralogy analysis.

Data Analyses

One-way analysis of variance (ANOVA) tests were used to compare effluent flow rates and volumes among treatments. On each day from Tuesday through Friday, all three bins experienced approximately the same amount of drying time since the previous stormwater introduction; therefore, these runs were treated as statistical replicates. Tests were performed using Statistica 7 (StatSoft, Inc., Tulsa, OK). Fisher's LSD, Bonferroni, Scheffe, and Tukey's HSD post hoc tests were used to compare treatment means; reported results are from Tukey's HSD tests.

Particle size distribution of the soil depth profiles is presented in the results as the 10^{th}, 25^{th}, 50^{th}, 75^{th} and 90^{th} percentiles (D_{10} through D_{90}). Mean particle size in each depth profile was analyzed separately for each percentile using one-way

ANOVA. Overall mean and median particle sizes were also analyzed for each depth profile using ANOVA. Coefficient of uniformity (C_u) was calculated as D_{60}/D_{10}, and particle size range was calculated as D_{90}/D_{10}. ANOVA was used to analyze differences in C_u and range by soil depth. The three bins were treated as statistical replicates for all particle size tests because the same media was used in all three treatments.

RESULTS

Effluent Flow Rates

The control treatment had larger effluent flow rates than both newspaper treatments during the low-flow test (Figure 1).

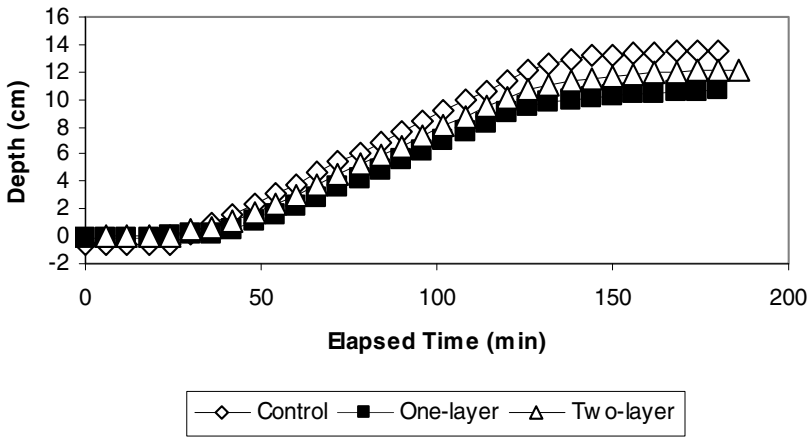

Figure 1. Effluent depths from one representative day (6/23/08) of the low-flow test.

This difference was statistically significant for the Tuesday through Friday runs when composited over both Week One and Week Two (Table 2a).

Table 2. Results of ANOVA Tests Comparing Differences in Effluent Flow Rates

a

Test	Overall Model[a]	Control vs. One-Layer[b]	Control vs. Two-Layer[b]	One-Layer vs. Two-Layer[b]
Full Test	$F_{2,16} = 9.03$ $p < 0.01$	$p < 0.05$	$p < 0.01$	ns
Week One	ns			
Week Two	$F_{2,5} = 11.8$ $p < 0.05$	$p < 0.05$	$p < 0.05$	ns

Full Test	ns			
Week One	$F_{2,9} = 6.84$ $p < 0.05$	$p < 0.05$	ns	ns
Week Two	$F_{2,9} = 21.6$ $p < 0.001$	ns	$p < 0.05$	$p < 0.001$

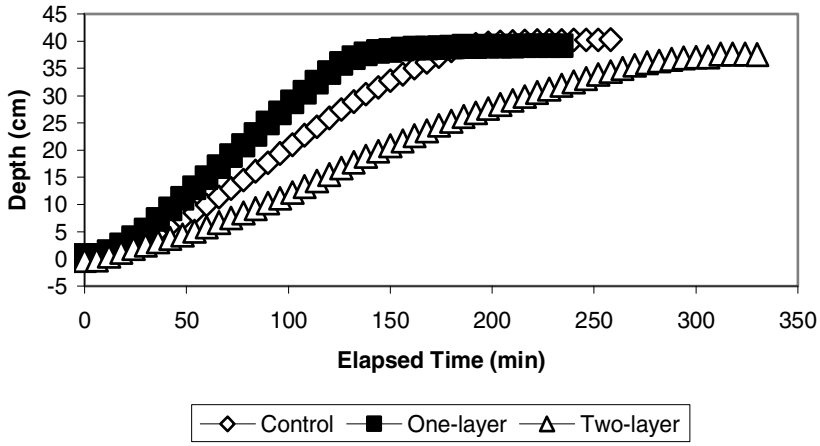
[a] Results from one-way ANOVA tests. Post hoc tests were performed when ANOVAs were significant.

[b] Results from Tukey's HSD post hoc tests.

Note: Tuesday through Friday results from the low-flow test are presented in part a; Tuesday through Friday high-flow test results are in part b. Nonsignificant results are indicated by the abbreviation "ns".

The two newspaper treatments were not significantly different from each other. There were no significant differences in flow rates during Week One Tuesday through Friday runs, but the control treatment had significantly higher flow rates than both newspaper treatments during Week Two Tuesday through Friday runs (Table 2a).

A much different pattern emerged during the high-flow test. Surface ponding occurred in all three treatments, and drainage times increased. Overall, the two-layer treatment had much smaller effluent flow rates than the other two treatments (Figure 2).



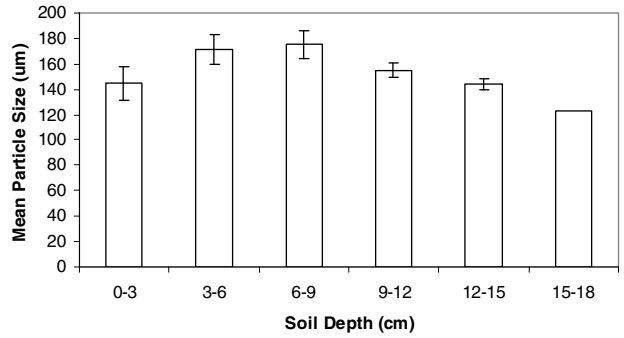


Figure 2. Effluent depths from one representative day (7/23/08) of the high-flow test.

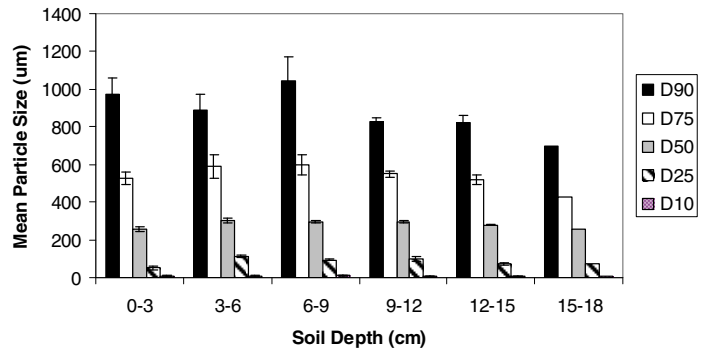
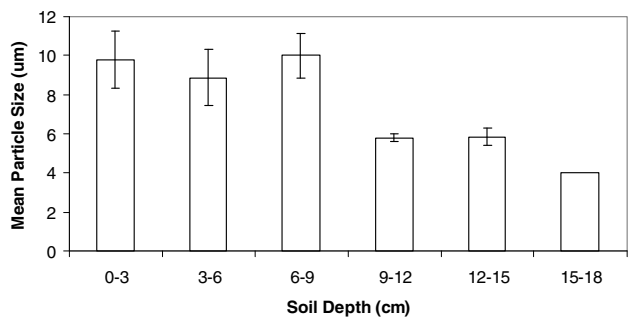


The Tuesday through Friday runs demonstrated no significant differences in flow rates during the high-flow test taken as a whole (Table 2b). During Week One Tuesday through Friday runs, flow rates were significantly larger in the control treatment than the one-layer treatment (Table 2b). However, during Tuesday through Friday runs of Week Two, the two-layer treatment had significantly smaller flow rates than both the control and one-layer treatments (Table 2b).

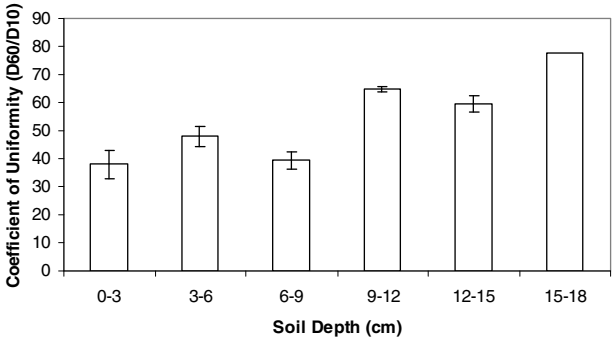
Media Grain Size Analysis



The media was found to contain a high percentage of silt and clay and had a low organic matter content (Table 1). No significant differences were found in particle size distributions among 3-cm depth profile increments in any of the parameters tested. However, there were some nonsignificant trends in the data. Overall, there was a trend toward smaller particle sizes with depth in overall mean particle size and mean particle size in the 90^{th}, 75^{th} and 10^{th} percentiles (Figures 3a-c).

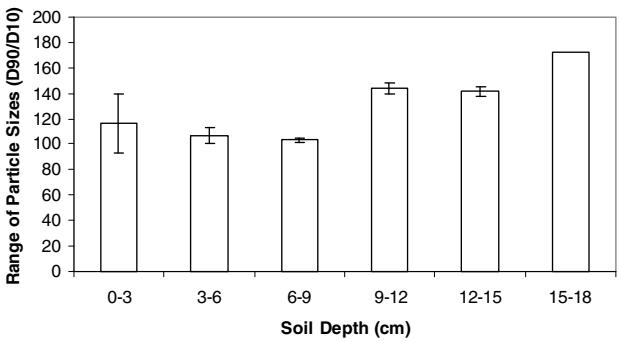
a

b



c

Figure 3. Mean particle size overall (a), by percentile (b), and for D_{10} (c). Error bars represent standard errors at each soil depth increment.



The trend was particularly apparent in comparing the first three depth increments (0-3, 3-6, and 6-9 cm) with the last three depth increments (9-12, 12-15, and 15-18 cm), so the analyses were rerun compositing the first three and last three depth increments. Mean particle sizes were significantly larger in the upper 9 cm of media compared to the bottom 9 cm when the first three and last three soil depths were composited for analysis. The primary clay minerals contained in the media were illite, kaolinite, goethite, gibbsite, and a vermiculite/chlorite-like mineral.

There was also a trend of increasing coefficient of uniformity and particle size range with depth in the media profile (Figures 4a-b), again, with the most visible difference between the first three and last three depth profiles. Both coefficient of uniformity and particle size range were significantly lower in the upper 9 cm of the

media compared to the bottom 9 cm when the first three and last three soil depths were composited for analysis.

a

b

Figure 4. Coefficient of uniformity (a) and range of particle sizes (b) by soil depth. Error bars represent standard errors at each soil depth increment.

DISCUSSION

There were some differences between the control treatment and the two newspaper treatments, but because all three treatments demonstrated extensive surface ponding and slower drainage times during the high-flow treatment, the shredded newspaper is likely not the only factor impeding drainage. Other likely factors include the nonwoven geotextile wrapped around the drainage pipe and the relatively large percentage of clay particles in the media. The results from the media grain size analysis suggest the clay may be playing a role in reduced drainage capability. In particular, smaller mean particle sizes, both overall and at D_{10}, in the lower 9 cm of the media compared to the upper 9 cm, suggest that the smaller clay particles may be migrating to the lower half of the media profile (Figure 3) and forming a clay layer that impedes drainage. The larger coefficient of uniformity and range in the lower 9 cm compared to the upper 9 cm of the media (Figure 4) suggest that the particle size distribution is less uniform and spans a wider range of particle sizes at depth. This pattern points to the presence of more small clay particles in the lower half of the media profile, which could inhibit drainage. The clay contained in the media consists of minerals which are not typically prone to swelling; however, illite is known to absorb water and become gel-like if saturated. This could have a negative effect on drainage.

The shredded newspaper does affect effluent flow rates. There are some indications that the newspaper may be impeding drainage compared to media that does not contain the newspaper (Figures 1 and 2). The difference in flow rates is not large enough to conclude that shredded newspaper layers are an impractical soil amendment in rain garden applications.

CONCLUSIONS

Results of this bench-scale study indicate that layers of shredded, unprinted newspaper in rain garden media reduce stormwater effluent flow rates. However, the reduction in flow rates is not large enough to preclude the use of shredded newspaper layers in rain garden applications. Findings also suggest that great care should be taken in choosing engineered media. A media with too much clay or too great a range in particle sizes could result in downward migration of small particles. This could negatively impact drainage rates.

EPA Aging Water Infrastructure Research Program: State of the Technology for the Condition Assessment and Rehabilitation of Wastewater Collection Systems

Daniel J. Murray, Jr., P.E., M.ASCE[1]

[1]U.S. Environmental Protection Agency, Office of Research and Development, National Risk Management Research Laboratory, 26 W. Martin Luther King Drive (689), Cincinnati, Ohio, 45268, PH (513) 569-7522, e-mail: murray.dan@epa.gov

ABSTRACT

In 2007, the U.S. Environmental Protection Agency's Office of Research and Development (ORD) initiated a new research program to address our nation's aging water infrastructure. Under this new program, ORD established the goal to conduct research and demonstrations, and develop technical guidance to transfer innovative technologies and approaches for:

- More cost-effective operation, maintenance, repair and replacement of aging and failing drinking water and wastewater systems and
- Development and application of advanced designs and management approaches for drinking water and wastewater systems.

In addition, in its research plan for this new program, ORD structured the program following an advanced asset management framework. Under this framework, the program would focus primarily on buried water infrastructure and investigate new and innovative technologies and approaches for condition assessment, rehabilitation and infusion of advanced concepts. This paper presents the issues and state of the technology for the condition assessment and rehabilitation of wastewater collection systems, as defined to support this new research program.

CONDITION ASSESSMENT OF WASTEWATER COLLECTION SYSTEMS

Since the passage of the Water Pollution Control Act Amendments, better known as the Clean Water Act (CWA), in 1972, the major focus of sewer system condition assessment and rehabilitation has been the reduction of infiltration and inflow (I&I). Requirements for sewer system assessments were codified in the Rules and Regulations for Sewer Evaluation and Rehabilitation (40CFR35.927) and stated that U.S. EPA construction grants could not be approved unless there was documentation that sewer systems contributing to municipal wastewater treatment plants were not exhibiting "excessive infiltration and inflow." (EPA, 1991)

The focus of sewer system condition assessment and rehabilitation on the reduction of I&I, almost exclusively targeted excessive hydraulic loading in collection systems and at treatment facilities to lower capital and operation and maintenance costs, and to prolong the lifetime-capacity of the treatment facility. (EPA, 1991) While I&I still plague our current wastewater collection systems and is linked to our current challenges relating to sanitary sewer overflows (SSOs) and wastewater blending, comprehensive asset management is broadening the focus of sewer system condition assessment. In addition to condition assessment that seeks to determine

excessive hydraulic loading and I&I, currently practiced comprehensive asset management assesses the likelihood that a capital infrastructure asset will deteriorate and potentially fail, and the consequences of that deterioration and failure in terms of costs and effect on the system's ability to deliver desired services and meet performance measures. (GAO, 2004)

As the focus of condition assessment continues to broaden to include targets beyond the reduction of excessive hydraulic loading due to I&I, sewer system inspection technologies and investigation approaches must evolve. More innovative technologies will take advantage of observation and detection technologies, such as sonar, laser, ultrasonic, and infrared, not traditionally applied to sewer system investigation. In addition, the deployment of these non-traditional technologies will be supported by emerging digital, modular, and robotics technologies to greatly expand the "reach" of sewer system inspection techniques.

Corrosion of wastewater collection infrastructure, especially concrete sewers, is a significant cause of deterioration and premature failure. When exposed to the internal atmosphere of gravity sewers which is characterized by high humidity and the presence of hydrogen sulfide, sulfuric acid corrosion negatively affects concrete surfaces, mortar, and metal reinforcement material. Given this universal challenge for wastewater utilities, this research program will look into innovative inspection technologies and condition assessment methods that address corrosion-related wastewater infrastructure issues.

Deteriorating collection systems can result in excessive infiltration of rising groundwater during high water table seasons and wet weather events, and the export of recharge water from watersheds. When this is combined with increased impervious surfaces and water withdrawals resulting from urban growth, the effect of these man-made influences on the natural water balance can result in reduced flows in streams affecting aquatic ecosystems and decreased water availability. The application innovative assessment techniques to determine relationships between aging infrastructure and altered water balances, leading to measures to reduce or mitigate resulting adverse consequences is needed.

Force mains are a relatively small, but important, segment of the wastewater collection system infrastructure needing assessment. Force mains convey pumped sewage. There are about 30,000 miles of force mains in the nation. Based on a sewer pipe inventory of approximately 600,000 miles, force mains comprise about 5% of the total, by length. Because of hydrogen sulfide generation in wastewater collection systems, force mains are more prone than drinking water pipes to corrosion at the crown of the pipe. The average length of force mains is around 3600 ft. About 60% of the total length of force mains is constructed of ferrous materials, with ductile iron being the dominant material. A significant percentage of ductile iron installed has an internal lining that is most commonly cement mortar. For diameters of 36 inches and greater, pre-stressed concrete cylinder pipe (PCCP) and concrete cylinder pipe (CCP) are the dominant types. For diameters up to 20 inches, asbestos cement has a small but not insignificant percentage. For diameters less than 12 inches, polyvinyl chloride (PVC) and polyethylene (PE) account for about a third of the length installed. Because most force mains are in constant service and cannot be accessed internally for inspection without expensive by-passing arrangements, condition assessment is often difficult. Innovative, external condition assessment technologies are needed to facilitate inspection of force mains while they are in operation.

Related to wastewater collection system inspection and condition assessment is the evaluation of sewer system security vulnerabilities. In today's climate, vulnerability assessment of the collection system should be an integral part of an overall system condition assessment program. A recent GAO report found that few utilities have or are planning to install monitoring or security devices to detect and prevent system intrusions. (GAO, 2006) Recent work, funded by EPA, has been conducted by ASCE and WEF on monitoring systems and physical security enhancements, including security measures for wastewater collection systems. This program will coordinate with EPA's Water Security Division and National Homeland Security Research Laboratory to assist wastewater utilities in developing and implementing comprehensive inspection and condition assessment programs.

STATE OF THE TECHNOLOGY

The ability to visually examine the internal condition of a gravity sewer using internal cameras, usually closed circuit television (CCTV), has been the most important development in the area of inspection and condition assessment, leading to the current operation, maintenance and rehabilitation techniques employed by wastewater utilities. Incremental improvements continue to be made to CCTV technology and as electronic components become more affordable, this technology can be applied by most contractors and plumbers. Basic CCTV systems which can inspect small-diameter sewer and drain pipes can be purchased for less than $1500. Also, a standard investigation of a sewer line can cost a utility no more than $1 per foot. (WERF, 2004) In addition, the National Association of Sewer Service Companies (NASSCO) provides a wide range of training programs to standardize the application of condition assessment techniques. NASSCO's programs address the assessment of sewer pipe, manholes and service laterals.

Most utilities have established fairly simple rating systems which use the results from CCTV investigations to make an overall assessment of each section of sewer being inspected. This rating can then be combined with other data and information, such as results from hydraulic evaluations, sewer location, known soil conditions, and operational records, to determine maintenance and system rehabilitation priorities. However, CCTV assessments are qualitative and rely heavily on the skill of the investigation personnel to make judgments on the condition of the sewer. Also, this technology does not provide quantitative data to determine variations in sewer dimensions, subtle deformations, or debris level. Also, CCTV does not permit assessment of pipe condition below the water line within a sewer. While many sewers can be inspected during dry weather conditions to limit this issue, most trunk sewers maintain a fairly high flow and diverting these flows for inspection purposes is difficult. (WERF, 2004)

The application of CCTV in combination with newer technologies is currently being used in sewer inspections. Sonar technology, which uses high-frequency sound waves, can identify defects, especially large cracks, in the wall of sewer pipes and because it is almost exclusively designed to work underwater, it can overcome one of the shortcomings of CCTV. Laser technology can be used to identify variations in sewer pipes above the water line. Comparison of laser images of the interior dimensions of a sewer over time can be an effective method to determine temporal deterioration. (WERF, 2004)

One potential research issue emerges from this analysis of the state of technology for condition assessment. Given the ubiquitous application of CCTV for sewer inspections and condition assessment, a state of the art evaluation and technology transfer product on optimized application of CCTV results for condition assessment could be generated in the early phases of this research program. Wastewater utilities that are well known for their innovative application of CCTV could be identified and a best practices assessment and tool produced. In addition, this effort could include optimizing the use of existing and historical data and information, in combination with CCTV information to establish baseline assessments.

REHABILITATION OF WASTEWATER COLLECTION SYSTMES

The objective of system rehabilitation is to ensure the overall viability of the collection system to maintain operational and structural integrity and to prevent or reduce infiltration, inflow and exfiltration and their negative environmental impacts. There are several primary concerns related to deteriorating sewers. On a daily basis, significant pipe defects can cause blockages that lead to dry weather sewer overflows and backups into buildings. Water that flows into sewer pipes through defects (holes, cracks, failed pipe joints) can weaken the critical soil-pipe structure. Fine soil particles carried into the sewer can eventually reduce soil support to a point causing pipe deformation and/or subsidence. Exfiltration of water from the sewer into the surrounding soil can also weaken support provided by the soil. Soil movement due to traffic movement can exceed design assumptions and result in soil-support related problems. Deposition of material and sewer blockages can result in septic conditions due to flat grades, high ambient temperatures and poor ventilation. These conditions are ideal for the development of sulfuric acid and resulting crown corrosion which reduces the structural integrity of concrete material and the reinforcing steel, commonly used sewer materials. High rates of infiltration and inflow can lead to sewer overflows, basement backups, significant system capacity issues and excessive peak flows at pumping stations and at treatment plants. Although an infrequent occurrence, exfiltration of sewage into the surrounding soil can lead to groundwater and soil contamination. In some instances, water pressure drops in water distribution pipes adjacent to exfiltrating sewers can result in contamination of the potable water supply. In many cases, these problems are the result of faulty sewer designs. In addition, inadequate inspection, quality assurance and poor construction workmanship during sewer installation can result in long-term problems due to poor workmanship. (Tafuri and Selvakumar, 2002)

Generally, rehabilitation includes a broad spectrum of approaches, from repair to replacement that attempt to return the system to near-original condition and performance. Rehabilitated systems can be improved to provide hydraulic conditions and structural integrity better than the original sewer. Repair techniques are used when the existing sewer is structurally sound, provides acceptable flow capacity and can serve as the support or host of the repair method. When the existing sewer is severely deteriorated, collapsed, or increased flow capacity is needed, it is usually replaced. Current rehabilitation methods generally address unsound structural conditions. A wide range of causes can be responsible for sewer line deterioration and failure. These include:

- inadequate or improper bedding material,
- chemical attack,

- traffic loadings,
- soil movements,
- root intrusion,
- compromised joint integrity,
- subsequent construction damage,
- groundwater fluctuations,
- poor design and installation, and
- inadequate maintenance. (WERF, 2000)

Effective system rehabilitation programs require a complete understanding of the condition and performance of the collection system, including factors that affect system integrity and operations. Pipe age is a factor; however, pipe deterioration is very complex and it is usually a combination of several factors that causes failures and influences rehabilitation decisions, leading to a very complex decision-making process. Pipe materials, bedding and backfill materials, surrounding soil conditions, loads and stresses on the pipe, groundwater levels, sewage and soil acidity, sewage dissolved oxygen levels, and electrical and magnetic fields are factors that negatively impact long-term integrity and operational performance of the collection system. The results from a sound system inspection and condition assessment program provide critical input to decision support tools that evaluate the condition of the system based on structural, hydraulic, service delivery, water quality and economic factors.

Building connections to street sewers, referred to as house or service laterals, can contribute as much as 70 to 80% of the infiltration to a sewer. Fluctuating ground water, variable soil characteristics and conditions, traffic, erosion, washouts, etc., cause enormous stresses on house/service lateral pipes and joints. Connectors and fittings in many cases do not retain their watertight integrity while adjusting to these factors. Some connections react to soil acid and may totally disintegrate in a few years. These conditions often result in major points of infiltration at the connection of the house/service lateral to the street lateral or main. With current technology, rehabilitating building connections has become technically feasible but, because of the shear number of connections and cost for service renewals, is a significant additional cost. Economics and conditions of service renewals may make this difficult to address systematically. The problem is both critical and sensitive because of legal jurisdiction, private ownership and costs associated with disturbance to the occupant and destruction of valuable landscaping. Because of this, municipalities are often reluctant to address infiltration and inflow problems from these sources. (Tafuri and Selvakumar, 2002)

STATE OF THE TECHNOLOGY

Collection system rehabilitation includes a wide range of repair and replacement options that can be used to return the system to acceptable levels of performance. Pipeline rehabilitation procedures are usually preceded by some form of cleaning to remove foreign materials before other phases of rehabilitation. The removal of roots, sediments, and debris is also a critically important practice for maintaining operational performance levels including ensuring proper flow conditions, reducing infiltration and exfiltration and preventing structural damage to the pipeline. Common repair methods of chemical and cement grouting address problems associated with groundwater movement, washouts, soil settlements, collapses, and soil voids. Grouting is

marginally effective in reducing or eliminating infiltration but will not significantly improve the structural condition and has a limited life-cycle. It does, however, help stabilize the surrounding soil mass. Other system repair approaches include sliplining, spiral-wound pipe, segmented liner pipes, cured-in-place pipe (CIPP), fold and form pipe, close-fit-pipe, coatings, mechanical sealing devices, and spot repair. Many rehabilitation methods marginally reduce pipe cross-sectional area and can reduce hydraulic performance, but generally improve the system hydraulics.

Trenchless technologies have moved to the forefront of sewer system rehabilitation. Many are proprietary systems and the details of installation procedures and materials are trade secrets, limiting the ability to compare and evaluate competing approaches. For some techniques, codes and standards have been developed; however, because of the rapidly evolving technology in rehabilitation, standards and codes often lag behind. Trenchless technologies are applied in both repair and replacement situations. Pipe replacement technologies include pipe bursting, pipe splitting, pipe reaming and pipe eating. These trenchless replacement techniques install a new sewer in the location of the old pipe without total surface digging and accompanying traffic and business disruptions.

It is significant to mention that past studies have found that rehabilitation of sewers at the street alone does not completely solve the infiltration problem. Successive rainfalls can elevate the groundwater table to levels where entry occurs through service laterals. When performed, rehabilitation of service laterals is generally done by point repair or replacement; cured-in-place lining, sliplining and pipe bursting are sometimes used. These approaches do not overcome the private ownership problem or the problems associated with the location and configuration of the line (sharp bends/transitions) or the line condition (massive roots).

System rehabilitation includes repairing or replacing appurtenances (manholes, pump stations, wet wells, and siphons) which is an important component of a comprehensive program. About 30 to 50 percent of system infiltration and inflow is due to defects in or near appurtenances, in particular, manholes. For example, manhole covers submerged in one inch of water can allow as much as 75 gallons per minute to enter the system depending on the number and size of holes in the cover. Rehabilitation of manholes, pump stations, and wet wells includes spray-on coatings, spot repairs, structural liners, and replacement. Rehabilitation of siphons includes some of the options available for pipelines such as grouting and lining. Many siphons have been rehabilitated using either CIPP or high density polyethylene (HDPE) liners. (Tafuri and Selvakumar, 2002)

Selection of rehabilitation methods and materials suitable for various parts of the wastewater collection system remains an issue, especially due to ever emerging new materials and methods of construction. Uncertainty in the selection of appropriate repair and replacement techniques is partly related to the lack of understanding of the capabilities of each methodology to solve the problem in the long term. Reliable rehabilitation product performance under actual field conditions, especially over longer periods of performance, is lacking. Data on the effectiveness and longevity of rehabilitation technologies and materials and life-cycle cost information will be useful in determining whether rehabilitation or replacement is more cost effective.

The introduction of sewer pipes made from plastic materials has replaced in the market the more traditional sewer pipes constructed from concrete, clay and ductile iron. Plastic pipe has and continues to be an area of innovation for sewer pipes. The most commonly used materials for wastewater applications are polyvinyl chloride (PVC), polyethylene (PE) and glass reinforced plastic (GRP). Plastic pipe innovations include structured wall pipe and composite pipe that use different pipe materials to address both structural and corrosion issues. The application of plastic pipe in wastewater is becoming standard practice, resulting in the need for determining long-term performance and related testing. In addition, raw materials and formulations can vary widely, resulting in different quality pipe for the same plastic.

ABSTRACT

Maximizing on-site stormwater management is one of the key concepts of distributed stormwater controls, such as those used as a part of Low Impact Development (LID) and sustainable sites approaches. These approaches are usually expressed as (1) maximize on-site depression storage and infiltration, (2) minimize runoff discharge by minimizing directly connected impervious area (DCIA), (3) maximize flow paths and time of concentration, and (4) maximize the potential for evaporation and/or evapotranspiration (ET). A few process models are available to evaluate these types of distributed stormwater control alternatives directly. The purpose of this paper is to describe how to evaluate and optimize distributed urban stormwater control options in a spreadsheet environment. One methodology to evaluate stormwater control alternatives is to compare total runoff volume from long-term continuous simulation. Using a lumped simulation model, it can be difficult to adequately represent the physical characteristics of distributed onsite LID options. Another alternative evaluation and optimization method based on lot-level detailed functional spatial information and explicit rainfall-runoff estimation is presented in this paper.

INTRODUCTION

Excess runoff drainage and flood control have been the main targets of stormwater management in the past. This approach generally relied upon designing for larger storm events and larger watersheds. Usually, 5- to 10-year return periods were used for designing drainage systems and 25- to 100-year periods were used for designing flood control facilities. However, the most frequent and highly contaminated urban runoff is typically contributed by storm events with a two-year or less return period (Guo and Urbonas 1996; Pitt 1999). Guo and Urbonas (1996) show nearly 95 percent of runoff producing events may be smaller than a two-year storm as demonstrated by the runoff event distribution for Denver, Colorado. Shueler (1992) described 6-month or shorter frequency storms likely contribute approximately 90% of the annual pollutant load. A number of technical approaches have been applied to reduce the negative impacts of these smaller storms. Those efforts are usually a suite of best management practices (BMPs) termed LID or Sustainable Urban Drainage Systems (SUDS) (British terminology).

Most of the LID/SUDS style approaches are developed with a highly distributed spatial pattern. Maximizing onsite stormwater management is a key concept of distributed stormwater controls. One of the most effective runoff quality controls is reducing the quantity of runoff, i.e. peak and volume (ASCE-WEF 1992). One of the more effective ways to solve urban runoff problems is to control them as close to the source as possible (Dunne and Leopold 1978; ASCE-WEF 1992) by maximizing onsite infiltration and minimizing runoff discharge as summarized below.

- Maximize onsite depression storage and infiltration
- Minimize runoff discharge by minimizing directly connected impervious area
- Maximize flow paths and time of concentration
- Maximize the potential for evaporation and/or evapotranspiration (ET)

A few process models are available to evaluate these types of distributed stormwater control alternatives directly. This paper will describe a methodology to evaluate and optimize distributed urban stormwater control options in a spreadsheet environment.

EVALUATION OF DISTRIBUTED ONSITE STORMWATER CONTROLS

Process dynamic models can be applied to evaluate the performance of distributed stormwater controls. However, the models usually need a number of modeling parameters and relatively high level of technical experience. It is difficult to conduct a wide range of onsite BMP scenario analyses and apply design optimization when using stand-alone models. Some organizations have arranged relatively simple evaluation tools for the purpose of evaluating onsite LID/SUDS and other BMP options. For example, the Emeryville spreadsheet BMP model (Emeryville, CA) uses a runoff coefficient (i.e., Rational Method) for analyzing lot-level to neighborhood-scale BMP sizing. The Green Calculator (Center for Neighborhood Technologies, http://greenvalues.cnt.org/calculator) estimates the benefit of onsite LID BMP options on a neighborhood-scale by applying the curve numbers (i.e., TR-55) and the Modified Rational Method. The Northern Kentucky Spreadsheet Tool uses a TR-55 based approach for sizing BMPs with lot or site-level spatial scales. However, little background information is available to customize the models for other locations.

The Rational Method was originally developed to estimate a peak discharge from a site by a selected frequency design storm. This approach is frequently used for drainage system design. In applying this method, all of hydrologic conditions (e.g., surface condition, soil types, slope, depression storage, infiltration loss, etc.) at a drainage area are expressed in a single implicit modeling parameter, i.e., the runoff coefficient. Most available reference data for runoff coefficients are usually arranged by surface conditions and soil types. It may be difficult to model smaller areas with varied land use characterizations and soils when applying stormwater controls by manipulating a single lumped runoff coefficient. The NRCS Curve Number (CN) method was initially developed to estimate total runoff volume by applying a design storm (USDA-SCS 1986). The original model was introduced to aid in the design of flood controls based on agricultural and rural watershed conditions. The CN method

estimates runoff volume by using a single modeling parameter, i.e., the CN. This CN implicitly represents all of land surface and soil conditions at the drainage area as well.

Runoff occurs when rainfall satisfies surface storage and infiltration capacity during a certain period. Instead of using a single implicit parameter, it would be better to apply surface storage and infiltration rate directly in estimating runoff volume. Surface storage and infiltration capacity can explicitly represent a wide range of surface and soil conditions, including distributed onsite LID/SUDS and BMP options. Estimating runoff from rainfall can be expressed as follow:

$$Runoff = Rainfall - Storage - Infiltration$$

Storage in the above equation can include depression storage (DS) or initial abstraction for the runoff from a given contributing area. *Storage* also includes the stormwater control practice design storage volume, as well. Infiltration typically occurs only in pervious areas. *Infiltration* can be modeled by using a fixed infiltration rate, the time-dependent Horton's infiltration equation, or the physically based Green-Ampt equation. In this paper, a long-term continuous rainfall-runoff model was arranged by applying DS, design stormwater storage of a control practice, and a fixed infiltration rate. Each runoff estimation model for subareas and runoff control practices are presented in the next section.

MODEL ARRANGEMENT

A spreadsheet model was developed to evaluate the performance of distributed onsite LID options based on a conceptual residential lot. The lot consists of a rooftop, driveway, and yard. Four onsite BMP options were considered in the model: bioretention; paver blocks on driveway; grass swale in yard, which can drain and infiltrate rooftop runoff; and a green roof. Lot layout and potential BMPs are schematically presented in Figure 1. Table 1 shows sizes of each surface component with its DS and infiltration rate.

Table 1. Status of a Residential Lot.

Surface	Rooftop	Driveway	Yard	Sum
Area (m^2)	200	40	760	1000
DS (mm)	2.5	2.5	5.1	
Infiltration (mm/hr)	0	0	5.1	

It is assumed that 10% of rooftop runoff drains to the driveway and the remaining 90% runoff drains to the surrounding yard. The yard area that receives rooftop runoff was modeled as a grass swale in this analysis. This grass swale area was assumed to be 10% of the yard, which represents the existing condition.

In this analysis, the ultimate goal of onsite management controls was to manage the same runoff volume of pre-development condition runoff with post development

management controls by applying 10 years of data using continuous simulation. The pre-development condition was assumed to have grass or shrub covered pervious area, which has a higher DS (7.6 mm or 0.3 inches) and infiltration rate (6.35 mm/hr or 0.25 inch/hr) than the existing yard.

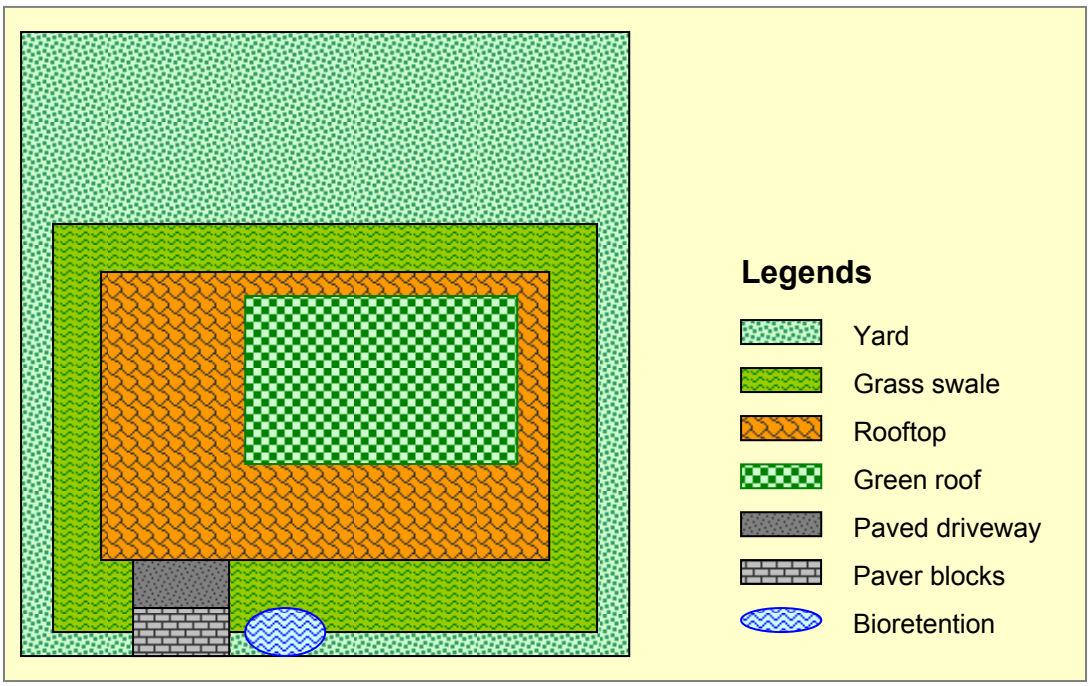

Figure 1. Schematic Lot Layout with Potential Onsite Control Practices.

Stormwater flow paths with onsite runoff management options are presented in Figure 2. If a certain BMP system is not included (i.e., no selection of the BMP), stormwater flow is simply bypassed to the next component.

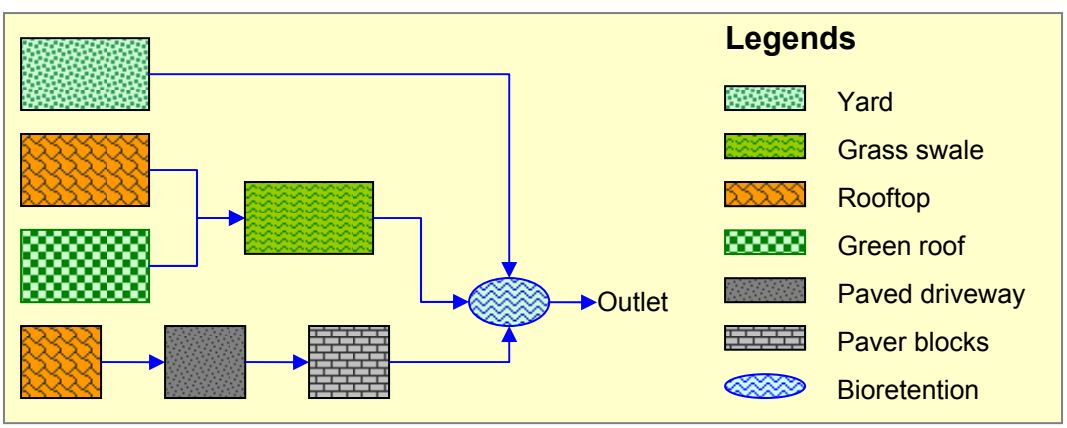

Figure 2. Stormwater Flow Paths with Potential Onsite Control Options.

During wet periods, runoff from each subarea and control practice was estimated as follows:

- Runoff from rooftop = *Rainfall – DS*

- Runoff from yard = *Rainfall – DS – Infiltration*
- Runoff from paved driveway = (*Rainfall* + *Runon* from rooftop) – *DS*
- Runoff from green roof = *Rainfall – Design Storage*
- Runoff from paver blocks = (*Rainfall* + *Runon* from paved driveway) – *Design Storage – Infiltration*
- Outflow from grass swale = (*Rainfall* + *Runon* from rooftop and green roof) – *DS – Infiltration*
- Outflow from bioretention = (*Rainfall* + *Runon* from yard, grass swale, and paver blocks) – *Design Storage – Infiltration*

While DS and design storage of a control practice would be filled by stormwater during wet periods, both can recover (dry out) during dry periods. Recovery could occur through evaporation and infiltration for paver blocks; ET for green roofs; and ET and infiltration for bioretention systems. Existing monthly average pan evaporation data from Chapel Hill, NC (Robinson 2005), which is close to Raleigh, NC. were used in this analysis. Using the pan evaporation data, monthly average ET was estimated by the following equation (Brouwer and Heibloem 1986):

$$ET = K_{pan} \cdot Evaporation$$

where, K_{pan} = pan coefficient; and *Evaporation* = pan evaporation from a free water surface.

The pan coefficient (K_{pan}) was assumed to be 0.75 in this analysis. Infiltration was estimated by applying soil infiltration rates and durations. To avoid any negative numbers or unrealistic values beyond the management practice design characteristics, MIN and MAX functions were used in the spreadsheet model.

MODEL APPLICATION

A case study was conducted by applying 10 years of long-term hourly precipitation records from Raleigh, NC to the model. Annual average precipitation is 1,116.2 mm (43.94 inches) during the period from January 1997 to December 2006. In order to conduct least-cost design optimization of distributed onsite control practice options, required cost functions for individual systems were arranged by applying site specific cost data from the same area (Hathaway and Hunt 2007) as shown below:

- Cost for bioretention ($) = 49.649 $(Area)^{0.9037}$
- Cost for green roof ($) = 135.71 $(Area)^{0.9596}$
- Cost for permeable pavement ($) = 103.44 (Area)
- Cost for swale ($) = 8.18 (Area)

where, (Area) = surface area of each BMP (m^2)

In this case study, design characteristics and surface areas of individual LID management controls were assumed as follows:

- Bioretention
  - Surface area: up to 3% of the lot
  - Design storage: 152.4 mm or 6 inches (e.g., 18 inches of media with 33% void space)
  - Infiltration: 5.1 mm/hr or 0.2 inch/hr (It is assumed to be the same as yard.)
- Green roof
  - Surface area: up to 50% of rooftop
  - Design storage: 26.7 mm or 1.05 inches (e.g., 3.5 inches of media with 30% void space)
  - No infiltration was assumed at green roof.
- Paver blocks
  - Surface area: up to 90% of driveway
  - Design storage: 61.0 mm or 2.4 inches (e.g., 12 inches of media with 20% void space)
  - Infiltration: 3.8 mm/hr or 0.15 inch/hr (It is assumed to be a little lower than yard, which has 0.2 inch/hr because of possible compaction during paver block installation.)
- Grass swale
  - Surface area: up to 40% of yard (Actually, it varies from 10 to 40% because 10% of the yard was already assumed as grass swale based on the existing condition as described earlier.)
  - DS: 6.35 mm or 0.25 inches (It is assumed a little higher than other grass area, which has 0.2 inches of DS.)
  - Infiltration: 5.1 mm/hr or 0.2 inch/hr (It is assumed to be the same as yard.)

Based on the goal of managing long-term runoff volume from developed areas to match pre-development runoff, the performance of onsite control practices was estimated as:

$$Performance = \frac{(Runoff_{current} - Runoff_{BMPs})}{(Runoff_{current} - Runoff_{pre-dev})}$$

where, $Runoff_{current}$ = runoff from the currently existing condition;
$Runoff_{BMPs}$ = runoff from the lot with management practices; and
$Runoff_{pre-dev}$ = runoff from pre-development condition.

If the performance reaches 100%, the onsite runoff control practices exactly mimic the pre-development conditions based on long-term runoff volume control.

Given the cost functions and the design constraints of individual onsite control options, then optimal solutions for specific stormwater volume control performances can be found by solving the following optimization problem:

Minimize *Total cost*
Subject to *Volume control performance ≥ Specific performance level*
Satisfy the design constraints of individual control options

In this case study, a number of least cost optimizations for sizing onsite control options were conducted with 5% increments of the stormwater volume control performance. Optimal sizing of required onsite runoff control practices for achieving a wide range of the volume control performance are presented in Figure 3. Because of the cost functions, bioretention was picked first and green roof was picked last as target performance increased.

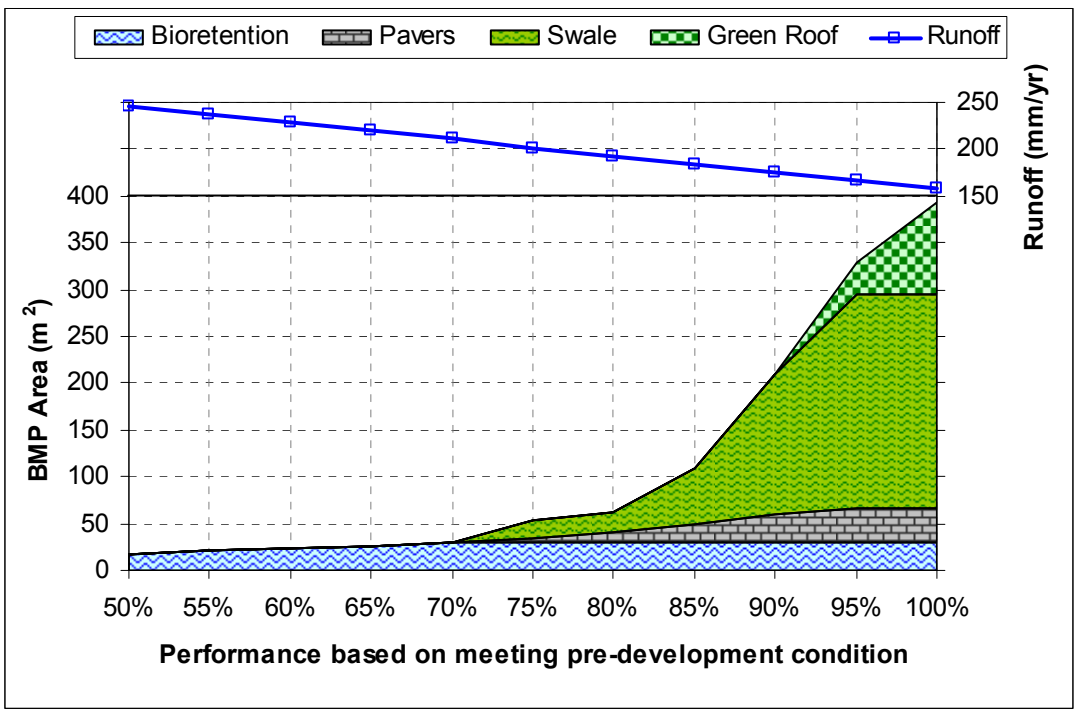

Figure 3. Optimal Sizes of Onsite Control Practices based on Performance Optimization.

Removed stormwater volumes by onsite control practices are presented in Figure 4. The figure indicates that bioretention and paver blocks controlled a greater portion of runoff volume even though their sizes, based on percent of surface area, were smaller than the other control options. These two control practices could facilitate both onsite storage and infiltration while the other two practices could provide only one of the two processes for reducing volume (i.e., grass swale could provide little storage of stormwater (beyond the small DS) and green roof could not infiltrate stormwater). Once runoff was captured through storage of onsite control practices during wet periods, the captured stormwater could be removed within the site by infiltration and ET (or evaporation for paver blocks). The removal functions can extend to the dry periods following the rainfall event until the captured stormwater has been removed from the control systems. While the grass swale was implemented in a larger area,

especially for higher performance ranges, the effective stormwater control volume was smaller than other practices because infiltration in the grass swale could occur only during wet periods. If the grass swale is designed with some storage capacity (e.g., by applying check dams), this control practice may perform more like a bioretention system. Storage volumes managed through bioretention systems and grass swales were decreased when implementing upstream control options based on controlling the runoff before reaching theses management controls.. Similarly, the runoff volumes necessary at downstream control options were decreased as the sizes of upstream control options increased.

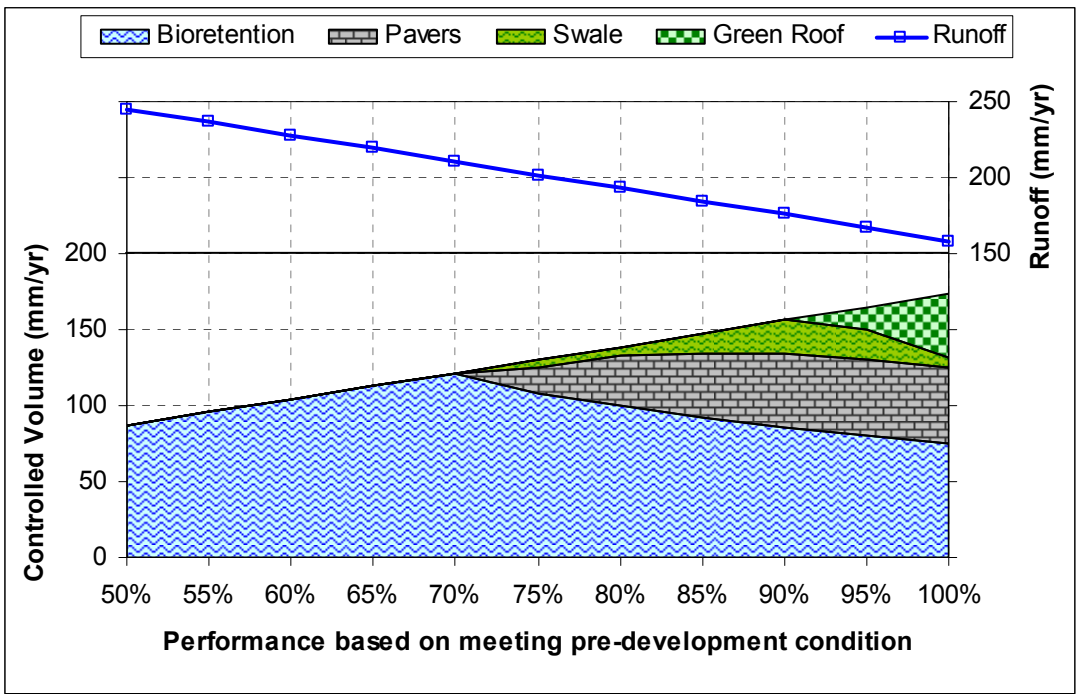

Figure 4. Volume Controlled by Onsite Control Practices based on Performance Optimization.

The total and marginal costs of the runoff control practice options are shown in Figure 5. As shown in the figures, to achieve higher performance in order to meet the goal of matching pre-development condition requires larger sizes of onsite BMPs and, similarly, requires a higher cost. This trend is most notable as the marginal costs of controlling unit runoff by onsite control practices increases to achieve greater than 90% performance. Instead of achieving 100% performance within the site, utilizing centralized regional control practices (e.g., a detention basin) could be a more cost-effective approach for the higher performance ranges. In this case, highly contaminated frequent smaller storms can still be controlled by distributed onsite practices.

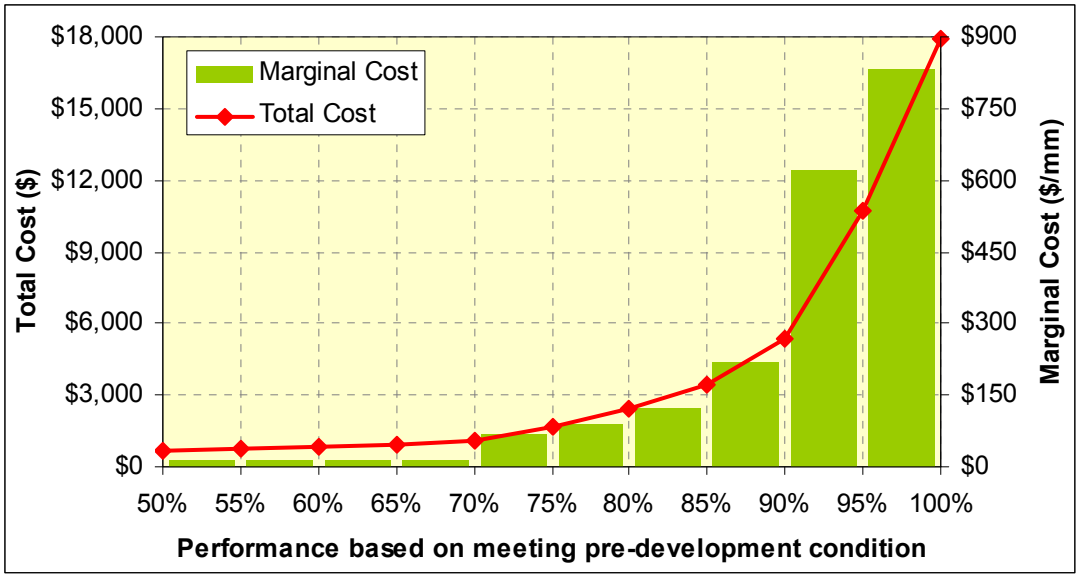

Figure 5. Costs of Collective Onsite Control Practices based on Performance Optimization.

SUMMARY AND CONCLUSIONS

This paper introduced an evaluation and optimization method for lot-level onsite LID control practice options using explicit modeling parameters. Four onsite management practice options for a residential lot were considered meeting pre- and post-development long-term runoff volumes. The four management practices modeled were bioretention, green roof, paver blocks, and grass swale. The application of this methodology may be applied to larger areas with additional runoff management options. Water quality simulation can be incorporated into the developed model if additional modeling parameters are available (e.g., buildup/washoff, inflow concentration, background concentration, pollutant removal rate, etc.). Applying site-specific data is critically important in finding the optimal management practice configuration because results could be varies substantially based on local site conditions. Because of this sensitivity analysis should also be considered when doing this kind of optimization.

The effect of rainwater harvesting systems on the growth of Atriplx shrubs in semi arid land in western part of Libya was evaluated using two of rainwater harvesting systems (Contour lines and Negarim). Plant height, crown length, crown circumference and maturity were evaluated as measures to the effectiveness of these rainwater harvesting systems. Three micro-catchments area (10.2, 12.5, and 15.5 m^2) for each system were used. The catchment area was calculated on the basis of the average annual rainfall, surface runoff coefficient, plant water requirement, and root zone area. The ratio of the cultivated area to the catchment area was found to be 1:15. The growth of Atriplx shrubs was evaluated for two consecutive years. Both contour lines and negarim rainwater harvesting systems gave better results compared with the growth of the control shrubs (shrubs that were planted outside the W.H. systems). The overall efficiency of the systems varied from system to system and from catchment area size to other size. The contour line system and the larger ratio of the catchment area to the cultivated area were found to be strongly related to the growth of the shrubs.

INTRODUCTION

Rainfall is the major source of livelihood to the farming communities in Libya. The average annual rainfall drops from 350 mm near Mediterranean coast in the north to less than 100 mm in the central zone, where semi-desert/ desert climate dominates. Further in the south, full desert conditions prevails. Only a narrow northern band receives reasonable rain. Most of the area of the country is either rainless or receives negligible rain that does not help much in biomass production.

The rain-fed agriculture that contributes to production of grains and oils, mainly concentrates in the western mountains, green mountains in the east and valleys or wadies of deep soils and areas of runoff concentration. Traditionally, dams, cisterns and semi-circular (*lunar*) bunds are used as a way for rainwater harvesting. The existed water-harvesting infrastructure deteriorated due to lack of maintenance and being at low-priority, and it continued to be abandoned till recent past when the water resources became very limited and deteriorated in quantity and quality. Recently the government lunched a program to improve the existing rainwater harvesting systems with the adoption of latest technology and development in this field. As a result of that, the Agricultural Research Center (ARC) in Libya in cooperation with the International Center for Agricultural Research of Dry Areas (ICARDA) had conducted a field experiment in order to demonstrate the usefulness of water harvesting systems that suits to the country environment. The experiment aims at real-time testing and evaluating two potential micro-catchment rainwater harvesting systems in order to improve bio-mass production in a certain agro-climatic and geo-physical environment, which largely prevails in the northern areas of Libya.

EXPERIMENT SITE

The experiment site was chosen at the Gharian Pasture Project which is located at region of Qdama. Qdama is about 40 km south of Gharian city (13^{O} 6' longitude and 31^{O} 55' latitude). Figure 1 shows the project location. The site represents a large area with similar characteristics and it is in easy approach to manage. Moreover, it is located in a region designated as grazing area, which is in match with the project objectives. Australian Atriplex was tested for its succession by using contour ridges and Negarim basin rainwater harvesting systems. The main characteristics of the area around and the experiment site are as follows:

Climate

The experiment site is characterized by its semi-desert climate. Longtime data of nearby stations shows an average annual rainfall of 144 mm, and average annual of maximum and minimum temperatures being 23.3^{O}C and 13.3^{O}C respectively. Temperature may go above 40^{O}C in summer and drop below zero in winter. Monthly climatic data shows that rainfall is likely to exceed evaporation during December, January and February and thus moisture storage should take place. Rainfall in March might just balance the evaporation. This balance might shift in April, when evaporation is likely to higher than the rainfall; however, residual moisture might cover a part of the moisture deficit. May, June, July and August being no rainfall, should be high moisture deficit months, when the plants should suffer from very low

evaporation and thus little or no growth. Rainfall in September, October and November might partly cover the moisture deficit till the time when rainfall is higher than the evaporation. So, the rainfall is one of the most important climatic parameters for the survival and succession of biomass in an area, which does not have other source of fresh water resources.

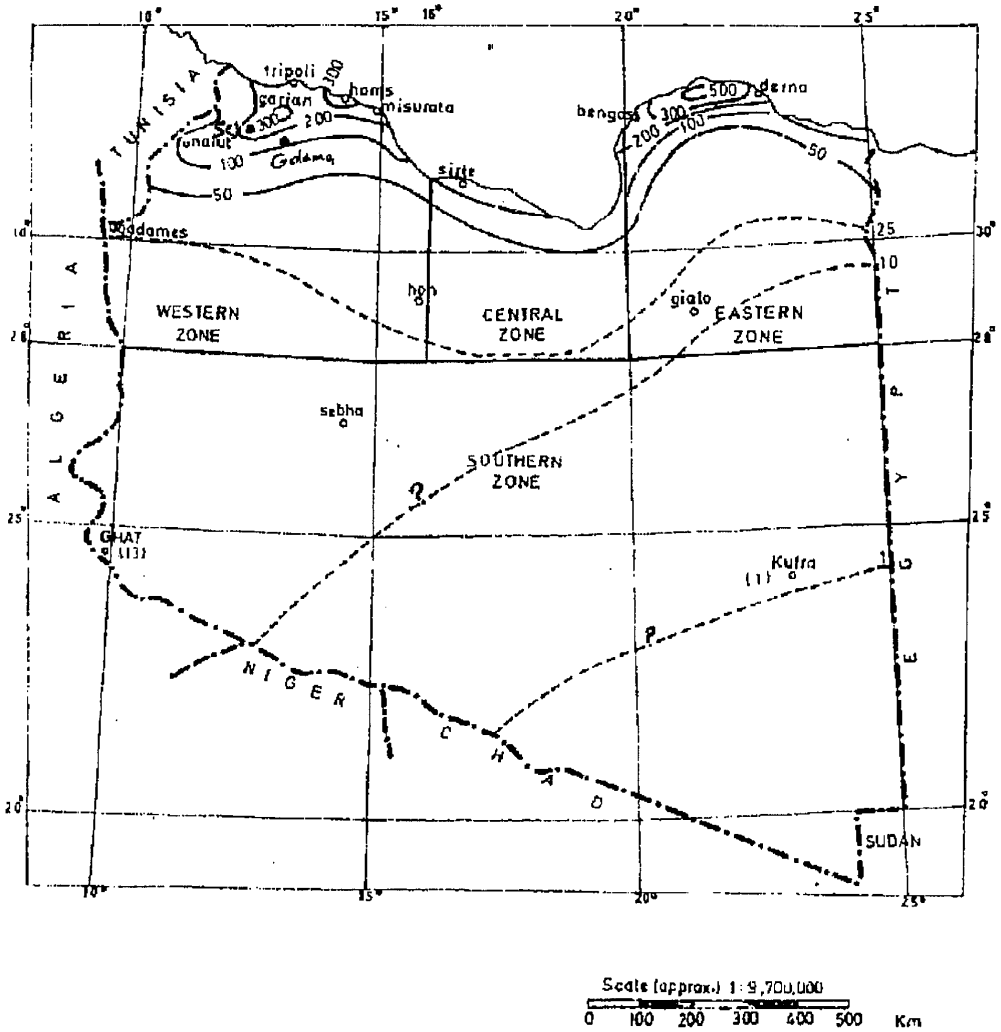

Figure 1: Isohyftal Map also shows the project location

Topography, Soil and Land Cover

The topography is rolling and undulating with slope variation between 2 and 20%. Dominant ground slope at experiment site is about 5%. A soil profile at the site indicates that the soil consists of 30 cm thick silt over a deep fragile layer limestone. It was noticed that plant roots have penetrated deeply into this layer. The soil can be classified as *Calcic Xerofluvents*. The family of *Artemisia Herb Alba* and *Hamada Scoparium* generally dominate in the area of the experiment. *Stipa Tenacissima* also sparsely exists.

EXPERIMENTAL DESIGN

The experiment aims at verifying the difference of biomass production with and without using water-harvesting systems and to quantifying this difference among control and two treatment cases. A recording rain gage was available near the experiment site and is the main source of site-specific rainfall data. Two potential rainwater harvesting systems, contour ridges and Nigarim basin, were evaluated. Three replicas of each were tested in order to minimize the experimental error.

The ratio of catchment to cultivated area (C/CA) was calculated on the basis of average annual rainfall, effective root zone and crop-water requirement with the use of values of runoff coefficient (50%). A C/CA value of 15:1 works out for the experiment site. Therefore, three sets with C/CA of 15:1, 12:1 and 18.75:1 were developed. The design parameters for contour ridges and Negarim basin are given in Table 1.

Table 1*:* Design parameters of contour ridges and Negarim micro-catchment water harvesting basins

C/CA	Contour ridges			Negarim basin		
	Mark	Total area (m^2)	Distance between ridges (m)	Mark	Basin total area (m^2)	Basin dimensions (m*m)
12:1	C1	10.2	6.8	N1	10.2	3.2*3.2
15:1	C2	12.5	8.4	N2	12.5	3.6*3.6
18.75:1	C3	15.5	10.4	N3	15.5	3.95*3.95

Field layout of experiment is shown in Figure 2. *Atriplex* was cultivated in each micro-catchment.

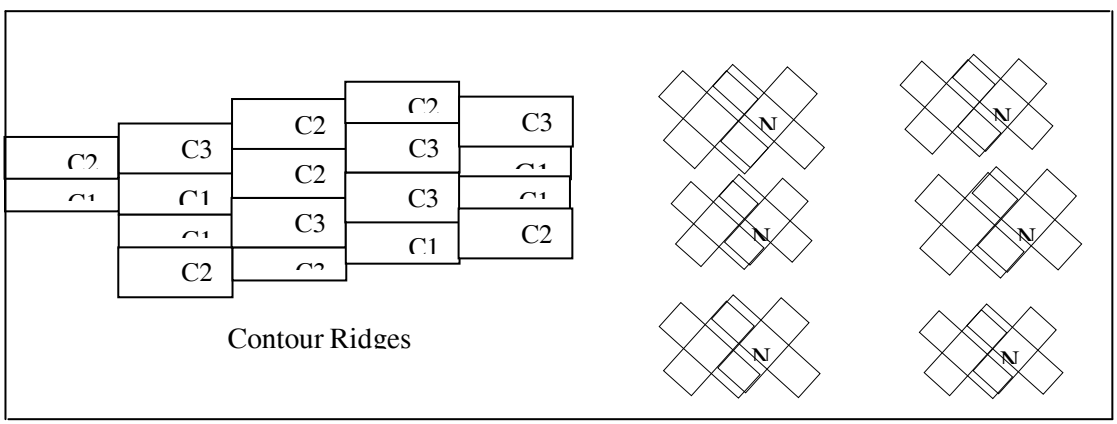

Figure 2: Field Layout of the Experiment

DATA COLLECTION ANALYSIS

The rainfall events for a period from 1998 – 2001 were recorded at rain gauge. Rainfall data of these events was collected from the rain gauge record.

Monthly and mean-monthly rainfall in mm at Qdama for period 1997-2001

Year	Sep	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	June	July	Aug	Annual
1997-98	74.5	38.0	0.0	26.5	49.0	13.0	54.2	0.0	0.0	0.0	0.0	0.0	255.2
1998-99	0.0	0.0	17.5	17.0	26.0	61.1	24.1	0.0	0.0	0.0	0.0	13.5	159.2

2000-01	0.0	94.0	0.0	0.0	16.3	80.8	0.0	6.2	0.0	0.0	0.0	0.0	197.3
Mean-monthly rain	***20.8***	***33.0***	***9.3***	***24.4***	***26.9***	***57.7***	***19.6***	***1.6***	***1.6***	***0.0***	***0.0***	***3.4***	

Atriplex growth was recorded at each micro-catchment, by the end of year 2000/2001, which includes plant height, crown diameter and plant maturity. A summary of collected data is given in Table 2 below.

Table 2: Summary of collected data on plant succession

Treatment	Cultivated area	Catchment area	Total area	Avg plant height	Avg crown length	Avg diameter	Biomass	Maturity
	m^2	m^2	m^2	cm	cm	cm	cm^3	%
Control				53.0	26.0	49.0	49004	16
C 1	0.785	9.4	10.19	59.0	57.0	90.0	362435	66
C 2	0.785	11.7	12.49	53.0	53.0	71.0	209731	51
C 3	0.785	14.7	15.49	62.0	58.0	110.0	550913	79
N 1	0.785	9.4	10.19	56.0	25.5	75.0	112598	44
N 2	0.785	11.7	12.49	55.5	39.0	71.0	154330	50
N 3	0.785	14.7	15.49	58.0	42.0	83.5	229875	62
C for Contour ridges and N stands for negarim basin								

RESULTS AND DISCUSSION

Rainfall

Rainfall data at Qdama from years 1997-2001 is presented in Figure 3(a), which shows an average annual rainfall of 199 mm. A comparison between long-time average (144 mm) and the average during study period reveals that as a whole the study period yielded high average and can be regarded as relatively wet period. Examining the data infers that 2–3 events of rainfall equal to or greater than 30 mm occur in every season. This means that a significant chunk of the annual rain falls in these 2–3 events and is thus available for shorter duration if not properly stored

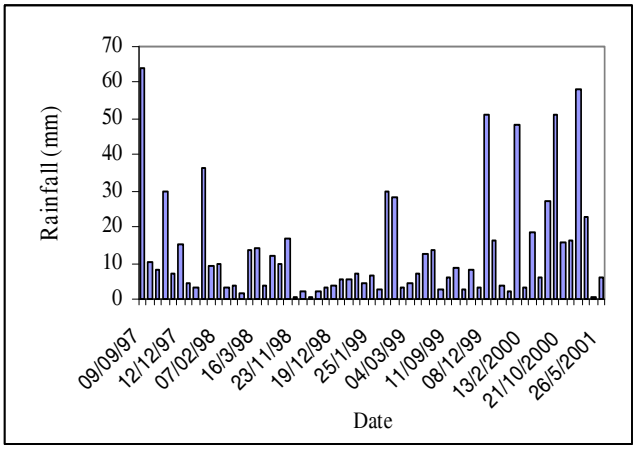

Figure 3(a): Event rainfall at Qdama, from 1997-2001 (Near water harvesting site)

Knowledge of month-wide distribution of rainfall is important to know the amount of water available for the biomass in rain-fed areas. Figure 3(b) shows mean-monthly and monthly rainfall at Qdama for the study period. Monthly rainfall also shows a high variability. Based on four-year data, it also shows zero rainfall in one of the four years (December is rainless for 25% of time), two out of four years (September, October, November and March are rainless for 50% of time), three of the four (April and May are rainless for 80% of time). January and February receives rainfall for 100% of time. The variability along mean is also high. It could negatively affect the biomass, if rainless conditions for the above-mentioned months continue for a couple of consecutive years.

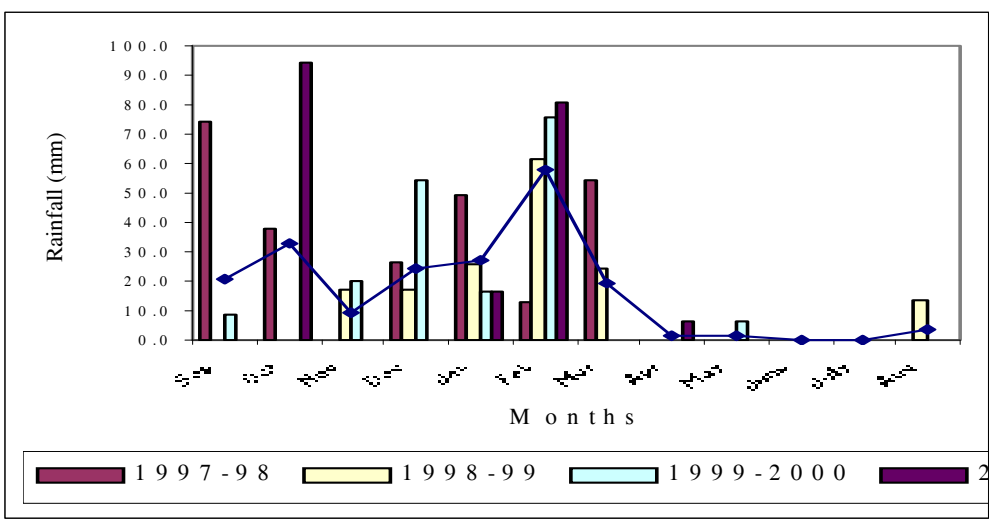

Figure 3(b): Monthly and mean-monthly rainfall at Qdama for the study period (1997 – 2001)

Atriplex succession in relation to treatments

Figure 4(a) is based on summary results, which shows the variation in plant height, crown sizes and plant maturity in relation to control, and three treatments of each contour ridges and Negarim basins. The results show a good survival rate for both the treatments and control case. These also indicate that for plant succession, both treatments performed better than control case, when the performance of contour ridges with a catchment area of 14.7 m^2 was the best among all treatments.

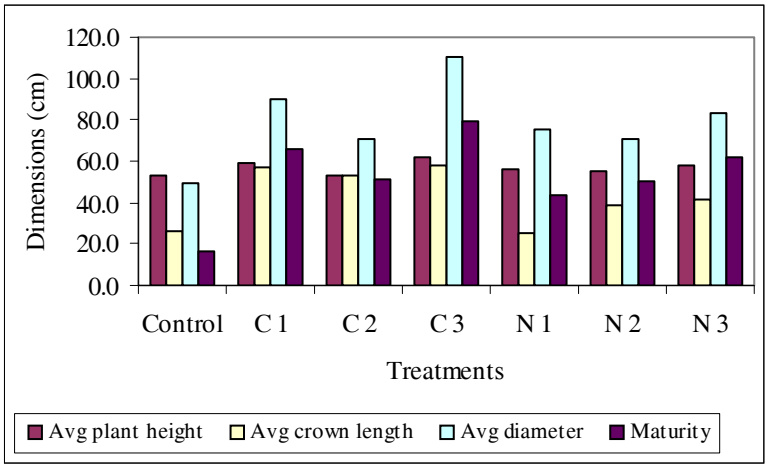

Figure 4(a): Plant height, crown sizes and maturity in relation to treatments

Figure 4(b) shows the variation of biomass in relation to size of catchment area for Negarim basins and contour ridges. It indicates that biomass growth was higher in case of contour ridges as compared with Negarim basin for all three catchment sizes, however, the catchment area of 14.7 m^2 performed better than the catchment areas of 11.7 and 9.4 m^2 for both the treatments. The performance of contour ridges with the catchment area of 14.7 m^2 was best among all alternatives. The volume of biomass for treatments as compared with control case is higher by 2.3 to 11 times, which shows the usefulness of water harvesting techniques. Figure 5 shows views of the shrubs growth.

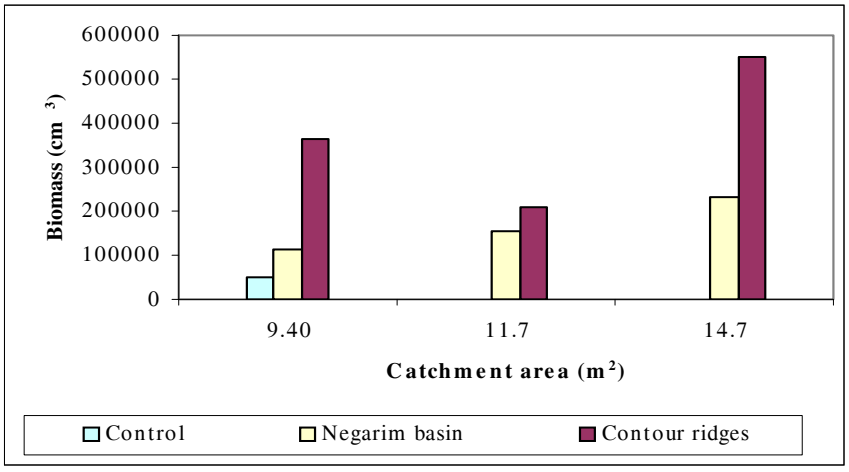

Figure 4(b): Biomass variation in relation to catchment area and treatments

Figure 5: General view of Atriplex growth inside the W.H. techniques

CONCLUSION:

As a result of this experiment, Contour ridges technique gave better results than the Negarim but we can not generalize this conclusion from a first evaluation unless the experiment is repeated.

The Experiment has proved that the Atriplx can be planted in downhill areas where was believed that in semi arid areas, only the bottom of the valley can be cultivated. The techniques used in the experiment are very simple and they can be constructed manually or by simple machines. The Contour ridges technique can be used for more than purpose, for example the area between the ridges can be cultivated by another grazing species.

Evolutionary Optimization of Combined Sewer Overflow Control

Andrea Zimmer[1], David Hill[2], Barbara Minsker[1], Avi Ostfeld[4], Arthur Schmidt[1]

[1]Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, [2]National Center for Supercomputing Applications, University of Illinois at Urbana-Champaign, [4]Civil and Environmental Engineering, Technion - Israel Institute of Technology

ABSTRACT

Model predictive control (MPC) is coupled with a real-coded Genetic Algorithm to predict a decision sequence that minimizes combined sewer overflow (CSO) volume for a 3-hour rainfall event over a hypothetical sewer system. Rainfall is transformed to overland runoff through the cell model which depicts each sewershed (draining to an overflow dropshaft) by two linear reservoirs in series, and water entering the interceptor is routed downstream to establish water levels at the dropshaft connections. A pumping rate at the most downstream end of the interceptor plus one sluice gate position for each dropshaft connection will be altered to produce the best control strategy. Resulting management scenarios disperse overflows differently throughout the sewer, but may yield similar overflow volumes. This paper describes the simulation approach taken and displays the overflow distribution for favorable control sequences.

INTRODUCTION

Combined sewers, such as those found in the Chicago region, are susceptible to overflows during severe rainfall events when runoff from urban sewersheds enters interceptor conduits through sluice gate connections. This runoff combines with sanitary sewage and may overwhelm the interceptor capacity. In an effort to minimize overflows that occur when flows exceed the sewer capacity, a genetic algorithm has been applied to a generalized hydrologic-hydraulic model to generate optimal management scenarios for a hypothetical sewer network.

Recent advances in the real-time control of sewer overflows include work by Darsono and Labadie (2007) to minimize overflow volumes and maximize flow to a wastewater treatment plant. A volume-based overflow control strategy is determined to be preferable to a pollution- or emission- based control. Pleau et al. (2005) use a multi-objective non-linear programming algorithm to minimize overflows (among other goals) in the Quebec sewer system by computing water levels for a control horizon discretized into 5-minute intervals. Generalized reduced gradient search has been applied to reduce combined sewer overflows by Cembrano et al. (2004); water levels are predicted for a 30-minute horizon at 5-minute control intervals. Rauch and Harremoes (1999) apply model predictive control in conjunction with a genetic algorithm to maximize the mean dissolved oxygen concentration below an urban wastewater system.

Application of model-based predictive control for real-time decision support has also been applied to the problem of aircraft arrival scheduling; Hu and Chen (2005) minimize the airborne delay of aircraft approaching a runway. Lee et al. (2005) utilize rolling horizon control and a binary coded genetic algorithm to minimize vehicle delays in real-time traffic signal control. Naeem et al. (2005) apply a genetic algorithm and model predictive control to the operation of an autonomous underwater vehicle. Further investigation of genetic algorithms used for predictive control has indicated that population initializing and sizing should be altered slightly for the specific predictive application (Onnen et al., 1997). A real-coded GA is appropriate for the CSO application addressed in this paper because it eliminates the need for the control variables to be converted to binary coding and enables the problem to be optimized without restructuring the physical formulation.

METHODS

The MPC formulation involves minimizing the predicted volume of overflow, V, calculated at sequential 15-minute time increments Δt, to be evaluated out to time horizon $t + (\Delta t \times N)$ based on system information available at time t.

$$\text{minimize} \sum_{k=1}^{N} \{V(t + (k \times \Delta t))|t\} \tag{1}$$

The variable t indicates the current time, and N is the number of time intervals in the prediction horizon. The value of N is set to 8 to designate a 2-hour prediction horizon divided into 15-minute intervals. The volume depends on the values of the current and future control signals which consist of one pumping rate and three sluice gate positions and are designated by the vector Y in Eqn. 2.

$$\sum_{k=0}^{N-1} \{Y(t + (k \times \Delta t))|t\} \tag{2}$$

The summation indicates the inclusion of all control signals within the prediction window. At time $t+1$, the control signal $Y(t)$ is implemented in the hydrologic-hydraulic model, and the computation is repeated with the prediction horizon (k) moving forward one interval. The interval t is advanced with k at Δt until no additional overflows are predicted within the window $t + (\Delta t \times N)$.

Within the MPC algorithm for the hydrologic-hydraulic system, the cell model introduced by Diskin et al. (1984), and further utilized by Karnieli et al. (1994) and Ostfeld and Pries (2003) is utilized to route excess rainfall water overland to each connecting structure. The model convolutes rainfall in accordance with a unit hydrograph U that has been created for the two linear reservoirs in series (Dooge, 1973) that represent each sewershed.

$$U(t) = \frac{e^{-t/K_1} - e^{-t/K_2}}{K_1 - K_2} \tag{3}$$

The variables K_1 and K_2 are the storage coefficients of each reservoir (in units of 1 over time); in this case $K_2 = 0.1K_1$ and K_1 is proportional to the sewershed area (A_c)

and an overall mean reservoir coefficient (A_{KC}) that can be used for calibration during implementation in an actual sewershed. The mean sewershed area is given as A_m.

$$K_1 = A_{KC}\left[\frac{A_c}{A_m}\right]^{0.5} \tag{4}$$

The hydrograph unit U is the inverse of time. The resulting hydrograph flows (Q_n) are generated for each sewershed through convolution of the linear system, where M is the number of input rainfall pulses (P_m) and n is the current time step.

$$Q_n = \sum_{m=1}^{n\leq M} P_m U_{n-m+1} \tag{5}$$

The precipitation P is a volume. Flows from each sewershed into the interceptor are calculated by equations derived by Swamee (1992) for flow under a sluice gate. Flow can occur either from the connecting structure to the tunnel or from the tunnel to the connecting structure. If the sluice gate is not submerged, the flow can be calculated by Eqn. 6

$$Q = 0.864ab\sqrt{gh_0}\left(\frac{h_0 - a}{h_0 + 15a}\right)^{0.072} \tag{6}$$

where a represents the height of the sluice-gate opening, b is the width of the gate opening, h_0 is the upstream water depth (the higher of the tunnel and the connecting structure water surface elevation), and g is gravitational acceleration. The same variables hold for the case of submerged flow in Eqn. 7

$$Q = 0.864ab\sqrt{gh_0}\left(\frac{h_0 - a}{h_0 + 15a}\right)^{0.072}(h_0 - h_2)^{0.7}\left[0.32\left[0.81h_2\left(\frac{h_2}{a}\right)^{0.72} - h_0\right]^{0.7} + (h_0 - h_2)^{0.7}\right]^{-1} \tag{7}$$

where h_2 is the tailwater depth (the lower of the connecting structure water surface elevation or the tunnel water elevation at that point.) Water is permitted to flow only when h_0 is larger than h_2. Revised sluice gate calculations may be implemented in the final model.

Currently, hydraulic routing computations are simplified by assuming a level pool solution (LMNO Engineering, 2008) for interceptor water level. This results in Eqn. 8, where the volume (V) is calculated from the sluice gate equations and the time step, and the distance along the tunnel wall to which the water rises, S, is translated to a water surface elevation. The slope of the interceptor Φ is 0.0015, and r is the pipe radius.

$$V = \pi r^2\left(S + \frac{r}{\tan\emptyset}\right) \tag{8}$$

Once water elevations are established throughout the system, the elevations in the interceptor at the connecting structures can be compared with the water surface

elevations within the connecting structures. The sluice gate equations (6 and 7) can then be applied to determine the direction and the magnitude of flow.

The MPC algorithm implemented for this study is similar to the algorithms used by Onnen et al. (1997) and Naeem et al. (2005) and is illustrated in Figure 1. Chromosome genes represent percentages of sluice gate closures or the percent of maximum pumping rate and are coded between 0 and 1 and rounded to one decimal place. After initialization and mutation, the gene values are set to 0 or 1 if they are negative or greater than 1, respectively. Each gene can take one of 11 possible values.

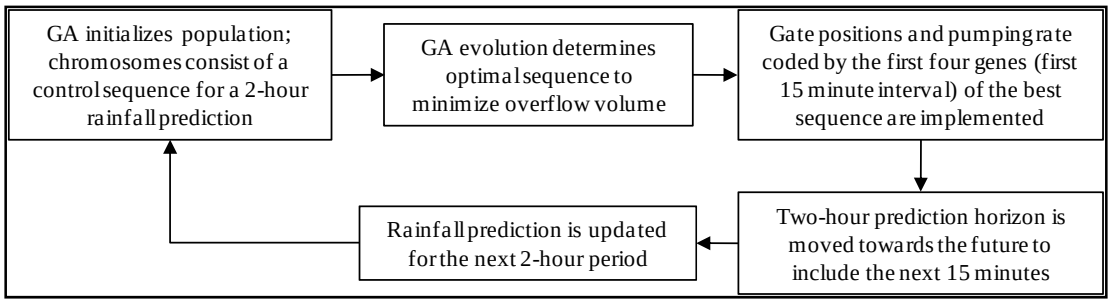

Figure 1: MPC Schematic

The genetic algorithm initializes a population of chromosomes composed of genes, and iteratively applies the operators of selection, crossover, and mutation to produce chromosomes of higher fitness. Real-coded genes increase the algorithm search space, and as a result, mutation rates and/or population sizes should be increased to ensure adequate search (Tate and Smith, 1993). Wright (1991) also supports higher mutation rates. Herrera et al. (1998) summarize numerous methods for real coded GA crossover and mutation; they resolve that non-uniform mutation (NUM) appears to yield fine tuning and the best results in later stages of the GA. Chen (2003) and Chang and Chen (1998) resolve that in terms of crossover, blended crossover (BLX-0.5) exhibits the best performance.

The GA used in this study uses binary tournament selection with replacement where the individual with maximum fitness (minimum overflow volume) is chosen. BLX-0.5 crossover is implemented as described by Herrera et al. (1998) and Eshelman et al. (1993). This method requires the definition of two limits and one integer.

$$c_{min} = \min(c_i^1, c_i^2), c_{max} = \max(c_i^1, c_i^2), I = c_{max} - c_{min} \quad (9)$$

Where the c values represent the gene values from the parent individuals at the i^{th} location. The value of each of two new genes, h_i, is computed to be a random number on the closed interval given in Eqn. 10.

$$[c_{min} - I \cdot \alpha, c_{max} + I \cdot \alpha] \quad (10)$$

To enable local search, the GA used in this study also employs non-uniform mutation based on a mutation size that decreases as the number of generations increase (Herrera et al. 1998; Michalewicz 1992). For this operator applied in generation t, where g_{max} is the maximum number of generations, the value of the mutated gene c_i' is given in Eqn. 11.

$$c_i^{'} = \begin{cases} c_i + \Delta(t, b_i - c_i) \; if \; \tau = 0 \\ c_i - \Delta(t, c_i - a_i) \; if \; \tau = 1 \end{cases} \tag{11}$$

where τ is a random number that can be either 1 or 0 with 50% probability, b is the closed domain to which the mutated gene is constrained, and Δ is the function in Eqn. 12.

$$\Delta(t, y) = y\left(1 - r^{\left(1 - \frac{t}{gmax}\right)^b}\right) \tag{12}$$

where r is a random number from the closed interval 0 to 1 and b is a parameter taken to be 5 in accordance with the value applied by Herrera et al. (1995). For all steps, the maximum number of generations is set to 100; this number must be specified when using non-uniform mutation.

Three approaches are compared for population initialization at each new time interval. The first involves randomly initializing every chromosome (by generating 32 new genes with values between 0 and 1). The other methods constitute identifying the best chromosome from the last time window, and shifting the genes 4 places to the left to retain system knowledge gained in the last interval. Four new randomly generated values are placed at the end of the string to simulate decisions for the next 15 minutes of rainfall. The gene shifting procedure is shown in Figure 2.

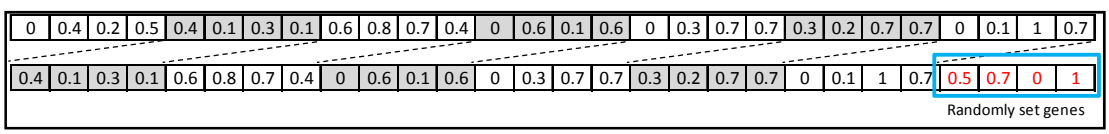

Figure 2: Gene Shifting Method

The second method reinitializes the entire new population with the chromosome of shifted genes (as a result the population only differs by the last four genes of each chromosome). The third strategy entails reinitializing only two members in the next population with these genes. Two chromosomes in the initial GA population for the next time window are replaced with the shifted values, while the remaining chromosomes are randomly initialized.

CASE STUDY

The combined generalized hydraulic model, MPC algorithm, and GA system is demonstrated using a small test case that is roughly based on a portion of the Chicago Tunnel and Reservoir Plan (TARP) system. Case study results are analyzed in order to facilitate development of the decision sequence optimization system as well as provide insight as to regions of the hydrologic-hydraulic system where more accurate modeling is needed.

The coupled hydrologic-hydraulic model used to simulate the rainfall to runoff process is depicted in Figure 3. The system consists of three sewersheds, represented by squares 1 through 3 that are connected through connecting structures (nodes 1 through 3) to conduits 1 through 3 that convey water to a downstream treatment plant and pumping station; arrows designate the flow direction.

The conduit diameters (D), upstream elevations (El_u), downstream elevations (El_d) and lengths (L) are included in Figure 3. Sluice gates that restrict water flow to and from the conduits are located in each connecting structure. The area of watershed 1 is 161 hectares, the area of watershed 2 is 243 hectares, and the area of watershed 3 is 81 hectares. The flow from each of the three sewersheds that enters the conduits is routed downstream to establish water levels throughout the sewer. Water levels at each connecting structure determine whether an overflow will occur. Overflows can occur in the following three ways, volume from each of which is given equal weight within the optimization.

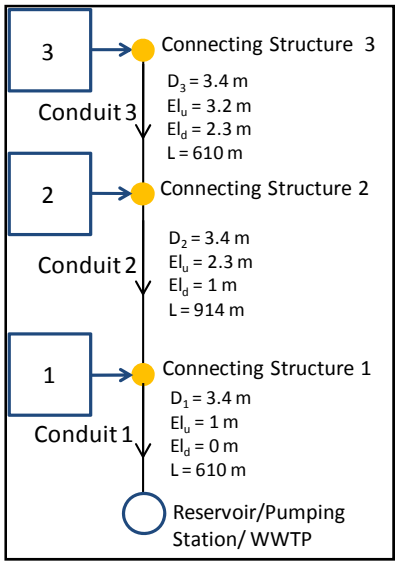

Figure 3: Hypothetical System

1) Local CSO: Water can overflow the connecting structure if the flow in from overland is greater than flow permitted to leave through the sluice gate to the conduit.
2) Pump Station CSO: If the pumping station lifts more water than the treatment plant capacity, water must overflow as opposed to entering the treatment plant.
3) Global CSO: Flows into the reservoir may be greater than the pumping capacity, and water can back up along the interceptor. When the elevation of water in the interceptor is greater than the water level in any of the connecting structures, flow exits the conduit into the connecting structure through the sluice gate, constituting an overflow.

The minimum cumulative volume of sewer overflow events throughout a 3-hour storm (and resulting 5-hour overflow duration) is sought for the watershed-interceptor system. This volume will be achieved through the optimal sequence of management decisions (consisting of a single pumping rate and three sluice gate positions at multiple time steps) derived using model predictive control. Three random number generator seeds, constituting trials 1 through 3, are utilized to provide an overview of possible sequences.

In the results presented, the algorithm is implemented assuming the rainfall is known for the 3-hour storm (displayed in Table 1) and no changes in the prediction occur.

Table 1: Simulated Rainfall

15 minute interval	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
Rainfall (cm/hr)	0	1.3	1.3	1.3	1.3	2.5	2.5	2.5	2.5	1	1	1	1	0	0	0	0	0	0

The 0 cm/hr rainfall input is continued until all overflows have subsided.

Each gene is represented by one integer (that takes a value from 0 to 10) and four genes represent the system at each 15-minute interval. For a 2-hour prediction horizon, the chromosome length is determined in Eqn. 13.

$$4\left(\frac{variables}{interval}\right) \times 2(hours) \times 60\left(\frac{minutes}{hour}\right) \Big/ 15\left(\frac{minutes}{interval}\right) \qquad (13)$$

Eqn. 13 indicates a total of 32 genes per chromosome. The population size will be set to the chromosome length times a constant value of 8 for a value of 256, as suggested by Onnen et al. (1997.) This population size may be reduced when a more physics-based hydrologic-hydraulic model is implemented in order to allow all chromosomes to be evaluated within 15 minutes.

RESULTS AND DISCUSSION

Initially, a crossover probability of 0.5 is used for single point real crossover; nonuniform mutation is used for 100 generations and a mutation probability of 0.01. Figure 4 demonstrates the spatial and temporal overflow distribution when the GA initializes a generation and does not perform further operations for the optimization routine for the 20 interval (5-hour) decision sequence. Only one value of the random seed is used.

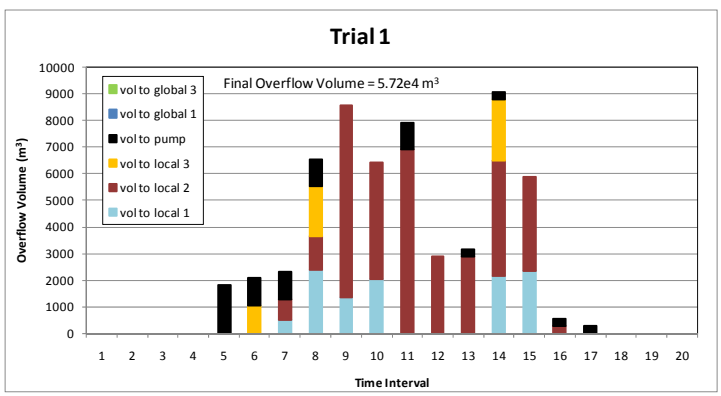

Figure 4: Implemented Sequence for Trial 1

The cumulative overflow volume is 5.72e4 cubic meters. The overflow distribution demonstrates that the largest volume is partitioned as a local overflow out of dropshaft 2 (at the sewershed with the largest drainage area.) CSOs at the pump station also exhibit a large volume, indicating that the pumping rate is increased substantially above the treatment plant capacity.

Initial GA Results

The GA is utilized to transform chromosomes over 100 generations, and three different random seeds (trials) are utilized. Figures 5 through 7 show the implemented sequences for each trial produced by the lowest fitness chromosomes in the final generation at each time increment.

Results show that decisions made at time intervals when very little rainfall has entered and/or remains in the system do not significantly impact the total overflow volume. Many different decision sequences, which differ in the decisions made during early and late time intervals, demonstrate equivalently optimal fitness. For a 2-hour window starting at time step 1, the only overflow that is predicted to occur is at the eighth time step at dropshaft 2. All chromosomes for all seeds predict this local overflow; but the series of gate closures and pumping rates previous to this interval differ.

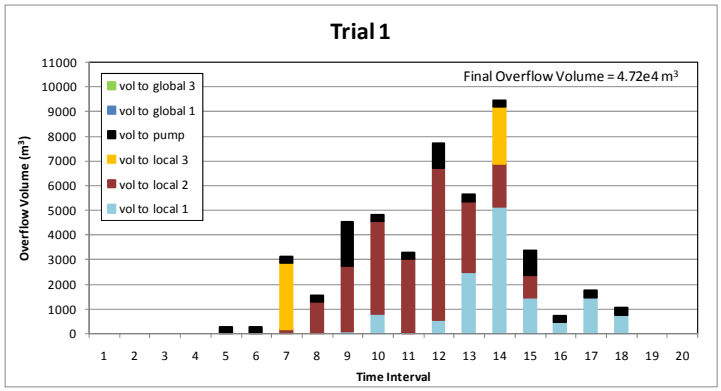

Figure 5: Implemented Sequence for Trial 1

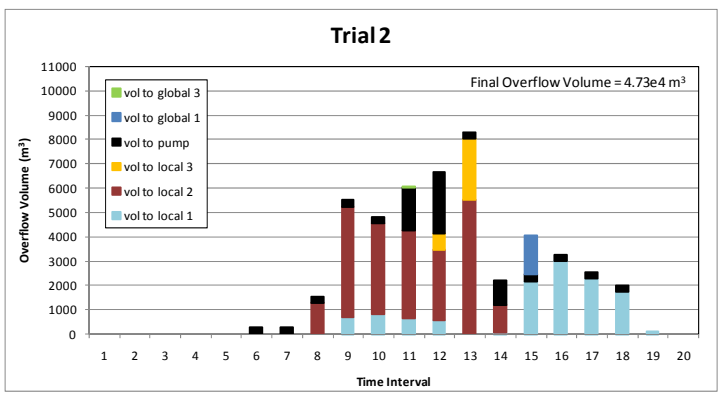

Figure 6: Implemented Sequence for Trial 2

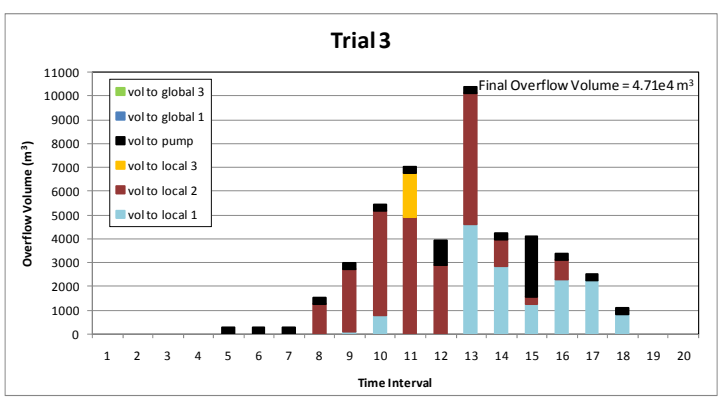

Figure 7: Implemented Sequence for Trial 3

The strategies proposed by the different seeds differ significantly; however local overflows at connecting structure 2 dominate for early time intervals for all seeds and a large number of local overflows at dropshaft 1 occur later in the storm. Local overflows at structure 1 indicate that sluice gate 1 is closed to prohibit global overflows that may be caused at that location because once more water enters the sewer, connecting structure 1 will be the first affected by backups.

The population size used in this algorithm is fixed, and a high mutation rate is necessary to expand the breadth of the search at least for early generations. The mutation rate is increased to 0.05 to aid in the search for good solutions for a large

real-coded alphabet, and elitism is introduced. BLX-0 and BLX-0.5 crossover are introduced, and although they have no effect on their own, introduction of chromosome shifting significantly effects the overflow volumes obtained.

Results for Revised GA Parameters

Introduction of the gene shifting strategy for population initialization significantly reduces the overflow volumes, and leads to a convergence among spatial and temporal overflow partitioning for all three trials. At the same time period for all three trials, the volume is partitioned to the same local or global overflows. The average volume generated over the storm duration decreases from 4.72e4 cubic meters to 4.60e4 cubic meters. The improved performance obtained by gene shifting may be amplified by the deterministic rainfall assumed in this problem. Further work will implement more realistic, changing precipitation forecasts necessary to validate the superiority of the gene shifting strategy.

The distribution of overflows throughout the system is shown in Figures 8 through 10 for population initialization with two chromosomes with shifted genes. The predictions (final chromosomes) for intervals beginning at time steps 1 through 4 and from steps 18 though 21 differ the most due to lack of water in the system.

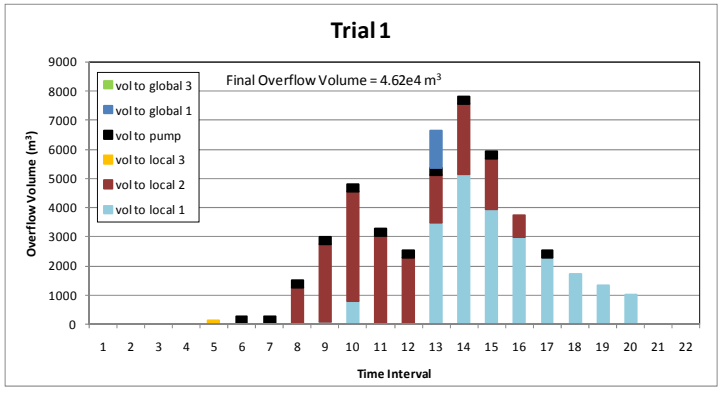

Figure 8: Implemented Sequence for Trial 1

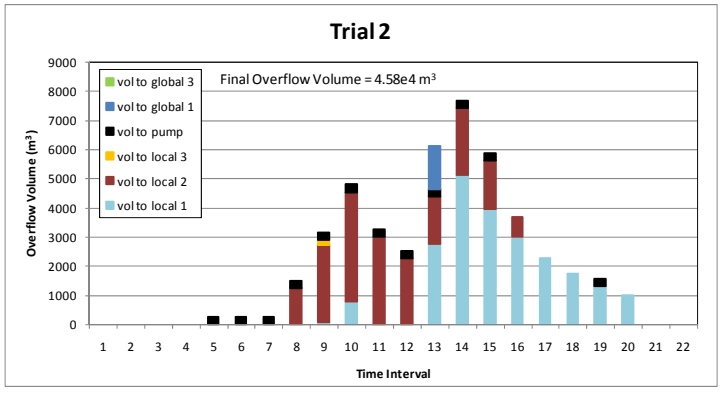

Figure 9: Implemented Sequence for Trial 2

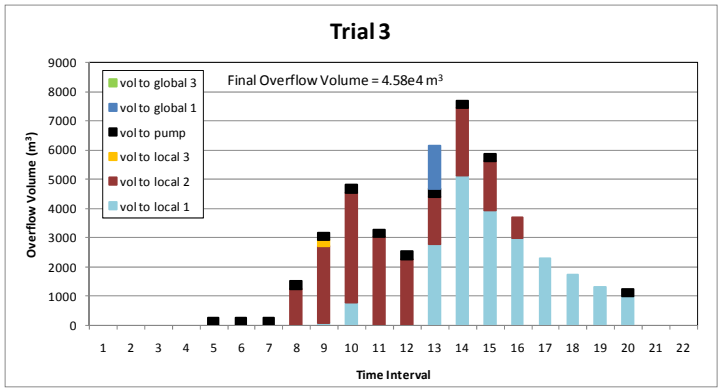

Figure 10: Implemented Sequence for Trial 3

The implemented decision variables demonstrate that that the best management strategy is to keep the pump on at the capacity closest to the treatment plant rate throughout the storm event rather than pumping at higher rates at inconsistent intervals. All trials also indicate that sluice gate 2 should be fully open for the middle intervals of the rainfall, and towards the end of the rainfall, sluice gate 1 should be fully closed and sluice gate 3 should be partially closed while water from sewershed 2 is pumped out of the system. The three strategies extend the number of intervals for which overflows occur from 19 to 20. For all trials, one global overflow occurs at time interval 13, and no overflows occur after interval 20.

CONCLUSIONS AND FUTURE WORK

This study develops a real-time GA-based control system for managing CSOs. The system employs a real coded genetic algorithm to develop management strategies that most effectively reduce overflow volume over a 5-hour window using 15-minute control intervals and a 2-hour planning horizon. At each control interval, the system re-evaluates the optimal 2-hour decision sequence to account for changing precipitation conditions. The system is implemented in a case study roughly based on a portion of the Chicago TARP system.

The decision sequences that produce the lowest CSO volume are obtained when the genes for the best chromosome in the previous time window are shifted for initialization in the next window; this method of initialization propagates knowledge of the best management strategy to the next generation. Additionally, this method of population initialization allows decision sequences derived from different random seeds to converge to similar partitioning of overflow volume for the entire 5-hour optimization period. It may prove beneficial to initialize only two members of the subsequent population with the shifted genes, allowing the remainder of the chromosomes to be randomly generated, thus enlarging the search space. This method may also save computational effort; fewer GA generations may be required to reach a good solution when genes shifted from the previous time interval are utilized.

Future work will include further evaluation of the genetic algorithm. New strategies of population initializing at each time window should incorporate evaluation of the necessity of rerunning the algorithm at every 15 minute interval for low changes in rainfall rate. A threshold change in rainfall rate may exist below which the decision

sequence remains consistent for the initial steps of a new time window. The effects of population size on minimum fitness and the types of chromosomes of minimum fitness should be further examined; high mutation rates should be evaluated as a substitute for increases in population size.

Different weights could be assigned to the location and timing of overflows. This extension would be valuable for possible use within a water quality model in which portions of the receiving waterway downstream of certain sewersheds are more sensitive to overflow contamination than others. The analysis may restructure the spatial and temporal patterns observed for the equivalent weighting presented.

The insight into GA parameters and physical characteristics for this case study will be applied to a more physics-based model, in which interceptor hydraulics will be based on the methodology proposed by Hoy (2005). A hydraulic performance graph (HPG) and a volumetric performance graph (VPG) will be established for each conduit. The HPG ensures conservation of momentum for the reach and is a collection of the backwater profiles of the reach created through the gradually varied flow equation (Chow, 1959).

$$\frac{dh}{dx} = \frac{S_0 - S_f}{1 - F^2} \tag{14}$$

The HPG has been used to analyze open channel stage-discharge relations (Schmidt, 2002) and applied to unsteady flow routing by Gonzalez-Castro (2000). The VPG introduced by Hoy (2005) describes the volume stored in the reach for each flow condition described by the HPG, and ensures conservation of mass for the reach.

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q_{lateral} \tag{15}$$

The change in flow area with respect to time plus the change in flow rate with respect to distance is equal to any lateral inflows to the reach. All water entering the conduit system is immediately transferred to the downstream reservoir and from there is routed back upstream to establish conduit water level in accordance with work done by Oberg et al. (2001). The HPG and VPG files are created offline for a range of flow rates and downstream boundary conditions for the sub-conduits through tools scripted in *C++* (Oberg, 2008). The graphs will be used for interpolation during the MPC algorithm.

At each time step, the HPG is used to find the upstream water surface elevation for each conduit given the average flowrate and the downstream water surface elevation. The VPG is used to determine the storage in each reach for the current time step, using the same inputs utilized for the HPG. Optimization is performed to find the minimum least squares solution that equates the change in storage with space to the change in storage with time, that is, to minimize the difference: $\Delta S_{time} - \Delta S_{space}$ for each conduit. The solution will provide flow rates for each sub-conduit which can then be utilized to find upstream water surface elevations throughout the system.

The finalized coupled hydrologic-hydraulic model will be used to evaluate the sensitivity of local, global, or pump station overflows to system management. The procedure will eventually be extended to the Metropolitan Water Reclamation

District of Greater Chicago's (MWRDGC) Tunnel and Reservoir Plan (TARP). The system will be utilized with real-time precipitation updates, and calibrated to CSO data provided by the MWRDGC.

ABSTRACT

In northern climates, runoff from standard pavements has varying seasonal effects on the surrounding environment. Year-round runoff carries transportation associated contaminants into surface waters. During the winter and spring, deicing practices for pavements result in high levels of chloride-laden runoff that is both toxic to aquatic biota and degrades drinking water supplies. The use of pervious pavements for parking lots for new and redevelopment projects are one watershed-based strategy that can both mitigate impacts for new development and reverse impacts in areas with redevelopment. This study presents the findings from 2 pervious pavements, a pervious concrete and a porous asphalt parking lot, studied at the University of New Hampshire Stormwater Center. Winter in particular places great demands on pavements however it was observed that due to the well-drained nature of the reservoir base that freeze thaw was limited. Surface infiltration rates, frost penetration, degree of snow and ice cover, and surface friction were measured on a monthly basis to assess winter performance. Frost penetration was observed to reach depths of eighteen inches however, surface infiltration capacities remained in excess of 200-in/hr. Analysis of snow and ice cover and pavement skid resistance demonstrated that up to 75% less salt was needed for porous asphalt to maintain equivalent or better surface conditions as the reference dense mix asphalt lot. The annual median snow and ice surface cover for the porous asphalt lot was not significantly different than the reference lot with salt applications four times greater ($p=0.749$ @95% CI). The annual median weighted skid resistance for the porous asphalt lot was 12% greater than the reference lot with greater salt application ($p=0.061$ @95%CI). Pervious concrete did not demonstrate substantial salt reduction capabilities during storm events; however, 'black-ice' formation did not occur during freeze-thaw conditions indicating possible annual reductions. Pavement color and shading were found to be major factors influencing the amount and duration of snow and ice cover on the pervious concrete lot.

INTRODUCTION

The implementation of the National Pollutant Discharge Elimination System (NPDES) Phase II regulations has helped to fuel the research, development, and implementation of innovative Best Management Practices (BMP) for managing and treating stormwater runoff. Since 2003, the University of New Hampshire Stormwater Center (UNHSC) has set out to evaluate over twenty types of BMPs in a fully-monitored field setting. One class of BMP that is at the forefront of the industry and is being adopted in both the public and private sectors is permeable pavements. One of the major benefits of permeable pavements is their dual function as a transportation surface and self-contained stormwater management device. The research has demonstrated that porous asphalt may allow for a 77% annual salt reduction for winter maintenance over conventional practices on impermeable asphalt (Houle, 2008). To date, the UNH Stormwater Center (UNHSC) has constructed and tested two types of permeable pavement parking lots: porous asphalt and pervious concrete, both of which are located at the UNH campus in Durham, NH. The objective of this study is to compare and contrast a series of winter performance metrics of porous asphalt (PA) and pervious concrete (PC). Topics discussed include frost penetration, hydraulic performance as measured by infiltration capacity, winter performance based on snow and ice cover and surface friction. Historically, there has been some debate among the engineering community on how permeable pavements perform in northern climates; part of this debate stems from the confusion between a true porous asphalt stormwater management system versus open-graded friction course (OGFC), for example, which is typically used in highway application and differs from PA by its impermeable asphalt base (Kandhal and Mallick, 2002). This paper to addresses these misconceptions and identifies the potential benefits of permeable pavements.

BACKGROUND

Permeable pavements differ from standard dense-mix asphalt in that the "fines" (particles smaller than 600 microns) are removed from the aggregate mix, thereby allowing the formation of pores for water to pass (Cahill et al., 2003; Ferguson, 2005). Porous asphalt typically consists of stone aggregate, binder material, and other modifiers and should demonstrate a void space of 18% to 20% (Briggs, 2006). Pervious concrete, on the other hand, consists of hydraulic cement, stone aggregate, water, and a combination of various chemical additives (admixtures) to enhance the performance, strength, and ease of placement. Typical void space of a pervious concrete pavement should be between 15% and 25% (NRMCA, 2007). In the case of the UNHSC designs, the porous asphalt lot was placed in one, four-inch lift while the pervious concrete lot was poured to a six-inch depth. Both of these surfaces were placed over a choker (stone) course underlain by 12-inches or more of a bank run gravel filter course. Design specifications can be found online at the UNHSC (2007).

Many of the sub-base design considerations for porous asphalt and pervious concrete stormwater management systems are similar to those that would be inherent of most infiltration-based BMPs. For instance, both UNHSC designs consist of a bank-run-gravel (BRG) filter course underlain by crushed-stone reservoir layer. The

thicknesses of these layers vary between systems, ranging from 14-inches (PC) to 24-inches (PA) of filter course and 4-inches (PC) to 21-inches (PA) of crushed-stone reservoir. The total sub-base depth of the PA site was greater than the PC design in order to meet seasonal-high-groundwater separation restrictions and due to the presence of a less permeable native sub-grade soil. Historically, the sub-base of many porous asphalt systems consisted of only crushed stone; however, with the addition of the filter course, the water quality performance of the porous asphalt system is substantially improved, resulting in the removal of most stormwater contaminants (hydrocarbons, microorganisms, sediment, metals) (Roseen et al., 2009). The major differences between these systems (PA and PC, in general) are primarily in the wearing course mix designs.

The UNHSC porous asphalt (PA) site is a hydraulically isolated 5,000 ft^2, 17-space parking lot that was installed in 2004. Directly adjacent to this PA lot is an equally-sized dense-mix asphalt (DMA) parking area that is also hydraulically isolated. The DMA lot was constructed concurrently with the PA site to serve as a control for most performance metrics. Both lots are located along the perimeter of a nine-acre, asphalt commuter parking lot. The UNHSC pervious concrete (PC) site was installed in August, 2007. It is approximately 20,000-ft^2 and includes 75 parking stalls. It serves as a parking lot for several nearby dormitories and is used to capacity primarily from September to May. Adjacent to the PC site, is a university-maintained standard asphalt lot that was used as an additional reference location for the study.

The winter climate (January through March) in Durham, NH generally consists of average temperatures near 27.7 ^{o}F, with maximum and minimum temperature of 37.5 ^{o}F and 17.3 ^{o}F, respectively. Total precipitation during this time period is approximately 16.4 inches and snowfall is around 63.1 inches (NHSCO, 2008).

METHODOLOGY

Frost depth penetration within the two types of permeable pavement was measured using a field assembled frost gauge (Ricard et al., 1976) installed in a screened, PVC groundwater monitoring well. Frost depth was determined by measuring the depth of frozen water-methylene blue solution. Frost depth and air temperature were recorded regularly from December 2007 to April 2008.

Surface Infiltration Capacity. Hydraulic performance of the permeable pavements was evaluated by measuring the surface infiltration capacity (IC) on a near-monthly basis beginning soon after installation. A falling head surface inundation (SI) test (Bean, 2005) was used for this process. This involved pouring a known volume of water into a cylinder and measuring the time required for the water to enter the pavement surface. Measurements were taken at three randomly selected locations (A-C) on the PA lot beginning in 2004, and at six locations (A-F) on the PC lot beginning in 2007. A double-ring infiltrometer (DRI) test was used at one location at the PA lot (Point C) because the IC rate was too low to be accurately represented with the SI device (Briggs, 2006) and further explanation can be referenced in Houle (2008).

Salt Application. Salt was applied to the parking lots in a manner designed to mimic municipal anti-icing and de-icing strategies, and consistent with the general practices employed by the University of New Hampshire. Application rates were selected based on percentages of the recommend standard of practice rate of 3.0-lbs per 1000-ft^2 of application area (MPCA, 2006). The rates used in Houle (2008) (100%, 50%, 25%, and 0%) were applied to 20-ft by 20-ft sections of the driving lane through the pervious concrete lot (Figure 1). The remaining driving lane area received a 100% application rate. The salt used was standard rock salt with less than 10% added fines by mass; it was identical to the mix used in the '06-'07 study.

The number of salt application rates for the porous asphalt and dense-mix asphalt lots was altered from the previous winter. The entire PA lot received a rate of 25% of the standard of practice while the DMA lot received a 100% rate (Figure 1). Evaluation areas included isolated parking stalls, as was the case in Houle (2008) and the lots as a whole. This change in methodology was performed in order to quantify any differences that may exist between driving lanes and parking stalls.

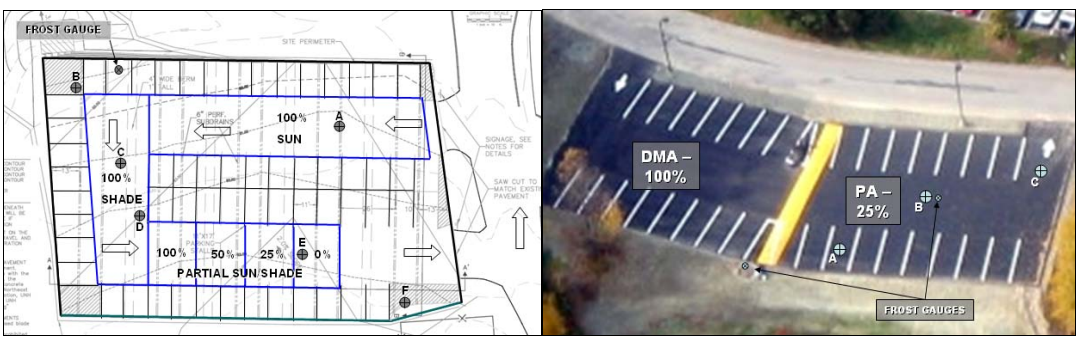

Figure 1: Pervious concrete (PC) (left) and Porous asphalt (PA) and dense mix asphalt (DMA) (right); Salt application rates, frost gauge and IC locations shown

Visual Observations and Documentation. Before, during, and after storm events, photos were taken of each study area and the specific event characteristics were recorded. Pavement conditions, type and amount of snow and ice cover, and weather conditions were of primary interest. Apparent effects from shading or direct sunlight was also recorded. Photo documentation was necessary to substantiate the findings and to display comparative results of the different pavements. Evaluations typically occurred at various times during and up to three days after precipitation events.

Friction Measurements. The skid resistance of all pavement types was measured using a Munro Stanley London British Pendulum Skid Resistance Tester. Each measurement was classified based on the form of surface cover that was present during the reading, including: dry, wet, snow, slush, compacted-snow, and ice covered pavement. The method for using the skid resistance tester followed ASTM Standard E 303–93 (2004). As explained in Houle (2008), the device measures the energy loss of a rubber slider as it is swung against the test surface. A British Pendulum Number, or BPN, is generated and can be directly related to a pavement coefficient of friction (Munro Environmental, 2007). The higher the frictional resistance of the surface, the greater the resulting BPN.

Skid resistance measurements were taken at various locations within each study area, repeated five times, and seasonally averaged in order to characterize the variability in friction between each type of pavement cover. The mean values were then multiplied by their respective surface cover type percentages in order to develop a weighted friction value for each observation. The significance of the weighted friction value was to obtain a number that can easily be related to safety for each of the varying salt application rates.

Statistical Comparison Methods. A 'Student's t' means comparison test was employed for all portions of this study to determine differences in central location (mean) for two independent data sets (Helsel and Hirsh, 2002). Group comparisons with p-values less than 0.05 (with a 95% confidence interval) were deemed statistically different. These analyses include surface infiltration capacity, snow & ice cover, and skid resistance.

RESULTS AND DISCUSSION

Frost Depth Penetration. A time-series from November 2007 to April 2008, displaying frost depth in the porous asphalt and pervious concrete lots, is shown in Figure 2. Frost depth within the systems is plotted against average daily air temperature and frost depth at one reference location in soil adjacent to the PC study areas. Rain events as occurrences are plotted as vertical dashed lines. A clear repeatable phenomena is observed where depth of frost penetration is reduced following a rain event. This occurs on 6 occasions. The same response is not observed in the reference location, likely due to lack of infiltration of meltwater as is observed in the corresponding open-graded materials. The degree of response has not been examined with respect to rain depth or other important factors. Rain events occur throughout the winter and are commonly mixed with snow and ice. It is apparent from the figure that the PC responded quicker to lower air temperatures and maintained a greater frost depth than the PA system until early February when a sudden decrease in depth of frost was observed. It is believed that the rapid decrease in frost depth was due to a 1.66" rain-equivalent snow and rain event on 2/5/08 that thawed the systems, which is consistent with findings by Backstrom (2000) and Houle (2008). This was observed for another large storm on the 2/26 of nearly 1" rain-equivalent. Shortly after this rapid thawing process, the PA lot refroze to a frost depth of about thirteen inches while the frost depth in PC lot stayed nearly constant at eight-inches. A possible explanation for this may be due to water levels and latent heat within the two systems. The PC frost gauge well is located at the low-point of the lot and in an area where the total system depth is about 30-inches. At the time of observation, the water level was consistently about 26-inches below the pavement surface (at the base of four-inch perforated sub-drains). The water level in the PA lot on the other hand, was approximately 37-inches below the pavement surface. Researchers in Sweden discovered that high water content in the sub-soils beneath permeable pavements creates a high level of latent heat within the system, which can help resist freezing of the sub-base materials (Backstrom, 2000). The higher ground water level in the pervious concrete system may have supplied enough latent heat to minimize its frost depth.

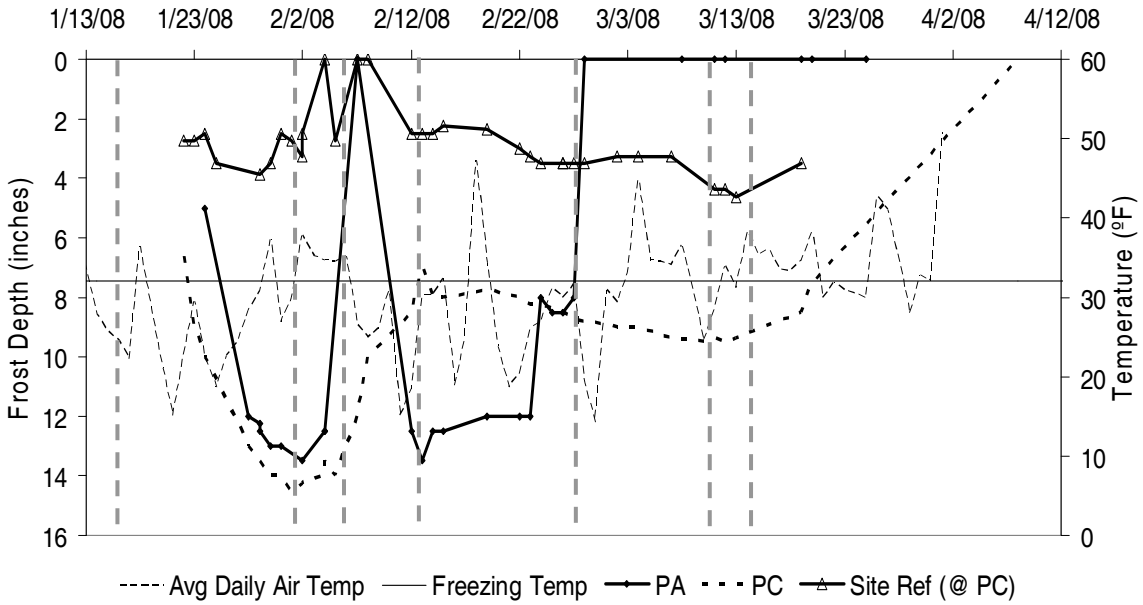

Figure 2: Frost depth penetration comparison between permeable pavements and reference soil sites (11/07 – 4/08); (Rain events shown with vertical, dashed lines)

Another interesting finding from this data is that frost depth in the PA system reached zero, and was sustained, over four weeks earlier than the PC lot. This discovery can be explained by the fact that the black PA surface possesses low albedo and therefore retains more solar energy in the winter than lighter colored surfaces and the more rapid response in frost depth variability in the dark colored pavement. Concrete pavements have been shown to exhibit surface temperatures up to 10-degrees Fahrenheit lower than asphalt pavements when subjected to similar sun exposure conditions (Cambridge Systematics, 2005). Shading of the PC lot may have also contributed to the longer frost depth duration.

In addition, the permeable pavements demonstrated similar freezing depths to the tree filter treatment unit, suggesting that frost penetration can be comparable to other existing stormwater BMPs, even with several inches of open-graded surface material (Houle, 2008). The one major difference between the pavements and the tree filter is the time it took to reach the maximum frost depths. The lag of the tree filter may be attributed to snow-pack insulation that was present much of the winter. It is also worth noting that no damage or heaving due to freeze-thaw was observed at these lots since their respective installations.

Surface Infiltration Capacity. The surface infiltration capacity was measured at both permeable pavement lots. Figure 3 is a time series and box and whisker plot of the IC data for the PA lot. In the time series plots, each point on the figure represents an average IC measurement; the location and testing method used is indicated by the

different markers. The average daily air temperature (A.D.A.T.) is also shown on the figure. In the box and whisker plots, the maximum and minimum observations are represented by the upper and lower whiskers, respectively, and the median values are shown by the gray bar through the 'boxed' segment of the data. The infiltration rates for the PA lot were typically found to be greater than 500 in/hr (Houle, 2008). During the first year of study, IC rates were highest during the winter and spring seasons, even with frost penetration reaching up to six-inches (Briggs, 2006). Since the first year of testing, higher IC rates were typically observed during the summer months; however, winter rates never dropped below 250 in/hr at Locations A and B. Asphalt binder drain-down of approximately 0.5% was identified (Houle, 2008) and thought to contribute to the infiltration rate decline observed during the first summer of study. The low infiltration capacity at Location C was determined to be an anomaly due to over-compaction during placement and clogging from tracked/blown sediments. Further explanation of the IC results can be referenced in Houle (2008) and Briggs (2006).

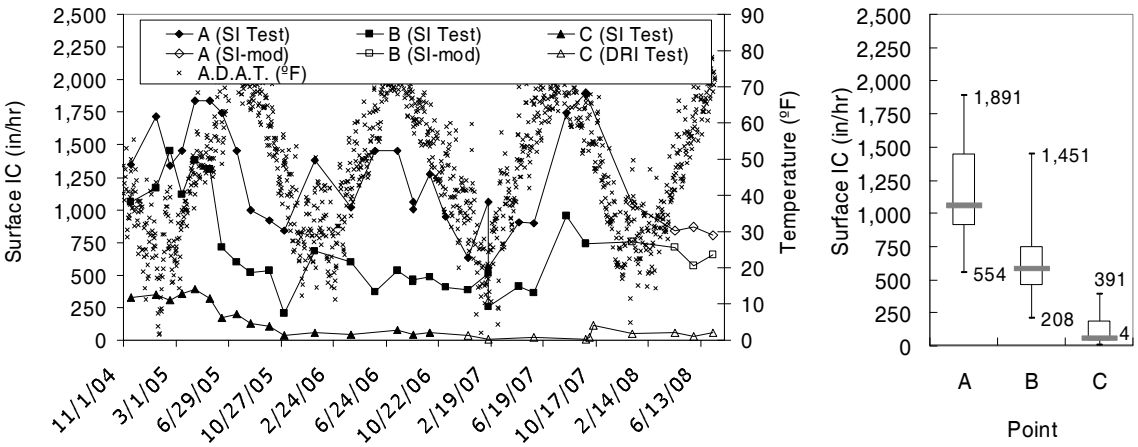

Figure 3: Porous asphalt surface infiltration capacity (Houle, 2008; Briggs, 2006); Time-series of surface IC (left); Box and whisker plots of surface IC (right); [(SI = surface inundation; DRI = double-ring infiltrometer; SI-mod. = modified SI), (Mod. SI appears to report lower infiltration rates, further study needed for correlation), (Pavement cleaning occurred 9/23/07)]

The IC testing at the PC lot was monitored at six locations. Even though considerable variability existed between locations, five of the six sites exhibited median IC rates in excess of 1,600-in/hr, nearly matching the highest values recorded on the PA lot (Figure 4). The only site below this value was near the entrance of the lot, a location where sand and other debris was commonly tracked and deposited from the nearby roadway. Nevertheless, all of the observed rates surpass rainfall intensities that one might experience in New England. [The 50-yr rainfall intensity for a 5-minute time of concentration in Strafford County, NH is approximately 8.0-inches per hour (NHDES, 1992)].

Winter Storm Event Characteristics. The results for one season of winter precipitation events are presented beginning in December 2007 and ending in March 2008. The types of storms evaluated during this season consisted of light to heavy snowfall, sleet, freezing rain, rain, and various combinations of each, with air temperatures ranging between -5ºF and 62ºF (UNHWS, 2008) (Table 1).

Visual Observations. Provided that plowing occurred shortly after the end of snow events, it was commonly observed that the PA pavement became clear of snow and ice earlier than the dense-mix asphalt lot. This observation is exemplified by the photos in Figure 5. These illustrate the PA and DMA lots at 11:20AM after morning plowing. A thin layer of snow is present on both lots because most plowing operations have difficulty removing all cover due to vehicular compaction and irregularities of the pavement surface as well as the plow blade itself. The figure show the same lots one-hour and forty-minutes later. The PA lot is distinctively clear of snow and ice while the conditions of the DMA lot only exhibit minimal melting. Estimates of surface cover amounts at 1PM were 15% snow for the PA lot and 50% snow for the DMA lot. Air temperatures ranged from 31.3ºF at 11:20AM and 37.6ºF at 1PM. These observations correlate well with assessments made during the 2006-2007 winter on the same parking lots (Houle, 2008).

Figure 6 shows the two pavements after a freezing-rain event (air temperature of 42.3ºF). It is clear from these photos that the ice on PA had melted and drained through the pavement far earlier than the DMA lot based on the amount of standing water and ice on the DMA surface. Standing water on pavements is a problem because it will often refreeze during the night creating unsafe surface conditions that require deicing salt applications. Standing water was never observed on the porous asphalt lot. It should be noted that freezing-rain events often created icy conditions on both the PA and DMA pavements when air temperature remained near or below 32ºF. When temperatures exceeded this point, the porous asphalt typically responded quicker than the DMA, as is the case in the figure.

Table 1: Winter storm event characteristics ('07-'08); (S = Snow; R = Rain; I = Ice) (NCDC, 2008; NHSCO, 2008; UNHWS, 2008)

Date	Precipitation Type	Snow Depth (in.)	Water Equivalent Depth (in.)	Max Temp (ºF)	Min Temp (ºF)

The PC lot demonstrated mixed results based on the amount of shading that each section of the lot received. Much of the lot was shaded due to dense fir tree cover around the perimeter; some areas were in shade at all times of the day. The lot was divided up into three main sections in order to characterize this spatial variation. The photos in Figure 7 demonstrate the shading trends that were common through the majority of the winter; all were taken concurrently at 11AM on 2/27/08. The figure depicts the variations of three shaded conditions: the driving lane that was typically in the sun with clear weather conditions; a driving lane that received partial sunlight; the driving lane almost always in the shadow of the surrounding trees.

Figure 5: Changing pavement conditions with time: PA vs. DMA; (12/14/07) PA at 11:20AM (top-left); PA at 1PM (top-right); DMA at 11:20AM (bottom-left); DMA at 1PM (bottom-right)

Figure 6: Instantaneous pavement conditions after freezing-rain: PA vs. DMA; (1PM on 2/2/08) PA (left); DMA (right)

Figure 7: Pervious concrete surface conditions with varying levels of shading; (11AM on 2/27/08) In sun (left); In partial sun (center); In shade (right)

Despite the difficulties created by shading, the PC lot performed extremely well during freezing and thawing weather conditions as measured by the amount of black ice formation. Figure 8 is a comparison the PC lot and the adjacent standard asphalt reference lot that is maintained by the university. The photo shows a driving lane of the PC lot that is completely dry and nearly free of snow while the nearby standard lot in is almost entirely covered with black-ice and water. These photos were taken at 12:50PM on 2/16/08 when the air temperature was approximately 22.5ºF; a low of 14ºF was reached at 7:15AM (UNHWS, 2008). The standard winter maintenance practice for the UNH Grounds & Roads Dept. is that when nightly air temperatures are below freezing, salt is applied to most roads and parking lots to combat the formation of black ice. The DMA reference lot in the photo was treated in this manner. Conversely, no salt was needed on the PC pavement under these weather conditions since standing water was never an issue. In these photos, snow is observed in the parking stalls. The stalls are not plowed because often cars remain there before, during, and after snowfall events.

Figure 8: Pavement conditions after thawing and refreezing of meltwater; (12:50PM on 2/16/08) PC at 12:50PM (left); Stnd. Ref. lot at 12:50PM (right)

Snow/Ice Surface Cover Analysis. The amount and type of snow/ice surface cover (dry, wet, slush, snow, compacted-snow, or ice) that was observed on each study area after storm events was recorded in order to make comparisons between salt applications and pavement type. Data for the entire '07-'08 winter season was grouped and compared statistically and graphically. Figure 9 presents the snow and ice cover for all study areas; the median surface cover percentages are displayed next

to each data set. The salt application rates for each study area are specified as 100%, 50%, 25%, or 0% of the recommended application rate (3.0-lbs per 1000-ft^2; MPCA, 2006).

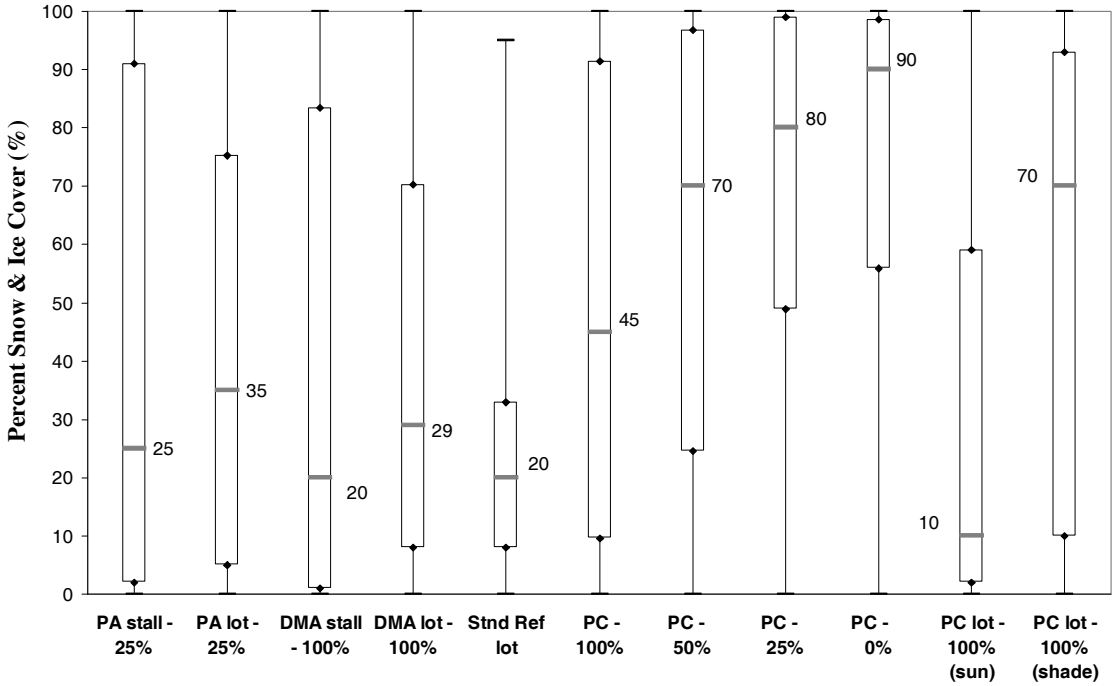

Figure 9: Comparison of snow & ice percent cover for all study areas ('07-'08); (Pavement type and salt application rate as percentage of 3-lbs/sf shown on x-axis)

The median snow/ice surface cover at the "DMA lot" is not significantly different (@95%CI, P=0.749) than at the "PA lot" even though the DMA received a salt application rate four times as great as the PA. A slightly higher application rate on the PA surface may have produced equivalent results between the two pavements.

When comparing the parking "stall" snow and ice cover data to the "lot" data in Figure 9, a difference of about 10% is shown for both the PA and DMA pavements even though each received the same salting rate. This disagreement can be explained by the amount of vehicular snow compaction at each observation area. The driving lanes, which make up a portion of the area included in the "lot" snow/ice surface cover observations, often experienced longer melting times than the parking stalls due to the difference in traffic and amount of snow compaction. Despite this disparity, no statistical difference in snow/ice surface cover was found between the data sets for the "lot" and "stall" areas at either the PA or DMA site (based on a p-value of 0.05).

The snow/ice surface cover measurements for the PC lot were considerably higher than the PA and DMA lots, but as one might expect, snow/ice surface cover increases with decreasing salt use. As mentioned previously, a possible explanation for the dramatic difference can be attributed to shading of the PC lot. The four PC study areas were located in an area that received only partial sunlight. This claim is supported when comparing the data sets for the PC lot that were in the sun and in the shade. A strong statistical difference exists between the sunny and shaded study areas

at the PC lot (p = 0.001) demonstrating that a factor other than salt application was contributing to the amount of snow/ice surface cover.

Frictional Properties of Pavement Surfaces. Frictional measurements were taken on all pavements with the British Pendulum Tester during and after storm events. All types of pavement conditions observed were evaluated, including dry, wet, snow-, slush-, compacted snow-, and ice-covered pavement. The data were grouped by pavement type and analyzed statistically to determine median skid resistance values for each type of surface cover (Figure 10). The median values for each group are displayed on the figure below each data set. Student's t-tests were performed to show how porous asphalt and pervious concrete compare to the conventional pavements in this study (Houle, 2008).

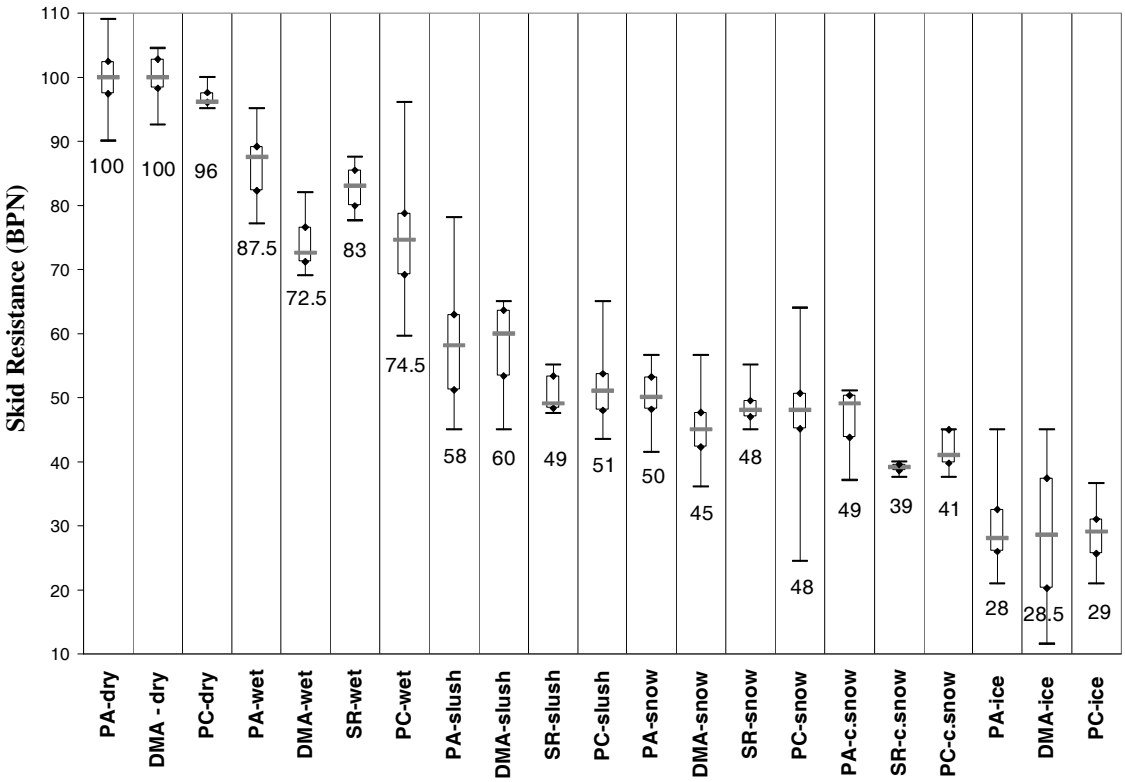

Figure 10: Skid resistance for all pavements and winter surface conditions ('07-'08) [(PA = porous asphalt; DMA = dense-mix asphalt; PC = pervious concrete; SR = standard (asphalt) reference), (Median skid resistance value displayed under each group)]

Of the four pavement types studied, porous asphalt was found to have the highest skid resistance for wet, snow-, and compacted snow-covered pavement, this is likely due to the large aggregate gradation (Figure 11) and the lack of fine particles in the mix. Literature suggests that coarser aggregate gradations will produce rougher pavement surface textures (Asi, 2007; Manuba et al., 2007). The PC demonstrated moderate skid resistance values for dry, wet, and snow-covered pavement. The smooth PC surface finish may have also contributed to the lower skid resistance when compared to the tackiness of asphalt mixes. It is significant to note the similarities in

skid resistance for PA and DMA between this winter and the '06-'07 winter presented in Houle (2008) despite differences in winter charateristics. The median values exhibit only slight differences between seasons, some of this variation may be due in part to the inclusion of additional snow/ice surface cover types (slush and compacted snow) in the '07-'08 winter.

By multiplying the mean skid resistance values by the snow and ice surface cover percentages a weighted skid resistance value was developed (Figure 11). The purpose of a weighted skid resistance was to assign a single number that can describe the pavement safety when compared to standard, dry conditions. The median skid resistance for the "PA lot" was 12% higher than the "DMA lot" even though the salt application rate was a quarter of that which was applied to the DMA surface. Similarly, the standard reference lots, which received regular plowing and salting by the UNH Grounds & Roads Dept., also demonstrated lower frictional resistance than the porous asphalt lot. The weighted skid resistance for the PA "stall" measurements in Figure 11 correlate extremely well with the data from the '06-'07 winter. A median value of 77 BPN was observed for the '07-'08 winter with the 25% salt application rate, whereas for the '06-'07 winter, a BPN of 79 was shown (Houle, 08). The "stall" measurements serve best for making comparisons between winters because the '06-'07 study focused only on areas that were not utilized for parking. A p-value of 0.662 was calculated between winters for the PA lot, suggesting that annual differences in weather conditions did not statistically change the results. The difference between the two seasons for the DMA parking stall study areas was 7 BPNs with a p-value of 0.298, also suggesting no statistical difference between winters (@95% CI).

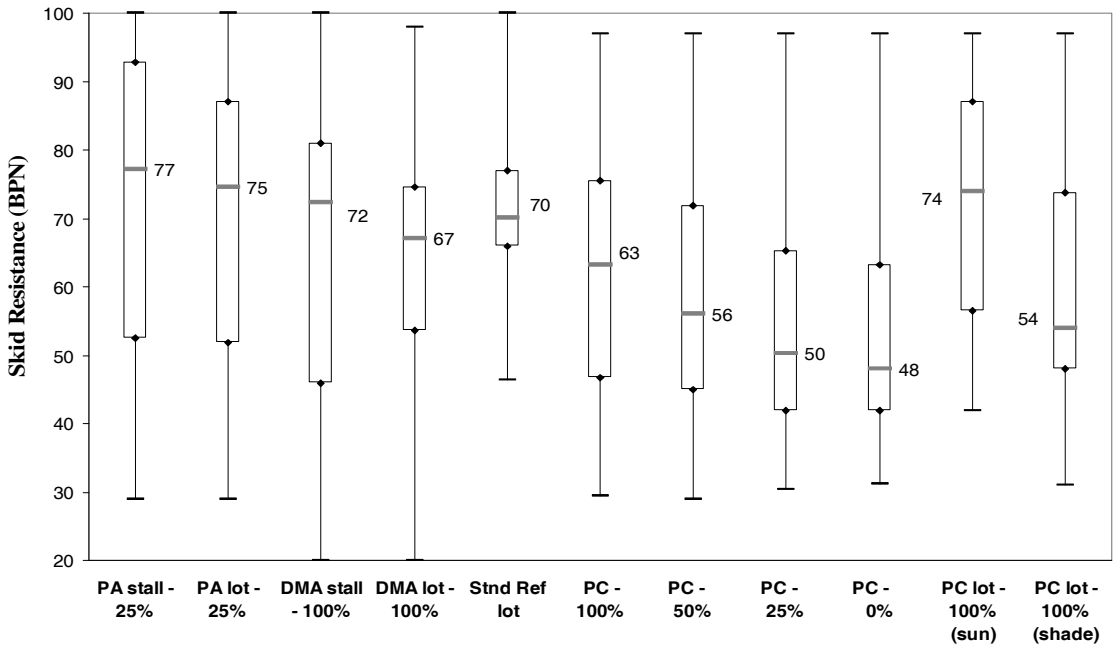

Figure 11: Weighted skid resistance as a function of surface cover ('07-'08) (Pavement type and salt application rate as percentage of 3-lbs/sf shown on x-axis)

The weighted skid resistance values for the pervious concrete parking lot study areas were considerably lower than both the PA and DMA pavements, despite salt application. This is likely due in part to a number of factors. As mentioned previously, the four main study areas did not receive as much sunlight as the other pavements because of a heavily wooded perimeter. Additionally, the pervious concrete lot is a much more trafficked parking lot due to its proximity to three adjacent dormitories; therefore, vehicle compaction of snow cover prior to plowing was often a problem. Operational constraints limited plowing maintenance for this project to one time per storm event. For this reason it was not uncommon for snow in the lanes to be driven on for several hours before plowing. Lastly, the measured skid resistance values for most types of pavement cover on the PC were lower than the other pavements, which will inherently produce lower weighted skid resistance values. Conversely, when looking at the data for the section of the PC lot that did receive sunlight, the skid resistance is similar to the results for the PA data set. This is a significant finding considering that permeable pavements may be most applicable for large, commercial settings where heavy tree cover is uncommon, and should be further investigated.

P-values less than 0.05 indicate that a statistical difference may exist between weighted skid resistance data sets. When comparing the results for PA to DMA using a Student's t-tests, the p-values are only slightly greater than 0.05, suggesting that the data sets may be marginally different and that PA with a 25% salt application may be safer than DMA with the recommended 100% application rate. This finding is consistent with results from Houle (2008). When comparing the PC study area that is primarily in the sun to the study area primarily in the shade a p-value of 0.004 is shown, suggesting a strong difference. Also of importance are certain data sets that are not statistically different. The PC lot study area in the sun compared to the PA lot demonstrate very similar weighted skid resistance results ($p = 0.847$). This is a notable finding because it shows that pervious concrete may exhibit similar surface conditions to porous asphalt if used with full sun exposure. A comparison between results for the DMA lot and for the Standard Reference Lot also exhibits a high p-value. This fact helps to verify that the winter maintenance methods used in this study were similar to the methods used by UNH Grounds & Roads.

CONCLUSIONS

Two years of winter performance evaluations have demonstrated that PA can perform extremely well in northern climates. Frost depth penetration and freeze-thaw temperature cycles have not compromised the integrity of the system structurally, visually, or hydraulically. Research has shown (both through literature and field testing) that PA exhibits greater frictional resistance and can become clear of snow and ice faster than conventional pavements. Substantial reductions in annual salt loads for anti-icing/deicing practices were observed, reaching over 70% during the study. Providing that plowing was regularly performed, salting was needed only for events where freezing rain created icy conditions. No salt was required on days when refreezing of meltwater was a problem on standard asphalt.

The results obtained from studying PC varied from PA but showed strengths in other areas. The surface infiltration rates measured on the PC lot exceeded those

that were observed on the PA. The benefit of this is that the PC will have a greater tolerance for clogging if sand or organic debris is present at the site. Additionally, binder drain-down is not a consideration with PC, as is the case with some PA mixes, making for a possible longer service life. Overall, the skid resistance and salt reduction capabilities for the PC lot were not as great as was shown for the PA. It is suspected that shading was the main contributing factor for this finding. The reasoning for this can be explained when looking at sections of PC pavement where shading was not as prominent and trees did not obstruct direct sunlight. Under these conditions the results drastically improve and the weighted skid resistance is shown to surpass that of the DMA lot. In addition to the shading, it is believed that the white pavement color of the PC contributed to the high levels of snow and ice cover. White pavements are more efficient at reflecting radiation, which can be beneficial in the summer months by lowering surface and air temperatures and consequently reducing the urban 'heat island' effect often associated with black, asphalt-based pavements, but non-ideal during the winter since the absorption of heat into the pavement will help to melt snow and ice (USEPA, 2007). Salt reductions during freeze-thaw events were achievable provided the lot was adequately plowed after storm events, an important consideration for all pavements not just PC.

Abstract: In the United States Environmental Protection Agency's National Water Quality Inventory in 2000, 13% of the river and stream miles that were surveyed were impaired by pathogen indicator bacteria (USEPA 2002). Stormwater runoff is a transport mechanism for indicator bacteria to receiving waters, resulting in an increased risk to public health through consumption of contaminated shellfish or ingestion by swimmers. Urban stormwater is commonly treated by stormwater Best Management Practices (BMPs), each of which provides some combination of natural treatment mechanisms and fosters certain environmental conditions. Although BMPs have been studied in detail for many pollutants, little peer-reviewed literature is available which documents their ability to remove or inactivate indicator bacteria. The North Carolina State University Department of Biological and Agricultural Engineering evaluated 10 stormwater BMPs in Charlotte and Wilmington, NC, to evaluate their efficiency with respect to indicator bacteria removal. The study practices included two bioretention cells, four stormwater wetlands, two wet ponds, and two dry detention areas. Data collected from these studies indicates that positive removal of indicator bacteria is possible in many types of BMPs; however, removal can be highly variable from practice to practice. Further, stormwater BMPs may foster environments where indicator bacteria can persist, becoming sources of indicator bacteria. Finally, even if positive reductions in indicator bacteria are noted, research indicates that achieving effluent concentrations of indicator bacteria consistent with USEPA standards may be difficult with many types of BMPs.

Introduction

In the United States Environmental Protection Agency's (USEPA 2008) National Water Quality Inventory in 2006, approximately 12% of the river and stream miles that were surveyed were impaired by indicator bacteria. Of the stream and river miles designated as impaired, either unable or partially unable to meet their designated use, more were impacted by this pollutant than by any other. Indicator bacteria were also the number one source of impairment in bays and estuaries, the number two source of impairment in oceans and near coastal areas, and the number three source of impairment along coastal shorelines (USEPA 2008). In light of the negative impact that indicator bacteria have on surface waters in the United States (indicating the

possible presence of pathogens), TMDLs have been established for impaired water bodies. Municipalities across the country are exploring options to reduce indicator bacteria inputs from point and non-point sources.

Numerous studies have indicated that development in watersheds leads to increased export of indicator bacteria. In a study of 18 mixed land use watersheds in West Georgia, Schoonover and Lockacy (2006) indicated that watersheds consisting of greater than 24% imperviousness exhibit higher fecal coliform concentrations than watersheds with impervious percentages less than 5% during both base and storm flow. Studies by Line et al. (2008) and Mallin et al. (2000) conclude similarly that urbanization in watersheds leads to increases in indicator bacteria export.

To test for the presence of harmful pathogens in surface waters, indicator species are used. Various indicator species have been used to assess water quality degradation due to pathogens including: total coliform, fecal coliform, *Escherichia coli* (*E. coli)*, and enterococci. In 1986, the EPA's Ambient Water Quality Criteria for Bacteria report (USEPA, 1986) discussed the merits of these various indicator species, and set a criteria whereby *E. coli* and enterococci are suggested as indicators in freshwater environments and enterococci is suggested as an indicator in marine environments. This criteria states that for fresh waters designated for use as full body contact recreational waters, the geometric mean over a 30 day period should not exceed 126 col/100 ml for *E. coli* and should not exceed 33 col/100 ml for enterococci. For marine waters designated for use as full body contact recreational waters, the geometric mean over a 30 day period should not exceed 35 col/100 ml for enterococci. The recommendation for fecal coliform, set in 1976 by the USEPA, is that the log mean over a 30-day period should not exceed 200 CFU/100ml (colony forming units per 100 ml) and no more than 10 percent of the samples should exceed 400 CFU/100ml (USEPA 1976).

Indicator bacteria can be removed from surface waters and stormwater through a number of natural processes, such as ultraviolet light (from sunlight), sedimentation, filtration, and various environmental factors. These environmental factors can include temperature, moisture conditions, and salinity (USEPA, 2001; Schueler, 2000; Arnone, 2007; Davies-Colley et al., 1994). Urban stormwater is commonly treated by way of stormwater Best Management Practices (BMPs), each of which provides some combination of natural treatment mechanisms. These BMPs include wet ponds, dry detention basins, wetlands, bioretention areas, and proprietary devices.
Although BMPs have been studied in detail for many pollutants, little peer-reviewed literature is available which documents their ability to remove or inactivate indicator bacteria. Six sites in Charlotte, NC, and 4 sites in Wilmington, NC, were monitored to determine indicator bacteria removal efficiency.

Site Descriptions

The stormwater BMPs evaluated in this project were monitored as part of the Charlotte – Mecklenburg Stormwater Services (CMSS) Pilot BMP Program and the

Burnt Mill Creek Watershed Restoration program in Wilmington, NC. As part of these studies, grab samples were taken and analyzed for both fecal coliform and *E. coli* from 6 stormwater BMPs in Charlotte, NC, and 4 stormwater BMPs in Wilmington, NC. In Charlotte, data were gathered from two dry detention basins, one wet pond, two stormwater wetlands, and one bioretention area. In Wilmington, data were gathered from one wet pond, two stormwater wetlands, and one bioretention area. Although data collection has been completed in Charlotte, the study in Wilmington was ongoing at the time of this publication. The characteristics of the BMPs from each city are given in Table 1.

Table 1: BMP and Watershed Characteristics

Site (Charlotte)	Watershed Size (ha)	Description	Estimated Curve Number
Dry Detention 1	2.4	Office Park - Buildings and Parking	85
Dry Detention 2	1.5	Office Park - Buildings and Parking	94
Wet Pond	48.6	Residential	75
Wetland 1	21	Residential	80
Wetland 2	6.4	Residential and School	83
Bioretention	0.4	Municipal Parking Lot	98
Site (Wilmington)	**Watershed Size (ha)**	**Description**	**Estimated Curve Number**
Bioretention 2	0.14	Parking Lot	98
Wetland 3	12.7	School Parking Lot and Fields	73
Wetland 4	2	Mulit-Family Residential	80
Wet Pond 2	4.7	Commercial	81

Dry detention basins fill with runoff during storm events and provide temporary detention while slowly draining over a span of approximately 48 hours. The primary pollutant removal mechanism in these systems is sedimentation. Charlotte, dry detention 1 was an extended dry detention basin which received runoff from a 2.4 ha watershed comprised of an office park and its associated parking areas, landscape features and buildings. The dry detention facility was well vegetated with grass and had good sun exposure. There was some evidence of erosion and sedimentation within the facility. Charlotte dry detention 2 was sited in a similarly sized watershed, 1.5 ha, also comprised of an office park. Like dry detention 1, this facility had good sun exposure, was well vegetated with grass, and had evidence of some erosion and sedimentation. Both facilities appeared to be mowed frequently. CMSS staff noted the frequent presence of birds around the basins, with bird droppings noted on the boxes which housed flow and water quality sampling equipment.

Wet ponds work on the principle of plug flow whereby influent runoff enters the pond and theoretically replaces the runoff that has been stored since then last storm event. Sedimentation in the basin is the primary pollutant removal mechanism as the stormwater slows, but some treatment is also provided via other mechanisms such as plant uptake, oxidation-reduction reactions, and adsorption as contact is made

between the soils and plants in the pond and the captured stormwater. The Charlotte wet pond was fed by a small, perennial stream and received stormwater runoff from a 48.6 ha watershed that was primarily residential. This pond was likely not originally created for stormwater management, and was constructed with no detention component. The estimated age of the pond was between 50 and 70 years old. Waterfowl were frequently observed at the pond during site visits. The pond was retrofit in the late 1990's to include a littoral shelf; however, the shelf was not planted and exhibited little vegetation during the study period. Despite the presence of trees around the BMP, there was good exposure on the pond. Wet pond 2 in Wilmington, NC, received runoff from a 4.7 ha commercial property which included a highly impervious 2 ha parking lot.

Wetlands are commonly installed as water quality devices, whereby they are sized to treat small (2.5 cm) storm events. These BMPs promote sedimentation much like wet ponds, but provide more intense contact between the captured stormwater and wetland soils and plants in shallow a system. Charlotte wetland 1 received stormwater from approximately 21 ha of residential area. This wetland exhibited common wetland topography, and consisted predominantly of shallow water depths. During the course of the study, however, there was very little vegetation in the wetland, likely due to poor soil conditions, prolonged periods of high water levels due to slow drainage, and the impact of waterfowl grazing. This lack of vegetation resulted in a larger amount of full sun exposure to water in the wetland than would typically be expected. Waterfowl were commonly observed at this site. Charlotte wetland 2 was constructed with similar topography, but exhibited exceptional plant growth. Charlotte wetland 2 received stormwater from 6.4 ha of residential area and a school. This wetland had two inlets, thus, weighted average influent fecal coliform and *E. coli* concentrations were calculated by weighting the grab samples at each inlet based on the total flow they contributed to the system. Wildlife was observed at Charlotte wetland 2 during the study. Wilmington wetland 3 treated runoff from 12.7 ha of a school, which included parking lots and practice fields. Wilmington wetland 4 is located in a multi-family residential complex. This wetland exhibits high amounts of infiltration in between storm events resulting in a normal pool where water is held mostly inside the deep pools.

Bioretention areas are filtration and infiltration BMPs. Stormwater enters the system and passes through a permeable soil media where pollutants are filtered, functioning similarly to sand filter systems. The BMP may pond water as much as 6 to 12 inches; however, it is drained within 12 to 24 hours. The system is intended to dry out in-between storm events. The Charlotte bioretention site received stormwater from a highly impervious 0.4 ha parking lot. This bioretention cell was studied and described in detail by Hunt et al. (2008). On at least one occasion, a diaper was observed in the parking lot, providing a potential source of bacteria to the BMP. Additionally, trees in the parking lot attract birds, and evidence of bird droppings have been observed by CMSS staff. Sun exposure in the BMP was fair, as it was limited by fairly dense vegetation. Wilmington bioretention area 2 was a sodded bioretention that treated the

runoff from a 0.14 ha parking lot at the headquarters of a coffee shop chain. The Wilmington bioretention area is broken into two paired cells, one with a 30 cm (1-foot) soil depth and one with a 60 cm (2-foot) soil depth. Observations have been made that the 30 cm deep cell receives more stormwater due to parking lot grading. This cell characteristically appears to stay more moist, likely due to the shallow soil depth and greater watershed area. Detailed surveys of the watershed area for the Wilmington bioretention area are planned to determine the exact sub-watersheds for each cell. Sun exposure at the Wilmington bioretention area is high.

With such highly variable uses, design specifications for the BMPs varied. Thus, there are some inherent differences in the function of the BMPs selected for this study with respect to both hydrology and water quality, making normalization problematic. However, these BMPs were selected because they are representative of the types of BMPs common to the City of Charlotte, NC, the City of Wilmington, NC, and elsewhere.

Monitoring Methods

Charlotte

As part of the Pilot BMP Program, grab samples were taken due to the small sample hold times required of bacteriological samples (USEPA, 2002). Grab samples were tested for fecal coliform and *E. coli*. Samples were collected at the various sites in Charlotte between March 2004 and October 2006. The monitoring period and number of samples collected at each site varied (Table 2).

Wilmington

Grab samples were also collected at each Wilmington, NC, site beginning in August of 2007. The samples from Wilmington were analyzed for enterococci and *E. coli*. Enterococci has proven to be a more reliable indicator species in environments with higher salinity (USEPA, 1986). Table 3 shows the number of samples collected at each site.

Table 2: Monitoring Period and Number of Samples Taken at Each Study Location

Site	Start	End	Number of Sample Tested For Fecal Coliform	Number of Samples Tested For *E. coli*
Dry Detention 1	Feb-05	Jul-06	9	9
Dry Detention 2	Jan-05	Dec-05	12	12
Wet Pond	Aug-04	Apr-06	14	10
Wetland 1	Mar-04	Jun-05	9	6
Wetland 2	Sep-04	Dec-05	15	10
Bioretention	Aug-04	Mar-06	19	14

Table 3 Number of samples taken at each Wilmington Study Site

Site (Wilmington)	Number of enterococci	Number of *E. coli* Samples
Bioretention 2	9	9
Wetland 3	9	8

Wetland 4	8	8
Wet Pond 2	8	8

Data Analysis

To adequately describe the bacteria sequestration and removal performance of each BMP, various analyses were performed. This included a calculation of concentration reduction efficiency and an analysis of effluent concentrations. The concentration reduction efficiency (CR) was determined by calculating the geometric mean of the influent and effluent indicator bacteria concentrations and using them in equation 1 below:

Equation 1: CR = 1 – (geometric mean outlet concentration / geometric mean inlet concentration)

Lastly, the geometric mean effluent concentrations of fecal coliform and *E. coli* leaving each site were compared to the maximum 30-day geometric mean for each indicator as established by the USEPA for full body contact (EPA, 1986; EPA 1976). This will aid in evaluating not only the efficiency of indicator bacteria removal for each system, but also the practicality of using stormwater BMPs to improve runoff from urban watersheds to indicator bacteria concentrations equal to or below targeted concentrations.

Results and Discussion

Table 3 presents the results for fecal coliform and Table 4 presents the results for E. coli for the BMPs studied in Charlotte, NC. Table 4 presents the results for *E. coli* and table 5 presents the results for enterococcus for the BMPs studied in Wilmington, NC. It should be noted that not all BMPs exhibit similar performance for both indicator bacteria for which they were tested. This indicates that BMP removal percentages generated for one indicator bacteria may not be applicable to other types of indicator bacteria data.

For the Charlotte BMPs, the wet pond, wetland 1, wetland 2, and bioretention area, exhibited greater than 50% removal of fecal coliform. The high fecal coliform removal determined for wetland 1 and wetland 2, 99% and 70%, is similar to that found by Birch et al. (2004) and Davies and Bavor (2000). For *E. coli*, only wetland 1 and the bioretention area provided high (> 50%) concentration reductions. Overall, wetland 1 and the bioretention proved most proficient at reducing influent concentrations of both kinds of bacteria. Wetland 1 had good sun exposure, likely leading to higher die off rates. Stormwater wetlands and bioretention areas also facilitate sediment removal through sedimentation and, in the case of bioretention, filtration and drying. All of these factors likely have some impact on indicator bacteria removal in stormwater BMPs. The poorest performing BMPs were the two dry detention basins. These systems had good sun exposure but remained moist for a substantial period of time after each rain event (per CMSS staff observation). It is possible that the wet soil provided an environment where the indicator bacteria could

persist for an extended period of time. Bird droppings were also noted by staff, likely leading to additional bacteria inputs to the BMP.

Table 3: Fecal Concentration Efficiency for BMPs in Charlotte, NC.

BMP Type	Fecal Coliform Concentrations (col/100ml)		
	Geometric Mean Influent	Geometric Mean Effluent	Concentration Reduction[1]
Dry Detention 1	1985	2873	-0.45
Dry Detention 2	1327	1590	-0.20
Wet Pond	9033	2703	0.70
Wetland 1	9560	184	0.98
Wetland 2	8724	3874	0.56
Bioretention	2420	258	0.89

1: Negative values indicate an increase in concentration
2: Significant reduction between the influent and the effluent

Table 4: *E. coli* Concentration Efficiency for BMPs in Charlotte, NC.

BMP Type	*E. Coli* Concentrations (MPN/100ml)		
	Geometric Mean Influent	Geometric Mean Effluent	Concentration Reduction
Dry Detention 1	915	1121	-0.22
Dry Detention 2	655	658	0.00
Wet Pond	2122	1153	0.46
Wetland 1	2400	106	0.96
Wetland 2	1295	864	0.33
Bioretention	241	20	0.92

For the Wilmington BMPs, the deep Bioretention cell 2, Wet Pond 2, and Wetland 4 all showed a fair ability to remove both types of indicator bacteria. The best performing of the BMPs was the Wet Pond 2, which removed a high percentage of *E. coli* and enterococcus. Further investigation is planned to determine factors which may lead to the high concentration reduction noted for this site. There is good sun exposure to the Wet Pond, potentially aiding bacteria removal. Studies by Mallin et al. (2002) and Davies and Bavor (2000) showed variable performance by Wet Ponds; however, two of the wet ponds evaluated in Wilmington, NC, by Mallin et al (2002) did show concentration reductions of greater than 50%.

Wetland 4 showed good performance for both indicator bacteria while Wetland 3 only removed enterococcus. However, influent *E. coli* concentrations to Wetland 3 were low, having a geometric mean of 255 MPN / 100 ml. It is possible that some natural background concentration of indicator bacteria is present and low influent concentrations of indicator bacteria result in poor performance when the data is evaluated using percent removal metrics.

Perhaps the most interesting relationship in the Wilmington data is the performance of the deep Bioretention 2 compared to the shallow Bioretention 2. The shallow cell showed poor performance for both *E. coli* and enterococci, and essentially acted as a source of bacteria. Further investigation of this cell has revealed that the shallow cell is potentially more moist due to a larger drainage area and shallow soil. This would provide a more favorable environment for indicator bacteria persistence and is concerning considering the potential for indicator bacteria removal that is seen in Bioretention 1 in Charlotte, NC, and in bioretention soil column studies performed by Rusciano and Obropta (2007).

Table 5: *E. coli* Concentration Efficiency for BMPs in Wilmington, NC.

BMP Type	*E. Coli* Concentrations (MPN/100ml)		
	Geometric Mean Influent	Geometric Mean Effluent	Concentration Reduction
Bioretention 2 (shallow cell)	111	792	-6.11
Bioretention 2 (deep cell)	111	44	0.60
Wetland 3	255	293	-0.15
Wetland 4	1315	720	0.45
Wet Pond 2	1621	83	0.95

Table 6: Enterococci Concentration Efficiency for BMPs in Wilmington, NC.

BMP Type	Enterococci Concentrations (MPN/100ml)		
	Geometric Mean Influent	Geometric Mean Effluent	Concentration Reduction
Bioretention 2 (shallow cell)	248	576	-1.32
Bioretention 2 (deep cell)	248	35	0.86
Wetland 3	1617	827	0.49
Wetland 4	2198	861	0.61
Wet Pond 2	497	52	0.89

Analysis of the geometric mean effluent concentrations from all BMPs reveals that not every BMP was able to reach EPA target concentrations for surface waters. The bioretention areas showed good performance for indicator bacteria. Other than the shallow bioretention cell, target concentrations were approached for fecal coliform, *E. coli*, and enterococcus via the bioretention cell in Charlotte, NC, and the deep bioretention cell in Wilmington, NC. Wetland 1 was also able to reach target concentrations for fecal coliform and *E. coli*, and Wet Pond 2 was able to reach or approach target concentrations for *E. coli* and enterococcus.

Conclusions

The results of this study support the literature that urban watersheds are a non-point source of bacterial pollution in surface waters. Even in watersheds consisting primarily of parking lots, concentrations of indicator bacteria entering BMPs can be higher than government assigned maximum values. Unfortunately, there are limited

data regarding bacteria removal in the stormwater BMPs commonly used to treat runoff from these urban watersheds.

This study suggests that some stormwater BMPs may effectively sequester and remove bacteria. Stormwater BMPs in both Charlotte, NC, and Wilmington, NC, were able to reduce indicator bacteria concentrations by over 50%. Bioretention cells in Charlotte, NC, and Wilmington, NC, performed well; however, the shallow bioretention cell in Wilmington, NC, indicates that some design features may impact the ability of a bioretention area to remove indicator bacteria. The Charlotte Wetland 1, which performed well for both fecal coliform and enterococcus, was atypical due to its lack of vegetated growth. The shallow water depths present in wetland 1 (15 – 45 cm) and minimal vegetative coverage led to more sun exposure than would normally be expected in a stormwater wetland. This high sun exposure may have led to increased indicator bacteria inactivation and removal by way of exposure to ultraviolet light. The substantial indicator bacteria removal in Wilmington Wet Pond 2 must be further explored to determine factors leading to its performance.

If the proper environment exists, it may be possible for stormwater BMPs to be sources of indicator bacteria. This may be due to both animal activity and to indicator bacteria persistence within BMPs. This was potentially the case for the two dry detention basins in Charlotte and the shallow Bioretention 2 studied in Wilmington, NC. This emphasizes the need for further study as to which environmental factors impact indicator bacteria sequestration, inactivation, and persistence in stormwater BMPs.

Acknowledgements
The authors would like to thank Charlotte – Mecklenburg County Stormwater Services for funding the research in Charlotte, NC, and collecting the data discussed herein. In particular, the authors thank Ron Eubanks, John Beller, and Jeff Price for their sample collection and analysis. The authors also would like to thank the Cape Fear River watch for their support with samples collection in Wilmington, NC. In particular, the authors wish to thank Joe Abbate.

John Sansalone, University of Florida, Environmental Engineering Sciences, 218 Black Hall, Gainesville, FL 32611 (email: jsansal@ufl.edu) for Field Verification Sub-Committee

ABSTRACT

Guidance from information and field testing concepts examined by the ASCE/EWRI Subcommittee on Field Testing is presented. Field-testing of manufactured treatment devices requires critical planning and implementation through all steps of the verification process from watershed/catchment selection, to testing and analytical protocols, to data evaluation and quality assurance and control measures, to data reporting guidelines. Ultimately the goal of field testing is to provide verification of analytical or numerical models for BMPs that have been developed through scaled or full-scale controlled physical model testing. The desired goals and outcomes must be known and designed into the entire verification process. Ultimately, the entire process leads to a defensible model that represents a quantitative yardstick for both deterministic and probabilistic evaluations of a BMP for stakeholders across a range of regional conditions.

This committee is focused on field verification of a BMP for separation of particulate matter (PM) from rainfall-runoff and snowmelt. Towards this goal, the entire gradation of PM requires characterization for a BMP field evaluation, in particular the suspended fraction because of the mobility and acute bio-availability of this finer fraction. On the other hand, the coarse sediment fraction is of particular importance because this coarse fraction fills many BMPs and is most labile. A fundamental, transferable and defensible methodology is considered which includes particle size distributions (PSD) combined with gravimetric index tests for PM: total suspended solids (TSS) and suspended sediment concentration (SSC). TSS by definition is the PM fraction remaining suspended in an Imhoff Cone after one hour, although current methods utilize sub-sampling generate controversy as to the meaning of the measurement. However TSS remains in use because of ubiquitous usage, regulatory significance and as an important index of treatability. In contrast, SSC provides a gravimetric analysis of the entire sample and therefore limited bias, and outstanding reliability and repeatability. Quality assurance and feedback protocol are a necessary part of the testing protocol. We must recognize the range of challenges and collect sufficient representative data within an event and across events so that the role of such uniqueness can be quantified for the specific BMP or BMPs tested.

The committee is developing a multi-tiered approach to field testing predicated on the intended utilization and rigor required for the defensible and transferable examination of BMP behavior; thereby removing BMPs from the category of "black-boxes". Testing protocols with a basis of scientific knowledge are needed because the complexity for field testing of uncontrolled and episodic events is significant. This complexity extends to watershed characteristics, rainfall-runoff event characteristics, operation and maintenance requirements, system sizing tied to hydrologic and PM loadings, testing methodologies including mass balances and the non-stationary behavior of the BMP. A testing protocol must dictate methods to minimize bias, such that system performance can be effectively evaluated within a defensible level of statistical confidence. Additionally, such testing must ensure that valid comparisons between BMPs can be

conducted and that the protocols and results for such BMP testing are provided in a transparent and available format. The dataset provided should be sufficiently populated with an event and between events that defensible models can be developed from the results of the BMP testing and comparisons between BMPs can be made with statistically significant inferences.

As the committee moves forward, major technology protocols and reports will be reviewed. Guidance documentation will also be compared with TARP (Technology Acceptance Reciprocity Partnership) and TAPE (Technology Assessment Protocol- Ecology's) considerations. Field Testing guidance are developed as part of the ASCE/EWRI Committee on Guidelines for Certification of Manufactured Stormwater BMPs.

INTRODUCTION: Transferability of Hydrologic and PM Loadings

Controlled or uncontrolled field-testing of manufactured BMPs (unit operations and processes) still relies to a large extent on measurements of hydrologic loadings and particulate matter (PM). The most common measurements include TSS and SSC, both gravimetric indices as well as turbidity. A focus on PM has a fundamental rationale. While the dissolved fraction must be addressed and is bio-available; pollutants can partition to and from PM in many watershed and BMP conditions. PM measurements are coupled with hydrologic loadings from the watershed and hydraulic measurements in the BMP. In general, while watershed processes can be categorized and modeled, each watershed is different and unique with respect to BMP loadings of hydrologic, chemical, biological and PM quantities. Climates are different across the USA. However, despite such differences small watershed that commonly load manufactured BMPs can exhibit similar loading behaviors for different climates. For example, Figure 1 compares Trenton NJ to Gainesville, FL and Figure 2 summarizes the frequency distribution of events for each locations.

Annual average	Gainesville, FL	Trenton, NJ
Temperature	68.4 °F / 20.2 °C	54.8 °F / 12.7 °C
Humidity	78.2%	65.0%
Mean PDD*	3.1	2.3
# of events / yr	117	159
Precipitation	45.7 in / 1116 mm	41.6 in / 1057 mm

*: Previous dry days

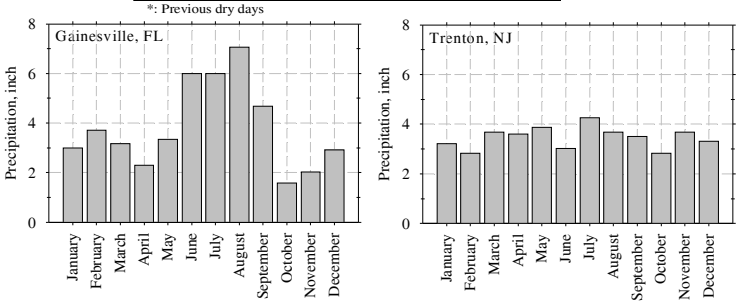

Figure 1. Comparison of the annual average and monthly average climate data for Gainesville, FL and Trenton, NJ.

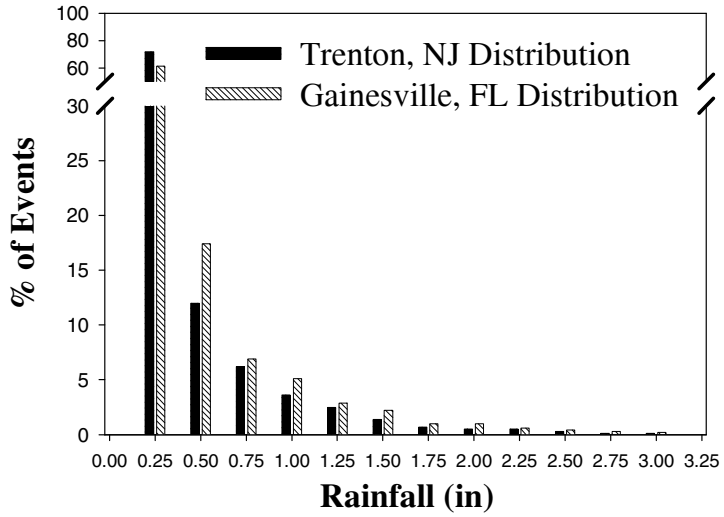

Figure 2. Frequency distribution of rainfall depths based on 30+ years of data from NOAA for both localities.

Despite specific climate differences, the two locations on the eastern seaboard of the USA have many rainfall frequency similarities with similar total annual rainfall depths. We can recognize these differences and similarities and collect sufficient representative data so that the role of such uniqueness can be quantified for the specific BMP or BMPs tested. What is more challenging than minor differences in climate are the very disparate methodologies of PM protocols that range from gravimetric index tests such as the traditional total suspended solids (TSS) method adopted from wastewater treatment evaluations, or the more recent suspended sediment concentration (SSC) method, index tests such as turbidity testing, to more fundamental methods of particle size distributions (PSDs). Each index method provides an indication of BMP performance with respect to PM; however a more fundamental, transferable and defensible methodology includes PSD (and specific gravity) and turbidity testing that are paired with a representative gravimetric index test for PM. In other words, SSC and PSD must be paired to provide a complete gravimetric description of the gradation. Field testing is predicated on the intended utilization and the rigor required for the defensible and transferable application of BMP performance results between localities of reasonably similar hydrologic loadings. Differences can be addressed through collecting a sufficient number of events to provide a distribution of hydrologic loadings that are comparable across regions. In addition to hydrologic loadings, knowledge of PM loadings is important. While both the fine suspended fraction and coarse sediment fraction are each important for BMP field testing, field testing requires the transport of a hetero-disperse PSD so that the BMP can be tested and examined across the gradation. This committee has the benefit of protocols such as TAPE and TARP that can be used as examples. The guidance that each protocol provides, while not universal is instructive when considering PM and the BMP separation of PM and building further guidance. It should be recognized that the entire gradation of PM should be representatively characterized for a BMP, in particular the suspended fraction, because of the mobility and acute bio-availability of this finer fraction. Figure 3 illustrates an example of an event mean PSD for a small watershed in Gainesville, FL. This urban catchment on the University of Florida campus is loaded by biogenic and anthropogenic PM loadings. The event mean PSD illustrated is compared to that of the NJCAT gradation. Again, despite the differences between New Jersey and Gainesville, Florida, the

similarity between PSDs is striking. It should be noted however that there is variability around the event mean; as there would be for any constituent.

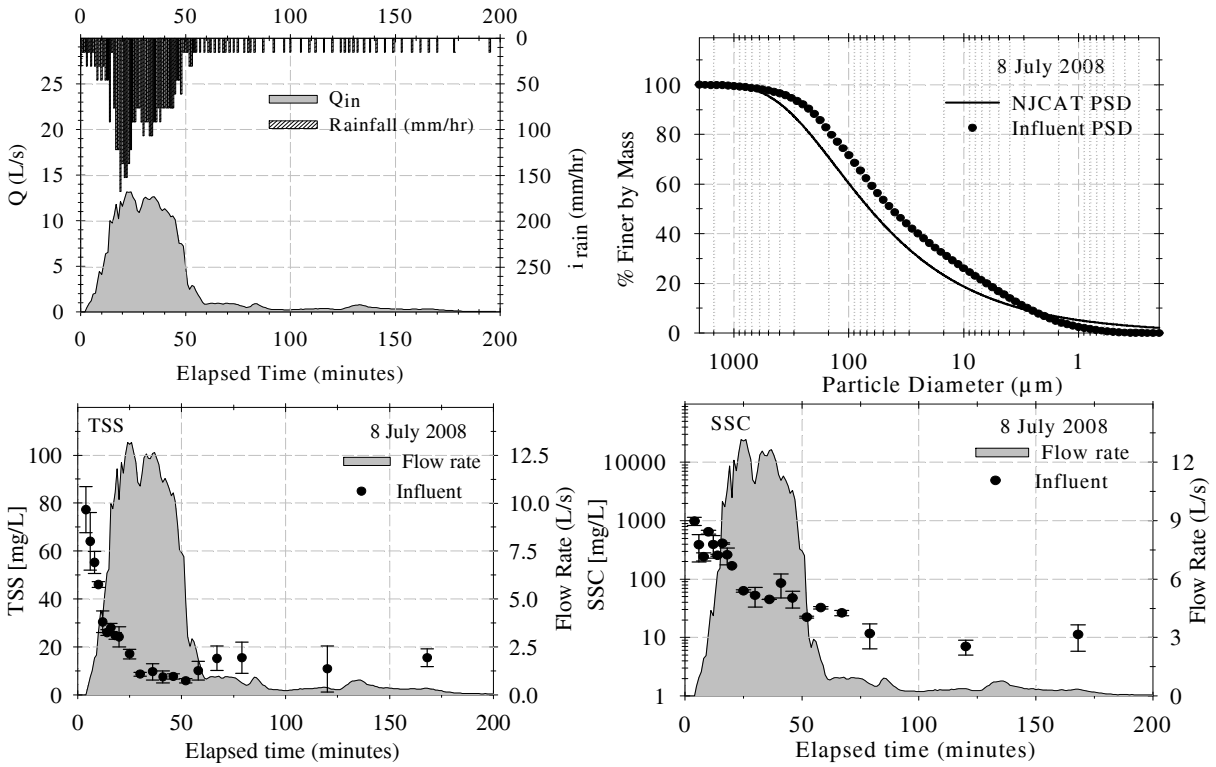

Figure 3. Coupling of hydrologic loads with PM measurements. The PSD illustrated is the event mean PSD.

Figure 3 illustrates a number of important phenomena that the committee is addressing. First, the highly unsteady nature of the hydrologic phenomena provides a far more challenging testing environment for a BMP and for the evaluators. The temporal hydrologic behavior is not known a-priori nor is the arrival of the event. Certainly, representative hydrologic measurements and sampling are challenging with such unsteady behavior. BMP behavior is directly impacted by such unsteady behavior that is not represented by controlled testing. However, such uncontrolled testing is not as readily amenable to model development or parametric analysis. Despite such unsteady behavior the event mean PSD is very similar, albeit slightly finer than an NJCAT gradation. The event-mean PSD and NJCAT are equally hetero-disperse. Such results suggest that a hetero-disperse NJCAT gradation for regulatory testing not only has the attributes of a defensible testing gradation, the NJCAT gradation has a reasonable granulometric resemblance to real gradations, albeit an event mean PSDs. If we step back and examine aggregate gravimetric indices such as TSS (PM < ~ 25 µm) there are a number of important observations. First, there is a clear mass-limited behavior between flow and TSS concentration that is driven by hydrology. The function of a BMP will be driven by this relationship between hydrology and load, with the caveat that such behavior is not known a-priori. When comparing TSS to SSC, it can be observed that TSS for this catchment is a small fraction of SSC. This is a result of the small watershed and source area configuration of the watershed. The high levels of SSC early in

the event are biogenic and larger anthropogenic sediment (> 75 μm) that are transported but not replenished during the event. This SSC material was generated between events and washed off during the rising limb of the runoff hydrograph. Early in the event the BMP (and the field sampling) is challenged by high flows, neutrally-buoyant biogenic material and coarse (> 75 μm) anthropogenic PM. SSC follows a more attenuated mass-limited behavior. Given the hetero-disperse nature of the PSD, representative automated sampling is challenging.

GENERAL DESCRIPTION OF BMP FIELD VERIFICATION AND MODELING

The basis of transport and fate of PM and other pollutants in natural and engineered BMPs, at the most rigorous macroscopic level of description, are the Navier-Stokes (NS) equations. Derivation of the NS equations to examine fate and mitigation strategies starts with the basic laws of conservation of mass, momentum and energy which apply to all natural and engineered BMP systems. The resulting equations would be the Navier-Stokes (NS) system of non-linear partial differential equations (PDEs) for multi-phase hydrodynamics and the fate (separation) of entrained pollutants (for example, particles) and the partitioning to these particles. While such a defensible analysis of field BMP performance is rare it is important to recognize that BMPs are amenable to such rigorous analysis whether the BMP is a simple batch settling tank or a screened hydrodynamic separator. The transport and fate of particles and pollutants (such as phosphorus that partition and distribute to particles) with such a defensible methodology for a BMP requires the following components.

Field Verification Components (with general BMP assessment needs)

1. **Geometric data component**: These are the data which geometrically define the domain of the BMP, essentially the BMP control volume (overall dimensions of the BMP system). For example the BMP system could be a wet vault, a hydrodynamic separator pre-treatment device or a combination of multiple unit operations and processes (UOPs) such as a wet vault followed by a cartridge filter. The geometric data are commonly generated by as-built drawings, as-built surveying data, manufacturer's drawings/specifications and surveying data for inflow and outflow geometries (pipe dia., slope, material, outflow geometry, soil cover, elevations, etc.). In modeling efforts, a Computer Aided Design (CAD) module is used to generate and modify (in the case of design or retrofits) the geometry of the BMP system. The data inputs are:
    a. A three dimensional description of BMP system through detailed CAD drawings or engineered drawing, including all inflow and outflow conveyance geometries. From such data, stage-storage, stage-outflow, inflow-storage functions are developed.
    b. This should be a common and conventional requirement for urban drainage and BMP system design/construction. Those who are carrying out the modeling, the CAD tasks, and those gathering field data and geometric data inputs should have the background and experience for such tasks.
    c. This is not significantly different than conventional as-built data, but with the need for standardization across protocols.

2. **Boundary-initial conditions data component:** These are the data that define the "quantity" and "quality" parameters at the BMP system boundaries. These parameters are classified as:

- **Hydrologic** (rainfall, previous dry hours, wind, air temperature, relative humidity, infiltration, evaporation, watershed storage, watershed characteristics),
- **Hydraulics** (flow rate, velocity, cross-sectional flow area, wetted perimeter, roughness, shear stress, hydrodynamic regime, temperature, degree of saturation, residence time distributions, RTD as developed from tracer studies),
- **Chemistry** (chemical species concentrations, temperature, turbidity, dissolved gas concentrations, partitioning, kinetics, pH-redox couples), and
- **Particulate** (particle size distributions, PSDs, particulate matter measured as suspended sediment concentration - SSC, suspended solids measured as TSS, trash, floatables, constituent distribution on PSDs, specific gravity, surface area, surface charge, solubility, exchange capacity, leaching, sludge and sediment properties including depth, density and cohesive-frictional properties)
- **Porous medium, soil or filter matrix** (porosity, pore size distribution, media or soil size distribution, tortuosity, effective porosity, surface area, exchange capacity, mineralogy, aquifer dynamics, equilibria, kinetics, breakthrough, hydrodynamics, moisture content – hydraulic conductivity relationships and head loss, leaching)
- **Vegetation** (species, hydraulic and friction properties, uptake and release equilibria, growth and uptake kinetics, leaching, specific gravity, flexural properties)
- **Microbiological** (species, size, charge, number, specific gravity, growth kinetics, uptake rates, hydrodynamic selection criteria and washout)

These parameters apply to the inflows, the BMP system and outflows. Even this list of parameters provided herein is not exhaustive and it should be recognized that the scope of this committee is most directly towards PM separation. However, these are coupled phenomena, and as such the role of vegetation (such as in an infrastructure-constrained bio-detention cell), microbiology and chemistry are important for the fate of PM across a BMP. It is readily apparent that such boundary and initial condition data requirements are significant and many are significantly different as compared to conventional data collection practices, as can be seen from the list of parameters in each category. Therefore, at this point in time, three levels of boundary/initial conditions field verification requirements are proposed. These field verification requirements will be defined in three levels:

- "***Level 1***" field verification requirements are for event-based BMP examinations. ***"Level 2***" field verification requirements are more detailed, are appropriate for monitoring and modeling event-based BMP examinations, and require temporal input and output data, as well as event-based system data.
- "***Level 3***" requirements are research or specialized datasets for BMP examinations examining specific pollutants beyond PM, nutrients or metals, for example, microbiological, that is combined with modeling and water chemistry examinations such as charge, volume and mass balances.

Commensurate with the available length of the paper, the following is a draft summary of the field verification requirements for a BMP under a detailed Level 1 requirement.

Number of Events Monitored: (12 calibration, 3 verification events for modeling)

a. A minimum of 12 calibration and 3 verification events are required for a BMP system. Events should occur in a one year period, and event rainfall depth should be at least 0.25 inches. There should be at least 24 previous dry hours. This is similar to

other BMP testing protocols around North America. Event mean flows should be reasonably distributed between 25 and 75 % of the BMP design flow rate.

Hydrologic: (initial storage depth required for CFD)

a. A ***watershed delineation*** so that a rainfall-runoff model can translate rainfall loadings to runoff loadings at the BMP system location for the watershed of interest. This is a hydrologic modeling input and should be a current and conventional requirement for BMP systems in any protocol.
b. A ***frequency distribution of the historical rainfall record*** for the watershed or locality. The maximum time increment between rainfall depth measurements during the event should be no greater than the time of concentration for the watershed. This is a hydrologic modeling input and should be a current and conventional requirement for BMP systems in any protocol.
c. A ***watershed-based and event-based temporal rainfall record*** for storm events captured. Representative rainfall depths should be recorded in increments of 0.01 inches or in time at increments no greater than 5 minutes for the watershed. This is a hydrologic modeling and should be a current and conventional requirement for BMP systems in any protocol.
d. A measurement of ***previous dry hours (pdh), wind speed and direction, air temperature, evaporation indices, and relative humidity*** for the watershed or locality on an event-basis. These data are readily available from a number of sites around most MS4s and do not require a weather station for the watershed where the BMP system is located.
e. A measurement of ***initial runoff storage depth and sludge depth*** should be made in the BMP.

Hydraulic:

a. ***Flow depths and velocities*** at increments no greater than 5 minute intervals for the entire inflow and outflow duration for each inflow and each outflow of the BMP system. These are direct BMP verification inputs and should be a current and conventional on-line measurement requirement for BMP systems.
b. ***Temperature***, for simplicity at increments to match hydraulic flow measurements for the entire inflow and outflow duration for each inflow and each outflow of the BMP system, as well as initial storage and final storage temperatures. These are indirect BMP inputs (to specify aqueous viscosity and density), and should be conventional on-line measurement requirement for BMP systems.
c. A ***temporal RTD*** for a high-flow calibration event and a lower-flow calibration event using a conservative tracer. This is carried with a known mass input of conservative tracer in the influent and temporal automated sampling of effluent with temporal discrete samples (not composited).
d. ***Pressure measurements*** should be made as a function of volume treated for BMP systems that contain a porous media including in-situ soil filters, taken on-line just upstream and downstream of filter. This is a critical need for porous media systems.
e. A ***calibration curve*** should be provided for each hydraulic measurement for each event. This should be required in any quality assurance plan.

Chemistry:

a. ***Constituent species and phases*** are analyzed from duplicated composite samples to provide event mean concentrations (EMCs). Recognizing that automated samplers cannot reproduce a representative PM; but to avoid endless debate over this topic, this methodology will nominally refer to "sampling" but not a method. These duplicate composited samples for an event will be composited by representative samplers for the entire duration of influent and effluent flow. The sampler is setup to house 4, 4 L (minimum composite volume) samples, unless larger volumes (i.e. 6 L composite samples) are possible. This additional volume is important for effluent samples. It is fully recognized that EMCs eliminate any temporal understanding of influent and effluent transport, and automated samplers cannot representatively sample influent and effluent flows (particularly influent particulate matter (PM) larger than approximately 75 μm and neutrally-buoyant material). However, for the sub-75 μm PM and the operationally-dissolved fraction of constituents such index methods will have to suffice until more representative measurements become more viable for common "Level 1" applications. Constituent selection is dependent on the receiving water impairments, BMP system and watershed. Calcium and alkalinity are also important measurements. An event-mean analysis of rainfall should be conducted.
b. All ***constituent analyses are conducted on fractionated (filtered) samples***; creating a dissolved fraction and a particulate fraction, operationally-separated using a 0.45 μm membrane filter. As with automated sampling and EMCs this masks the continuum of partitioning, but is a Standard Method, recognized by most laboratories, and will have to suffice. A digestion process is utilized to examine the constituent concentration associated with the dry PM (as TSS) retained on the membrane filter after the dry filter with dried TSS is weighed and the dry filter weight subtracted. The exact volume filtered to generate the TSS is also recorded along with the dry TSS mass retained on the membrane filter. It is noted that this fractionation occurs after the sample is pre-screened by passing each composite sample separately through a #200 (75 μm) stainless steel or nylon sieve (discussed in the particulate section).
c. A ***sample holding time of less than 24 hours***. No sample shall be held for more than 24 hours before analysis between the time the sample was taken and fractionation between dissolved and particulate-bound fractions, even under refrigerated conditions. While partitioning occurs at much shorter time intervals, within hours, there is currently no practical method to fractionate rapidly without on-site personnel.
d. ***On-line temporal chemistry measurements*** should include pH, redox (hydrogen-based offset provided), temperature, turbidity, total dissolved solids – TDS and conductivity for influent and effluent. The on-line measurement technology has advanced to the point that these are commonly deployed applications for BMP systems.
e. A ***calibration curve*** should be provided for each chemistry measurement for each event. This should be required in any quality assurance plan.

Particulate:

a. A ***measured volume for each duplicated composite sample*** should be determined to the nearest 10 mL. Duplicated 4-L (or larger if possible) and 20-L composite sample should be prepared with the exact volumes recorded. The 4-L duplicated influent and effluent composite samples will be used for obtaining datasets d, e and f. The 20-L influent and effluent composite samples will be used for obtaining datasets b, c and h.

b. ***A pre-screening through a #200 (75 μm) stainless steel or nylon sieve*** of each duplicated 4 L composite sample and 20 L composite sample should be first carried out before fractionation at the 0.45 μm level by passing the entire volume that is free of any holes or grid weighed and gently disaggregated. This dried material will then be dry-sieved through the standard (#50) 300 μm, (#80) 180 μm, (#100) 150 μm and (#140) 106 μm sieves. A mass balance shall be made by summing the mass components on each sieve allowing no greater than a 5% mass balance error from the original dry weight.
c. A ***determination of constituent mass distribution as a function of PSD*** is made through the appropriate extraction or digestion process for each particle size. This is more easily carried out for the influent samples. For the effluent samples, there may only be sufficient PM to carry out a larger than 75 μm analysis and a smaller than 75 μm analysis since a digestion process requires approximately 0.2 to 0.4 g of dry PM. This may require the utilization of larger effluent volumes to pass through the 75 μm pre-screen and the 0.45 μm membrane filter.
d. A ***set of 3, 500 mL TSS sub-aliquots is taken*** from each pre-screened duplicated composite sample that is well-mixed and these aliquots are taken and labeled in a consecutive manner. Before each sub-aliquot is taken, a turbidity measurement at mid-depth is taken. Each aliquot is taken from mid-depth of the composite volume. Each aliquot shall be completely filtered through a 0.45-μm filter, dried and analyzed for TSS and VSS using Standard Methods protocol. The relative percent difference between sub-aliquots must be < 10% on a gravimetric basis for TSS. The filtrate is saved, separated as required, and preserved for dissolved constituent analyses.
e. A ***set of 3 alkalinity sub-aliquots*** are also taken for alkalinity and other constituent measurements of choice for the filtrate.
f. A ***set of 3 PSD sub-aliquots***, approximately 750 mL will be used for PSDs for the sub 75 μm fraction. It is recommended that as part of any database these sub 75 μm fractions be compiled and also combined with the matching fraction larger than 75 μm to create a database that is available for BMPs, land use, cover conditions, hydrologic regions, seasons, etc. These PSD sub-aliquots must be matched with their TSS or SSC sub-aliquot partners in order to convert % volume of particles to an absolute gravimetric value in mg. Note that turbidity measurements are also included to examine the relationship for a site between turbidity and TSS (or SSC).
g. An ***estimation of sludge (sediment) depth*** should be made at the beginning and end of the monitoring. A 2000 dry grams sludge (sediment) sample should taken from the BMP (location determined from modeling or measurement of short-circuiting) for determination of PSD, specific gravity and contamination levels as a function of PSD.
h. ***A determination of specific gravity for the sub 75 μm and larger than 75 μm fractions*** for each 20 L composite sample should be made for 2 calibration events. Analysis will require the entire dry mass for each fraction of influent and effluent.

Porous medium, soil or filter matrix: (datasets a and b are required for CFD)

a. A ***representative set of porosities*** of a porous medium, whether surrounding soil of an infiltrating BMP or as a filter matrix should be measured.
b. A ***representative set of filter or soil media size distributions*** should also be measured.

Vegetation:

a. An ***identification of the vegetation species*** and approximate size should be provided.

Microbiological:

a. An ***identification of the redox conditions and microbial consortium*** and their numbers in the water column or media (or soil) column should be approximated.

CONCLUSIONS

While field verification of manufactured BMPs is more complex and uncertain than controlled, scaled or full-scale BMP testing utilized for numerical (or analytical) model development, parametric evaluations, or controlled performance evaluations; field verification of a BMP is a logical and required step. The Field Verification Sub-Committee of the Guidelines for Certification of Manufactured Stormwater BMPs Task Committee is in the process of developing guidance for field verification protocols for manufactured stormwater BMPs. This paper illustrates the complexity of uncontrolled field loadings with respect to hydrology and PM while outlining one level of requirements involved with defensible and transferable field verification for a BMP. The requirements and level-of-effort increase with the level of field verification required; as illustrated herein. When combined with controlled laboratory testing and scaling for the same BMP; that allow rigorous mechanistic analysis and model development, the combination of such testing/monitoring campaigns with field verification of the same BMP results in a tripartite verification of BMP behavior. While data from controlled studies are more readily amenable for BMP comparisons, although there still seems to be some murkiness regarding simple concepts such as creation of an NJCAT gradation, field verification is much more challenging given the lack of control. Despite such uncontrolled conditions, existing protocols such as TAPE and TARP are a reasonable starting point with reasonable applicability across regions. An example is provided comparing Trenton, New Jersey loadings to Gainesville, Florida. Rainfall frequency distributions, annual depths and event mean PSDs for Gainesville are relatively similar to Trenton. Even if similarities are somewhat more disparate than the example given, tools such as frequency distributions, fundamental data collection (as opposed to indices such as an EMC) such as PSDs and the coupling of hydrology with PSDs allow the transferability of field verification. Such verification should be sufficient in scope, depth and quality that a public database of testing should be available to cut through the murkiness of BMP claims. With the inherent requirement for accuracy and representativeness, the more fundamental and precise is the data collection, the greater the potential for transferability and comparability of BMPs. Even though the Committee focus is limited to PM the Sub-Committee and Task Committee have more work to carry out. This document as well as future documents will not be without controversy but are intended as a significant step forward. The creation of a more uniform defensible and transferable laboratory, scaling and field verification program for BMPs allows a representative “chili-cookoff” for BMPs which benefits all stakeholders and most importantly the environment.

From Grey to Green: Strategies and Concepts for Implementing Green CSO and Wet Weather Solutions

ABSTRACT

Sustainable wet weather and Combined Sewer Overflow (CSO) solutions that utilize green infrastructure and solutions are an increasing topic of interest. Identifying suitable locations for green infrastructure, developing appropriate concepts and quantifying their impact can be challenging. In the content of this paper, the authors will provide three strategies that address these challenges and present a comprehensive and holistic approach to incorporate green solution technologies into wet weather and CSO Long Term Control Plans.

KEYWORDS

Sustainable planning, watershed planning, green infrastructure, green solutions, best management practices (BMPs), natural systems, BMP locator, Green Filter, combined sewer overflow (CSO), stormwater management, geographic information system (GIS), source control, water quality, Hydrologic and Hydraulic Modeling.

INTRODUCTION

Black & Veatch (B&V), in collaboration with Patti Banks Associates (PBA), is developing Combined Sewer System (CSS) solutions for communities across the country. Specifically, their efforts in two Midwestern cities; Kansas City, Missouri and Omaha, Nebraska are of interest. Recently the regulatory community has focused on "green infrastructure" to help supplement communities' Combined Sewer Overflow (CSO) Long Term Control Plans (LTCPs). In March of 2007, the Environmental Protection Agency (EPA) released guidance encouraging the use of green infrastructure stating that green solutions "could be both cost effective and an environmentally preferable approach" in helping to solve CSO problems.

The following discussion addresses specific approaches for using green infrastructure for CSO control. The approaches attempt to answer some of the more challenging questions regarding their use which include:

- How should the best sites for incorporating the technologies be located and prioritized?
- What type of green technologies and concepts make the most sense at specific locations?
- How can the benefits of green infrastructure be quantified?

The authors present a methodology for locating green infrastructure at a macro scale, develop green infrastructure concepts for identified locations and present a method for quantifying the benefits of green infrastructure. These three methodologies can be used in conjunction to create a more sustainable and holistic approach for developing CSO and wet weather solutions.

Green infrastructure includes a universe of technologies that offer a wide variety of benefits. Green infrastructure technologies focused on CSO and stormwater runoff control include, but are not limited to: detention and retention practices such as wetlands, dry and wet extended detention and retention basins, infiltration and filtration practices like pervious pavement and bioretention, conveyance practices such as vegetated swales and bioswales and rainwater harvesting practices like cisterns and rain barrels. Dispersed detention and retention practices are particularly interesting because they have the potential to maximize source control while efficiently using available land.

Over the last several years, the use of green infrastructure technologies, or Best Management Practices (BMPs), has increased within the stormwater and CSO communities. Green infrastructure is a break from more traditional wet weather engineering practices, where conveyance was maximized and hydrologic residence time was minimized. The traditional approaches to controlling wet weather runoff focused on removing water as quickly as possible through engineered pipes and conveyance channels. However, the focus on conveying water quickly has led to unanticipated and significant problems in the nation's receiving streams. Urban stream corridors around the country are becoming degraded; pollutant loadings in runoff are left unfiltered and are conveyed directly to receiving streams; impaired waters are negatively impacting wildlife and natural ecosystems; beach closings still occur on the coasts; fecal coliform and E. coli concentrations in receiving streams continue to exceed, sometimes by orders of magnitude and the list of problems goes on.

Green infrastructure departs from the traditional engineered schemes in the developed landscape by attempting to mimic eco-systems and return the landscape to a more natural state. For example, these technologies can provide wet weather runoff control by:

1. Increasing infiltration
2. Increasing evapotranspiration
3. Adding surface detention and retention storage
4. Increasing initial abstraction
5. Lengthening the hydrologic residence time
6. Disconnecting impervious areas from the sewer system

7. Filtering runoff and removing pollutants before they enter receiving water bodies
8. Enhancing chemical, typically through biological processes, and physical break down of contaminants before reaching receiving water bodies.
9. Providing CSO and stormwater runoff source control

In addition to the technical benefits, green infrastructure can typically be incorporated with less impact and disturbance to the surrounding community while offering multipurpose benefits not associated with traditionally engineered wet weather solutions. The multipurpose benefits can include community aesthetic enhancements, added recreational opportunities, greater public acceptance and enhanced economic vitality and property values. Also, unlike many traditional solutions, green infrastructure can provide highly tangible and visible solutions which stakeholders can better appreciate and value.

The CSO and wet weather benefits provided by green infrastructure technologies are the main topic of this paper. CSO problems are often complex and encompass vast sewer systems serving highly developed areas. Traditional CSO solutions (i.e., grey solutions) such as deep tunnels, storage tanks, high rate treatment systems and treatment plant and pump station upgrades will continue to be the main components of any CSO LTCP. However, green solutions specifically targeted at reducing the inflow to combined sewer systems may potentially minimize the cost and magnitude of the grey CSO solutions. Water quality will be improved and a wide range of the benefits previously noted will be provided.

The excitement surrounding green infrastructure and sustainable planning efforts, specifically those focused on CSO control, has created an interest in incorporating these technologies into ongoing wet weather and CSO planning and solution efforts. Several distinct schemes may be used to incorporate green solutions into a CSO LTCP and such schemes are discussed herein. First, the Green Filter (i.e., green infrastructure locator) identifies and prioritizes locations across a community that is suitable for green infrastructure technologies. Second, concepts and rendering of specific green solution approaches for use in developed areas is presented. Finally, a Hydrologic and Hydraulic (H&H) Modeling exercise is presented that attempts to estimate the effectiveness of green infrastructure technologies on reducing the wet weather runoff from a basin.

The goal and objective is to find sustainable approaches and solutions for current and future complex wet weather problems. As the world continues to remind us, nothing we do is truly independent. As we learn the hard lessons of the past, reinventing our thinking to promote sustainable environmental, social and economic solutions for all future generations is now, more than ever, paramount.

METHODOLOGY AND DISCUSSION

As discussed in the introduction, the authors presented a process herein to link the identification and prioritization, design and modeling of green infrastructure. Although each of the three processes are discussed below in independent sections,

the intent of this paper is to show how these concepts can be used together to achieve more sustainable CSO and wet weather control solutions.

1. Green Filter

a. Methodology

In fully developed communities, which are those typically targeted by CSO regulations and in need of better wet weather control, frequently few large open spaces remain that are suitable for land-intensive green solution technologies such as wetlands and detention basins. Therefore, a computerized analysis that can quickly process and locate existing open space of all sizes across wide area is an invaluable tool. For both the Kansas City and Omaha CSO programs, the ESRI ArcGIS ModelBuilder tool was used to develop such a model. The Green Filter model was based on the following data:

1. High resolution Digital Elevation Models (DEMs)
2. One-acre Resolution Landsat Enhanced Thematic Mapper Plus (ETM+) images
3. Parcel Data and Right of Way Boundaries
4. Impervious Coverage
5. National Wetland Inventory (NWI) and Flood Insurance Rate Maps
6. Soil Data
7. Natural Resources Inventory Land Cover Classifications or GAP Analysis Land Cover Analysis
8. High Resolution Surface Drainage Network

Figure 1 provides a graphical representation of the ArcGIS ModelBuilder tool along with the input data used to identify green infrastructure opportunities for the Omaha, Nebraska CSO program. A similar configuration was used for the Kansas City, Missouri CSO program. It should be noted that the ArcGIS Model Builder is flexible and can be adjusted depending upon local conditions and needs. The subsequent text describes the Omaha green infrastructure locator methodology in greater detail as one example of this tools' capabilities.

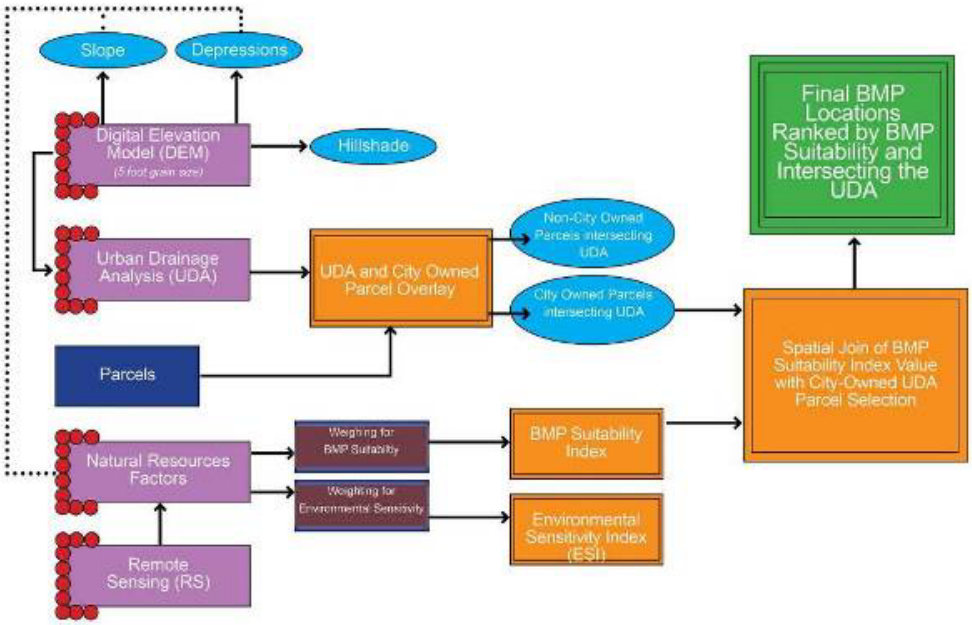

Figure 1. Green Solutions Locator Model Overview

The Green Filter uses a raster-based analysis to classify natural resources and identify green solution opportunities and constraints. The rasterization process converts spatial data into pixels as opposed to polygons or linear features as performed with vector analyses. Raster analyses are more appropriate for the green solutions modeling process because much of the base information (such as the DEM and Landsat data) is already in raster format. In addition, raster data can be more easily compiled and incorporated into statistical models to generate useful outputs.

Initially, a 5-foot grid cell DEM for the entire city of Omaha, derived from 2-foot contours provided by the City, was developed. The DEM was the basis for the subsequent evaluation of urban hydrology and catchments, slope, hillshade, and existing depressional storage areas.

In lieu of local natural resources mapping, the modeling team used 1-acre Landsat satellite imagery to classify and rank land cover types. Multispec image processing software (Purdue Research Foundation, 1994-2008) was used to classify the cover types. ETM+ bands 2 (0.52-0.6m), 5 (1.55-1.75m), and 7 (2.08-2.35) were classified to identify tree canopy land cover, open / under story land cover, and open / agricultural land cover. The results were statistically verified using Multispec.

In Omaha, the modeling team developed two distinct weighting distributions, one which weighted the sensitivity of natural resources from the most sensitive to the least sensitive (the environmental sensitivity index or ESI), and one which weighted the natural resources from the most to the least appropriate for constructing BMPs on them (BMP weighted ESI or Green Filter).

For the Green Filter suitability index weighting, wetlands, high quality vegetation and 100-year floodplains were devalued because it didn't make sense to construct BMPs in areas that are environmentally sensitive and already functioning in a natural way. Areas that were identified in the ESI to be highly sensitive natural resources were not considered to be good locations for the future incorporation of BMPs. Conversely, depressions, alluvial valleys and poor quality vegetated spaces were increased in value for the BMP weighted ESI. This would highlight those areas that could potentially provide the greatest wet weather benefit if they were to be retrofitted with BMPs. The Green Filter weighting factors were determined through discussions with the Omaha CSO Program Management Team (PMT) and City staff. The modeling team further refined the weighting factors based on experience and research (Dunne et al., 1978). A schematic of the GIS Green Filter model inputs and corresponding weighting factors to develop the Green Filter Suitability Index used by the Omaha CSO program are presented by Figure 2. Note that each parcel with the City limits was assigned a green infrastructure "suitability score" based on this screening criterion.

Next, using contour data, an urban drainage analysis (UDA) was developed for the entire City. The UDA reviews hydrology and City parcel data to identify those parcels that currently intercept and/or are adjacent to "significant" overland flow paths (i.e., for Omaha, flow paths that drain greater than approximately 2 acres). The ArcGIS ARChydro extension was used in combination with City topography to create a this detailed flow line network, which was overlaid on the City's parcel mapping to identify properties that intersect or are adjacent to these major surface flow lines. A 15-foot buffer was applied to the flow line to identify adjacent rights-of-way or roadways that could be used to capture runoff along a flow line. Parcels intersecting surface flow lines were identified and extracted for further consideration.

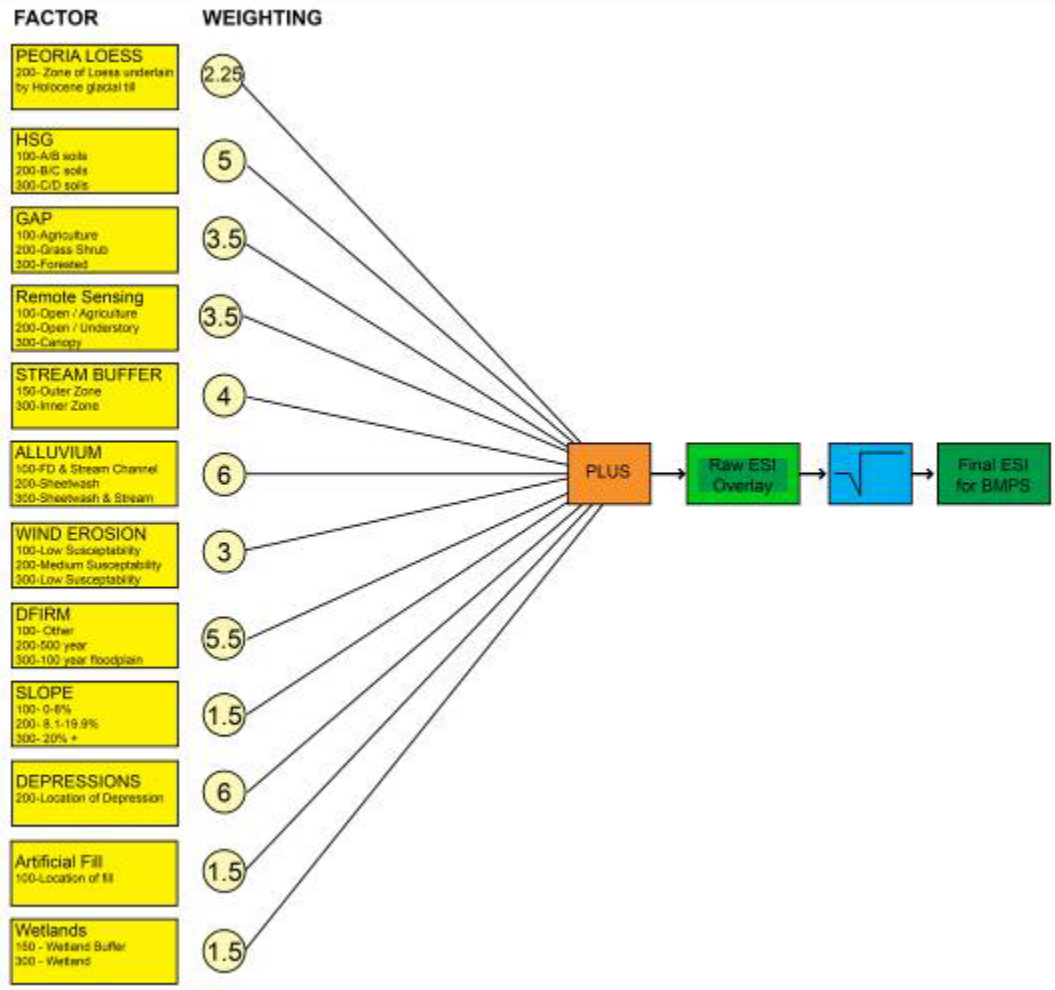

Figure 2. BMP Suitability Index

To complete the Green Filter effort, the value of the BMP suitability index was joined to City-owned and non-City-owned parcels identified by the UDA analysis. This created a prioritized green solution opportunities GIS layer which is located near significant overland flow paths. In other words, the process highlighted areas most suitable for wet weather green infrastructure retrofits. Output and results from the Omaha Green Filter process are presented within the following section.

b. Results of Green Filter

The Green Filter was used to produce maps of possible green CSO BMP opportunities across the 100-square mile area of the City of Omaha. In addition, the identified locations were prioritized and ranked depending upon the suitability of each location to be modified into a highly valuable green solution technology. The suitability of each site is color coded on a spectrum where the color red denotes the least suitable locations and the color blue indicates locations most suitable for green solution technologies. Per the request of the City, the modeling

team developed a tiered result system by varying the inclusivity of ownership records in the parcel codes within the model. This variation allowed the team to screen out parcels based on ownership. The following parcels are displayed in descending order according to those of most interest to The City.

- City owned parcels (i.e., Tier 1)
- Educational and institutionally owned parcels (i.e., Tier 2
- All property parcels (i.e., Tier 3).

The graphic results from the Green Filter GIS model are presented for each tier by Figure 3 Figure 4 and Figure 5, respectively.

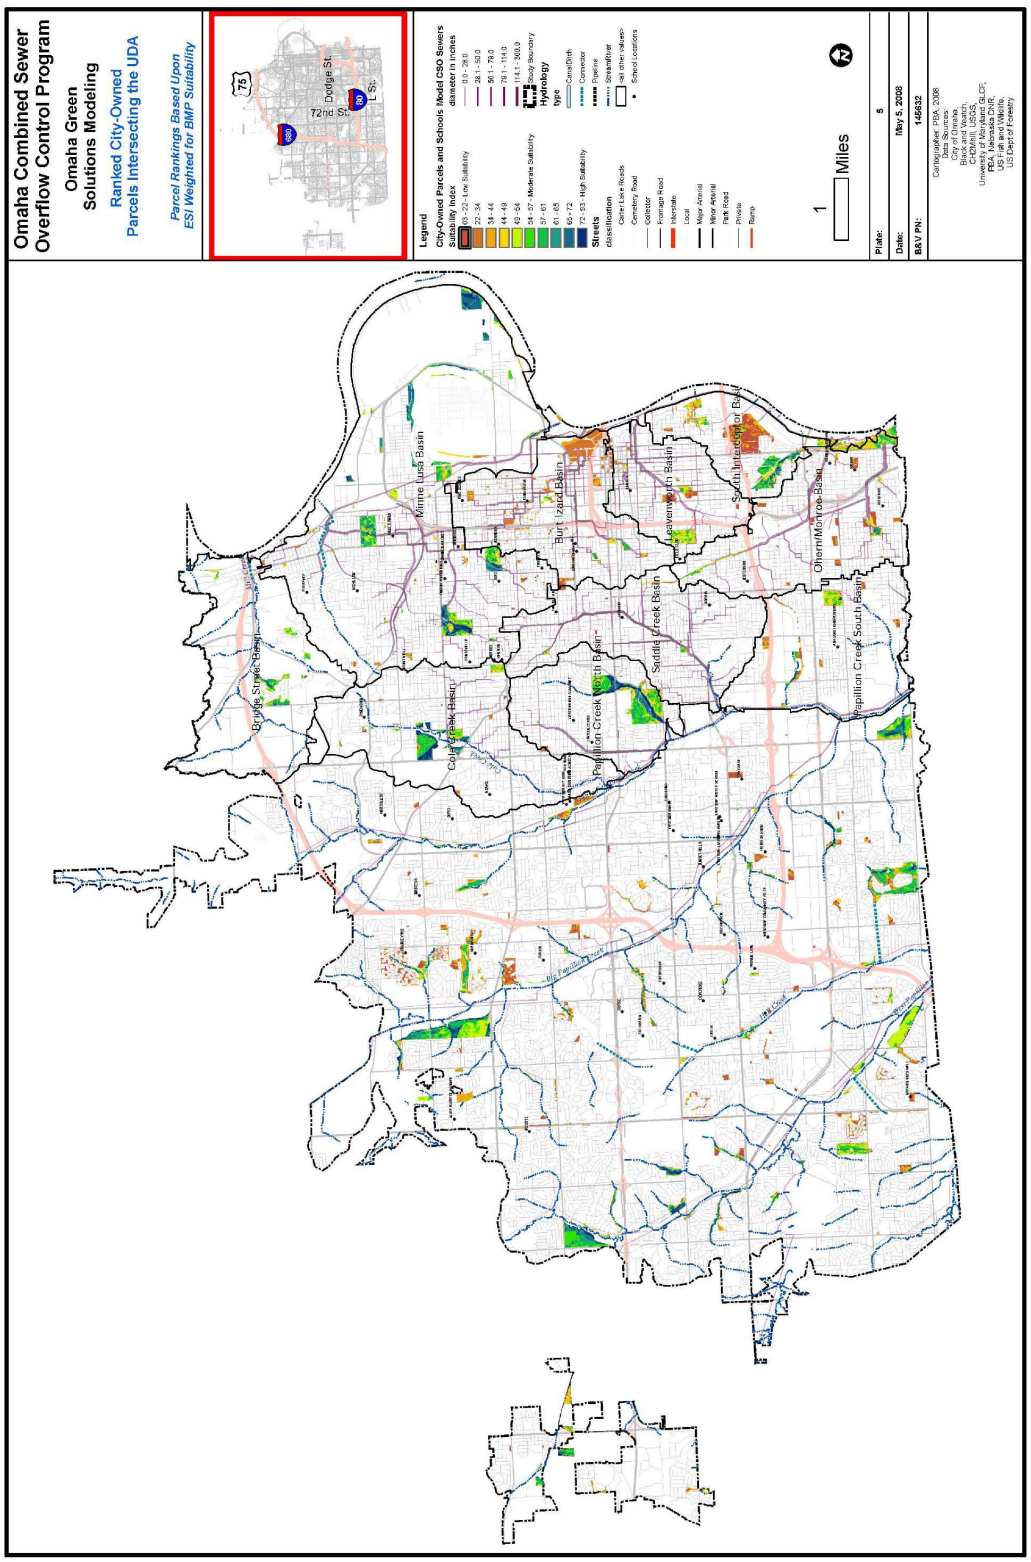

Figure 3. Green Filter Tier 1: City-Owned Green Infrastructure Opportunities

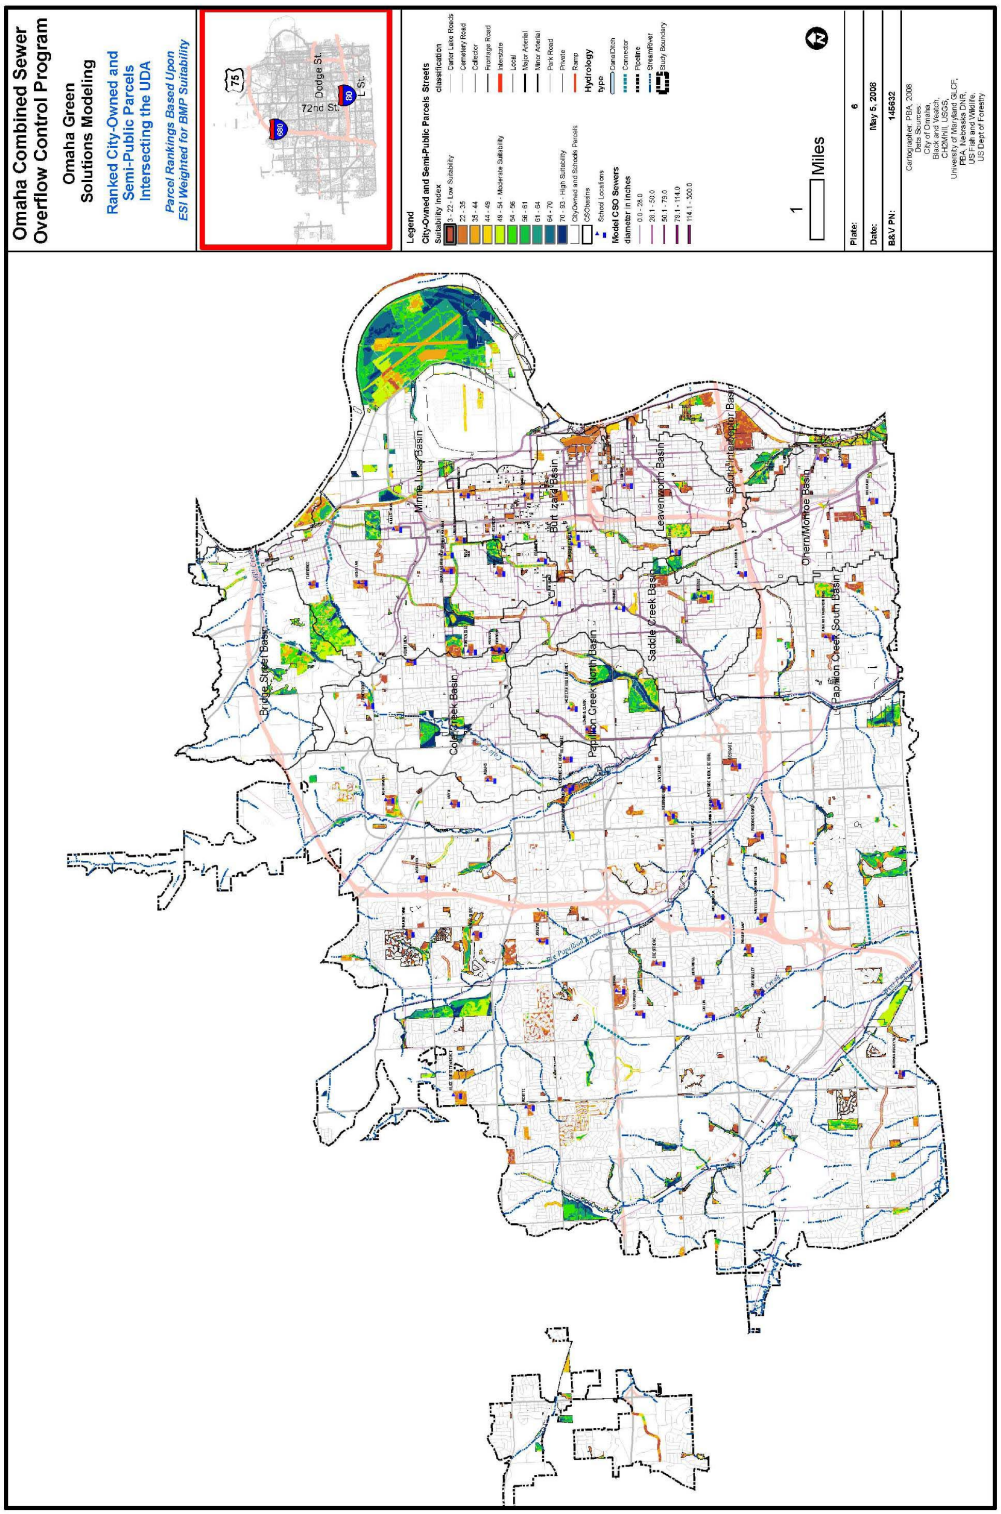

Figure 4. Green Filter Tier 2: City-Owned, Educational, and Institutional Green Infrastructure Opportunities

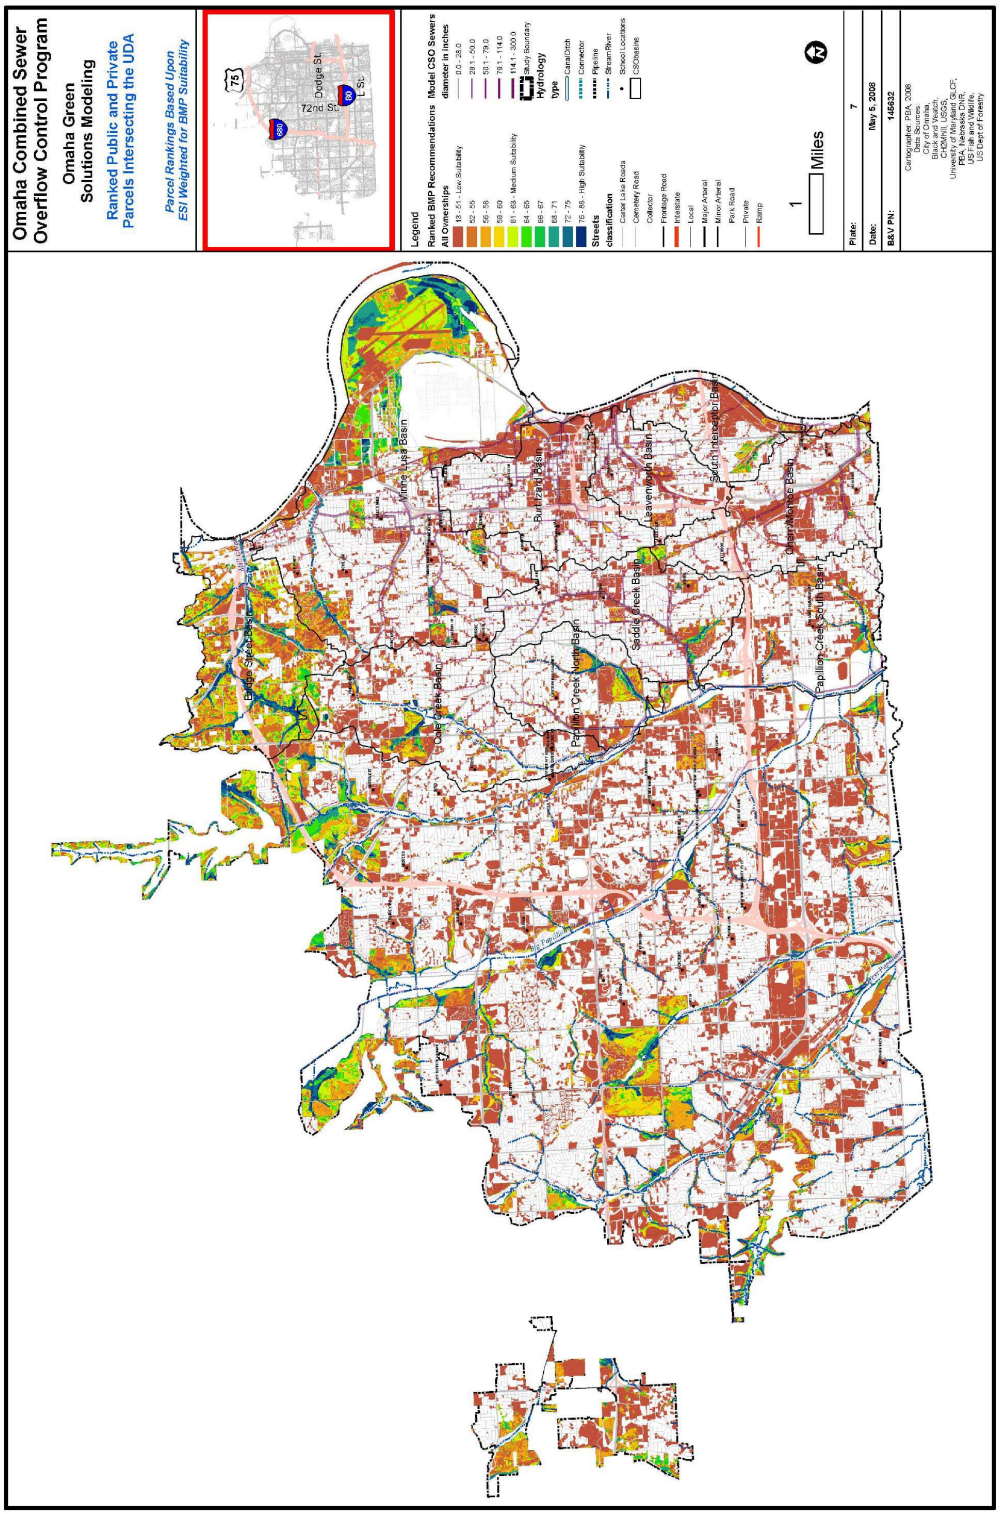

Figure 5. Green Filter Tier 3: All Green Infrastructure Opportunities

In total, the City-Owned Tier 1 analysis identified 1,291 publicly owned sites totaling 6,111 acres that could be considered for public green infrastructure within the Omaha area. The most suitable locations for those technologies are shown in blues and greens by Figure 3. Most of the identified City-Owned opportunities can be categorized as open spaces in the urban core, or remnant alluvial valleys and stream channels in the suburban areas. Many of the opportunities received high Green Filter suitability scores as these opportunities are well suited for receiving, treating and detaining large volumes of wet weather runoff. Basically, these sites, which could create opportunities for larger public amenities (such as new ponds, wetlands, and detention facilities located within existing parks and City owned open spaces) while reducing wet weather runoff and CSO frequency, would provide The City with the most value for their dollar.

When the City, Educational and Institutional Green Filter Tier 2 analysis was considered, 2,852 opportunities were identified within the Omaha City limits. If green solutions were to be considered at these locations, partnerships between the City and educational / institutional groups would need to be established. For Omaha, this tier identified some large natural features such as land owned by the airport authority and large swaths of privately held forested land. Furthermore, the suitability of some private BMP opportunities identified within Tier 2 was more mixed than the City owned Tier 1 opportunities. This occurred because the soils, vegetation and hydrology have been disrupted by development and the ArcGIS model reflected this within its calculated BMP suitability ranking of each site. Other sites within Tier 2 have large open spaces, such as playgrounds, fields, tracks, lawns and gardens which are located adjacent to large buildings. It may be feasible that the large educational and institutional sites could be retrofitted with green solution technologies so that runoff from the site would be captured within the available, directly adjacent, open space.

If all parcels (i.e., Tier 3) that intersect major overland flow paths were considered, a very detailed fluvial pattern would emerge within the City. Within Tier 3, more than 645,000 green solution opportunities were identified in Omaha. Prior to Omaha's development, these parcels were once part of the natural riparian corridor that conveyed overland runoff from the area to the local surface waters. As a result of years of development, the majority of the identified opportunities within Tier 3 were calculated by the GIS Green Filter to have a medium to low BMP suitability ranking. Furthermore, it is neither feasible nor pragmatic for the City to attempt installation of small green solution technologies on each identified parcel. In most cases, scattered and uncoordinated green solutions would be ineffective at solving the wet weather and end-of-pipe problems on a watershed scale. The usefulness of this layer is better targeted for comprehensive planning purposes. For example, the Tier 3 findings could be used as a guide to more systematically incorporate wet weather BMPs into a City's long-range planning and development.

Now that the Green Filter GIS model, which identifies appropriate locations for BMPs, has been detailed, specific concepts and BMP designs for the identified locations will be discussed.

2. Concepts, Layouts and Sizing of Identified BMP Opportunities - Minne Lusa Basin; Omaha, Nebraska

Based upon the Green Filter GIS process, the Program Management Team (PMT) and City requested that the best opportunities identified by the Green Filter be selected and refined. With the top opportunities identified (see Figure 6), detailed locations and sizing of appropriate green infrastructure technologies were developed for each site. Note that the Green Filter identified two general sites within the Omaha Minne Lusa Basin. There were:

1. Larger City-Owned Open Spaces
2. City-Owned Rights-of-Way (i.e., street and boulevard corridors)

For this paper, three of the Green Filter identified locations have been included herein for discussion. To size and cost out each facility, the runoff from the 1" design storm was used. The runoff was calculated using the "Short-Cut Method" (MARC and APWA, 2008) and is presented below. Note that although planning level costs for each site were developed, this information has not been included herein.

Short-Cut Method Equation:

$WQv = P * Rv$

Where:

WQv = Water Quality Volume (inches)
P = Rainfall event in inches (the Water Quality Storm of 1.37 inches or other appropriate amount, with the approval of the city engineer)
Rv = Volumetric runoff coefficient = 0.05 + 0.009(I). I = Percent site imperviousness (%)

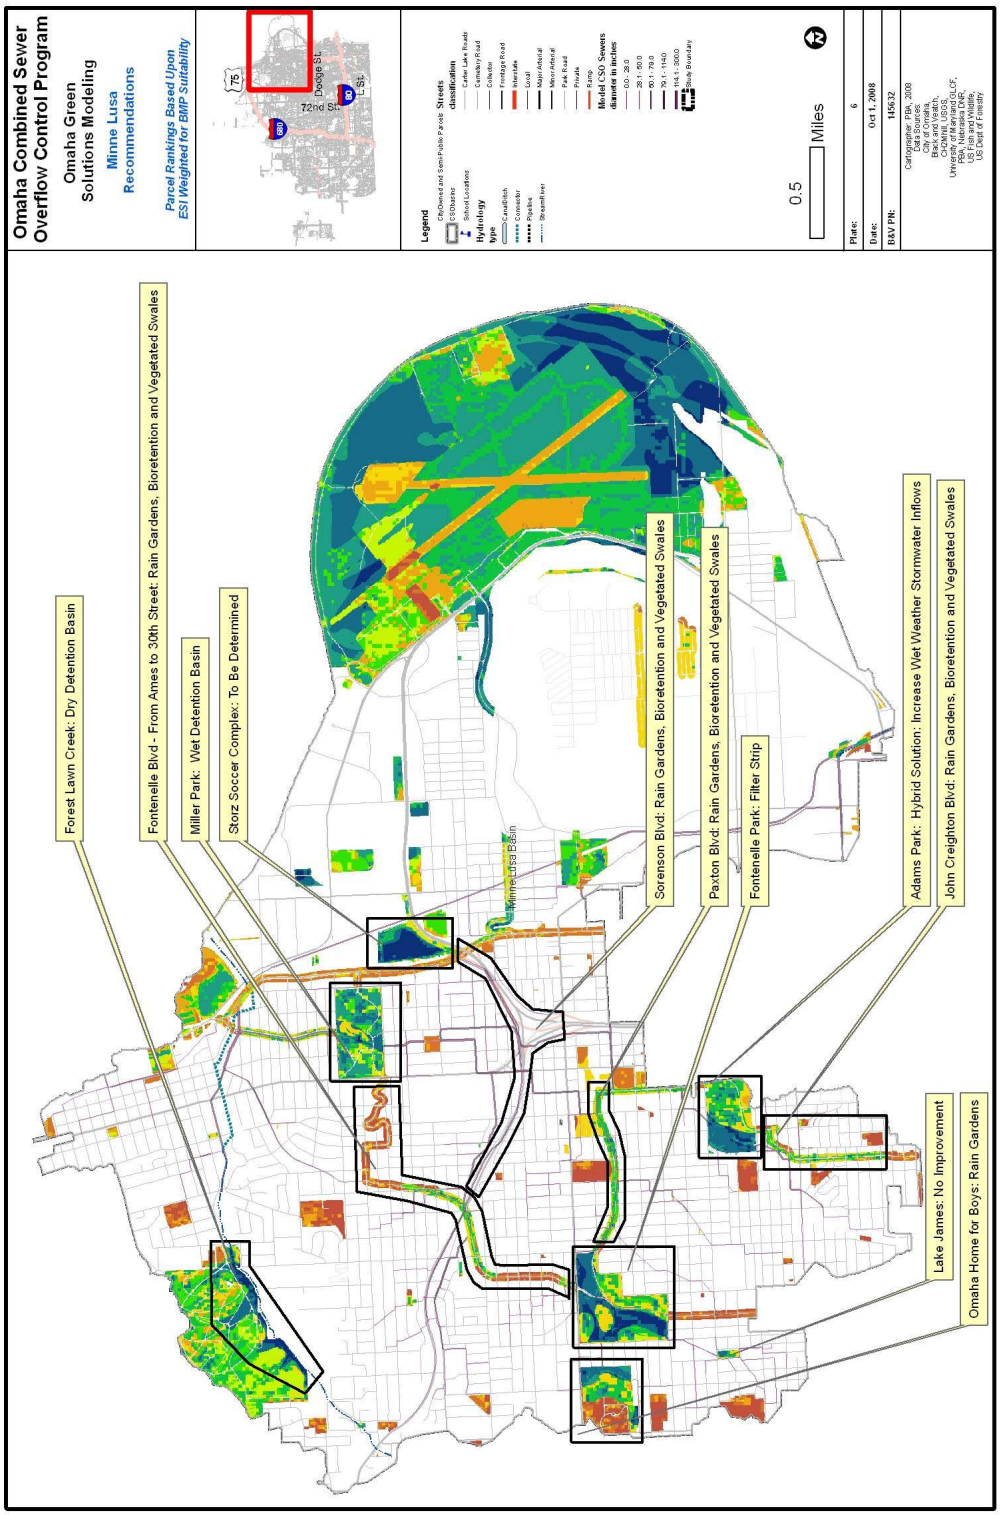

Figure 6. Top Minne Lusa Basin Green Infrastructure Locations and Recommendations

c. Adams Park Wetland and Lagoon Green Solutions Concept

Adams Park, as shown by Figure 7, is a publicly owned site with an existing wetland and lagoon. The Green Filter identified this location as an optimal place to add more BMPs. Upon review, it appears that the existing wetland and lagoon at the Park site could be enhanced by reconfiguring the upstream combined sewer collection system. It was determined that upstream sewer separation could be expanded to supplement stormwater inflow to Adams Park. In addition, downstream sewer separation was proposed which would allow stormwater from Adams Park to remain separated by a dedicated stormwater outfall.

Results from the detailed hydrologic evaluation of Adams Park showed that the proposed modifications could result in the storage of 9.1 acre-ft of wet weather runoff from 1-inch rain event. Furthermore, the modifications would allow Adams Park to receive more stormwater inflow, assist in improving the water quality of additional stormwater, serve to detain more wet weather runoff, and, in combination with downstream sewer separation, would keep stormwater runoff from mixing back into the combined sewer system.

In other words, this specific concept provides an integrated wet weather and CSO solution. The Green Filter identified the site, while the specific concept presented maximizes the sites ability to achieve multiple wet weather treatment solutions.

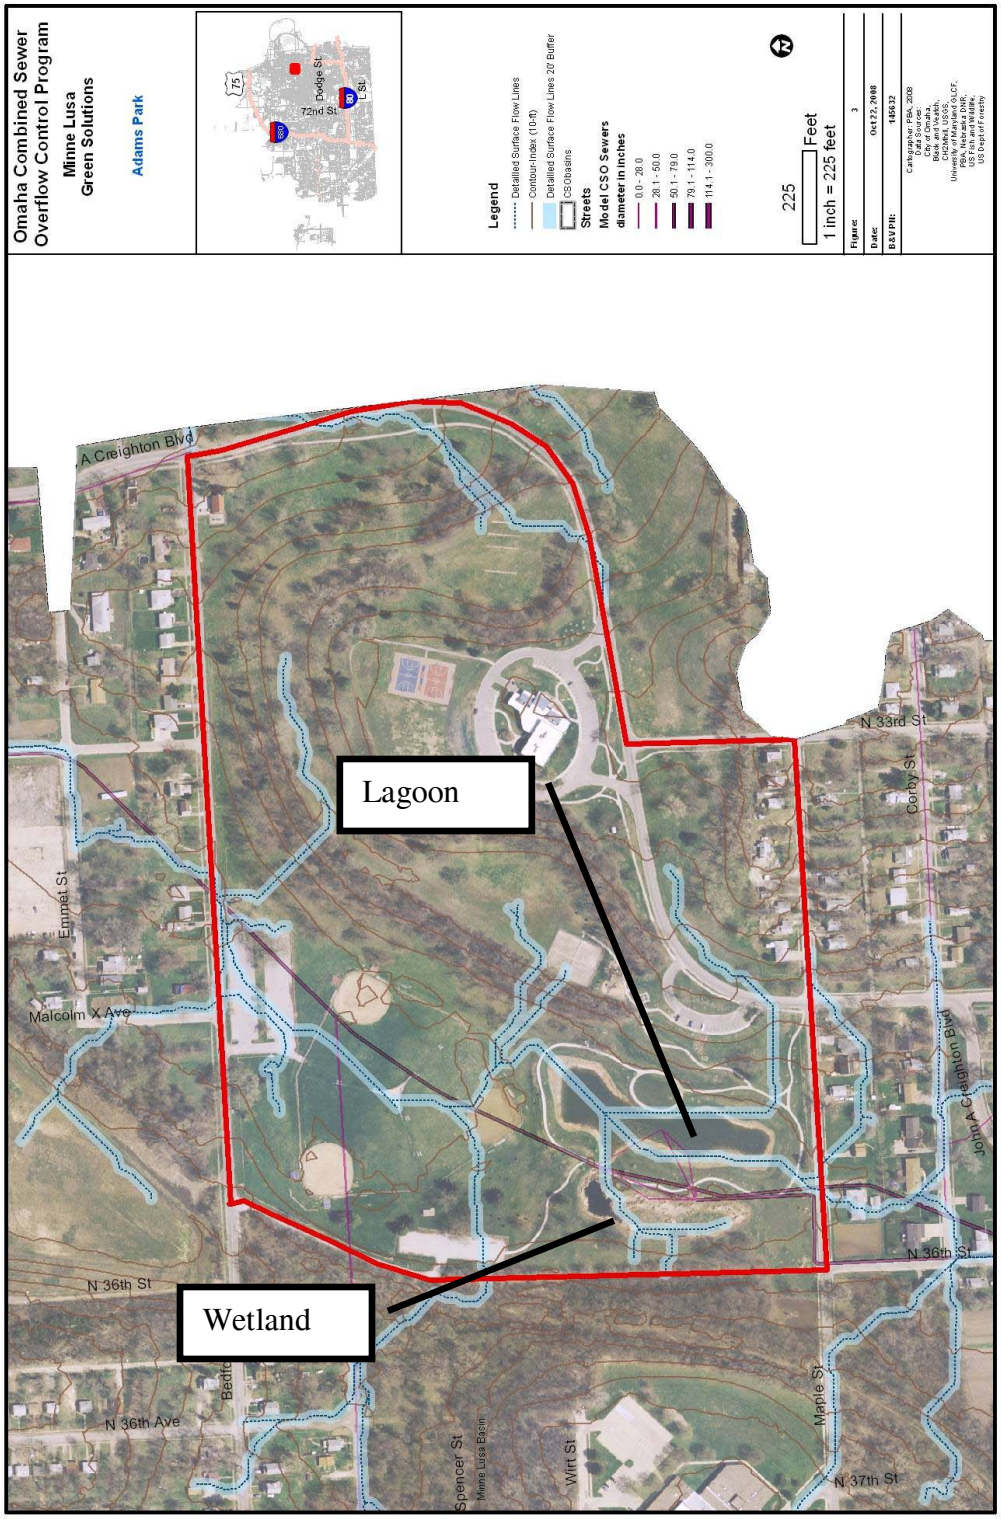

Figure 7. Adams Park Green Solution

d. Omaha Home for Boys Green Solutions Concept

Although the Omaha Home for Boys site is a privately held site, it has a significant amount of open space (approximately 66 acres) and was identified by the Green Filter as a good site for BMPs. Upon review, the site is located on a hill therefore making it a good location for potential green solutions along the extremities of the site (positioned to capture runoff from the site). Two areas on the site were proposed to be transformed into rain gardens, and would collect runoff from the Omaha Home for Boys site. The proposed watershed areas and corresponding rain gardens are presented by Figure 8. Since ample space exists on the site, the footprints of the rain gardens were sized so that runoff would be no greater than 1 foot deep following a 1-inch storm within the proposed rain gardens. The runoff calculation was performed using the Short-Cut Method, as previously discussed, and the drainage areas to the rain gardens were calculated using the GIS model. Results from the detailed hydrologic evaluation of the Omaha Home for Boys showed that the proposed modifications could result in the storage of 0.5 acre-ft of wet weather runoff from a 1-inch rain event.

Note that because the Omaha Home for Boys site is a private entity, the City of Omaha is not currently pursing the green solution option presented herein. Obviously, buy-in from the land owner would be a necessary step before the propose option discussed herein could become a reality. However, this option does show that opportunities exist on privately held sites that could benefit the overall basin.

Figure 8. Omaha Home for Boys Green Solution Concept

3. John Creighton Boulevard Green Solutions

The Green Filter also identified old riparian corridors where public right-of-way open space now exists. For example, the John Creighton Boulevard corridor, as presented by Figure 9, is an example. This Boulevard Corridor could be retrofitted with a number of small rain gardens, bioretention and vegetated swales that would be located in the existing right-of-way. Rain gardens could be built where the exiting topography is flat and the ratio of the watershed area to open space is small. Bioretention could be built where the existing topography is flat and the ratio of the watershed area to open space is high. Vegetated swales could be used on areas that are steeper to convey overland flow into the adjacent rain gardens and bioretention facilities.

A detailed hydrologic evaluation was performed within GIS to identify the specific watershed areas that drain into the Green Filter identified right-of-way open spaces. Using the Short-Cut Method, runoff estimates were calculated to determine the approximate runoff volume to each open space from a 1" rainfall. Results from the detailed hydrologic evaluation of this boulevard corridor determined that a combination of rain gardens, bioretention and vegetated swales located within the wide right-of-way could store the 1.0 acre-ft of runoff from a 1-inch rain event. Furthermore, there are 2 acres of available open space along this boulevard corridor so the average depth in the available right-of-way green solutions following a 1-inch rain would only be 0.5 ft.

Thus, John Creighton Boulevard corridor may be well suited for a green solution retrofit having a number of small rain gardens, bioretention and vegetated swales. Additionally, the boulevard corridor was historically a stream channel, so development of a green infrastructure system is a partial restoration of the historic riparian corridor.

Although parkways have a good potential (i.e., available open space) for being retrofitted with green infrastructure, utility conflicts such as water, sewer, gas, and electrical lines in addition to large trees could be encountered. This would make parkway retrofits potentially complicated and problematic which would increase the project's uncertainty and corresponding project costs. Due to the potential of utility conflicts, the boulevard alternatives are not being carried forward as viable CSO green solution at this time by the City of Omaha. However, the concept will remain open for further discussion and analysis as the CSO program moves forward.

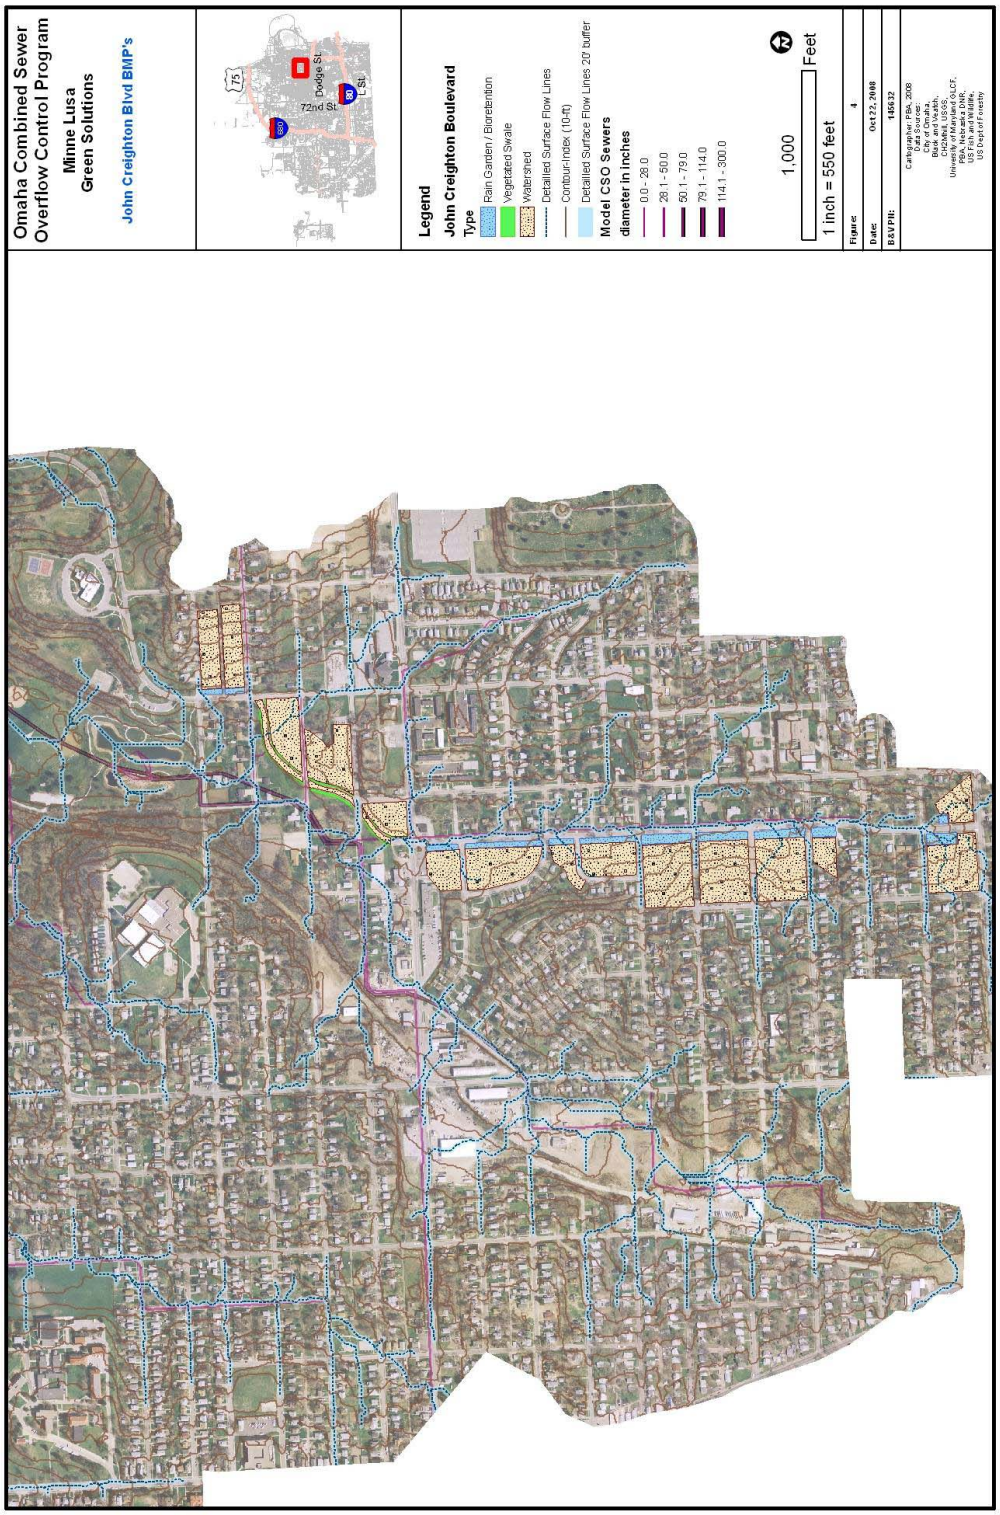

Figure 9. John Creighton Boulevard Right of Way Green Infrastructure Concept

4. Hydrologic and Hydraulic Modeling of Green Infrastructure – An Estimate of Effectiveness

The Green Filter has been discussed previously and presents a method to systematically identify, on a large scale, appropriate sites for BMPs. Furthermore, some specific green technologies have been presented that could work well on specific identified sites within urban areas. However, another important part of the Green Solutions process is to quantify, on a large scale, what impact multiple dispersed green infrastructure has on the overall basin-wide runoff characteristic.

Typically, to achieve CSO reduction and treatment goals established by the regulatory agencies, communities have relied on heavily engineered solutions (i.e., grey solutions). Grey technologies include sewer separation, deep storage tunnels, tank storage, high rate wet weather treatment facilities and pump station and treatment plant upgrades. Since traditional grey technologies are large in scale and focused on addressing in-system combined sewer flows, modeling and estimating the effect of these grey technologies is straight forward using common hydrologic and hydraulic (H&H) pipe and node models.

One of the difficulties of incorporating green infrastructure is determining the overall benefit from numerous distributed green infrastructure technologies on the reduction of the CSO frequency and volume. As presented earlier, green solutions technologies, unlike most grey CSO solutions, are typically smaller in scale. Because communities targeted by CSO regulations are generally fully developed, large open spaces for sizable green solution technologies, such as wetlands and detention basins, may be limited. The lack of available and sizable open space requires that green solution plans include smaller and more distributed practices. Examples of more distributed technologies include, but are not limited to, rain gardens, rain barrels, swales, bioretention cells, bio-swales, and infiltration basins (also referred to as Low Impact Development green solution technologies).

The challenge with quantifying numerous and highly distributed wet weather control green technologies is that the complexity of standard H&H models must be significantly increased to estimate their effectiveness. For example, instead of having one major structure to incorporate into an H&H model (like a large deep storage tunnel or detention basin), there may be dozens or hundreds of proposed distributed green technologies across an area of interest. To physically represent each green solution technology, the H&H model must be of sufficient resolution to capture each BMP and its associated processes. Furthermore, without the use of models to represent the complex nature of the collection system interactions, it is difficult to truly evaluate what impact distributed green infrastructure can have on basin wide runoff characteristics as well as on proposed large scale grey solutions.

To help answer the question regarding how much green infrastructure can reduce the frequency and volume of wet weather runoff and CSOs, a pilot H&H model was developed. The model was set up to estimate the effectiveness of a

distributed network of residential, parcel-scale BMPs for controlling the stormwater runoff from a combined sewer subbasin within Kansas City, Missouri. Using the Green Filter GIS model discussed previously along with some standard green technology designs, a dispersed network of green solutions was modeled. The modeling team assumed suitable open space identified by the Green Filter would be retrofitted with shallow extended dry detention basins. The selected locations for the green infrastructure retrofits within the subbasin are shown in red by Figure 10.

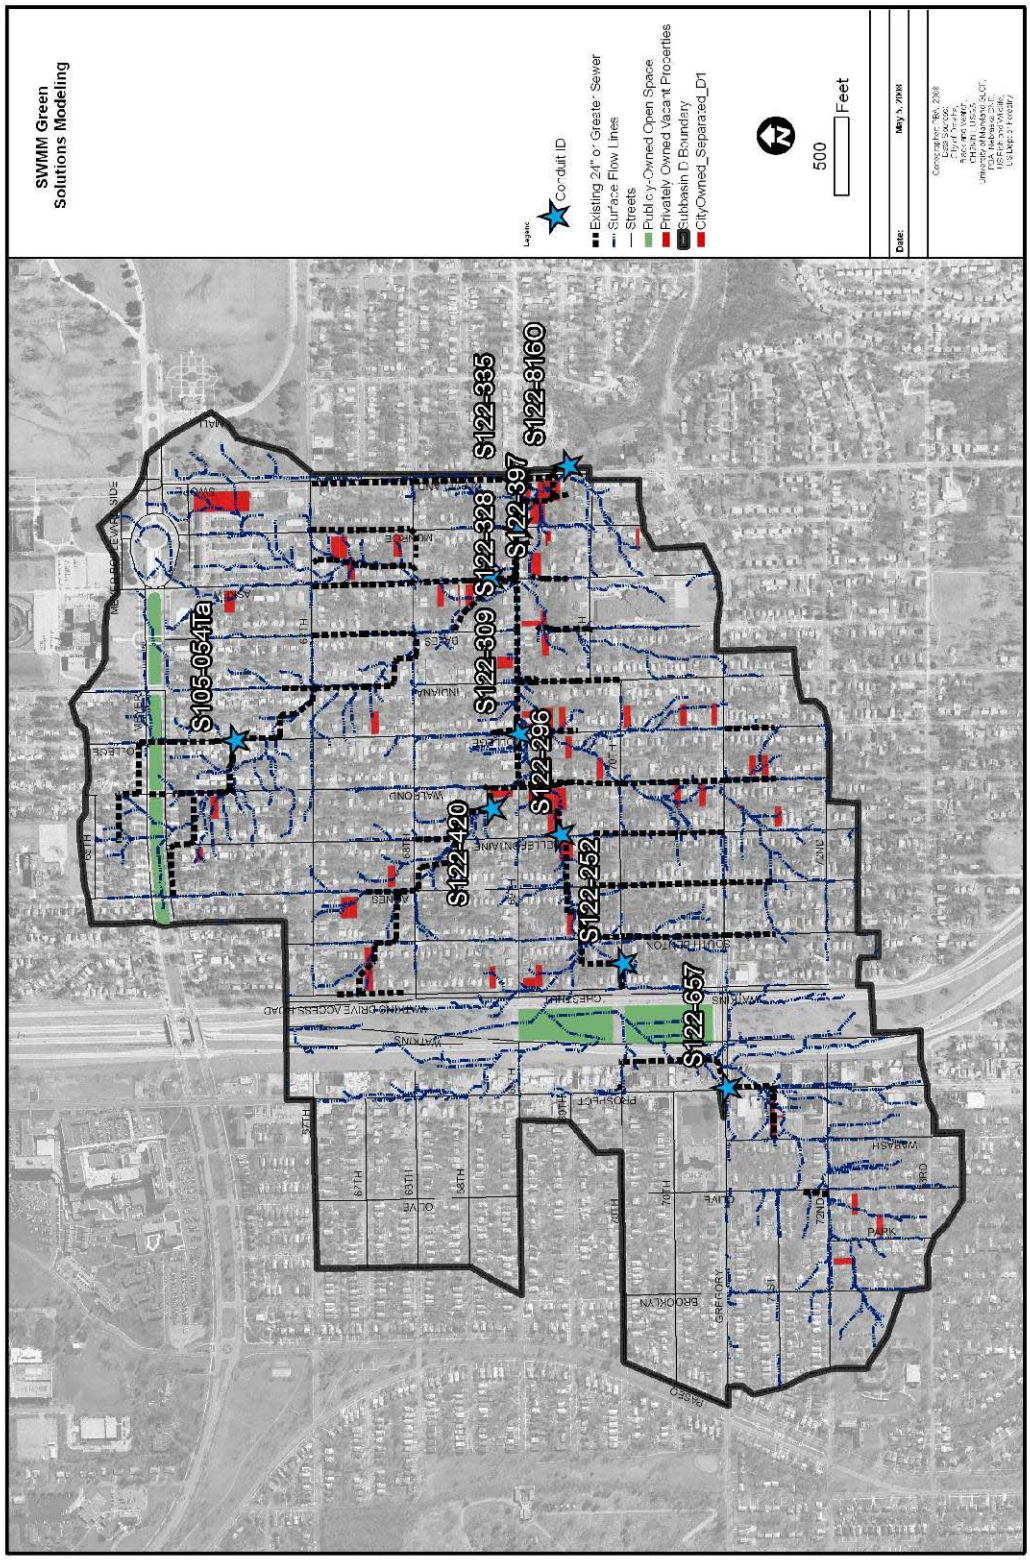

Figure 10. Dispersed Green Solution Modeling

The identified green solution locations were then input into an existing (developed previously for use in characterizing the CSS wet weather response), system-wide, XP-SWMM Version 9.51 (XP Software, Inc.) H&H model to determine their effectiveness at providing CSO control. The green infrastructure retrofits were input by breaking up (i.e., finer resolution) the existing model hydrologic subcatchments to capture and represent each parcel-scale green solution technology independently. Figure 11 illustrates the concept.

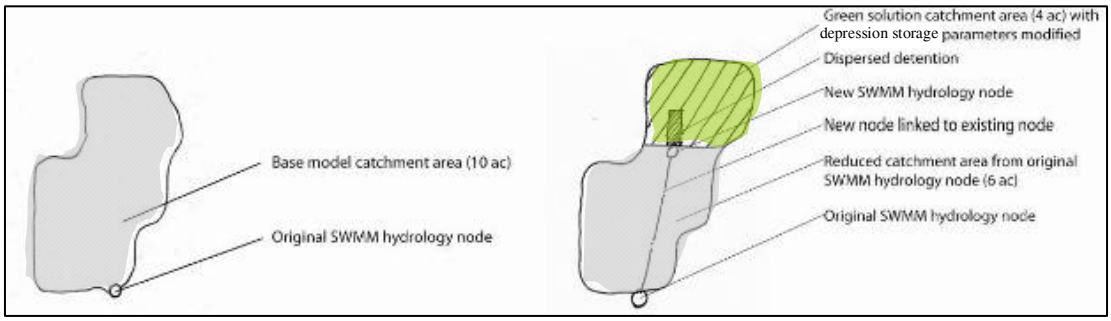

Figure 11. Green Solution Modification of a Traditional H&H Model

The detailed process to add each green solution to the existing XP-SWMM H&H model is summarized below:

1. One new SWMM runoff node was added for each green solution and a new conduit was added to link the new runoff node to the existing model catchment runoff node.
2. The catchment area for each green solution was defined as the Residential Block Area draining to the green solution (i.e., the area above the 6-inch curb and gutter system typically referred to as a "block". Streets were assumed to break up hydrologic connections).
3. For simplicity, roof areas were excluded from the catchment area. It was assumed that runoff from the roofs was directly connected to the sewer system. This was done because an accurate estimate of the number of directly connected roof areas was not available at the time of model development.
4. All green solutions catchments were assumed to be 100-percent pervious.
5. A Manning's C value of 0.03 was input for all green solutions catchment areas to represent mature vegetation (i.e., trees, grass, and shrubs).
6. The catchment infiltration parameters were set to reflect silty clay soils.
7. Each green solution was assumed to be 0.914 meters (3-feet) deep. The dispersed detention area was multiplied by two-thirds to define the useable detention area (i.e., assumes 0.3 meter [1 foot] of freeboard). The total detention storage for each green solution was calculated.
8. The storage volume for each green solution was converted into an area-depth. This value was then input into the H&H model as the updated depression storage for the BMP catchment.

After configuring the XP-SWMM model by incorporating the green solution technologies, a 20-hour, 4.57 cm (1.8 inch) storm was simulated within the model. This storm is equivalent to a rain event in the Kansas City, Missouri region that occurs approximately 4 times per year (Design Year for CSS Analysis Technical Memorandum, 2006), a design frequency that many regulators select as a level of control for CSO LTCPs. If a community can store and treat combined sewer flows from a wet weather event of this frequency without having a CSO event occur, they are presumed to have met receiving water quality standards. Therefore, the H&H model was configured to determine the effect that the green infrastructure had on this specific wet weather event. For reference, a hyetograph for this design storm is presented by Figure 12.

In total, 33 dispersed green infrastructure retrofit opportunities were identified within the investigated subbasin and input to the H&H model. Figure 13 shows the location of the BMP retrofits (in red) along with their corresponding catchment or tributary areas (in blue). A review of this figure shows that a significant area (shown in blue) of the overall watershed could be drained to the proposed 33 dispersed BMPs within this area.

The green infrastructure XP-SWMM model incorporated all 33 identified green solutions opportunities within the 20-hour, 4.57 cm (1.8 inch) rainfall event simulation. The output from the modified H&H model was compared to the baseline H&H model (i.e., without green solutions) already developed for the CSO program. The comparison focused on two main parameters of interest, peak flow and runoff volume reduction from the identified subbasin of interest.

The pilot green solution modeling effort indicated that dispersed green infrastructure covering approximately 4 percent of the total surface area of sub-basin, as shown by Figure 13, could reduce the peak runoff flow rate by approximately 60 percent and total runoff volume by approximately 55 percent. While the results are preliminary and should be refined through further conceptual design and model development, the analysis indicates that these technologies have considerable potential to affect and reduce the runoff loading to the CSS if applied basin-wide. Furthermore, although B&V and PBA are not directly involved, the City of Kansas City is investigating a green solutions concept within the Marlborough neighborhood, similar in concept to the one presented herein, as part of their CSS Long Term Control Plan. Flow monitoring performed for that work will help to better define the effectiveness from green solution strategies such as the one presented herein.

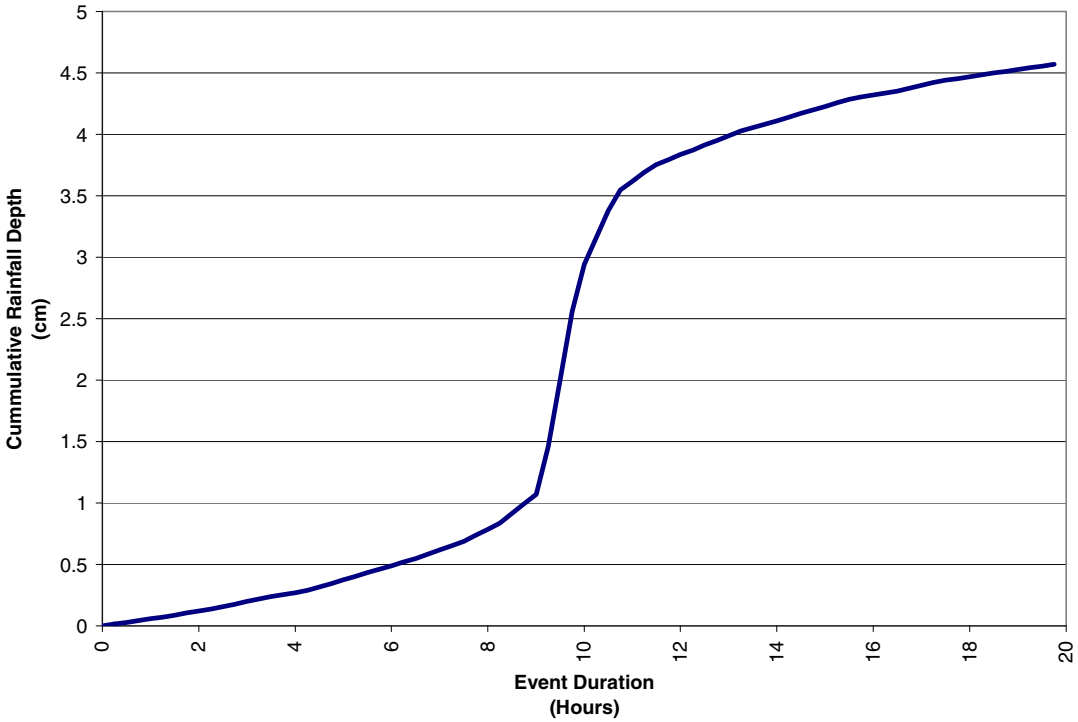

Figure 12. Design Storm Cumulative Hyetograph

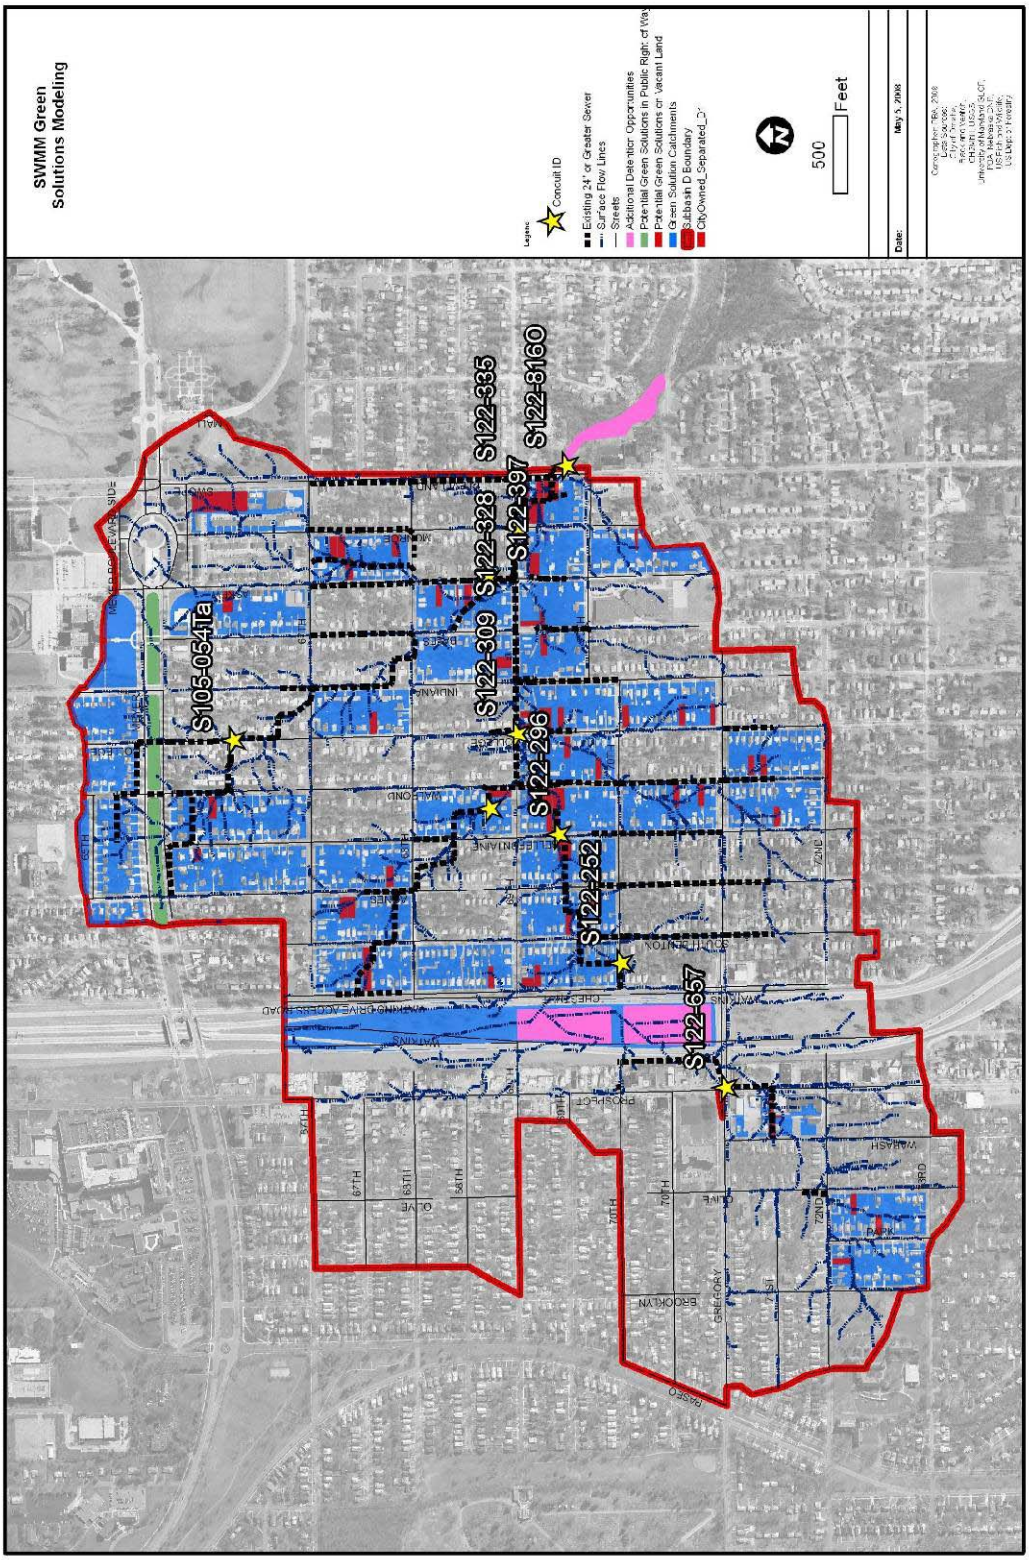

Figure 13. Dispersed Green Solution Hydrologic and Hydraulic Modeling Example

SUMMARY AND CONCLUSION

It is proposed that locations for green infrastructure should be identified and prioritized first to determine where spending time, money and resources would be the most beneficial. It serves little purpose to incorporate green infrastructure simply for the sake of doing it, if the economic, technical and societal impacts are not maximized. The Green Filter provides a flexible, GIS methodology for both identifying and prioritizing these locations, based on a community's specific conditions, to help satisfy its unique needs and objectives.

Second, detailed layouts and concepts for possible green infrastructure ideas should be considered that match the specific locations identified by the Green Filter with appropriate green solution concepts and technologies. Concepts were shown herein that could be effective in both open space applications and linear right-of-way boulevard applications located within developed areas.

Lastly, a preliminary H&H modeling exercise was presented that estimated the effectiveness of green infrastructure on wet weather runoff. The preliminary results showed that green solutions could result in a sizable reduction of wet weather runoff and corresponding CSOs from a specific area. It appears that these technologies could be used as a source control to reduce both the magnitude and cost of wet weather grey infrastructure. Furthermore, with communities (i.e., Kansas City) actively investigating green solutions strategies such as the ones presented herein, more data will soon be available to better refine the H & H modeling procedures. Through refinement and ongoing work, these models will continue to get better at quantifying the benefits of wet weather green infrastructure on CSO and wet weather solution schemes.

There is much work to be done as sustainable planning concepts and green infrastructure are incorporated into traditional wet weather and CSO solutions. However, the initial results are promising. By locating, selecting and quantifying specific green infrastructure for use in a community's long term wet weather and CSO solutions, we are closer to achieving our collective goal of attaining a more sustainable future. The past demanded that we change, the present shows opportunities where we can, and the future is more promising because we are now, more than ever, committed to seizing sustainable opportunities wherever they are found.

ACKNOWLEDGMENTS

Black & Veatch and Patti Banks Associates would like to acknowledge the City of Kansas City, Missouri and the City of Omaha, Nebraska as well as their program management teams. A significant portion of the material presented herein was developed by Black & Veatch and Patti Banks Associates in coordination with the two communities' ongoing CSO programs. The CSO programs consist of multiple engineering and planning firms and Black & Veatch and Patti Banks Associates are a part of those larger team efforts.

In addition, Mark Seip with HDR Engineering in Kansas City, Missouri is acknowledged for providing data and background information so that the green solution H&H modeling discussed herein could be performed.

Abstract: Although rainwater harvesting (RWH) is gaining popularity as a sustainable water supply source in urban as well as rural areas, estimating required storage remains an important design challenge. This paper develops a robust, yet computationally simple equation for calculating required storage capacity for a RWH system, which is generally applicable in the United States (U.S.). A simulation model with a daily time step and a yield-after-spill algorithm is used to generate empirical Storage – Reliability – Yield (SRY) relationships for RWH systems at 232 U.S., first-order precipitation gaging stations with long daily precipitation records. A regional regression modeling approach is used to combine system parameters (daily yield, collection area, reliability) with climatic variables (e.g. standard deviation of daily rainfall) to predict required storage capacity. Nationwide regression models for fixed reliability cases (80, 90, 95, 98%) demonstrate good fits (R^2> 0.95) between model predictions and simulated storage capacities. The fits improve (R^2>0.97) when the nation is broken down into smaller, more climatically homogeneous regions.

1. Introduction

Recently, rainwater harvesting has drawn increased attention in many regions of the world as a sustainable and economic water source. Rainwater harvesting has maintained its importance as a water source for small-scale agriculture and as a primary water sources in remote locations in rural areas and islands. In the past few decades, rainwater harvesting has also become a popular supplemental (and generally non-potable) water source in urban and suburban areas.

As the variable costs of rainwater collection tend to be quite small, the largest economic consideration is the initial capital cost to construct the system. In most cases, the most important design decision is how much storage capacity to build. While the performance of rainwater harvesting systems depends on only a few system parameters, and the location's rainfall pattern, estimating required storage can be difficult and is often performed through a collection of rules-of-thumb, local experience, rough calculations, and judgment. The performance and sizing of rainwater harvesting systems have been explored in the past with a range of approaches including water balance and mass-curve analysis (Handia et al., 2002; Goel and Kumar, 2005; Panigrahi et al., 2007 among others), probabilistic methods (Ree et al., 1971; Lee et al., 2000; Guo and Baetz, 2007), economic optimization (Pandey et al., 1991; Dominguez et al., 2001; Liaw and Tsai, 2004), and detailed simulation and performance analysis (Hermann and Schmida, 1999; Fewkes, 2000; Villareal and Dixon, 2005; Ghisi et al., 2007).

If RWH is to become a more widely used method of water supply, a simpler, more generalized method of storage design would be invaluable. Examining the behavior of the system, and specifically, the relationship between the storage, demand, collection area, and reliability is crucial to designing the storage.

Although not specifically recognized in most of the RWH literature, this relationship is directly analogous to the common Storage-Reliability-Yield (SRY) relationship used for reservoir analysis (see for example, McMahon and Adeloye, 2005; Vogel and McMahon, 1996; and Vogel and Stedinger,1987). Conceptually, the RWH system is remarkably similar to a reservoir system. Both have a fixed storage capacity, a characteristic volumetric demand, and a volumetric inflow determined by natural hydrologic processes. A reservoir's inflow is determined by the volumetric flow of the stream or streams that feed it. The flow in the stream however, is a function of the precipitation falling in its (finite-area) watershed, which is directly analogous to precipitation falling on a RWH system's fixed collection area. The SRY framework, therefore, is well suited to analyzing the characteristics of a RWH system.

Though they have not recognized the analogy to the reservoir SRY relationship, many RWH modelers have recognized the relationship of the key storage, reliability and yield variables (Schiller and Latham, 1987; Fewkes, 2000; Villareal and Dixon, 2005). None of these authors, however, have sought to generalize the relationships they discovered over larger areas. Looking to the analogy of reservoir behavior, at least two methods of generalizing behavior-based statistical properties of the hydrologic inputs appear in the literature.

The first method is the Gould-Dincer equations which calculate the reservoir storage for a desired reliability using an estimate of the critical drawdown sequence length based on several properties of the streamflow sequence (mean flow, coefficient of variation, Cv) and the reservoir yield. This approach has been extended to a wide range of streamflow distributions (see Gould, 1964; Vogel and McMahon, 1996; McMahon and Adeloye, 2005), but the differences in statistical character of rainfall versus streamflow, and the fact that the method does not take into full consideration the sequential nature of the inflows, make it unsuitable for RWH analysis. Thus, we turn to a second approach.

Regional regression approaches have proven extremely valuable in estimating a range of hydrologic parameters over a geographic area, most notably, streamflow (Jennings et al., 1994; Vogel et al.,1999a). More recently, however, regional regression has proven capable of estimating reservoir storage on a global geographic scale calculated by a sequent peak algorithm or behavioral model by using reservoir yield and various annual streamflow statistics as regression variables (McMahon et al., 2007).

Multivariate regression has been used to investigate RWH system behavior by Lee et al. (2000), who apply it to a RWH irrigation system in China. They use a single-site regression equation to predict the relationship between the system parameters including collection area, reliability, storage, and irrigable area (a measure of yield). Since only a single site is considered, the character of the hydrologic input (rainfall) is built into the model, and they focus instead on relationships between failure probability, collection area, storage, and other system parameters. Guo and

Baetz (2007), spurning the regression approach in favor an approach grounded in stormwater detention theory, demonstrate analytically that differences in RWH system behavior can be explained by statistical properties of the rainfall sequence. The research in this paper differs significantly from all previous research because it is our goal to develop a generalized regression model suitable for determining the relationship among rainwater harvesting system storage, reliability and yield over the entire continental U.S.

2. RWH Simulation and the Storage-Reliability-Yield Relationship

In order to understand the behavior of rainwater harvesting systems over large geographic areas, simulations using daily precipitation as input were performed. A set of 232 first-order precipitation gages from the National Weather Service's Cooperative Station Network with high-quality daily records are selected for simulation. The stations are well distributed across the continental United States and have a median record length of 59 years.

The simulation approach was designed to develop the SRY relationship by generating constant reliability curves at several useful reliabilities for a rainwater harvesting system. The reliabilities chosen for analysis are 0.80, 0.90, 0.95, and 0.98. The Yield-After-Spillage algorithm, widely used in the rainwater harvesting literature (Jenkins et al., 1978; Schiller and Latham, 1987; Fewkes, 1999; among others), is selected for the simulations. The simulations run for a single combination of yield and storage, track daily storage and whether the daily yield is met each day. The number of days with failure is recorded, and used to compute time reliability, q_t, defined in Equation 1.

To allow comparability between stations, all simulations are run for a unit collection area (Ac). Additionally, the yield is normalized to the mean daily rainfall (μ_{dp}) of each station to generate the unitless yield ratio, α (Equation 2), which describes the average fraction of available water used. The simulations were performed at 20 yield ratios per station to define each constant reliability curve, with α ranging from 0 to 1. The storage was then varied for each yield ratio to generate the desired reliability. Storage is normalized to collection area to generate the physical storage ratio, Sr (Equation 3).

$$q_t = 1 - \frac{d_f}{n} \qquad \textbf{Equation 1}$$

$$\alpha = \frac{y}{\mu_{dp} \cdot A_c} \qquad \textbf{Equation 2}$$

$$S_r = K/A_c \qquad [ft^3/ft^2] \qquad \textbf{Equation 3}$$

Where d_f is the number of days when yield is not met, n is the simulation length in days, y is daily volumetric yield, and K is total volumetric storage capacity.

For the purposes of modeling, a few assumptions are necessary. The runoff coefficient is assumed to be one, and no first flush is modeled. The precipitation gages, which melt snow, treat all precipitation as rain. .

The constant reliability curves generated by the modeling can effectively describe the full SRY relationship when plotted. Figure 1 shows a full set of reliability contours generated from the model by using precipitation data from Los Angeles, CA.

This is the typical shape of the SRY relationship, with lower reliability contours lower and less curved than the higher reliability contours because greater storage is required to satisfy higher reliabilities. The position of the individual contours varies considerably by station, however, as Figure 2 illustrates. Figure 2 displays the 90 % reliability contour from a range of cities with widely ranging climate types.

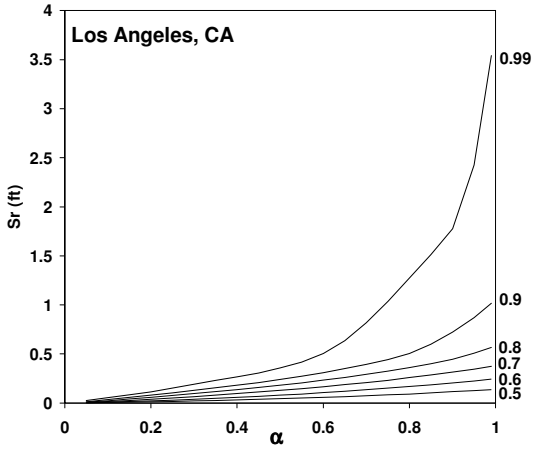

Figure 1. Constant reliability Storage-Yield contours for Los Angeles, CA

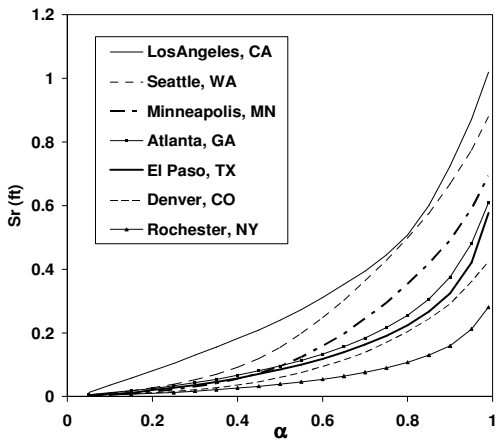

Figure 2. Comparison of modeled 90% reliability curves for 7 cities.

3. Regression Analysis

This study employs multivariate least-squares regression as the method of generalizing the SRY relationship across the entire U.S. The physical storage ratio is the dependent variable in all cases. The independent variables are a combination of system parameters and statistical parameters of the climate record.

The two goals of the regression modeling in this study are (1) to determine which precipitation parameters affect the SRY relationship, and (2) to develop an accurate, generalized predictive model for required system storage.

All the analyses use ordinary least squares (OLS) regression with the dependent variable (response) being the physical storage ratio (S_r). The regression equation is of the general form:

$$Sr = e^{\beta_0} \cdot X_1^{b_1} \cdot X_2^{b_2} \cdot \ldots X_m^{b_m} \cdot Y_1^{c_1} \cdot Y_2^{c_2} \cdot \ldots Y_n^{c_n} \qquad \textbf{Equation 4}$$

where X_i, i= 1…m, describe physical system parameters such as the demand fraction (α). Y_j, j = 1 …n, describe local climate parameters.

The following sections detail the system parameter variables and the climatic variables selected for evaluation in the regression model, followed by the generalized storage regression.

Rainwater Harvesting System Parameters

This study considers as major RWH system parameters reliability, yield, and collection area. Reliability and yield parameters are clearly important to the SRY relationship, and must be in any regression unless held constant. Reliability has been held constant, as four constant reliability storage-yield relationships are evaluated. Collection area clearly has an impact on the amount of rainwater that can be captured, but in this study, both the storage and yield parameters are normalized to collection

area, so it does not require a separate variable. Thus, yield is clearly the most important system parameter. Besides yield ratio (defined in Eqn (2)), some common transformations of α are investigated.

The parameter m, known as the resilience index (or drift), defined as (1-α)/Cv is well known as a useful parameter describing storage reservoir behavior. Reservoirs with m values greater than Cv tend to exhibit within-year behavior (they refill in most years), and those with m < Cv tend to exhibit over-year behavior (Vogel et al., 1999b). For this study, Cv is the coefficient of variation of the *daily* precipitation record. It was found that stations were overwhelmingly *over-day* systems.

With these parameters, it is also possible to apply additional transformations to further linearize them with respect to S_r. One way to investigate such transformations is to attempt single-site regression models relating storage only to system parameters. A single-site regression analysis was performed for all stations to try to find the form of the regression model describing the relationship between S_r and α for a constant reliability curve. The model in Equation 5 is sufficient to explain more than 99% of the variability (adjusted $R^2 = 0.99$) at any site in the study for any of the reliability curves.

$$ln(S_r) = b_0 + b_1 (-ln(\alpha))^d \qquad \textbf{Equation 5}$$

Equation 5 is basically a log-linear model with one key difference. The logarithmically-transformed dependent variable (α in this case) is further transformed by raising it to the "d" power. While the overall model is not log-linear, the transformation caused by the d parameter can still be incorporated in a log-linear model. Replacing $\ln(X_1)$ in (6) with $(-\ln(\alpha))^d$, we find that exponentiating both sides to base e results in Equation 7, a formulation similar to that of Equation 4. (We will refer to $(-\ln(\alpha))^d$ as the a^d transformation.) Note that for the generalized regression, d must be solved from Equation 5 using data from all stations before Equation 6 is used to fit all of the other parameters.

$$Sr = e^{\beta_0} \cdot e^{b_1 \cdot (-\ln(\alpha))^d} \cdot X_2^{b_2} \cdot \ldots X_m^{b_m} \cdot Y_1^{c_1} \cdot Y_2^{c_2} \cdot \ldots Y_n^{c_n} \qquad \textbf{Equation 6}$$

Initial regression trials demonstrated that m did not have nearly as much explanatory power as α or a^d, so only the latter two were tested further.

Climatic Variables

The system parameters alone may well explain a large portion of the variability of regional regression models. After all, at every station, S_r generally increases as α increases. It is clear, however, from Figures 1 and 2 that the SRY relationship can vary considerably by station, and is dependent on more than reliability and yield alone. This study investigates a range of possible input parameters for use in making an improved general regression model for predicting storage. Table 1 identifies the rainfall parameters investigated. The parameters are divided into three classes by their relative ease of calculation and requisite knowledge of statistics by the user. Class 1 is composed of traditional descriptive and order statistics of the complete daily rainfall series for a given location. Additionally, we include the lag-1 daily serial correlation (ρ), which can serve as a rough indicator of the general arrival pattern of

storms, and the transformation, $(1+\rho)/(1-\rho)$ derived using two completely independent approaches by both Phatarfod (1986) and Vogel and McMahon (1996).

Table 1. Daily rainfall parameters used in regression modeling

Class	Variable	Description
Class 1 Full Record	μ	Mean
	σ	Standard deviation
	Cv	Coefficient of variation
	γ	Skewness
	κ	Kurtosis
	p_{zero}	Proportion of days in rainfall record with zero rainfall
	ρ	lag-1 serial correlation (autocorrelation)
	$(1+\rho)/(1-\rho)$	transformation of ρ
Class 2 Wet-day only (zeroes removed)	μ_w	Mean
	σ_w	Standard deviation
	Cv_w	Coefficient Of Variation
	γ_w	Skewness
	κ_w	Kurtosis
	$x_{1/2,W}$	median of wet-day rainfall
Class 3 L-moment and Fitted Distribution Parameters	τ_2, τ_3, τ_4	2^{nd}, 3^{rd}, and 4^{th} L-moment ratios of the full rainfall record
	$\tau_{2W}, \tau_{3W}, \tau_{4W}$	2^{nd}, 3^{rd}, and 4^{th} L-moment ratios of the wet-day rainfall record
	$\alpha_{P3}, \beta_{P3}, -\xi_{P3}$	Shape, scale, and (negative) position parameter of fitted Pearson-III distribution to the full rainfall record
	$h_K, \alpha_K, -\xi_K$	"h" shape, scale, and (negative) position parameter of fitted Kappa distribution to the wet-day rainfall record
	$(1+k_K)/(1-k_K)$	transformation of k_K, the "k" shape parameter of fitted Kappa distribution to the wet-day rainfall record

Class 2 includes similar types of statistics, but instead of the complete rainfall series, the wet-day series is used. The wet-day series excludes all zeros (and trace rainfall) in the record. The statistics available are virtually identical to Class 1, except that ρ becomes meaningless as removing the zeros destroys serial correlation. The median value, however, becomes meaningful, as it now has a value other than zero.

Both Class 1 and 2 precipitation parameters can be easily calculated with nothing more than the built-in functions in almost any basic statistical package, or spreadsheet program. Class 3 variables are different in that they require understanding of L-moments and fitting parameters to a probability distribution. Hanson and Vogel (2008) found that daily rainfall depth could be well approximated by the Pearson-III distribution for the complete series and the Kappa distribution for the wet-day series of rainfall. The parameters were fit to each rainfall sequence using L-moment estimators and the equations in the appendix of Hosking and Wallace (1997).

Fixed Reliability Regression Results

Regression results for the four fixed reliability cases are presented in Table 2. For each reliability case, the best regression for Class 1, Class 1 and 2 only, and all Classes of climate variables are included. Column 1 indicates the regression region, constant reliability, and the classes of variable considered. Column 2 gives the regression constant value and associated T-value in parentheses, while Column 3

gives the yield parameter, including the d value, the coefficient value and the T-value in parentheses. Columns 4-6 present the chosen climatic variables with the most explanatory power, with coefficients and T-values indicated beneath. Columns 7-9 contain the maximum variance inflation factor introduced by any single variable, the standard model error (SE), and the adjusted R^2 value.

Table 2 indicates that remarkably powerful regression models (adjusted $R^2 > 95$) for predicting required storage capacity can be generated for the entire U.S at fixed reliabilities. Somewhat surprisingly, the adjusted R^2 values actually increase as reliabilities increase. The coefficients of the a^d values are virtually unaffected by the class of climate variables are used. The less-easily-calculated Class 3 parameters lead to only somewhat improved regressions over the Class 1 and 2 variables, though variance inflation is considerably lower.

The climatic parameters selected demonstrate some definite patterns in the models. Of the Class 1 and 2 variables, the standard deviation of the wet-day series (σ_W), and (1+ρ)/(1-ρ) seem to occur most frequently. The β_{P3} parameter seems to be the precipitation parameter with the most explanatory power when all variable classes are included. It should be noted that β_{P3} and σ_W are highly correlated, so including both in a model leads to high variance inflation factors.

The models generally perform quite well, but an analysis of the residuals indicates some significant lacks of fit in certain geographic areas such as the Pacific Coast, South Florida, certain areas near the Great Lakes, and a few other places. Though it would be desirable to have a model that could predict storage at any location in the United States or world, regional regression analyses on smaller, more climatically homogenous regions should result in improved predictive power.

Regional Regression Results

Though the nationwide regressions were surprisingly powerful, considerable improvement may be gained by examining smaller, more homogeneous regions. The intent of this study is not to identify how to select appropriate regions for regional regression analysis for RWH system design. A diverse body of literature exists on how to select appropriate climate regions for regional regression analyses. In further studies, this may be an important element in developing more accurate regional regressions for designing RWH systems. One key requirement for any regional regression is data availability and spatial representativeness.

This study does not include enough stations to break the study area down significantly, so fixed reliability regressions are performed for only the three regions in Figure 3. The divisions roughly follow watershed boundaries and general climate character, but no specific methodology was applied in their selection, as that was not the intent of this study. The East, Midwest, and West Region contain 95, 85, and 52 stations respectively.

Figure 3: Three regions for regional regression analyses

Tables 3 displays the fixed reliability regression results for the East, Midwest, and West Regions, respectively, in much the same format as Table 2. An additional climatic variable is included in some models, and all models include all three classes.

In general, Table 3 displays better regressions than those performed for the entire U.S. R^2 values are higher than nationwide ones for comparable models for the East and Midwest Regions, but only slightly better for the West Region. One possible explanation for this difference is merely that fewer stations are included in the West, and station density is lower.

A more probable explanation is that the range of climates in the West is greater than in the East or Midwest, considering the West includes both arid deserts in the Southwest and temperate rainforests in the Northwest. This may be supported by the prominence of α_K in the West results, which discounts the influence of zeroes. Further division of the West region by climate type may then be recommended.

The East and Midwest Regions display high R^2 values overall. As in the nationwide regressions, either the σ_W or β_{P3} variables appeared prominently. Interestingly, ρ was more significant than $(1+\rho)/(1-\rho)$ for the Midwest, unlike the other regions. One especially peculiar feature of the Midwest regressions is that the value of d in the a^d parameter was greater in the 90% regression than the 80 %. The value of d in a^d generally exhibits a decreasing pattern as reliabilities increase.

On the whole though, these regression results demonstrate that statistical parameters of rainfall can be used very effectively to predict required storage over considerably broad geographic areas.

Conclusion

Calculating the required storage for a rainwater harvesting system often presents a difficult design challenge. This study considered the problem of how to simplify the calculation of storage by incorporating the robustness of information about a RWH system provided by a wide range of simulation experiments. Considering a rainwater harvesting system as a simple storage reservoir, a daily simulation model computed empirical SRY relationships at 232 U.S. locations.

We hypothesized that differences in SRY relationships between stations could be explained by daily rainfall parameters, which would make possible a generalized regression model capable of calculating required storage anywhere in the study area (United States). By including daily rainfall statistics along with system parameters in an ordinary least squares, a log-linear regression framework can lead to a surprisingly powerful generalized storage equation. When considering three sub-regions of the United States, the regression fits improved, presumably due to greater homogeneity in hydroclimatic characteristics.

The regression models presented can be used to get a relatively good estimate of how large to build a storage tank based on desired yield and reliability, collection area, and local rainfall statistics. The regression approach presented could easily be extended and, enables the creation of improved storage equations in the U.S. and other regions of the world.

How the Heart of America is *Goin' Green* to Solve Water and Sewer Issues

Lynn Hinkle[1] and Michael Ports, PE, PH, D. WRE[2]

To become "America's Green Region," here's how a city in the Heart of America created a strategy for green infrastructure with a unique public engagement effort that created a groundswell of grassroots support for stormwater management.

As budgets tighten and the economy shows stresses from high energy costs, leaders are putting on their thinking caps and becoming creative problem solvers. In one aging American city that straddles a state line, Kansas City, such regional initiatives as 10,000 Rain Gardens, Conversations on the Environment, a regional Sustainability Academy, and the Kansas City Power and Light utility agreement with the Sierra Club to use more alternative energy sources such as wind power, have brought national attention and widespread acclaim. The appeal of *goin' green* as a region means that Kansas City can become a national model for sensible, sustainable growth.

One way to be a national model is to learn from others about solving common urban issues like polluted stormwater runoff and raw sewage overflowing during wet weather due to antiquated combined sewers. Kansas City leaders have traveled to Seattle and Portland to view green solutions that treat water as a resource, capturing and using stormwater to recharge the water table. They have seen green infrastructure such as rain gardens, bio-retention facilities, and stream buffers, which reduce storm water runoff and water pollution, create recreational amenities, and protect natural resources. These green solutions are integrated and include renewable energy, solid waste recycling, mass transit, bike/pedestrian infrastructure and other measures that reduce greenhouse gas emissions and improve environmental quality.

[1] President, ASTRA Communications, 7908 NW Pleasant Ford Road, Kansas City, Missouri 64152.
[2] Principal Water Resources Engineer, Bergmann Associates, 8653 Baypine Road, Suite 100, Jacksonville, Florida 32256.

Aside from the environmental benefits, defining Kansas City as the premier green solutions region is a brilliant stroke that could attract commerce and increased federal funding for innovative approaches.

As the nation's center of sustainability, Kansas City would be uniquely positioned to attract new businesses and relocating existing ones, particularly those that dominate the green industry. The current green industry has no center the way other industries do. The technology industry has San Francisco's Silicon Valley, the American auto industry has Detroit, and Connecticut is home to most of the insurance industry. Could the green industry be "goin' to Kansas City"? That is the goal that a number of visionary leaders have been planning for the past three years.

Everyone wants to do their part to make Kansas City the premier clean, green community. The Mid-America Regional Council (MARC) has announced a plan to create "America's Green Region" including a suite of training symposiums for area professionals. MARC is the regional planning organization for the Greater Kansas City area, including transportation and mass transit. Currently there is no light rail and mass transit is limited to a bus system. The automobile is king in a city that stretches for 250 miles from north to south and east to west. The region lies within two states, Missouri and Kansas, and encompasses eleven counties and ___ municipalities. A new transit plan has been under development and a suggested starter route for light rail will be presented to voters in November 2008.

The private sector is squarely behind the sustainability movement. The Greater Kansas City Chamber of Commerce recently launched a Climate Partners initiative with 181 business members who pledge to assess, measure, and reduce their carbon footprints. Taking a similar tack, twenty mayors in the region have signed a Climate Protection Pledge. Not only do these leaders from both groups see environmental benefits, they also understand that the incorporation of sustainability improves the quality of life for their citizens as well as increase their bottom lines through new efficiencies.

The Kansas City, Missouri is preparing a Long-Term CSO Control Plan for the EPA to describe how the City will reduce six billion gallons of polluted stormwater runoff and sewage that is discharged into local waterways each year. Like many of America's older cities, the aging infrastructure and combined sewer systems in an 85-square block area of the city are in severe need of relief and repair. Traditional approaches are projected to cost more than four billion dollars over 25 years. A citizen group known as the Wet Weather Community Panel, has been meeting for five years and advocates the use of green solutions, resulting in a unanimous City Council Green Solutions Policy Resolution. The administrative regulation that went into effect on February 25 directs all City departments to incorporate green solutions into their policies, projects, and programs.

To ensure efficient adoption across City departments, the administrative regulation directs more than ten City divisions and departments to explore and implement green solutions. The policy also provides for the creation of a Green Team Committee, which will direct the City's green solutions efforts, approve modification of internal business processes necessary to implement green solutions throughout the City, and provide direction on innovative ways to add green solutions to City projects.

"City projects will be approached as opportunities to incorporate green solutions in a creative way to provide multiple benefits for the residents of Kansas City," said Dennis Murphey, chief environmental officer in the Office of Environmental Quality. "Solutions include reducing sewer overflows and basement flooding, improving water quality in area streams, making our city a more bike and pedestrian-friendly community, improving air quality, and reducing greenhouse gas emissions that contribute to climate change."

The City Council has unanimously embraced the two year Climate Protection Plan led by Murphey's office using a collaborative, all-volunteer workforce to investigate the best approaches for Kansas City to reduce its carbon footprint, setting a city government goal and a community goal. The plan covers policy and public outreach, carbon offsets and waste management, transportation, buildings, and infrastructure.

For the homeowner, multiple short-term benefits stem from the use of green solutions. Many are easy and affordable. Property owners in other cities such as Portland, Oregon, and Maplewood, Minnesota, have welcomed the addition of large rain gardens installed by the city in the rights-of-way along streets because they help alleviate street flooding. Additionally, a street lined with rain gardens creates a beautiful neighborhood amenity that increases property values. Green street landscape designs called "bumpouts" have been used as traffic calming features in some communities. An excellent example in Kansas City is found near City Hall on 12th Street. The benefits include improved air quality, and a cooling effect from the urban environment's heat island effect.

In the long run, Kansas City residents also will benefit. Homeowners that support the visionary efforts of their regional leaders and take their cue to apply green solutions at the home level will help keep costs of renovating sewer system infrastructure in line. By disconnecting downspouts that send thousands of gallons of roof runoff directly into sewers, and redirecting that flow into a beautiful rain garden or a practical rain barrel, we begin to be part of the wet weather solution, one home or business at a time.

Workshops and training seminars for the public and for professionals held the key to Kansas City's successful 10,000 Rain Gardens initiative. Organizers held to one rule: KISS….Keep It Simple Stupid! Many gardeners are willing to "dig in" with just a little direction. The active involvement of Master Gardeners and other professionals helped improve a series of half-day training classes on the fundmentals of rain gardens, and reached thousands of citizens. A 45-minute video, "How to Build a Rain Garden," takes the mystery out of rain gardens and demonstrates the required planning, installation, and maintenance.

Workshops for teachers helped them to establish living classrooms. Youth groups and schools are a natural path to creating watershed management curriculum that grows with the students. Training the Trainer programs were created to help master gardeners continue their outreach to the community.

Professional training seminars helped experienced nursery owners, landscapers, planners, engineers, and others in the community's green industry to learn the design and planting of rain gardens, bioswales, and green roofs. Even seasoned professionals can be intimidated or overwhelmed by new ways of landscaping for stormwater management. Workshops geared to professionals included materials on native plants that are appropriate regionally, which invasive plants to avoid, proper preparation of the bed material, and basic hydrology, site issues, standard designs and templates, practical exercises in designing rain gardens, design evaluation, common pitfalls and troubleshooting, how to handle slopes, and a way to network the group for future business opportunities through the website that was designed for 10,000 Rain Gardens, www.RainKC.com.

Rain garden designs that are provided to the public must be customized to the region. Creating the website allows citizens, government officials, and businesses to find good information that is appropriate for the Kansas City rain fall and weather patterns. Kansas City's average storm yields 1.37 inches of rain. The green solutions approach helps the city to absorb more of the rainfall naturally, keeping it from running off into the sewer system and overloading it during a storm. Cities are looking for locations in their built environment to add a layer of green, from flat rooftops in the urban core, to alleyways that can become pervious through the use of different materials, to rain gardens or rain barrels that allow the disconnection of downspouts from the sewer system and a place to catch and use the rain water productively.

Modern marketing and advertising techniques were employed in Kansas City's 10,000 Rain Garden initiative that helped to create awareness and interest in stormwater management. Statistics from citizen opinion polls demonstrated a fifty percent increase in knowledge about sources of pollution in local waterways after just three weeks of the initial television campaign on local news channels. The female mayor, Kay Barnes, was featured in the ads to lend credibility and to demonstrate the commitment of the City's political leadership to green solutions. The use of humor assisted in the engagement of citizens and civic leaders in the campaign.

Other outreach included a Speaker's Bureau of local rain garden and native plant experts, volunteers such as Master Gardeners, who had received the appropriate training, and landscape architects. Requests for speakers came through the website, which was prominently featured in the television ads. Signage and displays at large events assisted in reaching the targeted audiences. An intensive public relations effort extended every paid dollar and allowed for a larger national story to develop, attracting the attention of federal regulators at the Environmental Protection Agency, who became strong advocates for this initiative.

In spring of 2008, after a $2.3 billion plan for the sewer overflows was submitted to city leaders and was found to be lacking in green solutions, the leadership of Kansas City, Missouri, worked with regulators to extend the timeline for a completed plan by six months to allow for a more progressive and integrated approach to be developed. The goal of the City Council was to fund green solutions with as much as twenty percent of the $2.3 billion gray infrastructure plan, thus positioning the city to develop a stronger local economic engine of small, minority-owned and women-owned businesses to design, install and maintain the green roofs, green streets, and rain gardens that would relieve the aging sewer system of a significant amount of stormwater runoff by diverting and infiltrating it naturally.

The local congressional leadership agreed to support the City's efforts by seeking funding for research projects from federal agencies, and made it a top priority to develop a Green Collar Job Corps in the region. As Congressman Emanuel Cleaver noted, green collar jobs are always needed in the community, and cannot be shipped overseas. The development of a green work force will depend upon small businesses and entrepreneurs, and is a critical asset that will stabilize the local economy through good times and bad.

Measuring success includes quantitative measures that indicate how many jobs are created in a new market sector, how many gallons of runoff are diverted from the sewer system, how many rain gardens, green roofs, rain barrels are installed, how many

corporate partners participate, and the number of students educated about their watershed. A change in attitudes and knowledge about stormwater management can be measured as well. A baseline for future public surveys was established in 2005.

Changing behavior by engaging hearts and minds in the Heartland of America creates a template that is applicable to cities anywhere in the world. Water is at the core of the effort, and it is important to remember that citizens care about beauty, clean water, and wildlife, even when they live in the heart of a big city. Empowering citizens and leaders to be innovative, and to take an active role in solving community issues, has paid off for Kansas City in helping it retain its quality of life. By *goin' green*, this region expects to create long term benefits for all citizens that balances the economic, social and environmental needs of all.

Graywater Irrigation as a Means to Meet Water Demands in Arid Regions

Abstract

Graywater irrigation systems offer many benefits, however the use of such systems has not become widespread due to concerns about safety issues. While some states have begun to legalize and regulate the practice of graywater reuse for residential landscape, little guidance based on scientific data has been provided for the safe operation of graywater irrigation systems. Limited scientific data is available on the fate of graywater chemical and microbiological constituents and the effect of these constituents on plant health after graywater is applied for irrigation. In this research we have examined the long-term effects of graywater irrigation. We selected three households where graywater has been applied for irrigation for more than five years to include in this study located in California, Colorado, and Texas. Sampling locations were selected to encompass a variety of soil types and climatic conditions. Soil and plant samples have been collected in an area irrigated with graywater as well as a control area with analogous soil and landscaping that has been irrigated with potable water. Soil cores have been taken to a depth of 1 m and we have analyzed the presence of antimicrobials, and indicator organisms at depths of 0 - 13 cm, 13 – 30 cm, and 30 – 100 cm separately. Soil samples also were analyzed for indictor organisms including total coliforms, *E. coli*, *Enterococci*, *Clostridium perfringens*. In addition, infiltration tests were conducted in each sites to evaluate the effect of graywater on infiltration rate of soil.

1. Introduction

As communities throughout the United State and abroad are becoming interested in innovative approaches to water resource sustainability, household graywater reuse for landscape irrigation is gaining popularity. In a typical household, graywater (near 28 gallons per person per day) is nearly 50% of the total wastewater generated. If used for irrigation of a typical residential landscape, it could supply about 30% of the demand, and with increasing emphasis on xeriscape in the semi-arid West, it has the potential to supply 100% of the irrigation demand in some areas. A study conducted by the Soap and Detergent Association (SDA) in 1999 revealed that 7% of U.S. households were reusing graywater (NDP Group, 1999). Another study in the same year (Little, 1999)

found that 13% of the households in Arizona used graywater for irrigation with the most utilized source being from clothes washers (66%). Some states, including California, Arizona, and New Mexico have legalized the practice.

However, there are potential risks associated with graywater reuse for irrigation. The physical, chemical, and microbial characteristics of graywater are highly variable based upon the sources connected to the collection system, household inhabitants, household chemicals used by the residents for personal hygiene and house cleaning, personal care, plus medications and waste products disposed of in sinks (Eriksson et. al., 2002). Application of graywater may result in increased levels of pathogens, negative impacts to soil quality, potential groundwater contamination with chemical constituents present in graywater, or negative impacts to plant health. These risks should be further evaluated and methods of graywater application that minimize these risks should be understood.

A number of studies have inferred fecal contamination of graywater via the presence of indicator organisms (e.g., Novotny, 1990; Rose et al., 1991; Christova-Boal et al., 1996; Casanova et al., 2001; and Ottoson et al., 2003). A primary concern is the possibility of graywater irrigation being a pathway for the spread of human diseases. However, the fate of pathogens after graywater application is not well understood.

Application of graywater for irrigation may impact soil chemistry. Potential effects of graywater on soil chemistry include changes in pH, salinity, and concentrations of chemicals, specifically organics and metals, introduced by the graywater. Very few published studies were found that evaluated these changes in the soil. The Gray Water Pilot Project in the City of Los Angeles, CA (1992) conducted research on eight voluntary residential sites retro-fitted with graywater systems for the purpose of residential sub-surface irrigation. Results showed an increase in sodium levels (Na^+) and in the Sodium Adsorption Ratio (SAR).

While graywater reuse for household irrigation is widespread, potential effects to soil quality, groundwater quality, and plant health have not been adequately assessed. The application of any irrigation water will introduce chemicals to the soil and potentially have short- and long-term effects. This potential depends on application rate, chemical concentrations in the water, biodegradation rate of the chemical, sorption, leaching, and plant uptake. Graywater chemical constituents can potentially migrate to groundwater, surface water, and drinking water sources. In addition, pathogens present in graywater may persist and pose human health risks. Previous researches have not addressed impacts of graywater chemical constituents and pathogens on soil quality, groundwater quality, and plant health. In addition, household graywater has not been adequately characterized. The study presented herein describes scientific experiments to alleviate these information gaps regarding household graywater irrigation.

The objective of this research project is to elucidate information on the fate and occurrence of graywater chemical constituents and pathogens and their long-term potential impacts on soil quality, as a result of its application for residential landscape irrigation with the experiments on households with existing graywater irrigation systems. Soil samples have been collected and analyzed at households where graywater

has been applied for irrigation for at least five years. Results will provide guidance to decision makers, water agencies, regulators, product manufactures and consumers so that safe graywater irrigation systems can be installed and operated for household irrigation.

2. Materials and Methods

2.1. Site Description

Soil samples were collected from three selected households where graywater has been applied for irrigation for more than 5 years in California, Colorado, and Texas. A control area at each household was selected with similar landscape irrigated with fresh water. Soil samples were collected at different depths of 0-15, 15-30, and 30-100 cm. The diameter of soil cores was 0.8 inch and cores were collected within the root zone of irrigated landscape. Site specifics and sampling dates are summarized in Table 1.

Table 1. Sites Specification and Sampling Dates

Location	Graywater Source[a]	Pretreatment	Storage Tank	Years in Use	Months Irrigated	Household Population	Sampling Date
Fort Collins, CO	L, S, W, B	No	Yes	5	May-Oct.	2	11-Aug-08
Escondido, CA	L, S, W	Sand Filtration	Yes	10	10	2	20-Oct-08
Dallas, TX	L	No	No	31	12	2	15-Sep-08

a: L = Laundry, S = Shower, B = Bath, W = Washbasin

2.1.1. California

The existing household in Escondido, California was equipped with a more advanced irrigation system than other households studied here. The system was comprised of a slow sand filter, which was automatically backwashed daily, pump, and submerged drip system. Underground emitters were placed in the root zone of graywater irrigated plants. The installed emitters were very effective in that they prevent clogging resulting from root growth. The system was installed by ReWater. No problems operational have been encountered with this system in its 10 years of operation. Landscape was irrigated on a daily basis. Some problems were encountered with sampling at this household. Depth sampling was not feasible due to a layer of bedrock present at around 4-8" below ground surface (bgs). Because a very extensive area was irrigated with graywater at this site with varying landscape, samples were collected at various locations rather than conducting depth sampling to 3 feet. It was decided that depth sampling would not provide useful information at this site since water was observed to flow down-slope rather than vertically, due to the layer of bedrock. Soil samples were collected from three different areas of the yard irrigated with graywater, one area amended with manure and two areas with native soil. One sample was collected where graywater had migrated to the soil surface.

2.1.2. Colorado

The household with an existing system in Fort Collins, Colorado was equipped with a simple irrigation system consisting of a storage tank, pump, and coarse filter. No problems were encountered with sampling at this household.

2.1.3. Texas

Samples were collected from a household in Dallas, Texas where wastewater from a laundry machine has been drained to landscape for more than 30 years. Turf grass in the graywater irrigated area appeared very healthy. Of particular note was that free range chickens and a dog defecate in the area irrigated with graywater.

2.2. Materials

Triclosan >97% (HPLC) and triclocarban 99% were obtained from Sigma-Aldrich. LC/MS grade methanol, acetonitrile, water and acetone were from Honeywell Burdick and Jackson.

2.3. Analytical Methods

Soil samples were analyzed for total coliforms, *E. coli*, and *Enterococci* using the IDEXX Quanti-Tray® enumeration procedure with Colilert® reagent for total coliforms and *E. coli* and Enterolert™ reagent for *Enterococci*. In addition, *Clostridium perfringens* was measured according to the plate count method specified in the Bacteriological Analytical Manual (FDA BAM). Microbial biomass, microbial respiration, and dehydrogenase enzyme activity were determined in all samples by the method described by Horwath and Paul (1994).

Soil samples were assessed for presence of antimicrobials. Extractions were performed on all soil samples upon arrival in our labs by methods as describe by Dyer et al. (1996) and Halden and Paull (2005). In addition, common antimicrobials in personal care products, triclosan and triclocarban, were also be monitored by LC/MS (Halden and Paull, 2005). An Agilent 1200 (Agilent Technologies) High-throughput HPLC systems coupled with Agilent 6220 Accurate Mass Time of Flight mass spectrometer (Agilent Technologies) was used for determination of triclocarban and triclosan. Chromatographic separation was carried out at a HyperClone ODS C18 column (5 μm, 150×2.00 mm) from Phenomenex. The data were controlled and processed using MassHunter Workstation software. Sample volumes of 5 μL were introduced to the instrument with an auto-sampler. Column temperature was maintained at 35 ^{o}C at both right and left sides. A gradient method with a mixture of water (A) and methanol (B) was used as follows: initial mix of 40% water, 60% methanol, linear increasing to 100% methanol within 5 min and held for 11 min, then linear decreasing to initial 60% methanol within 2 min and finally a postrun at initial condition for 10 min, at flow rate of 0.32 mL/min. Electrospray ionization (with negative ion mode) mass spectrometer was used for the determination of triclosan and triclocarban. Several methods described in the literature were evaluated for the analytical determination of triclosan and triclocarban in extracted soil samples with LC-MS techniques. Chromatographic separation of the analytes was evaluated under various conditions. For the first runs, water and acetonitrile elution containing 0.1% formic acid as an additives were performed with different isocratic and gradient conditions. These conditions did not result in adequate separation. Acetonitrile and water mobile phases with 10 mM acetic acid reported by Halden and Paull (2005) were used through different isocratic and gradient methods. Although acidic mobile phase was recommended for determination

of triclosan and triclocarban, it was found that acid addition caused reduction in sensitivity. A mobile phase with 10 mM ammonium acetate reported by other researchers may improve chromatographic resolution slightly, but it reduces sensitivity as well. Chu and Metcalfe (2007) used methanol and water as mobile phases quantification of triclosan and triclocarban without additives by monitoring of specific transition ions for each analyte. Our work showed that optimum results were achieved when water and methanol were used for the mobile phases. Although chromatographic separation of the analytes is still poor, this method results in more sensitive chromatograms in much less time in compare with other methods.

Widely used surfactants including soap, linear alkyl benzene sulphonates, alcohol ethoxylates, and alcohol ether sulphates will be quantified by liquid chromatography/mass spectrometry LC/MS, (Levine et al., 2005) in the near future.

A single ring infiltrometer test was applied to each household site to estimate the infiltration capacity of graywater irrigated and control soils. The single-ring infiltrating device (approximately 20 centimeters (cm) diameter) was driven 5-6 cm into the ground using a large mallet and sealed by compacting native soils around the outside edges. At the beginning of the test, the device was filled with approximately 15 cm of fresh (i.e. tap) water. Water depth measurements were collected at intervals ranging from 30 seconds to 5 minutes for a minimum of 30 minutes. If the water depth dropped below 2 cm before the test was completed, the device was refilled back to a depth of 15 cm. With a few exceptions, two tests were conducted at each site, one at a location irrigated with fresh water (control site) and another at a location currently (or planned to be) irrigated with graywater (graywater site).

Table 2. Soil Microbial Data for Households with Existing Graywater Systems

State	Treatment	Soil Depth	Total Coliforms	E. coli	Enterococci	Clostridium perfringens	MBC[1]	Respiration rate	Dehydrogenase

[1]MBC = Microbial Biomass Carbon
[2]BDL = Below the Detection Limit

3. Results and Discussion

3.1. Soil Microbial Data

Pathogen indicator organisms were measured in soil samples to assess their fate after graywater application. Soil microbial data with existing graywater system has been summarized in Table 2. Numbers of total coliforms ranged from very low (11 cells g^{-1} soil in Colorado) to 137,000 cells g^{-1} soil in Texas. Total coliform numbers generally decreased with soil depth, with the exception of Texas soil receiving fresh irrigation water (Figure 1). No clear trend of an effect of graywater irrigation was observed on total coliform numbers in soil samples. Total coliforms were not higher in graywater irrigated soils compared to contol soils. Numbers were similar between control and graywater-treated soils at California, greater in control soil in Colorado, and greater in graywater-irrigated soil in Texas.

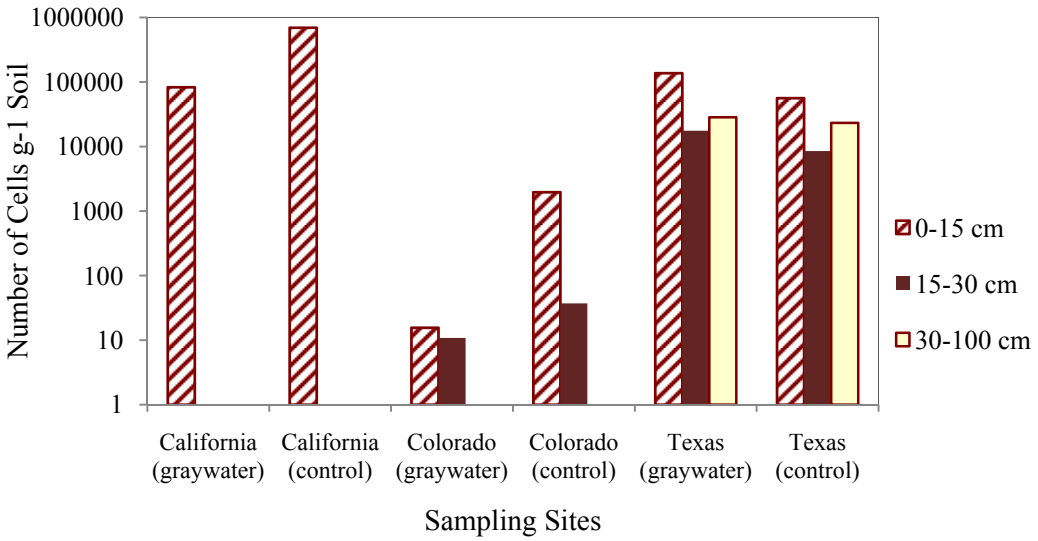

Figure 1. Number of Total coliform in soil samples

Numbers of *E. coli* were generally low or below detection limits in soils from California and Colorado (Figure 2). In Texas, *E. coli* numbers increased with soil depth for the graywater treatment, indicating downward movement of *E. coli* in soil receiving graywater. Numbers of *Enterococci* were highly variable, ranging from below the detection limit to greater than 35,000 cell g^{-1} soil, which occurred in graywater-irrigated soil in California (Figure 3). In Texas, surface soil receiving graywater contained more than twice the number of *enterococci* as surface soil receiving fresh water, potentially attributable to chickens in the area.

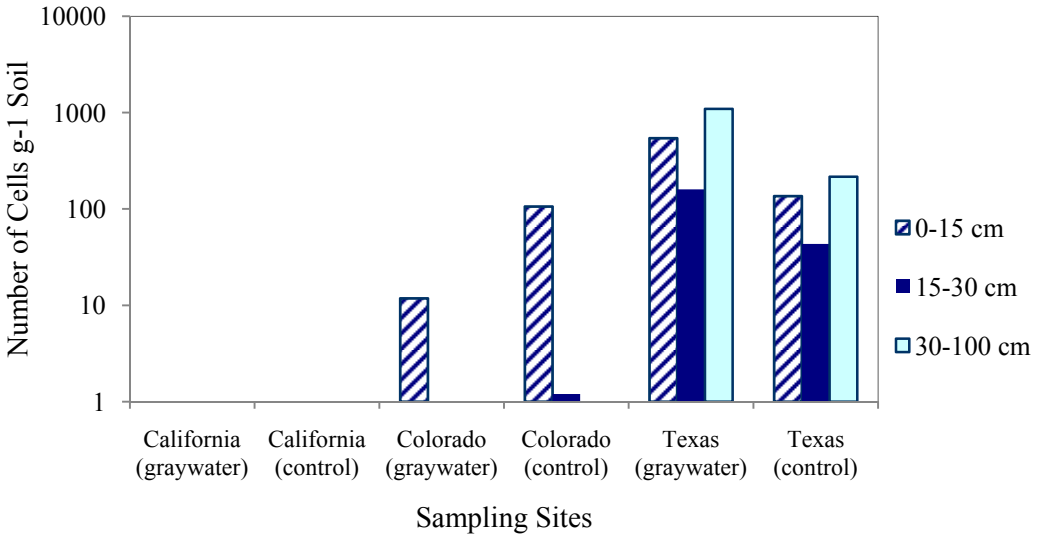

Figure 2. Number of *E Coli* in soil samples

No clear trend was observed regarding graywater effects on soil microbial biomass and respiration (Table 1). Microbial biomass and respiration were lower in graywater-treated soil in California, slightly lower in graywater-treated soil in Colorado, and higher in graywater-treated soil in Texas. Overall, Texas soils contained very large amounts of microbial biomass and had the greatest rates of respiration. Dehydrogenase is an intracellular enzyme involved in aerobic metabolic processes and is an indicator of microbial activity. Overall, rates of this enzyme were low in the Colorado soils, which corresponded to the relatively low microbial biomass at this site. Graywater did not affect dehydrogenase activity in Colorado or Texas. In California, dehydrogenase activity was greater in soil irrigated with graywater, despite the smaller microbial biomass in graywater-treated soil.

1.1. Soil Antimicrobial Analysis

The optimized analytical method previously described was applied to the analysis of extracted soil samples collected from different sites in CA, CO, and TX. Triclosan and triclocarban were not detected in any of the soil samples. The mass of soil extracted was 40 g, so the lower detection limit on the instrument was near 0.04 ng/g soil for both antimicrobials. Triclosan and triclocarban do not appear to be present in graywater irrigated soils at concentrations of concern.

1.1. Soil Infiltration Data

Each site offers unique conditions that exist due varying soil characteristics, particle sizes and varying depths to restrictive layers that may limit the vertical migration (and promote the horizontal migration) of graywater. Results from infiltration tests are summarized in Table 3. Preliminary results from paired infiltration tests comparing control (freshwater irrigated) locations to graywater irrigated locations suggest that long-term application of graywater may enhance infiltration; however, additional tests

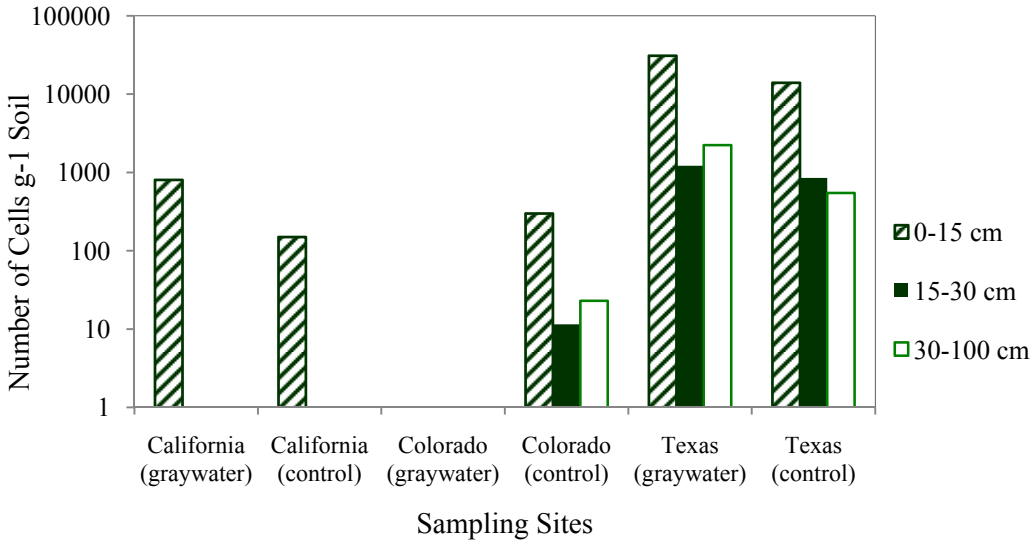

Figure 3. Number of *Enterococci* in soil samples

and analysis should be conducted before reporting definitive conclusions. Of note is that the site where the infiltration test conducted in the control area at the California site was highly sloped whereas the area within the graywater irrigated soil was not as sloped, resulting in substantial horizontal flow of water. Therefore, results from the California infiltration study were not interpreted. Two infiltration tests were conducted at each site; one where graywater is currently used for irrigation and another where freshwater is used for irrigation. This one set of paired tests may not be adequate to conclude with certainty whether or not graywater irrigation has a significant impact on the infiltration rates of soils. In the future, it may be useful to conduct infiltration sites at multiple locations within each site to better understand the influence of graywater on soil infiltration rates. A modified method of the single-ring infiltration test developed by Bouwer (1999) could be conducted during future field visits to better estimate the vertical and horizontal proportions of hydraulic conductivity.

Table 3. Summary of infiltration test results

Site	Dominant Soil Type	30 min Infiltration (in)		Restrictive Layer	Max. Soil sample Depth (in)	GW Impact to Infiltration Rate
Colorado	Loam	Graywater	1.6	20 - 40 (bedrock)	36	yes
		control	2.3			
Texas	Silty Clay	Graywater	40.0	20 - 40 (bedrock)	36	yes
		control	55.0			
California	Gravelly Loam	Graywater	15.3	4 - 20 (bedrock)	< 6	n/a
		control	10.0			

2. Conclusion

Pathogen indicator organisms were measured in soil samples to assess their fate after graywater application. No clear trend of an effect of graywater irrigation was observed. However, it is notable that pathogen indicators were generally not found to be higher in soils irrigated with graywater than control soils irrigated with freshwater. Pathogen indicators were highest in soils where animals defecated in the area and where soils were amended with manure. No clear trend was observed regarding graywater effects on soil microbial biomass and respiration. Triclosan and Triclocarban were both below detection limit in soil samples, which may indicate that graywater irrigation has no effect on the presence of these compounds in soil. Preliminary infiltration test results suggest that long-term application of graywater may enhance infiltration; however, additional tests and analysis should be conducted before reporting definitive conclusion.

ABSTRACT

Harris County, Texas, one of the most heavily populated and fastest growing areas in the nation, has 25% of its 1800 square miles located within the 1% annual chance floodplain. The District, in association with the Federal Emergency Management Agency (FEMA) recently completed a county-wide Flood Insurance Study for Harris County, Texas (Houston, Texas) also known as the Tropical Storm Allison Recovery Project (TSARP), which encompassed the restudy of 22 major watersheds and approximately 1300 miles of channels. The hydrologic and hydraulic (H&H) models produced as part of this study became effective in June 2007 and the citizens, developers and engineers within Harris County are now actively using them. It is HCFCD's desire to protect their significant investment in these models by ensuring their efficient management and update into the future. As a result, the number of requests for the effective Flood Insurance Study models and the resultant frequency of updates to these models have prompted Harris County Flood Control District (HCFCD) to implement an automated system for model management.

The solution currently under development is known as the Model and Map Management System (M3). The M3 will tackle the difficult problem of the on-going management and update of models in the highly active floodplain-related development environment of Harris County. A major part of this problem is that multiple projects tend to impact the same streams and watersheds, which can lead to the development of hydrologic and hydraulic studies based on out-of-date or conflicting H&H models. The effective model at the time a floodplain development permit application was started may have been replaced with a revised model by the time of the permit application submission. The M3 system will provide HCFCD and the development community with a set of tools that will address this contemporaneous permitting issue through the maintenance of up-to-date models, provision of notifications of potentially overlapping studies, provision of efficient model distribution and submittal functionality, and seamless integration into the FEMA LOMC process.

In addition to efficiently managing the use and update of models through the FEMA process, the M3 also will provide the District with powerful tools for their own internal management and planning activities. The M3 system includes management tools, such as a Model Explorer, that will provide comprehensive documentation of and access to all the H&H modeling and supporting documentation developed for studies within their jurisdiction. Having this information at their finger tips will allow the District to thoroughly evaluate the impacts of capital projects, plan more effectively for periodic watershed-scale master planning and study updates, and provide a higher level of service in their planning and management operations.

INTRODUCTION

Harris County is one of the fastest growing communities in the nation with 25% of its 1800 square miles located in the 1% floodplain. The numbers of requests for effective floodplain models and the resultant frequency of updates to those models have prompted HCFCD to implement an automated system to manage the models. With the system in place, the potential flooding risk to Harris County citizens will be reduced, by insuring that engineers are always using the best and most up-to-date information for planning and development.

In response to Tropical Storm Allison, which caused severe flooding in Houston, the Harris County Flood Control District (HCFCD) in association with the Federal Emergency Management Agency (FEMA), did a county-wide update of its floodplain models. Recently completed, the Tropical Storm Allison Recovery Project (TSARP), resulted in the restudy of 22 major watersheds and approximately 1300 miles of channels using HEC-HMS and HEC-RAS. FEMA has recently accepted the models and the citizens, developers and engineers within Harris County are actively using the models.

A model and map management program has been created by the HCFCD to protect the 30 million dollar investment that FEMA and the HCFCD made in TSARP. Through the model management program, HCFCD will update the HEC-HMS and HEC-RAS models and implement policy which will standardize the processes used to keep the models valid, up to date, accurate, and consistent into the future.

The objective of the model management program is to standardize the process through which developer engineers will be able to modify the models. The reasons for these modifications could range from flood control or development projects of varying size to hydraulic changes such as new bridges. With the standardization, new policies have been implemented to help in the review of the models and to protect the integrity of the models. Furthermore, with standardization, the final product received by the HCFCD from the engineer will be consistent and all new or modified hydrologic or hydraulic features will be consistent from one project or study to another. The goal is to provide consistent, up to date models and to ensure coordination between the end users and regulatory entities on all potentially

conflicting studies. Internal polices will be defined and clarified to allow for quick, efficient decisions during the model review process.

A key component of the model management program is the model and map management system, or the M3 system. The M3 system is comprised of (1) a geographic information system (GIS)–based, Arc Hydro compliant, enterprise database of spatial information that describes the watershed and stream network for Harris County and provides linkages to associated hydrologic and hydraulic models, (2) a directory structure and allocated server space for the archival of models and supporting data, (3) a web portal for checkout and submittal of models and tracking of study status, and (4) an accompanying Environmental Systems Research Institute (ESRI®) ArcMap-based extension for internal processing and data management. The extension can best be described as a workbench for the retrieval, distribution, and management of the effective and legacy models for Harris County. This paper discusses the process which the HCFCD has undertaken to ensure efficient management of hydrologic and hydraulic models for the Harris County area and to develop the M3 tools to provide this management and coordinate the use of the models into the future.

THE PROBLEM OF CONTEMPORANEOUS FLOOD STUDIES

The efficient management and maintenance of flood models presents a number of challenges. These challenges include effective coordination of the FEMA update process, rapid development, and the resultant changes in land use and topography, changes in HEC-HMS and HEC-RAS versions, and standardization between studies performed by various contractors. However, the key issue in the day to day management and maintenance of floodplain models is the handling of multiple studies that involve the same stream(s) and model(s).

Growth and development within unincorporated Harris County has been rapid during the past decade. This is clearly reflected in the statistics for approved plan sets since 2001 in the three most active watersheds within Harris County. These statistics, shown in Table 1 are based on HCFCD Watershed Department data.

Table 1. Approved Plan Sets by Watershed from 2001 to 2007.

Watershed	Total	Average/Year
Greens Bayou	1520	253
Cypress Creek	1652	275
Addicks Watershed	895	149

While many of these developments are small and will not be reflected in the effective models, there will be a significant number that result in the need for a FEMA Letter of Map Revision (LOMR). In addition, the HCFCD has completed a number of Capitol Improvement Projects (CIP) since 2001 that must also be reflected in the

models. Invariably there will be situations where multiple development and/or CIP projects result in simultaneous studies on the same modeled stream.

The central issue associated with the maintenance of the effective model set is the need to address and manage this contemporaneous use of the same models for multiple permit requests (studies). The situation will arise when ongoing studies by more than one engineer, developer, municipality or other entity require the use of the same hydrologic and hydraulic models or hydraulic models that have direct impacts on each other (near confluences). This situation is illustrated in Figure 1.

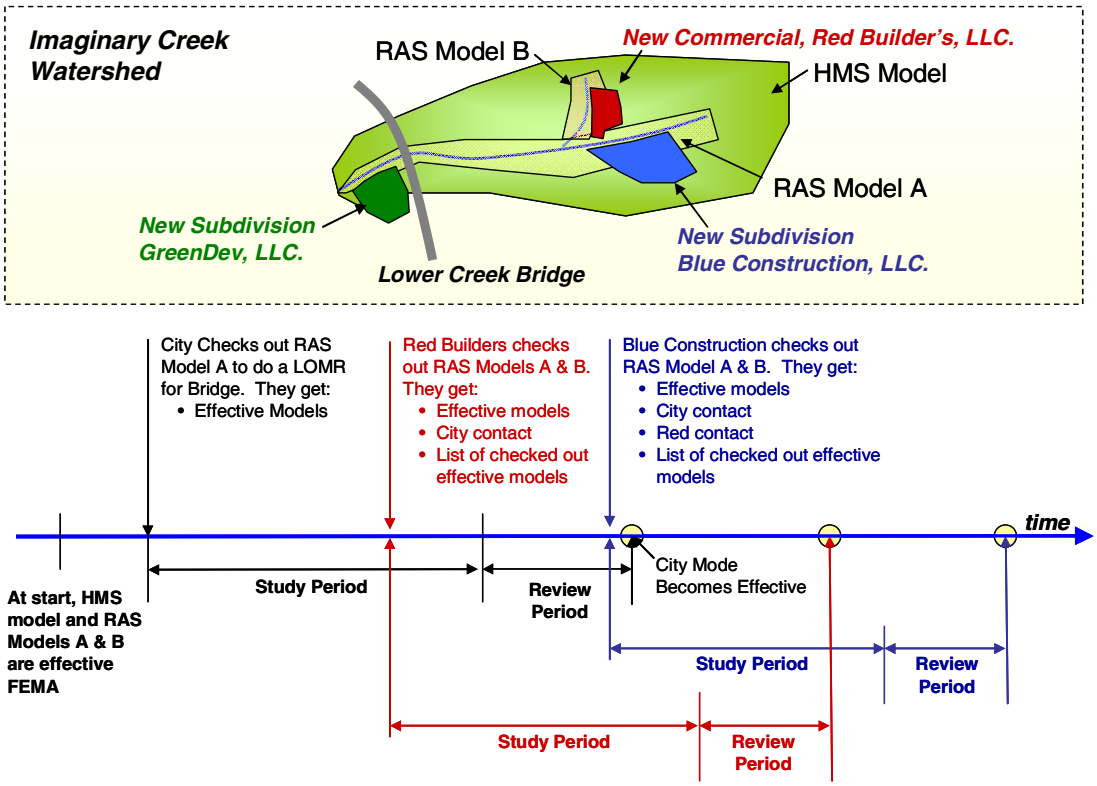

Figure 1. Hypothetical Usage Timeline Illustrating Contemporaneous Permitting Issues Addressed by the M3 System.

The figure shows a hypothetical watershed that is subject to heavy development. Three separate entities study the creek at the same time. First, the city in which the creek lies uses the effective hydraulic model to produce a LOMR for a bridge crossing the river. The process of creating this LOMR may take several months and consists of a stage during which the city is producing the new model, and a phase during which that model is being reviewed. Collectively, the life cycle of the process may take more than one year. While the city produces its new model, Red Builders, LLC starts the process of applying for a permit for a new development. Red Builders request the effective model before the City has had the chance to submit their revised model and so Red Builder's permit is based on the effective model in existence before the city revises it. While both the city and Red Builders are revising the effective model, Blue Construction, LLC, requests the effective model for a hydrologic study

of a new subdivision they plan to build. They request the model after the City has submitted their new version of the effective model, but before that model has been approved and made effective.

This figure illustrates the potential for study time frames to overlap for the same stream. This situation is most critical when one or more of the permits associated with the requests will require the submission of a Letter of Map Revision (LOMR). The submission of a LOMR will result in a change in the effective hydraulic model for the stream. This change in the effective model will need to be reflected in any uncompleted studies on the same stream. The issue is further complicated by the fact that the initial requestor may not ultimately be the first to resubmit their revised model.

Due to the ramifications of the contemporaneous permit request issue, it is critical that the M3 system efficiently manage multiple overlapping requests and provide timely notification to impacted requestors. The management of this issue was a focal point in the ultimate configuration and capabilities of the system.

MODEL MANAGEMENT SOLUTION APPROACH

To properly document, develop, and implement a solution for the issues described above, a four phase plan was developed by HCFCD for the Model Management Program. These four phases include 1) an update of the HCFCD modeling standards, 2) development of a process to update the supporting data for modeling, 3) a systematic approach for the update of watershed studies, and 4) development of a system to facilitate the distribution and update of models and supporting data – the M3 system.

The key components of Phase 1 of the plan were the development of consistent model standards and identification of the processes required for model management and tracking. The standards developed in Phase 1 will ensure that any revisions made to the effective models by users after the June 18th, 2007 effective date for the Harris county-wide study will be efficiently incorporated and disseminated. This phase also included the initiation of preliminary tracking of projects through the model checkout and check in process. This will allow HCFCD staff to efficiently track the potential changes to the models and facilitate the notification of the end users in the occurrence of overlapping or adjacent studies. This preliminary tracking system has subsequently been incorporated into the more comprehensive M3 system.

The objective of Phase 2 of the solution approach was to develop the processes required for management of the support data associated with the effective HEC-HMS and HEC-RAS models and to prepare data that will be used during Phase 3, the Model and Map Update Program (MMUP). First the watersheds must be evaluated and prioritized to determine which watersheds will be updated first. Second, the data supporting the models must be processed and updated. This supporting data includes catalogs of on-site detention ponds, LiDAR data, land use data and model calibration

data. An evaluation matrix was developed for each of the watersheds in Harris County to rank the watersheds relative to the following three issues: 1) rate of development, 2) existing modeling issues and inconsistencies, and 3) CIP projects constructed or planned for the watersheds. Rankings were assigned for each of the three issues and each issue was weighted equally. While all of the watersheds will be updated on a regular basis, the watersheds with the highest rankings will be updated first and potentially more frequently. This effort has occurred in parallel to the development of the M3 system and will ultimately be managed by M3.

The objective of Phase 3, the MMUP, is to systematically update the models and associated data. These updated models will be used to properly document the benefits of proposed HCFCD design projects. The level of effort for MMUP can be split into three tiers with respect to the type and size of the modeling effort. A Tier 1 model update will apply to watersheds that are very active from a development and CIP perspective. Tier 1 updates will consist of land use updates, LiDAR updates, modifications to unit hydrograph parameters (TC&R and DET variable), updated storage routing (SV-SQ relationships), update/fix of modeling inconstancies, updates to reflect CIP projects, and updates to the current version of HEC-HMS and HEC-RAS. Tier 2 will focus on updating or fixing modeling inconsistencies, updates to reflect CIP projects, and updates to the current version of HEC-HMS and HEC-RAS. Tier 3 will be used on watersheds with significantly less development activity, but that need to be updated to the current version of HEC-HMS and HEC-RAS.

Phase 4 focuses on the Model and Map Management (M3) System. The M3 lies at the heart of the HCFCD model management solution and will integrate the MMUP with the ongoing, incremental evolution of models due to projects that generate LOMCs. Version 1.0 of the M3 system has been implemented and is currently being used to manage the model request and study tracking process. Development of additional components and capabilities for the M3 is ongoing. The design and functionality of the system is discussed in the following sections.

MODEL AND MAP MANAGEMENT SYSTEM DESIGN

The design strategy for the M3 system focused on collaborative development of requirements between the HCFCD and the development teams. This collaboration was necessary primarily due to the complex nature of the problem that the M3 system is intended to solve. As discussed previously, the processing and tracking of contemporaneous development permit applications for a stream and associated models is the key issue that must be addressed in order to effectively manage model updates. *The general solution for this problem is careful management of permit applications, the use of algorithms for identifying possible conflicts, the pro-active notification of all involved system users of potential conflicts, and the general encouragement of communication among users through technology*.

Figure 2 illustrates the M3 design. The M3 system is based on an enterprise SDE ArcGIS geodatabase. In addition to the enterprise database there is an archive of

hydraulic and hydrologic models that is maintained in a carefully defined directory structure.

The public face of the M3 system is a web portal, which is maintained outside the HCFCD firewall. As requests for models are received, they are communicated securely to the M3 system via custom web services. Web services also handle communication about the status of requests to the public. For example, if a developer has previously requested models for a river with intent to write a permit application for development, the M3 system will inform the developer if another request comes in with the same intent. Transfer of effective models is done via secure ftp. The M3 web services are currently under development and represent an exciting new way of conducting secure public-to-regulatory agency permitting processes.

The M3 workbench component is an ESRI ArcMap 9.2 extension. This component is the user interface for most of the functionality provided by the Request Processing functional component. The workbench will be installed on several HCFCD machines and will be the primary tool used by HCFCD staff for working with the M3 system. As the tool is an ArcMap extension, it will immediately fit within the GIS solution that HCFCD is currently using.

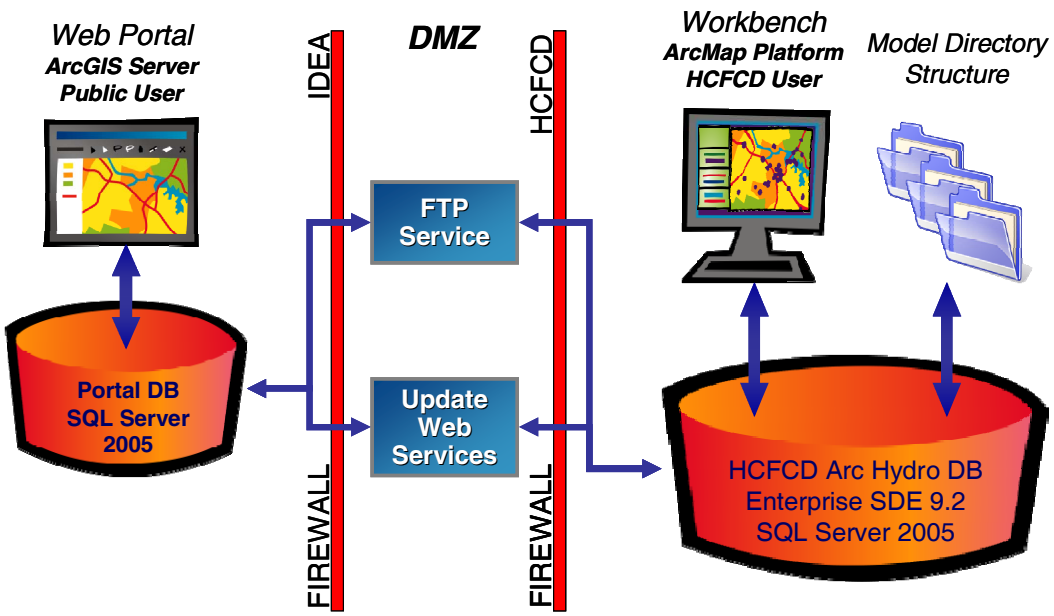

Figure 2. Physical System Components Comprising the Solution Architecture.

The workbench provides essentially two sets of functionality: model exploration and request processing, which are described in detail below:

M3 MODEL EXPLORATION

The M3 workbench includes a section dedicated entirely to model exploration called the model explorer. With the tools provided, the user can select a stream and

immediately see all the available models for that stream or its watershed. The model explorer interface is illustrated in Figure 3. In this example, the cyan colored stream segment indicates the stream that has been selected by the user. The tree on the left displays 1) all the hydraulic models available for the selected stream, 2) all the hydraulic models for the streams within the watershed that includes the selected stream, and 3) the hydrologic models for that watershed.

Once a particular stream has been selected, there are several options available to the user. They have the option to graphically compare profiles or cross sections from the various models. The user can also open a selected model directly in the software in which it was developed. For example, the user can open the hydraulic model directly in HEC-RAS. The M3 system protects effective and legacy models from being directly edited by dynamically controlling the read-only properties of the models and offering the user the option to copy the entire model to another directory for editing and other uses.

Perhaps the most valuable function of the model explorer is its model catalog editing capabilities. Any authorized HCFCD user may add models to the catalog so that other users can access them in the future. Moreover, users are required to add metadata to the models to describe why they were created, who was involved, and other important information related to the development of the model.

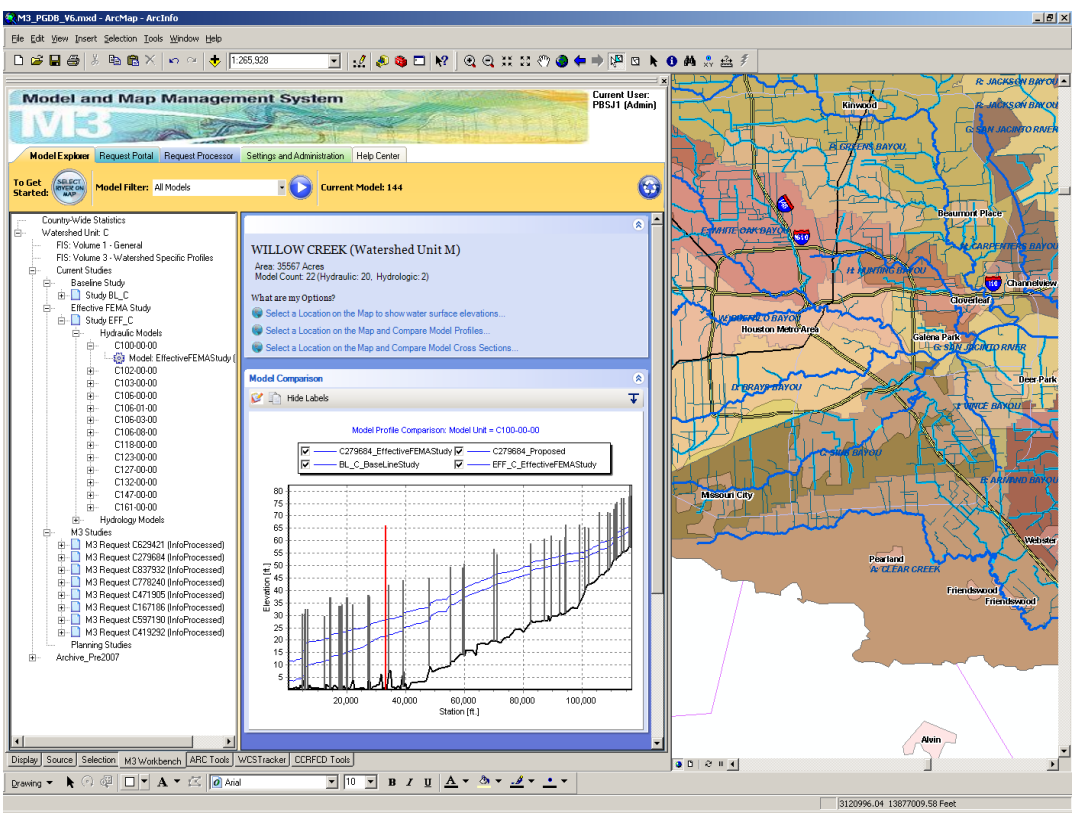

Figure 3. The M3 Model Explorer – Comparison of modeled river profiles from two HEC-RAS models for the same river.

M3 MODEL REQUEST PROCESSING

Version 1.0 of the M3 system, which is currently deployed and in use for the management of HCFCD models, consists of the enterprise geodatabase and workbench components along with partial versions of the internal and external web portals. These tools provide HCFCD staff with the ability to review model requests and quickly bundle the resultant models and supporting data for distribution; track the status of a study generated by a model request; coordinate notification of potentially impacted parties and accept submitted models from end users. Key among this functionality is the component for coordination of notification. This component will automatically generate notifications for studies impacted by the contemporaneous permitting issue. Notifications will be generated for many events. Some examples are a) when a new model request is received that indicates the need for a LOMR, b) when a study that includes a CLOMR or LOMR is submitted to and accepted by HCFCD, and c) when a CLOMR or LOMR has been approved by FEMA. The M3 workbench will allow HCFCD staff the opportunity to review the default notification and either add additional information or send the notification in its default form. The default notification includes a map showing the location of the requestor's study along with the locations of the other study or studies that may impact the models for the requested stream, the study identifiers and basic information about these other studies and HCFCD staff contact information for coordination with the parties involved with the other studies. An example of the workbench interface is shown in Figure 3. The timeline chart in this figure shows the active requests for the selected river. We can see from the chart that there are several contemporaneous requests, each of which may lead to a permit application.

In addition to the coordination and notification features of the M3, version 1.0 of the system provides a number of additional tools that will help HCFCD staff manage, distribute, and maintain the effective set of floodplain models. The workbench allows HCFCD staff to quickly review model requests generated by the external web portal, add or delete models from the default set of models identified by the system and efficiently bundled the models, and associated support data for distribution through the FTP site. The system allows HCFCD staff to track and update the status of studies, modify the submittal and review dates initially generated for studies, and graphically visualize the status of studies. The system also will flag requests that require HCFCD attention for processing or review.

Version 2.0 of the M3 system will provide a number of additional capabilities that will facilitate the review of submitted studies, allow internal users to access and retrieve both the FEMA effective model set and other legacy models that will be incorporated into the directory structure, add additional notification and coordination functionality, facilitate the management of studies and associated models through the full review process including review and acceptance of FEMA CLOMRs and

LOMRs, and add other miscellaneous functionality. Version 2.0 of the system is currently under development and will add this and other functionality over the next year.

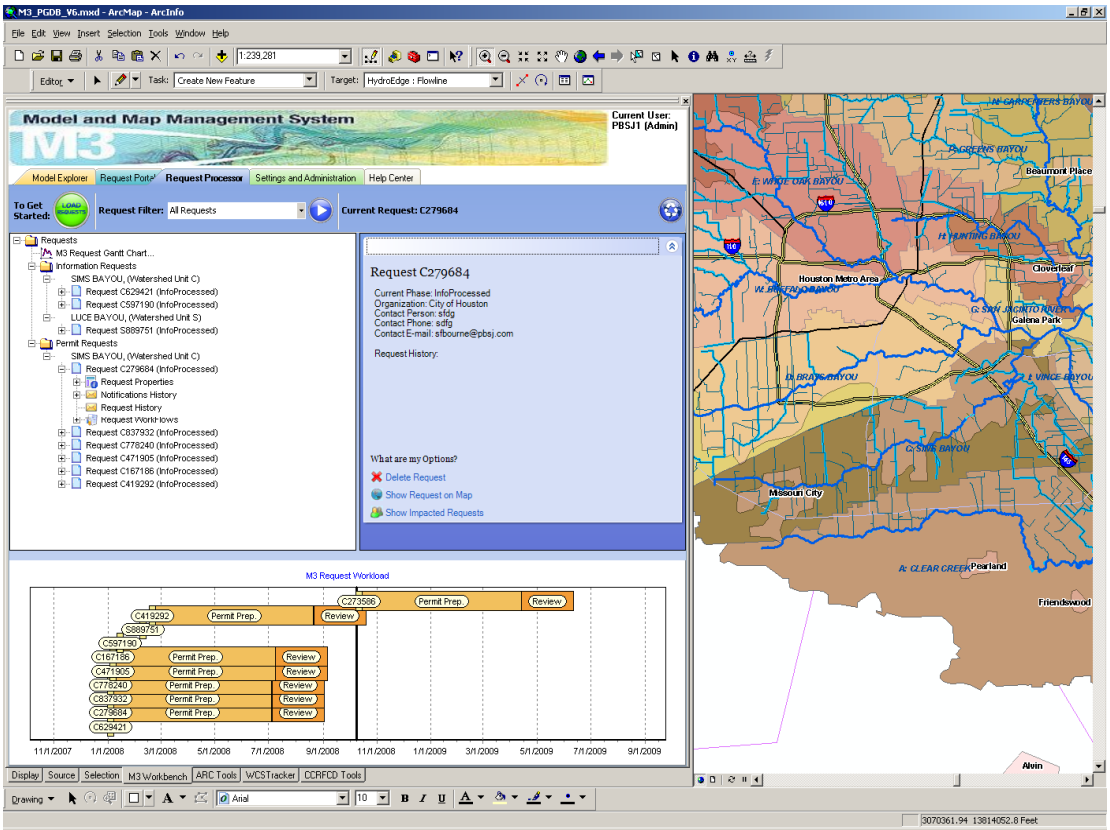

Figure 3. M3 Request Processor Interface

CONCLUSIONS

The ultimate goal of the model management program is to serve the residents of Harris County by ensuring that the models used to address floodplain permitting issues are as up-to-date, consistent, and accurate as possible. It will also serve to protect and enhance the significant investments made in the models developed for Harris County. These models will continue to evolve, as managed by the M3 system, to reflect the current conditions within the various watersheds. This approach suggests an obvious synergy with the FEMA LOMC process. HCFCD has initiated discussion with FEMA to become the "custodian" of the effective models for Harris County. This role could ultimately include the centralization of the LOMC process with the HCFCD as part of their existing Cooperating Technical Partnership Agreement (CTP). Such a partnership with FEMA should help to ensure better communication between the various entities within Harris County and more efficient update and distribution of hydrologic and hydraulic models.

Hydrologic Footprint Residence: A New Metric to Assess Hydrological Alterations Due to Urbanization

ABSTRACT

Urbanization modifies hydrological processes in a watershed as surface alterations, such as the use of impervious cover, increase runoff volumes and modify the temporal patterns of the hydrograph. Higher peak flows and increased flood duration often lead to erosion and degradation of ecosystems. Typically, the peak flow for a design storm is used to assess the impact of land use change on the hydrological cycle. This approach, however, does not capture the extent of hydrologic change and impact on downstream communities. Floodplains have an important function in controlling downstream floods and sustaining sensitive ecosystems. This research proposes a new metric to quantify the effects of development based on the change in floodplain areas. The Hydrologic Footprint Residence (HFR) is proposed to evaluate the modification of floodplain areas and duration of a flood's residence. HFR can be used to analyze hydrological changes, gauge riparian ecosystem health, and develop watershed management plans. The use of HFR is demonstrated for a case study located on the Texas A&M University campus to evaluate the hydrologic impact of watershed development.

Keywords: hydrologic sustainability, floodplain modeling, urbanization, watershed management.

INTRODUCTION

Many regions in the world suffer with the impacts of change in land use and land cover. For example, urbanization converts natural cover, such as forest and grassland to urban areas. Urbanization transforms the landscape through the construction of roads, sidewalks, buildings and parking lots, which directly impact the hydrologic cycle. Increased impervious areas result in higher volumes of runoff, higher and faster peak flows, and more frequent and severe floods. In dry periods, increased imperviousness results in a deficit of groundwater recharge, lowering the base flow (EPA 1993, Bertrand-Krajewski et al. 2000, Tang et al. 2005). These impacts directly affect humans and ecosystems communities, which according with Richter et al. (1996) are directly dependent on the duration, frequency, and magnitude

of high and low flows. Human communities may experience extreme water shortages during dry weather, loss of property due to increased flooding, and loss of water supply due to poor water quality (EPA 2004). Management of increased stormwater runoff volumes is needed that will prevent degradation of the natural hydrologic flow regime and enable a balance among economic prosperity, environmental responsibility, and social fairness.

Development can be planned to maintain pre-development hydrologic flow characteristics through low impact development (LID) or Best Management Practices (BMPs), which are a set of techniques, measures, or structural controls that mitigate the volume of stormwater runoff and improve the quality of stormwater runoff (EPA 2004). BMPs that are designed to reduce alterations in runoff volumes, such as detention ponds, are typically designed based on a peak flow value, where the discharge for a certain frequency does not exceed pre-development conditions. Typical flow-based criteria, however, do not provide a comprehensive measure of the downstream impact of development, as urbanization changes both the inundated area of a floodplain and the duration of a flood. For example, the placement of a detention pond will sustain high flows for long periods of time, potentially causing a dramatic shift in the health of the in-stream ecosystem. A peak flow-based metric does not capture the extent of alteration in the hydrologic flow regime. A metric that better represents the extent of hydrologic change and the impact on downstream communities is needed to facilitate a sense of ownership of the impact of urbanization on downstream communities.

The objective of this work is to present a hydrologic sustainability metric to better quantify the impact of urbanization on downstream water bodies. The Hydrological Footprint Residence (HFR) is designed to capture both temporal and spatial hydrological changes due to urbanization by calculating the inundated areas and the duration of a flood.

HYDROLOGICAL FOOTPRINT RESIDENCE

Consider a flood that passes through a river reach in a hypothetical watershed (Fig. 1). At each time step, the flowrate in the channel is based on the rainfall-runoff relationship that governs the watershed response. The quantity of flow in the channel inundates a corresponding area of land, as specified by the elevation of the water surface and the geometry of the channel and floodplain, and the time series of inundated land is plotted similar to the hydrograph. The extent of flooding in the reach due to the specific rainfall event can be evaluated as the area under the inundated land curve, which represents the amount of land that was inundated and the duration of the time that each unit of land was inundated. The area under the inundated land time series curve is termed the Hydrological Footprint Residence (HFR).

ILLUSTRATIVE CASE STUDY

The HFR is simulated for an illustrative watershed for a set of design rainfall events. The selected case study is the west campus watershed of Texas A&M University (TAMU). The campus straddles two watersheds, with a portion of the campus drainage traveling southeast through Wolf Pen Creek towards the Navasota

River. The west campus area drains southwest through White Creek toward the Brazos River (Fig. 2). Due to increasing development, storm water runoff discharged to White Creek has steadily increased. The creek has undergone a transformation from a small and slow moving creek to a large creek that moves large amounts of storm water during typical rainfall events, and erosion has undermined the creek bank at several critical locations.

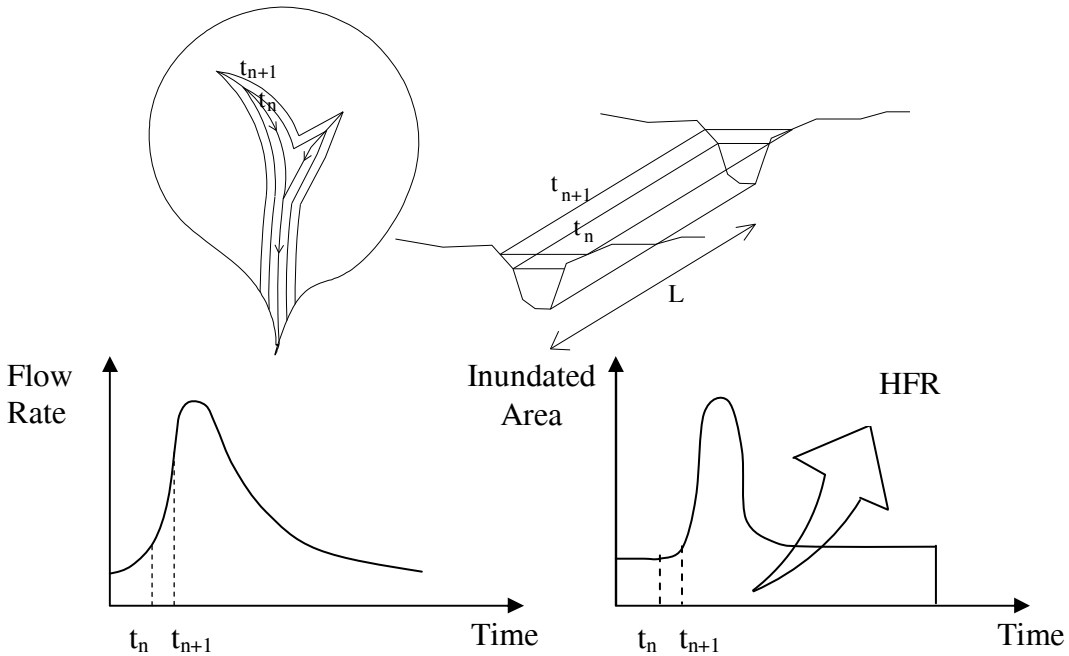

Figure 1. Illustrative calculation of HFR in a hypothetical watershed.

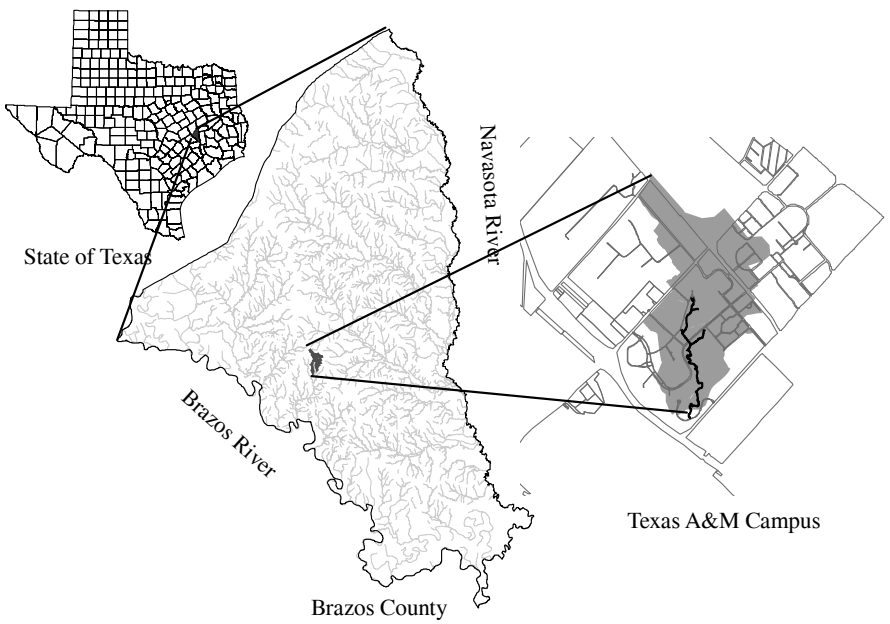

Figure 2. Location of Texas A&M West Campus

A hydrological and hydraulic model of West Campus has been developed to study the increased flows and corresponding erosion issues (AECOM 2008). The hydrological model, implemented within HEC-HMS (Army Corps of Engineering 2006), is used to convert the rainfall into overland runoff, and the hydraulic model Stormwater Management Model (SWMM) (EPA 2008), to route the runoff in the drainage network and open channels.

The main watershed of the West Campus covers 3.18 km² and discharges into Tributary D (Fig. 3). The percent of imperviousness of the watershed is approximately 40.7 %, and for the main cover type of the watershed, landscaped areas, the curve number is 77, according to the Bryan/College Station Unified Stormwater Design Guidelines (Bryan/College Station 2007). The drainage network in the watershed is composed of 442 segments, classified as round, box, elliptical storm sewer and open channel. The length of the open channel section of Tributary D is approximately 2 km.

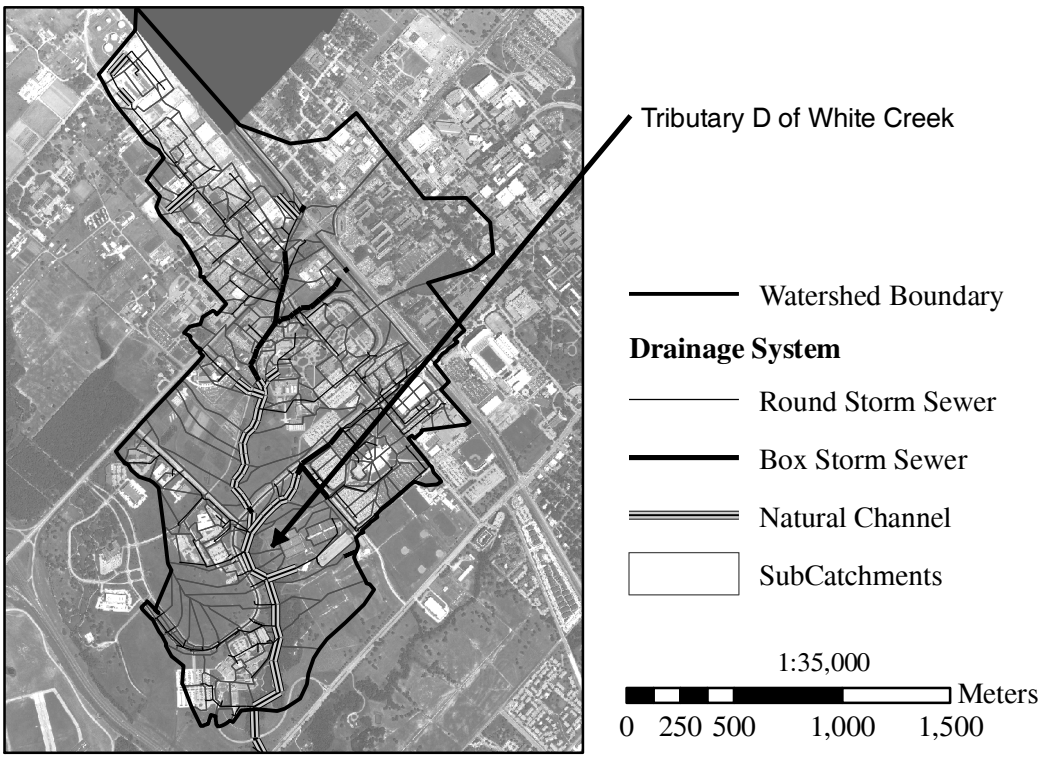

Figure 3. Watershed D located on TAMU West Campus.

PRELIMINARY RESULTS

To simulate the HFR for a rainfall event, the hydrograph and time series of depth of flow were simulated using the HEC-HMS/SWMM modeling framework. The time series of inundated area was calculated for each of the 26 reaches in Tributary D (Fig. 4), based on the geometry of the reach and the depth at each time step. For each reach, the HFR was calculated as the area under the inundated land curve, and the composite HFR for the total watershed is the sum of the incremental HFR values.

HFR was simulated for three 24-hour rainstorm events, corresponding to 2, 10 and 100-year return periods. The accumulated depths of these design storms are 112.3, 189 and 288.3 mm, respectively. Each rainstorm was modeled using the Type III SCS distribution, which simulates the highest intensity rainfall at 50% of the rainfall duration.

Figure 4. Twenty-six reaches of Tributary D.

The simulation results for the three storms are shown in Table 1. The total runoff generated by the simulation was 74.5, 142.2 and 240.4 mm, respectively. The peak flows computed for the last reach of the watershed were 28.3, 61.3 and 93.7 m³/s. The three hydrographs at the outlet of Watershed D are shown in Fig. 5.

Table 1. Simulation results for 2, 10 and 100 years - 24 hours storms.

Storm	Precipitation	Run Off	Peak Flow	HFR
(24 hours)	(mm)	(mm)	(m3/s)	(m² x hours)
2 yr	112.3	74.5	28.3	196141
10 yr	189.0	142.2	61.3	258060
100 yr	288.3	240.4	93.7	330691

The values of HFR calculated using the described approach are 198141, 258060 and 330691 m².hours. Figure **Figure** 6 presents the time series of the inundated area for the entire reach.

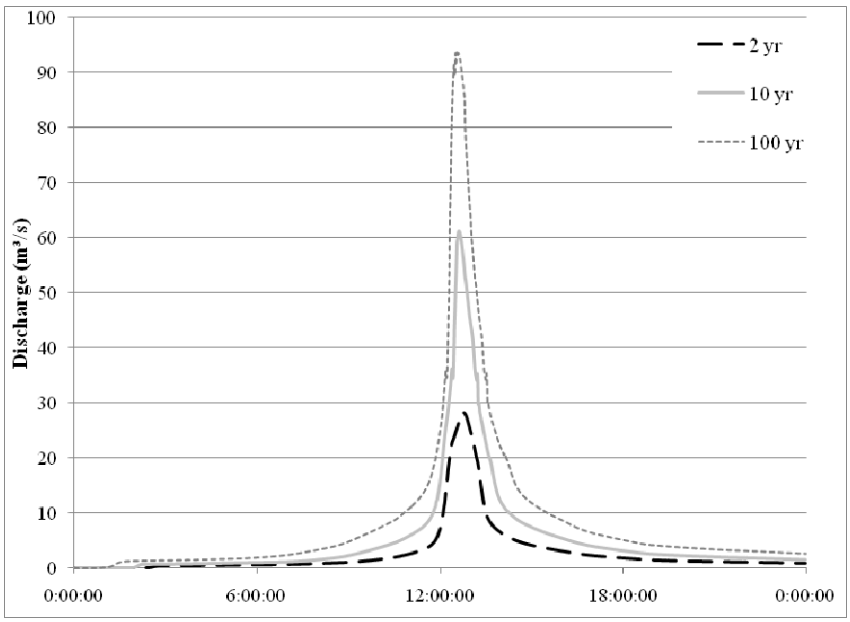

Figure 5. Hydrographs at the outlet of Watershed D for three design storms.

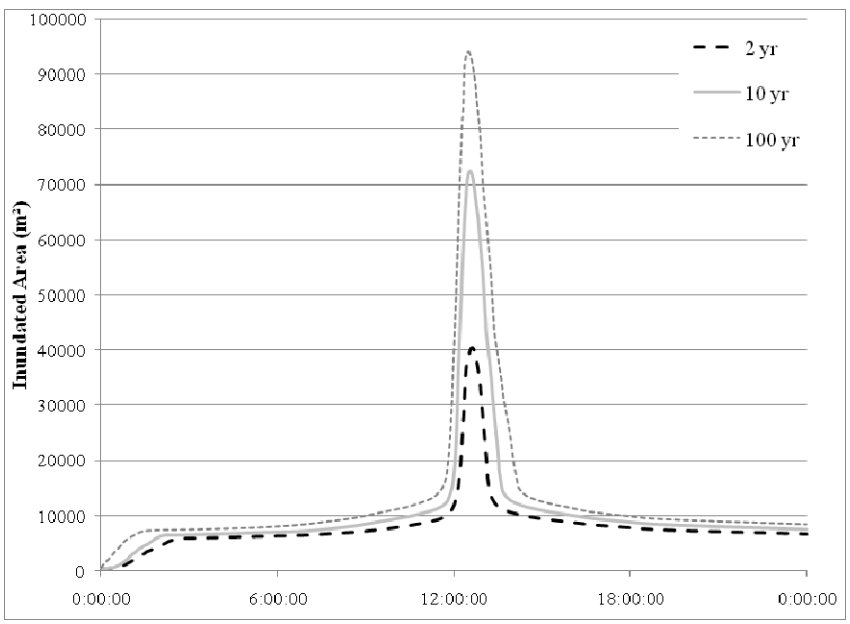

Figure 6. Inundated areas at all reaches in Tributary D for three design storms.

ON-GOING INVESTIGATIONS

The HFR is presented here as a new metric that is designed to assess the hydrological alteration of a receiving water body due to urbanization and development. Calculation of the HFR was demonstrated for a watershed on TAMU West Campus using a hydrological and hydraulic model for three design storms.

Future investigations will assess the use of HFR to compare watershed management and development scenarios. Further development of campus, best management practices and LID strategies will be simulated and evaluated by comparing HFR values to those for pre-development conditions.

ACKNOWLEDGEMENT

Although the research described in this article has been funded wholly or in part by the United States Environmental Protection Agency through Grant #SU833944, it has not been subjected to the Agency's required peer and policy review and therefore does not necessarily reflect the views of the Agency and no official endorsement should be inferred.

The authors express their thanks and appreciation to the Texas A&M Physical Plant, Engineering Design Services (TAMU PP/EDS), College Station, Texas, Gary Struzick of Klotz Associates, and Anthony Holder of Turner, Collie and Braden, both of Houston, Texas for their help and sharing of valuable storm water, rainfall, survey, and data base information. This additional information was gathered in a separate project funded by Texas A&M Utilities, College Station, Texas and managed by TAMU PP/EDS.

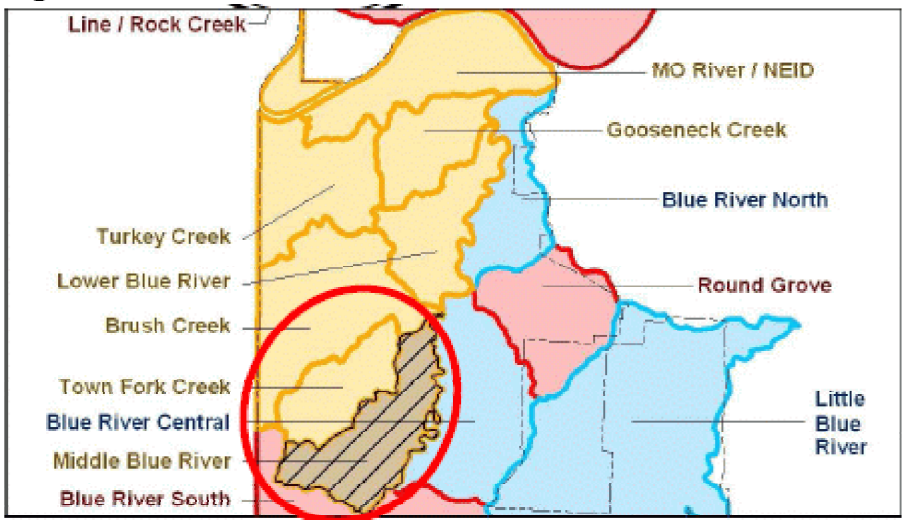
ABSTRACT



A demonstration project to show the efficacy of stormwater best-management practices deployed in an urban midwestern neighborhood. The large-scale demonstration depends on reliable flow monitoring to verify stormwater invention by the green solutions and reduction of flows to the combined sewer collection system. The flow monitoring includes both temporal and spatial controls.

BACKGROUND

The City of Kansas City has a combined sewer collection system in the older part of the city, approximately 56 mi^2 (145 km^2). Detailed analysis of appropriate engineering controls to reduce overflows (CSOs) were tailored to each watershed.

The Middle Blue River watershed (shown in Figure 1) was initially recommended to have two large underground detention tanks ($3.5x10^6$ gallons ($13.25x10^3$ m^3) total) from a strict, traditional engineering analysis to reduce overflows to the Blue River.

Figure 1. Middle Blue River watershed location

GREEN SOLUTIONS

A groundswell of interest in raingardens and other stormwater best-management practices (BMPs) happened about a year before the CSO correction plan was finalized. A combination of cost-benefit analysis and a desire include green solutions in the plan indicated an excellent candidate watershed for a significant implementation of green solutions was the Middle Blue River watershed.

The choice of the Middle Blue watershed is optimal for urban, midwestern sites for the following reasons:

- clay soils (low permeability)
- older neighborhood -- soils probably compacted
- middle-class neighborhood (no vacant/abandoned properties)
- traditional neighborhood - no raingardens or early-adoptors of progressive technologies
- 90% residential/single-family homes
- high-intensity, low-duration thunderstorm rainfalls
- mild slopes
- no public parks in demonstration area

While the study area may be optimal for demonstrating the efficacy of green solutions in reducing stormwater inflow to the combined sewer system, thereby reducing overflows, this study area presents significant placement challenges for green solution installations. Green solutions will be limited to public right-of-way along the streets.

FLOW MONITORING

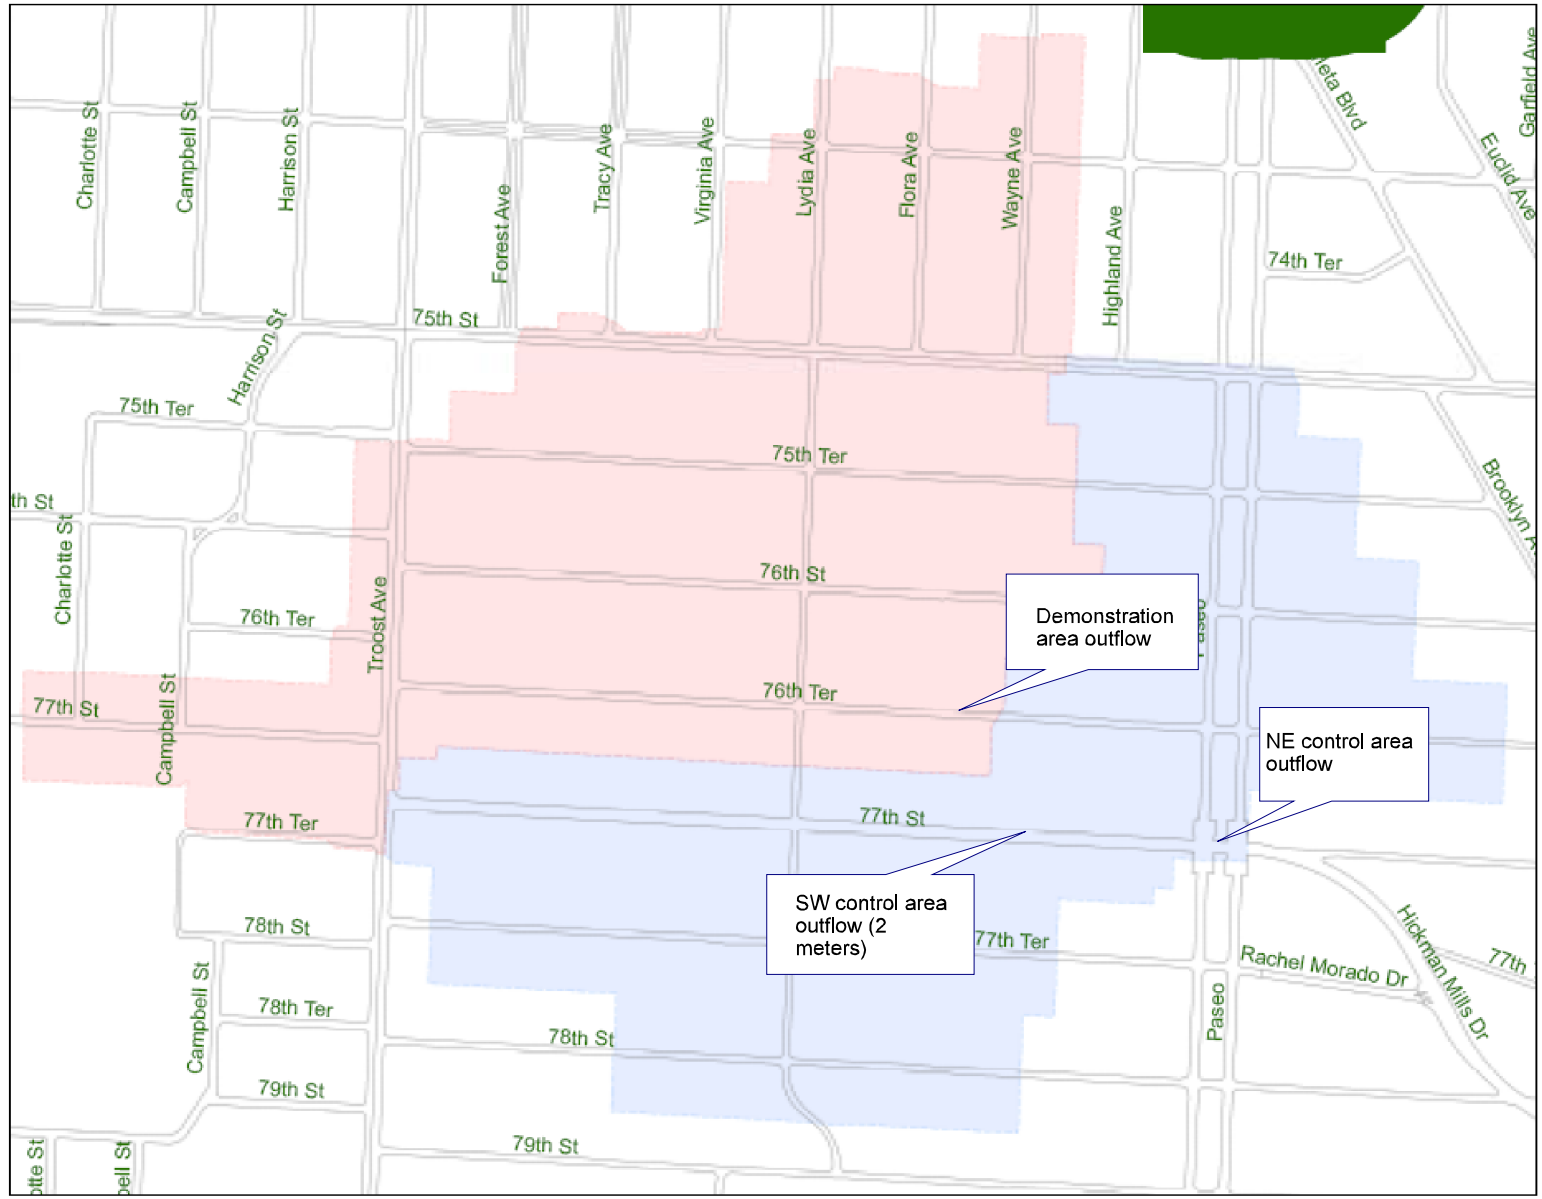
A double-control flow monitoring program was evaluated to (a) establish the rainfall-runoff response in this small watershed, and (b) measure any reductions in stormwater runoff after installation of the green solutions. The flow metering was installed at four locations in September 2008, as shown in Figure 2. The temporal control data will run from September 2008 to September 2009, when construction of the green solutions will be largely complete and some interception of the stormwater will begin.

The spatial control will be monitored throughout the project life. The demonstration project area is ~100 acres (40 ha) and the control area is 86 acres (35 ha). One can observe that the control area is contiguous to the demonstration area and will receive virtually identical rainfall events.

RAINFALL MONITORING

Detailed, rainfall intensities and total daily rainfall depths will be recorded within and close to the demonstration and control areas, subject to placement constraints.

CONCLUSIONS



A carefully-designed flow monitoring program will support hypothesis-testing for green solutions performance in a combined sewer area. Control data for the flow monitoring is in both the temporal and spatial domains.

ABSTRACT

A U.S. EPA study evaluated the impact on disinfection during peak flows (wet-weather flow events) when a portion of the flow to the wastewater treatment plant (WWTP) bypasses secondary treatment prior to disinfection. The practice of bypassing secondary treatment during peak flows, referred to as "blending," takes place when the volume of primary treatment flow exceeds the capacity of the secondary treatment. The bypassed flow is only treated by primary clarification before it is recombined with the fully treated secondary effluent prior to disinfection. Blending practice prevents passing of excess flow to secondary treatment, which could result in inactivation and destruction of the vulnerable biological process. The trade-off is that during blending only a portion of the total flow receives full secondary treatment.

The study was conducted at three WWTPs in New York City, ranging from 60 MGD to 275 MGD capacity. A total of four dry-weather and 12 wet-weather events were sampled and analyzed. Three samples from four sampling points of the treatment train in the WWTP were collected per event. The principal analytical parameters were fecal coliform, *Enterococcus*, viruses, and protozoa. Other parameters included total residual chlorine, BOD_5 , and TSS.

The difference between wet-weather blending and dry-weather final effluent results ranged from a half order of magnitude to one order of magnitude higher at two plants for fecal coliform and at one plant for *Enterococcus.* A difference of three orders of magnitude higher, which represents a significant impact, was observed at one plant for fecal coliform and at two plants for *Enterococcus.* During blending, average effluent BOD_5 and TSS concentrations remained above 30 mg/l at two out of three plants. The third plant had average effluents above 30 mg/l for both BOD_5 and TSS; however, the plant was undergoing a partial construction at the time of sampling, which was causing lower treatability. When blending occurred, the sampled WWTPs removed, on average,

between 97% coliphage and enteric viruses, approximately 71% of *Cryptosporidium* and between 40% and 88% of *Giardia.*

A maceration procedure was used for disinfected, final effluent samples prior to analyses for fecal coliform and *Enterococcus.* Maceration exposes the occluded and clumped-together bacteria. For the majority of samples, particle maceration of effluent samples resulted in some (in most cases, less than half an order of magnitude) increase in both fecal coliform and *Enterococcus* values during both wet- and dry-weather. At one out of three plants, in each instance, maceration of effluent samples resulted in one order of magnitude increase in fecal coliform during wet-weather and *Enterococcus* during dry-weather.

KEYWORDS

Disinfection, blending, pathogens, peak-flow, wastewater treatment plant, fecal coliform

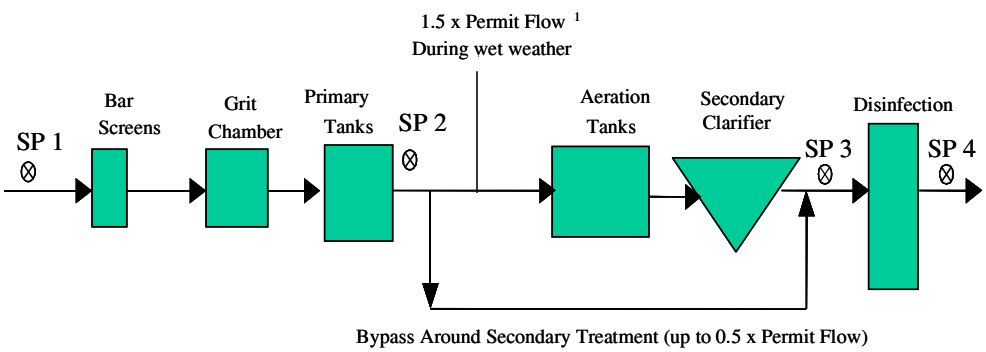
INTRODUCTION

This study evaluated the effect of wet-weather blending on the concentration of fecal coliform and *Enterococcus* indicator bacteria, protozoa, viruses, total residual chlorine, 5-day Biological Oxygen Demand (BOD_5), and Total Suspended Solids (TSS) in the treatment plant final effluent (1). The practice of bypassing secondary treatment during peak flows, referred to as "blending," takes place when the flow rate of primary treated effluent exceeds the capacity of secondary treatment. Accordingly, the bypassed flow is only treated by primary clarification before it is recombined with the treated secondary effluent prior to disinfection. Blending practice prevents passing of excess flow to secondary treatment, which could result in inactivation and destruction of the vulnerable biological process. The trade-off is that during blending only a portion of the total flow receives full secondary treatment.

The U.S. Environmental Protection Agency's (EPA's) 1994 CSO Policy (2) encourages delivery of maximum flows to the WWTPs, while ensuring that bypasses would not result in effluent water quality violations. Consistent with that principle, blending of flows at treatment plants serving combined sewer systems is economically viable provided that acceptable treatment is achieved. As a protective measure of public health, the practice of blending is much superior to the release of untreated combined sewer overflows (CSOs) and/or incidents of basement flooding.

This study was designed by the U.S. EPA's Urban Watershed Management Branch in Edison, NJ as an cooperative effort of several EPA groups (National Risk Management Research Laboratory, National Exposure Research Laboratory, Office of Policy, Economics, and Innovation, Office of Wastewater Management and Office of Science and Technology under the Office of Water, EPA's Region 2 Laboratory in Edison), and two non-EPA agencies (Interstate Environmental Commission (IEC) – a tri-state (New York, New Jersey and Connecticut) regulatory water pollution control agency and the New York City Department of Environmental Protection (NYCDEP). Under contract to

the EPA, the IEC was the main performing organization. The IEC selected the WWTPs, prepared the Quality Assurance Project Plan (QAPP), interacted with the NYCDEP, collected and distributed the samples for analyses, and reported on the results.



This study was conducted at three WWTPs in New York City, whose capacities ranged from 60 MGD to 275 MGD. The three plants selected, receive their flow from combined sewer systems. The treatment process at each of the plants, typical of all 14 NYCDEP plants, includes: coarse screening and de-gritting, preliminary treatment, primary treatment, secondary treatment, disinfection, and sludge treatment. It is important to mention that the disinfection process used at NYCDEP plants is hypo-chloride disinfection. Dechlorination is not used at NYCDEP plants.

PROJECT DESIGN

The principal element of the project design was the selection of four sampling points (SPs) along the WWTP's treatment train. (Figure1). The sampling locations were: SP1 at entrance of flow to plant, SP2 after primary treatment, SP 3 after secondary treatment and point of blending, and SP 4 after disinfection. SP4 was the critical sampling location, as it was the final plant effluent for release to the receiving waters, where the apparent impact of blending could be measured. Figure 1 also shows the schematic of the blending practice during peak flow wet-weather which typically happens at NYCDEP plants after the influent flow exceeds one and a half times the permit flow limit for the plant.

Another important part of project design was an ample sampling period that included a total of four dry-weather and 12 wet-weather events. For bacterial sampling, three samples from each sampling of the four sampling points shown in Figure 1 were collected per event. The study had a generous selection of pathogens in addition to conventional pollutants to be evaluated in the disinfected effluent generated from both wet- and dry-weather events. Analyses of protozoa and viruses are not routinely done at the WWTP but were done in this study.

Bacteria Sampling, Analyses, and Maceration Procedure

During each sampling event, three grab influent samples each were collected at SP1 (prior to any treatment), at SP2 (primary effluent), at SP3 (prior to chlorine contact tank), and SP4 (post chlorination). The samples were analyzed for fecal coliform and *Enterococcus* using the most probable number (MPN) method. There were a total of five sampling events per plant with at least one dry-weather (non-blending) event and four wet-weather (blending) events. During wet-weather events, all samples were collected at peak flows, after plants started bypassing secondary treatment. The dry-weather event was used for comparison purposes.

A maceration procedure was conducted for a limited number of bacteria analyses. Maceration exposes the particle-associated and occluded, and clumped together bacteria and achieves a thorough enumeration. The study consisted of two parts: maceration optimization and maceration of final effluent samples (SP4) to determine if maceration had any impact on results. The maceration optimization procedure was conducted during one wet-weather blending event and one dry-weather non-blending event at one of the WWTPs to determine the optimum speed (revolutions per minute (rpm)) and time (seconds) of the multi-speed (3,500-22,000 rpm) laboratory blender that was used for maceration of effluent samples during the subsequent wet- and dry-weather runs. Upon completion of the maceration optimization - achieved at speed of 22,000 rpm and time of 60 seconds - 36 dry-weather and 36 wet-weather macerated analyses were performed for fecal coliform and for *Enterococcus.* Each of the three final effluent samples involved in the experiment was analyzed as a regular unmacerated sample for comparison purposes. The macerated samples showed higher concentrations of bacteria.

Protozoa, Virus, and Coliphage Sampling and Analyses

At two of the Plants (selection of two Plants instead of three Plants was due to the budgetary constraints), four sampling events - three during wet-weather blending and one during dry weather - were conducted for protozoa (*Giardia* and *Cryptosporidium*), viruses (adenovirus, astrovirus, enterovirus, reovirus, rotavirus, norovirus and Hepatitis A (HAV), and coliphage (male-specific and somatic). Each sampling event at a Plant was comprised of ten grab samples for protozoa analyses and ten grab samples for viral analyses. The protozoan and viral sampling consisted of three grab influent (SP1, prior to any treatment), one grab primary effluent (SP2), three grab pre-chlorinated effluent (SP3, prior to chlorine contact tank) and three grab effluent (SP4, post chlorination) samples collected at 45-minute intervals.

For the protozoan portion of the study, *Giardia* and *Cryptosporidium* were detected and enumerated using EPA Method 1623 (3). Since this method provides for quantification of *Giardia* and *Cryptosporidium*, but does not determine viability or infectivity, ten split samples per plant were sent for infectivity analyses for *Cryptosporidium* using a published method with some modification (4 & 5). Following infectivity determination, molecular confirmation of the genotype was ascertained by PCR analysis for all samples, except for the positive control (6). For the virus portion of the study, ten samples per plant were submitted to quantitative analyses using EPA ICR Methodology (3). In addition, analyses for the detection and quantification of male-specific and somatic

coliphage were performed on all samples using a soft agar overlay procedure. The EPA report from the study provides a complete list of references for all of the above methods. (1).

RESULTS

Bacteria

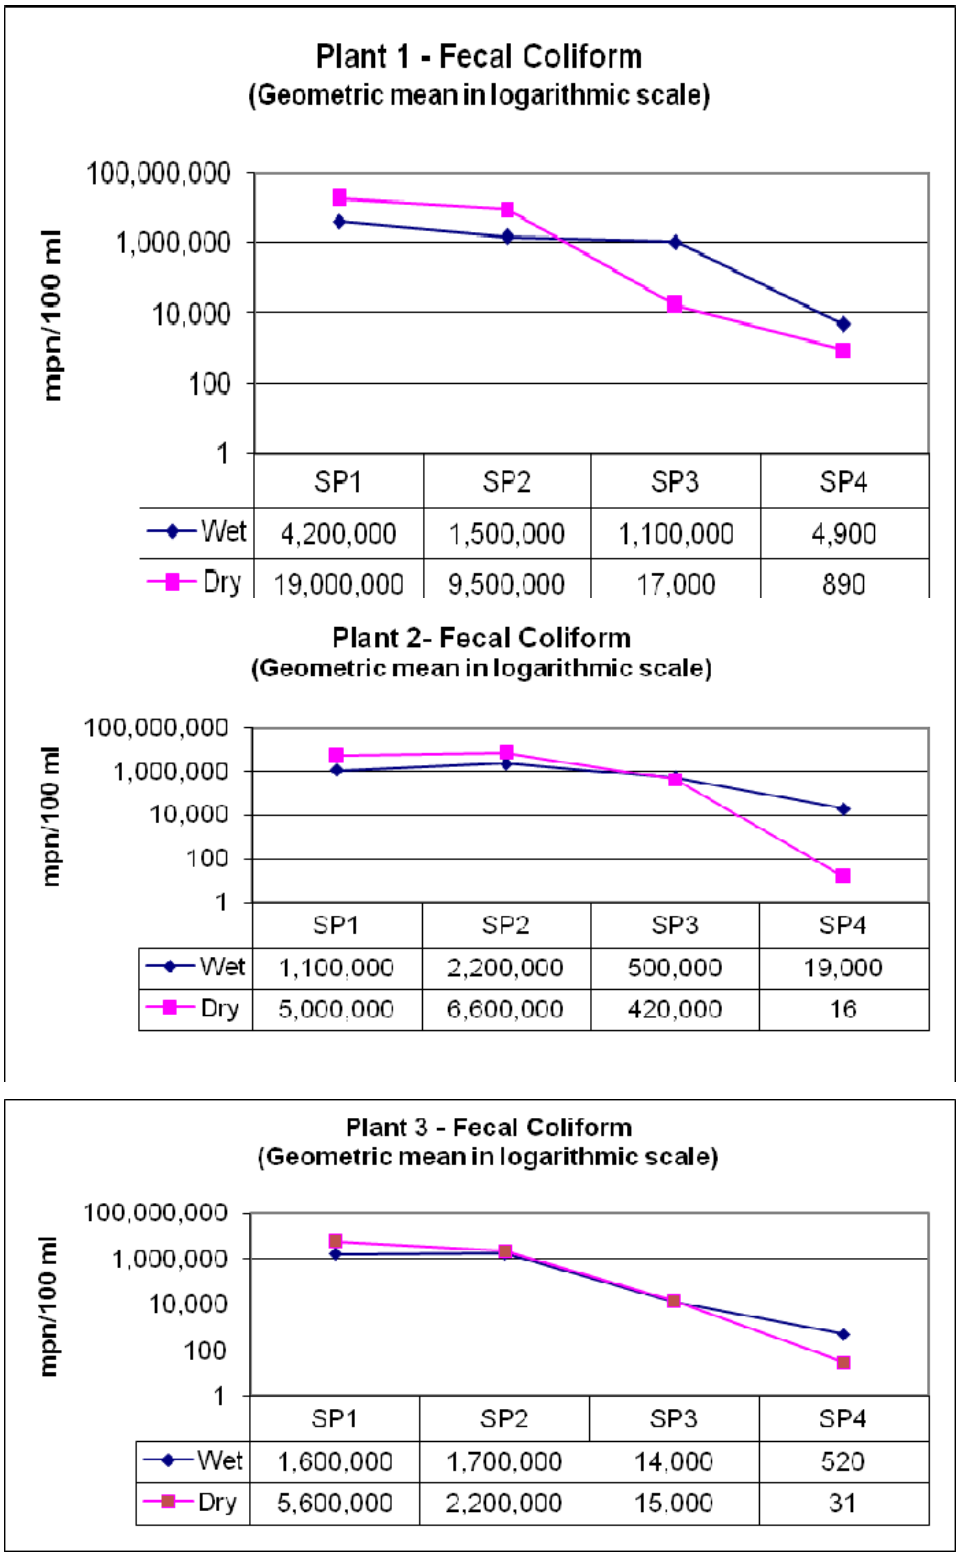
For both fecal coliform and *Enterococcus* concentrations in the disinfected final effluent during wet-weather blending were higher than the corresponding dry-weather non-blending concentrations. For both fecal coliform and *Enterococcus* at Plant 3 and for fecal coliform at Plant 1, the concentrations of wet-weather blending and dry-weather non-blending effluent were between a half and one order of magnitude higher. Disinfected effluent fecal coliform and *Enterococcus* concentrations were significantly higher (three orders of magnitude) during wet-weather blending versus dry-weather non-blending for both parameters at Plant 2 and for *Enterococcus* at Plant 1 (Table 1). In addition, the order of magnitude reduction between influent and effluent ("kill") was at least two orders of magnitude higher in most (five out of six) cases at all three plants during dry-weather non-blending as compared to wet-weather blending (Table 1).

Table 1. Fecal Coliform and *Enterococcus* Concentrations

Plant	Average Flow (MGD)	Operating Mode	Fecal Coliform –Geometric Mean (MPN/100ml)			*Enterococcus* –Geometric Mean (MPN/100ml)		
			Influent	Effluent	Order of Magnitude Reduction	Influent	Effluent	Order of Magnitude Reduction
Plant 1	239	Wet Blending	4,200,000	4,900	10^3	890,000	17,000	10
	122	Dry	19,000,000	890	10^5	470,000	20	10^4
Plant 2	125	Wet Blending	1,100,000	19,000	10^2	260,000	14,000	10
	31	Dry	5,000,000	16	10^5	220,000	3	10^5
Plant 3	469	Wet Blending	1,600,000	520	10^4	280,000	870	10^3
	238.5	Dry	5,600,000	31	10^5	1,700,000	120	10^4

Graphic representation of fecal coliform and *Enterococcus* concentrations, during dry-weather non-blending and wet-weather blending is shown in Figures 2 and 3 below.

Figure 2. Fecal Coliform Concentrations at All Three Plants



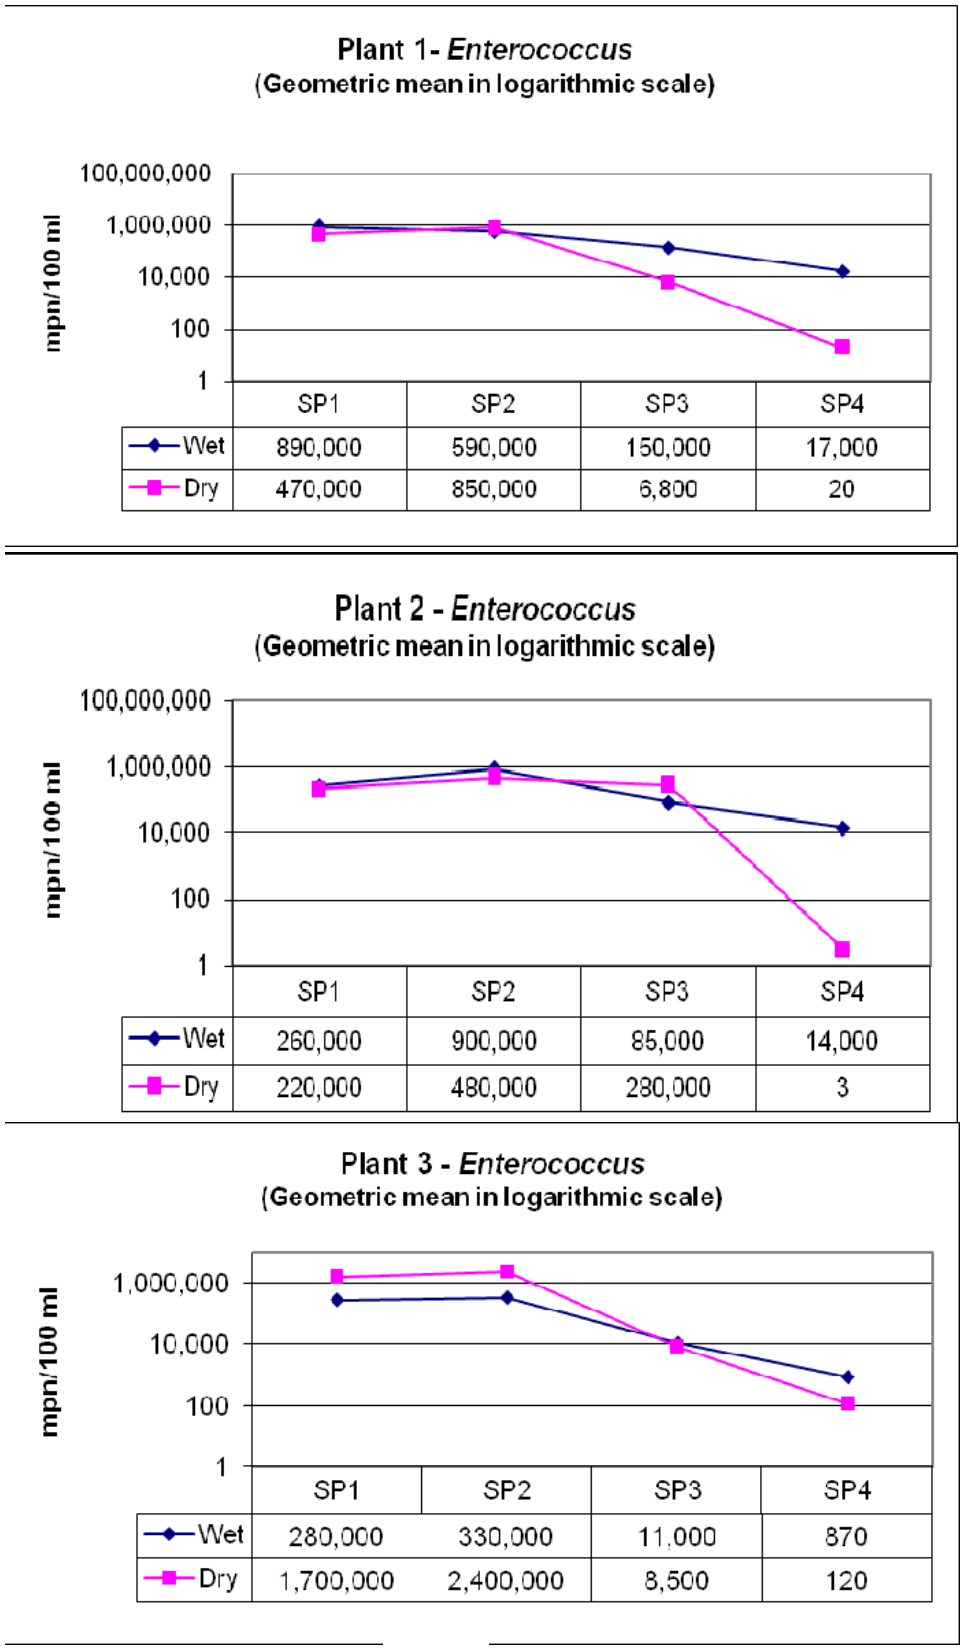


Figure 3. *Enterococcus* Concentrations at All Three Plants

Protozoa

Effluent concentrations of *Cryptosporidium* parvum were higher during wet-weather blending at one plant (Plant 1) when compared to dry weather non-blending. The *Crypotosporidium* parvum effluent concentrations during wet-weather were low, mostly in single or low double digits, with average percent removal of 71% at Plant 1. Average percent removal for Plant 2 could not be estimated, since less than three detectable results were reported (Table 2 and Figure 4).

Infectious *Cryptosporidium* parvum concentrations at both plants were mostly low or non-detectable. Only two out of nineteen infectious *Cryptosporidium* parvum effluent samples showed a detectable value; only one of these two samples showed the presence of *C. Parvum* Genotype II.

Effluent concentrations of *Giardia* were one order of magnitude higher during wet-weather blending versus dry weather non-blending at both Plant 1 and Plant 2. The geometric mean of *Giardia* effluent results during wet weather were at in low triple digits, with 88% removal, at Plant 1 and with 40% removal, at Plant 2. (Table 2 and Figure 5).

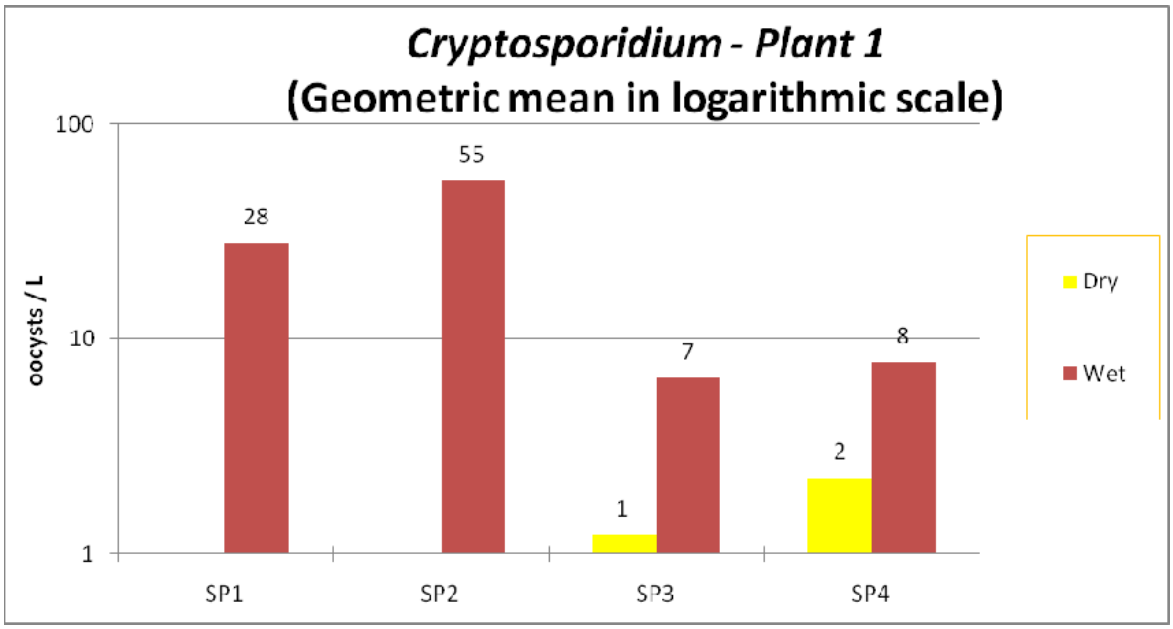

Table 2. Range of Final Effluent Concentrations for Protozoa

Plant	Operating Mode	*Giardia* cysts/ L (enumerated values)		*Cryptosporidium* oocysts/ L (enumerated values)		Infectious *Cryptosporidium* *MPN/L*	
		Range	Geometric Mean	Range	Geometric Mean	Range	Geometric Mean
Plant 1	Dry	6 – 21	12	1 – 8	2	<0.2	NA
	Wet Blending	40 – 720	148	<0.2 – 52	8	<0.3 - <9.2	NA
Plant 2	Dry	2 – 4	3	2 – 4	2	<0.2	NA
	Wet Blending	7 – 720	105	<0.2 – 2	NA	<0.5 – <2.4	NA

Note: NA =Less than three detectable results were reported, hence geometric mean could not be calculated

Less than three detectable *Giardia* results were reported for the SP2 location at Plant 1 during dry weather, hence geometric mean could not be calculated. Dry-weather results for SP1 and SP2 locations at Plant 1 were affected by clogged filters and, hence, prevented the full detection of *Giardia* and *Cryptosporidium.* Therefore, dry-weather SP1 and SP2 results for Plant 1 should not be used for deriving conclusions for this study.

Figure 4. *Cryptosporidium* Concentrations

Viruses

With relatively high plant influent results during wet-weather blending, the effluent results for enteric viruses were, on average, in single digit or low double-digit infectious units/L in final effluents, with average percent removal between 98% and 99% for Plant 1 and 99% for Plant 2. (Table 3). Cell lines are human or animal cells that are grown in a laboratory and used for detection of the presence of a particular organism. In this study, four cell lines were used for detection of enteric viruses:

1. BGM – Buffalo Green Monkey cell line
2. MA-104 – derived from Rhesus monkey kidney
3. PLC/ PRF/5 – human hepatoma cell line
4. CaCo-2 – human intestinal cell line

Table 3. Average Percent Removal of Viruses during Wet Weather

Plant	% Removal of BGM	% Removal of MA-104	% Removal of PLC/PRF/5	% Removal of CaCo-2 cells
Plant 1	98%	98%	98%	99%
Plant 2	99%	99%	99%	99%

The cell lines that were used for detection of enteric viruses using ICC-PCR and/or PCR methods are shown in Table 4.

Table 4. Detection by Cell Line

Cell Line	Viruses Targeted for PCR Detection
BGM:	Enterovirus, Reovirus
MA104:	Enterovirus, Rotavirus, Reovirus
PLC/PRF/5	Adenovirus
CaCo-2	Enterovirus, Astrovirus

Table 5. Range of Final Effluent Concentrations for Viruses

Plant	Operating Mode	BGM Infectious Units/L		MA-104 Infectious Units/L		PLC/PRF/5 *Infectious Units/L*		CaCo-2 *Infectious Units/L*	
		Range	Geom. Mean	Range	Geometric Mean	Range	Geom. Mean	Range	Geom. Mean
Plant 1	Dry	1 – 3	2	1 – 5	2	2 – 5	3	<1 – 1	NA
	Wet	3 – 143	14	<2 – 393	21	9 – 32	18	1 – 34	4

Coliphages

Coliphages are bacteriophages that infect *Escherichia coli* (*E. coli*). They are frequently viewed as alternate bacterial indicators, representing enteric virus contamination. Analysis of the results for the two plants, at which the coliphage samples were collected, shows that male-specific coliphage was consistently lower during wet-weather blending vs. dry-weather conditions throughout - Plant 1. At both SP3 and SP4 for Plant 2, there were no significant differences between wet-weather blending and dry-weather non-blending conditions.

Graphical representation of viruses results is shown below by each of the four cell lines (Figures 6, 7, 8, and 9).

Figure 5. ***Giardia*** **Concentrations**

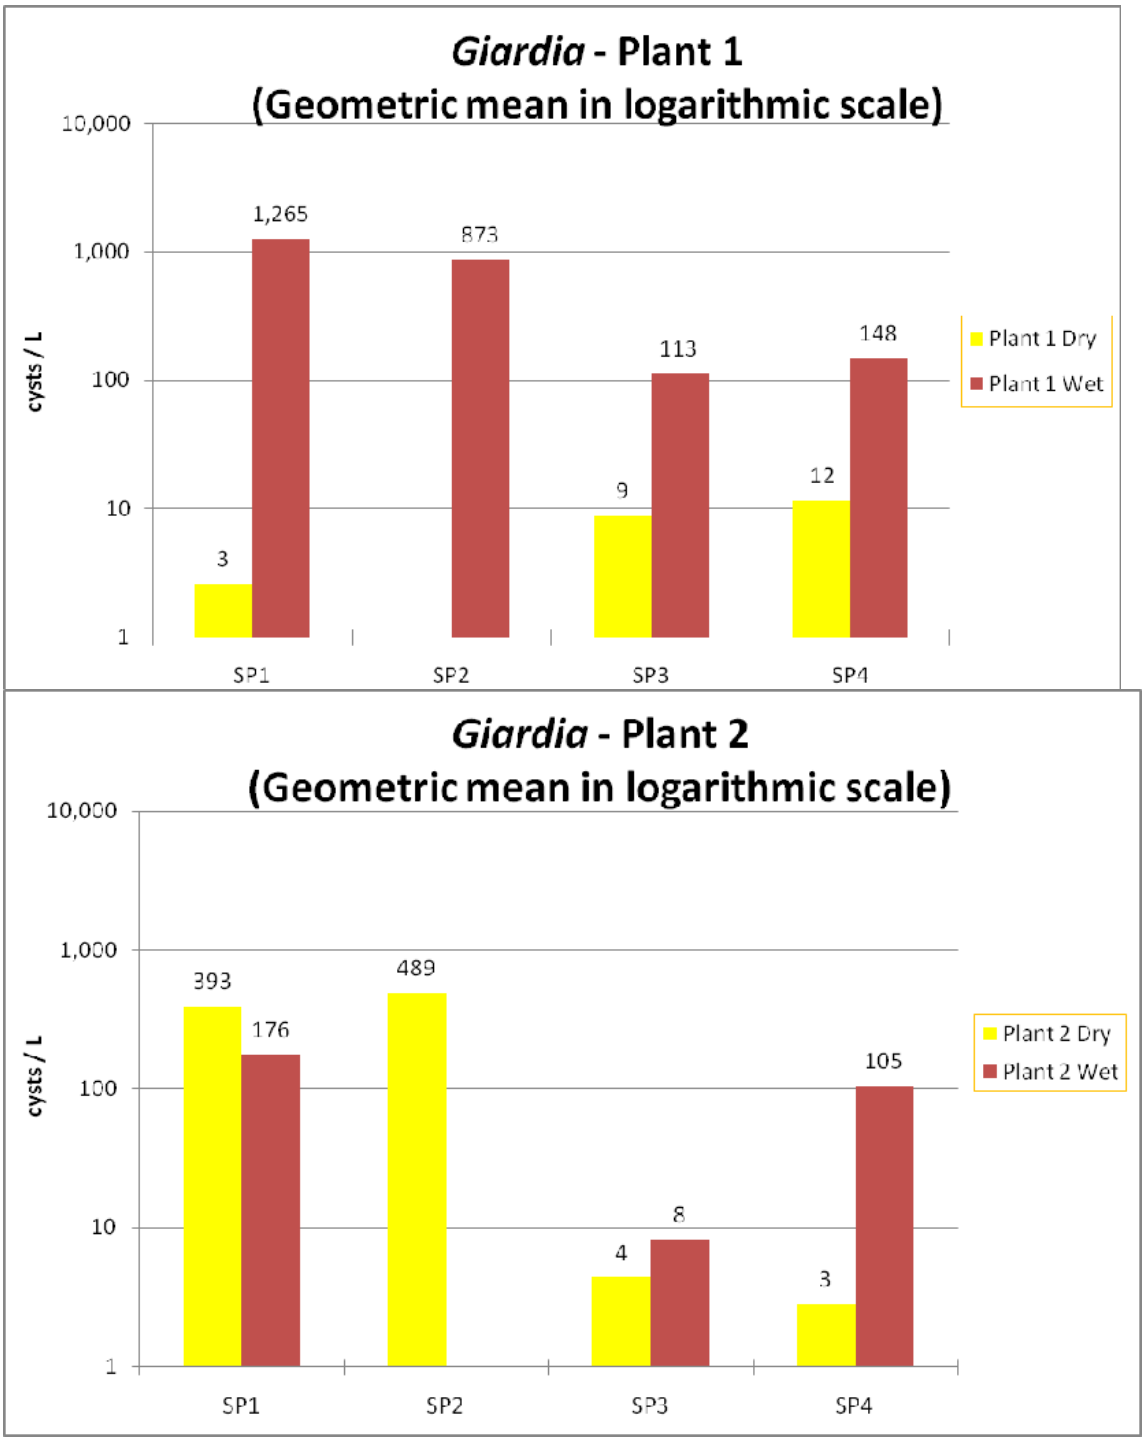

Figure 6. Buffalo Green Monkey Cell Line Viruses Concentrations

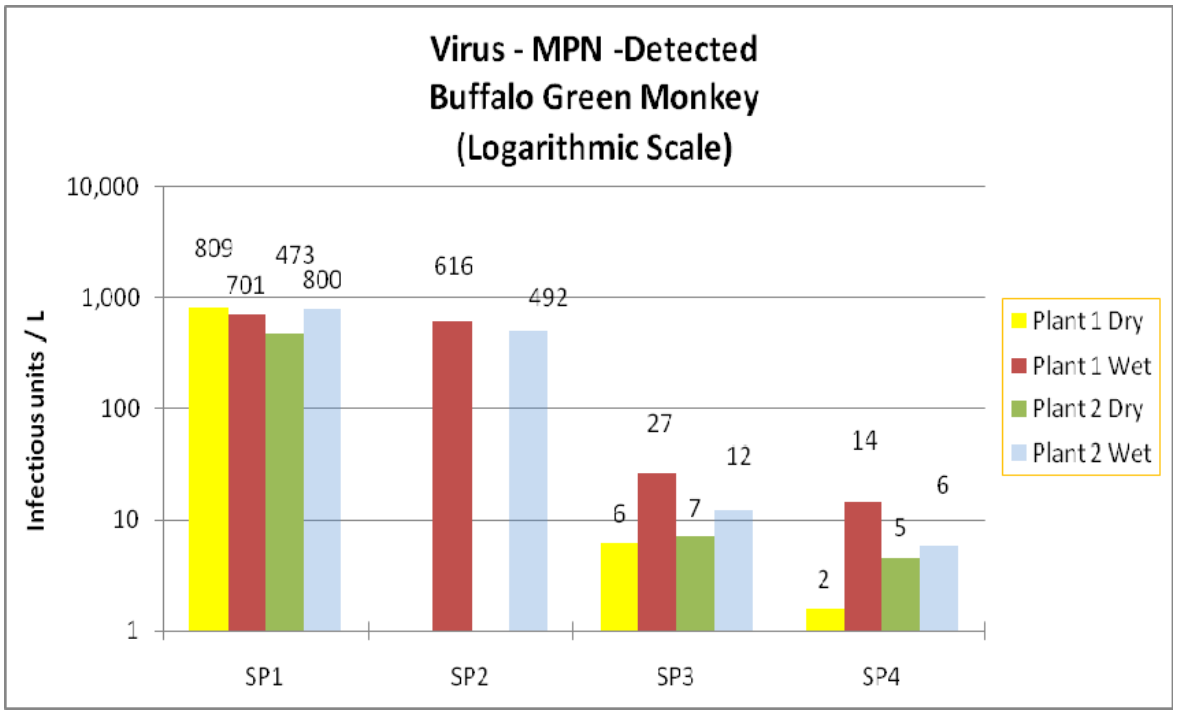

Figure 7. MA-104 Cell Line Viruses Concentrations

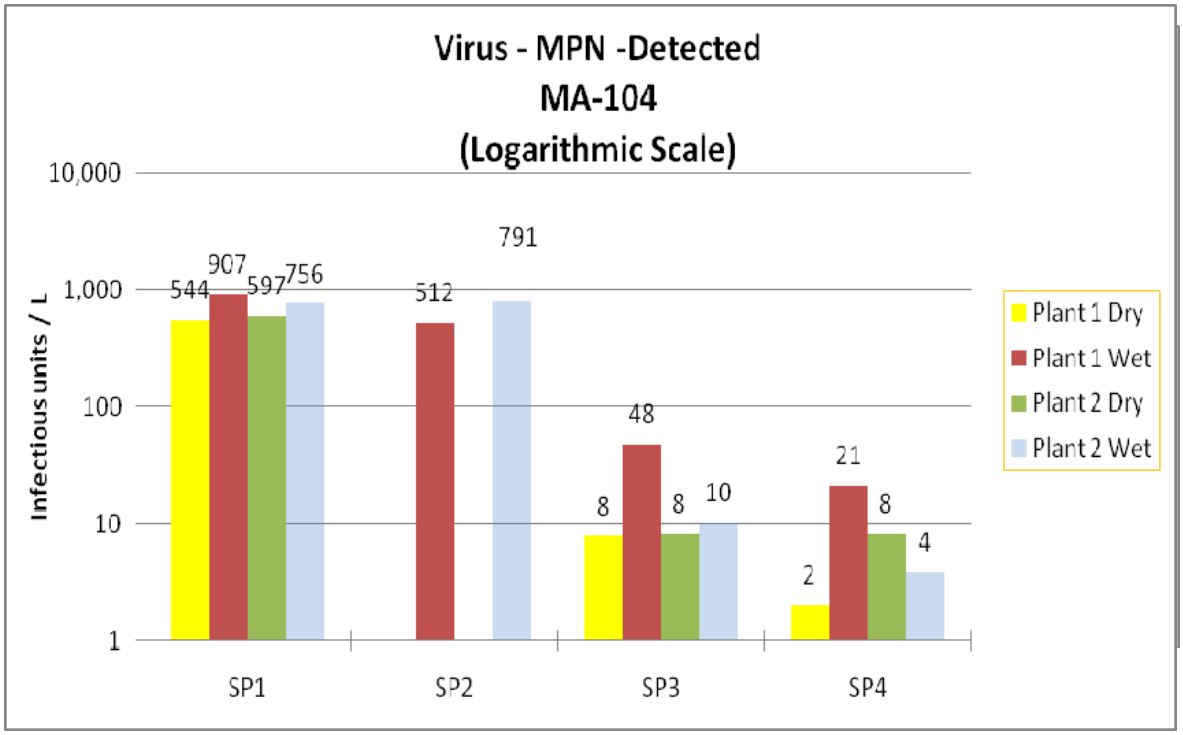

Figure 8. PLC/PRF/5 Cell Line Viruses Concentrations

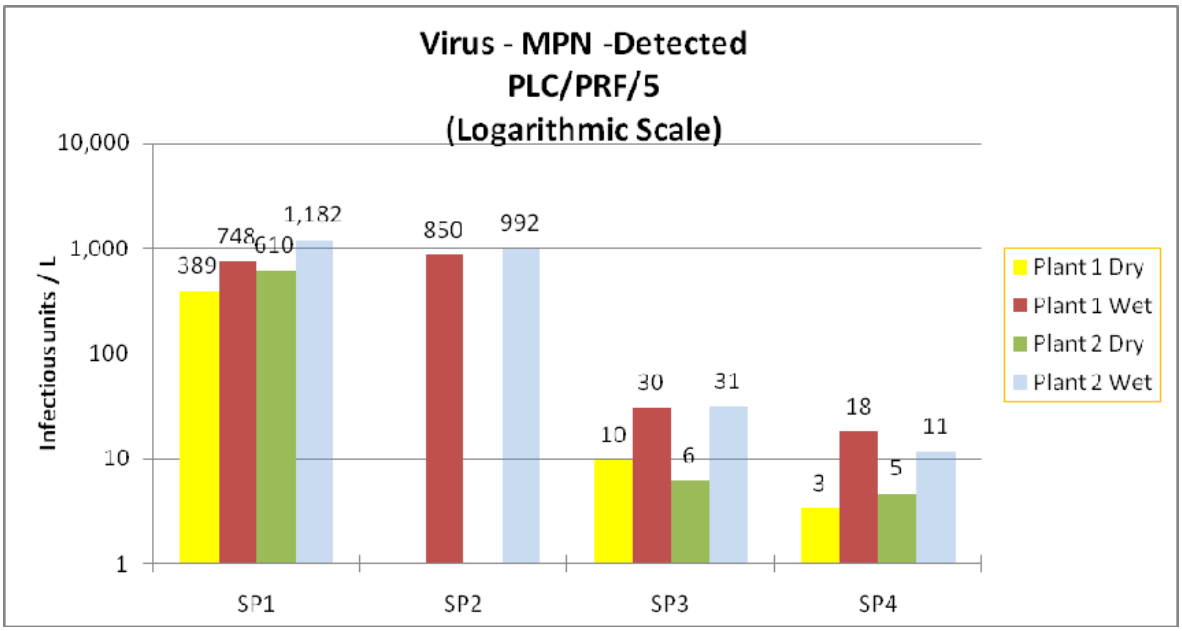

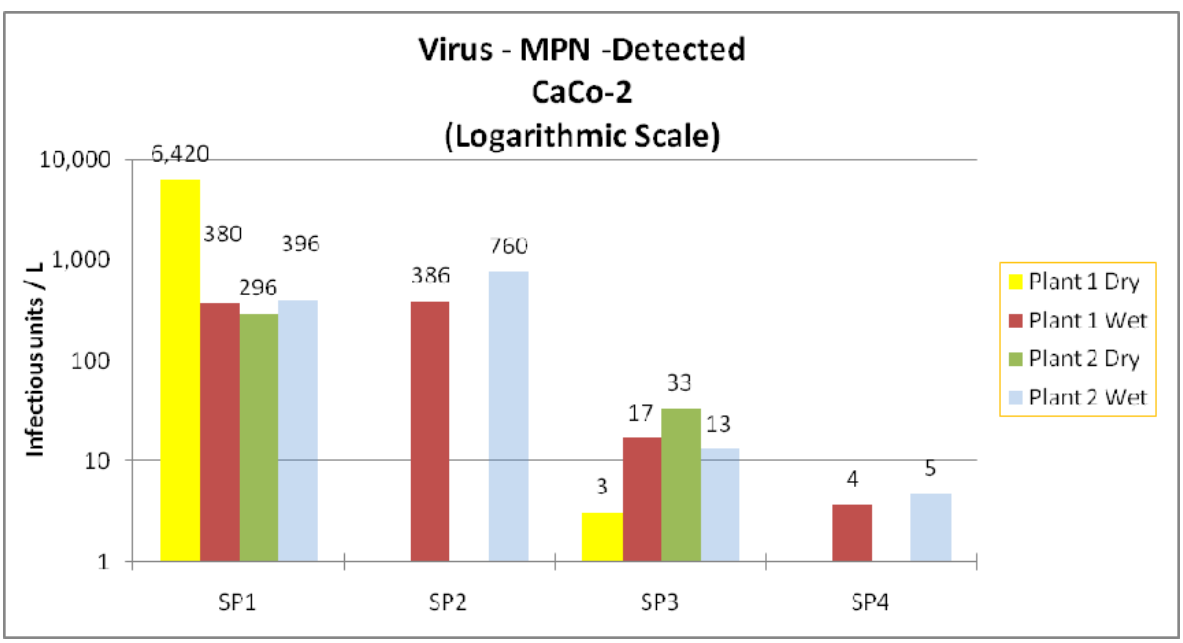

Figure 9. CaCo-2 Cell Line Viruses Concentrations

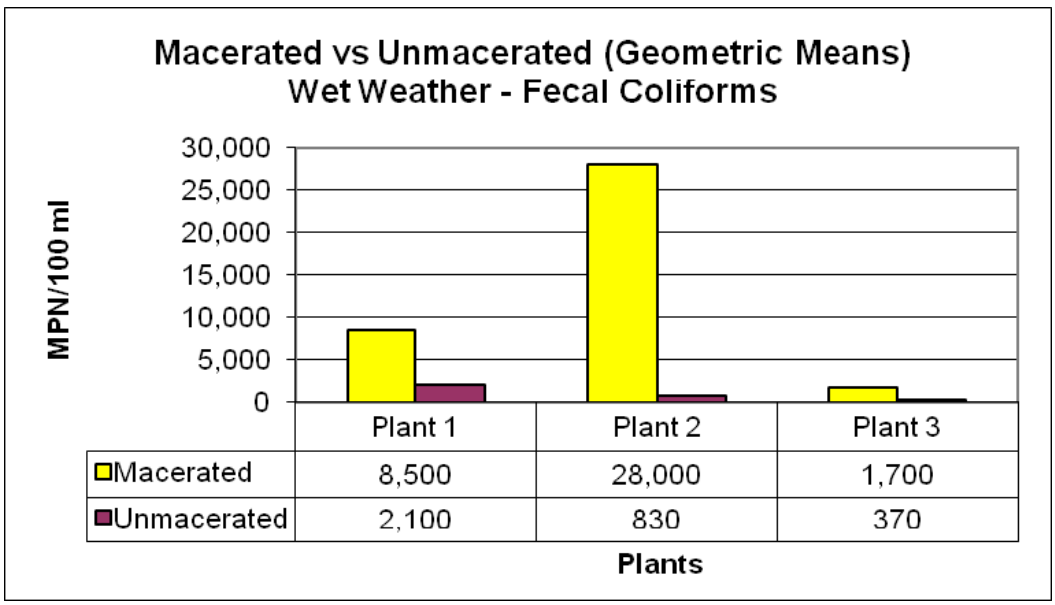
Maceration Results

For the majority of samples, maceration of effluent samples did result in increase in both fecal coliform and *Enterococcus* concentrations for both wet and dry weather. After maceration, significant increase in concentrations of one order of magnitude was observed only during dry weather for *Enterococcus* at Plant 1 and during wet weather for fecal coliform at Plant 2. A smaller increase of half order of magnitude was observed for fecal coliform during dry weather at Plant 1.

Figure 10. Wet-Weather Fecal Coliforms Macerated versus Unmacerated



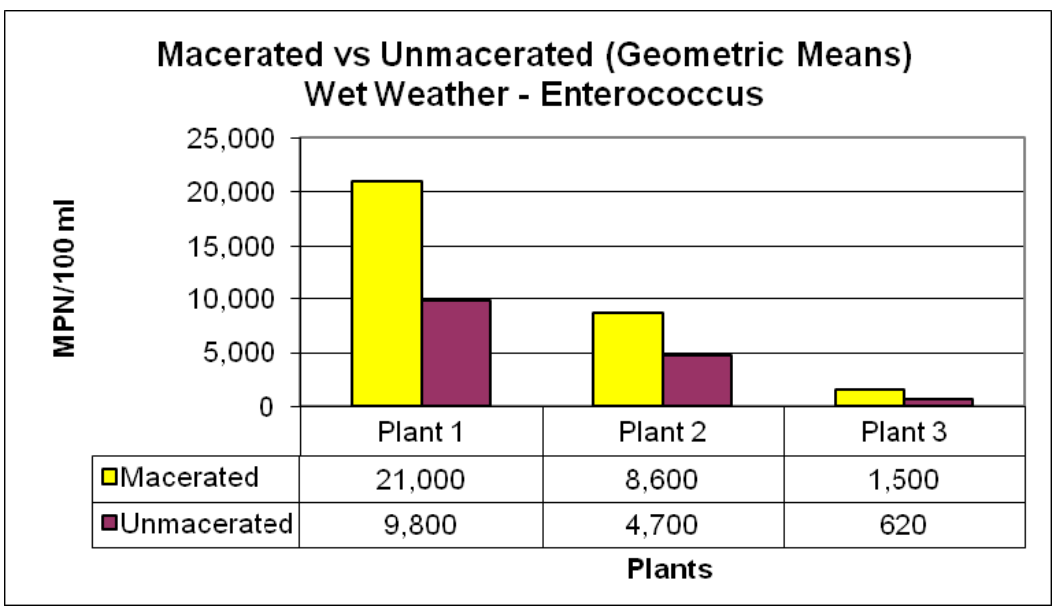


Figure 11. Wet-Weather *Enterococcus* Macerated versus Unmacerated

BOD_5 and TSS Results

The study showed that during blending, effluent BOD_5 and TSS concentrations at Plant 1 and Plant 2 were, on average, below 30 mg/l, and effluent BOD_5 and TSS concentrations at Plant 3 were, on average, above 30 mg/l. BOD_5 and TSS percent removal during blending remained, on average, above 80% at Plant 2, above 70% at Plant 1 and showed a more significant decline at Plant 3 where it was 45% for BOD_5 and 17% for TSS. The most probable reason for a poorer performance of Plant 3 was an occurrence of a major upgrade during sampling. See Table 6.

Table 6. BOD_5 and TSS Total Percent Removal

Plant	BOD_5 % - Dry Weather	BOD_5 % - Wet Blending	TSS % - Dry Weather	TSS % - Wet Blending
Plant 1	92%	77%	89%	71%
Plant 2	88%	81%	99%	89%
Plant 3	93%	45%	93%	17%

The average of BOD_5 wet-weather blending effluent concentrations was 24 mg/l at Plant 1 (values ranged from 9.5 to 37 mg/l), and 22 mg/l at Plant 2 (values ranged from 9 to 30 mg/l). The average of TSS wet-weather blending effluent concentrations was 29 mg/l at Plant 1 (values ranged from 22 to 33 mg/l) and 20 mg/l at Plant 2 (values ranged from 13 to 26 mg/l).

Total Residual Chlorine (TRC) Results

There was no significant correlation between TRC versus plant flow. Chlorine residual concentrations were, on average, higher during wet-weather blending versus dry weather at all three Plants. It has been observed that the chlorine contact times were shorter during blending events due to higher flow rates.

CONCLUSIONS

As presented in the previous sections, the data on key pathogens, pathogen indicators, TSS and BOD show a negative impact of the blending practice on the WWTP performance and on the quality of the final effluent. A definite impact of blending is clearly visible when comparing the dry-weather non-blending to wet-weather blending results. This comparison showed that at two plants fecal coliform and *Enterococcus* concentrations in disinfected effluent were on average one to three orders of magnitude higher during wet-weather blending versus dry-weather non-blending. *Cryptosporidium* and *Giardia* effluent concentrations were also higher during wet-weather blending versus dry weather. Effluent concentrations of viruses were between a half and one order of magnitude higher during wet-weather blending versus dry weather at Plant 1 and similar at Plant 2.

However, there are several important reasons why these data should be accepted with caution and why this or similar studies should be continued:

1. This study was an ambitious undertaking, but it was conducted in a single geographic area and with a limited number of data points. These results should be viewed as plant specific. Conclusions should not be drawn on a national scale, and the results from this study should not be used in support of any regulations.
2. During the sampling period, Plant 3 was undergoing a major upgrade, which appeared to have an adverse impact on treatment quality, especially during wet-weather blending. Therefore, all results for Plant 3 should be viewed with caution.
3. The blending practice, although undesirable compared to non-blending, provides considerable protection of public health compared to the release of untreated overflows. It is possible that the design and operational characteristics of the individual treatment plants are significant factors affecting the ability of individual plants to perform satisfactorily during wet-weather blending.
4. Capability of the secondary treatment to reduce viruses concentrations to the double digit levels sheds good light on the WWTP performance in wet-weather.
5. The results of this study need to be supported by additional data collected not only at the WWTPs studied by this project but also by WWTPs with separate sewer systems and WWTPs located in other geographical areas.
6. Other studies of this type, such as the ongoing *blending study* conducted by the Water Environment Research Foundation (WERF) should be followed to exchange ideas, compare results and reinforce findings.
7. Continuation of the study at the same three or at different New York City plants would be a start in the right direction. Such a study would substantially increase the number of data points needed for reaching valid conclusions. This continuation would involve analyzing for fecal coliform, *Enterococcus, Cryptosporidium*, *Giardia*, and viruses in samples collected during one dry weather, three wet-weather non-blending (not done in this study), and three wet-weather blending events. For bacteria, maceration of the final effluent samples would be also done to achieve truer enumeration.

ABSTRACT

This research investigates the hydrologic sustainability of urban development and stormwater management for a watershed on the Texas A&M campus. The main Texas A&M campus has become increasingly urbanized, resulting in areas of imperviousness that generate higher rates of runoff. This growth has proceeded unchecked, and significant growth and development are planned for the future. Both increased rates of runoff from previous development and the impact of anticipated development should be addressed through mitigation efforts. This research provides a means to assess watershed health through biological indicators, water quality indicators, riparian ecosystems, the floodplain footprint, and the long term flow regime. A modeling framework is implemented to couple hydrologic and hydraulics models to simulate a set of watershed management plans that employ alternative best management practices. Development plans will be evaluated based on a set of comprehensive metrics that synthesize ecological, hydrologic, and environmental aspects of watershed health. The selection of management plans based on these metrics will enhance the environmental sustainability of further campus development.

INTRODUCTION

Urbanization of watersheds leads to an increase in peak flow and volumes of stormwater runoff and fundamentally alters the characteristics of the flow regime and therefore the health of the in-stream ecosystem. More sustainable development in a

hydrologic context would enable the stream to maintain its natural variability and flow characteristics. Best Management Practices (BMP) are a range of technologies and methods for mitigating increased stormwater runoff and have provided an appropriate approach for controlling the volume of flow and limiting the amount of sediments and pollutants that would otherwise be washed into the stream. For example, detention ponds are typically designed to match pre-development peak flows (EPA 2004). While centralized BMP placement may reduce peak flows and may effectively remove pollutants, the natural hydrology may become dominated by inadequate base flow or flashy hydrology, which negatively affects the ecosystem (Coffman 2000). Alternatively, Low-Impact Development (LID) is a selected set of BMPs that enable the design of management strategies with the goal of either maintaining or replicated the pre-development hydrologic regime. LID principally uses the tactic of controlling stormwater at the source through the use of micro-scale stormwater retention areas, landscapes that act as stormwater facilities, and the protection of riparian buffers and other environmentally sensitive site features (EPA report 2000). LID strategies include permeable pavements, rainwater harvesting systems, green roofs, and vegetated swales.

The purpose of this paper is to explore through a simulation study the placement of LID strategies, including rainwater harvesting systems, permeable pavement, and riparian buffer systems, on a campus watershed for improvement of the hydrologic sustainability. The watershed has experienced development in recent years, through the construction of buildings, roadways, and parking lots. To simulate the pre-development flow regime, data from 1940 is incorporated into a hydrologic modeling framework. The flow regime for the current conditions and different LID placement scenarios are simulated and compared to the predevelopment flow regime to evaluate hydrologic sustainability.

TEXAS A&M UNIVERSITY CAMPS: PAST, PRESENT, AND FUTURE

The main Texas A&M University (TAMU) campus, located in College Station, Texas, covers an area of 5,280 acres (21.37 square kilometers), most of which are not densely developed. Since 1962, the campus witnessed unprecedented growth with a student population increasing from 7,500 to 45,000. The main campus consists of a mix of old and new structures which reflect the evolution of the university footprint over the past 130 years. Construction and development have led to degraded hydrologic conditions, especially during peak flow conditions, which lead to street flooding and in-stream erosion.

The two sections of campus, Main Campus and West Campus (3.03 and 4.39 square kilometers, respectively), are separated by a four-lane road and railway track (Fig. 1). The campus straddles two watersheds, and the Main campus drains southeast toward the Navasota River while West campus drains southwest through White Creek into the Brazos River. While West Campus is less developed than Main Campus, development that has taken place over the last 50 years on West Campus has greatly increased the impervious surface and volume of storm water draining into White Creek, subsequently degrading the structure of the creek and the ecosystem. Tributaries C and D that contribute to White Creek have undergone a transformation from small and slow moving creeks to large creeks that move large amounts of storm

water during a typical 2-5 year rainfall event. The TAMU Physical Plant Utilities commissioned a study to assess the extent of erosion within the watershed and to propose the most effective engineering solutions (JF Thompson, 2005). The study documented the erosion and massive slope failure that has occurred throughout the extent of the creek's channel, and predicted that, if left unmitigated, erosion would likely undermine adjoining structures including buildings, roads, bridges, and ponds. As a result of this study, immediate protection of critical locations was recommended, and riprap and gabions with vegetation were implemented to decrease velocities in stream.

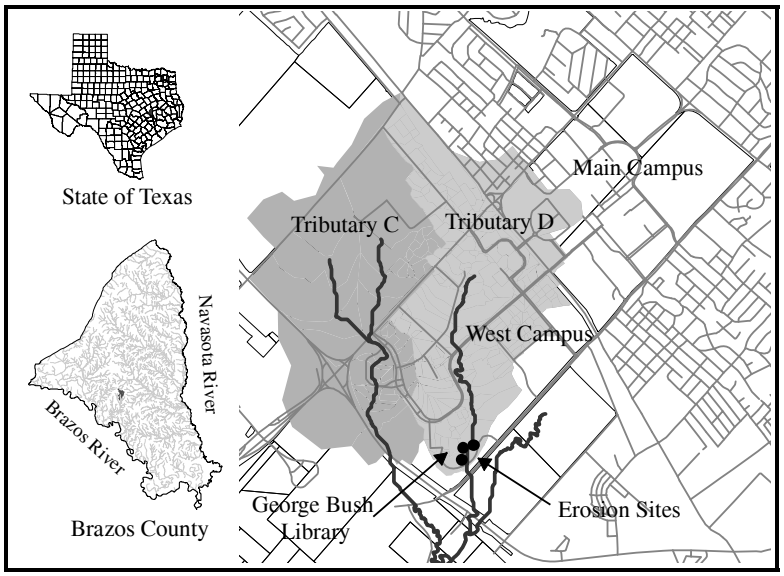

Figure 1. Location of Texas A&M campus; West Campus Watersheds C and D; Tributaries C and D; and the location of erosion problems

To prevent further damage and improve the aesthetics of the campus as a whole, a master plan was commissioned and was released in July 2004 (Barnes Gromatzky Kosarek Architects and Micheal Denis & Associates, 2004). It assesses the present strength and weaknesses of the campus and sets the tone for future construction and landscape development as the university enhances its physical environment. The master plan proposes an extension of the civic structure and landscape that exists on Main Campus into West Campus. As the number of buildings on West Campus is expected to approximately double, the replacement of parking areas with green spaces, buildings, and garages is suggested to mitigate environmental implications of increased impervious areas. Thompson (2005) suggests that a more comprehensive stream restoration plan is required to address erosion and hydrologic problems in the long term and plan for the further development of West Campus as proposed in the master plan.

LOW IMPACT DEVELOPMENT STRATEGIES

Three LID strategies, including a riparian buffer system, permeable pavement, and rainwater harvesting systems, are considered for mitigating the impacts of development in the campus watershed.

Riparian Buffer System. The campus master plan suggests that Tributary D should be developed as a greenway. The area can be restored to its natural state by encouraging the use of native Texas riparian landscape. A 300 feet (approximately 90 meter) wide riparian buffer, divided into three cores (inner, middle and outer) is proposed (Fig. 2). It is expected to act the backbone of the natural enhancement around which other segments will be organized.

The proposed Greenway is a strip of riparian buffers and linear strips of vegetation between the aquatic ecosystem and the upland habitats. Such systems are usually located adjacent of streams, rivers, lakes, reservoirs, and other inland aquatic systems. They are different from riparian corridors, which primarily facilitate the movement of wildlife. Their purpose is to improve water quality (Fisher et al., 2000). Riparian buffer strips can reduce stream sedimentation in several ways. They trap terrestrial sediment in the surface runoff and reduce the velocity of the sediment bearing storm-water, allowing more time for the sediment to settle out. They also stabilize stream banks and prevent excessive channelization, they moderate flows during floods, and they contribute large wood to the stream, assisting stabilization by acting as soil rebar (Wenger, 1999).

The first five meters on the outer side of the strip is the most important as it screens out large particles. Smaller sized particles are more difficult to remove by filtering through grass, and generally require a zone of woody vegetation to intercept them (Garabaghi et al., 2001). Vegetation already existent along the riparian zone will be retained and protected and it must be ensured that drainage does not interfere with the hydrology of the buffer. The buffer tree canopy should be maintained to balance both understory and overstory vegetation. The buffer can also include sedimentation detention structure, such as depressions in the ground, vegetative filter strips, permeable barriers, and infiltration structures such as gravel trenches.

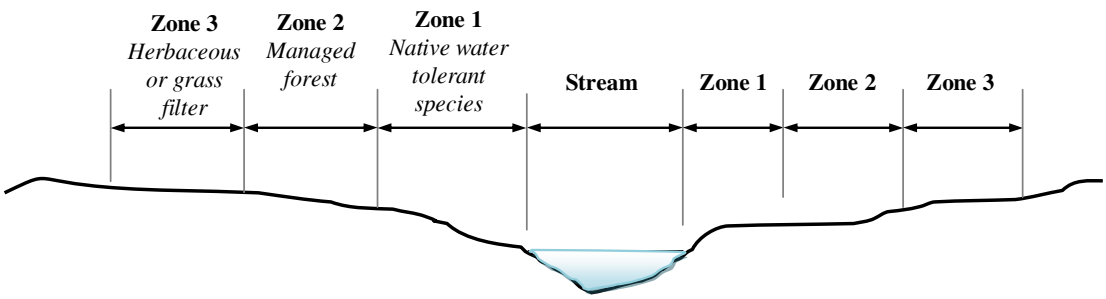

Figure 2. Schematic of riparian buffer system

Permeable Pavement. Permeable pavements systems generally consist of a matrix of concrete blocks or plastic web-type structure with voids that are filled with a material of high permeability (sand, gravel or even soil). The voids hold the precipitation, allows water to infiltrate and be retained within the highly permeable matrix as it slowly infiltrates into the underlying soil (Brattebo and Booth 2003). Permeable pavement may replace traditional pavement or concrete infrastructure for sidewalks, roads, and parking lots. A set of studies have documented the ability of permeable pavement to reduce the volume of stormwater runoff and the amount of

contaminant washed from parking lots into surface water bodies (Braune and Wood 1999).

Rainwater Harvesting Systems. Rainwater harvesting is an ancient practice that has been receiving attention, fueled by water shortages from droughts, pollution and population growth (Nolde 2007). While originally used to collect water in depressions for irrigation, the practice of collecting rainfall from rooftops was later adapted for domestic water supply in rural areas and islands (Kahinda et al. 2007; Michaelides and Young 1983). More recently, environmental concerns have increased the appeal of green building practices, including rainwater harvesting systems, in urban areas. Rainwater harvesting is especially appealing as it combines the benefits of water reuse with runoff reduction and groundwater recharge, and has been proposed as a means to conserve rainwater and reuse it for landscaping (Porter et al. 2007).

MODELED SCENARIOS

A hydrologic and hydraulic model of Watersheds C and D in West Campus for current conditions was developed by AECOM (AECOM 2008). Geographical, hydrologic, and meteorological information were incorporated within HEC-HMS (Army Corps of Engineering 2006) for hydrologic simulation. Watersheds C and D were divided into sub-watersheds, delineated corresponding to storm sewer manholes, culverts, channel junctions, buildings, and streets. Curve numbers for the watershed, specified in the Bryan-College Station Unified Design Guidelines (2007), range between 75 for natural woodlands and natural grasslands and 77 for landscaped area. Streets, building roofs, and parking lots contribute to the percentage imperviousness for each sub-catchment. The Storm Water Management Model (SWMM) (EPA 2008) was used for hydraulic simulation. SWMM is a dynamic rainfall-runoff simulation model for both flow and water quality of a single storm event or a long-term continuous storm event. It extracts the flow hydrograph information from HEC-HMS at subbasins to route hydrographs through sewers, conduits, and open channels (AECOM 2008). As the storm water infrastructure on West Campus consists of box and circular storm sewers and two tributaries of White Creek, the hydraulic model consists of a combination of links and nodes representing the storm water infrastructure.

A set of scenarios were considered and compared to the Existing Conditions, which are represented in the current model. A 2-year 24-hour rain event with a cumulative depth of 4.42 inches (112.3 mm) (TxDOT 2004) was used to evaluate new scenarios, including Predevelopment Scenario, Riparian Buffer System, Permeable Pavement, and Rainwater Harvesting.

Predevelopment Scenario. An aerial photograph from 1940 is available (Texas A&M University Libraries Map & GIS Collection and Services) and was used to build the model of the predevelopment conditions. In 1940, most of the university infrastructure was concentrated on Main Campus, and West Campus was generally undeveloped and covered with natural grassland. A curve number of 75 was adopted for these areas (Bryan-College Station Unified Design Guidelines 2007).

In the current scenario, delineation of sub-watersheds was forced by curb gutters, inlets, conduits, and manholes. As the storm sewer infrastructure had not been implemented in 1940, the existing delineation of the sub-watersheds was restructured to reflect the natural topography of the watersheds for pre-development conditions. After this restructuring, the total number of sub-watersheds modeled in the predevelopment scenario is 52, compared to 327 in the existing conditions. The present channel configuration and cross section of the open channel in Tributaries C and D were adopted from the 2008 conditions.

Riparian Buffer System. The riparian buffer system is modeled using the recommendations of the campus master plan which proposes a riparian buffer along the creek. The buffer is divided into three zones; the outer zone being an herbaceous or grass filter strip, the middle zone consisting of managed forest of fast growing or native species, and the inner zone being native species that are water-loving or water-tolerant. A model of the buffer strip is incorporated within the HEC-HMS-SWMM model. Appropriate sub-catchments were delineated representing the buffer on both sides of the creek. While the standard design manual specifies a curve number of 75 for both natural grassland and natural forest (The Bryan-College Station Unified Design Guidelines 2007), other research suggest a wide range of curve numbers for grass, brush and woods based on hydrologic condition (e.g. McCuen, 1989). To simulate the presence of a buffer strip, a sub-catchment is created for each zone (outer, middle, and inner) with a curve number that reflects the type of vegetation.

Permeable Pavement. Few studies have investigated the mechanistic modeling of pervious pavements. Leming et al. (2007) identified a method for calculating a curve number for pervious pavement, which is implemented for this study. This method approximates the initial abstraction as the volume of water stored by the pervious pavement, based on the depth and porosity of the pavement. The following equations are used to calculate the corresponding curve number for a system of permeable pavement designed to store a 24-hr 2-yr storm, as demonstrated in Leming et al. (2007):

$$I_a = P_{24-hr,2-yr} \text{ (mm)} \quad (1)$$

$$S = \frac{I_a}{0.2} \text{ (mm)} \quad (2)$$

$$CN = \frac{100}{\left(\frac{S}{254}+1\right)} \quad (3)$$

where $P_{24\text{-}hr,2\text{-}yr}$ is the depth of a 24-hr 2-yr storm (mm); I_a is the initial abstraction (mm); S is the maximum potential retention (mm); and CN is the curve number.

For the 24-hr 2-yr storm of 112.3 mm, the curve number is calculated as 31.2. Currently in West Campus, 41% of the watershed is total impervious area and 6.5% of the watershed is uncovered asphalt parking lots. A weighted curve number approach is taken to calculate the new curve number for each sub-watershed, based on the acreage of pavement in that subbasin.

Rainwater Harvesting Systems. The approach taken to simulate the rainwater harvesting is similar to the simulation procedure for the permeable pavement, employing the assumption that the precipitation from a 2-year 24-hour storm event will be collected from the roof of buildings within the watershed. The curve number is calculated as 31.2, based on Eqns. 1-3. Buildings on West Campus provide a total roof area of 227,150 square meters, or 3.2% of the total area.

PRELIMINARY RESULTS

Based on the modeling approaches described above, the characteristics for four scenarios as implemented in Watersheds C and D were calculated and summarized in Table 1.

Table 1. Scenario characteristics

Scenario	Total Pervious Area (%)	Total Impervious Area (%)	Area Represented as LID (%)	Weighted Curve Number
Pre-development	93%	7%	-	76.6
Existing Conditions	73%	27%	-	82.7
Permeable Pavement	73%	20.6%	6.4%	78.4
Rainwater Harvesting System	73%	23.8%	3.2%	80.5

A set of preliminary results have been generated to demonstrate the hydrologic differences between the existing and pre-development conditions. Four catchments in West campus were further examined (Fig. 3). The characteristics of these catchments under pre-development and existing conditions are summarized in Table 2. Values for curve numbers increase by 5-13% (Table 2) for these catchments. The hydrographs at the outlets are generated for existing and pre-development conditions for the 24-hr, 2-yr rainfall event (Fig. 4). The impact of increased imperviousness is seen clearly in both the increased peak flow and decreased time to peak.

Table 2. Physical characteristics of four selected sub-watersheds.

Catchment	Area (km^2)	Pre-development Conditions			Existing Conditions		
		CN (perm. areas)	% Imp.	Weighted CN	CN (perm. areas)	% Imp.	Weighted CN
C North	0.48	75	3%	75.6	77	11%	79.3
C South	0.15	75	0%	75.0	77	20%	81.1
D North	0.84	75	26%	81.0	77	51%	87.8
D South	0.36	75	16%	78.6	77	60%	89.5

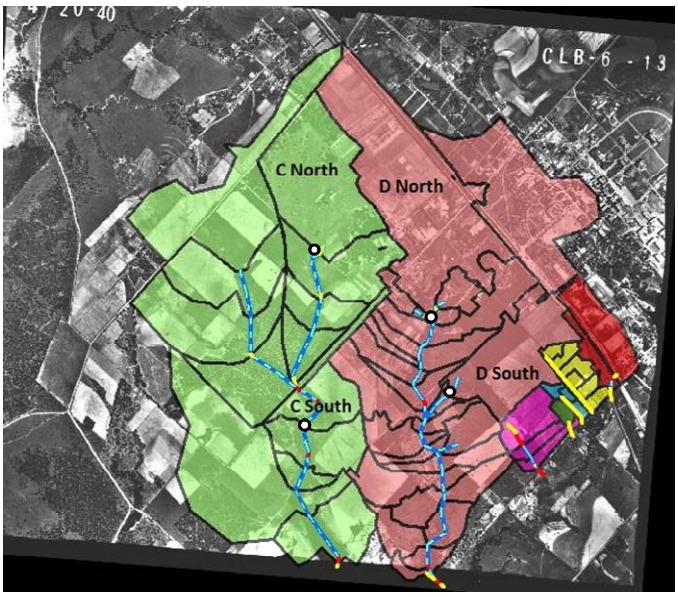

Figure 3. Location of four selected sub-watersheds on West Campus: C North, C South, D North, and D South, overlaying aerial photograph (Texas A&M University Libraries Map & GIS Collection and Services). Open circles show location of sub-watershed outlet.

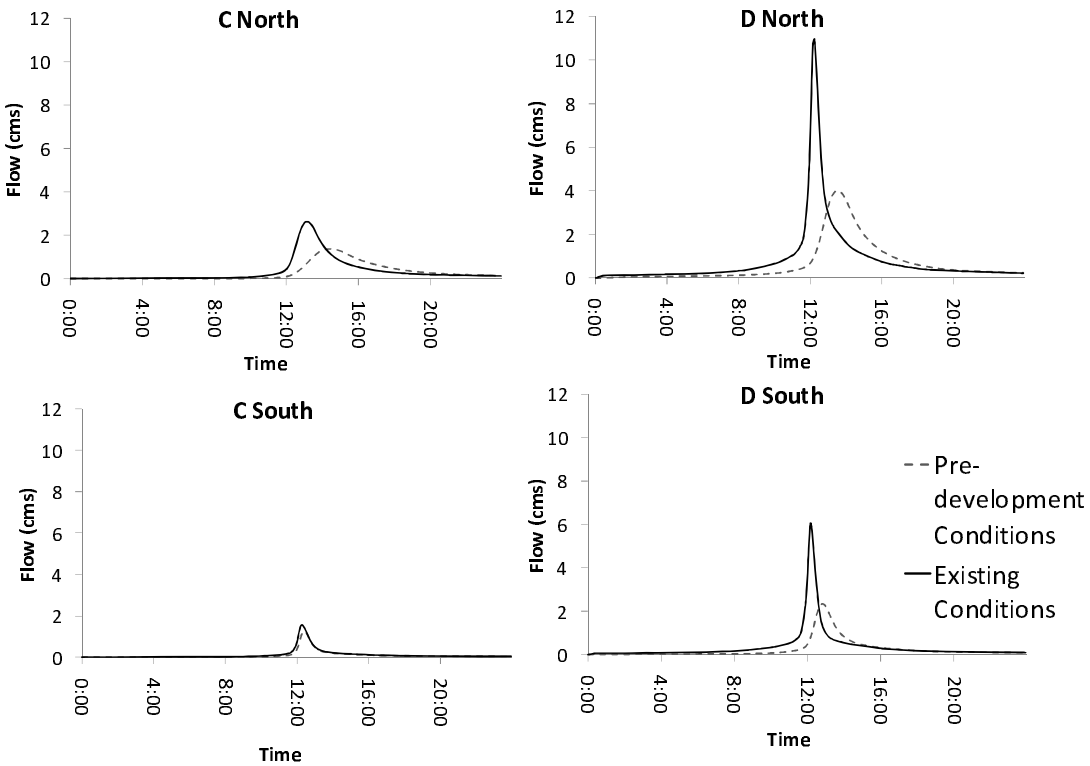

Figure 4. Hydrographs for pre-development and existing conditions at four selected sub-watersheds.

ONGOING WORK

This paper presents preliminary work to explore more hydrologically sustainable options for the current level and planned level of development in a campus watershed, as compared to pre-development conditions. LID strategies under consideration include both structural and ecological changes that may be designed and implemented to restore the creek to its predevelopment flow regime.

A Riparian Buffer System is suggested to improve both hydrological conditions and conditions for ecosystems. This system will be simulated to evaluate its contribution to hydrologic sustainability of the tributary. Two structural LID strategies, permeable pavement and rainwater harvesting systems, are designed to retain a 2-year 24-hour storm event so that there would be no runoff from these areas. Further modeling techniques will be explored to investigate the hydrologic performance of these LID strategies for 10-year and 100-year rainfall events. For larger events, rainfall that is not captured by the porous pavement will runoff as sheet flow. Rainfall that overflows the rainwater harvesting storage system will be discharged through the existing sewer system.

For future work, we will model the hydrologic effects of the development proposed in the master plan and investigate the effects of utilizing the three LID strategies described here.

ACKNOWLEDGEMENTS

Although the research described in this article has been funded wholly or in part by the United States Environmental Protection Agency through Grant #SU833944, it has not been subjected to the Agency's required peer and policy review and therefore does not necessarily reflect the views of the Agency and no official endorsement should be inferred.

The authors express their thanks and appreciation to the Texas A&M Physical Plant, Engineering Design Services (TAMU PP/EDS), College Station, Texas, Gary Struzick of Klotz Associates, and Anthony Holder of Turner, Collie and Braden, both of Houston, Texas for their help and sharing of valuable storm water, rainfall, survey, and data base information. This additional information was gathered in a separate project funded by Texas A&M Utilities, College Station, Texas and managed by TAMU PP/EDS.

AN INVESTIGATION OF INFILTRATION IN A CONSTRUCTED STORMWATER WETLAND AND IMPLICATIONS FOR GROUNDWATER QUALITY

Gerrad Jones[1], Kristen Mogavero[1], and Bridget M. Wadzuk[1]

[1]Department of Civil and Environmental Engineering, Villanova University, 800 Lancaster Avenue, Villanova, Pennsylvania, 19085;PH (610) 519-5365, FAX (610) 519-6754; email: gerrad.jones@villanova.edu, kristen.mogavero@villanova.edu, bridget.wadzuk@villanova.edu, M.ASCE

ABSTRACT

Traditionally, detention basins and constructed stormwater wetlands (CSW) have been used primarily for peak flow reduction and water quality improvement and are assumed to possess negligible infiltrative capabilities. However, the potential for storm water infiltration within these structures and the associated non-point source pollution of groundwater can not be ignored based on untested assumptions. The purpose of this research was to assess the infiltration capacity of a mature CSW on Villanova University's campus, in Villanova, Pennsylvania. Piezometers located within the CSW were monitored to develop a water budget and a chloride mass balance. The vertical gradients in the piezometers alternated between recharge and discharge patterns, with downward recharge gradients for baseflow conditions and upward discharge gradients after rainfall events. Preliminary water budget and chloride mass balance analyses suggest considerable reductions in volume and chloride load over a 6.5 day baseflow period in December, 2008. Although these findings suggest infiltration contributes to the water budget, it is unclear whether other explanations (e.g. perched water table or chloride stratification) could account for these patterns. Infiltration may be the most parsimonious explanation, but further research needs to be conducted to determine whether the negligible infiltration assumption is valid.

1 INTRODUCTION

Increased impervious surfaces around urban areas has adversely affected watersheds directly and indirectly (Arnold and Gibbons 1996). Water intercepted by impervious surfaces is conveyed to gutters, drains, or directly into bodies of water. The resulting flow has higher velocities and greater volumes when compared to similar watersheds with less impervious cover, which affects biota within the watershed and results in scour and erosion (Arnold and Gibbons 1996).

Water that is intercepted by impervious surfaces collects pollutants including sediments, nutrients, metals, petrochemicals (Weiss et al. 2008). Non-point source pollution from stormwater runoff is documented as a leading cause of impairment in freshwater lakes, rivers, and estuaries (U.S. EPA 2005). Although the concentration of these pollutants may be relatively small at their source, the total sum of these pollutants can become toxic as they collect in downstream receiving water bodies.

To mitigate the effects of large volume, high intensity flows generated from urban stormwater runoff, infiltration best management practices (BMPs) have become increasingly popular. Infiltration BMPs reduce runoff volumes by infiltrating stormwater into the soil where it is transported by sub-surface flow and/or recharges groundwater aquifers (PSBMPM 2005). Peak rate reduction BMPs are thought to have minimal volume reducing capabilities. Such BMPs include detention basins and CSWs, which are surface stormwater structures that provide temporary storage of stormwater runoff to prevent downstream flooding. These systems are thought to be relatively impermeable because the soils have been compacted and have low hydraulic conductivities (PSBMPM 2005).

With the rise in popularity of infiltrating stormwater management techniques, concern has arisen regarding potential groundwater contamination. Kwiatkowski et al. (2007) concluded that infiltration BMPs do not adversely affect the groundwater when properly located; however, the placement of BMPs can be dictated by necessity instead of ideality and ponded infiltration should not be ignored when considering the fate of pollutants and the potential for groundwater contamination (Weiss et al. 2008). Because infiltration within CSW's has largely been disregarded, the overall goal of this study was to assess the infiltration capacity of a CSW on Villanova University's campus. This was accomplished by 1) monitoring piezometers to discern vertical groundwater flow gradients, 2) constructing a water budget for Villanova University's CSW, and 3) performing a chloride mass balance on a chloride tracer study. If surface and ground water interactions are negligible, anomalous losses or gains of water and chloride should be minimal. Conversely, if anomalous losses or gains of water and chloride comprise a substantial portion of the total inflow or load, than surface and ground water interactions cannot be ignored.

2 SITE DESCRIPTION

The Villanova CSW is a mature wetland system located on Villanova University's campus in Villanova, Pennsylvania. The CSW was originally a detention basin that was retrofitted in 1999. During base flow conditions, a continuous flow of water enters the system from two pipes that drain Villanova University's campus and serves as the primary inputs of water into the system. The drainage area is approximately 23 hectares, and of this area, 57%, 31%, and 12% of the surfaces are impervious, semipervious, and pervious, respectively.

Since 2003, the Villanova CSW has been monitored for quantity and quality (Rea 2004; Woodruff 2005; Flynn 2008). During 2007, approximately 20% more water entered the system than exited for the entire year. Due to infrequent calibration, however, the quality of historical quantity data must be interpreted with caution. There is 60% and 80% removal efficiency of total phosphorus and total nitrogen, respectively for base flow conditions (Rea 2004); however, no research had been done to determine interactions between surface water and groundwater, which could have implications for the observed water quality improvements. Rea (2004) found that chloride concentrations between the inlet and outlet were similar for base flow conditions, with a 5% maximum removal. This suggests that chlorides within Villanova's CSW are relatively nonreactive and that infiltration may be negligible. A water budget and a chloride mass balance are developed as part of the current

research to further investigate the validity of these findings. A series of four piezometer nests in the CSW are monitored to discern vertical flow gradients and identify whether groundwater recharge or discharge is most probable.

3 METHODS

3.1 Piezometers

In November, 2007 four piezometer nests were installed within the CSW. When two or more piezometers are installed at the same location but at different depths, the vertical differences in head between the piezometers is indicative of vertical flow patterns. Each nest consists of three piezometers installed to depths of 0.9, 1.8, and 2.7m (3, 6, and 9 ft) below the ground surface. The water level in the piezometers was measured two to four times a week from January 2008 to December 2008. A downward gradient is indicative of a groundwater recharge system (i.e infiltration is occurring) while an upward gradient indicates groundwater discharge.

3.2 Water Budget

A water budget is a method for balancing the input and output of a system. Based on the conservation of mass, the water budget for the CSW can be summarized as follows:

$$\frac{dV_{sys}}{dt} = Q_{in} - Q_{out} \pm Q_{accumulation} \quad (1)$$

where $\frac{dV_{sys}}{dt}$ is the change in surface water volume within the system over time, and Q_{in}, Q_{out}, and $Q_{accumulation}$ are the volume rates of water coming into , out of , and accumulating within the system, respectively. Due to conservation of mass, and assuming constant density, the change in volume over time is zero. Equation 1 is reduced and rearranged to:

$$Q_{in} = Q_{out} \pm Q_{accumulation} \quad (2)$$

The flux terms (Q_{in} and Q_{out}) can be summarized as follows:

$$Q_{in} = Q_{inlet} + \frac{P}{\Delta t} \quad (3)$$

and

$$Q_{out} = Q_{outlet} + \frac{(E + T + I)}{\Delta t} \quad (4)$$

where Q_{inlet} and Q_{outlet} are the volume rates of water entering and exiting the system though pipes respectively, P is precipitation, E is evaporation, T is transpiration, I is infiltration, and Δt is the time step. Substituting equations 3 and 4 into 2 yields:

$$Q_{inlet} + \frac{P}{\Delta t} = Q_{outlet} + \frac{(E + T + I)}{\Delta t} + Q_{accumulation} \quad (5)$$

The present study for water budget analysis was conducted from December 4-10 under base flow conditions (steady state) resulting in negligible accumulation.

During this time, the average temperature was 2.5°C, so evaporation and transpiration were assumed to be negligible. Precipitation was zero. Reducing equation 5 and rearranging for infiltration yields:

$$\frac{I}{\Delta t} = Q_{inlet} - Q_{outlet} \quad (6)$$

To measure water inflow and outflow, three American Sigma 950 Flow meters were used at the inlet and outlet pipes at five minute intervals. The inlet and outlet flow rates were inserted into equation 6 to determine the volume of water infiltrated.

Darcy demonstrated that the discharge rate of water flowing through a soil under a hydraulic gradient is related to the hydraulic conductivity:

$$q = K_s iA \quad (7)$$

where q is the discharge rate, K_s is the saturated hydraulic conductivity, i is the hydraulic gradient, and A is the cross sectional area of the sample. If equation 7 is multiplied by time, the resulting equation is:

$$I = K_s iAt \quad (8)$$

which represents the volume of water infiltrated over a given time interval (from equation 6).Rearranging equation 8 to solve for saturated hydraulic conductivity yields:

$$K_s = \frac{I}{iAt} \quad (9)$$

The hydraulic gradient, *i*, is $\frac{dh}{dL}$, the change in head over the length of soil sample assuming saturated conditions. For the CSW, dh represents the depth of ponded water above the water table and dL represents the length of the soil column above the water table. Because the CSW has continuously ponded water, the soil beneath the system was assumed saturated. The water table was approximated using a linear regression model between four points at which the water table was known: three boring wells and Mill Creek, the downstream receiving water body (Blackmore 2006; Figure 1). The surface water elevation of the CSW was subtracted from the extrapolated groundwater table to calculate dh. A 2007 land survey of Villanova's CSW was used to get the ground elevation. The dL was determined by subtracting the ground elevation from the water table elevation. The hydraulic gradient was calculated at 40 points in five foot intervals along the cross section of the CSW shown in Figure 2. These estimates were averaged to estimate the total hydraulic gradient for the CSW. The ponded surface area of the CSW was used as the cross sectional area (A) and was determined using aerial photographs of the CSW and ArcMap 9.2. The time interval encompassed the duration of the study (6.48 days). Using these values it was possible to derive the average saturated hydraulic conductivity value for the CSW soils. The calculated hydraulic conductivity values were compared to values obtained from flexible wall falling head permeameter and a constant head permeameter tests that were conducted in October, 2008. The

calculated values were also compared to published values for similar soils (Johnson and Jensen, 2001).

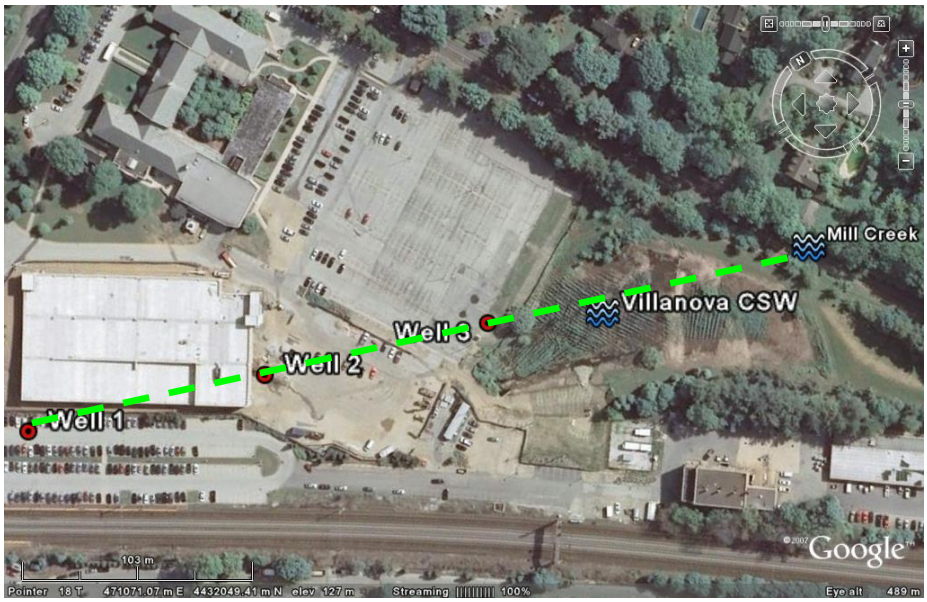

Fig. 1 The water table surrounding the CSW was determined from four locations on upstream and downstream ends (image obtained from Google Earth).

3.3 Chloride Mass Balance

Similar to the water budget, the mass balance is an application of the conservation of mass. The mass balance can be summarized as follows:

$$\frac{dM_{sys}}{dt} = \frac{M_{in} + M_{generated} - M_{out} - M_{reacted} \pm M_{accumulated}}{\Delta t} \qquad (10)$$

where $\frac{dM_{sys}}{dt}$ is the change in chloride mass within the system, M_{in} and M_{out} are the chloride mass entering and exiting the CSW respectively, $M_{generated}$ and $M_{reacted}$ is the mass of chloride generated or removed through chemical reactions, and $M_{accumlation}$ is the chloride mass that accumulates with the system. Chlorides move through natural systems unchanged so $M_{generated}$ and $M_{reacted}$ are negligible; assuming negligible accumulation and conservation of mass, equation 10 reduces to:

$$Mi_n = M_{out} \qquad (11)$$

On December 4 2008, 1080 grams of deicing salt was added to the inlet of the CSW. On December 6, 2008 a snow event introduced an additional unknown mass of chlorides into the wetland system as a result of roadway de-icing. Therefore, the initial chloride loading was unknown and was calculated by multiplying the inflow by the measured chloride concentrations and time. The chloride concentrations were monitored continuously (every five minutes) using conductivity probes (CTD-Divers by Schlumberger) at the inlet and outlet. The equipment was calibrated prior to the start of the study and was tested for accuracy using a solution of known conductivity at the end of the study to insure the divers were taking accurate measurements.

A relationship between the conductivity readings and chloride concentration was established. The maximum conductivity recorded by the probes was 2500 µS/cm. Deicing salt was added to each of three water samples until conductivity readings reached 1500, 2000, and 2500 µS/cm. The chloride concentration of the prepared samples was tested and the corresponding conductivity and chloride values were used to create the calibration curve (Figure 2). The calibration curve was used to obtain chloride concentrations based upon conductivity readings. The chloride concentration was multiplied by time and the flow of water entering and leaving the CSW to obtain a chloride load at the inlet and outlet, respectively. The mass of chloride entering the system was compared to the mass of chloride leaving.

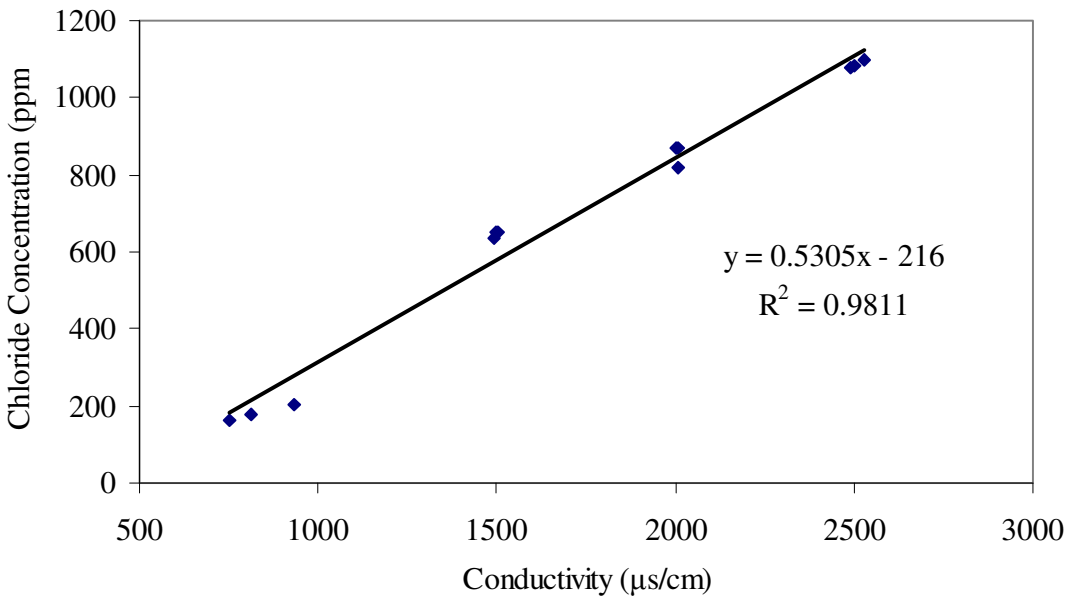

Fig. 2 Conductivity chloride calibration curve.

4 RESULTS

4.1 Piezometers

The piezometer readings indicate the existence of downward vertical flow gradients within the CSW, which occurs predominantly during baseflow conditions. The occurrence of precipitation and the number of days since a storm event seem to be the driving force behind whether an upward or downward flow gradient exists. During baseflow periods (i.e. no precipitation for at least 72 hours), downward flow gradients are predominant. However, storm events induce a reversal to an upward gradient, indicating groundwater discharge to the CSW. Figure 3 shows the water levels in the piezometers at one of the nests from August 1 to September 14, 2008 and the resulting gradient reversal following storm events.

4.2 Water Budget

Based on the water budget analysis, the inflow volume was greater than outflow volume by 57.8% during the 6.48 day experiment (Table 1). This suggests that infiltration was a large contributor to the overall water budget since other sources of water loss have been assumed negligible for the duration of the study.

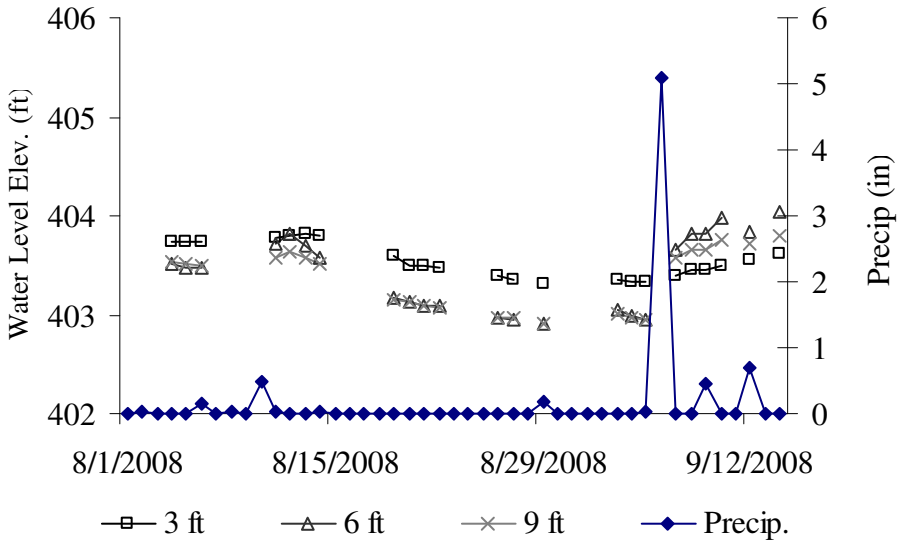

Fig. 3 Piezometer Readings and Precipitation

The water table between the three wells and Mill Creek formed a near perfect linear relationship (y = -0.0184x + 419.44 ft, y = -0.0184x + 127.84m, R^2 = 0.9999, Figure 4). Using the Darcy Equation (equation 9), the average saturated hydraulic conductivity for the entire CSW was calculated to be 2.61 cm/day (1.03 in/day) (Table 1), which is between the two values determined using a flexible wall falling head permeameter and a constant head permeameter, which ranged from 0.0014-9.20 in/day. Furthermore, Blackmore (2006) classified soils immediately adjacent to Villanova's CSW as ML and SM soils. For compacted ML soils, the hydraulic conductivity ranged from 0.92-5.40 in/day, and for compacted SM soils, the hydraulic conductivity ranged from 1.90-10.90 in/day (Johnsen and Jensen, 2001).

Table 1. Values used to calculate the average hydraulic conductivity (Equation 9).

Total Inflow (Qin)	55,372 ft^3, 1567m^3
Total Outflow (Qout)	31,928 ft^3, 904m^3
Total Volume Infiltrated (I)	23,444 ft^3, 663m^3
Ponded Surface Area (A)	42,549 ft^2, 3957m^2
Avg. Hydraulic Gradient (i)	1.44
Total Time (t)	6.48 days
Avg. Hydraulic Conductivity (Ks)	1.03 in/day, 2.61cm/day

4.3 Chloride Mass Balance

Conductivity is a good surrogate measure of chloride concentration (R^2=0.98, Figure 2). The chloride loading leaving the CSW was 500% less than that of the inlet, suggesting a significant removal of chlorides through the CSW (Figure 5). Previous estimates of the retention time under baseflow were about 50 hours (Wadzuk et al. 2006).

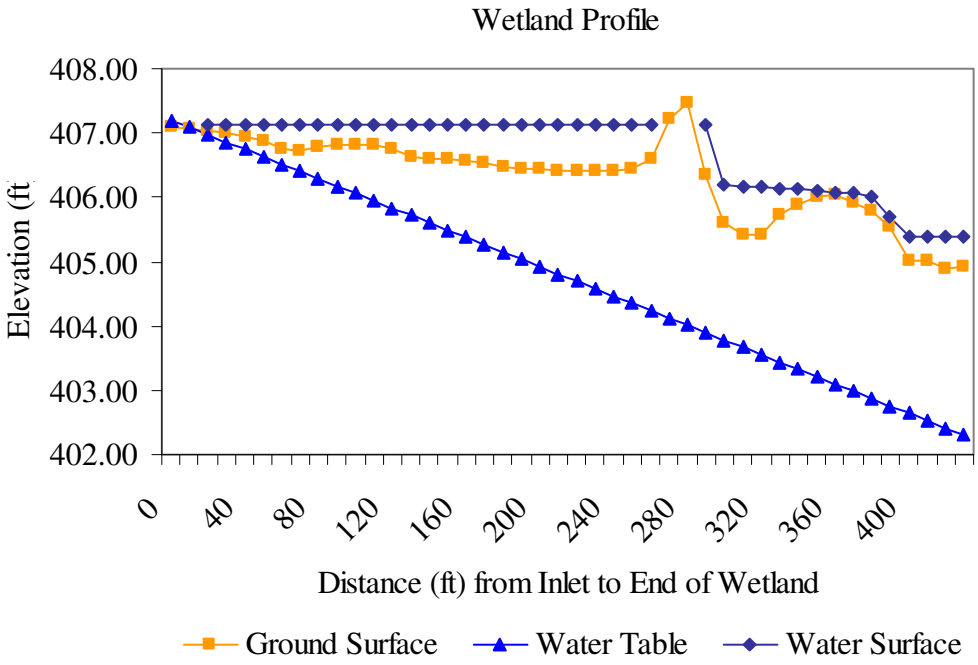

Fig. 4 Cross sectional profile of the wetland was used to calculate the gradient over 40 intervals. Note the groundwater intersects the surface at one location, the inlet.

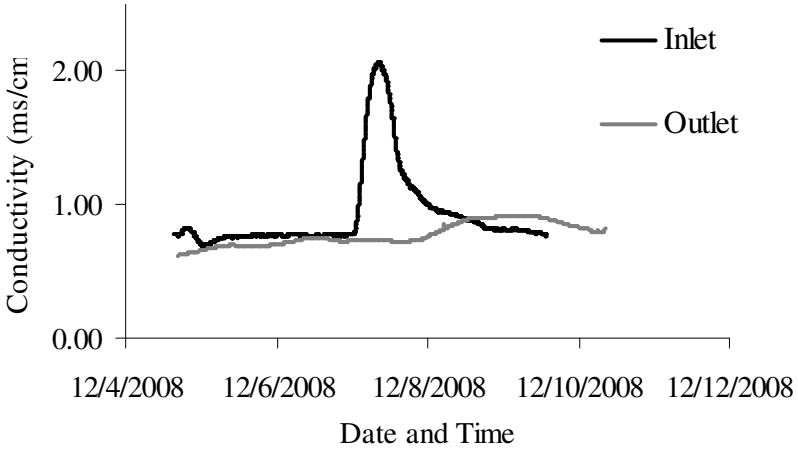

Fig. 5 Inlet and outlet conductivity readings

5 DISCUSSION

The downward flow gradients observed in the piezometers during baseflow conditions suggest that infiltration is occurring. Forty to 49% percent of the total flow moving through the wetland over the year occurs during baseflow conditions (Woodruff, 2005) and any pollutants introduced to the CSW during baseflow, as well as storm flow conditions, could be infiltrated into the groundwater. The downward flow gradients, however, do not conclusively show that infiltration is occurring, but rather that it could be occurring if the soil is permeable enough to allow infiltration to occur. The results of the water budget and chloride mass balance analyses further

suggest considerable infiltration is occurring within Villanova's CSW; however, in order to draw accurate conclusions based on these results, the major assumptions made within the water budget, the chloride mass balance, and the Darcy Equation need to be addressed.

Due to the low average temperature (2.5°C) in conjunction with high average relative humidity (84%), evaporation and transpiration were assumed to be negligible. Additionally, plants lose water through transpiration during metabolic activities and for cooling. The occurrence of low temperatures and the assumption that plants were dormant during the study period provides validation for the assumption of minimal water losses due to transpiration.

During this study the flows were measured using Sigma 950 flow meters. These sensors are prone to take inaccurate readings at low flows. Given that this was a low flow study, some inherent error surrounds the flow readings; however, all the flow meters were the same and were likely to have responded similarly to low flows thereby minimizing the effects of this problem. Furthermore, all instrumentation was calibrated daily to ensure the most accurate flow readings.

Twenty-four hours after chlorides were added to the inlet, conductivity readings were taken in a vertical cross section of the water column. Within this cross section, the conductivity at the surface was 800 μS/cm while that at the bottom (~0.5 m below the surface) was 5000 μS/cm. Like other wetland systems, Villanova's CSW has a deep organic litter layer. It is possible that within this litter layer, chloride stratification occurred within the water column. Because little water flows through this layer, it is possible that chlorides could have accumulated within the CSW. Therefore, the accumulation assumption may have been violated. Rea (2004) noted, however, that inlet and outlet chloride concentrations were similar and suggested that chloride concentrations pass uninhibited through the system. Regardless, any conclusions based on the fate of chlorides should be made with caution.

The ground surface elevation of the CSW averaged 0.45m (1.5 ft) above the estimated groundwater table. The logical question to follow is, "how is the surface water ponding on top of the groundwater?" It is possible that the CSW is atop a perched water table. In this case, the CSW would be on top of a limiting layer resulting in a gradient of zero (dh=0). As a result, infiltration would be negligible. However, a perched water table does not explain the 43% reduction in water moving through the CSW. Furthermore, a perched water table would not explain the reduction in chloride concentration since chlorides would not have been able to penetrate the limiting layer. It is possible that the CSW is actually a mounded system that resulted from the constant inflow of water from Villanova's campus. Villanova's CSW was originally a detention basin that was designed to retain water. Therefore, overland flow and any discharge from the University's campus would collect within the basin. If the infiltration rate over the entire area of the CSW was less than the inflow rate ($I/\Delta t < Q_{inlet}$), then water would pond on the surface of the CSW. This condition would also result in saturated soils, an assumption on which the Darcy Equation is based, which validates the calculation of the hydraulic conductivity. The correlation of the hydraulic conductivity value obtained using the Darcy Equation with published values for similar type soil indicates that the estimated volume of infiltrated water is realistic. Therefore, using the Darcy Equation to account for

anomalous losses within the water budget seems plausible.

6 CONCLUSIONS & RECOMMENDATIONS

Urban stormwater runoff is one of the greatest sources of water quality impairment in rivers and lakes (U.S. EPA 2005). With the rise in popularity of stormwater management techniques that infiltrate polluted runoff, there is concern regarding potential groundwater contamination. Because of the risk of polluting groundwater, the goal of this research was to determine whether infiltration was negligible within peak rate reducing BMPs. In constructing a water budget over a 6.48 day base flow period, anomalous losses accounted for 43% of the total volume of water within the system. Infiltration is the most parsimonious explanation accounting for losses within the system. Similarly, chloride loadings were reduced by 500%; however, due to stratification and a thick litter layer within the CSW, it is unknown whether or not losses in chlorides were due to movement into the groundwater or storage within the wetland system.

Before any definitive conclusions can be drawn about infiltration within this system, multiple base flow water budgets need to be conducted. Furthermore, low flow equipment should be used in order to have the most accurate readings of inflow and outflow data. Finally, more research needs to be conducted to determine the fate of chlorides within the system. Specifically, how does adding chloride to the surface water affect the chloride concentration in the ground water? This could easily be examined using piezometers at varying depths with the soil column below the CSW. Chloride concentrations leaving the CSW could be compared to chloride concentrations at the headwaters of Mill Creek. If chlorides are leaving the CSW and entering the water table, they should appear within the headwaters of Mill Creek.

The findings of this study suggest that infiltration may be a substantial portion of the CSW water budget; however, before any definitive conclusions can be drawn, more research needs to be conducted, specifically addressing the low flow measurement problem and the fate of chlorides within the system. Research regarding infiltration in this CSW will be on-going, and any associated water quality impacts will be investigated.

ABSTRACT

Low Impact Development (LID) strategies are being encouraged in many communities as an approach to reduce potential adverse impacts of development on receiving streams. Many questions exist regarding how well various LID strategies perform in different settings, just as similar questions have been raised regarding performance of traditional stormwater best management practices (BMPs). Over a decade ago, Urban Water Resources Research Council (UWRRC) members worked to develop a set of standardized monitoring and reporting protocols for traditional BMPs and establish a master database for the purpose of evaluating BMP performance and the factors affecting performance. This effort culminated in the International Stormwater BMP Database (www.bmpdatabase.org), which contains data for over 350 BMPs and continues to operate as a clearinghouse for stormwater BMP data and performance analyses. During 2008-2009, the Stormwater BMP Database project expanded to better integrate LID into the database. This paper provides a condensed overview and progress report on the LID-focused effort, including the following topics: 1) monitoring guidance for LID at the overall site development level; 2) an overview of recent changes to the stormwater BMP database to better accommodate LID studies, 3) a summary of LID studies currently included in the database; and 4) initial concepts related to evaluating performance of LID studies.

ACKNOWLEDGEMENTS

The International Stormwater BMP Database project is a long-term project that was conceptualized in 1996 by Urban Water Resource Research Council members and funded by the U.S. Environmental Protection Agency. The project has grown and been sustained by support from many individuals and organizations, both financially and through submission of BMP studies. Supporting organizations include the Water Environment Research Foundation, the U.S. Environmental Protection Agency, the Environmental and Water Resources Institute of the American Society of Civil Engineers, the Federal Highway Administration, and the American Public Works Association. During 2008-2009, the primary project focus has been on better integration of LID into the database. This effort has included monitoring, standardized reporting protocols, and analysis approaches that better assess hydrologic performance of BMPs and overall LID sites. In December 2008, an expert panel was convened to provide input and guidance on this effort. Geosyntec Consultants and Wright Water Engineers (WWE) would like

to acknowledge the following experts who were instrumental in developing many of the concepts included in this paper:

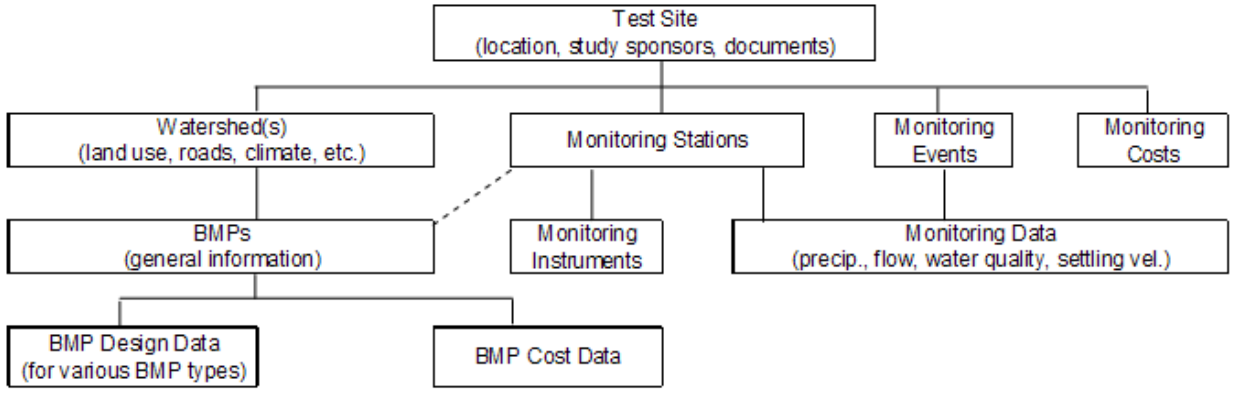
Richard Horner, P.E., Ph.D., University of Washington
Bill Hunt, P.E., Ph.D., North Carolina State University
Bob Pitt, P.E., Ph.D., University of Alabama
Robert Roseen, P.E. Ph.D., University of New Hampshire
Robert Traver, P.E., Ph.D., Villanova University
Ben Urbonas, P.E., Urban Watersheds, LLC

INTRODUCTION

Low Impact Development (LID) strategies are being encouraged in many local communities as an approach to reduce potential adverse impacts of development on receiving streams. Many questions exist regarding how well various LID strategies perform in different settings, just as similar questions have been raised regarding performance of traditional stormwater best management practices (BMPs). This paper highlights work completed under the International Stormwater BMP Database Project during 2008-2009 to provide guidance related to LID monitoring, reporting and analysis. *(Note: At the time of submission of this paper, key aspects of these efforts had been released in draft form for review and comment; therefore, the www.bmpdatabase.org website should be referenced for the most current version of recommendations provided in this paper.)*

GENERAL FRAMEWORK FOR LID MONITORING GUIDANCE

While many of the individual LID techniques are comparable to some types of traditional stormwater BMPs, LID is an overall design philosophy based on the implementation of multiple, distributed small-scale controls throughout a development site. Monitoring guidance applicable to traditional BMPs can generally be followed when monitoring individual LID BMPs. However, effectively monitoring overall LID sites can offer a unique challenge and is the focus of a stand-alone chapter in the 2009 update to the *Urban Stormwater BMP Monitoring Manual* (Geosyntec and WWE 2009). In order to provide guidance for LID monitoring studies, it is important to understand the type of LID site being monitoring, included the following general settings:



1) **Individual LID Practice Monitoring**: In this case, an individual LID practice (e.g., a bioretention cell, a biofilter, or permeable pavement parking lot) is isolated to monitor performance. This may also include monitoring a combination of practices in series within a relatively small drainage area such as a biofilter preceding a bioretention cell in a parking lot. These types of monitoring programs can generally follow the guidance for traditional stormwater BMPs, with particular attention to designing studies in a manner that incorporates a robust hydrologic monitoring component and properly addresses the challenges that come with monitoring small watersheds with often poorly structured inflow and outflow monitoring stations. A number of studies exist that demonstrate individual LID practice monitoring approaches such as Hunt et al. (2008), Davis (2008), Emerson and Traver (2008), Barrett et al. (2006), Roseen et al. (2009), and Li et al. (2009).

2) **Overall Site Level LID Monitoring**: In this case, the composite site level performance which includes multiple distributed controls is monitored. Fewer examples exist for these types of studies, with several notable examples including the Somerset Development in Maryland (Cheng et al. 2003), Jordan Cove in Connecticut (Claussen 2007) and Burnsville, MD (Barr 2006). Due to the varying types, number, and spatial distribution of the LID practices, and the lack of specific discharge locations, these types of monitoring study designs can present significant challenges to the researcher. In many cases, the designs of sites must specifically incorporate features to facilitate effective monitoring. Historically, reference or "parallel" watershed study designs have often been used to assess performance at the site level. Alternatively, "before and after" studies can provide insight into how well a LID site is performing relative to pre-development hydrology, which is a fundamental goal for LID projects.
3) **Hybrid LID-Traditional Site Level Monitoring**: In this case, a site to be monitored may include multiple distributed controls and LID principles, but it may also incorporate some traditional larger-scale stormwater management components at the downstream end of the study site, particularly for flood control. For example, a study by Selbig and Bannerman (2008) involves a Cross Plains, WI LID site with multiple distributed controls and a larger-scale infiltration basin located at the downstream end of the drainage. Retrofits of existing subdivisions would often fall into this category. Historic approaches to monitoring these types of sites are similar to those for the overall LID-based site development described above. These types of sites may be more straightforward to monitor relative to the overall LID-based sites because there is often a centralized discharge point to facilitate sample collection.

ENTERING LID STUDIES INTO THE INTERNATIONAL STORMWATER BMP DATABASE

When submitting a LID study to the BMP Database, data must be entered in accordance with BMP Database Reporting Protocols specified in the 2009 Excel spreadsheet package downloaded from www.bmpdatabase.org/DataEntry.htm. Figure 1 provides a simple overview of the general types of data requested, followed by brief descriptions of each major component.

Figure 1. Overview of Data Requirements for Submittal to the BMP Database

General Test Site Information

The purpose of the general test site data set is to identify the study, its location, climate characteristics, involved parties and cost of monitoring for the study. Additionally, the "study documents" spreadsheet enables the user to attach supporting information such as links to published studies, quality assurance plans, photos, BMP and site layouts, and other information.

Watershed Information

The purpose of the watershed table is to identify the conditions in the area tributary to the BMP. For example, important factors for successful designs of infiltration-type BMPs include watershed parameters such as soil type, imperviousness, and storm drainage system efficiency. More than one watershed may be entered for LID studies that use a reference (i.e., control) watershed to assess performance. For LID studies, there may also be more than one reference watershed in cases where pre-development hydrology and water quality for the site are monitored, along with a comparative watershed developed using traditional development designs. In order to conduct valid comparisons of performance between test watersheds and reference watersheds, it is critical to thoroughly document the watershed conditions for both. For example, a test and reference watershed could have a similar tributary area and number of homes (e.g., "look the same"), but the underlying soil types could be dramatically different, which would be a critical difference between the two watersheds in terms of evaluating performance of the LID design.

General BMP Information

General information and cost data for BMPs are requested for all BMP types, including structural and non-structural BMPs and site-scale LID sites. General information requested includes parameters such as date of installation, various basic design parameters, maintenance and rehabilitation types and frequencies, and cost data. Additionally, BMP-specific design parameters are also requested. An overview of the types of information requested for structural, nonstructural, and LID sites is provided below.

Structural BMPs

Data requested for each structural BMP vary according to the following common groups of BMPs: Detention (Dry) Basins, Retention (Wet) Ponds, Infiltration Basins, Percolation Trenches/Dry Wells, Porous Pavement, Wetland Basins, Wetland Channels/Swales, Biofilters (buffer strips and swales), Media Filters, Bioretention, Stormwater Harvesting (cisterns), Green Roofs, and Manufactured Devices. An "Other" BMP category is also provided to enable flexibility for entry of BMPs that may not fit a pre-defined category. A "Treatment Train" BMP option is also provided. Most of the design parameters requested in the structural BMP tables are required in order to compare the effectiveness of various BMP designs. Table 1 provides a summary of LID practices currently entered into the database. Table 2 provides a summary of design data requirements proposed for bioretention practices, including the "general" BMP information requested for all BMP types.

In order for monitoring data to be interpreted in proper context, it is important to provide thorough documentation of the BMP as constructed in the field, identify whether engineering oversight was provided during construction, and provide a proper description of the BMP's condition during the study. For example, a common problem with bioretention cells and pervious pavements is that the as-built conditions deviate from the design. Without such

information, poor performance of a BMP may be falsely attributed to design characteristics, when the design conditions did not actually exist in the field. Additionally, a well designed and properly installed, but poorly maintained BMP, is unlikely to perform well. It is important to clearly document the maintenance and/or rehabilitation status of the BMP so that researchers using data from the study can appropriately group BMPs with comparable maintenance conditions for performance analysis. The BMP Database accepts properly conducted studies, regardless of whether the BMP performs well, because one of the primary long-term purposes of the BMP Database is to identify factors affecting BMP performance. Improper installation and poor maintenance are key factors that must be properly documented.

Table 1. Overview of Bioretention, Green Roof and Porous Pavement Studies in the BMP Database as of January 2009

LID Techniques Monitored	Source of Studies
Porous Pavement (10)	Southwest Florida Water Management District; Urban Drainage and Flood Control District, Denver CO; City of Austin, TX
Bioretention (10-15)	University of New Hampshire Stormwater Center; North Carolina State University; Villanova Urban Stormwater Partnership; City of Portland, OR, Bureau of Environmental Services
Green Roofs (4)	City of Portland, OR, Bureau of Environmental Services

Non-Structural BMPs

Non-structural BMP data requested are generally narrative/descriptive information on the type and extent of BMP practice being implemented, as well as cost data. Non-structural BMPs are divided into the general categories of education, maintenance, recycling, and source controls. Non-structural practices are often a component of LID sites.

LID Sites

Because LID sites attempt to mimic pre-development site hydrologic conditions by controlling runoff close to its source, BMPs are typically dispersed throughout a development site. Reporting for LID sites includes both individual practices and performance for the overall site. In cases where individual LID practices (e.g., bioretention cells) are monitored, reporting protocols for the individual practices described under "structural BMPs" would be used. When site-scale LID monitoring is conducted, a set of parameters describing the extent to which a broad suite of LID practices is implemented would be entered, as summarized in Table 3. These reporting parameters would be requested in addition to the previously described watershed and monitoring data provided for conventional studies. As discussions related to reporting parameters and performance evaluation approaches for LID sites progress, it is anticipated that additional hydrologic parameters or metrics may also be requested for site-scale LID studies.

Table 2. Example of BMP Design Information Requested for Bioretention Practices
(Draft Released for Review and Comment January 2009; Subject to Revision)

General Information (all BMP types)	Bioretention Design Information
Type of BMP Being Tested (*from Pick-List)*	BMP Name
Basis of Design (e.g., 2-yr, 24 hr storm, water quality volume in watershed inches, etc.)	Type of Bioretention (Pick List: bioretention cell (non-linear), off-line bioretention, in-line bioretention, sloped (weep garden), sloped biodetention vegetative barrier, tree filter box)
Source of Design Guidance for BMP	Ratio of Tributary Area to Bioretention Surface Area (hydraulic loading)
Date Facility Placed in Service	Is Pretreatment Provided? (Y/N)
Number of Inflow Points	Description of Pretreatment, if present
BMP Designed to Bypass or Overflow	Description of Flow Entrance
Upstream Treatment Provided?	Bioretention Surface Area
Describe Upstream Treatment (if any)	Ponding Volume above Bioretention Media Surface
Name of Upstream BMP(s) (comma separated list upstream to downstream)	Average Ponding Depth above Bioretention Media Surface
General Configuration of BMP in Tributary Watershed (i.e., end of pipe, source control, off-line, on-line)	Is "Internal Water Storage Zone" Created? (Y/N)
Was qualified engineering oversight provided at construction? (Y/N)	Subsurface Storage Volume
Was structure installed as designed? (Y/N)	If subsurface storage provided, then height of outlet above bottom of bioretention media
Maintenance and Conditions of BMP	Bioretention Media: Natural or Amended
Maintenance Type and Frequency	Bioretention Media Depth
Last Rehabilitation Date	Bioretention Media Design Specifications
Type of Rehabilitation	Bioretention Media "P" Index (Phosphorus Index)
Description, Types, and Designs of Outlets	Description of Supplemental Bioretention Media Characteristics (clay content, pH, cation exchange capacity, carbon:nitrogen ratio, moisture content, metals contents, inerts content)
Qualitative evaluation of condition	Description of Vegetation Community (canopy layers and their approximate cover [stems/acre], species)
For BMPs without permanent pool, does surface ponding exist beyond design drain time?	Description of Mulch (if present)
If clogging present, estimate % of total surface area of structure affected	Surface Infiltration Rate
Describe BMP/Comments	Design Infiltration Rate (including safety factor for clogging)
	Is an Underdrain Provided? (Y/N)
	Description and Dimensions of Underdrain, if present
	Underdrain Gravel Layer Thickness, if present
	Description and Dimensions of Surface Overflow, if present
	Is a Hydraulic Restriction Layer (Liner) Provided? (Y/N)
	Description of Hydraulic Restriction Layer, if present

Table 3. Site-scale Low Impact Development
(Released for Review and Comment January 2009; Subject to Revision)

Low Impact Development at Site Level Design Information (Source: Horner 2009)	
Parameter	**Explanatory Comment**
BMP Name	Name of the Overall LID Site
Describe Site Design	Provide a brief overall description providing context for how specific design elements fit together.
Describe Monitoring Design	Provide a brief description of monitoring design to ensure proper use of data by others.
Comments/Other Description	Additional information, as desired by data provider.
Describe the Extent to Which the Following LID Practices Were Implemented in Site Design:	**Instructions:** These are narrative fields, but quantitative data should be provided to the extent it is available. If the practice is not implemented, this should be stated instead of leaving the field blank. For discrete practices (e.g., permeable pavement, bioretention), design data should also be provided in their respective BMP tables.
Conservation	Conserving natural areas including existing trees, other vegetation, and soils.
Minimizing Disturbance	Minimizing soil excavation and compaction and vegetation disturbance.
Minimizing Building Coverage	Minimizing impervious rooftops and building footprints.
Minimizing Travelway Coverage	Constructing streets, driveways, sidewalks, and parking lot aisles to the minimum widths necessary, provided that public safety and a walkable environment for pedestrians are not compromised.
Maintaining Natural Drainage Patterns and Designing Drainage Paths to Increase Time of Concentration	Maintaining natural drainage patterns and designing drainage paths to increase time of concentration—Maintaining depressions, natural swales, emphasizing sheet flow instead of concentrated flow; increasing the number and lengths of flow paths; maximizing non-hardened drainage conveyances; and maximizing vegetation in areas that generate and convey runoff.
Source Controls	Minimizing pollutants; isolating pollutants from contact with rainfall or runoff by segregating, covering, containing, and/or enclosing pollutant-generating materials, wastes, and activities; conserving water to reduce non-stormwater discharges.
Permeable Pavements	Constructing low-traffic areas with permeable surfaces such as porous asphalt, open-graded Portland cement concrete, coarse granular materials, concrete or plastic unit pavers, and plastic grid systems (areas that should be considered for permeable surfaces include, but are not limited to, driveways, patio slabs, walkways and sidewalks, trails, alleys, and overflow or otherwise lightly-used parking lots).
Natural Drainage System Elements	Bioretention area (rain garden), vegetated swale, vegetated filter strip.
Stormwater Harvesting	Cisterns, rain barrels.
Green Roof (vegetated)	Vegetated roofs with stormwater-related design components.

Monitored Events, Monitoring Stations and Monitoring Results

The BMP Database requires information to be provided regarding the events monitored, instrumentation at monitoring stations, and monitoring results. For sites also monitoring groundwater levels, soil moisture or particle size distributions, the water quality spreadsheet can be used to enter such data. Data types requested for LID studies include:

- **Precipitation:** Date/time that the event began and ended, total depth and peak one-hour precipitation rate. This is important because performance may be significantly different depending on the type of storm event.
- **Flow (Runoff, Bypass, Base Flow):** Storm runoff directly affects the hydraulics of BMPs. Types of runoff data requested include runoff volumes into, from or bypassing the BMP, and peak flow rates.
- **Water Quality:** Water quality data in combination with flow data for a monitoring event are used to calculate loads of each constituent, which are fundamental for comparing the performance of BMPs at different sites, locations and regions.

EVALUATING PERFORMANCE FOR LID STUDIES

When comparing LID (and/or other distributed controls) sites, performance metrics are needed that move beyond water quality and into evaluation of site hydrology. This can be facilitated by reporting a set of composite site characteristics and hydrologic performance metrics that collectively quantify the extent of LID implemented at a site. Some of these metrics are easier to obtain than others; however, a broad list is provided below for consideration and represents initial brainstorming for performance metrics that could be applied to LID studies. These concepts will continue to be refined during 2009. (*Water quality evaluation would follow approaches similar to traditional BMP studies as described in Geosyntec and WWE [2009] and are not repeated below, but can be obtained from* www.bmpdatabase.org.)

Composite Site Characteristics

An ideal set of composite site characteristics allows for quantification of the extent of LID at a site so that comparisons can be made among LID sites regardless of size, location, and other environmental factors. These characteristics can be estimated for a site, regardless of whether LID techniques have been implemented or whether development has yet occurred. Some composite site characteristics that could be considered include:

- Hydrologically available temporary storage at the site, potentially including these components:
    - Surface storage, including natural, pervious, and impervious depression storage and surface detention that is not surface discharged. This would represent volume that is eventually lost through ET and/or infiltration but would not become a surface discharge.
    - Surface storage, including natural, pervious, and impervious depression storage and surface detention that is eventually surface discharged, but after detention and/or filtration that slows the discharge.
    - Subsurface LID practice temporary storage including all pore space within LID practices (e.g., in bioretention soils, stone infiltration trenches, planter media, green roof media, etc.) that it is not surface discharged. This would also represent volume that is eventually recovered through ET and/or infiltration.

  - Subsurface LID practice temporary storage including all pore space within LID practices (e.g., in bioretention soils, stone infiltration trenches, planter media, green roof media, etc.) that is eventually surface discharged via an underdrain system.
  - Volume in tanks or surface or subsurface detention facilities that is eventually recovered through ET and/or infiltration.
  - Volume in cisterns and rain barrels in excess of average long-term retained volume that is eventually recovered through ET (e.g., irrigation reuse, cooling water makeup reuse, drip hose, etc.) and/or infiltration.
- The tributary areas and characteristics to each of the components above, perhaps expressed as weighted site averages.
- Estimated volume of pore space within the natural duff layer, compost, mulches, etc.
- Maximum (summer), minimum (winter) and annual average potential vegetative canopy interception.
- Area weighted saturated hydraulic conductivity and field capacity of the top foot of native or post construction soils not within LID features.

Hydrologic Performance Metrics

Another method for comparing sites is to treat certain hydrologic performance metrics as indicators of the extent of LID present at a site. Such metrics should represent the combined long-term effects of all LID practices on the surface water flows at a site. In December 2008, an expert panel was convened to provide input on potential approaches to evaluating LID sites, an initial set of potential metrics was proposed for evaluating LID sites (Horner 2009) and include:

- Largest rainfall event (depth and duration) producing no discharge.
- Long-term cumulative discharge volume per unit rainfall (long-term volumetric runoff coefficient).
- Largest rainfall quantity producing no discharge with a "wet" versus "dry" Antecedent Precipitation Index (API). API is defined as APIt = Rt-1 + k*APIt-1, where APIt is the index for day t, APIt-1 is the index for the previous day, Rt-1 is the rainfall depth for the previous day in inches, and k is a coefficient reflecting the relative rate of soil drying (Linsley, Kohler and Paulhus 1982). The value of k can range from approximately 0.85 (sand) to 0.98 (clay). "Wet" is considered to be API > 0.6 and "dry" as API <0.6.
- Average of storm-by-storm volumetric runoff coefficient under wet and dry API.
- Largest rainfall quantity producing no discharge with a varying 7-day antecedent rainfall.
- Peak flow rates for specific average rainfall intensities over the time of concentration. For example, if the time of concentration for a site is 10 minutes, the peak flow rate resulting from an average intensity of 0.1 in/hr, 0.2 in/hr, 0.3 in/hr, etc., over 10 minutes under varied antecedent moisture conditions.
- Hydrograph lag time (time to center of mass of outflow hydrograph volume minus time to center of mass of outflow hydrograph).
- Time of concentration under varied rainfall intensities and APIs determined from analysis of hyetographs and hydrographs.

Additionally, other metrics are also being considered, such as those proposed by Davis (2008) for evaluation of bioretention cells. These metrics include: three metrics for describing the restoration of hydrologic conditions by bioretention facilities: 1) the peak flow rate ratio of effluent to influent (R_{peak}), 2) the peak discharge time span ratio of effluent to influent (R_{delay}),

and 3) the effluent/influent volume ratio (f_V). An example of application of the Davis metrics to six bioretention cells is provided by Li et al. (2009).

CONCLUSIONS

During 2008-2009 substantive revisions to the International Stormwater BMP Database have been completed and others are underway. These include development of monitoring guidance for LID studies, data reporting protocols, and initial development of concepts enabling assessment of performance among LID sites. See the www.bmpdatabase.org website for the most up-to-date monitoring and reporting protocols.

Abstract

The City of Kansas City Missouri is perfectly positioned for demonstrating the use and effectiveness of applying green infrastructure for combined sewer overflow (CSO) control. The Kansas City Water Services Department (WSD) provides wastewater collection and treatment for approximately 650,000 people, located within the City and in 27 tributary or "satellite" communities. Approximately 56 square miles within Kansas City, south of the Missouri River, are served by combined sewers. The City's combined sewers overflow to a number of receiving streams, including the Kansas River, the Missouri River, the Blue River and Brush Creek. Kansas City has also suffered from severe flooding issues. Lives have been lost and significant property damage has occurred as a result of flooding, in large part due to substantial increases in stormwater runoff from ever-increasing impervious surfaces.

Kansas City's WSD has conducted extensive modeling and economic studies of its combined sewer system over the last 5 years, in preparation for submittal of its long term control plan to EPA, in January 2009. These studies and recent funding opportunities have provided the impetus for selection of Kansas City as a case study location to demonstrate the efficacy and sustainability of green infrastructure approaches in an urban-core neighborhood served by a combined sewer system. The intent of this project is to compile data and demonstrate the water quality and quantity results from larger scale application of LID or micro-BMP retrofits in a subcatchment.

Installed monitoring equipment will measure changes in peak flow, total volume and pollutant mass of storm events and overflows for a two-year period. The project also includes working with community-based partners to plan, design, implement, monitor and evaluate green infrastructure acceptance from a socio-economic context. Economic, hydraulic, and water quality modeling is also being done. Results from pre-implementation monitoring and expected modeling outcomes developed to date will be presented.

Key Words: Urban Stormwater and Wastewater Management, CSO Reduction, Modeling, Economic Analyses, Wet Weather Flow

Introduction

Advanced design concepts such as Low Impact Development (LID) and Green Solutions (or upland runoff control techniques) are currently being encouraged by the U.S.EPA (EPA) as a management practice to contain and control stormwater at the lot or upland residential parcel level. These controls have shown that when implemented and maintained properly, they can increase retention at the runoff source – decreasing the runoff volume entering the drainage system and the demand on a drainage system. Both developed stormwater and combined sewersheds can benefit from the added storage from areas retrofitted with bioretention cells or rain gardens and other management, e.g., inlet retrofits or curb-cuts with tree plantings.

This paper documents an effort by the U.S. EPA to demonstrate the efficacy of implementing integrated, green infrastructure-based solutions to support control of wet-weather flow pollution problems in an urban core neighborhood within a combined sewer system. This pilot project is part of a larger adaptive management approach to incorporate Green Solutions into the Kansas City long term control plan. The project involves local and regional efforts to provide the "basis-for-success" of the implementation of Green Solution infrastructure and stormwater management at the neighborhood, watershed, and regional levels. The project will demonstrate the strategy and methodology, including model support, for identifying where and how Green Solutions will be implemented within Kansas City, Missouri.

The key objectives in this project are to:

- Demonstrate the efficacy and sustainability of green solutions in an urban-core neighborhood having a combined sewer system
- Develop a methodology for implementation of Green Solutions
- Compile data to demonstrate the effects on the receiving system of Green Solutions for an urban watershed
- Measure the changes in both the peak flow, total volume and pollutant mass of a storm event in the receiving system or the reduction of combined wastewater volumes, pollutant loads and overflows
- Develop a model for predicting the quality and quantity benefits of implementing Green Solutions

- Compare economic costs and benefits of integrated green and grey solutions

Background

The City of Kansas City Missouri is perfectly positioned for demonstrating the use and effectiveness of applying green infrastructure for combined sewer overflow (CSO) control. The Kansas City Water Services Department (WSD) provides wastewater collection and treatment for approximately 650,000 people, located within the City and in 27 tributary or "satellite" communities. Approximately 56 square miles within Kansas City, south of the Missouri River, are served by combined sewers. The City's combined sewers overflow to a number of receiving streams, including the Kansas River, the Missouri River, the Blue River and Brush Creek. Kansas City has also suffered from severe flooding issues. Lives have been lost and significant property damage has occurred as a result of flooding, in large part due to substantial increases in stormwater runoff from ever-increasing impervious surfaces.

Kansas City's WSD has conducted extensive modeling and economic studies of its combined sewer system over the last 5 years, in preparation for submittal of its long term control plan to EPA, in January 2009. These studies and recent funding opportunities have provided the impetus for selection of Kansas City as a case study location to demonstrate the efficacy and sustainability of green infrastructure approaches in an urban-core neighborhood served by a combined sewer system.

The study area is a 100 acre subcatchment shown in Figure 1. The selected sewershed contains commercial, medium density, and some high density residential land uses. An adjacent 80 acre subcatchment has been selected as a control

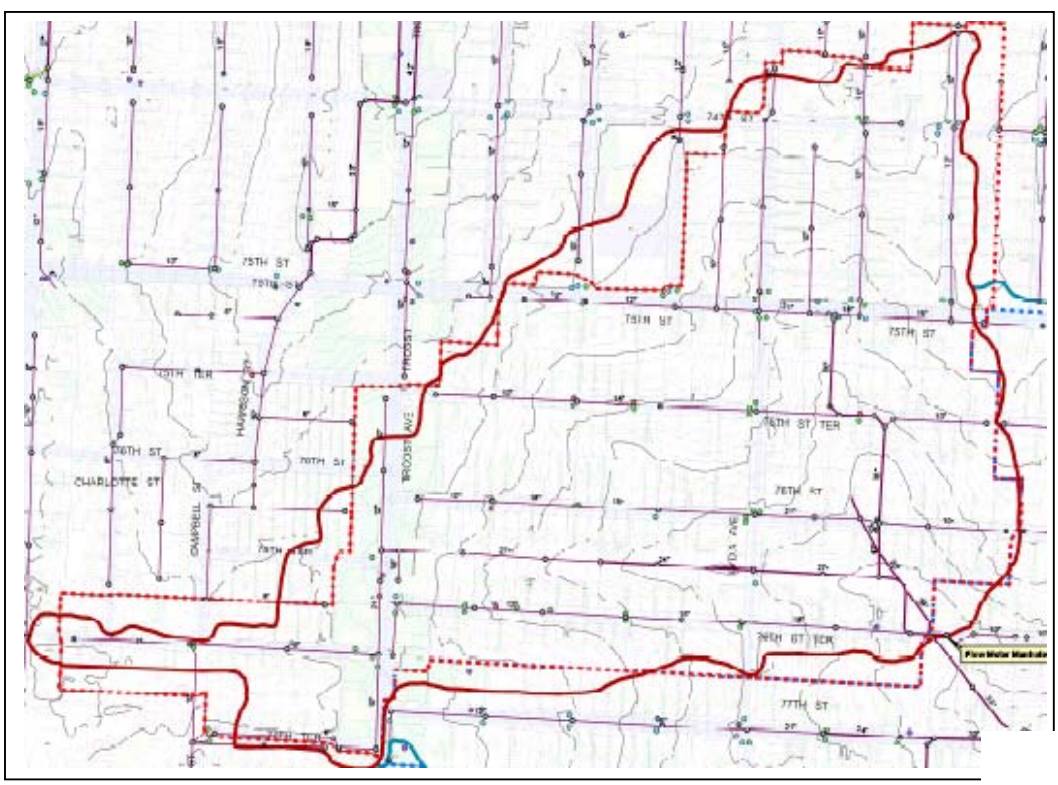

Figure 1. Sewershed of the pilot project. Solid red line indicates the watershed boundaries while the dashed red indicates the sewershed boundaries.

watershed.

Technical Approach for Monitoring and Modeling Interactions

Pre and post-control installation monitoring of the combined sewer flows in the drainage area below the area where the stormwater management controls are being installed are critical components to this project. The stormwater management controls in the demonstration area drain to the municipal combined sewer drainage system in the Middle Blue River watershed. This drainage pattern will allow isolation of the benefits of the upland stormwater controls with minimal flows coming from outside areas. The watershed model (WinSLAMM) and the sewerage model (SWMM) will be calibrated for this area using the pre-construction flow, Land use characterizations and water quality data. Both dry and wet weather flow data will be recorded. The calibrated models will be used early in the project to predict the benefits of the upland controls, and these predictions will be verified as the controls are installed. After the models are calibrated and verified for the demonstration area, they will be used to predict the benefits of wider application of the upland controls across the city. Specifically, the models will predict the decreased runoff volumes and peak runoff rates associated with upland stormwater controls to alleviate problems in the combined sewer system. Water quality benefits associated with stormwater pollutant discharge reductions of wet weather particulates (including particle size distributions), nutrients, bacteria, and heavy metals will be quantified. WinSLAMM will be used to calculate the stormwater contributions to the combined sewerage system during wet weather by providing a time series of flows and water quality conditions, for various types of upland controls, while SWMM, with its detailed hydraulic modeling capabilities, will focus on the interaction of these time series data with the sewage flows and detailed hydraulic conditions in the drainage system. Both models will be used interactively emphasizing their respective strengths.

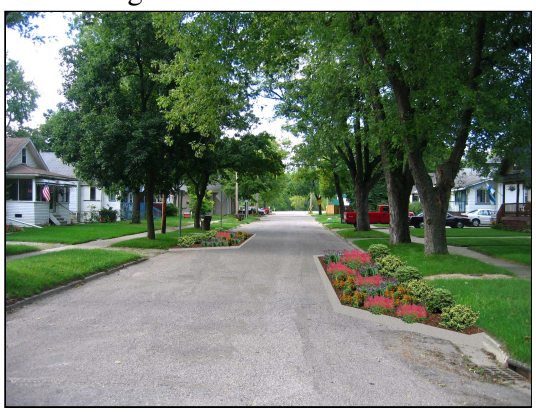

Figure 2. Rendering of Curb Extension Swales.

Figure 3. Rendering of Permeable Pavement Sidewalk and Bioretention.

Detailed monitoring of the upland stormwater controls (rain gardens, biofiltration devices, rain barrels and larger cisterns, inlet inserts) will be used to calibrate and verify the stormwater models reflecting local conditions (soils and rainfall patterns). WinSLAMM contains numerous upland control options, including development conditions (such as downspout disconnections and other impervious

area disconnections, and amended soils), and specific controls that focus on runoff reduction (grass swales, biofilters, rain gardens, beneficial reuse of stormwater, etc.) that can be modeled (Figure 2 and 3). It can be applied to individual control locations, to land use areas having many controls, and to larger areas having multiple land uses. WinSLAMM has been successfully used to produce detailed hydraulic calculations of infiltration

devices considering detailed geometries of the device, underlying soils, amended soils, gravel storage layers, and hydraulic outlets. Variabilities in soil properties affecting infiltration can be large. WinSLAMM therefore includes stochastic elements that consider these variabilities in the resulting calculations. Newer additions to the model that will be used for this project include detailed evapotranspiration calculations that consider specific plants and root characteristics.

Completed Monitoring

This project is compiling data to demonstrate the water quality and quantity results from larger scale application of LID or micro-BMP retrofits in a subcatchment. To date over four months of quantity data has been collected from seven locations in the test watershed. Table 1 indicates the flow meter identification number, pipe size, owner and their purpose for the study.

Table 1 – Flow Monitoring Site Summary

Subsystem	Manhole	Diameter (inch)	Flow Meter Owner	Purpose
UMKC01	S128-498	42	KCMO (OCP)	Pilot Project Flow Basin
UMKC02a	S128-422	30	KCMO (OCP)	Control Flow Basin
UMKC02b	S128-420	24	GBA	Control Flow Basin
UMKC03	S128-426	30	KCMO (OCP)	Control Flow Basin
KCMO01	S128-556	18	GBA	Pilot Project Flow Basin
KCMO02	S128-555	27	GBA	Pilot Project Flow Basin
KCMO03	S128-471	18	GBA	Pilot Project Flow Basin

This data has captured four wet weather flow events as shown in Figure 4. Flow of one of these events for three of the seven monitoring locations is shown in Figure 5.Water quality monitoring equipment will be installed in close proximity to three of the flow monitoring stations and will also record control practice in and out measurements.

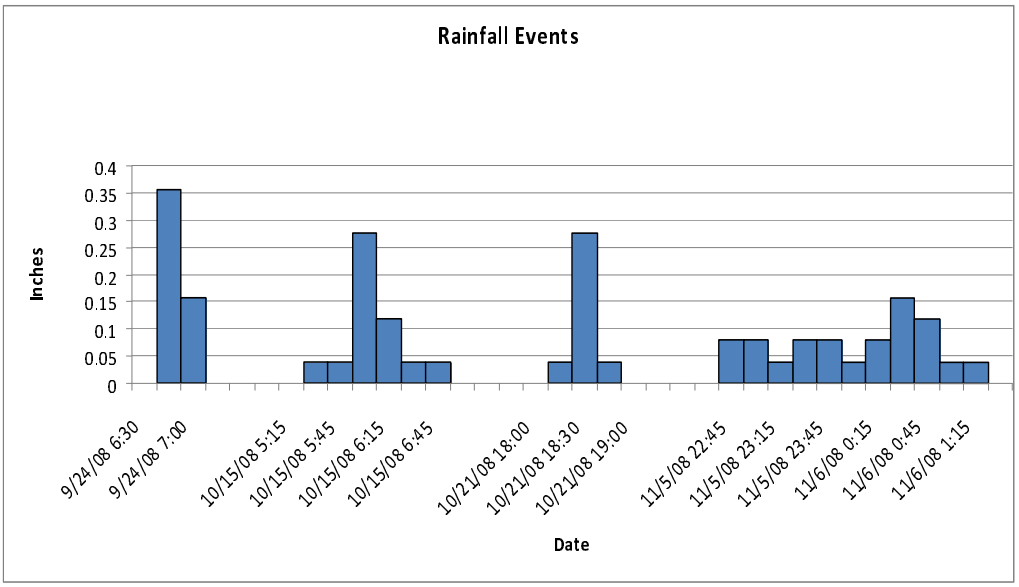

Figure 4. Rainfall data from four events.

Overall, this monitoring scheme will measure changes in peak flow, total volume and pollutant mass of storm events and overflows for a two-year period. Detailed monitoring of selected controls (rain gardens, biofiltration devices, rain barrels and larger cisterns, inlet inserts; green roofs) will be used to calibrate and verify the stormwater models reflecting local conditions (soils and rainfall patterns). Water quality samples will be collected using automatic samplers and data will be downloaded from data acquisition modules following rainfall events. The practices will be inspected for general conditions regularly. Data collected will include the rainfall record and flow data. Laboratories for analyses will include University of Missouri – Kansas City (analytes will include fecal coliform, COD, suspended solids, pH and turbidity), University of Alabama (analysis of solids), and The City's WSD laboratories (analytes include nutrients, metals, pesticides and/or oil & grease). All laboratory analyses and data collection follow an EPA approved quality assurance project plan.

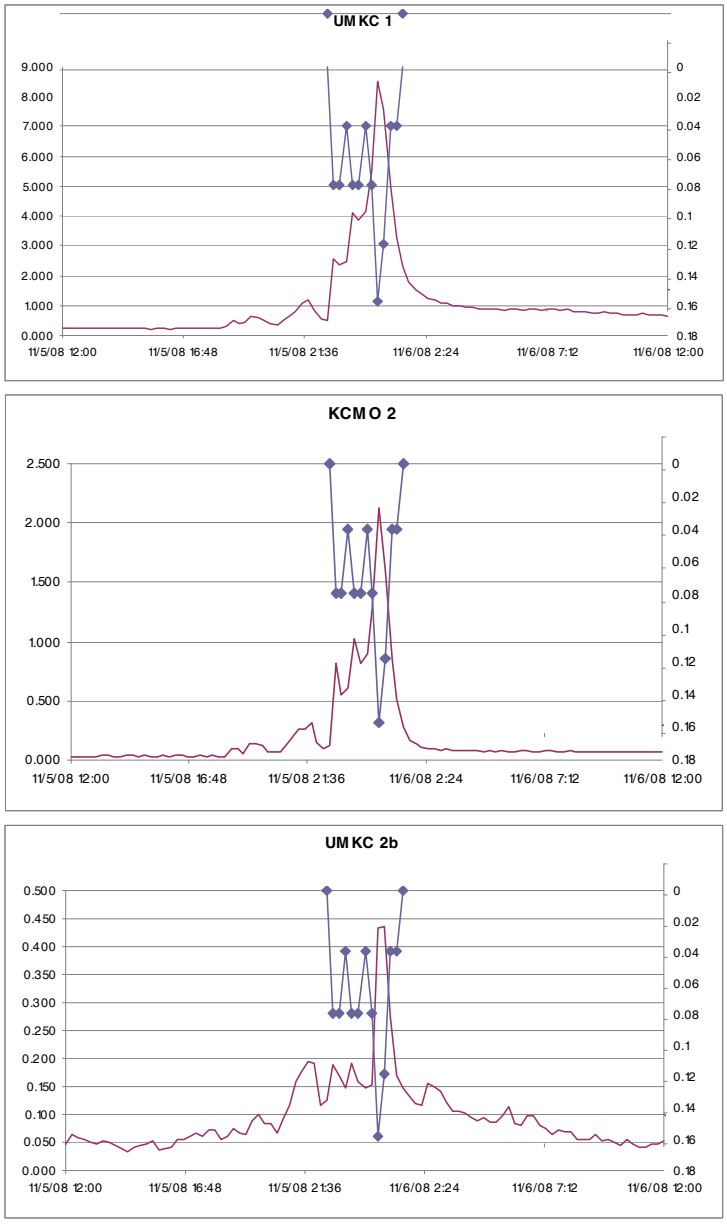

Figure 5. Rainfall data and flow data from three gauges for a November wet weather events.

Selection of the Most Appropriate Combination of Controls

There are many control options that can be used to reduce stormwater discharges to combined sewer systems. Infiltration of excess stormwater will be one method examined during this Kansas City project. Other options will include development modifications associated with disconnection roof rains and other impervious areas from direct connections to the combined sewer, and the beneficial use of the stormwater during dry weather. Combinations of these approaches will

likely be the most effective, depending on specific characteristics of each area being examined.

The selection of the most appropriate combination should use decision analysis methods. Decision analysis is a systematic procedure that enables one to study the trade-offs among multiple and usually conflicting objectives. An alternative procedure is to separately determine the programs necessary to meet each objective and to use the least costly program that satisfies all the identified critical objectives. This is an acceptable procedure some of the time, but it may not result in the most cost-effective program, especially when multiple and conflicting objectives need to be considered. Pitt and Voorhees (2007) presented a description and examples of using decision analysis methods with WinSLAMM for complex stormwater projects and the following summary is from that publication.

There is a great deal of information calculated by WinSLAMM during an analysis for a site and stormwater management alternative. In most cases, just a few of the values are sufficient for quick comparisons. These include the overall percent runoff and particulate solids reductions, the final Rv and runoff volume, and the resulting particulate solids yields and concentrations. Recent enhancements to WinSLAMM also now enable the costs and the expected habitat conditions of the receiving waters to be directly calculated and compared, in addition to flow-duration information. The batch processor option of WinSLAMM is frequently used to automatically examine all the land use and stormwater control options for a relatively large area, such as for city-wide analysis, especially when used in conjunction with GIS data.

The techniques of decision analysis, as described by Kenney and Raiffa (1976), can be used to aid in the selection process. This method uses utility curves and trade-offs between the different attributes. The utility curves should be based on data and not reflect personal attitudes or objectives, while the trade-offs between the attributes reflect different viewpoints. This decision analysis method is a powerful tool that can be used to compare the rankings of alternative stormwater management programs for different groups. In many cases, final rankings may be similar amongst the interested parties, although their specific reasons vary. This tool also completely documents the decision making process, enabling full disclosure.

Current Status of Project

Results from pre-implementation monitoring and expected modeling outcomes developed from monitoring data will be presented to support detailed hydraulic and water quality analyses providing before and predicted post Green Solution implementation information for planning and design at the site, sewershed, and watershed levels.

Refined land use characterizations have recently been completed to assess accuracy of GIS land use layers and to verify existing land use metadata is defined in the same manner as land use codes to be used in the WinSLAMM model for accurate model predictions.

Project Outcomes

It is expected that the methodology used to determine site selection will provide the best technical, political, social, and cost effective location based on modeling and considered needs of the neighborhood, WSD, and for water quality benefits. The modeling approach will provide a scientifically sound basis for the locations, types, and design of the stormwater management practices selected for this project. The initial outcomes from this project including planning and design process determination and modeling approach will be of interest to other engineering and planning professionals.

KANSAS CITY, MISSOURI
OVERFLOW CONTROL PLAN SUMMARY

January 2009

Terry Leeds[1], **Scott Struck**[2]
[1]Water Services Department, City of Kansas City, MO, [2]Tetra Tech, Inc

Kansas City's Sanitary Sewer System

Kansas City began building the basic sewer infrastructure that would allow the City to grow and prosper over 150 years ago. Amazingly, some of that infrastructure is still in use today. While focused on controlling overflows, a significant portion of the Overflow Control Plan addresses repairing, improving, and maintaining the City's basic sanitary sewer system so that it can be used by Kansas Citians for years to come.

Kansas City's overall sanitary sewer system is comprised of both combined and separate sewer systems. A combined sewer system is simply a single sewer system that carries both sewage and stormwater. Kansas City has 58 square miles of combined sewers. Typically these systems are in the oldest areas of the City and are not capable of carrying the large amounts of stormwater that now run off of our urban landscape. During moderate to heavy rainfall events, the system will reach capacity, overflow, and discharge a mixture of sewage and stormwater directly to our streams and rivers. Although there is a desire to minimize these overflows, the discharge of combined sewer overflows is not uncommon from combined sewer systems and is allowed under a National Pollutant Discharge Elimination System (NPDES) permit issued to Kansas City's Water Services Department by the Missouri Department of Natural Resources.

The remainder of Kansas City's sanitary sewer system is considered a separate system. A separate sanitary sewer system collects sewage and a relatively small percentage of inflow (stormwater) and infiltration (ground water which gets into the sewers through cracks) and is not designed to overflow unless a storm occurs which exceeds the sanitary sewer design capacity. In Kansas City, however, the separate sanitary sewer system is in great need of repair. Stormwater entering through joints, broken pipes and manholes, and unpermitted direct connections causes the system to overload during rain events much smaller than its design storm. When flows in the sanitary system exceed its capacity, it too overflows a mixture of sewage and stormwater. Unlike combined sewers, however, overflows from the separate sanitary system are not currently authorized in the City's discharge permit.

Developing the Overflow Control Plan

In 2003, Mayor Kay Barnes appointed the Wet Weather Community Panel to help guide the City's efforts in addressing combined sewer overflows and flooding issues. This group has met extensively over the last five years and established goals by which the Overflow Control Plan and Kansas City's stormwater initiatives have developed.

Goals and objectives of the Wet Weather Community Panel are as follows:

- Minimize loss of life and injury and reduce property damage due to flooding
- Improve water quality
- Maximize economic, social and environmental benefits

Almost 300 different alternative solutions were evaluated during the five year development of the Overflow Control Plan. Alternatives were evaluated by cost, feasibility, ability to control overflows, and multi-benefit potential to help control stormwater. In an effort to maximize benefits received from the investment, final alternatives were also evaluated for potential to incorporate green infrastructure as part of the proposed solution.

TRIPLE BOTTOM LINE
People, Planet, and Prosperity: Sustainable design establishes a balance between social, economical and environmental factors – between people, prosperity and the planet. Within the triple bottom line cycle, the benefits propagate naturally into other areas.

SYSTEMS THINKING
Systems thinking is a unique approach to problem-solving that examines systems in a holistic manner. Essentially, the only way to fully comprehend why a problem or issue occurs is to understand the part in relation to the whole.

INTEGRATED DESIGN
Through a process of integrated design, which is both an organized collaboration between disciplines and an interweaving and interconnectivity of man made and natural systems, teams create design solutions that are both environmentally responsible and that achieve the highest level of design excellence. The practices of our civic leaders, ecologists, engineers, architects, landscape architects, and craftsmen requires an understanding of a number of complex and varied issues and the ordering of those issues, based on project needs, desires and abilities. Successful design requires a process that includes all stakeholders in its dialogue and encourages feedback in a process of continuous refinement and improvement.

Adaptability in Future Years

This Overflow Control Plan is premised on an adaptive management approach. Adaptive management integrates design, management, and monitoring to

systematically test assumptions, learn from results, and adapt future plans throughout implementation. Its uniqueness is grounded in the flexibility it can bring to the Overflow Control Plan and the City's ability to meet regulatory requirements and achieve "triple bottom line" results. Integrating adaptive management principles into the Overflow Control Plan will require strong leadership, strategic business planning, an effective performance measurement system, and a "continual improvement" operational framework.

The adaptive management framework will be applied to the Overflow Control Plan on various levels. Adaptive management will be part of the overall programmatic approach, and will also be specifically applied at the basin and project level. Data gathered through project implementation will provide opportunities for feedback loops that subsequently inform decision-making at the basin level and ultimately at the overall program level.

A critical aspect of adaptive management is the ability to measure and evaluate project activities, which requires the identification of performance indicators, or measures of success. As this Overflow Control Plan moves forward, performance indicators that relate to overall program development and implementation will be formulated to measure program success in reducing sewer overflows and maximizing social, economic and environmental opportunities for the Kansas City community. Additionally, specific performance indicators will be devised to evaluate success at both the project and basin level.

As part of the adaptive management approach, the proposed Overflow Control Plan focuses on first repairing the existing system and reducing inflow and infiltration, while also measuring the potential of green infrastructure. Completing these activities early in the program will allow the City to use monitoring, modeling and measurement tools to evaluate program results, and adapt the plan accordingly, before constructing more expensive structural controls.

In addition to conducting a regulatory review of the plan every five years, the Overflow Control Plan incorporates intermediate, internal program reviews occurring at the mid-point of each 5-year cycle that will focus on the direction of the Plan and its benefit to the rate payers and citizens of Kansas City.

Public Policy Changes

The Overflow Control Plan is just one element of a comprehensive approach to position Kansas City as America's Green Region. The broader approach will systematically incorporate low impact development strategies, tools, and practices that focus on maintaining the natural hydrologic cycle. A great example of this strategy is the City's recent adoption of a stream setback ordinance in August of 2008. Other initiatives which will enhance the effectiveness of this plan include:

INTEGRATION WITH OTHER CITY AND REGIONAL EFFORTS
The Overflow Control Plan will complement and be integrated with other city and regional programs related to integrated water resource management, climate protection, land use, community development, parks and trails, air quality, and transportation.

DEVELOPMENT REGULATIONS FOR PUBLIC AND PRIVATE PROPERTY
A review of the full city development code to support broad low impact development strategies will be used to formulate proposed code revisions to be submitted to the City Council for its review and approval.

STORMWATER ENGINEERING CRITERIA, STANDARDS AND SPECIFICATIONS FOR NEW AND REDEVELOPMENT PROJECTS
Existing standards applied to public and private projects alike, will be reviewed to ensure that low impact development benefits are maximized through state-of-the-art stormwater management practices.

URBAN AND COMMUNITY FORESTRY PROGRAM
Expanded urban forestry programs will achieve multiple benefits, such as improved air and water quality, reduced energy use and urban heat islands, and restored habitat and biodiversity.

STANDARD OPERATING PROCEDURES
City operations and maintenance practices will be guided by new procedures to capitalize on the many opportunities to implement more distributed, green infrastructure solutions, and to ensure the long term effectiveness of these practices.

Cost and Affordability

A financial capability assessment for the recommended Overflow Control Plan was prepared using procedures suggested by the EPA. The EPA's approach calls for an evaluation of costs of the proposed improvements against Kansas City's median household income. In general, the EPA considers wastewater costs below two percent of median household income to be an acceptable cost burden to ratepayers.

As suggested by the EPA, costs for implementing the Overflow Control Plan were estimated in current day dollars at $2.4 billion. Based on the cost and a preliminary 25-year implementation schedule, the affordability assessment determined that the Overflow Control Plan would result in a cost to Kansas City residents of approximately 1.7% of median household income. This will impose a heavy financial burden on Kansas City residents.

Overflow Control Plan

The Overflow Control Plan was developed to meet regulatory requirements put forth by the Environmental Protection Agency (EPA) and the Missouri Department of Natural Resources (MDNR) related to minimizing overflows from the combined and sewer separate sewer systems. This plan meets those objectives by providing a planned list of improvements targeted at capturing for treatment, approximately 88% of combined sewer overflows, and controlling sanitary sewer overflows during a 5-year rainfall event. While it would be desirable to completely eliminate all wet weather sewer system overflows, the financial burden that would be placed on the rate payers to achieve those goals would simply be too great.

The Overflow Control Plan addresses issues beyond combined sewer overflows, such as deferred maintenance, repairs, and overflow control in all parts of the sanitary sewer system. Completing these repairs not only extends the life of the system for future generations, but they also help in reducing the size of the problem which Kansas City must overcome.

While this Overflow Control Plan is recognized as one of the "greenest" ever developed, WSD will strive to make it even greener through the adaptive management approach described above. There is a desire to utilize above ground, green infrastructure in a manner which provides substantial ancillary benefits to Kansas Citians beyond sewer overflow control, such as cleaner air, cooler ambient air temperatures, recreational and aesthetic amenities, and economic opportunities. This plan lays the ground work for Kansas City to realize those benefits with a substantial, initial investment in green infrastructure and an adaptive management approach that will allow additional green infrastructure to be utilized as its benefits to the system and the City are measured and confirmed.

PUBLIC EDUCATION AND OUTREACH

Active citizen participation will be critical to the overall success of the Overflow Control Plan. To facilitate this participation, the City will partner with neighborhood associations to develop a public education and outreach program that helps inform citizens of the problem and their role in the solution. Creating successful individual projects is also highly reliant on positive citizen participation. Throughout the life of the plan, public education and outreach will also focus on informing citizens about proposed project designs, schedules and progress towards completion. Funding for public education and outreach has been estimated at $12 million, to be spent over the life of the program.

RAIN GARDENS AND DOWNSPOUT DISCONNECTS

Since 2005, Kansas City's award-winning 10,000 Rain Gardens Campaign has focused on educating homeowners on the positive effects of rain gardens. In the Overflow Control Plan, the campaign's focus will be expanded to include an aggressive rain garden establishment program along with a new downspout disconnection program. Funding for the program is estimated at $5 million. The

initiative, which will incentivize citizens to disconnect their downspouts, will also include assistance and information related to helping homeowners and businesses manage and hold water on their own property.

GREEN COLLAR JOBS AND WORKFORCE DEVELOPMENT

Preparing our community for the work required in the Overflow Control Plan is critical. Every dollar of this $2.4 billion investment that can be kept within Kansas City is a dollar of economic development opportunity for our local businesses and residents. To keep those dollars home, local minority and woman owned business enterprises, design firm, contractors, and the City itself will have to ramp up their capabilities and skill sets. The plan includes $5 million to be utilized in job creation and work force development initiatives related to program specific objectives. The City will work with job training and work force development organizations to develop a green collar jobs program related to green infrastructure and sustainable projects proposed in the program. New jobs will help address many concerns, among them unemployment, community support and long term maintenance obligations for green infrastructure.

MONITORING AND MODELING

One of the first activities in the Overflow Control Plan will be to install additional flow meters and level sensors in both the combined and separate sanitary sewer systems. The results of monitoring will help in the development of enhanced system models, evaluating enhanced performance in the system and potential water quality improvements.

Current system models analyze performance characteristics in pipes 24 inches in diameter and larger. In order to evaluate the potential impact of green infrastructure solutions, these models will need to be extended further up the drainage basins. Technical models will be complemented by a triple bottom line evaluation framework including well specified social, economic, and environmental metrics. Once system models and related evaluation frameworks are developed, adjustments to the design, construction, and operation of remaining components will be analyzed throughout implementation of the Overflow Control Plan. Funding for the enhanced monitoring and modeling activities has been estimated at $24 million over the life of the program.

Blue River Watershed Management Plan

One important premise of this Overflow Control Plan, and indeed the City's more comprehensive approach to managing water resources, is to approach planning and management from a holistic watershed perspective. The benefits of watershed-based planning and management are many. Approaching water resource management from a watershed perspective allows the resource itself to become the focal point of study, leading to a more complete understanding of the various impacts on the water body. A watershed approach is also more cost-effective, because it embraces the

involvement of key stakeholders in the process and allows for coordination and communication in addressing pollution sources and issues. Moreover, a watershed approach is the best method of maximizing social, economic, and environmental benefits, because the approach itself is grounded in a broader focus on all activities within a watershed that might have an impact on human health and the environment.

A large portion of the flow and bacterial loading in the Blue River comes from upstream of Kansas City. For this reason, simply reducing overflows from Kansas City's sewer system may not be enough to meet MDNR's water quality standards in the stretch of the Blue River between 59th and 95th Streets. The water quality standard in this stretch of the Blue River is more stringent than the standards applicable to adjacent upstream and downstream reaches of the Blue River. For these reasons, the Overflow Control Plan includes $2 million as Kansas City's contribution to the preparation of a Blue River Watershed Management Plan. A watershed management plan for the Blue River, developed together with Johnson County and other significant watershed stakeholders, is critical to determining the best methods to address the pollution issues that affect this waterway, and to determining appropriate water quality standards for all reaches of the Blue River.

COMBINED SEWER SYSTEM

About 58 square miles within Kansas City are served by combined sewers. This area is generally bound by the Missouri/Kansas state line on the west, 85th Street on the south, the Blue River on the east, and the Missouri River on the north. The area served by the combined sewer system is subdivided into seven principal basins, Gooseneck Creek, Lower Blue River, Town Fork Creek, Brush Creek, Middle Blue River, Northeast Industrial District, and Turkey Creek/Central Industrial District. North of the river, the Charles B. Wheeler Municipal Airport is also served by combined sewers.

The estimated overflow volume from Kansas City's combined sewer system in a typical year is 6.3 billion gallons. Overflow frequency varies significantly within the individual basins, with the average overflow frequency estimated at more than 18 times in a typical year.

In the combined sewer system, repairs to the existing system are scheduled to occur early in the implementation of the Overflow Control Plan. The early years of the plan will also include aggressive pilot projects focused on developing green infrastructure solutions, which will modify proposed structural solutions scheduled for construction in the later years of the plan. The middle years of the plan will focus on maximizing the capacity within the existing system and analyzing the results of source volume reductions and pilot projects, together with improvements to the City's wastewater treatment plants. The final years of the plan will address necessary improvements to the City's wastewater treatment plants and adjustment and construction of proposed structural storage solutions.

NEIGHBORHOOD SEWER REHABILITATION

The first objective of the Overflow Control Plan is to maximize the effectiveness of the existing system. The Overflow Control Plan includes $122 million in capital maintenance and repairs to neighborhood sewers in the combined sewer system. These repairs will help reduce the amount of stormwater entering the system, will address significant outstanding maintenance items, and will improve system performance and life span. To minimize disruption to the neighborhood and improve efficiencies, the City will coordinate sewer rehabilitation efforts with other planned infrastructure projects.

GREEN INFRASTRUCTURE PILOTS AND PARTNERSHIPS

The Overflow Control Plan includes $28 million of funding dedicated to developing green infrastructure pilot projects and partnerships in the combined sewer basins. While proven individually or as part of small systems, green infrastructure has yet to be utilized in a widespread effort to address combined sewer overflows. By developing large scale pilots, the City will be gathering the information required to effectively implement green infrastructure on a much broader scale while simultaneously constructing a portion of the basin specific solution. Green infrastructure partnerships will focus on creating private sector participation in the pilots and proposed basin solutions.

The first pilot project will be implemented in the Middle Blue River Basin as part of the Marlborough Green Infrastructure Project. In this pilot, green infrastructure is planned to provide distributed storage of stormwater throughout a 100-acre area of the neighborhood. The area is primarily residential, but does include commercial businesses. In addition to gaining valuable information about the effectiveness of green infrastructure in controlling combined sewer overflows, this initial pilot will evaluate alternatives to achieve additional plan objectives, including:

- Effectiveness of green infrastructure as a systematic solution;
- Codes and ordinances in conflict with green infrastructure utilization;
- Socio-economic benefits/change;
- Construction techniques and costs on a wide-scale programmatic level;
- Interdepartmental coordination to minimize neighborhood disruption;
- Development of preliminary green design standards for Kansas City;
- Maintenance approaches and costs;
- Public/Private partnership opportunities; and
- Community interaction and support of green infrastructure practices.

Other pilot projects will be developed in the early years of the plan based on the specific basin solutions proposed. In order to develop green infrastructure strategies that will be applicable across Kansas City, it is important that the development of those pilots consider different land uses such as industrial areas and urban areas.

The 100-acre Marlborough Pilot Project area represents the largest focused installation of green infrastructure for combined sewer overflow control in the United States currently.

MARLBOROUGH GREEN INFRASTRUCTURE PROJECT

As mentioned in the previous section, the Marlborough Pilot Project will help define the utilization of green infrastructure across many areas of the City. However, this 100-acre pilot project is only a portion of the area in Marlborough where the use of green infrastructure looks very promising.

Four basin areas in the combined sewer system were evaluated to determine the opportunity for green infrastructure utilization. Based on this analysis, it was determined that an area in the Middle Blue River Basin, was a prime candidate to implement a green infrastructure approach. This area, located in and around the Marlborough neighborhood, is comprised of approximately 744 acres draining to combined sewer overflow outfalls 059 and 069.

The draft Overflow Control Plan called for two underground storage tanks and associated pumping equipment to store and transfer approximately 3.5 million gallons of anticipated overflow from these outfalls. In the selected Plan, these tanks have been replaced with an equivalent amount of storage in the basin itself through the use of green infrastructure.

While final designs will be modified based on results of the pilot project in the basin, initial estimates indicate that green infrastructure in the 744-acre area could include as much as 330 curb inlet modifications, and 25 acres of rain gardens, bioswales, permeable pavement, and green roofs.

A capital budget of $40 million has been included in the plan for the remainder of green infrastructure construction in this 744-acre area. The proposed sole reliance on utilizing distributed green infrastructure to achieve combined sewer overflow control performance goals in an area of this size is unprecedented in both scale and scope at the national level.

SYSTEM IMPROVEMENTS

Many of the improvements proposed in the Overflow Control Plan relate to improving the performance of the sanitary sewer system itself. The investment in these facilities will help the City in their daily duties of collecting and treating sewage, as well as help reduce overflows and system backups by pushing more flow through the system. Additionally, some areas of the system have extra capacity and can be modified to store flows within the system itself. This approach of maximizing the use of the City's existing investment is fundamental in the proposed Overflow Control Plan.

SEPARATION PROJECTS

In many areas of the combined sewer system, it is less costly to modify the existing system so that it functions as a separate sanitary and storm sewer system. These areas typically have a separate sanitary sewer system already functioning in the general area, which at some point connects to the combined sewer system. Separating the systems involves eliminating those interconnection points and providing new sewer lines that convey sewage only.

While these separation projects may be small in scope, their proximity to neighborhoods makes them disruptive to the everyday life of citizens. The City will focus on minimizing disruption through the use of innovative design, construction and management techniques aimed at shortening construction times, limiting disruption, and coordinating with other planned improvements in the neighborhoods.

STORAGE PROJECTS

Despite all of the significant system repairs and improvements and green infrastructure projects proposed in this Overflow Control Plan, the potential still exists that these improvements may not be sufficient to reduce sewer overflows to the levels intended. In that case, structural storage components will have to be relied upon to meet regulatory requirements. For that reason, this Overflow Control Plan includes contingency plans for the construction of structural storage facilities.

It is important to understand that the adaptive management approach used throughout this plan gives the City the opportunity to gauge the effectiveness of the system repairs and improvements and green infrastructure projects as Overflow Control Plan implementation progresses. If those activities result in meeting the sewer overflow requirements in effect in the later years of this plan, then the need for structural storage facilities will be greatly diminished, if not eliminated. The intent of this Overflow Control Plan is to focus on all reasonable methods of reducing or eliminating the need for structural storage facilities, yet retain the option to construct some or all of those storage facilities if no other reasonable alternatives are available to meet regulatory requirements in effect in the later years of this plan.

The structural storage projects currently proposed as the contingency approach in the Overflow Control Program are comprised of deep tunnels used to store and convey sewer overflows during rain events until such time as the sewer system has capacity to accept those flows. Deep tunnel storage has been proven to be a cost effective method of storage on a per gallon basis. It is also less disruptive than above ground storage solutions. The disadvantage of utilizing a tunnel system is that for the most part, the tunnels serve only one purpose, storing combined sewer overflows.

Throughout implementation of the Overflow Control Plan, the City will actively evaluate emerging technologies and other storage alternatives. Final evaluations will take into account social, economic, and environmental aspects of the proposed solutions as they pertain to meeting regulations and improving the economic vitality and quality of life in Kansas City.

SEPARATE SANITARY SEWER SYSTEM

Kansas City's separate sanitary sewer system is comprised of nine principal basins, covering 250 square miles of the City. The four separate sanitary sewer system

basins north of the Missouri River are the Northern and Northwestern watersheds and the Line Creek/Rock Creek and Birmingham/Shoal Creek basins. The five separate sanitary sewer system basins south of the Missouri River are the Blue River North, Round Grove, Blue River Central, Blue River South, and Little Blue basins.

Under existing conditions, the collection systems and wastewater treatment plants have adequate capacity to convey and treat dry weather flows. During heavy rainfall, however, the amount of water infiltrating into the sewers exceeds the system's capacity.

In addition to the uncontrolled overflows from the separate sanitary sewer system, a constructed sanitary sewer overflow is present at the lower end of the Line Creek system. The plan addresses flows from this structure as an early priority.

Recommended strategies in the separate sanitary sewer system include reducing inflow and infiltration of stormwater by repairing the existing system where cost-effective. A combination of wet weather storage and treatment will also be provided to address inflow and infiltration determined to be too expensive to keep out of the system. Because work in the separate sanitary sewer system relates only to repair of the sanitary sewer system, green infrastructure is not included in the proposed plan.

In the separate sanitary sewer basins, a design storm with duration of 24 hours and a depth that would be equaled or exceeded, on average, once every five years was utilized to develop the Overflow Control Plan. In Kansas City, that design storm would result in a rainfall depth of 4.68 inches.

INFLOW/INFILTRATION REPAIR WORK

Many parts of the separate sanitary sewer system are in need of general repair and have experienced deferred maintenance. In addition to extending the life of the system, these repairs will help reduce the amount of rainwater inflow into the system. Inflow, however, is not the only problem. The age of the system and the construction techniques utilized at the time of construction create many challenges in keeping rainwater from entering the system below ground. To combat these issues, the Overflow Control Program proposes an aggressive infiltration reduction initiative focusing on lining existing pipes within the system to combat infiltration through pipe joints and connection points. While effective, the system itself is so large geographically that inflow and infiltration reduction efforts are only expected to partially reduce the amount of stormwater entering the system.

SYSTEM IMPROVEMENTS

Addressing overflows from the constructed sanitary sewer overflow located within the Line Creek/Rock Creek basin, just upstream from the Line Creek Pumping Station, is a priority to the City. The plan provides $37 million for construction of a 30 million gallon per day high rate treatment facility to be constructed near the Line Creek Pumping Station early in the program. This facility will allow the City to begin treating sewage overflows early in the program and will stay in service until final solutions are implemented.

Ultimately, it is anticipated that wet weather flows from the Line Creek/Rock Creek and Northwestern basins will be transported through a conveyance and storage tunnel to the Birmingham Wastewater Treatment Plant. The Plan also provides $44 million in funding for a high rate treatment facility to be added to the Birmingham plant to address peak wet weather inflows.

STORAGE PROJECTS

Two major structural storage projects are currently proposed in the separate sanitary sewer areas. Similar to the storage projects in the combined sewer area, through an adaptive management approach, the City will retain the flexibility to reduce the size or eliminate these storage projects depending on actual flow reductions achieved in early phase projects.

The North Bank Tunnel is proposed as the primary solution to store sanitary sewer overflows from the entire separate sanitary sewer system north of the Missouri River. In addition to providing 42 million gallons of storage, this tunnel also provides conveyance capacity in an undersized portion of the system.

South of the Missouri River, the plan proposes 68 million gallons of tank storage to hold excess inflow and infiltration from the Blue River South Basin and flows from Johnson County Wastewater. The adaptive management approach of the plan gives the City the flexibility to postpone final decisions on storage capacity until the results of ongoing technical and contractual discussions between Kansas City and Johnson County Wastewater are fully evaluated. The cost for addressing Johnson County Wastewater flows to the 87th Street Pumping Station will be recovered through either increased rates charged to Johnson County Wastewater or other funding agreements. Should Johnson County choose to manage the flows themselves, the proposed storage necessary will be reduced accordingly.

Preliminary Schedule

Financial projections prepared for the Overflow Control Plan suggest that between 25 and 33 years will be needed to complete construction of the projects identified in the Plan and other presently identified wastewater utility capital needs. Each of those projections is predicated upon acceptance of a heavy financial burden by the City and its ratepayers. Wastewater rates are expected to almost quadruple over the next 13 years, eventually leading to a cost to residents in the City's retail service area equivalent to 1.7 percent of the City's median household income. Completing the Overflow Control Plan at the lower end of the 25-33 year range will require the identification of revenues other than presently projected user rate increases sufficient to comply with any new regulatory requirements and other wastewater utility capital improvement needs.

As we continue to work with the agencies to finalize our commitment to protecting our region's streams and rivers, we will continue our efforts to establish a final implementation schedule acceptable to the agencies that maximizes our opportunities

to benefit from the adaptive management approach and recognizes our responsibility to properly operate and maintain the system while responding to future requirements in an ever-changing regulatory environment.

Estimated Cost of Selected Plan in 2008 Dollars

Project Description	Estimated Cost (in Millions, 2008 $)	
	Capital	Annual
Programmatic Elements		
Enhanced Monitoring and Modeling	$24	$1.0
Public Education and Outreach	12	---
Rain Gardens and Downspout Disconnects	5	---
Green Collar Jobs and Workforce Development	5	---
Blue River Watershed Management Plan	2	---
Subtotal, Programmatic Elements	**$48**	**$1.0**
Combined Sewer System		
Green Infrastructure Pilot Projects and Partnerships in CSS	$28	$1.40
Neighborhood Sewer Rehabilitation	122	---
Sewer Separation	104	0.26
Outfall Consolidation Piping	35	0.06
Increased Collection System Capacity	39	0.58
In-Line Storage and Other Improvements in Existing System	22	0.16
Distributed “Green” Storage (Outfalls 059 and 069)	40	2.00
Deep Tunnel Storage and Pumping	576	5.34
High Rate Treatment and Other WWTP Improvements	428	15.63
Subtotal, Combined Sewer System	**$1,393**	**$25.44**
Separate Sanitary Sewer System		
I/I Reduction	$172	---
Increase Collection System and Pumping Capacity	26	$0.03
North Bank Tunnel System	371	1.78
Tank Storage at 87th Street Pumping Station	265	1.13
Interim Line Creek Wet Weather Treatment Plant	37	0.53
Additional Pumping Capacity and Wet Weather Treatment at Birmingham WWTP	72	3.16
Subtotal, Separate Sanitary Sewer System	**$943**	**$6.63**
TOTAL ESTIMATED COST	**$2,384**	**$33.07**

Kansas City's Stream Setback Ordinance: A Case Study on the Benefits of Stream Buffers in Urban Areas

Laurie Brown, Scott Schulte, and Bryce Lawrence[1]

[1]Patti Banks Associates, 929 Walnut, Suite 200, Kansas City, MO 64106; PH (816) 756-5690; FAX (816) 756-1606); email: llbrown@pbassociates.com, sschulte@pbassociates.com, blawrence@pbassociates.com

Abstract

Riparian buffers provide direct public and environmental benefits by stabilizing streams, separating people and structures from flood hazards, protecting public infrastructure from damage, and improving water quality. They also provide indirect benefits such as habitat preservation, recreational opportunities, public amenities and increased property values.

Over the past 5 years the City of Kansas City, Missouri (City) systematically evaluated stream quality throughout the city and quantified the relationship between riparian buffers and stream quality. A comprehensive stream asset inventory demonstrated that the health and stability of the City's streams is influenced by the quantity and quality of riparian buffers. The results are bolstered by other studies from the Kansas City region, and support national research on the importance of stream buffers as a watershed management tool.

For this reason, the City adopted a stream setback ordinance in August 2008 that prohibits floodplain development, while focusing on preserving adjacent riparian buffers through development controls, low-impact development provisions, and incentives. This groundbreaking stream setback ordinance uniquely addresses stormwater management, natural resource protection, and future development by protecting sufficient riparian buffer to maintain the City's streams and environmental quality, while providing development incentives and flexibility to developers affected by the buffer. Flexibility, through the provision of "conservation development" options protects significant riparian resources while at the same time allowing development within the outer zone of the buffer.

Introduction

Management of stormwater runoff is a critical issue for both urban and rural communities. The conversion of once well vegetated land into homes, institutions, commercial or other urban related developments radically changes what happens to stormwater runoff. Where it once was slowed down by nature and allowed to gradually soak into the ground, now it is directed to storm sewers or detention basins that simply send the problem downstream to someone else. As a result, communities throughout the country are looking for innovative ways to deal with wet weather issues and are focusing specifically on stormwater runoff and municipal sewer systems.

In the past, solutions have often been highly engineered, expensive, and unsightly, with little regard for natural resources. Recently communities have begun looking into their future and are seeing green, including money savings and natural resource conservation. The City is currently faced with a $4 billion bill to fix its wet weather problems. Of this total bill, approximately $1.8 billion is for the stormwater program and $2.2 billion is for the combined and sanitary sewer overflow control program. Kansas citians are looking to their City to lead the way in integrating protection of water resources and wildlife habitat into the solutions derived for wet weather problems. The stream setback ordinance is just the initial step the City is taking to solve wet weather problems, save money, and literally green the city for future generations.

Setback ordinance implementation presents some interesting challenges and opportunities to developers, planners, and City staff. This paper discusses the ordinance and describes two project examples that show how the ordinance is being applied to urban sites, illustrating its application and implications for design and development. These projects include a data center and a major industrial/commercial development. In each case, the setback ordinance has required the designers to rethink site design and stormwater management. By addressing stream setbacks early in the development planning process, riparian buffers were integrated into these projects as design elements and site amenities without sacrificing project objectives.

Ordinance

The City began developing a stream setback ordinance in 2005 as part of a comprehensive Development Code update. At the same time, the City was also addressing stormwater issues through its' KC-

One Stormwater Master Plan Program and combined sewer overflows through the Overflow Control Program, which are included under the City's Wet Weather Program.

City staff and consultants working on the ordinance implemented public involvement early in the ordinance development process by meeting frequently with a variety of stakeholders inside and outside of City government, particularly development attorneys and engineers. These particular stakeholders and members of the Development Code Steering Committee requested that the ordinance meet certain criteria, including:

- Clearly defining regulated streams
- Being easy to understand and administer
- Applying uniformly and equally to all streams and projects
- Using common information
- Incorporating the latest scientific research and buffer recommendations

The final adopted stream setback provisions were significantly influenced and improved by this group's comments and suggested improvements.

The final ordinance includes a three-tiered riparian (stream) buffer system to reduce flooding and protect water quality and city infrastructure. Regulations within this ordinance are stricter closer to the stream. Thus, the type and number of allowable uses increases with distance from the stream as dictated by the buffer zones. The outer zone offers the greatest flexibility to developers, guaranteeing them the right to develop. The outer zone is regulated for higher quality development use.

The ordinance (see Figure 1) requires a 25 foot streamside zone where uses are strictly limited to infrastructure and trail crossings. The middle zone incorporates the Federal Emergency Management Agency (FEMA) or city-designated 1 percent (100-year) floodplain or the limits of the 1 percent (100-year) conveyance and jurisdictional wetlands. Uses allowed within the middle zone are infrastructure and trail crossings, utility corridors, and recreational trails. The outer zone extends at least 75 feet from the outer edge of the middle zone and includes slopes greater than 15 percent or mature riparian vegetation areas contiguous with the middle zone. If steep slopes or mature riparian vegetation is present, the outer zone is expanded to encompass these resources. The maximum extent of the outer zone is established at the landowner's election, it can be 75, 150, or as much as 250 feet from the outer edge of the middle zone. At all times the

landowner has the option of developing up to 40 percent of the outer zone provided that a continuous 25 foot strip of outer zone vegetation is maintained to avoid fragmenting the vegetated area. The Open Space and Conservation Development portion of the City's Development Code provides the flexibility to maximize development of the cleared portion of outer zone.

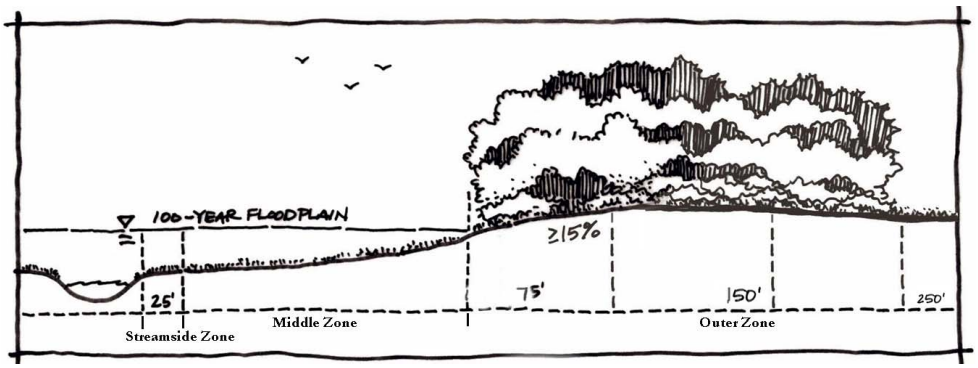

Figure 1. Three-tiered buffer zones in the setback ordinance.

The final Stream Setback Ordinance and Conservation Development Code were adopted by City Council on August 20, 2008. The ordinance and code became effective February 14, 2009.

Implementation

Implementation of the setback ordinance is presenting challenges and opportunities for the City and the development community. The stream setback ordinance guarantees developers the right to develop 40 percent of the outer zone area and the conservation development ordinance provides options to maximize its value. In the following two examples, the designers were required to rethink site design and stormwater management in order to successfully integrate stream buffers into these projects as design elements and site amenities without sacrificing project objectives.

Data Center

A 40-acre greenfield site in northern Kansas City was identified as an ideal location for a large data center. The site, post-agricultural fallow land, is a wide open hilltop with a major roadway on the north and west, a residential subdivision on the south, and pasture on the east. A narrow strip of fencerow vegetation and one wet pond are located on the eastern side of the proposed development site. The developer believed the land had minimal constraints and would easily accommodate the 100,000 square foot facility.

Natural resources on the development site include a first or second order stream tributary that is regulated subject to the City's stream setback ordinance, and two jurisdictional wetlands. One wetland is in the floodplain (middle buffer zone) and the other is outside of the floodplain by approximately 10 feet (see Figure 2).

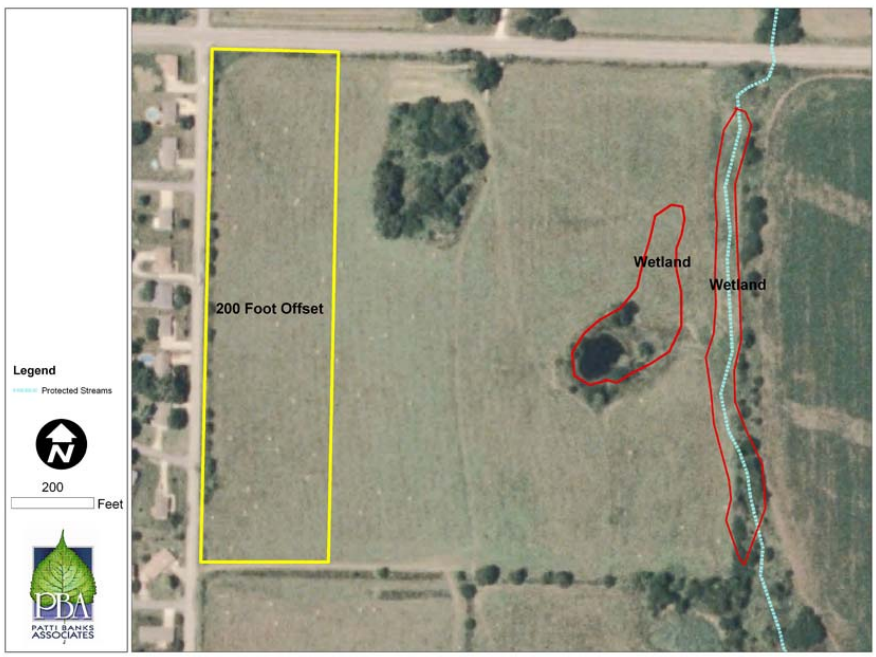

Figure 2: Data Center natural resources and development constraints base map.

The developer was advised that site development must comply with the City's newly adopted stream setback ordinance and that a riparian buffer must be established. Additionally, a 200-foot no-build offset was required on the western side of the property to screen the project from nearby residences.

Runoff from the proposed 100,000 square foot data center roof and parking area would significantly impact the adjacent wetlands and stream. Additionally, the large amount of impervious surfaces would require significant detention and water quality treatment as required by City stormwater engineering regulations.

Full site development, placement of stormwater facilities, and the space needed for the stream buffer presented a challenge to the design team. The designers met the challenge and created an amenity for nearby residents.

Fortunately, the outer zone of the buffer may be varied in width as long as 60 percent of its area is preserved as permanent open

space. This flexibility allowed designers to meet stormwater design requirements, comply with the riparian buffer, protect the wetlands, and meet the developer's goals. The buffer was narrowed on the north end to accommodate a power substation and was widened in the central site to incorporate the two wetlands, reconnecting these to the riparian system and improving the ecological function of the existing site. The stormwater detention facilities were designed and placed within the 200-foot offset on the western side to create a green stormwater solution (see Figure 3) and a visual amenity on the otherwise unusable space. The project is considered a success by everyone involved.

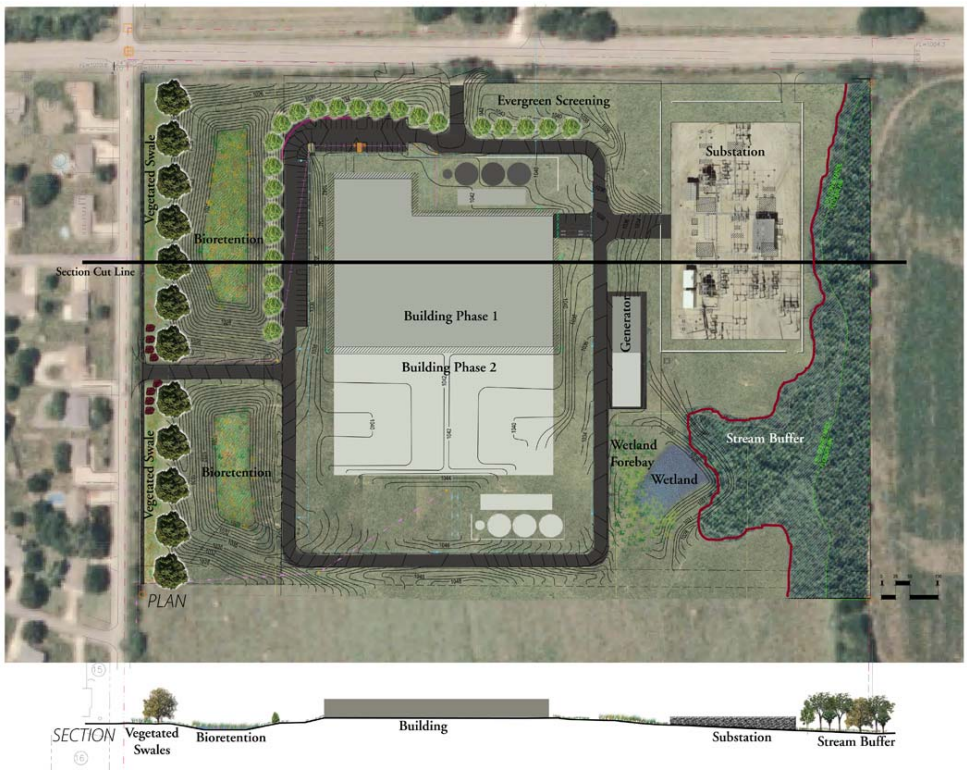

Figure 3: Data Center design protecting the stream buffer and wetlands.

Intermodal BusinessCentre

The Kansas City International Airport (KCI) Intermodal BusinessCentre (IBC) project consists of a 602-acre commercial development that will include distribution centers, air cargo facilities, light manufacturing, office space and commercial businesses. The project is located adjacent to the southeastern corner of Kansas City International Airport on City-owned land (see Figure 4).

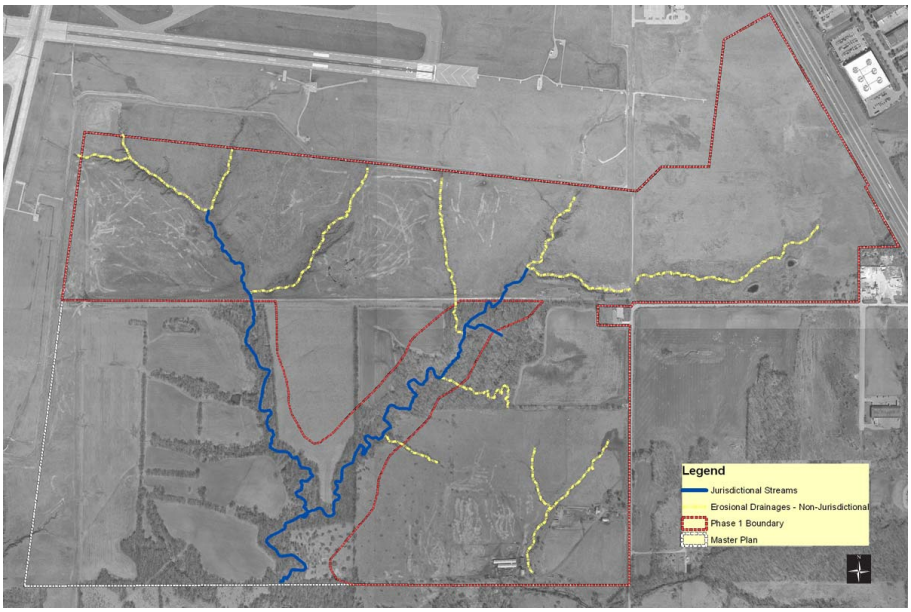

Figure 4. The KCI IBC development site.

The project site lies within the headwaters of the Brush Creek watershed which contains valuable natural resources, including wetlands, prairies, forests, high quality streams, and lakes. While still mostly undeveloped, the Brush Creek Watershed is expected to experience rapid development over the next decade. Thus, it is critical to protect the headwaters of Brush Creek during the development process. Topography throughout the project site is gentle to moderately steeply rolling hills with steeper topography adjacent to the stream channels. The project site's primary resources are located within the riparian corridor associated with Brush Creek.

Past management of natural resources within the project area was dictated by federal regulations. The Federal Aviation Administration (FAA) provides regulations and guidance to airports regarding land management practices aimed at minimizing human/wildlife conflicts at airports and on surrounding lands. The airport is located in a predominantly agricultural area with significant wildlife that poses a potential hazard to aircraft operations.

Project impacts are limited to Brush Creek as there are no jurisdictional wetlands within the development site. Other natural resources have been removed closest to the airport to minimize human/wildlife conflicts.

From the initiation of this development project, the developer proposed a stream buffer zone to avoid impacts to the higher quality stream resources located within the central portion of the project site (independent of the stream setback ordinance). The design team was

able to focus development and management of stormwater outside of the primary Brush Creek channel and the stream buffer area. The developer's buffer averages between 150 and 200 feet from the top of bank on each side of the stream (see Figure 5). Comparison of this buffer to the City's stream setback ordinance showed that this buffer actually exceeds requirements of the stream setback ordinance. Riparian vegetation will be restored in portions of the buffer to improve the quality and function of the stream corridor.

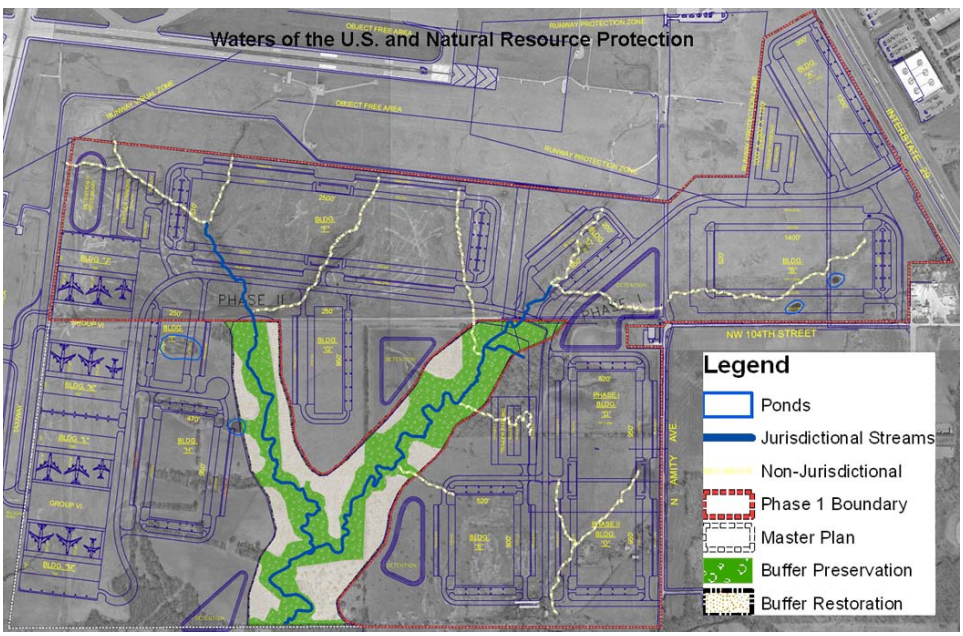

Figure 5. Site Plan with riparian buffer and natural resources to be protected during development.

In addition to the stream setback, all stormwater discharges have been designed to maintain stream stability and provide water quality treatment in accordance with American Public Works Association (APWA) Section 5600 Stormwater Design Criteria (APWA 2006) and the *Manual of Best Management Practices for Stormwater Quality* (BMP Manual; APWA and Mid-America Regional Council (MARC) 2008).

Summary

The stream setback ordinance developed and adopted by the City sets new precedents nationally by protecting mature riparian vegetation and incorporating conservation development. Developers are guaranteed the right to develop while the City is guaranteed the protection of its valuable water resources.

The design teams for both the Data Center and the Intermodal BusinessCentre realized the critical value and necessity of integrating existing resources into their development plans. Valuable natural resources were integrated into the overall site design to create plans that offer amenities to both the site users and adjoining landowners while protecting valuable water resources for the City and meeting the goals of the developers.

The stream setback ordinance is just the first major step the City has taken as it works to solve numerous wet weather problems. The riparian buffers that will be protected by this ordinance will greatly enhance the City's ability to protect water quality while promoting wildlife habitat and creating public amenities such as trails while encouraging development. It should attract new development while avoiding creating costly future infrastructure problems for the City.

ABSTRACT

Introduction. Major floods have caused millions of dollars of damages, taken lives, and degraded Kansas City's streams. The City's Stormwater Management Program identified needed improvements over the last decade for the 320 square miles within the corporate boundaries. Approximately 1,000 projects were identified with estimated costs of about $1.8 billion to upgrade the drainage system and protect the residents, homes, and businesses in Kansas City.

Goals and Objectives. The City implemented the KC-One project to develop the tools needed to make Kansas City's Stormwater Management Program a leader in the region. The City needed to develop a Capital Improvements Program to equitably prioritize the large number of identified projects. More importantly, it needed to identify more sustainable solutions to flooding problems and land development than the traditional methods used in Kansas City, develop policies and regulations to manage stormwater in a sustainable manner, develop a funding plan, and identify the staff needed to adequately manage the program.

KC-ONE

KC-One is a comprehensive City-wide stormwater management plan for the City of Kansas City, Missouri. The KC-One plan, part of the City's overall Wet Weather Program, clarifies responsibilities within the City, recommends policies and procedures, establishes priorities, provides timelines and schedules, and offers funding recommendations for comprehensive stormwater management. The comprehensive plan includes recommendations in the following areas:

- Policy: incorporates best management practices (BMPs), stream protection, land use planning, development plan approval, floodplain management and permit compliance.
- Administration: defines roles and responsibilities of City departments, staffing needs, operations and maintenance.

- Stormwater Master Plan Review: combines watershed master plans into a coherent and usable access system, creating a centrally organized geographic information system.
- Capital Improvement Program: re-prioritizes improvements in 35 watersheds after applying "Green" multi-purpose solutions while complementing the overflow control program (OCP) and improving Municipal Separate Storm Sewer Systems MS4 permit compliance.
- Public Involvement: lays the foundation for expanded stormwater management and the use of green solutions.
- Funding: identifies approaches and options to address capital, administrative, and operational needs.
- Implementation: formulates a comprehensive plan to achieve results.

TWO PHASES

The work for KC-One was segmented into two phases. The purpose of Phase I was to establish the vision, principles, and priorities for the new stormwater management program in Kansas City, Missouri. These key elements then guided the development of the scope of work, budget, and schedule for the remainder of the project during Phase II. Phase I involved working with numerous stakeholders, including the City's Water Services Department, other City departments, elected officials, regulators and other stakeholders. Thus, the stakeholders helped formulate the scope of work, budget, and schedule for development of the comprehensive city-wide stormwater management program. A series of one-on-one interviews and stakeholder workshops culminated in a consensus on the vision, guiding principles, and priorities for stormwater management.

The results from the majority of the one-on-one interviews yielded certain recurring themes. Those recurring themes may be summarized as follows:

1. Focus on reducing flooding, protecting natural resources and improving water quality.
2. The primary obstacle is funding. Innovative approaches and solutions are needed that combine local, state and federal sources of funding.
3. A big picture view is needed that incorporates "Green" infrastructure into multi-objective and multi-use solutions.
4. Public involvement and education is the key to building support and implementing effective programs.

KC-ONE VISION AND MISSION

Four conclusions may be drawn from the major outcomes of Phase I. The first is that there is wide understanding among the identified stakeholders. Not only do they understand the current situation and its problems, they seem to understand what is needed to solve the problems and improve the situation. Secondly, a majority of the stakeholders have the will to make tough decisions and implement solutions. That will is underpinned by the political support of the local elected officials. The third is a general desire to improve the City's overall quality of life--in all

neighborhoods and communities. The fourth is the realization that no program will be accepted by the community unless it is accountable to the community. Actions or specific solutions will be accepted and funded only if they are effective and economical.

Specific Phase I deliverables included a vision, mission statement, set of guiding principles, stormwater management strategy, and scope of work for Phase II. The KC-One vision is

Stormwater management in KC is a holistic regional watershed planning, operating, and growth strategy.

That vision is supported by the KC-One mission to

- Protect and benefit citizens
- Provide sound and consistent development policy
- Conserve and restore natural resources
- Be regional in scope and implementation

During Phase I, consensus was reached on the following policy issues:

- The stormwater management program should apply throughout the entire City, including the areas with combined sewers, where different regulations apply;
- Water quality should be improved and protected throughout the City;
- Floodplain management criteria should be based upon the 100-year flood;
- Stormwater facility designs should be based upon the regionally developed American Public Works Association (APWA) Section 5600 design standards.
- Stormwater facility design should also be based on the APWA BMP manual, which requires new development to manage both quality and quantity of runoff.

POLICIES

Recommendations have been developed throughout the course of the project from its inception in 2004 through preparation of the final report. Many of these recommendations have been implemented and are already providing benefits. Two of the most important recommendations were to adopt new drainage design standards and to implement a stream buffer ordinance to protect the City's streams. Regulation and management of the City's natural resources are the most effective means to protect the City's streams and to achieve the goals of the Wet Weather Program.

Adoption of the new drainage design standards was accomplished in October 2006. These new standards were developed to protect streams from erosion and sedimentation that often occurs during construction, to reduce water pollution carried into streams and treatment facilities during storm events, and to leave a buffer zone between waterways and development to reduce property damage and protect the stream corridor. New standards include:

- APWA 2100-Clearing and Site Preparation Standards: These standards give builders and developers guidelines and criteria for preparing their site(s) for construction. This includes clearing, demolition, grading, erosion control, tree

protection, dust control, waste disposal, temporary entrances and fencing, vegetative buffers, etc.

- APWA 5100-Sediment and Erosion Control Standards: These design criteria and engineering standards address erosion control issues from project planning stages and construction stages to mitigation methods and engineering solutions for roadways. Many temporary and longer-term solutions are described as well as educational and certification requirements. Erosion controls address prevention, while sedimentation controls mitigate erosion already occurring.
- APWA 5600-Storm Drainage and Facilities Standards: These design standards provide developers and cities with guidelines for stormwater drainage and treatment infrastructure. They include a Channel Stability Assessment Matrix and methods for estimating runoff and flows/capacity of gutters, culverts, etc. These standards also address the benefits and issues of using natural streams as part of stormwater management plans as well as engineered channels and engineered structures in stream channels. These criteria make open channels the highest priority and strive to maintain pre-development runoff conditions for a full range of storms.
- BMP Manual: The Manual of Best Management Practices for Stormwater Quality describes BMPs for stormwater management in the region. It requires new development to manage runoff water quality based on changes in runoff conditions. These practices include many of nature's own stormwater management strategies such as using native species, wetlands, bioretention, and rain gardens to filter pollution out of runoff and slow the water down, which allows it to percolate into the soil. Better stormwater infrastructure are also addressed, including pervious pavements, constructed wetlands, and engineered stream corridors, making water quality management choices flexible. The BMP methods described can help treat 1.4 inches of rainfall daily (instead of overloading treatment facilities) providing treatment for runoff from over 90 percent of the region's storm events.

  The hierarchy of priorities for stormwater quality management that the BMP Manual promotes is as follows:

  1. Preserve and promote natural hydrology: Preserve open space, preserve native vegetation and soils, and restore native vegetation and soils;
  2. Infiltrate the runoff through constructed systems;
  3. Filter the runoff through constructed systems; and
  4. Store and treat the runoff.

While adoption of the APWA and BMP standards cited above is an important first step in protecting the City's streams, a stream buffer ordinance was needed to further regulate the floodplains and protect habitats along the streams. Under the City Planning and Development sponsored project to update the Zoning Ordinance and Subdivision Regulations, a stream buffer ordinance was developed to implement the recommendations of KC-One. The stream buffer ordinance will become effective February 14, 2009.

- Stream Buffer Ordinance: Stream buffers are a component of the Zoning Ordinance and Subdivision Regulation Update designed to keep homes, businesses and other built infrastructure away from stream banks, to prevent property damage from flooding and other water quality issues resulting from development occurring too close to streams. The stream buffer ordinance is considered the most effective BMP, and establishes zones to enhance stormwater management.
    - Streamside zone
        - 25 feet wide, each side of stream
        - Allows utility crossings
    - Middle zone
        - Includes 100-year floodplain and wetlands
        - Allows utility and recreational corridors
    - Outer zone
        - Extends a minimum of 25 feet outside of middle zone
        - Includes steep slopes and adjacent wildlife habitat areas
        - Allows conservation development

While the City has made great progress in proactive stormwater management and natural resource protection, additional policy recommendations will further improve natural resources and prevent flooding. These include stormwater management design standards that require the reduction of runoff from new development and redevelopment, provide incentives for homeowners and business owners to install stormwater best management practices, and proactive management of floodplains to prevent development in areas that are projected to flood as the City develops.

ADMINISTRATION

The Administration Plan includes a discussion of organizational theory, industry trends, and considerations for change with respect to how the Stormwater Utility Division is organized. This section also includes a review of the key processes that either the Stormwater Utility Division executes or should be executing as it looks to increase its level of service and effectiveness. Major recommendations include the following:

- Elevate Stormwater within the Water Services Department (WSD) organizational chart to "peer" status with Water and Wastewater, to be led by an Assistant Director.
- Conduct an annual Stormwater Summit: This approach would gather the managers who lead organizations that either own or contribute to key stormwater processes to a workshop designed to clearly delineate the following stormwater issues:
    - Strategic direction and priorities
    - Identify process owners and accountability plans
    - Promote dialogue among stormwater contributors and mutual ownership of challenges

Attendees would include WSD departments as well as other City and external departments which are relied upon to achieve stormwater goals.

- Update the business plan annually: This recommendation is intended to increase the frequency of strategic planning performed for stormwater functions. The plan would develop annual stormwater goals and should address major objectives related to all stormwater functions. Strategic, quantifiable priorities would be highlighted, and tactics to achieve those priorities would be identified. The plan should be accompanied by a set of financial projections and related operational metrics for a minimum of a 5 year period.
- Add incremental staff and resources over time as available funding and additional responsibilities increase.
    - Priority should be placed on adding identified resources in the areas of Maintenance and Watershed Management, which includes staff to manage capital improvements projects and support "green" initiatives.

CAPITAL IMPROVEMENTS PLAN

The Stormwater Utility Division has developed Watershed Management Plans for the City's 35 drainage basins over the last decade. These Watershed Management Plans have identified approximately 750 projects to upgrade the drainage system to reduce flood hazards and to meet drainage design standards. Each of these projects was prioritized within the watershed that they occurred, but a comprehensive prioritization process including all of the projects was not completed. Therefore, one of the primary Phase II tasks of KC-One was to develop the comprehensive list of projects and reprioritize them. The table below provides a summary of the recommendations.

Watershed	Total Projects	Total Cost	Total Green Cost	Total Transportation Cost
Birmingham Bottoms	6	$13,080,000	$12,340,000	$0
Blue River	113	$426,190,000	$28,200,000	$30,310,000
Brush Creek North	33	$256,410,000	$7,460,000	$1,330,000
Brush Creek South	8	$109,890,000	$0	$0
Buckeye	5	$6,550,000	$2,690,000	$0
Burlington	13	$2,410,000	$1,360,000	$660,000
Dyke's Branch	22	$5,940,000	$50,000	$280,000
East Fork Shoal	8	$960,000	$0	$960,000
First	11	$1,250,000	$0	$510,000
Fishing	16	$7,170,000	$220,000	$4,710,000
Hickman Mills	22	$8,630,000	$0	$5,120,000
Indian	42	$62,880,000	$26,310,000	$6,210,000
Line	98	$63,130,000	$30,140,000	$9,200,000
Little Blue	101	$44,710,000	$14,560,000	$15,320,000
Little Shoal	15	$12,130,000	$9,850,000	$2,210,000
Mill	19	$7,690,000	$2,750,000	$1,310,000
NEID (All)	17	$86,080,000	$18,770,000	$700,000
Randolph	2	$8,830,000	$0	$0
Rock	6	$1,970,000	$1,120,000	$290,000
Rocky Branch	20	$6,460,000	$360,000	$3,770,000
Round Grove	43	$28,550,000	$14,990,000	$13,280,000
Rush/Walnut	30	$10,230,000	$6,250,000	$0
Searcy	7	$39,610,000	$3,320,000	$1,690,000
Second	20	$6,310,000	$2,060,000	$6,310,000
Shoal (Lower)	8	$970,000	$330,000	$0
Todd	7	$3,750,000	$1,430,000	$330,000
Town Fork	16	$72,420,000	$25,000,000	$460,000
Turkey (including CID)	15	$574,840,000	$0	$0
Upper Shoal	49	$15,550,000	$8,030,000	$4,100,000
TOTAL	**772**	**$1,884,600,000**	**$217,590,000**	**$109,050,000**

The final Capital Improvements Plan will be defined by the available funding. Projects have been categorized by well-known historic flooding problems, projects that can be solved by green solutions, transportation projects that have historically been funding through Public Improvements Advisory Committee sales tax revenues, and remaining projects.

Following are the general recommendations for defining the highest priority projects:

- Projects that address historic flooding areas such as Southwest Boulevard, Westport, Freighthouse District and Gardner Avenue;
- The top 100 projects that involve green solutions; and
- The top 100 remaining projects that provide the most benefit for the lowest cost.

FUNDING PLAN

Funding stormwater management programs for the City may be achieved through various methods, some of which are applicable to funding operating costs and others to funding major capital improvement costs. Only a few of these methods have sufficient flexibility and revenue generating ability to be used as a primary source of funding. The City should take into account the implications of the Hancock Amendment when considering new funding sources or adjustments to existing fees and charges.

A stormwater utility user fee is a flexible, reliable source of revenue, and with proper design, is an equitable method of charging for stormwater services. It is therefore recommended that the City adopt a policy to transition to a stormwater user fee as the primary source of funding the City's stormwater management program over the long-term, including both operation and maintenance expenses and capital related costs. State and Federal grant funding should be used to leverage the local revenues. Other funding sources such as in lieu of construction fees, inspection fees, and plan review fees should be utilized as appropriate as supplemental funding. Although the supplemental sources will not generate a significant amount of revenue, they will enhance the overall equity of the stormwater user fee structure.

Based on the estimated cost of anticipated stormwater capital projects, a significant increase in the stormwater utility user fee will be required to fund both operating and capital costs. A transition period of several years should be allowed for this conversion, during which time stormwater utility user fees can be increased at a rate that is deemed acceptable to customers and by the City Council. During this transition period the stormwater utility needs assurance that funding of capital improvements will be made available either through the current sales tax or an alternative mechanism. It is recommended that the City consider seeking approval of additional sales taxes under House Bill RSMo 644.032 (for stormwater control and/or parks), or other statutory provisions to supplement current revenue sources during this transition period.

Revenues from system development charges will provide a new source of income for funding capital improvements related to growth and development, and will enhance the equitability of cost recovery.

PUBLIC INVOLVEMENT

The *10,000 Rain Gardens* program, which was begun in November 2005, led by Kansas City's Water Services Department, and supported by then-Mayor Kay Barnes, was contained within the scope of KC-One to begin community outreach for the purposes of "education, communication, and public involvement." KC-One took *10,000 Rain Gardens* through its first year; its management was then shifted to the Overflow Control Plan (OCP) City-wide program.

10,000 Rain Gardens has called upon the creativity of citizens, corporations, educators and non-profit organizations to join with government in creating pieces of the solution to the City's stormwater challenges. By providing both homeowner-based information and professional-level training and certification, *10,000 Rain Gardens* has succeeded in bringing the enormity of the challenge down to a personal scale. This alone helps citizens relate to the City's challenge and feel empowered by contributing to the stormwater solution on a yard-by-yard basis.

IMPLEMENTATION PLAN

Implementing the recommendations of the KC-One Plan will help the City achieve the goals of its Wet Weather Solution program:

- Minimize loss of life and injury and reduce property damage due to flooding;
- Improve water quality; and
- Maximize economic, social, and environmental benefits, optimize infrastructure investment and enhance natural habitats.

Achieving these goals will take many years and require new sources of revenue, changes in policies, additional staff, and the construction of stormwater management facilities across the City.

Implementation recommendations are categorized as either high priority or medium priority. This distinction is made based on a balance of considerations including the expected degree of impact and the availability or anticipation of funding. Within the high or medium priority designations, recommendations are further stratified to reflect a relative time line for implementation as follows.

- Critical – as soon as possible
- Near-term - within the next three years
- Mid-term – within the next three to five years
- Long-term – more than five years

CONCLUSION

KC-One has provided the foundation for increasing the scope and influence of the City's Stormwater Management Program. Key to success of the Program is providing additional funding to implement the recommendations from KC-One. As stormwater revenues increase, the level of service provided by the Program will increase and the goals of the Wet Weather Program will be achieved.

Laboratory Testing Guidelines for Certification of Manufactured Stormwater BMPs

Bannerman, Roger[1]; Bruijn, Hans de[2]; Karimipour, Shohreh[3]; Kayhanian, Masoud[4]; Mailloux, Jim[5]; McDonald, Jon[6]; Miller, Mark[7]; Mohseni, Omid[8]; Osei, Kwabena[9]; and Perry, Scott[10]

Abstract

For the past decade, manufactured stormwater best management practices (BMPs) have been widely used in urban areas to remove suspended solids from stormwater runoff to meet the local and federal government agencies' standards. The ASCE/EWRI Task Committee on Guidelines for Certification of Manufactured Stormwater BMPs formed a subcommittee to develop the laboratory testing guidelines. The focus of this subcommittee has been on developing laboratory testing guidelines to assess the efficiency of the devices used for physical separation of the full spectrum of stormwater-borne non-dissolved solids. In general, these devices include hydrodynamic separators and filters.

After reviewing the protocols developed by organizations, but not limited to, the state of Washington Technology Assessment Protocol-Ecology (TAPE), the state of Wisconsin Method for Predicting the Efficiency of Proprietary Storm Water Sedimentation Devices, the TARP Protocol for Stormwater Best Management Practice Demonstrations, the subcommittee utilized the experience obtained from the laboratory tests conducted on these devices and employed the material in the existing protocols to develop the testing guidelines. These guidelines are designed to conduct robust laboratory testing with stated repeatability. The guidelines encompass three separate series of tests for addressing three different processes: (1) Testing to determine the efficiency of hydrodynamic separators in removing suspended sediments, (2) testing to quantify sediment retention of hydrodynamic separators, and (3) testing to determine the efficiency of filters in removing suspended solids.

Introduction

For the past decade, manufactured stormwater treatment devices, also known as manufactured best management practices (BMPs), have been widely used in urban areas with the goal of removing pollutants from stormwater runoff. The main advantage of these devices is their small foot print where space is limited. These

devices can be divided into two main categories: (1) settling devices, and (2) filters. The settling devices, primarily hydrodynamic separators, remove pollutants by settling the particles, while filters remove pollutants through the attachment of particles to the media filter. Hydrodynamic separators are often designed to remove floatables, e.g. oils from stormwater runoff.

These devices have been monitored in the field and tested by either the manufacturers' laboratories or other independent laboratories under a set of specific conditions. There are few protocols or guidelines for the performance assessment of these devices. Therefore, in 2007, the Stormwater Infrastructure Committee of EWRI's Water, Wastewater, and Stormwater Council (WWSC) in collaboration with the Wet Weather Flow Technology Committee of the Urban Water Resources Research Council (UWRRC) formed a committee to develop guidelines for certification of manufactured BMPs. In May 2007, six subcommittees were formed to develop the guidelines. This paper is a summary of the work done by the members of the Laboratory Testing Subcommittee.

Development of the Laboratory Testing Guidelines

The goal of the subcommittee has been to develop laboratory testing guidelines to assess the efficiency of the devices, i.e. hydrodynamic separators and filters, used for physical separation of particles (the full spectrum of stormwater-borne non-dissolved solids) from stormwater runoff. The guidelines are intended to include scouring of the removed particles under high flow conditions. The guidelines do not include removal of trash, leaves and hydrocarbon products.

The first task of the subcommittee members was to review and assess the existing protocols. Some of the protocols reviewed have not been finalized, however, the subcommittee decided to review all the existing knowledge in the community before attempting to draft new guidelines. Therefore, several protocols were reviewed and their pros and cons were summarized. Among them were (1) Technology Assessment Protocol-Ecology (TAPE 2002) papered by the Washington Department of Ecology as part of their Stormwater Management Manual (SWMM) that includes stormwater treatment facility design criteria, performance goals, and a process evaluating the performance of stormwater treatment facilities, (2) the New Jersey Department of Environmental Protection (NJDEP 2003) for evaluating hydrodynamic separators, (3) the protocol developed by the Wisconsin Department of Commerce and the Wisconsin Department of Natural Resources (WDC & WDNR 2007) for evaluating hydrodynamic separators, (4) the draft standard for Measurement of Suspended Sediment Removal Efficiency of Hydrodynamic Stormwater Separators and Underground Settling Devices prepared by the ASTM, (5) the Laboratory Testing Specifications for Manufactured Water Quality Structure prepared by the Ohio DOT, (6) the Laboratory Testing Protocol for Manufactured Stormwater Treatment Systems prepared by the City of Indianapolis, (7) the Procedure for Lab-based Testing of a Hydrodynamic Separator by the Direct Method prepared by Hydro International, and (8) Procedure for Lab-based Testing of a Hydrodynamic Separator by the Indirect Method prepared by Hydro International.

In addition to summarizing the pros and cons of all these protocols, the main features of the first three protocols were compared and summarized in a single table (Figure 1). The main three protocols specified target removal efficiencies and designed the procedure to meet the targets.

Table 1. Summary of the parameters used in the NJDEP, WDNR and TAPE protocols.

FEATURE	NJCAT/NJDEP	WA DOE	WI DNR
Specified Test Material	5% - 500-1000 µm 5% - 250-500 µm 30% - 100-250 µm 15% - 50-100 µm 25% 8-50 µm 15% 2-8 µm 5% 1-2 µm (d50 ~67 µm)	OK-110 (d50 ~110 µm)	0.90 lb US F-95 1.2 lb OK-110 0.25 lb Sil-Co-Sil 250 4.0 lb Sil-Co-Sil 106 1.0 lb Sil-Co-Sil 52 2.0 lb Min-U-Sil 40 1.0 lb Min-U-Sil 30 1.0 lb Min-U-Sil 15 4.0 Min-U-Sil 10 (d50 ~8 µm)
Target Influent Concentration	100, 200, 300 mg/l	100, 200 mg/l max.	150-250 mg/l
Flow Increments	25%, 50%, 75%, 100% and 125% of unit's rated treatment capacity	50%, 75%, 100% and 150% of unit's rated treatment capacity	5%, 20%, 50% and 100% of unit's rated treatment capacity
# of Tests	3 for each flow rate and concentration (15 total)	2 for each flow rate and concentration (8 total)	1 for each flow rate and concentration for 2 models min. (8 total)
Preloaded Sediment for Resuspension Test	Specified test material at 50% and 100% of unit's rated sump capacity	Specified test material at 100% of unit's rated sump capacity	15% ASTM C33 Conc. Sand 10% NJ 0 Sand 20% NJ 4 Sand 15% Flint #12 Sand 10% Flint #15 Sand 15% F60 Grade Sand 10% 20/40 Oil Frac 5% HI-50

Min. Performance	70% as SSC/50% as TSS at rated treatment capacity	80% removal as TSS at rated treatment capacity	Flow limited to 83% of allowable based on resuspension test
Sampling Method	Not specified	Not specified (grab samples or compositing inferred)	Total mass fed & collected in separator + 5 grab samples for influent/effluent SSC & TSS + PSD from all
# of Models	One	One	Two minimum (Ratio between surface areas of primary settling chambers of at least 2.5)
PSD Analysis	None specified	Optional laser diffraction	Feed per ASTM C117, C136 and D422 Influent/Effluent residuals per same methods for >63 µm, Coulter counter for <63 µm
Temperature	73-79 °F max.	None specified	50-80 °F

FEATURE	NJCAT/NJDEP	WA DOE	WI DNR
Other Aspects			False floor allowed to simulate 50% sediment load – system run clean Recommended 5 lbs of accumulated sediment in unit
Pros	1. Flow increments cover wide range of operation	1. Single, commercially available feed material in range of expected removal capability 2. Simple, conservative resuspension test	1. Direct sediment collection w/sampling backup 2. Resuspension test using material representative of captured sediment 3. Testing more than one model allows more direct scaling method
Cons	1. Preloaded sediment conflicts with direct collection to determine removal efficiency 2. Complex feed and resuspension test material mixture 3. Sampling methods not clarified	1. Sampling methods not clarified 2. Resuspension test method needs clarification	1. Fine feed material largely not captured at typical flow rates 2. Complex feed and resuspension test material mixtures 3. Mandatory PSD analysis expensive

The subcommittee decided to prepare the guidelines using the existing protocols. However, instead of specifying the flow rates, the particle size distributions, influent concentrations, etc., the committee has organized the guidelines with the goal of developing performance functions for the tested devices. A performance function for a tested device allows the cities, counties, and other local government agencies and end users to evaluate the performance of a tested device under a variety of climatic and environmental conditions without the requirement of further testing of that device. In order to develop the performance function of a device, only the range of tested flow rates, particle size distributions, and influent concentrations would be determined in the guidelines.

Subsequently, the Laboratory Testing Subcommittee formed three task groups to prepare the first drafts for (1) removal efficiency testing of hydrodynamic separators, (2) sediment retention testing of hydrodynamic separators, and (3) removal efficiency testing of filters.

Since hydrodynamic separators are primarily cost effective for removing sand and very coarse silt particles, and sampling these particles could cause large errors in the results, especially in the effluent pipe, the subcommittee agreed to recommend a semi-mass balance method for testing hydrodynamic separators. In a semi-mass balance method, it is required to weigh the amount of sediment to be fed into a hydrodynamic separator prior to each test, and at the end of each test to collect, dry and weigh all the sediments removed by the device. For testing filters, however, sampling of influent and effluent is allowed if the non-organic particles fed into the device during the test are fine silt or smaller.

The Laboratory Testing Certification Guidelines is comprised of four main sections. The first section is on the terminology used in the guidelines. The other three sections are the documents prepared by the task groups on testing the removal efficiency of hydrodynamic separators, sediment retention testing of hydrodynamic separators and filter testing. Each section includes the general features of the laboratory test stand, characteristics of the materials fed into the system or used to preload the system, measurement of the hydraulic characteristics of the device during a test, measurement of the materials removed by each device, and measurement of the materials washed out of a preloaded device. Testing filters includes (a) removal efficiency test, sediment retention test and clogging test which is to measure the changes in head and discharge over time.

Summary

The ASCE/EWRI Task Committee on Guidelines for Certification of Manufactured Stormwater BMPs formed a subcommittee to develop the laboratory testing guidelines. The objective of this subcommittee was to develop guidelines for laboratory testing to assess the efficiency of manufactured devices for physical separation of the full spectrum of stormwater-borne non-dissolved solids.

The laboratory testing guidelines includes a terminology section, and three sections on testing the removal efficiency of hydrodynamic separators, sediment retention testing of hydrodynamic separators and filter testing. The foundation of these laboratory testing guidelines are based on the existing protocols, however, the main difference is in developing performance functions for the tested devices which can be used under a variety of climatic and environmental conditions.

ABSTRACT

Data from about 160 neighborhoods in six Jefferson County, AL drainage areas were intensively investigated to determine the surface covers for each land use type. The data shows that the watersheds are highly impervious, with three of them having more than 50% of the watershed area composed of impervious cover. However, TR-55 (USDA 1986) guidance still shows that the impervious cover for all land uses investigated to be much greater than we observed for our area. It was also concluded that the variabilities of the surface covers within the different land uses for the investigated areas was small, especially for the impervious covers.

The percentage of directly connected impervious cover (DCIA) was determined by direct field observations and this data was also compared to commonly use empirical equations. Equations for determining DCIA developed during prior studies were fitted with our observed DCIA for our data, but they did not result in good relationships, especially when analyzed at the land use level. There was a good comparison between Sutherland's "highly connected basins" equation and the fitted equation for our overall data. However, the residual analysis for the regression model was poor, suggesting that the power equation may not be applicable to our data in our region. Suitable equations were developed for each land use separately, showing that a single equation could not be accurately used to estimate DCIA for all regions and land uses.

KEYWORDS: land use, land cover, imperviousness, impervious cover, runoff

INTRODUCTION

An urban area inventory for watershed development conditions should be part of any comprehensive stormwater management plan, when the goal is to understand the sources of pollution and the magnitude of the expected runoff. The watershed inventory would, therefore, assist in the selection of the most beneficial stormwater control practices. The type of urban development in an area can have a major impact on the local hydrology and water environment. This inventory can therefore be used to support many decision making activities and to increase the success of local stormwater monitoring. Past studies (Schueler 1994; USEPA 1994; Arnold and Gibbons 1996; Booth and Jackson 1997) have demonstrated the importance of knowing the areas of the different land covers in each land use category and the storm drainage characteristics (grass swales, curb and gutters, and the roof drains). Increasing levels of impervious surfaces

associated with urbanization result in higher volumes of runoff with higher peak discharges, shorter travel times, and more severe pollutant loadings. Urban imperviousness is an important indicator for urban watersheds in measuring the impact of land development on drainage systems and aquatic life (Schueler 1994). However, there are many different types of impervious surfaces and their direct connectivity to the drainage system is an important attribute affecting stormwater runoff.

The purpose of this research was to provide more details on impervious surfaces for different land uses in the Southeast, as the literature information on impervious cover is not very accurate when applied to local conditions. There are a lot of assumptions about impervious area characteristics for different types of land uses, but very little data has been available to support these assumptions. As part of this research, the Little Shades Creek watershed (Jefferson County, near Birmingham, AL) and five highly urbanized drainage areas situated in Jefferson County, AL (in and near the city of Birmingham) were surveyed in detail to determine the actual development characteristics and their variability. Jefferson County is the largest county by population and fifth by size (NACO 2001) in the state of Alabama having Birmingham as the county seat. This was historically a heavily industrialized area. Rainfall occurs year around, although is generally driest in the fall. About 55 inches of rainfall occurs in a normal year, but recent years have been marked by a significant drought. With the decreased rainfall, more attention is being placed on regional water resources, including stormwater.

To determine how land development variability affects the quantity and quality of runoff, different land surfaces (roofs, streets, landscaped areas, parking lots, etc.) for different land uses (residential, commercial, industrial, institutional, etc.) were directly measured. Surface cover of 125 neighborhoods located in the Little Shades Creek watershed and 40 neighborhoods located in five of Jefferson County's highly urbanized drainage areas were analyzed to determine the actual development characteristics and their variabilities. The locally verified WinSLAMM model (Pitt and Voorhees 1995 and 2002) was then used to determine the sources of critical pollutants, and to predict their loads and concentrations. Statistical analyses were conducted at several levels to establish the quantitative and qualitative runoff sensitivity associated with variations of site characteristics.

ESTIMATION OF IMPERVIOUS AREA

Imperviousness is an important indicator for analyzing and measuring the impact of urbanization on drainage systems and aquatic life because the impervious cover is a variable that can be quantified for different types of land development and has long been found to be directly related to the amount and rate of runoff from an area (Schueler 1994; Arnold and Gibbons 1996; Booth and Jackson 1997).

Urban imperviousness is site-specific and can be complicated to measure. There are several methods used to measure the actual and "effective" impervious cover, some of which are more accurate than others. These methods include direct measurement from aerial photographs and satellite imagery, estimation of impervious cover based on land use, estimation from road density (length of road per unit area), and estimation of impervious cover from population data. The most common methods of determining directly connected impervious cover are field measurements and empirical equations. Several studies have dealt with imperviousness and its estimation (as reported by Heaney et al. 1977; Boyd et al. 1993 and 1994; Novotny and Olem 1994; Debo and Reese 1995). Table 1 shows some of the studies that have estimated or measured impervious cover for different regions. Booth and Jackson (1997) explained the limitations of

using total impervious area (TIA) in urban hydrology analyses and suggested using directly connected impervious area (DCIA) to describe urban development, but noted that its direct measurement is complicated. Consequently, empirical equations for determining DCIA have been developed as part of several different studies (Alley and Veenhuis 1983; Laenen 1983; Sutherland 2000).

Alley and Veenhuis (1983) developed an empirical equation that shows the relationship between the directly connected impervious area and the total impervious area for a highly urbanized area in Denver, CO:

$$DCIA = 0.15 * TIA^{1.41} \quad (1.1)$$

Sutherland (2000) developed an equation based on USGS work completed in Portland and Salem, OR that describes the relationship between effective impervious area (EIA or DCIA) and total impervious and has its general form as:

$$EIA = A\ (TIA)^{B} \quad (1.2)$$

This equation has the same form as used by Alley and Veenhuis (1983), where *A* and *B* are coefficients that satisfy the following criteria: TIA = 1 then EIA = 0% and TIA = 100 then EIA = 100%. This equation has several alternatives known as the "Sutherland Equations" (Sutherland 2000) developed to apply to various conditions of subbasins which might exist in a watershed.

Values of imperviousness can vary significantly according to the method used to estimate the impervious cover (Lee and Heaney 2003; Ackerman and Stein 2008). These researchers concluded that the main focus should be on DCIA when examining the effects of urbanization on stormwater quantity and quality. Reducing the DCIA by disconnecting the impervious surfaces (sidewalks, rooftops, parking areas, and streets) from the drainage system will not restore hydrologic function to pre-development levels, but will improve the base flows, lessen the frequency of bank erosion, and improve stream functions. From a hydrological point of view, road-related imperviousness usually exerts larger impacts than the rooftop-related imperviousness, because roadways are usually directly connected while roofs can be hydrologically disconnected (Schueler 1994).

FIELD DATA COLLECTION

For this study, a locally calibrated version of WinSLAMM was used to compute the runoff quantity and quality for Little Shades Creek watershed near Birmingham, AL and for five additional Jefferson County drainage basins.

The field data used for modeling was gathered manually as part of a cooperative study conducted by the University of Alabama at Birmingham, the Jefferson County office of the U.S. Natural Resources Conservation Service (NRCS), the U.S. Army Corps of Engineers, and other city and county governments. The field data collection effort for the five additional Jefferson County drainage basins reported in this paper was performed during the author's master thesis research (Bochis 2007). Every impervious surface was checked to estimate its properties and connectivity. Streets were classified according to their drainage system: with curb and gutter (directly connected to the storm drainage system) or with swales (disconnected). Also, the pavement material of every street and parking lot was examined and classified.

DESCRIPTION OF STUDY AREAS

The Little Shades Creek watershed has an area of about 8 square miles and was about 70% developed at the time of the initial surveys (mid 1990s). It lies under the jurisdiction of several municipal governments as well as the county government, which made land development highly variable and uncoordinated. Many types of land development are represented, even though the residential areas, mostly as single family residential units, are predominant. Sixteen land use categories belonging to major land uses such as residential, commercial, institutional, industrial, and open space were surveyed by investigating about 10 neighborhoods for each land use. The predominant land use in the watershed was residential land, subdivided according to the density type, and age (Table 2).

The stormwater drainage system was predominantly formed of curbs and gutters in good or fair condition with very little use of grass swales. Most of the roofs (pitched in residential and institutional areas and flat in the other areas) were found to be directly connected to the drainage system. The streets and most of the commercial parking lots had asphalt pavement, but industrial parking lots and residential sidewalks/driveways had smooth concrete as their predominate surface cover. As expected, the largest fraction of impervious cover was found in the commercial areas, followed by industrial, freeway and institutional land uses.

RESULTS AND DISSCUSIONS

Impervious Cover Variability

Regardless of the method used to estimate imperviousness, field verification is necessary. Field verification is also the only accurate method that can be used to estimate the directly connected portion of the impervious area (Gregory, et al. 2005). Therefore, in addition to field surveys, aerial photographs and satellite images were used to assist in the measurement of the actual coverage of each type of surface in each neighborhood studied, and were used to supplement the field collection information. Table 2 shows the percentage impervious and pervious coverage for the land uses found in the Birmingham, AL study areas. Table 3 shows the existing land uses with their average DCIA and the corresponding coefficients of variation.

Table 3. Directly Connected Impervious Areas in Birmingham, AL Area (Bochis 2007)

Land Use	Directly Connected Impervious Area (%) Local Conditions	COV	TR-55 Estimates (using interpolation)
High Density Residential	19	0.48	52
Medium Density Residential	13	0.68	39

Industrial	50	0.66	72
Open Space	***9***	***1.21***	-

* Bold values represent the extremes of DCIA (%) and their coefficient of variation

Those drainage basins have most of the impervious surfaces directly connected to the drainage system, except for the low density residential and open space land uses which have the lowest connectivity and the greatest coefficient of variation. The other extreme case is the commercial land use, which has almost all impervious cover connected and little variability.

A power equation was fitted to the data based on the empirical equations for determining DCIA from TIA as suggested in the literature. The plot shown in Figure 1 relates the percent directly connected impervious areas to the total impervious areas for all of the individual homogeneous land use sites investigated (Bochis 2008).

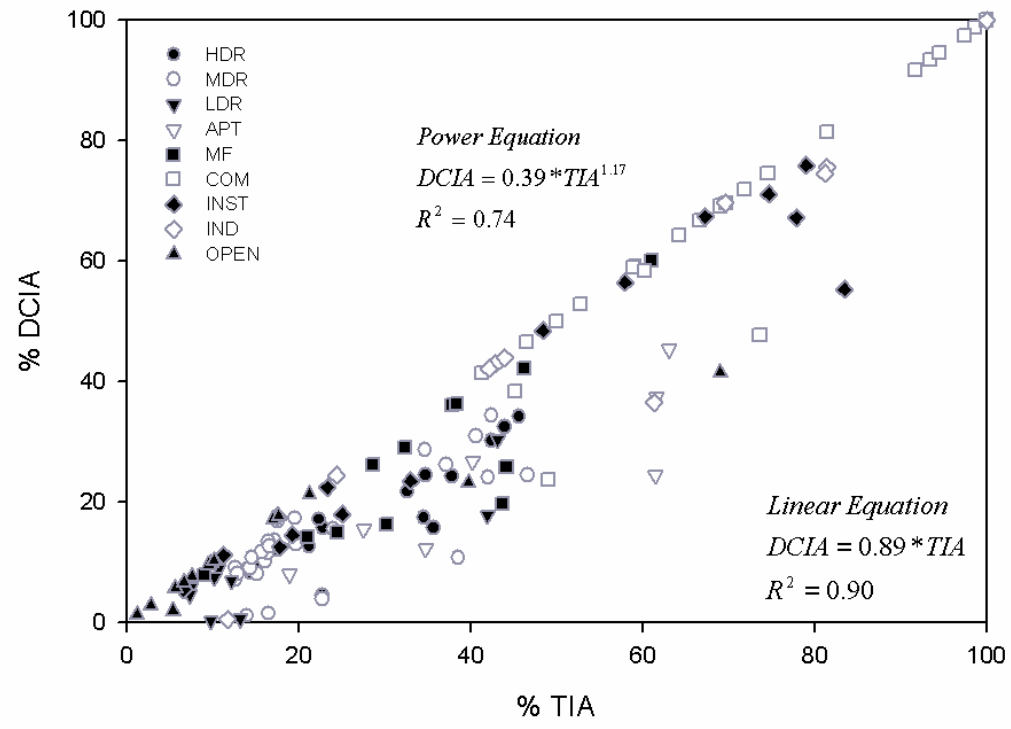

Figure 1. Empirical Estimation of DCIA based on TIA for Birmingham, AL Study Areas (Bochis 2008)

This figure shows that the combined study areas' DCIA might be a power function of TIA, as suggested by Sutherland (highly connected basin, 2000), and Alley and Veenhuis (1983). For these drainage basins, most of the impervious surfaces are directly connected to the drainage system. The fitted equation for the entire study areas is comparable to one of the Sutherland equations used for highly connected areas where the drainage collector is a storm sewer with curb and gutters, and the roofs are connected. The power equation was fitted separately for each individual land use in the study areas. The *A* and *B* equation coefficients, along with their coefficients of determination and residual P-values are presented in Table 4. This data shows that DCIA of each land use is not always a power function of TIA, suggesting that power fitting cannot be successfully applied to Alabama's local condition. We found that the linear equations better fit our data (Table 4).

Table 4. Equation Coefficients for Each Land Use Existent in Birmingham, AL Study Area (Bochis 2008)

	Power Equation				**Linear Equation**		
Land Use	**A coeff.**	**B coeff.**	**R^2 value**	**Residuals p-value**	**A coeff.**	**R^2 value**	**Residuals p-value**

Industrial	0.04	1.78	0.75	0.068	0.95	0.94	0.382
Open Space	1.05	0.92	0.91	**<0.005**	0.67	0.87	0.373

* Bold values represent statistically significant equations

Other reported literature impervious cover conditions are not very accurate when applied to local conditions. The TR-55 (USDA 1986) (Table 1) method overestimate the impervious cover for all land uses investigated, because TR-55 likely assumes that most of the impervious areas are directly connected to the drainage system. Table 2, Table 3 and Figure 2 show that impervious areas in the six Jefferson County watersheds are almost entirely directly connected, and that there is a large variability among and within the land uses. In the case of residential land uses (high, medium and low density), the predominant land use in the study area, the TR-55 method gave values of impervious cover which are about three times higher than the observed values. This overestimation will lead to significant overestimations in runoff volume.

We used a Pearson correlation matrix to relate the magnitude of the relationships between the field measurements and predicted concentrations for those highly urbanized drainage areas. The matrix illustrated that runoff volume can be mostly predicted by using DCIA, TIA, and parking lot areas. Also, there are high correlations between several pairs of parameters, showing that some pollutants concentrations (COD and phosphorus) are directly related to the particulate solids concentrations.

Expected Biological Conditions as a Function of Impervious Area

Table 5 is a summary of the existing land uses that were monitored as part of this research. The data shows that three watersheds are highly impervious, with more than 50% of watershed being composed of impervious cover. The expected biological conditions of the receiving waters were calculated by WinSLAMM to be "poor" for the base conditions having no stormwater controls (based on the Center for Watershed Protections' Impervious Cover Model). The highly impervious watersheds (ALJC001 and ALJC012), which have mainly industrial and commercial land uses respectively, have higher values of Rv (about 0.6) but lower values of TSS concentrations, compared to the watersheds dominated by residential land uses (ALJC009, ALJC010, and Little Shades Creek). In this area, the main sediment sources are the landscaped areas, and not the parking or storage areas, or streets.

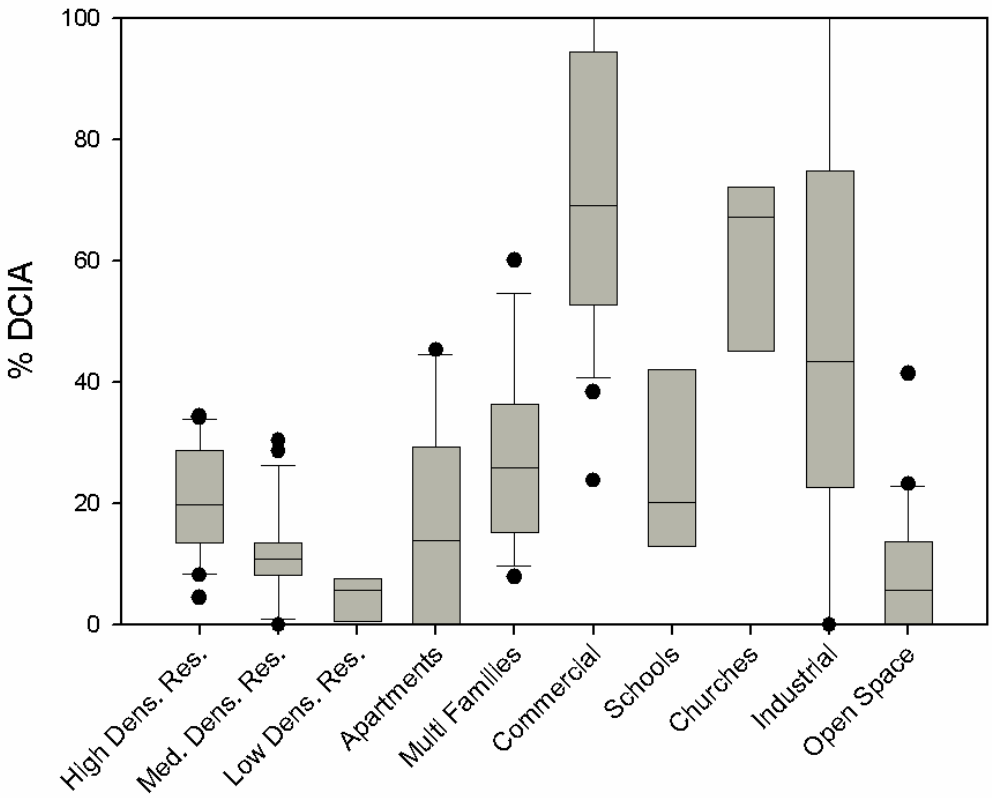

Figure 2. Percent of Directly Connected Impervious Area by Land Use for Little Shades Creek and Jefferson County, AL Watersheds (Bochis 2007)

The residential watersheds are closer to the threshold between fair and poor expected biological conditions (an Rv of about 0.25) than the industrial and commercial watersheds, as expected. WinSLAMM was used to investigate the relationship between watershed and runoff characteristics for each of the individual 160 neighborhoods investigated. An example evaluation of the relationships between the directly connected impervious area percentages (DCIA %) and the calculated volumetric runoff coefficients (Rv) for each land use category (using the average land use characteristics) in the Little Shades Creek watershed, based on 43 years of local rain

data showed that there is a strong relationship between these parameters for both sandy and clayey soil conditions.

Table 5. Runoff Quantity and Source Area Drainage Connections by Land Use for Birmingham, AL Sites (Bochis 2007)

Watershed ID	Major Land Use	Area (ac)	Pervious Areas (%)	Directly Connected Impervious Areas (%)	Disconnected Impervious Areas (%) (draining to pervious areas)	Volumetric Runoff Coefficient (Rv)	Expected Biological Conditions of Receiving Waters
ALJC 001	Industrial	341	25	72	2.8	0.67	Poor
ALJC 002	Industrial	721	40	53	7.3	0.51	Poor
ALJC 009	Residential High Density	102	54	34	12	0.37	Poor
ALJC 010	Residential Medium Density	133	64	28	7.9	0.30	Poor
ALJC 012	Commercial	228	36	61	3.4	0.61	Poor
Little Shades Creek	Residential	5120	67	21	12	0.29	Poor

The fitted exponential equations are (Bochis and Pitt 2005):

$$\text{Sandy soils: } R_v = 0.062e^{0.031*DCIA} \quad (R^2 = 0.83)$$

$$\text{Clayey soils: } R_v = 0.15e^{0.017*DCIA} \quad (R^2 = 0.72)$$

It is interesting to note that the Rv is relatively constant until the 10 to 15% directly connected impervious cover values are reached (at Rv values of about 0.07 for sandy soil areas and 0.16 for clayey soil areas), the point where receiving water degradation typically is observed to start. The 25 to 30% directly connected impervious levels (where significant degradation is observed), is associated with Rv values of about 0.14 for sandy soil areas and 0.25 for clayey soil areas, and is where the curves start to greatly increase in slope.

CONCLUSIONS

The data collected for the Jefferson County watersheds show that this area in Birmingham, AL, has an average impervious cover of about 39%, of which about 25% is directly connected to the drainage system and 14% drains to pervious areas (Tables 2). Table 5 is a summary of the discharge conditions for the study drainage areas and shows that three urban areas are highly impervious, with more than 60% of the watershed areas being composed of impervious covers. It also shows the expected conditions in the local receiving waters due to the measured amounts of impervious cover from these local land uses. The stream quality is damaged to severely damaged, a fact confirmed by in-stream investigations by the Storm Water Management Authority Inc. biologists. As expected, the land use with the least impervious cover is open space (parks, cemeteries, golf course), and the land uses with the largest impervious covers are commercial areas, followed by industrial areas. It was found that the impervious areas in the Little Shades Creek and Jefferson County watersheds are almost entirely directly connected, but

that there is a large variability between the land use categories. It was found that for a typical residential land use located in the Birmingham area, the total amount of impervious area does not vary much. There is an apparent variability in front landscaped vs. back landscaped areas, the reason being the position of the house on the lot, but the total amount of landscaped areas has a low variability for residential land use areas.

Urbanization radically transforms natural watershed conditions and introduces impervious surfaces into the previously natural landscape. Total impervious areas are mostly composed of rooftop and transportation related components that can be either directly connected or disconnected to the drainage system. The impervious areas that are directly connected to the storm drainage system are the greatest contributor of runoff and stormwater pollutant mass discharges under most conditions. The amount of impervious cover has become recognized as a tool for evaluating the health of a watershed and serves as an indicator of urban stream quality. Knowledge about the impervious surfaces, and how they can be managed, is an effective stormwater management tool and can be used to help reduce the impacts of developments within watersheds.

ACKNOWLEDGEMENT

The authors acknowledge Stormwater Management Authority Inc. at Birmingham, AL for their help with the monitoring data and satellite images, and the Jefferson County "Earth Team" of the local USDA office, that in a volunteer effort, collected the Little Shades Creek field information during the mid 1990s. Also, a special thanks to The University of Alabama graduate students who helped in the Jefferson County drainage areas field data collection.

Linking Environmental Assessment and Solutions

L Gosselink[1], C. Herrington[1], and R.H. Glick[1]

[1]Watershed Protection and Development Review Department, City of Austin, PO Box 1088, Austin, TX 78767 ph: (512)974-2550 email: leila.gosselink@ci.austin.tx.us, chris.herrington@ci.austin.tx.us; roger.glick@ci.austin.tx.us

Abstract

The City of Austin is proposing a revised water quality problem score calculation for its master-planning process, which is used to direct allocation of resources for capital projects, programs and regulations. This change is proposed to address the challenge that Resource Managers face in identifying ecological assessment methods appropriate to their resource setting and particular information needs. Ecological assessment tools such as the City's Environmental Integrity Index (EII) include such a comprehensive suite of parameters that teasing apart the data to identify solutions and quantify potential benefits is difficult and not well documented. The revised problem score methods are more transparent and targeted to specific solution opportunities.

Background

Protection of our nation's waters has risen in priority as effects of urbanization began to impact what are characterized as the many "beneficial uses" of the surrounding water bodies. The focus has gradually grown to encompass protecting not only our water supply sources, but the stream systems that lead to it, flowing through our parks, neighborhoods, and wildlands. In addition to water quality measures, the health of the benthic community is often measured as a reflection of long-term impacts from flow variation, sedimentation, erosion and loss of riparian vegetation. The degradation of the stream systems reduces support of the aquatic ecosystem, and impacts to the urban environment by limiting contact and noncontact recreation.

The nation continues to look at water chemistry, and more recently biological communities, to assess large streams with standards and to direct efforts to reverse impairments. However, the complex issues of setting impairment levels for other concerns have not yet been addressed in many states and municipalities, examples including nutrient levels that cause algae blooms, toxins in sediments, riparian vegetation and litter. So, while some problems are addressed and prioritized separately by programs such as TMDLs or stream restoration projects, it is more

difficult to prioritize a multitude of different problems from a single funding source such as a drainage fee.

The City of Austin began a comprehensive assessment program under its drainage-funded department (WPDRD, the Watershed Protection and Development Review Department), where flood and erosion projects focus on safety issues and property damage. The Environmental Resource Management Division, meanwhile, generated an Environmental Integrity Index (EII) using six sub indices as a measure of the (1) health of the aquatic life, support of (2) contact and (3) non-contact recreation, (4) the physical integrity, (5) water quality, and (6) sediment quality. The specific field measures under each of these categories were selected after careful review of other current water quality monitoring and assessment protocols. In particular, the US Environmental Protection Agency (USEPA) Rapid Bioassessment Protocols (Plafkin, et al. 1989) and the Texas Natural Resource Conservation Commission, (TNRCC) Use Attainability Assessment and Physical Characteristic Assessment (TNRCC, 1988) were useful references. The EII generates an overall score of watershed health reported on a 0-100 scale (bad to good); the methodology for the EII is provided in "Environmental Index Methodology" (COA 2002).

Prior City of Austin Work

The solutions, Capital Improvement Projects (CIP), programs such as education programs and regulations are provided primarily through the City's drainage fee, in addition, problems and projects may be allocated to other departments such as the Austin Water Utility. A prioritization of all problems is required for planning and funding allocation for these programs. Thus, EII scores are translated to problem scores which are used in the prioritization process.

Previous water quality problem scores were calculated by the formula:

$$\text{Problem Score} = \sum_{i=1}^{n} [(W_{cur}*RV_{cur}*CPS*) + (W_{fut}*RV_{fut}*FPS)]$$

where n = number of receiving waters
W_{cur} = Weight assigned to Current problems
RV_{cur} = Resource Value for Current Conditions
CPS = Current Problem Severity Score (see Table 1 for measured parameters)
W_{fut} = Weight assigned to Future problems
RV_{fut} = Resource Value for Future Conditions
FPS = Future Problem Severity Score

Previous water quality problem score calculation methods for each of these factors have been characterized as overly complex, lacking transparency and strongly influenced by the various weighting factors. Problem severity was based on a "goal gap." Current and future scores were combined, although programmatic and regulatory changes (i.e., new or revised development ordinances) are the preferred

solution for future problems. The previous problem score method, based on the average of all six EII sub-indices and their many factors, tended to dilute scores resulting in an indirect linkage between problems and specific solutions. Predicting and measuring the performance of solutions was also difficult and measureable success of one type of problem was diluted by those problems not addressed.

The method for calculating the water quality problem score has been revised and updated generally following the methods used by the WRE to address unacceptable decreases in EII scores according to the departmental action plan (COA 2003, COA 2005, COA 2007).

The field measurements were evaluated with field staff and problem score components were selected that met the following criteria:

a. Solutions will provide direct or indirect protection or enhancement of beneficial uses such as aquatic life support (ALS) and for receiving waters (RW) such as lakes.
b. There is an identifiable and feasible solution through City funding or actions
c. The problem and benefits can be quantified with specific performance measurements and environmental indicators.

Ten problem components were selected that met the criteria.

1. Toxins in sediments –
    a. Benefits: Reducing toxins (PAHs, metals, pesticides) in sediments improves Aquatic Life Support and Receiving Water conditions.
    b. Solutions include engineered controls, such as water quality ponds to capture sediment-sorbed contaminants in stormwater, and regulations such as the City's ban of coal tar-based sealants.
    c. Performance Measures: Estimates can be made of loads reduced and sediment toxin concentrations will be measured after solution implementation.
2. Bacteria from animals (dogs, livestock, wildlife) –
    a. Benefits: Reducing bacteria protects contact recreation in both the stream segment and the receiving water body. .
    b. Solutions include primarily programmatic solutions such as the "Scoop the Poop" education program.
    c. Performance Measures: Bacteria concentrations will be measured.
3. Sewage (bacteria, nutrients, algae) –
    a. Benefits: Reductions in bacteria, nutrients and algae growth protects contact recreation, noncontact recreation, water quality and aquatic life uses in the streams and receiving water bodies
    b. Solutions will be mainly referred to the Austin Water Utility for CIP projects.
    c. Performance measures: Bacteria and nutrient concentrations as well as algae presence will be measured.

4. Fertilizer Runoff (nutrients, algae)
    a. Benefits: Reduction in nutrients reduces algae and enhances recreational opportunities in the stream segment and the receiving water body. .
    b. Solutions can include both engineered controls and programs such as the City's "Grow Green" education program..
    c. Performance measures: Nutrient concentrations as well as algae presence will be measured.
5. Litter
    a. Benefits: Reduction in litter, trash & debris enhance recreational uses of streams and lakes.
    b. Current solutions including the City's Keep Austin Beautiful Program; the lake cleanup program can also be targeted to the most problematic areas.
    c. Performance measures: The litter assessment (part of EII) as well as the Ladybird Lake Visual Index of Pollution are the current measures for this problem.
6. Construction runoff (TSS)
    a. Benefits: Reduction in sediments washing into stream segments will enhance habitat for Aquatic Life Support.
    b. The principal solution would be to notify the City's Code Enforcement staff of targeted areas or specific site problems to enforce construction BMP requirements..
    c. Performance will measured by a reduction in the TSS in baseflow as well as sediment depth in the streambed.
7. Unstable channels (erosion)
    a. Benefits: Improved bank stability and channel restoration to a more natural condition will benefit the aquatic life by providing better habitat as well as reducing erosive sediment loads
    b. Solutions are comprised of bank and channel restoration projects.
    c. Performance will be measured by an improved habitat score, reductions in suspended sediments in the stream and transported to the receiving waters, and reduced sediment depth on the streambed.
8. Poor riparian vegetation (poor riparian zone width and quality)
    a. Benefits: Improved riparian vegetation and width will provide better habitat and environment for aquatic communities. In addition, improvements may enhance the aesthetics for noncontact recreation activities. as well as the ancillary benefit of capturing washoff pollutants draining through stream buffer areas.
    b. Solutions will take the form of re-vegetation programs which will frequently be combined with erosion control and bank restoration projects.
    c. Performance will be measured by a the direct assessment of vegetative protection and riparian width.

9. Altered hydrology (current flow regime, flashiness & baseflow presence)
    a. Benefits: Enhancing baseflow & reducing flashiness may be perhaps the most beneficial action for improving benthic community health in the Austin area. Recreational opportunities associated with water resources are enhanced too by increased presence of baseflow. Water quality improvements will also be seen with a reduction in stagnant pools.
    b. Solutions for enhancing current baseflow conditions are difficult, but the use of ponds with infiltration capacity and the cumulative effects of programs to encourage and build small scale rain management systems such as rain gardens may show some results.
    c. Performance will be measured by long-term flow monitoring and analysis of the flow parameters used to identify problems as well as the direct measure of aquatic life.
10. Future problems (future flow regime, flashiness & baseflow presence)
    a. Benefits: Preventing degradation of the natural flow regime where it still exists in Austin creeks is, likewise, a critical factor for maintaining aquatic life. Recreational use will likely degrade with reduced baseflow. Additionally, the development and increased impervious cover that degrade flow regimes are also the primary factors for many of the other problems identified for current conditions (fertilizer, bacteria, toxins), thus the future flow assessment will be used as an indicator for all future water quality problems.
    b. Solutions for preventing baseflow degradation will most likely be regulatory protective measures, protection of undeveloped lands and headwater areas through purchase programs or buffer protection, engineering flow control requirements, and cooperative agreements with regulatory agencies in the stream segments outside of the City's jurisdiction.
    c. Performance will be estimated with hydrologic modeling exercises and long-term monitoring of both streamflow and aquatic life..

These proposed problem factors will better reflect actual environmental conditions; the worst problems will have the highest scores, will use the most indicative factors, and will enable more specific evaluation of post-implementation solution effectiveness.

Methods

Using functional methods such maxima of critical parameters, the WQ score calculation allows a simplified illustration of stream segment conditions as well as source specific interpretation to inform the public and provide geographical targeting information to program managers. A major revision includes the substitution of hydrologic parameters for the direct use of benthic community health indices.

There are currently 118 EII reaches monitored by the WRE surface water team (watersheds with relative EII condition shown in Figure 1), selected on the basis of similar hydrology, geomorphology, land use, point sources and predicted future impacts. Note that the narrative scales of the EII and the problem score are reversed such that a larger EII score reflects a more positive condition while a larger problem score reflects a more negative condition. Flow information will be taken from long-term gauging stations. Soil and Water Assessment Tool (SWAT) models, calibrated for gauged watersheds and extended to all monitored reaches by Water Quality Monitoring team (WQM) staff, will be used to predict reach flows. Future flow conditions will be predicted by replacing current land use with predicted future land use provided by planning staff.

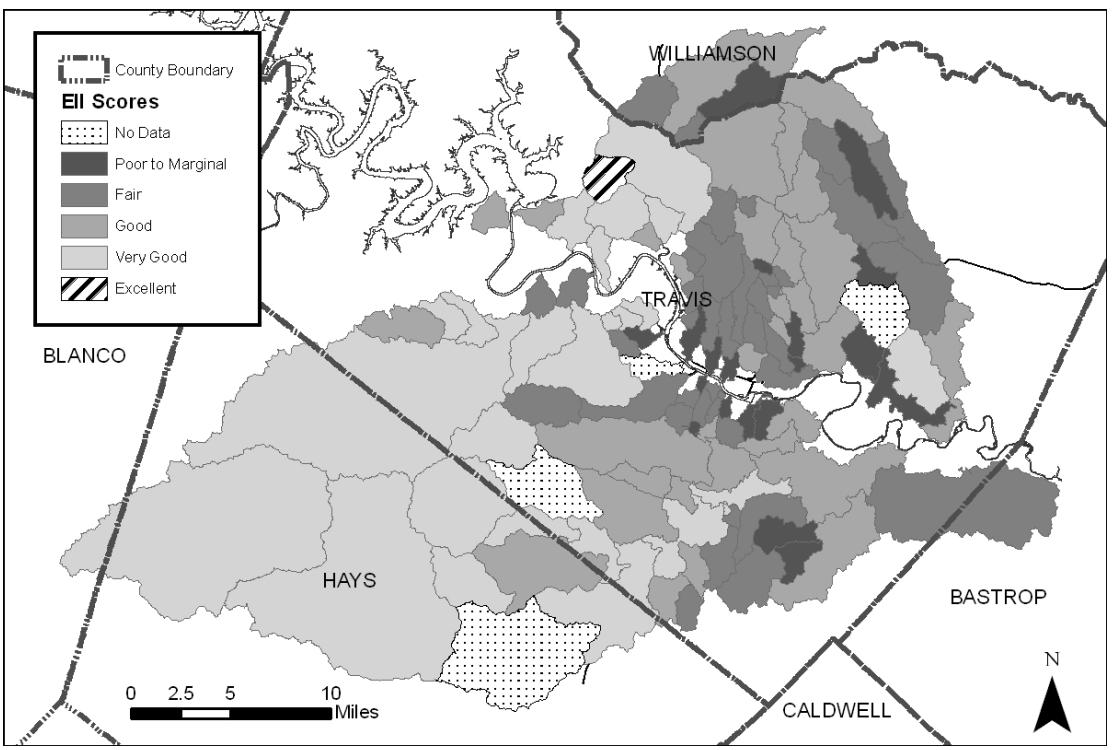

Figure 1. EII reach conditions (2005-2007 sampling events), Austin, TX

The calculation method for each problem score component is detailed below. EII scores are scaled 0-100 (bad to good) and are thus frequently "inverted" (subtracted from 100) to yield a problem score that are scaled 100-0 (bad to good). Problem scores may be less than zero for some problems resulting from the subtraction of two unrelated EII components, and negative problems should be considered as low priority and set to zero in any score combination method.

Toxins in Sediment = 100 – min(PAH, pesticide or metal EII)

Sediment data are collected from the mouth of each EII-monitored watersheds and analyzed for PAHs, pesticides and metals. Sediment EII scores are intended to be

representative of the toxic load for the entire watershed. The worst (lowest) EII component (PAH, pesticide or metal) is used in the calculation.

Litter = 100 – (Litter EII)
Litter EII component scores collected for the aesthetics sub-index are subtracted from 100 to identify reaches with litter problems. EII litter scores are based on a visual assessment litter quantity and type at the representative monitoring site for each reach. Potential solutions include creek cleanups organized through groups like Keep Austin Beautiful and further source investigation through creek walks or aerial photography analysis.

Bacteria from animals = min(nutrient or %algae EII) – (bacteria EII)
The problem of bacteria from animals, e.g. pets or livestock, was constructed to identify reaches with low concentrations of nutrients (ammonia, nitrate and orthophosphorus) and algae (as characterized by the percent algae coverage component of the aesthetics sub-index) but high fecal bacteria indicative of fecal contamination from animal sources and not leaking wastewater infrastructure. Areas with high fecal bacteria concentrations that are influenced by runoff from high-traffic dog parks would exemplify high priority problem reaches. The dual use of the worst (lowest) nutrient or algae EII component allows for reaches that may have low instream nutrient concentrations because of high algal biomass accrual and are thus nutrient enriched systems. Example solutions include education programs like the COA Scoop the Poop campaign to reduce fecal contamination within the reach.

Sewage = 100 – average[bacteria EII and min(nutrient or %algae EII)]
The sewage problem was designed to identify reaches with both high nutrients (ammonia, nitrate or orthophosphorus) and fecal bacteria typical of areas affected by leaking wastewater infrastructure. Again, the worst (lowest) nutrient or algae component EII score is used to more accurately represent the level of nutrient enrichment present. Problem areas could be recommended to the Austin Water Utility for further investigation and remediation of failing wastewater infrastructure.

Fertilizer Runoff = (bacteria EII) – min(nutrient or %algae EII)
Effectively the inverse of the bacteria from animals problem, the fertilizer runoff problem is constructed to identify reaches with low bacteria and high nutrients or algae cover indicative of reaches affected by nutrient enrichment from excessive or improper lawn fertilizer usage. Note that EII scores are 0-100 (bad to good) such that the subtraction of a good bacteria EII component score from a bad nutrient or algae EII component score would yield a large fertilizer runoff problem score. Programs like the COA Grow Green education campaign and CIP projects to capture and treat stormwater runoff are example solutions that could be targeted to problem reaches.

Construction Runoff = (bank stability EII) – average(TSS, sediment deposition EII)
The sediment from construction runoff problem score was designed to identify reaches with stable channels but high instream total suspended solids (TSS from the EII water quality sub-index) and high substrate embeddedness (from the sediment

deposition component of the EII habitat quality sub-index). The worst of left or right bank stability are used in the calculation. Bank stability is included in the calculation to exclude highly depositional reaches where the source of stream sediments is likely bank sediments from erosion of unstable areas. Revised regulations and increased environmental inspections for code compliance are potential solutions which could be targeted to problem reaches.

Poor riparian vegetation = 100 – [(vegetative protection EII/100)*(riparian width EII)]

The inadequate riparian vegetation problem was designed to prioritize reaches with both low quality (i.e., low diversity) and low quantity (i.e., narrow) riparian zones. The calculation is done separately for the right and left banks and then the worst is used to represent the reach. Division of the bank vegetative protection score by 100 effectively converts it to a weighting factor to modify the riparian zone width component. Riparian zone assessments are completed as part of the habitat quality (a.k.a. physical integrity) EII sub-index. An optimal EII reach would have wide and diverse riparian zones on both sides of the creek. Stream bank restoration and re-vegetation are potential solutions for problem areas.

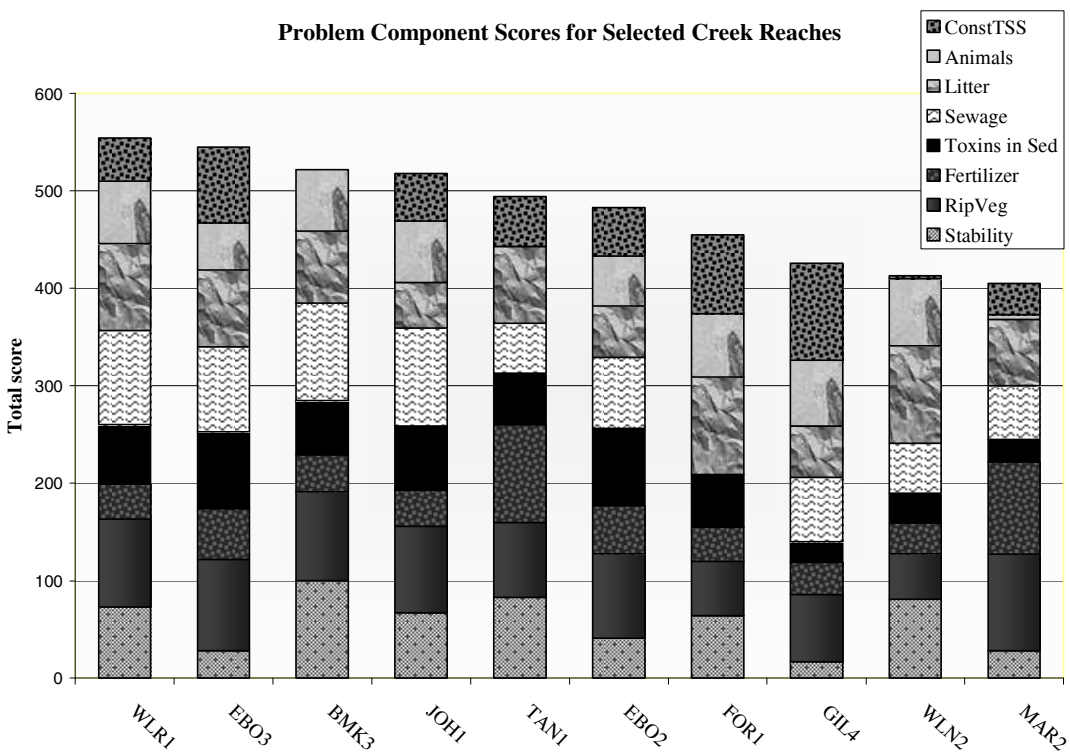
Unstable Channels = 100 – ¾*bank stability EII – ¼*channel alteration EII

The unstable channel problem score was designed to identify unstable creek reaches. The differential weighting of bank stability and channel alteration ranks altered, unstable reaches with the highest problem priority followed by unaltered, unstable reaches. The unstable channel problem will and the construction runoff problem are effectively mutually exclusive. Bank stability and channel alteration are collected during the habitat EII sub-index. The worst (lowest) of the left and right bank stability EII scores are used in the calculation.

Altered Hydrology = f(Annual avg. # of dry periods, Ln of 90th flow percentile)

The current altered hydrology problem was developed from a multiple linear regression of EII aquatic life scores versus a set of metrics describing the flow regime of the reach by the WQM team. The selected flow metrics are:

Annual avg. # of dry periods = Average of the number dry periods for each site
Ln of the 90 percentile = Natural log of the 90th percentile of flow (flow in cfs)



Flow metrics will be calculated from the output of SWAT models for all reaches for a pre-determined length of time preceding the evaluation year. The targeted problem is altered hydrology including both lack of baseflow and flashiness in response to runoff events. Flow is most likely the best predictor of future environmental conditions and can be predicted with SWAT models even in watersheds without continuous flow monitoring with reasonable accuracy. Because of the reliance of aquatic life community function on flow regime, hydrology is likely to be a good predictor of aquatic life integrity.

Future Problem = Future – Current Altered Hydrology Problem

The future problem score is simply the difference between the future altered hydrology problem score, calculated using the SWAT models incorporating predicted future land use, and the current altered hydrology problem score. Highest priority reaches would be reaches with more stable flow regimes now that are threatened in the future to exhibit flow regimes that lack baseflow and are more flashy in response to runoff events. A potential solution to future problem reaches would be targeted regulatory action to limit connected impervious cover and provisions for specific types of stormwater controls.

Results

The simplicity of the separate problem scores allows combining in more than one manner. Figure 2 below shows selected scores for several reaches with individual problem scores stacked. The staff who prioritize for CIP engineering solutions looked at the total of four components that may be remediated by ponds, revegetation and channel work. The highest priority segment was identified as TAN1, not the highest overall total score. The litter score of two segments below, WLR1 and EBO3, indicate that these two segments in the most highly urbanized area of Austin may need programmatic fixes for sewage & litter, but may not show the most benefit for CIP funds spent. Likewise, inspections to prevent construction TSS runoff in GIL4 may be the most cost-effective improvement in that reach rather than a CIP project.

Conclusions

The revised problem score method provides prioritization of specific water quality problems with practical solutions. The calculation of the individual scores is simple and maximizes the specificity of the EII field observations to discriminate between pollution sources. A creek segment such as WLN2 above has an overall EII score of good, yet has some creek stability problems and the highest reach litter score. These individual problems may be used to prioritize solutions for any of the programs or processes affected, and the overall combined score may be used in the mission integration process for the selection of CIP projects.

The easy visualization of the component parts of the proposed score will be implemented to test transparency in public venues, reflecting observed conditions by citizens; to test practicality, whether specific solutions tied to the indicated problems; and predictable, whether estimated benefits will match improvements from solution implementation.

ABSTRACT

Recent studies have indicated that the use of ecologically-based methods for stormwater treatment, including bioretention systems, may provide increased pollutant removal and protection of downstream receiving waters. However, there is little data addressing the long-term performance of these systems in the field or the effects of contaminant accumulation over time on treatment effectiveness. In this study, we present results from an ongoing three-year study of bioretention performance and contaminant fate at a 0.1 acre bioretention cell located in northeastern Kansas. Samples of influent and treated stormwater from storm events during 2007 and 2008 were analyzed for a range of water quality parameters, including total suspended solids, nutrients and total and dissolved Cu and Zn. Results of this sampling show that the bioretention system successfully removes > 70% of suspended solids and more than half of influent total metals. Removal of dissolved constituents is much lower, with the exception of nitrate, which had removal rates of up to 50% during the study. Improvements to the mulch material and vegetative establishment could potentially increase system performance for these constituents.

INTRODUCTION

Mitigating the impact of non-point source pollution has become increasingly important to maintaining surface water quality in the United States, particularly as point source pollutants have been reduced through effective regulatory control. The 2000 National Water Quality Inventory (United States Environmental Protection Agency 2002) reported that 40% of the nation's water bodies do not meet water

quality standards and identified non-point source pollution (NPS) in general, and urban stormwater runoff in particular, as a leading cause of surface water degradation. Stormwater runoff can contain a wide range of pollutants that can degrade receiving water quality and aquatic ecosystems, including suspended solids, excess nutrients, and toxic organic and inorganic compounds. Runoff from roads and other paved surfaces is particularly likely to contain elevated levels of heavy metals, including Cu, Zn, Pb and Cr, as well as suspended solids and nitrate (Shaver et al. 2007). Treatment strategies that address this broad spectrum of pollutants are required in order to minimize the effects of these contaminants on downstream receiving waters.

Engineered best management practices (BMPs) for stormwater must simultaneously provide for stormwater storage during high flow events and improve the quality of effluent water released from the system through contaminant removal. While a variety of design options exist for these systems, recent studies have indicated that the use of ecologically-based (or low-impact) BMPs provide superior pollutant removal to other treatment approaches (Weiss et al. 2007). The presence of soil, vegetation, and microbes in these systems allows for the removal and transformation of influent contaminants through multiple chemical, physical and biological processes, making them particularly useful for treatment of stormwater runoff containing a mixture of pollutants. The presence of a self-sustaining vegetative ecosystem can also aid in reducing maintenance and operating costs over the treatment lifetime.

For locations with relatively small watersheds and/or limited available space for BMP placement, bioretention cells represent one of the most attractive ecologically based treatment options. A bioretention cell is a compact system (as small as 0.05 acres) consisting of a thin layer of mulch over a filter layer composed of a sandy soil mixture, with a planted vegetative cover. Stormwater is channeled to the top of the treatment cell where it initially ponds and then slowly infiltrates into the soil matrix over a period of 8-24 hours. Sedimentation at the surface and filtration within the soil matrix are the primary removal mechanisms for suspended solids and solid-associated contaminants. Dissolved species are removed primarily through sorption to the filter material, although biological uptake and degradation may also play a role in the removal of nutrients and organic compounds. Previous studies have shown good potential for removal of metals and suspended solids with these systems, but poorer removal rates for nutrient compounds, particularly NO_3-N (Hsieh et al. 2007).

With their small footprint and potential to remove multiple types of contaminants, including toxic metals, bioretention systems may become an effective approach to improving the quality of stormwater runoff from roads and other paved surfaces. However, there is currently little data regarding the long-term performance of these systems in the field or the effects of contaminant accumulation over time on treatment effectiveness and lifespan. Additionally, there are likely to be regional issues involved in implementing these BMPs in the Great Plains region related to

growing season, storm frequency and duration, and soil drainage. (Many of the soils in this region have relatively high clay and low sand contents, leading to slower drainage and longer periods of standing water.) In order to address these issues and develop long-term data on system performance, we are conducting a three-year study of a bioretention cell located in northeastern Kansas. In this study, we present results from this ongoing study related to hydrological performance and contaminant removal at this location.

METHODS

The field site is a 0.1 acre bioretention cell built in 2005 to treat runoff from a 4-lane road prior to discharge into an adjoining lake. The surrounding area is undergoing rapid development, with several residential and commercial development projects currently underway or in the planning stages. Road traffic and associated pollutant loading from roadway runoff are therefore expected to increase over the next several years. Stormwater is collected in curbside sewers and transported to the cell through a single concrete pipe. A mesh bag trap in the storm sewer filters large particulates and debris from the runoff before it enters the bioretention cell. The cell itself consists of a 3 inch layer of wood chip mulch overlying a 2.5 foot layer of sandy loam soil. Treated effluent is collected in a perforated pipe that serves as a cell underdrain and then discharged into the lake through a surface level outfall pipe. An overflow sewer in the center of the cell allows for short-circuiting by a portion of the stormwater runoff during high rainfall events.

Rainfall data for storm events during the sampling period was obtained from the 9 stations of the Johnson County ALERT rain gauge data network (Young and McEnroe 2003) located within 3 miles of the field site. Total precipitation amounts were verified using an on-site rain gage. Runoff depths were calculated using tabulated runoff curve values based on a survey of ground cover in the watershed drained by the bioretention cell. The hydrological properties of the system were monitored in two ways: by observing the drawdown time for standing water after heavy rainfalls using an automated camera set to take pictures of a staff gage every hour, and by collecting data on water depth in the effluent pipe using a pressure sensor attached to a datalogger.

Water samples were collected at three locations within the treatment system. The first location was at the curbside storm sewer, prior to passing through the solids catch basin. Runoff was funneled through a plastic tube placed on the road surface and into a 1 L plastic bottle. The second collection site was at the discharge point of the storm sewer into the bioretention cell. Samples at this location were collected using a programmable auto-sampler (ISCO 6700) with attached flow meter. The third collection site was at an underground drainage pipe containing effluent from the bioretention cell. Treated water from the bioretention cell passes through this drain

prior to draining to the adjacent lake. Composite samples were collected from this location using an automated sampler and flow meter. Additional samples were collected by hand within 24 hours of storm events.

Samples of influent and treated stormwater from each storm event were collected within 48 hours of each storm event and then stored at 4 ºC until analysis. Samples for dissolved ion analyses were filtered through a 0.45 μm nylon filter prior to analysis. Total suspended solids tests were conducted on the same day as sample collection according to the 2540D procedure (American Public Health Association et al. 2005). Concentrations of major inorganic anions, including nitrate and phosphate, were measured using an ion chromatograph (Dionex Corp.) with a hydroxide eluent. Sample digestion for total metals analysis was carried out using concentrated nitric acid at a 10:1 sample:acid ratio. Inductively-coupled plasma mass spectrometry (ICP-MS) was used to screen initial samples collected in the spring of 2007 for dissolved and total metals. Based on these initial results, Cu and Zn were chosen for monitoring in subsequent samples. These samples were analyzed using flame or graphite-furnace atomic absorption spectroscopy, depending on the concentrations encountered.

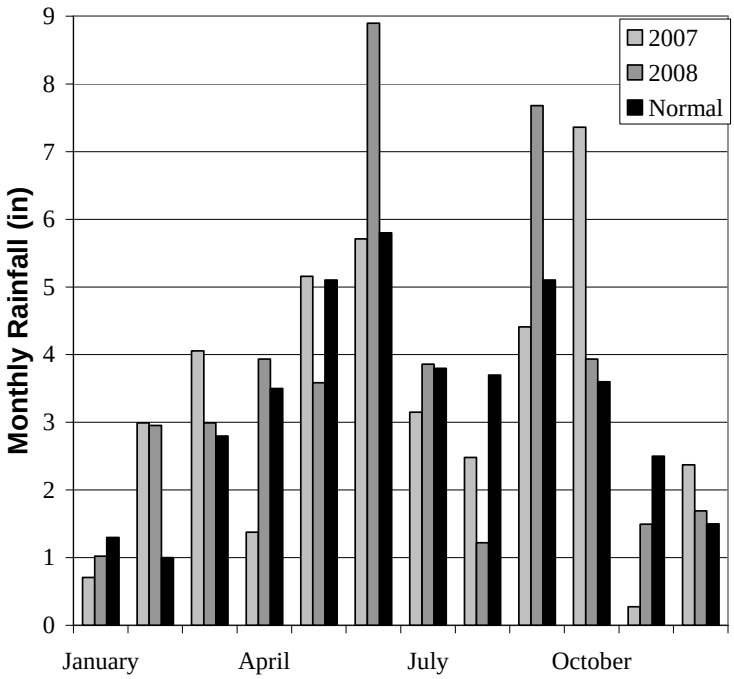

Figure 1. Average Monthly Rainfall during the Study Period.

RESULTS

The bioretention field study began in April, 2007. Figure 1 shows the monthly rainfall totals during the study period compared to normal rainfall amounts for these months based on historical data. Total yearly rainfall was 40.0 and 43.3 inches for 2007 and 2008, respectively, both slightly higher than the typical yearly value of 39.7 inches. The highest monthly rainfall was recorded in June 2008, at 8.9 inches. This unusually wet month resulted in sustained inundation of the bioretention cell for a period of approximately 2 weeks, and the only use of the site's overflow sewer during the sampling period. With the exception of this period, site drainage was within target design parameters, with drawdown occurring within 24-36 hours. The average drawdown rate was determined to be 0.18 inches/hour.

Table 1. Mean Suspended Solids and Metal Concentrations at Bioretention Cell Sampling Locations. All values in μg/L unless otherwise noted

	TSS	Zn		Cu	
	(mg/L)	Total	Dissolved	Total	Dissolved
Storm Sewer	343 ± 129	653 ± 150	44.9 ± 11.0	159 ± 54.4	9.83 ± 3.83
Bioretention Cell Influent	34.6 ± 13.7	303 ± 45.6	49.5 ± 11.9	82.8 ± 30.4	6.45 ± 3.58
Bioretention Cell Effluent	25.7 ± 13.5	194 ± 34.4	52.0 ± 15.8	50.0 ± 14.2	2.81 ± 0.97

Mean values for suspended solids and total and dissolved metal concentrations during the study period are listed in Table 1. Total suspended solids and metal concentrations were substantially higher than those reported in the 1983 USEPA Nationwide Survey (United States Environmental Protection Agency 1983). The effect of the particulate trap located in the storm sewer can be seen in the approximately 90% decrease in average suspended solids concentration from the roadway to the bioretention cell influent. Total metal concentrations also decrease between the two influent sampling locations, but by a much smaller factor than that for suspended solids. This indicates that both Zn and Cu are disproportionately bound to smaller particulates, which will be less likely to be removed in the large mesh filter bags used in the storm sewer.

Comparison of the average TSS values for the three sampling locations suggests that there is little additional removal of suspended solids provided by the bioretention cell itself. However, these average values do not take into account the substantial variations in influent TSS loading between different storm events. In order to account for this variation, removal rates for TSS and metals in the bioretention system were calculated on an event basis by assessing the difference between contaminant concentrations at each sampling location for each storm and then averaging these

removals. Removal rates were calculated based on the difference in concentration between the influent and outlet sampling location for three zones: the system as a whole (storm sewer to cell effluent), the bioretention cell itself (cell influent to cell effluent) and the storm sewer particulate trap (storm sewer to bioretention cell influent). Concentration-based data were used in all cases, with no attempts to account for loss of water volume in the bioretention cell due to evapotranspiration. Storm events where one of the influent concentrations was at or below detection limits were not used included in the datasets for these calculations.

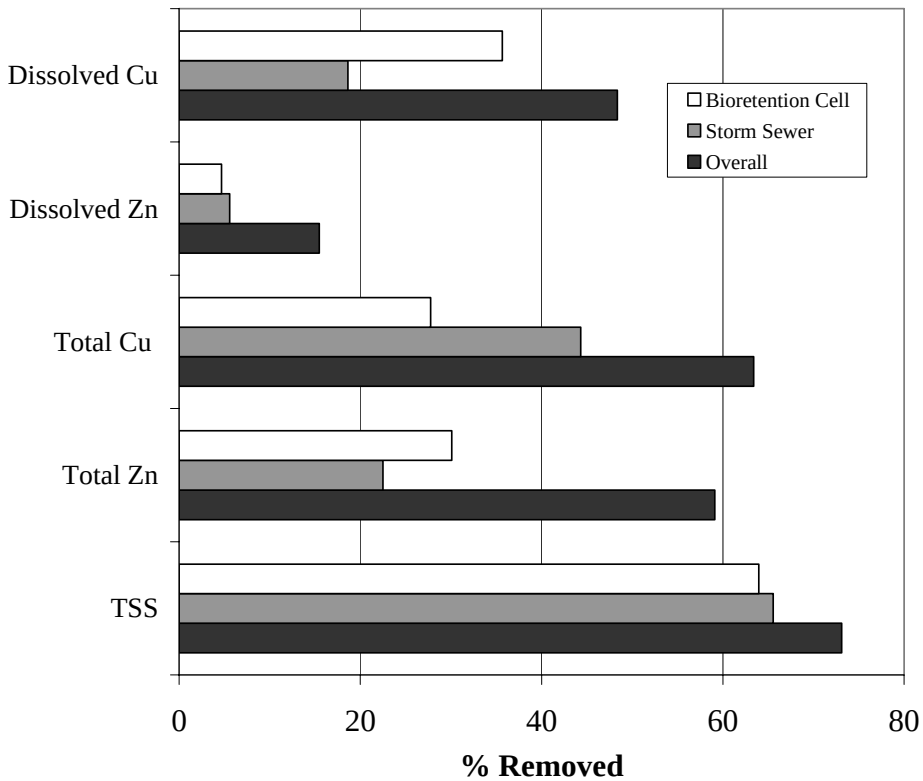

Figure 2. Contaminant Removal in the Components of the Bioretention Treatment System.

The effectiveness of the bioretention system at removing influent contaminants is shown in Figure 2. While the majority (~ 65 %) of suspended solid removal from the roadway runoff occurs in the storm sewer particulate trap, the bioretention cell also effectively removes the same percentage of influent solids. For both zones, as well as for the overall system, the percentage of influent solids removed increases with increasing concentration in the influent stormwater. TSS removal is in excess of 90% for most storm events where the concentration in the roadway runoff is greater than 100 mg/L. Total Zn and Cu removal percentages are lower in both the particulate trap and the bioretention cell itself. For Zn, in particular, this is partially due to very low dissolved metal removal rates of less than 20%. Dissolved Zn makes up almost 25%

of the total Zn in the bioretention cell effluent. The bioretention cell appears to be somewhat more effective at removing both dissolved and total copper, potentially due to the greater affinity of Cu for complexation with organic matter in the soil matrix.

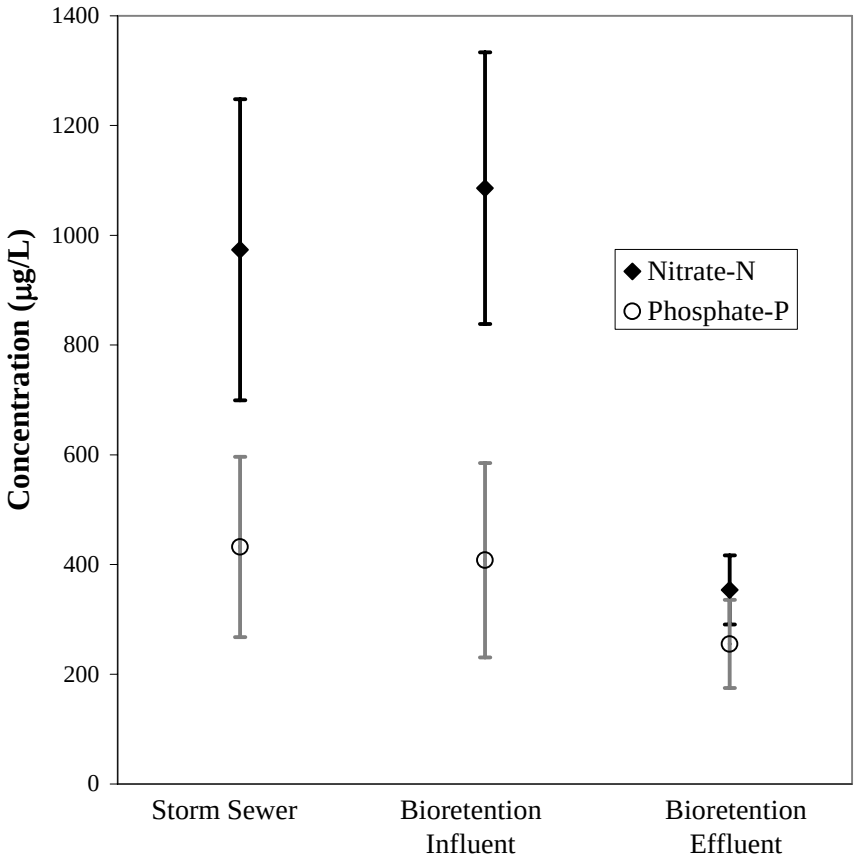

Figure 3. Mean Nitrate and Phosphate Concentrations at each Sampling Location in µg-N/L and µg-P/L.

Nutrient Removal: Mean nitrate and phosphate concentrations at the three sampling locations are shown in Figure 3. While phosphate concentrations are similar throughout the bioretention system, the nitrate concentration increases somewhat between the storm sewer and the bioretention cell influent. This increase is unlikely to be related to changes in total volume, since water is not retained for long in the storm sewer system. Possible sources of nitrate in the drainage area of this system include the vegetated berm surrounding the bioretention cell and the surface of the cell itself. In particular, water buildup on the cell surface during larger storm events may result in water mixing and nitrate release from the soil and vegetation immediately surrounding the storm sewer exit. Nitrate concentrations then drop substantially between the bioretention cell influent and effluent. While average phosphate concentrations are somewhat lower in the cell effluent than in the influent

stormwater, there were also multiple individual events in which an increase in dissolved phosphate was observed across the treatment system, suggesting that dissolved phosphorus retention may be a long-term cell performance issue.

Calculated removal percentages for these two compounds confirm that the bioretention cell removes a substantially higher fraction of influent nitrate (40%) than is typically observed for these systems. Nitrate removal has been improved in model systems by stimulating biological denitrification through the addition of biodegradable material at the cell effluent (Kim et al. 2003). Based on these results, it appears that a similar process is naturally occurring in this system. Biological denitrification may be enhanced in this system by relatively long stormwater detention times (24-36 hours, compared to recommendations of 8-12 hours in most design manuals). There is considerable biofilm growth on the inside of the bioretention cell effluent collection pipe, which may also play a role in the observed denitrification.

CONCLUSIONS

Sampling results presented here show that influent stormwater quality for the bioretention treatment system is typical of paved surface runoff, with elevated concentrations of suspended solids and total Zn and Cu. The use of a particle trap in the storm sewer considerably reduces loading of these contaminants to the bioretention cell itself, particularly with respect to suspended solids. This design choice adds to the maintenance requirements for the system, as the particle trap must be cleaned on a monthly basis, but will also likely prolong the lifespan of the bioretention cell by preventing clogging at the filter surface and reducing the rate of metal accumulation in the bioretention cell soil matrix.

The performance of the bioretention cell with respect to solid phase contaminants is in line with results from published field studies. Removal of suspended solids and particulate-associated metals is in the range of 50-70%, with little seasonal variation. Short circuiting of the treatment process occurred on several occasions due to extremely high rainfall in the first two weeks of June 2008, but the hydrological performance of the system is otherwise within the requirements for maintaining good vegetative cover and removing water from the site. System performance is weakest for dissolved metals and phosphorus, which show consistently low removal percentages. The high rates of nitrate removal observed here suggest that the 24 hr drawdown time observed in most storms is sufficient to allow for establishment of denitrifying bacteria in the bioretention cell. The overall effect on total nitrogen removal, however, is still under investigation. Further work for this study will focus on resolving this issue, and on improving system performance with respect to dissolved metal and phosphorus removal through changes or amendments to the soil mulch layer and/or the type and amount of cell vegetation.

ABSTRACT

When examining impaired river reaches, the primary focus is improving streamwater quality in the reach and downstream. The degree of damage to the river channel, the biological functions, and the river chemistry are assessed and restoration plans implemented. Few examine the causes of the degradation from upstream and upland areas and manage those problems before performing restoration work downstream. Without watershed management in the upper river system that addresses the stream's stressors, any restoration downstream becomes useless either relatively immediately or over time. Continued and potentially increased high peak flows from development during storms can wash out many restoration elements. Here, we examine the water management in the upper watershed of an unnamed tributary that passes through the Penn State Harrisburg campus, empties into the Susquehanna River, and eventually into the Chesapeake Bay. We also demonstrate the linkages between the lack of integrated water management and the current status of this tributary. The biota within the stream and surrounding the stream lack both diversity and richness. The streambanks are highly eroded and unstable. Current practices on campus (irrigation, grass cutting, etc.), as well as in the agricultural, residential, and industrial areas upstream, and any future campus development can hinder improving the stream's health. As restoration is being planned and implemented, the fact that this is an educational institution allows us to assess the stream's physical, chemical, and biological health both during dry-weather and wet-weather flows, as well as before and after restoration. We plan to evaluate whether on-land restoration and improved

stormwater management will affect the effectiveness of in-stream and stream buffer activities. We also plan to continue both biologic and chemical health evaluations of the stream as a function of land-use improvements. This project has supported several years of both undergraduate and Masters'-level research.

INTRODUCTION

Stream restoration, in recent years, has become a popular method in addressing water quality problems. Projects range from small undertakings such as creating a buffer zone along the streambank to large scale activities like repositioning the stream channel within the landscape. These projects can follow traditional engineering practices or be more holistic in nature. The primary focus, no matter the technique used, is to improve the present quality of water flowing in the stream.

Although the water quality can be improved at the point of restoration and further downstream, the potential for further degradation exists, particularly when degradative practices located upstream still exist and when future land development does not look off-site in evaluating its effects. With the lack of upstream water management, many type of restoration already in place will become useless. They may be removed due to uncontrolled high peak flows during storm events. Increasing the development in the upper watershed simply adds new pressure to the system, increasing the likelihood of failure of the restoration activities in the stream.

Using Penn State Harrisburg's natural resource, an unnamed tributary to the Susquehanna River, we examine the idea of water management both on campus and in the upper watershed to demonstrate how past and present management activities have affected the current state of an unnamed tributary to the Susquehanna River, which flows through campus. Chemical water quality assessments have been made as well as some biological assessments through the use of the stream as a living classroom for students. The stream has been used in ecology and engineering classes, as well as presenting research opportunities to both undergraduate and graduate students. We discuss what research and activities have been performed and possible outcomes of future activities that directly impact the stream.

SITE DESCRIPTION

The Campus Stream watershed has a rich history. Once farmland, the watershed was home to the United States Army's Camp (George Gordon) Meade in July, 1898. By July 1899, Camp Meade was returned to civilian use as a pickle farm for the H. J. Heinz Company until it was reclaimed for military use by the United States Air Force. The Olmsted Air Force Base was established in 1947 and retained ownership of a majority of the watershed until it was sold to the Pennsylvania State University in 1966 for establishment of the University's Capital College campus (Sitler 2007).

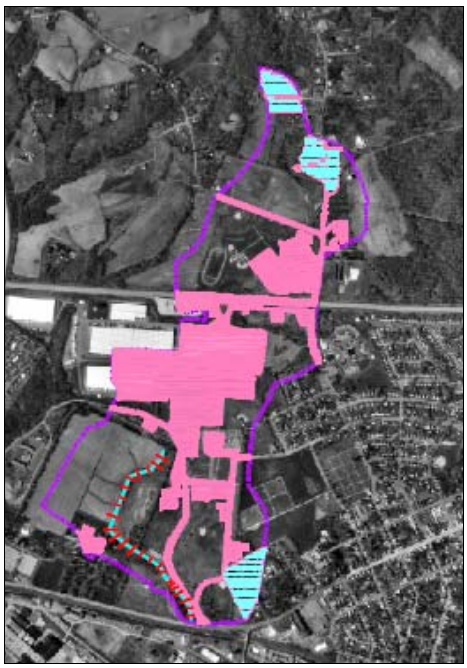
Located in south central Pennsylvania, an unnamed stream found on the campus of Penn State Harrisburg empties into the Susquehanna River and eventually into the Chesapeake Bay. Evidence of multiple engineering activities can be found along the stream (Figure 1a). The drainage area of the daylighted portion of the stream is 1.54 km (Sitler 2007). From where the stream daylights to the main entrance of the campus, the stream length is approximately 1.61 km (~1mi) long. Streambanks are steep, vertical, and easily erodible (Figure 1b). Located in the Piedmont Province, rock types in the study area comprise of sedimentary rock (red sandstone, shale, and conglomerate) and diabase intrusions (Siu 2006).

(a)  (b) 

Figure 1: (a) Past engineering practices at the campus stream downstream site, (b) Steep, vertical, erodible bank of campus stream.

Most of the drainage area surrounding the stream is behaves as an impervious surface. Immediately around the stream lie residential, institutional, commercial, industrial, and agricultural areas. The upper watershed contains more of the same. The impervious area in the watershed is shown in Figure 2. Using traditional definitions of impervious surface containing pavement and roofs, the pink color represents known impervious areas (rooftops, parking, etc.). The cyan color represents residential areas which are partially impervious (roofs, driveways, some sidewalks).

The campus history as the land use moved from agriculture to military to institutional has created unusual site conditions. The campus is in an area known historically for flooding. In addition, past military, agricultural, and other development activities appear to have left much of the ground on the campus itself compacted. While compaction has not been measured directly on campus, an analysis of the soils along the stream bank by Sitler (2007) found that the stream bank soils had bulk densities that were greater than the range listed for soils with limited grass growth and in the range of soils compacted by construction. Therefore, in order to minimize the land flooding and drain stormwater rapidly away from the land surface, a series of underground drainage pipes was installed. The storm drain network on campus, which discharges into the stream at several points along its daylighted and underground lengths, collects water directly roof drains, parking lots, and grassy surfaces.



(a)  (b) 

Figure 2: Watershed Boundary and Imperviousness (a) The drainage area of the Campus Stream encompasses a variety of land uses. The lack of stream channel, however, is indicative of the severity of channel impoundment through underground piping. (b) The current watershed is approximately 32% impervious. The pink areas may be considered totally impervious while the cyan color is residential and assumed to be partially pervious.

PAST AND CURRENT STORMWATER MANAGEMENT AFFECTING THE STREAM

Upper watershed: The upper watershed consists of a trucking/warehouse storage facility directly adjacent to the campus on the upstream side. Immediately upstream of the warehouse facility is the Pennsylvania Turnpike and a rest area, followed by (going upstream) a regional high school with outdoor athletic facilities, agricultural land and newer residential developments. The limited stormwater management in the upper watershed appears to consist of detention facilities.

Campus management: Current management at Penn State Harrisburg still reflects the historical stormwater management of previous land uses on that same land. Buildings from the military era are still in use today. These buildings and the more modern ones are directly connected to stormwater pipes, which empty into the stream that runs through campus. At some point in the stream's history, the stream channel was straightened and diverted at several locations. Bank destabilization, which still occurs today, has resulted in high vertical banks and the placement of riprap on portions of the stream (see Figure 1a,b). High peak flows during storms contribute to this bank destabilization. A detention pond, located alongside the stream, was intended to

decrease high peak flows by retaining nearby surface runoff from roads and open areas for release into the stream over a slower time period. The pond has not functioned properly, evidenced by high flows and bank erosion (Figure 3). In 2006, the detention pond was improved through area enlargement and more riprap placed at outfalls. High peak flows are evident still, regardless of these enhancements. The underlying problems in the pond design were not addressed.

Figure 3. Campus stream at bankfull conditions (< 1 year storm event). The detention pond is in the upper left corner and appears to be detaining little water, even during storms that cause bank full conditions in the stream.

Other problems and activities on campus contribute to poor stream health. For instance, water usage for gardening purposes has not been conservative. Watering grass has included directing the sprinkler into the storm drain as shown in Figure 4.

Figure 4: Campus lawn maintenance and water management.

Watering has occurred also on the same day forecast for rain or recently after a rainstorm. On occasion, watering has lasted for several hours. Lawn mowing near the stream impacts the stream's health as well. Grass clippings typically are left on the lawn instead of collected. Clippings also fall into the stream as the areas next to the stream channel are mowed. Figure 5 illustrates this and the fact that a riparian buffer does not exist. Grass is mowed up to the edge of the streambank. Grass clippings in

streams can increase the nutrient and pesticides concentrations as these compounds are released into the water. The lack of overstory cover increases the thermal radiation to this stream, thereby raising water temperatures and allowing stream evaporation in the summer to occur.

Figure 5: Grass clippings in the campus stream.

While the current conditions are not favorable for stream health, there is an interest in the administration in improving the campus' ecological health. Included in that is the desire to beautify the front entrance to the campus, which requires improving the stream. The activities described below have been designed to provide baseline information on the stream's health and prospects for improvement. Additional activities are ongoing in terms of determining effective watershed management. As described earlier, the stream and the land use activities are intertwined. The stream's health will not improve and restoration will not last unless sustainable stormwater management is implemented on campus. This campus provides an excellent opportunity for documenting the effects of retrofitting stormwater management practices – both structural and non-structural. The land is available and the people are interested.

EDUATIONAL ACTIVITIES AND RESEARCH

This stream offers many opportunities to students and for outreach activities. Students of all ages learn ecological, hydrological, engineering, and chemical concepts and their application to a real world situation. Examples of classes using the stream for projects or labs include Ecology, Hydrology, and Open channel hydraulics. Water quality monitoring techniques can be demonstrated also. Several Masters' papers and theses have revolved around different aspects of the stream. Subjects include streambank stability over time, modeling stormwater practices within the watershed, and gathering baseline data with the anticipation of changes to water quality as campus development continues.

Stream ecology: As part of several laboratory activities using the stream as a classroom, ecology students have learned about macroinvertebrate distribution, periphyton, and energy budgets. A project starting in February 2009 will measure stream water chemistry, flow, rainfall, macroinvertebrates and periphyton concurrently to elucidate relationships between them on this small headwater stream.

Siu (2006) noted green filamentous algae (*Cladophora* and possibly *Stigeoclonium*) growing in the streambed at various times of the year throughout the length of the stream. Observations also found a continual growth and decay cycle including algal mats at one study site during the study period. Stream organisms were low in diversity and individuals. Observations of gopher, bullfrog, minnows, and crayfish were made. Flocks of Canadian geese were observed to frequent the stream during migration periods. Samples of algae were taken to determine the presence and diversity of macroinvertebrates. Little diversity and few individuals were present. Most of the macroinvertebrates found were either pollutant tolerant or moderately so. Pollution sensitive species that would indicate good stream quality were mostly absent.

Stream chemistry: Data collection for baseline data of the stream began in 2005. Siu (2006) reports on a six-month water quality study examining baseflow conditions and conditions immediately after storm events. The study encompassed three seasons, late summer, autumn, and winter. General chemistry metrics such as pH, conductivity, turbidity, dissolved oxygen, and temperature were measured. Nutrients (nitrate, orthophosphate, and ammonia), total suspended solids, chemical oxygen demand, detergent, and fluoride were examined as well. Seasonal trends were found for nitrate and orthophosphate concentrations (Figure 6), turbidity, dissolved oxygen, and temperature.

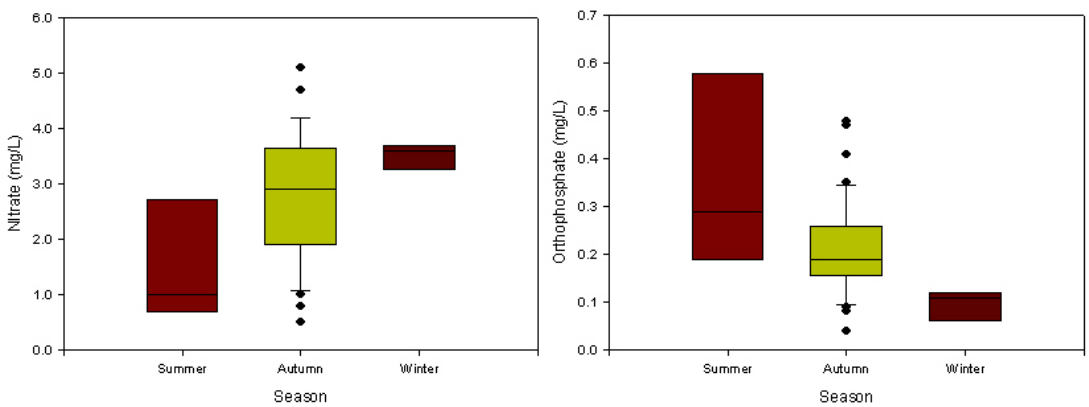


Figure 6: Seasonal nitrate and orthophosphate concentrations.

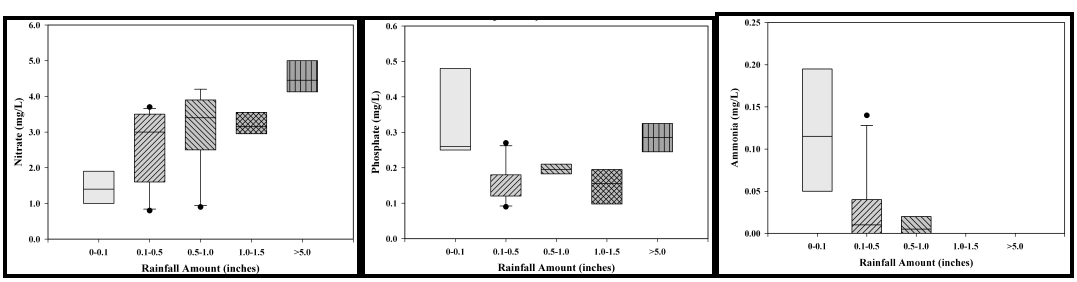

Figure 7: Nitrate, orthophosphate, and ammonia concentrations affected by rainfall intensity.

Nutrients (nitrate, orthophosphate, and ammonia) were affected by rainfall intensity (Figure 7). In both seasonal and rainfall intensity trends, orthophosphate and nitrate showed inverse relationships. Nitrate concentrations increased through the seasons and with an increase in rainfall intensity. Orthophosphate concentrations decreased as the seasons passed. Greater concentrations of orthophosphate occurred with the smallest amount of rain (0-0.1in). Ammonia concentrations were greatest also at this same rainfall intensity.

Work performed by Clark and Treese (2008) and Clark et al. (2009) determined concentrations of copper and other pollutants in campus stormwater that originated from roofing materials. Many building roofs on campus contain copper sheets or copper flashing. During storm events, copper is washed off these surfaces and enters receiving waters. To date, only stormwater runoff has been tested for copper. Campus streamwater has not been tested yet for heavy metals or organics. It would be anticipated that the sediments nearest the discharges from pipes draining the roofs with copper flashing most likely would contain elevated copper concentrations. The travel time in the stream is relatively short; therefore, without analysis, it would be difficult to predict whether equilibrium occurred and the copper had time to move from the water column (stormwater) into the sediment.

Engineering: Stream geomorphology and stormwater runoff volume, flow rate, and duration were modeled by Sitler (2007) to investigate what flows were likely to cause streambank erosion. Visual surveys of the stream during this period showed continued slumping of the streambanks after storms such as the one shown in Figure 3, which was a bankfull storm by flow but was smaller than the traditional bankfull definition of a 1 – 2 year storm. This event had a return interval of < 1 year. The modeling demonstrated the need for models that could work in the small size of the stream. The model showed no streambank slumping during the storms, while the visual observations noted substantial erosion.

Engineering classes such as hydrology and open channel hydraulics have used the stream in classroom projects to further enforce concepts taught in the classroom. These classes are concerned with the quantity of stormwater runoff and elevation of the water surface profile and spread of water in the floodplain during a flooding event. The results show that as the campus develops, the need for improved stormwater management will increase exponentially.

FUTURE PROJECTS

The Penn State Harrisburg campus is continuing to grow with the increase of students. Plans for future buildings and facilities on campus are underway. Students and others have been asked for their input in the decision making of future buildings and facilities. However, campus development must consider how construction can affect the campus stream. All phases of construction may become a risk to the stream's health. Improper installation or unintentional breach of stormwater control systems,

particularly for erosion control, can increase sediment loads and cause greater peak flows into the stream. In-stream habitats can become covered or lost. Stream organisms can become injured and there may be loss of oxygen. Continuation of streamwater monitoring is anticipated with the expansion of analytes for analysis to include heavy metals, organic pollutants, and chlorides.

The immediate area around the stream has the potential to be made into a space that can be enjoyed by the campus community and benefit the stream's inhabitants. Care needs to be taken that these types of improvements will not further impact the stream. For example, increasing or maintaining pervious cover rather than impervious cover will help decrease additional runoff entering the stream. Adding tree cover visually improves stream appearance but also improves soil quality, reduces pollutants and runoff entering the stream, stabilizes the ground, and reduces erosion. Reducing soil compaction or diverting stormwater runoff away from areas that behave as impervious, such as to rain gardens and other amenities, will mitigate the impacts on the stream.

Although improving campus stormwater controls will improve the stream's health, the quantity and quality of water from the upper watershed is crucial as well. This campus and its continued development provide an excellent opportunity for studying the impacts of relatively minor and inexpensive changes, as well as major ones, on stormwater generation, stream water quality and stream stability. Future campus stormwater management activities may include rainwater harvesting for irrigation, conversion of traffic islands to rain gardens, green roofing. The potential of these small, relatively-inexpensive changes on stormwater flow rates and duration currently are being modeled by a graduate student with the results available in May 2009. Future work will include monitoring the effectiveness of newly implemented practices on the stormwater and on the stream.

The education of students and the community about streamwater quality and stormwater through outreach activities will continue. The stream remains an outdoor classroom and living laboratory for present and future students and campus visitors. The size of the campus relative to the watershed, the location of the campus at the downstream end of the watershed, and the willingness of the campus community to engage in improved stormwater management for stream health makes it an ideal location to study the linkages between land use and ecology.

ABSTRACT

Many surface water bodies have been severely degraded by runoff from the centuries of continuous human development without regard to the impacts of stormwater. Local governments are beginning to responsibly respond to the need for action about increased imperviousness by adopting local Low Impact Development (LID) ordinances. The purpose of this study was to evaluate the hydrologic abilities of LID development to: reduce peak runoff flow rates to the pre-development values; to infiltrate the recharge volumes mandated by current criteria; and to attenuate the impacts of extreme storm events. A numerical simulation was performed on a 4-hectare site for pre-development as well as residential development with Conventional and LID stormwater management design scenarios. Research results from four years of intense monitoring of LID systems at the University of New Hampshire Stormwater Center were integrated into these hydrologic models. Analyses were performed for hydrologic soil types A and C, for storms with recurrence intervals of 0.17-, 2-, 10-, and 100-years, as well as 2-, 10-, and 100-years adjusted for climate change. The results show that the LID site design: generated much lower runoff volumes than the Conventional and Pre-development site conditions; infiltrated more than the recharge volumes required by current regulations; and attenuated the impacts of extreme storms modified for climate change.

KEY WORDS:
Low impact development, stormwater management, climate change, water scarcity, groundwater recharge, design storms, hydrologic impacts.

INTRODUCTION

In the last half century, water resources management has become increasingly problematic. In the summers we face more frequent limited drinking water availability, while in the spring and fall, we struggle with floods and repair flood damages. Sometimes the same repairs have to be repeated in consecutive years due to the same cause: increased runoff peak flow. These peak flows are exacerbated by human development as well as due to storm depths greater than the design events for the infrastructure.

The rate of climate changes directly affects how we design infrastructure and how we can mitigate its impacts on our communities and daily life. Evaluations of the last six decades of precipitation data in the US have found that storms with extreme precipitation have increased in frequency by about three percent per decade, varying regionally (Kunkel et al., 1999) and they are prone to increase by 10-40% by the end of the 21st century in the northern latitudes of North America (Parry et al, 2007). Warmer climate increases the risk of both floods and droughts, since the precipitation variability is also projected to increase. We will see precipitation events with increasing storm depths but with longer dry periods between events and subsequently extended periods of low streamflow (Union of Concerned Scientists 2006).

Stormwater infrastructure is usually designed to safely pass a 10-, 25-, 50-, or 100-year storm, depending on the degree of importance of the site. Storm depth values for each design storm are computed from the statistical evaluation of regional historic precipitation events. Unfortunately, these statistical analyses have not been updated for current precipitation patterns, and are based on decades old rainfall data. This means that infrastructure designed nowadays based on these criteria's are obsolete from their first day of installation. Comparing the precipitation data from the first and second half of the last century in the Chicago area (Angel and Huff, 1997), it was found that the rainfall intensities for the storm durations of interest in urban drainage design have had statistically significant changes. Increases of 28, 36, 43, 50, and 60% for return periods of 2-, 5-, 10-, 25-, and 50-years, respectively, were detected in the second half of the last century (Guo, 2006). According to Stack et al., (in review) who studied the rainfall data for southwest New-Hampshire, what were once 10- and 25-year storms, will become 25- and 100-year storms, respectively, in the mid-21st century.

Additional stress on infrastructure comes from connecting runoff from new developments to the existing stormwater sewer systems designed for past needs. In urbanized areas serviced by combined sewer systems, additional contributing areas can result in more frequent combined sewer overflows (CSO's). This contributes to both degradation of receiving water body quality and increases of peak flow rates and runoff volumes discharging into these surface water bodies.

The stormwater management challenges of the 21st century are to develop strategies that encompass climate change for the increasing impervious surfaces of

urbanization, while maintaining watershed health and fulfilling governmental requirements for stormwater quality. Several local governments responded favorably to the need to take action about increasing runoff volumes by adopting local LID ordinances. In addition, stakeholders have included LID practices in their planning. Although researchers have found that LID practices can address the main problems of current stormwater management, and many State Agencies have developed new manuals for stormwater management that include design guidance, there are still impediments to the full implementation of LID practices. Engineering teams find that there is not enough understanding of how the hydraulic response of LID practices change with system design variables, such as hydraulic conductivity, filter media thickness, distances between under-drains or the lack of them, and infiltration rates of the native soils. For the same reason, reviewing agencies do not yet have clear modeling guidelines for applicants.

Since 2003, the University of New Hampshire Stormwater Center (UNHSC) set out to evaluate stormwater treatment systems in a fully-monitored field setting. The systems are studied in a side-by-side setting (all receiving equivalent water quantity and quality) and can be categorized as: conventional practices (retention pond, detention pond, and swales), LID practices (sand filter, bioretention, gravel wetland, pervious concrete, porous asphalt, tree filter) and manufactured devices (subsurface sand filter, filtration, hydrodynamic separators). UNHSC research results show that the pollutant removal efficiencies and peak flow reduction obtained by LID systems are superior of those obtained by conventional and manufactured systems. (Ballestero et al., 2007).

The overall goals of this study were: to research the abilities of structural LID systems to attenuate the hydrologic impact of storms, compared to conventional stormwater designs; to study the ability of these systems to infiltrate stormwater ; and to assess how management strategies perform for expected climate changes. As an example of infiltration requirements, the New Hampshire Department of Environmental Services (NHDES) requires that for each new development, for the 2-year, 10-year, 25-year and 50-year, 24 hour design storms: “post-development peak flow rate shall not exceed the pre-development peak flow rates”; “post-development total runoff volume shall be equal to 90 to 110 percent of the pre-development total runoff volume” and “the annual average recharge volume for the major hydrologic soil groups found on the site should be maintained” (NHDES, 2007).

These recharge requirements are similar to those of other states in United States. (Table 1). These volumes can vary by state and they are normally meant to match the infiltration volumes of pre-development conditions. Since design precipitation intensities are predicted to increase (Kunkel at al., 1999) in the context of climate change, runoff volumes could increase to the detriment of infiltration. Milly et al, (2005) found that runoff would increase in the higher latitudes of North America by 10-40% by 2050. Although the goal of recharging stormwater is to preserve the water balance of the pre-developed conditions, current requirements regarding recharge

volumes are not meant to compensate for recharge loss in the context of climate change or for groundwater withdrawal for human consumption.

Table 1- Recharge depths required by different states and different soil types.

Hydrologic Soil Group	NHDES	MADEP	Philadelphia/for CSO-sheds
Type A	1cm (0.40in)	1.5cm (0.60in)	2.5cm (1in)
Type B	0.6 cm (0.25in)	0.9cm (0.35in)	2.5cm (1in)
Type C	0.3 cm (0.1in)	0.6cm (0.25in)	2.5cm (1in)
Type D	Not required	0.3cm (0.10in)	2.5cm (1in)

For this research, it was decided to hydrologically model a 4-hectare site for pre-development conditions, developed conditions with conventional stormwater management, and an LID approach. Special interest in this study was given to peak flow rates, recharge volumes, and runoff volumes generated under the same design storms by the different land use scenarios.

For the Jordan Cove project, where the LID hydrologic response was monitored and compared to the hydrologic response from a conventional site design, it was found that the LID site was performing better than the conventional site only for storm events smaller than 25 millimeters or shorter than 4 hours and for low antecedent moisture conditions (AMC). (http://www.jordancove.uconn.edu/index.html).

METHODOLOGY

Numerical simulation of the stormwater management of ten 0.4-hectare residential lots was studied for three scenarios: Pre-development, Conventional design, and LID design. Three hydrologic models were developed using the runoff modeling software HydroCAD 8.50. The three models are meant to represent the change in land use and how this alters the hydrologic responses of the site for the same design precipitation events. For the Pre-development site, the land use was chosen to be four hectares of woods and grass combinations in fair conditions and with a general slope of 5%. For the Conventional design, land use was 5% road, 3.6% driveways, 4.6% rooftops and the rest being 86.8% lawns. The site configuration is presented in Fig.1(a). Stormwater management for this site included a series of five catch basins, connected by underground pipes, which were designed to convey the 24 hour-10 year storm event. Each catch basin collects runoff from the lawns and impervious surfaces of two 0.4-hectare lots. The catch basins were modeled as ponds with the interconnecting pipes modeled as outlets. For the LID site design, the land use was 5% road, 3.6% driveways, 4.6% rooftops, 21.8% lawn and the rest of the 65% was conserved as the pre-development land use of woods and grass. The LID site configuration is presented in Fig.1(b).

Stormwater management for the LID site included nonstructural practices (land conservation and the use of natural features of the original site) and structural

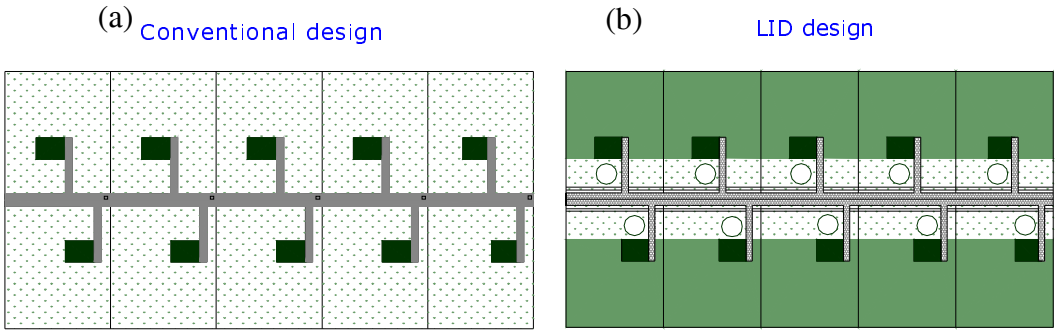

Figure 1. Conventional and LID site design configuration; dark green represent rooftops, grey represent the driveways and the road and light green represents undisturbed cover.

practices (porous pavement for driveways and road, bioretention systems that collect the rooftop runoff, and grassed swales on the sides of the main road which convey the runoff from lawns). Culverts underneath the driveways connect the grassed swales, which were designed to pass the 24 hour-10 year storm event. Bioretention systems were modeled as ponds which also allowed infiltration; they were designed to retain the "first flush" (the first 25 millimeters of rainfall), and had an overflow for larger events, which was directed towards the porous pavement driveways. As the modeling software did not contain special features for LID systems, the porous pavement was modeled as a pond with 30% void space, and for the outlets, a 15-centimeter diameter underdrain with exfiltration. This was considered to be a conservative approach, which gives an approximation of outflow through drains similar to the outflows observed at the UNHSC porous pavement site. In order to simulate the filtering time of runoff through the sand filter layer (the sub-base of the porous pavements), the inflow hydrograph was delayed by a time equal to the annual average lag time observed for monitored storms at the UNHSC porous pavement lot. The sub-base thickness for the driveways is represented by 7.5 centimeters of porous asphalt, 5 centimeters of crushed stone, and 20 centimeters of gravel on top of 10 centimeters of crushed stone. The gravel layer contains a 15-centimeter diameter underdrain, wrapped in 5 centimeters of crushed stone. In a similar way, the sub base for the road is represented by 10 centimeters of porous asphalt, 7.5 centimeters of crushed stone, and 35 centimeters of gravel on top of 20 centimeters of crushed stone. A 15-centimeter diameter underdrain is placed 10 centimeters above the bottom of the system (in the underlying crushed stone). This allows infiltration in between storms. The sub bases of the driveways and road are interconnected, allowing the water to travel from the driveway sub base into the road sub base. The grassed swales were modeled as ponds, which allow infiltration, with the primary spillway represented by the driveway culverts, and the secondary outlet represented by broad-crested rectangular weirs discharging into the porous pavements. This was meant to simulate the porous pavement run-on from swales after their capacity is exceeded.

These three site models were analyzed for hydrologic soil types A and C, with infiltration rates of 6.25 millimeters per hour and 50 millimeters per hour, respectively. The models were run and analyzed for type III, 24 hour storm events with recurrence intervals of 0.17-, 2-, 10-, and 100-years, as well as 2-, 10-, and 100-

years adjusted for climate change. Soil moisture conditions were selected as AMC-II. The total storm depths used in the analyses are summarized in Table 2.

Table 2 – Values of design storm depths for present conditions and those predicted for the climate change scenario

Design storm (yr)	2	10	100
Climate Change Depth Increase (%)	17	28	45
Current depth –cm (in)	7.53 (3.01)	10.86 (4.35)	15.75 (6.3)
Increased depth –cm (in)	**8.8 (3.52)**	**13.93 (5.57)**	**22.85 (9.14)**

RESULTS

Hydrographs from Pre-development, Conventional, and LID sites were analyzed by each design storm depth. The results were compared at the final site outlet structure, which was identical for the LID and Conventional sites, and then divided by ten, in order to find the hydrologic response of each residential lot (0.4 hectares).

Results for Hydrologic Soil Group A

For the hydrologic soil group A, the Pre-development site generated runoff for the 10- and 100-year storms, but not for storms smaller than the 10-year return period. The LID site generated runoff only for the 100-year storm, and the Conventional site generated runoff for all design storms investigated in the analysis. In the context of climate change, the Pre-developed site generated runoff starting with the 2-year storm, and for the LID site, only the 100-year storm generated runoff. Since the LID site generated runoff starting with a storm depth which is somewhere between the 10-year and the 100-year storm, this particular site was also analyzed for intermediate storm depths, and it was found that runoff was generated starting with the 50-year storm. The 50-year storm represents a 24-hour duration rain event with a total depth of 14.5 centimeters of precipitation.

Interestingly, a 45% increase in the 100-year storm (representing the effect of climate change), resulted in an increase of runoff volume of 170% for the Pre-developed site. The same change in the storm depth resulted in a 363% increase of runoff volume from the Conventional site and a 74% increase from the LID site. Analyzing the total depth of storms and their distribution as runoff and infiltration (Fig.2a and Fig.3a), it was found that the LID site retained up to 44% more water on the site than the Conventional site and up to 15% more than the Predevelopment site. Surprisingly, peak flow rate results show that the LID site reduced the peak flow rates to values smaller than those generated by the Pre-development site. Peak flow rates for the LID site were up to 58% less than the Pre-development values; while the Conventional site values were up to 188% more than the Pre-development site (the Conventional design objective was solely to drain the development of stormwater).

Results for Hydrologic Soil Group C

For the hydrologic soil group C, all three development scenarios generated runoff for all storms, the only exception being the LID site which did not generate runoff for storm depths up to 25 millimeters. The results are similar as those for the type A soil, but the changes were not as dramatic, because the initial infiltration capacity of the soil is lower. The 45% increase in the 100-year storm depth (representing climate change) resulted in an increase of runoff volume of 70% for the Pre-developed site. The same change in the storm depth resulted in an 82% increase of runoff volume for the Conventional site and a 36% increase for the LID site. Analyzing the total depth of storms and their distribution as runoff and infiltration (Fig.2b and Fig.3b), it was found that the LID site retained on the site up to 67% more water than the Conventional site and up to 24% more than the Predevelopment site. Results show that peak flow rates for the LID site were up to 73% less than the Pre-development values, while the Conventional site values were up to 76% more than those for the Pre-development site were.

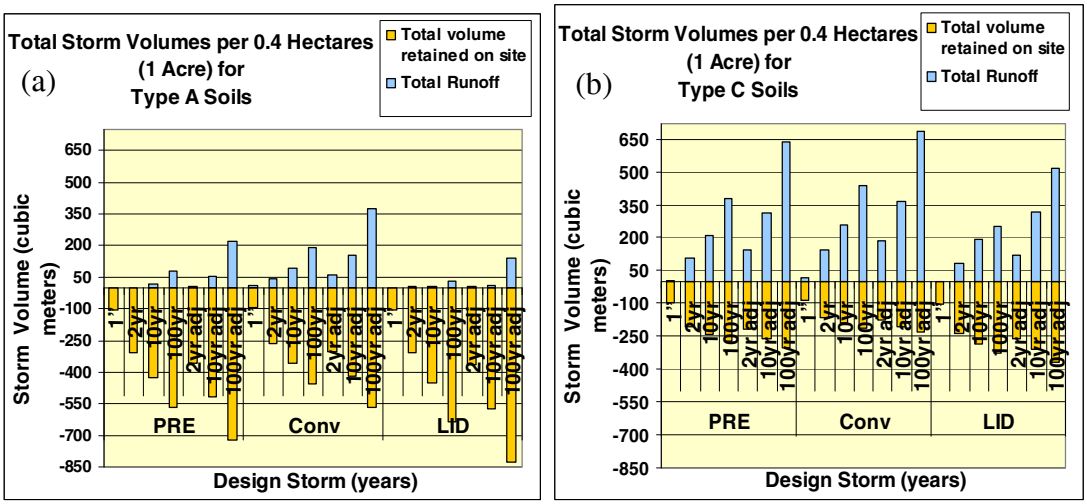

Figure 2. Total storm depth distribution: positive values represent runoff and negative values represent infiltration.

The study of daily precipitation data from 1915 to 2007 for Durham, NH shows that 99% of daily precipitation depths are 75 mm or smaller, with an annual average precipitation of 115 cm. As seen in Fig. 2, each site generates runoff starting with a certain storm depth. For example, the LID site generated runoff starting with the 2-years storm in a type C soil and with the 50-years storm in a type A soil. Assuming that all precipitation events smaller than the ones which generate runoff are retained on the site, Fig.4 show the summation of annual rainfall retained on the site by each land use scenario for hydrologic soil types A and C, for all storms of 75 mm and smaller. The results indicate that in a type A soil, the LID site recharges annually the same amount as the pre-developed site, while in a type C soil, the LID site recharges even more than the Pre-developed site. The Conventional site recharges the least out of the three sites for both types of soil, with an annual recharge decrease of 9.3 cm and 9.6 cm for type A and C soils, respectively, compared to pre-development conditions.

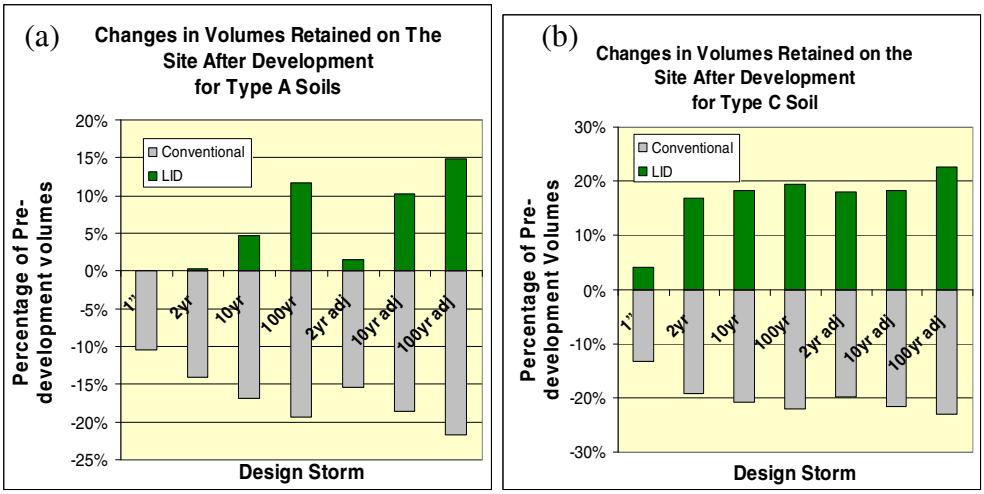

Figure 3. Total infiltrated volumes by Conventional and LID sites compared to the Pre-development site: the zero line represents the Pre-development. Positive values represent an increase of infiltrated volumes, while negative values represent decrease of recharge compared to Pre-development conditions.

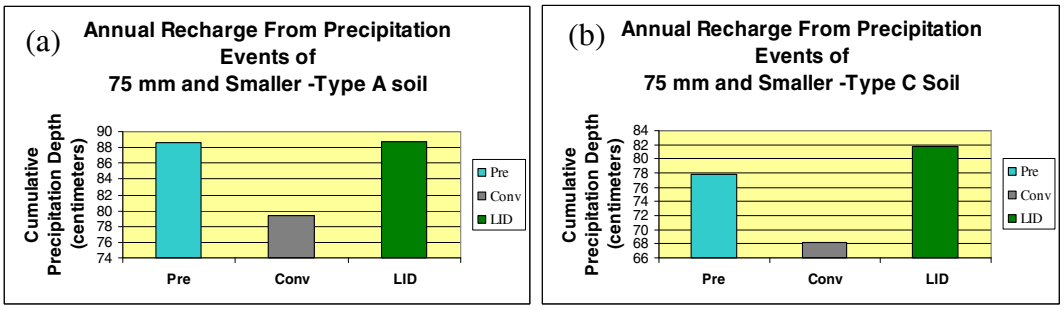

Figure 4. Summation of retained water volume (as depth) on the site for annual precipitation events up to the 2-year storm for type A soil(a) and type C soil(b).

DISCUSSION

The results of this study show that by using structural and nonstructural LID practices in stormwater management, the hydrologic characteristics of developed sites can be improved over that of a conventionally designed site by providing for additional storage in the LID systems, increasing infiltration, reducing runoff peaks, and delaying the runoff peak by routing the water through low hydraulic conductivity layers. The longer residence time of water in the LID systems allows groundwater recharge over a longer period, which in turn results in higher total volumes recharged per storm event. Contrasting this to conventional stormwater management practices which are meant to collect, concentrate, and convey runoff off site, LID principles imply that the runoff should be managed at the source and infiltrated at the source, when possible. These principles were reflected in the models used in this study, and the results showed that the requirements regarding peak flow rates, total runoff volumes, and recharged volumes could be met by using LID practices. The LID site generated runoff starting with the 2-year storm (7.5 cm) in a type C soil and with the

50-year storm (14.5 cm) in a type A soil, which implies that smaller storms are retained on the site. These values are much higher than the 1 to 2.5 cm required for type A soil and 0.3 to 2.5 cm required for type C soil found in Table 1.

LID systems are usually designed to retain, treat, and infiltrate the first 2.5 cm of rainfall: higher storm depths are by-passed. This explains, in part, the results of the Jordan Cove Project and is also a forewarning that LID design could be effective and more efficient if designed with built-in redundancy. In the model presented in this study, the bioretention system was also designed to retain the first 2.5 cm of rainfall, but a secondary spillway was designed to direct the higher bypass flows into the porous pavement driveways. Grassed swales were designed to pass the 10-year storm, but the swale secondary spillway was directed into the porous pavements. Porous pavement systems are usually designed for load capacity and frost depth (in cold climate zones) and then they are analyzed for their storage capacity. In most cases, the sub-base designed for these structural criteria allows for retention of much more than 2.5 cm of rainfall. When the porous asphalt hydraulic capacity is exceeded in a model, the sub-base depth can be increased in order to obtain additional storage. Routing the secondary spillways for swales and bioretention systems through the porous pavement sub-base makes a good use of the extra storage capacity available in the porous pavement system. This represents the site redundancy in this study and explains the peak flow rates and runoff volumes for the LID site being lower than the Pre-development conditions.

The overall results show that the LID site design:

- generated much lower runoff volumes than the Conventional and Pre-development site conditions;
- infiltrated more than the recharge volumes required by current regulations; and
- attenuated the impacts from extreme storms for both hydrologic soil groups A and C, since peak runoff flows rates from the LID site were lower than the peak runoff flow rates from the Conventional and the Pre-development sites.

Given the fact that the hydrologic conditions of the soils were improved by providing extra storage in the LID systems when developing only 13.2 % of the total site, it is believed that LID developments with greater densities could reduce the impacts of large storms even more.

Although this modeling approach is considered conservative and reflects research results from studying the porous pavement site at the UNHSC, assumptions used in this study should not be used for porous pavements with sub base materials different from those of the studied site (http://www.unh.edu/erg/cstev/pubs_specs_info/unhsc_pa_spec_07_07_rev_4_08.pdf). Future research efforts regarding hydrologic performances of LID systems should include the relationship between the outflow hydrograph and its design variables such as: porous media thickness, hydraulic conductivity, system geometry, and/or infiltration rates of native soils. Future research should focus on how runoff will change as a result of changes in precipitation patterns in the context of climate change and accurate estimates of

recharge needs in order to maintain the natural water balance of a site for different hydrologic soil types and for different groundwater withdrawal patterns.

CONCLUSIONS

Current stormwater management regulations are moving towards requiring hydrologic transparency of developments (post-development hydrology should match the pre-development hydrology). The only means of accomplishing this, particularly the infiltration aspects, is through LID designs. With new legislation paying closer attention to the implementation of sustainable development patterns, regulations for development that address recharge should encompass all the factors which impact groundwater and not only the lack of recharge due to land use changes.

In conclusion, it should also be mentioned that by practicing LID stormwater management, we are a step closer to sustainable development. Recharging precipitation is instrumental in maintaining the natural water cycle, and the results of this study showed that LID-SWM practices have the ability to infiltrate amounts of water that may compensate in the water balance of aquifers for both the lack of recharge due to impervious surfaces and withdrawal of groundwater for water supply.

ABSTRACT

Many stormwater management manuals and guidance documents have stated the importance and estimated the necessary frequency of maintenance for stormwater best management practices (stormwater BMPs), but few have been able to document the actual frequency and intensity of maintenance required to maintain a desired level of performance and efficiency. Increased attention to mass balance, numerical goals, total maximum daily loads (TMDLs), and non-degradation requirements has created the need for more emphasis on stormwater BMP operation and maintenance (O&M) in order to meet permitting and reporting requirements. The purpose of this paper is to advance knowledge about routine and non-routine maintenance so as to develop more useful O&M plans. To do so, we reviewed literature throughout the United States for maintenance costs and developed, distributed, and analyzed the results of a detailed municipal public works survey.

The specific goals of the survey were to identify and inventory O&M efforts and associated costs for stormwater BMPs. Survey questionnaires were sent to 106 cities, 28 of which responded. The survey related to the following topics: number of stormwater BMPs in the city, frequency of inspections and maintenance, average staff-hours spent per routine inspection or maintenance, complexity of maintenance, most frequent causes of performance deterioration, and cost of non-routine maintenance activities. The results of the survey revealed that most (89%) cities perform routine maintenance once per year or less. The most common causes of performance deterioration and the greatest expense were sediment buildup and litter/debris for most stormwater BMPs. The nationwide literature review resulted in predictive equations for O&M cost of stormwater BMPs as a function of total construction cost. A general rule of thumb is provided for estimating the relative importance of O&M in life-cycle costs.

INTRODUCTION

Structural stormwater ***BMP operation*** is the optimization of (1) pollutant removal and (2) reduction of runoff volume and rate via the management of stormwater networks or treatment trains. Stormwater ***BMP maintenance*** is the purposeful management of a stormwater BMP so as to maintain a desired level of performance and efficiency and consists of short-term (routine or more frequent), long-term (non-routine or less frequent), and major (rare) actions (Figure 1).

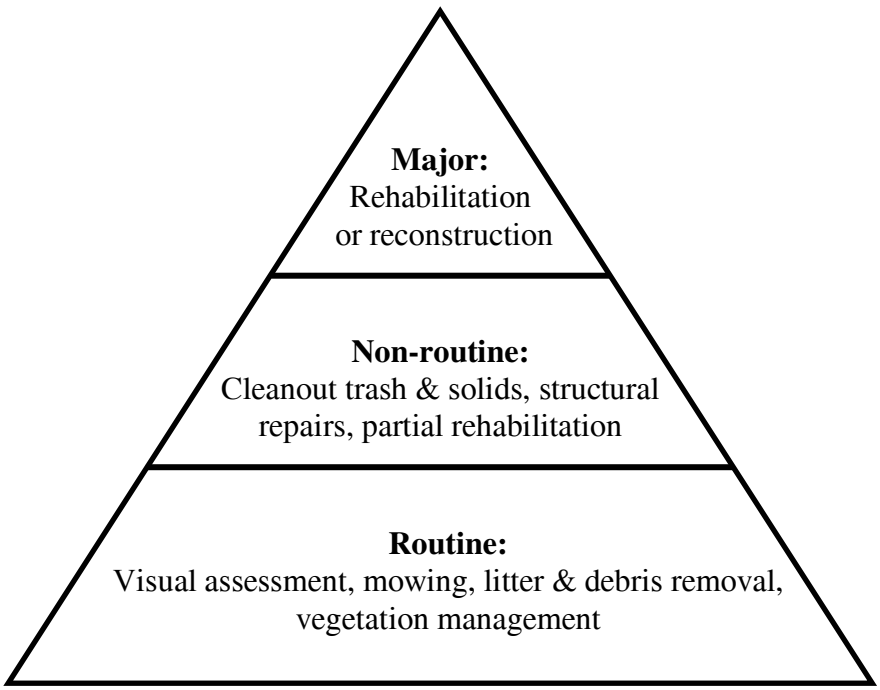

Figure 1: Stormwater BMP Operation & Maintenance Pyramid

Performance longevity of stormwater BMPs from their creation (design and construction) through operative stages (functional or not) is dependent on operation and maintenance actions. Because maintenance involves a significant amount of resources (personnel, equipment, materials, sediment disposal expense, etc.), the more that is learned about stormwater BMP operation, the easier it will be to maintain optimal performance as well as improve cost-effectiveness. The purpose of this article is to advance knowledge about short and long-term maintenance so as to develop more useful operation and maintenance (O&M) plans. To do so, we reviewed nationwide literature on maintenance costs and developed, distributed and analyzed the results of a detailed municipal public works survey.

The specific goals of the survey were to identify and inventory stormwater BMP maintenance activities. Survey questionnaires were sent to 106 cities in Minnesota, 28 of which responded. The survey included questions on the following topics:

- How many, and what type of, stormwater BMPs are in your watershed?
- How often are your stormwater BMPs inspected?
- What is the average staff-hours spent per regular inspection/maintenance?
- How complex is the maintenance of your stormwater BMPs?

- Which factors most frequently cause the performance deterioration of your stormwater BMPs?
- What are the costs for non-routine maintenance activities?

The questions for the survey were chosen to reflect key parameters necessary to reasonably budget and schedule inspection and maintenance. These factors will vary based upon stormwater BMP design, climate conditions, stormwater BMP accessibility, desired level of stormwater BMP performance, personnel and budgetary constraints, and maintenance strategies.

SURVEY RESULTS AND DISCUSSION

Inspection Frequency

As listed in Table 1, the majority (89%) of cities conduct routine maintenance actions once a year or less. Inspection frequency varies significantly due to stormwater BMP accessibility and management strategy (proactive vs. reactive). "We are working on and around the site every business day, and so inspections happen informally every day," said Julie Vigness-Pint, stormwater BMP Cost Share Coordinator at Ramsey-Washington Metro Watershed District, MN. A more common response was voiced by Jim Hafner, the stormwater manager for the City of Blaine, MN who stated "Our city has not had a proactive program for stormwater BMP maintenance. It has generally occurred when problems have popped up." The difference between proactive and reactive maintenance strategies and the execution of maintenance plans has resulted in a wide variation in the type and frequency of inspection and maintenance activities.

Table 1: Frequency of routine inspection and maintenance activities

Stormwater BMP Type	Number of Responses (n)	Less than once	Once per year	Twice per year	More than twice
		Percentage of Responses			
Wet Ponds	27	52%	44%	0%	4%
Dry Ponds	23	52%	48%	0%	0%
Constructed Wetlands	16	38%	56%	6%	0%
Surface Sand or Soil Filter	9	67%	33%	0%	0%
Infiltration Basins or Trenches	17	18%	76%	0%	6%
Rain Gardens	19	21%	42%	16%	21%
Porous Pavements	12	25%	50%	8%	17%
Filter Strips or Swales	12	58%	33%	0%	8%
Underground Sedimentation Devices	16	13%	56%	31%	0%
Underground Filtration Devices	9	44%	56%	0%	0%
Average		**39%**	**50%**	**6%**	**6%**

Staff Hours

Descriptive statistics for staff-hours spent on routine inspection and maintenance are shown in Table 2. For most stormwater BMPs, staff-hours per activity range from 1 to 4 hours, except constructed wetlands and rain gardens which

reportedly require more time for inspection and maintenance (typically between 1 and 16 hours). Rain gardens and constructed wetlands may require more staff-hours for inspection and maintenance because vegetation management can be significant in these practices.

Table 2: Staff-hours spent on routine maintenance actions

Stormwater BMP Type	Number of Responses (n)	Staff-hours				
		Max.	75th %tile	Median	25th %tile	Min.
Wet Ponds	24	120	3.5	2	1	0.5
Dry Ponds	19	5	2	1	0.5	0.5
Constructed Wetlands	14	60	9.5	1.5	1	0
Surface Sand or Soil Filter	7	3	2	1	0.5	0.5
Infiltration Basins or Trenches	17	60	2	1	0.5	0.5
Rain Gardens	13	80	16	1	1	0.5
Porous Pavements	9	6	4	2	1	0.5
Filter Strips or Swales	11	30	1.75	1	0.5	0.5
Underground Sedimentation Devices	14	360	3	1.25	1	0.5
Underground Filtration Devices	7	5	3.5	1	0.75	0.5

Maintenance Complexity

To assess maintenance complexity, a scale from 1 to 4 was used with 1 being minimal complexity (i.e. stormwater professional or consultant is seldom needed) and 4 being most complex (i.e. stormwater professional or consultant is always needed). For most stormwater BMP types, most respondents indicated that maintenance was minimal or simple, as listed in Table 3. Maintenance was viewed as moderate to complex most often for constructed wetlands (47%), porous pavements (46%) and surface sand and soil filters (38%). Porous pavements are fairly new in Minnesota, which may explain the more frequent requirement for evaluation by stormwater professionals.

Factors reducing stormwater BMP performance

Respondents were also asked to choose from a list of possible factors that most frequently caused deterioration in the performance of their stormwater BMPs. Sediment buildup and litter & debris accumulation were reported most frequently for most stormwater BMPs and possible factors, respectively (Table 4). Pipe clogging was reported frequently for wet ponds and dry ponds while invasive vegetation was reported frequently for dry ponds, constructed wetlands, rain gardens, filter strips, and swales.

Table 3: Complexity of maintenance activities

Stormwater BMP Type	Number of Responses (n)	Maintenance Complexity*			
		Min.	Simple	Mod.	Comp.
Wet Ponds	23	57%	30%	4%	9%
Dry Ponds	21	67%	29%	0%	5%
Constructed Wetlands	15	40%	13%	40%	7%
Surface Sand or Soil Filter	8	63%	0%	25%	13%
Infiltration Basins or Trenches	15	33%	40%	13%	13%
Rain Gardens	17	41%	29%	12%	18%
Porous Pavements	13	46%	8%	38%	8%
Filter Strips or Swales	13	62%	31%	0%	8%
Underground Sedimentation Devices	15	40%	33%	7%	20%
Underground Filtration Devices	10	50%	20%	10%	20%

*Maintenance Complexity is defined as:
Minimal - stormwater professional or consultant is seldom needed
Simple - stormwater professional or consultant is occasionally needed
Moderate - stormwater professional or consultant is needed about half the time
Complicated - stormwater professional or consultant is always needed.

Table 4: Percentage of respondents who indicated the factors listed most frequently for causing deterioration of stormwater BMP performance

	Number of Responses	Sediment buildup	Litter & Debris	Pipe Clogging	Invasive vegetation	Bank erosion	Groundwater level	Structural problems	Oil spill	Mechanical problems
Wet Ponds	90	26%	19%	21%	10%	11%	7%	7%	0%	0%

Underground Filtration Devices	8	50%	25%	13%	0%	0%	13%	0%	0%	0%

Maintenance Cost

Maintenance for sediment removal, converted to an annual cost, was the most reported and costly maintenance activity. There was also considerable variation in the maintenance costs, as illustrated in Figure 2 for sediment removal. The highest

median sediment removal costs were for porous pavement ($1700/yr) and underground sedimentation devices ($1000/yr).

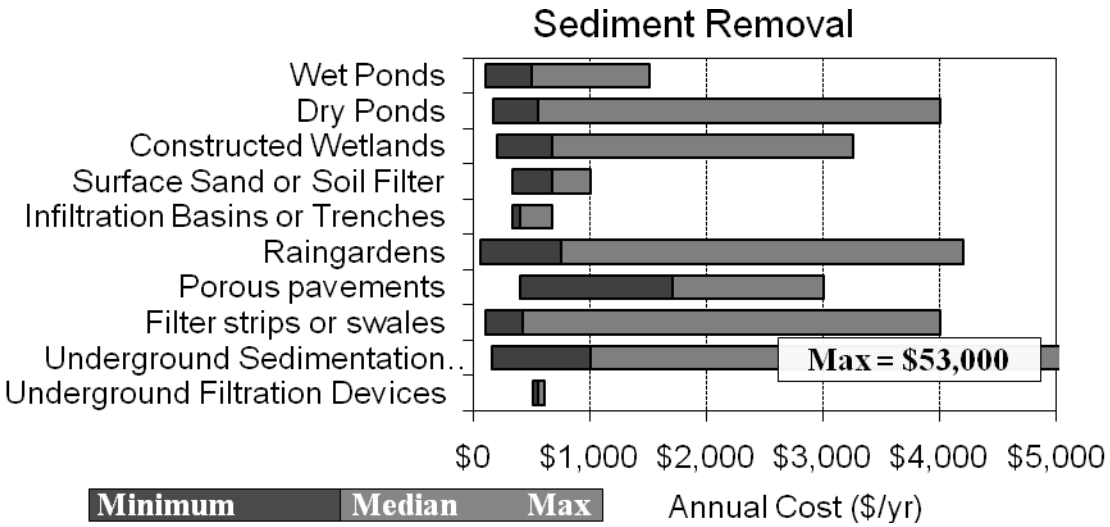

Figure 2: Annual cost of sediment removal for stormwater BMPs

OVERALL OPERATION AND MAINTENANCE COSTS

Publications throughout the United States that contained cost estimates of typical maintenance schedules for common stormwater BMP categories were reviewed. Cost estimates of annual operation and maintenance (O&M) expenses as a function of construction costs were developed for dry ponds, wet ponds, constructed wetlands, rain gardens, sand filters, and grassed/vegetative swales. All costs were adjusted by means of a 'Regional Cost Adjustment Factors' (USEPA, 1999) to reflect 2005 costs in Minnesota.

The U.S. Environmental Protection Agency (USEPA, 1999) published expected annual stormwater BMP O&M costs, as a percentage of total construction cost ranging from less than 1% for dry ponds to a maximum of 20% for infiltration trenches. More recent analyses (Landphair, et al., 2000; Wossink and Hunt, 2003) have expanded this range. Cost estimate data from the literature are shown on log-log scale in Figure 3 (Weiss et al., 2005) with the best-fit line (dashed line) and 67% confidence intervals (solid lines). Using known total construction costs excluding land costs and the equation of the best-fit line, the annual expected maintenance for each type of stormwater BMP can be estimated.

It is apparent from Figure 3 that O&M costs indicate an economy of scale for all stormwater BMPs. Predicted annual O&M cost, as a percentage of construction cost (excluding land cost), decreases with increasing total construction cost. Therefore, more expensive (and presumably larger) stormwater BMPs require a smaller fraction of the original construction cost for annual operation and maintenance. This trend is slight for sand filters and rain gardens (bioretention practices), and greater for wet ponds, dry ponds, constructed wetlands and swales.

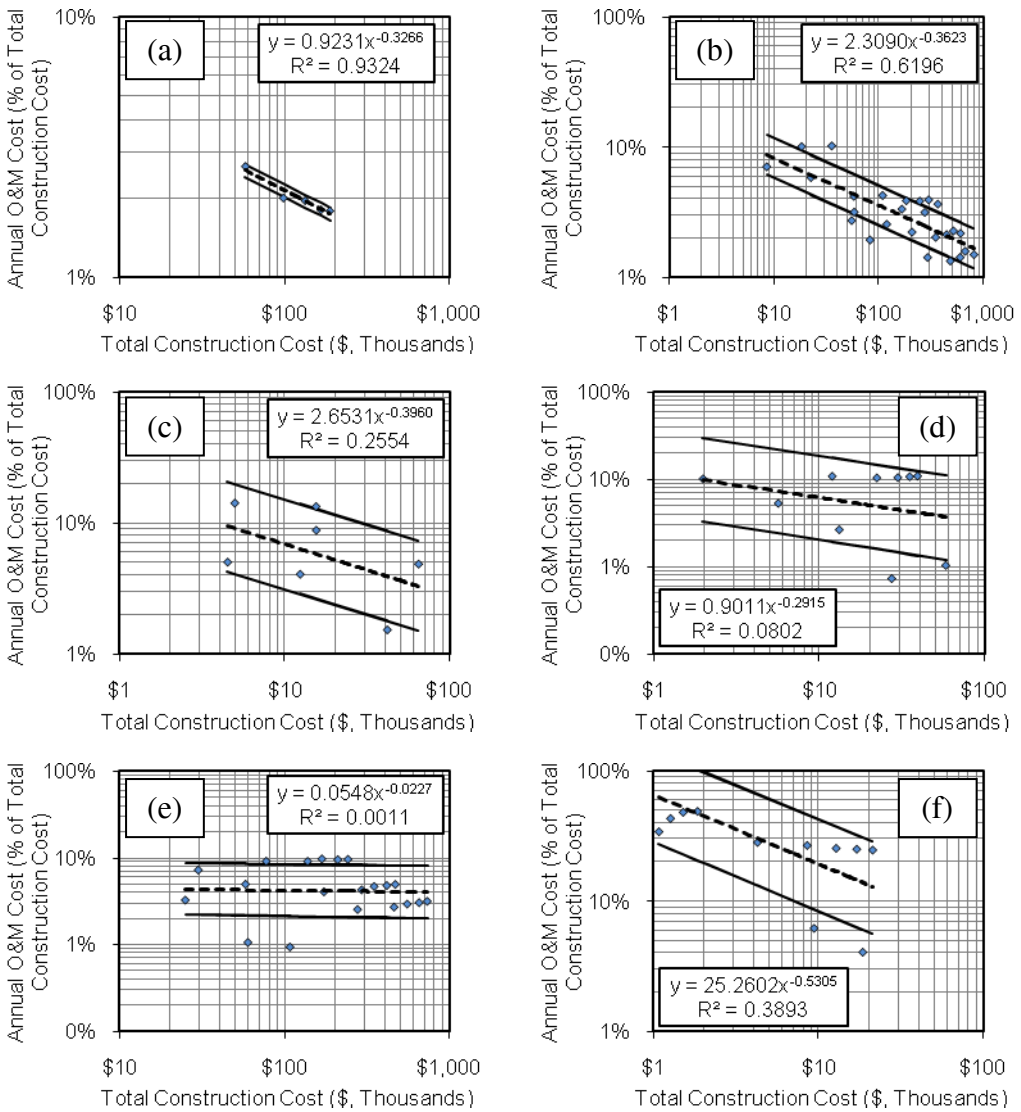

Figure 3: Predicted annual life-cycle O&M costs as a function of total construction costs in 2005 USA dollars (Weiss et al., 2005). (a) dry ponds, (b) wet ponds, (c) constructed wetlands, (d) rain gardens, (e) sand filters and (f) grassed/vegetative swales. Data from SWRPC (1991), Landphair, et al. (2000) and Wossink and Hunt (2003).

Operation and maintenance costs are a substantial portion of life-cycle stormwater BMP costs. As shown in Figure 3, the annual predicted O&M cost is roughly 10% of total construction costs for stormwater BMPs that cost $10,000 (2005 dollars) to construct. Therefore, O&M cost of these stormwater BMPs will roughly equal total construction cost after 10 years (in constant dollars). Similarly for stormwater BMPs that cost $100,000 (2005 dollars) to construct, O&M cost is roughly 5% and will roughly equal total construction cost for these BMPs after 20 years (in constant dollars). This estimation can be used as a general rule of thumb when planning, designing, and budgeting for installation of stormwater BMPs.

CONCLUSIONS

Many communities are struggling to define stormwater BMP operation and maintenance needs without readily available guidelines. As a step towards providing this information, a survey of cities was conducted to quantify the frequency of inspection, level of effort needed for routine maintenance, stormwater BMP deterioration factors, and maintenance complexity. In addition, a nationwide literature review was conducted to estimate operation and maintenance (O&M) costs for stormwater BMPs.

The results of the survey revealed that most (89%) cities perform routine maintenance once per year or less. The most common causes of performance deterioration were sediment buildup and litter/debris for most stormwater BMPs. Sediment removal is the most costly maintenance activity reported for all stormwater BMPs.

The nationwide literature review resulted in predictive equations for O&M cost of stormwater BMPs as a function of total construction cost. Operation and maintenance (O&M) cost is also shown to be a substantial portion of life-cycle cost for all stormwater BMPs and requires serious consideration. As a general rule-of-thumb, O&M cost for stormwater BMPs will roughly equal the construction cost (in constant dollars) after 10 years for a $10,000 installation and 20 years for a $100,000 installation (2005 dollars).

ACKNOWLEDGEMENTS

This study was performed as part of the research project "Assessment and Maintenance Stormwater Best Management Practices" funded by Minnesota Pollution Control Agency. We thank Lisa Thorvig, Roger Karn and Don Jakes for their support of this work. We are also grateful to the 28 cities for responding to our survey and providing information related to their experience with stormwater BMPs.

Abstract

Best Management Practices (BMPs) correspond to actions and practices used to reduce flow rate and the constituent concentration in urban runoff. The extended detention basin is the most widely used among various types of BMPs. This study addresses the design guidelines for extended detention basins by applying uncertainty analysis to predict the magnitude of the widely varying urban nonpoint source pollution concentration expected in the BMP influent and effluent. With uncertainty analysis considered, urban nonpoint source pollution can be predicted with greater accuracy and better detention basin design criteria can be established for the protection of receiving waters.

The International BMP Database (www.bmpdatabase.org), used for observed data in this study, is the database of monitored water quality data for nationwide BMP sites maintained by the U.S. Environmental Protection Agency (U.S. EPA) and the American Society of Civil Engineers (ASCE), et al.

This study uses and Total Suspended Solid (TSS) as the representative water quality parameter from extended detention basin. Hydrologic and BMP geometric data of watersheds correspond to the location of these detention basins. This study incorporates the k-C* model with uncertainty analysis to represent observed data. The k-C* equation was chosen for the detention basins performance model because this model has been widely used for representing wetland treatment performances, but also can consider the performance effect for the physical dimensions of the BMP. This study will be able to support stormwater management decision makers in building detention basins of appropriate sizes with a better idea of the expected performance and risk.

Introduction

Many attempts have been made to evaluate BMP performance. Historically, the efficiency of BMPs has been represented as percent removal of pollutants. Strecker et al. (2001 and 2004) argued that using percent removal as an indicator of efficiency often gives inaccurate results. They suggested that the efficiency of several BMPs might be better characterized by the effluent Event Mean Concentration (EMC) and that design standards should consider hydrologic losses that take place with some BMP types.

Many mathematical models have been developed to analyze and predict the water treatment. They attempt to represent complex treatment mechanisms through

simple mathematical expressions. One of the most popular mathematical model for wastewater treatment is the k-C* model, which has been widely used to describe pollutants removal in wetlands (Kadlec and Knight, 1996; Kadlec, 2000; Braskerud, 2002; Kadlec, 2003; Rousseau et al, 2004; Lin et al., 2005). International Water Association (IWA) (2006) provides design and condition guidelines of wetland using the k-C* model.

Uncertainty analysis is a tool commonly used in all disciplines of civil engineering. Various approaches have been used in uncertainty analysis including analytic methods, approximation methods and different types of Monte Carlo Simulation (MCS). One of the most well-known approximation methods is the First Order Second Moment (FOSM) method, also referred as the First Order Error Method or the First Order Variance Estimation method. The Latin Hypercube Sampling (LHS) method is a modified stratified sampling of MCS. It can provide accurate estimates of statistical variables of model output at much smaller computational loads than MCS (Melching, 1995).

The objective of this study is to presents a BMP performance model that evaluates TSS removal in detention basins by incorporating uncertainty analysis. The distribution of effluent EMC can be represented depending on the uncertainty of variables, both influent EMC (C_{in}) and areal removal rate constant (k) in the k-C* model. Data uncertainty, such as C_{in}, is evaluated with selected TSS data from BMP database. Model uncertainty is estimated from a regression relation of q and k.

Two uncertainty estimation methods are used to estimate effluent concentration, referred to plot the probability density function (PDF). The LHS has been chosen as the numerical estimation method and FOSM has been selected as the analytical approximation method.

The classical mathematical model of water treatment is the first-order decay model widely used to describe pollutant removal in wetlands, swales etc. (Careleton et al., 2001; Braskerud, 2002; Wong et al., 2006). Storage BMPs performance in stormwater is very similar to water treatment in wetlands. Similar aspects include variables such as geometric storage condition, inflow and outflow rates, and influent/ effluent concentrations. Thus, the models for water treatment have been applied to represent storage BMPs performance.

One of these models is the k-C* model. Many researchers applied this model to constructed wetland performance and proved good reproducibility of real situations (Kadlec, 2000; Rousseau et al, 2004; Stone et al, 2004; Kadlec, 2003). It can apply an "irreducible minimum concentration" to the first decay equation because the observed effluent concentration is converged with a constant value. Assumptions of the model are steady and plug flow conditions, which are valid assumptions used in representing flow hydrodynamics within wetland systems (Kadlec and Knight, 1996). The k-C* model is given by:

$$q\frac{dC}{dy} = k(C - C^*) \tag{1}$$

Considering y, the fraction of distance from inlet to outlet, setting y=1, integration of equation (1) gives

$$C_{out} = C^* + (C_{in} - C^*)e^{-k/q} \quad (2)$$

where:

C_{out} = effluent EMC (mg/L),

C_{in} = influent EMC (mg/L),

C* = background EMC or minimum output EMC (mg/L),

k = areal removal rate constant (m/day), and

q = hydraulic loading rate, defined as the ratio of the inflow discharge divided by the surface area of the system (Q/A) (m/day)

Despite these applications, the model has some drawbacks. It assumes steady-state flow condition and output concentrations are extremely sensitive to the areal removal rate constant, making it difficult to predict effluent concentration.

The k is related to q with the power function as shown in Figure 2. However, the output of the k-C* model is too sensitive to estimated k. Therefore, it is necessary to apply a prediction interval in k and q regression line. A Prediction interval is focused on variance of individual data while a confidence interval is focused on variance of a regression line. This study chooses the prediction interval of k since it is more necessary to know the performance for an individual event rather than the prediction of the average performance for many similar events (Barrett, 2005). The prediction interval in the regression line relating k and q are calculated by Equation (3) (Kutner et al. 2004).

$$t_{0.05} s \sqrt{1 + \frac{1}{n} + \frac{(X - \overline{X})^2}{\sum_{i=1}^{n} (X_i - \overline{X})^2}} \quad (3)$$

where

t = the t distribution for the appropriate degree of freedom (n-2),

n = the number of total data,

s = standard error of the regression,

X = average q at which the confidence interval calculated,

$\overline{X}$ =mean of observed q from monitoring data, and

X_i =individual observed q from monitoring data.

Study Approach

BMP performance data were collected from the International Stormwater BMP Database (www.bmpdatabase.org) maintained by ASCE and US EPA categorized as illustrated in Figure 1. For different BMPs, the database includes geometric information, event runoff volumes, water quality data, and other general information.

Table 1. Selected Best Management Practices in this study

BMP Type	BMP name, Location	Number of Data Set	Volume (m^3)	BMP size Surface area (ha)	Length (m)
Detention Basin	15/78, CA	17	1122.54	0.0977	60.96
	5/605 EDB, CA	2	364.66	0.0598	47.24
	605/91 edb, CA	5	69.57	0.0114	22.86
	Manchester, CA	12	252.79	0.0304	22.86

Based on the results obtained by the Nationwide Urban Runoff Program (NURP) study (US EPA 1983) and Van Buren et al. (1997), Strecker et al. (2001) remarked that stormwater constituents can be well represented by a lognormal distribution. Lognormal distribution was adjusted to C_{in} and C_{out} data to verify this statement. Figure 1 shows this distribution together with the empirical histogram for the site. It is observed that the lognormal distribution represent the data well. Similar results were obtained for the other locations in this study.

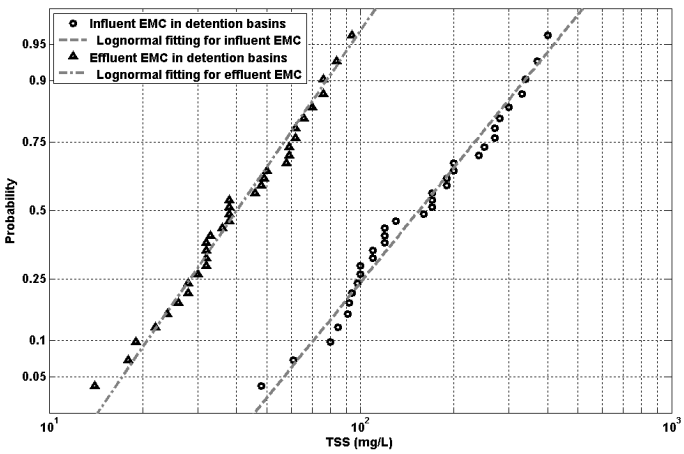

Figure 1. Lognormal probability plots of observed EMCs in detention basins

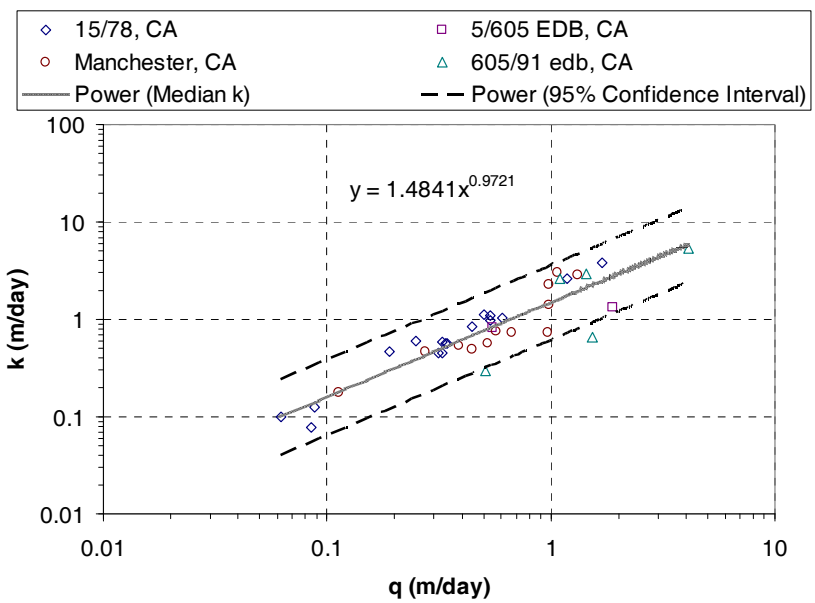
The k-C* model presented is used for simulating the performance of BMPs. Both parameters of the model, k and C*, depend on pollutant characteristics such as the particle size and settling velocity (Wong et al. 2002). Treatment systems receiving large particles concentrations will have a high removal rate and low C* since there is more sedimentation. Thus, there is a relationship between the parameter, k, and the settling velocities (or particle size) of suspended particles in the watershed. Parameter calibration for the k-C* model should be performed based on local conditions such as particle size distribution. Usually, C* depends on temperature and inflow concentration (Kadlec and Knight 1996). Although the areal removal rate constant, k ,has a theoretical link to settling velocity, field studies have shown that it is not necessarily the case for particles finer than about 40 μm (Wong, THF et al. 2002). Thus, the estimation of k is not straightforward. Scherup et al. (1990) found that the

k-values of the k-C* model are strongly dependant on the Hydraulic Loading Rate (HLR) (q). They proposed the following power relationship with coefficients a and b:

$$k = aq^b \tag{4}$$

This relationship is used in this study to estimate the value of k. However, k-values in the model are very sensitive and they must be estimated with more accuracy in order to obtain accurate effluent EMCs. Therefore, the need of high accuracy in the model causes the need of k for uncertainty analysis. A plot of k versus q based on storm event is shown in Figure 2 with a 95% prediction interval from Equation (4) for TSS in detention basins. Data are categorized by BMP and location. Values of the coefficients a and b in Equation (4) are 1.4841 and 0.9721. The distance between the median line and the prediction interval line means uncertainty in k. Thus, the log-transformed k is 0.437 from Figure 2.

This study suggested one constant value, 10 mg/L, for C*. Table 2 shows the required given information of input variables for uncertainty analysis of uncertainty in both C_{in} and k.



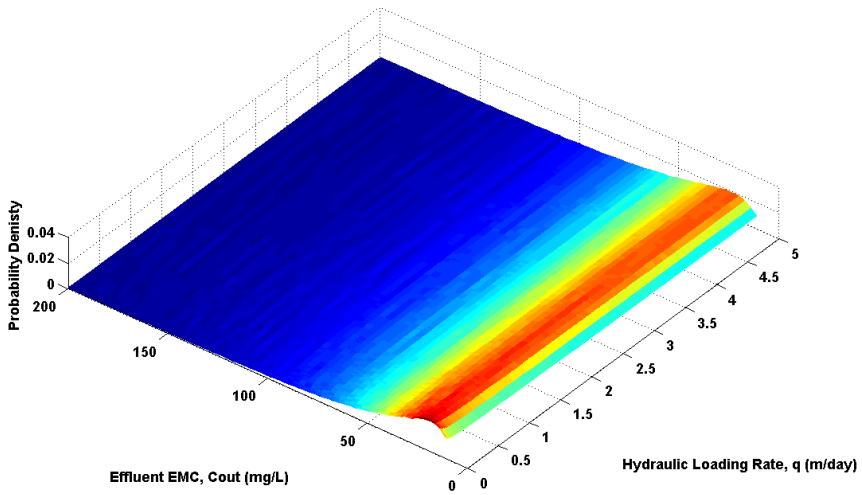


Figure 2. Estimated k vs. q using individual storm events

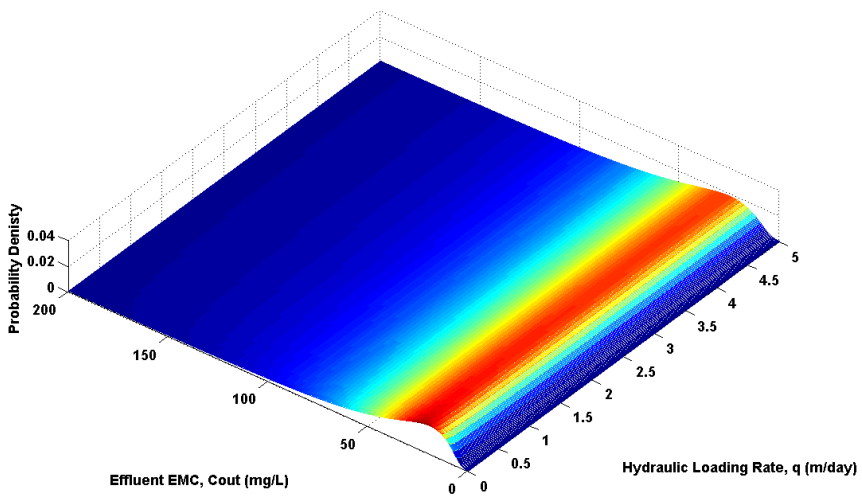
Table 2. Required parameters information of C_{in} and k for uncertainty analyses



Input Parameters	C_{in}		k	
Log-transformed Statistical Properties	mean	standard deviation	mean	standard deviation
Value	5.038	0.6083	$\text{Log}(1.4841q^{0.9721})$	0.4370

Results

This study assumes that there is no correlation between C_{in} and k for simpler calculations and the LHS method provides similar results with analytical simulations such as the derived distribution method. Thus, the LHS method is used in this section to evaluate the FOSM method. To apply the FOSM method, it is assumed that C_{out} is lognormally distributed. Figure 3 shows the PDF of effluent EMC depending on the q with the LHS and the FOSM methods. Most probability density values of effluent EMCs are placed below 50 mg/L without regards to q values.

(a)

(b)

Figure 3. $f(C_{out})$ **as function of q on considering uncertainty in both** C_{in} **and k ;(a) LHS, (b) FOSM**

Figure 4 shows a comparison of both PDFs for q=0.01 and q=5 m/day. Both distribution are more similar for q=5 m/day, but differences in the peak value and the shape are observed for q=0.01 m/day. The distribution of C_{out} for high q resembles a lognormal distribution. However, that is not the case for C_{out} distribution when low values of q are used.

LHS does not require identifying the type of distribution of output. In other words, it can be represented by any unknown types of distributions. However, FOSM assumes the distribution of output as lognormal distribution. Thus, the shape of the PDFs generated by the LHS and the FOSM method differ.

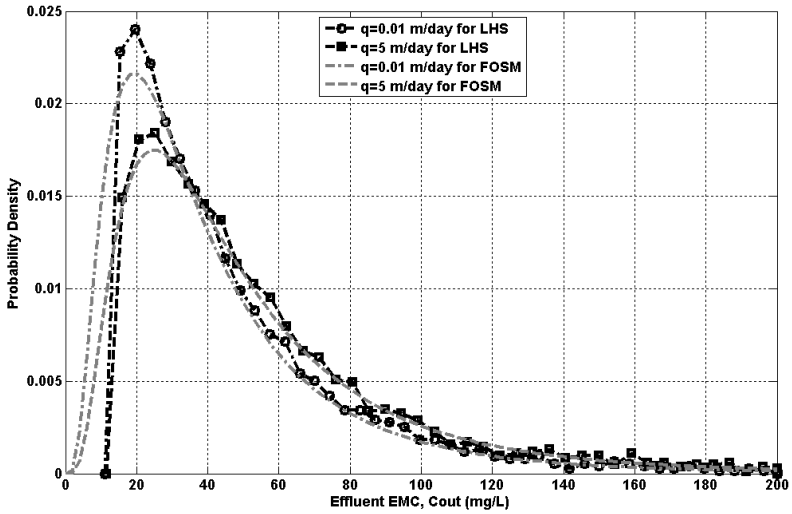


Figure 4. Comparison of $f(C_{out})$ as function of q on considering uncertainty in k between LHS and FOSM

Figure 5 shows PDFs obtained with LHS with confidence intervals of 50% and 95% and the observed data. About 70% of the total data are located within the 50% confidence interval and all observed data are located within the placed 95% confidence interval. Therefore, TSS treatment in detention basins is well explained by an uncertainty analysis that considers variability in both C_{in} and k.

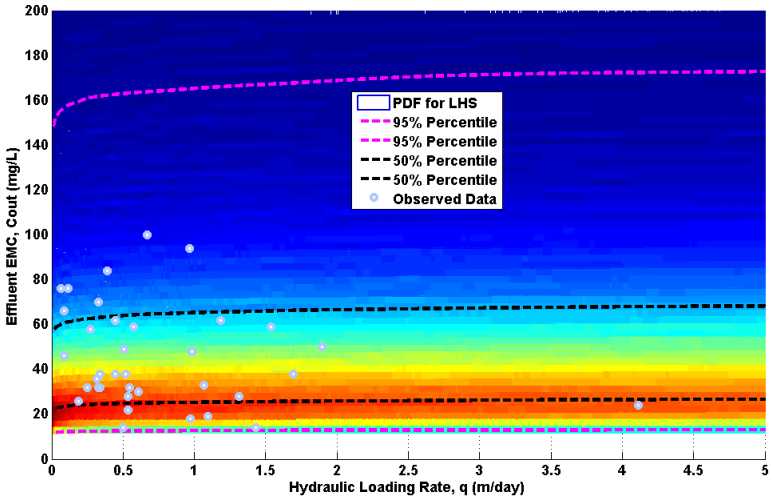

Figure 5. Uncertainty in both C_{in} and q: probability density functions of LHS including confidence intervals and observed data

Figure 6 compares the 50% and 95% confidence intervals obtained using LHS and FOSM when uncertainties in C_{in} and k are considered. They are different because the FOSM analysis assures a lognormal distribution for C_{out} while LHS method does not. This assumption is supported by the observed data, as shown in Figure 4. Thus, the assumption of lognormal distribution for C_{out} seems to be reasonable for estimating the variance of C_{out}.

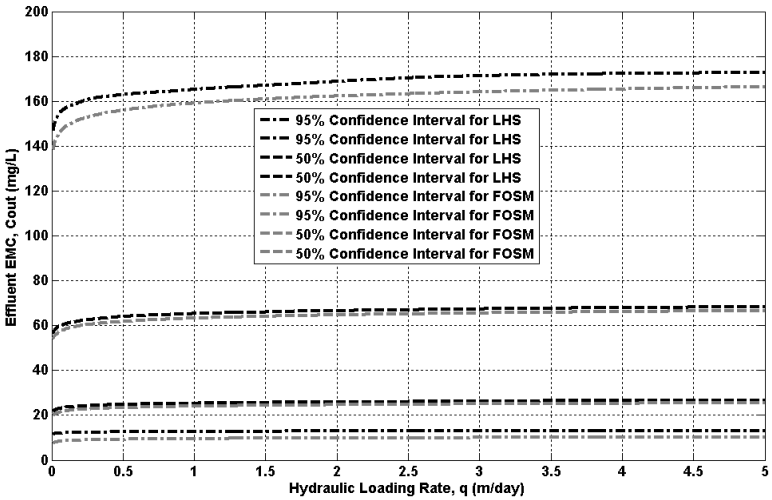

Figure 6. The comparison of confidence intervals between LHS and FOSM on considering uncertainties in C_{in} and k

Conclusion

This study has investigated the application of two uncertainty analysis methods in using the k-C* model to characterize the variability of C_{out} at the outlet of stromwater detention basins. Two methods were studied:

- FOSM is simple analytic method for uncertainty analysis. However, this method requires the distribution of the results to a known continuous distribution. Thus, the applicability of this method is reduced in the case that output distribution is not known.
- LHS is a stratified sampling method on MCS. It generates results through an appropriate sampling of the input variables and provides very accurate results even when distribution of the input variables is unknown and not unique.

Therefore, it is concluded that LHS is more efficient method to characterize the uncertainty of C_{out} when there is more than two variable parameters in the k-C* model.

With respect to the k-C* model and detention basins performance under uncertainty in input variables, the following is concluded:

- Observed variance of C_{in} is very large. This variance significantly affects the computation of effluent EMC using the model. For large values of q, the PDF of C_{out} resembles a lognormal distribution. This similarity is lost for smaller values of q.

Finally, it can be concluded that the k-C* model incorporating uncertainty analysis, represents the detention basin performance very well.

Abstract

A well known consequence of urbanization is an increase in impervious area (parking lots, streets, roofs, etc), which carries along with it a number of undesirable side effects; such as an increase in storm water runoff and often a degradation of downstream water quality. Storm water best management practices (BMP's) are currently being implemented in many communities across the United States to address these consequences. BMP's increase the pervious area in an urban environment and thus imitate natural storm water processes (i.e. infiltration, filtration, evaporation, etc). BMP's have been shown to reduce runoff quantity whilst improving runoff quality. One specific BMP, green roofs, are proposed to reduce storm water runoff through storage and improve water quality through filtration. While there are data that support these assertions, they are largely insufficient to describe the processes that produce the runoff and water quality changes. As a result, prediction of the hydrologic effects of green roofs (and other BMP's) over a range of conditions often relies on assumed adjustments to empirical parameters such as percent impervious or runoff curve number. In order to provide process-scale data describing hydrologic effects of green roofs, a monitoring system has been installed on an extensive green roof and an adjacent conventional roof on the new Business Instructional Facility on the University of Illinois Urbana-Champaign campus. The green roof being monitored is approximately 280 square meters with 0.20 meters of soil and a variety of sedums planted. The conventional roof is approximately 45 square meters. The green roof station is monitoring: volumetric water content at 15 locations, soil temperature at 9 locations, air temperature and relative humidity at two heights, rainfall, runoff, incoming and reflected solar radiation, and temperature underneath the roof at 5 locations. The conventional roof station is monitoring: roof surface temperature at two locations, air temperature and relative humidity at two heights, rainfall, horizontal wind velocity, runoff, incoming and reflected solar radiation, and temperature underneath the roof at 2 locations. In addition, automated samplers collect water quality samples from the runoff of both the green and conventional roofs and a passive atmospheric sampler monitors deposition of particles. To date atmospheric condition data and soil moisture and temperature data have been collected for 20 storm events.

Introduction

Urbanization in developed countries is increasing [Mentens et al., 2006]. With this increase in urbanization there are a number of adverse effects associated with stormwater runoff. Urbanization has been found to generally increase the size and frequency of floods due to the increase in stormwater runoff caused by a greater proportion of impervious surfaces [Konrad, 2003]. Furthermore, groundwater recharge is diminished, downstream ecosystems are degraded, and channels become unstable [Stone, 2004; Walsh et al., 2001; Bledsoe and Watson, 2001]. Stormwater BMP's can be incorporated into new development, or retrofit into existing infrastructure, to increase the amount of pervious area in urban environments. This increase in pervious area has been shown to reduce runoff quantity and improve runoff quality.

Green roofs, a structural BMP, manage stormwater in four ways: (1) through the process of infiltration the time to peak runoff is delayed, (2) the time to initial runoff is delayed due to infiltration and storage, (3) total volume of runoff is reduced due to storage of water by the soil and vegetation, and (4) pollutants deposited on the roof from the atmosphere are filtered out (Mentens et al, 2006). Moreover, green roofs may also reduce the urban heat island effect, as well as heating and cooling loads on buildings.

Previous Monitoring

A study conducted by the National Research Council of Canada provided thermal and stormwater runoff data from two different green roofs and a conventional roof. This study showed a greater reduction in heat flux through the green roof in summer than in winter. Furthermore, an annual average reduction in runoff volume of 57% was achieved by the green roof [Liu, 2005]. Another study conducted in Portland, Oregon showed the green roof could absorb approximately 69% of rainfall. The study also showed that water quality was improved through volume (loading) reduction as well as pollutant removal [Hutchinson et al., 2003]. A third study, which examined the effect of media depth and slope on water retention, found increasing the depth and decreasing the roof slope increased water retention and, surprisingly, vegetation had little effect [VanWoert et al., 2005]. Although helpful in illuminating general characteristics of green roofs, previous monitoring lacks in high resolution data that describes the physical processes. The goal of this monitoring is to provide a dataset such that these processes may be evaluated.

Experimental Method

The study area consists of an extensive green roof made up of four sections of vegetated beds and an adjacent conventional roof, see Figure 1. Figure 1 shows the location of:

1. The green and conventional roof weather stations.
2. Roof drain sets.
3. Soil moisture and temperature sensors.
4. The placement of the water quality and passive samplers.

5. The placement of the flow measurement devices (CR1, GR1, GR2, GR3) in the operational drains.
6. Conventional roof temperature probes.

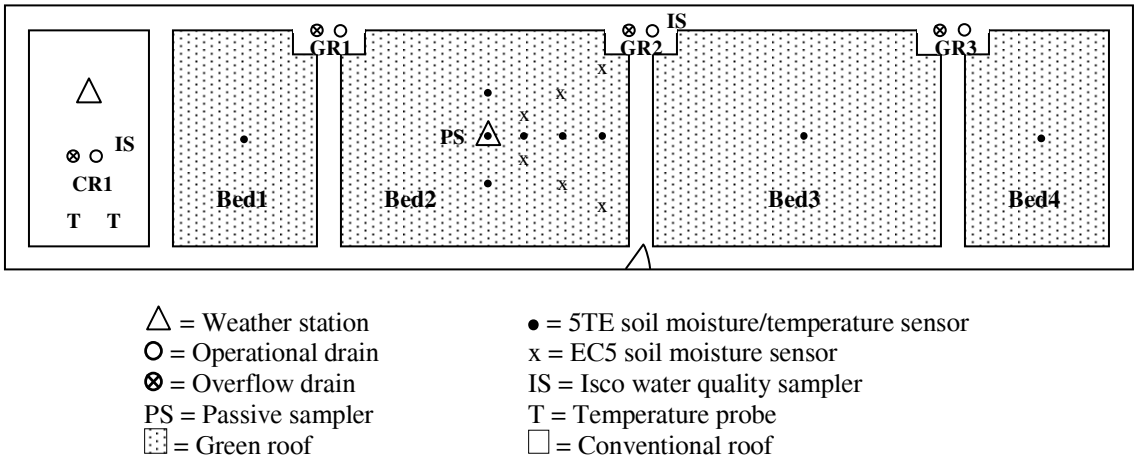

Figure 1. Schematic of green roof and conventional roof monitoring (not to scale)

The conventional roof, which covers approximately 45 square meters, is one story above the green roof and is accessed via a ladder. The total green roof area comprises of four beds with a total area of approximately 280 square meters. Each bed is surrounded by a vegetation free zone. The green roof was planted in July 2008 and therefore vegetation coverage is minimal, full vegetation coverage is attained after two years. Figure 2 shows a cross section of the green roof, vegetation free zone and drainage chamber. The green roof consists of six basic layers:

1. The substrate soil – approximately 20 cm.
2. A geotextile filter membrane, which prevents fine material from escaping the bed.
3. A water storage panel.
4. Moisture retention mat.
5. Insulation.
6. Root stop, protection membrane and roofing membrane.

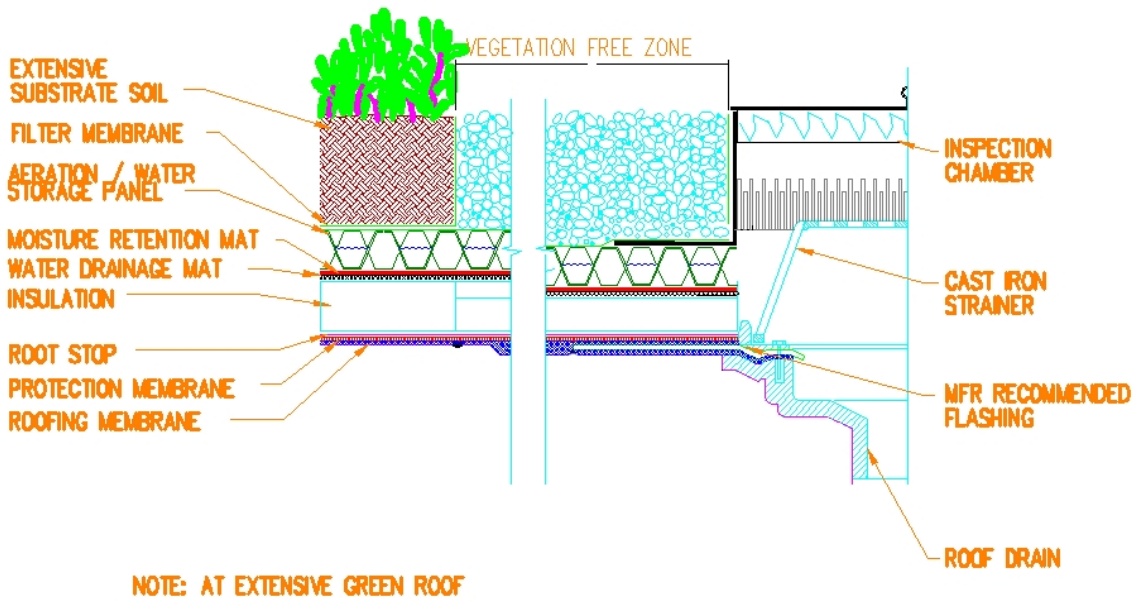

Figure 2. Cross section of green roof (courtesy Gilbane Inc.)

Figure 3. Conventional roof weather station

Weather Stations

Each weather station measures a number of atmospheric conditions and is powered by a solar panel which charges a battery. The weather stations are comprised of: a 10 foot tripod to which the sensors and solar panel are attached, an enclosure box which contains the datalogger and battery, see Figure 3. At each station a datalogger (Campbell Scientific CR1000) controls the sensors and stores the data. The green roof station incorporates a multiplexer due to the number of sensor inputs. All data are stored at one minute time intervals except for the flow measurement output which is stored at half second intervals when triggered. The flow measurement devices will be discussed in further detail later.

At each station relative humidity (RH) and air temperature probes are mounted on two foot crossarms at two heights above the roof, approximately 1.2 m and 2.2 m. The placement of the sensors was chosen to facilitate sensible and latent heat flux calculations. These conditions are measured using Campbell Scientific CS215's with radiation shield, see Figure 4. The temperature measurements have an operating range of -40 to +70°C and the relative humidity operating range is 0 to 100% RH (-20 to +60°C). The RH readings are temperature compensated to better than ±2% over the entire temperature range [CS215, 2008]. Table 1 shows the precision of the probe reading for different operating ranges. The output is percent relative humidity and degrees Celsius.

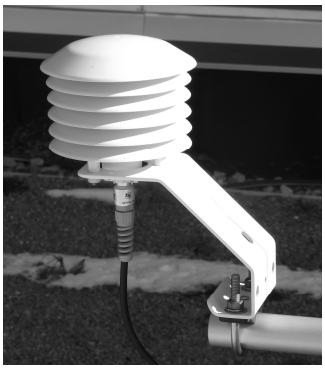

Figure 4. Air temperature and relative humidity sensor with radiation shield

Table 1. Precision of temperature and RH readings

	Accuracy	
Operating Range	Temperature	RH (at 25°C)
-40 to +70°C	±0.9°C	X
25°C	±0.3°C	X
+5 to +40°C	±0.4°C	X
10-90%	X	±2%
0-100%	X	±4%

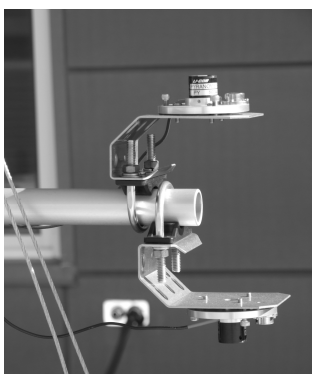

Figure 5. Up-looking and down-looking pyranometers

Both stations also measure incoming and roof reflected solar radiation using an up-looking and down-looking pyranometer (Campbell Scientific LI200X), see Figure 5. The LI200X uses a silicon photovoltaic detector to measure solar radiation (400 to 1100 nm). Like the CS215's the pyranometers are mounted on a 2 foot crossarm. The absolute error in natural daylight is ±5% but typically ±3% [LI200X, 2008]. Data is output in Watts/m^2 for each data interval and totalized in Mega Joules/m^2.

Precipitation is measured at both stations using a tipping bucket rain gage (Texas Electronics TE525WS), see Figure 6 . The gage measures rainfall in 0.254 mm increments. The gages were placed in close proximity to investigate the spatial variability of rainfall. Table 2 shows the precision of the rain gage for different rainfall rates [TE525WS, 2008]. Precipitation depth is totalized over the data interval.

Figure 6. TE525WS rain gage

Table 2. TE525WS rain gage precision

Rainfall Rate	TE525WS
Up to 2.54 cm/hr	±1%
2.54 to 5.08 cm/hr	+0, -2.5%
5.08 to 7.62 cm/hr	+0, -3.5%

Figure 7. Sonic anemometer

An ultrasonic anemometer (Gill Instruments WindSonic 2-D Sonic Anemometer) mounted on a two foot crossarm is used to measure horizontal wind speed and direction at the conventional roof station, see Figure 7. The sensor takes readings at a height of approximately 2.5 m above the roof and is oriented towards true north. Table 3 shows the operating range, precision and output resolution for the wind speed and direction readings [Gill, 2007].

Table 3. Specifications for sonic anemometer

	Wind Direction	Wind Speed
Operating Range	0-360°	0-60 m/s
Precision	±3°	±2% of reading
Output Resolution	1°	0.01 m/s

The roof temperature of the conventional roof will be measured at two locations. These measurements will be taken using Campbell Scientific CS107 temperature probes. Table 4 shows the specifications for these probes.

Two temperature probes will be placed inside the building under the conventional roof, while five probes will measure temperature under the green roof. Two probes will be placed under Bed3; all other beds will have one probe under them. Campbell Scientific

CS109 temperature probes will be used for the under roof applications. These probes are used in conjuction with two Campbell Scientific CR200 dataloggers placed under each roof. Table 4 shows the specifications for these probes [CS107, 2008 and CS109, 2008] . At the time of submittal no under roof probes had been installed.

Table 4. Temperature probe specifications

Sensor	Measurement Range	Thermistor Error	Equation Error
CS107	-35 to +50°C	<±0.2°C (0 to 60°C); ±0.4°C @ -35°C	<±0.01°C
CS109	-50 to +100°C	<±0.2°C (0 to 70°C); ±0.5°C @ -50°C	max error ±0.03°C @ -50°C

Soil Moisture and Temperature Sensors

Volumetric water content (VWC) is measured at 15 locations using two different sensors: Decagon Devices EC-5 and 5TE. The placement of these sensors can be seen in Figure 1. The placement was chosen to track moisture fronts on a process scale as they move through the growing media. All sensors are placed in a vertical position at the same depth, with the dielectric VWC probes extending from 10 to 5 cm deep. The EC-5 measures VWC while the 5TE measures: VWC, electrical conductivity (EC) and soil temperature. Both sensors were calibrated to the specific soil using five samples at different moisture contents. Moisture content was determined by drying the samples in a vacuum oven set at 70°C for 48 hours, for further details on the process see Decagon Application Note [Cobos, 2008]. Table 5 shows the specifications for the soil moisture sensors [ECH_2O, 2008 and 5TE, 2008].

Table 5. Specifications for EC-5 and 5TE sensors

	EC-5		5TE	
Parameter	Precision	Resolution	Precision	Resolution
VWC	0.02m^3/m^3	0.001 m^3/m^3	±0.01-0.02 m^3/m^3	0.0008 m^3/m^3
EC	X	X	±10% (0-7 dS/m)	0.01 dS/m (0-7 dS/m) 0.05 dS/m (7-23 dS/m)
Temperature	X	X	±1°C	0.1°C

Water Quality Sampler and Passive Sampler

Water quality samples will be taken at the conventional roof and green roof using ISCO automated samplers. A passive sampling device will be placed at the green roof station to sample atmospheric deposition of particles and polycyclic aromatic hydrocarbons (PAHs). The water quality samples will be analyzed for: organic compounds, major and trace elements, organic carbon, nitrates, radionuclides and suspended sediment. The atmospheric deposition samples will be analyzed for the same constituents sans suspended sediment. The automated sampler will be triggered by the datalogger based on the output of the flow measurement devices (described below).

Roof Drain Sets

Runoff from both the conventional and green roof areas is drained from the roof by paired sets of roof drains. The conventional roof has one set of drains while the green roof has three. Each set of drains consist of one operational drain and one overflow drain, see Figure 8. Runoff entering the operational drain is routed through the building to a stand pipe in cast iron pipe. The stand pipe is connected directly to the storm sewer. Runoff entering the overflow drain is routed to the outside of the building to notify maintenance personnel in the event the operational drain becomes clogged. The conventional roof overflow drain has a 5 cm tall collar, while the green roof drains have a 12 cm tall aluminum collar. These collars prevent runoff being routed to the overflow drain unless the operational drain is clogged and runoff begins ponding on the roof.

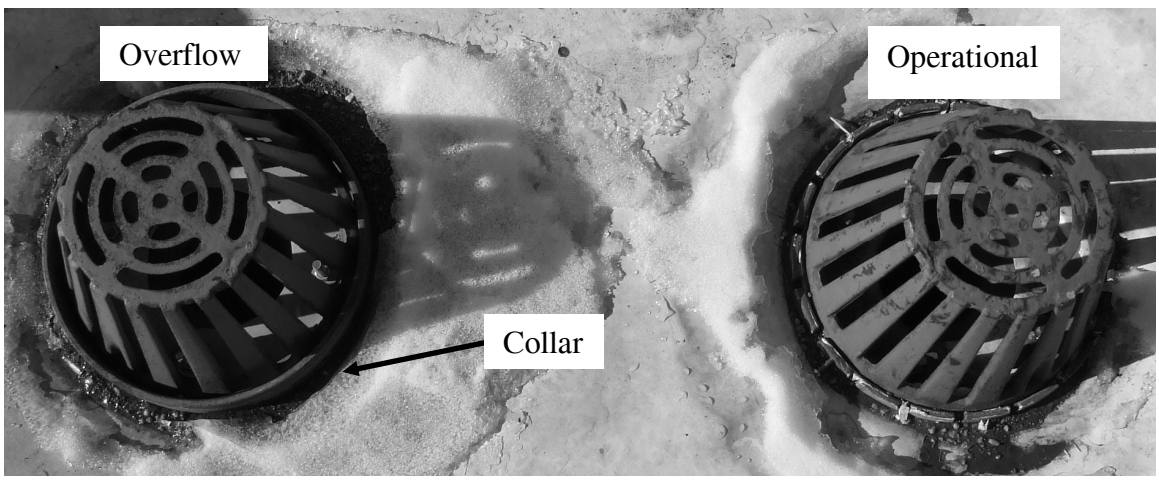

Figure 8. Conventional roof drain set

Flow Measurement Devices and Calibration

The flow measurement devices were designed and fabricated by the authors. Several options were discussed, including: tipping bucket devices located at an external downspouts, electromagnetic flow meters and a Wenzel flume [Wenzel, 1973]. These options were eventually abandoned due to prohibitive cost or access issues. The final design is a multi-stage combination weir and orifice that is retrofit to the existing roof drain. This design includes a 28 cm diameter plate with a vertical 10 cm length of 7.62 cm (3 inch) PVC pipe running through the center of the plate down into the drain pipe (Figure 9 and Figure 10). For low flow conditions a series of six, 0.64 cm orifices in the pipe; two 0.32 cm above the plate and four 0.95 cm above the plate convey the flow to the drain pipe. For larger flows a scalloped sharp crested weir conveys flows in excess of the capacity of the six orifices. The crest of the weir is approximately 2.2-2.5 cm above the plate. A pressure transducer (Keller of America Acculevel) is recessed 3.8 cm below the surface of the plate and outputs depth of water. Table 6 shows the specifications for the pressure transducer [Acculevel, 2008]. The 28 cm diameter plate is designed to sit on top of the operational roof drain flashing with the transducer sending data back to the

datalogger. The plate is caulked in place to insure all flow passes through the meter. Due to non-uniformity in the fabrication each device was calibrated separately. To date the meters have not been installed due to roof conditions and other delays.

Table 6. Acculevel specifications

	Acculevel
Pressure Range	0-90 cm WC*
Precision	0.25%

* WC = water column

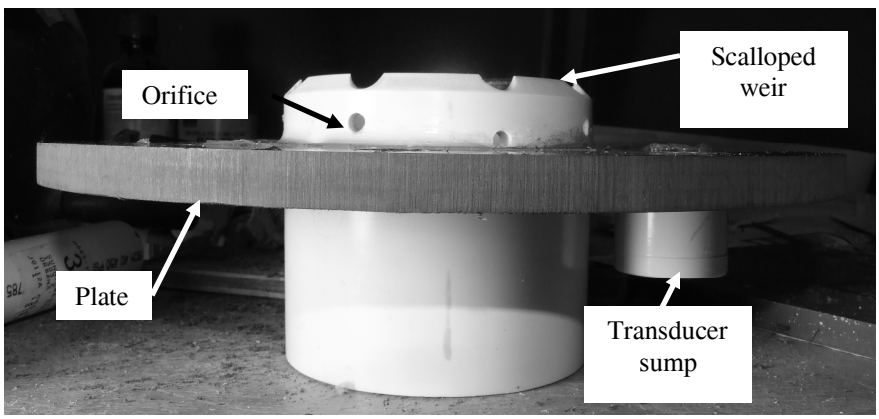

Figure 9. Side view of flow measurement device without pressure transducer

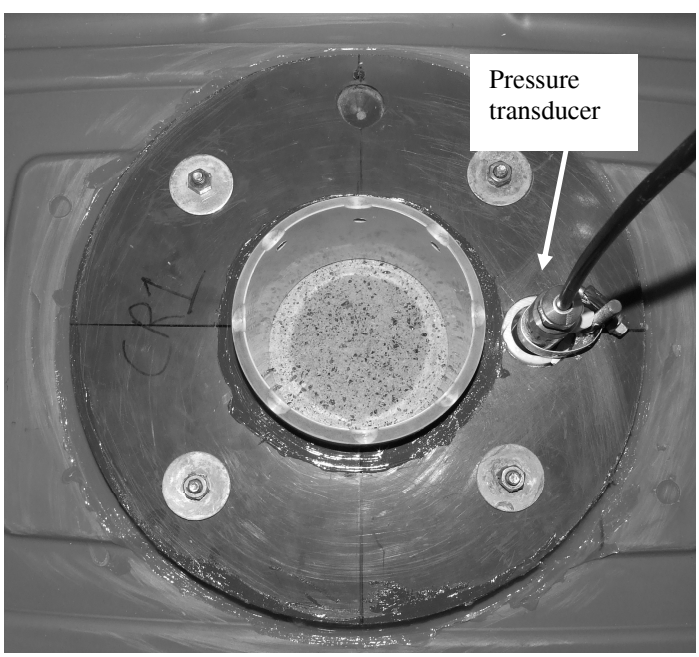

Figure 10. Top view of flow measurement device with pressure transducer

Calibration of the flow measurement devices was performed in the Ven Te Chow Hydrosystems Laboratory using volumetric measurements and a 5.1 cm (2 inch) electromagnetic flow meter (McCrometer UltraMag). Volumetric flow measurements were used for lower flows ranging from 0.3 liters/minute to 30 liters/minute. The

electromagnetic flow meter was used for higher flows (7 l/min to 200 l/min). A sample rating curve can be seen in Figure 11. The transitions between orifice and scalloped weir flow can be seen in the change of the curve slope. Furthermore, at higher flows (>200 l/min) above the scalloped weir a change in slope can be seen where the flow transitions from weir flow to orifice flow due to the weir becoming submerged. The standard deviation across the entire curve is approximately 10 l/min, most of this error originates from the transition at the scalloped weir.

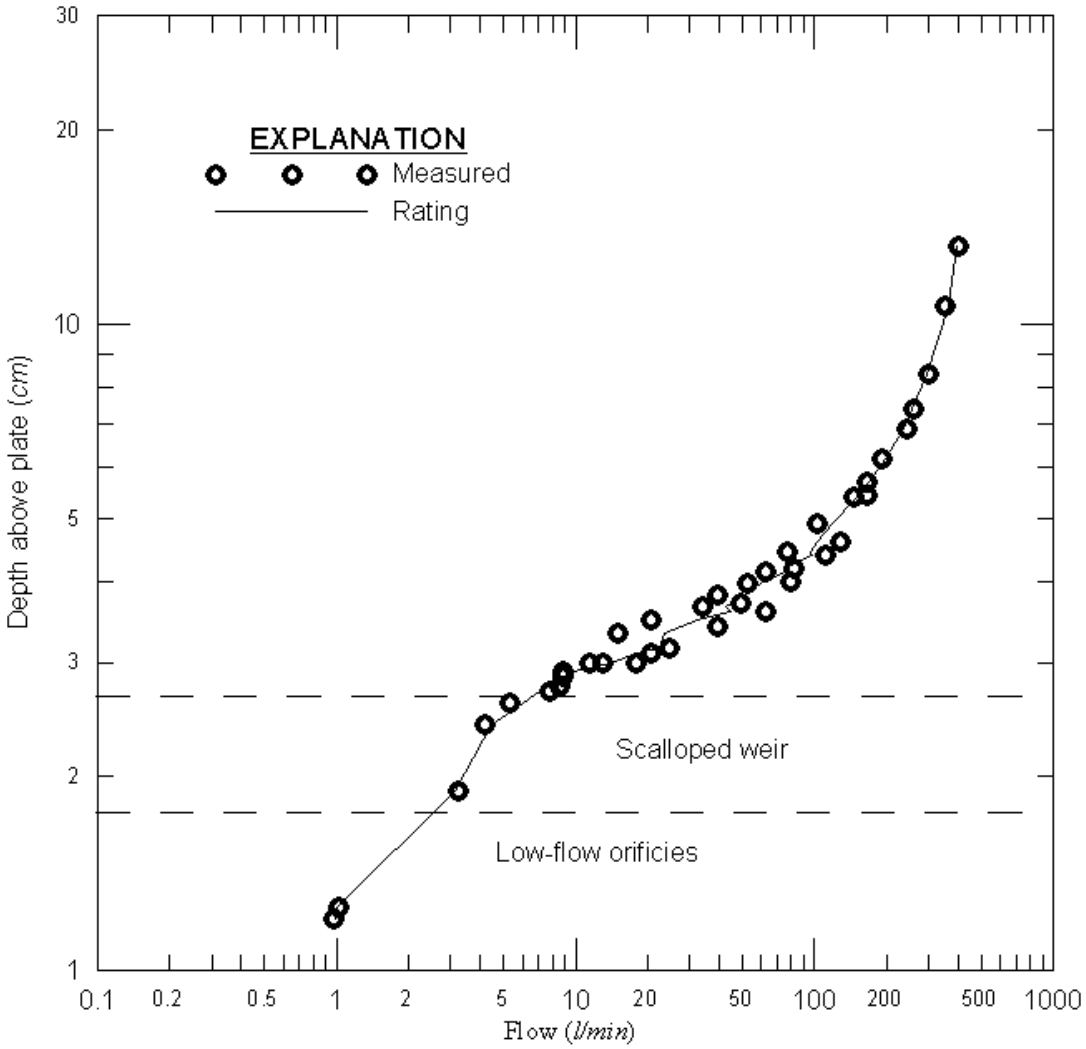

Figure 11. Sample rating curve for flow measurement device

Communications

Four wireless devices (Lantronix WiBox) will be used, one at each datalogger, to enable real-time monitoring and control of all devices. At the time of submittal data was being downloaded manually from the weather stations.

Sample Data and Discussion

To date atmospheric condition data and soil moisture and temperature data have been collected for 20 storm events.

Precipitation Data

Figure 12 shows all the precipitation data for the green roof gage for approximately 20 rainfall events to date. The storms range in duration from almost 8 hours with a total rainfall depth of 10.64 cm to small trace events.

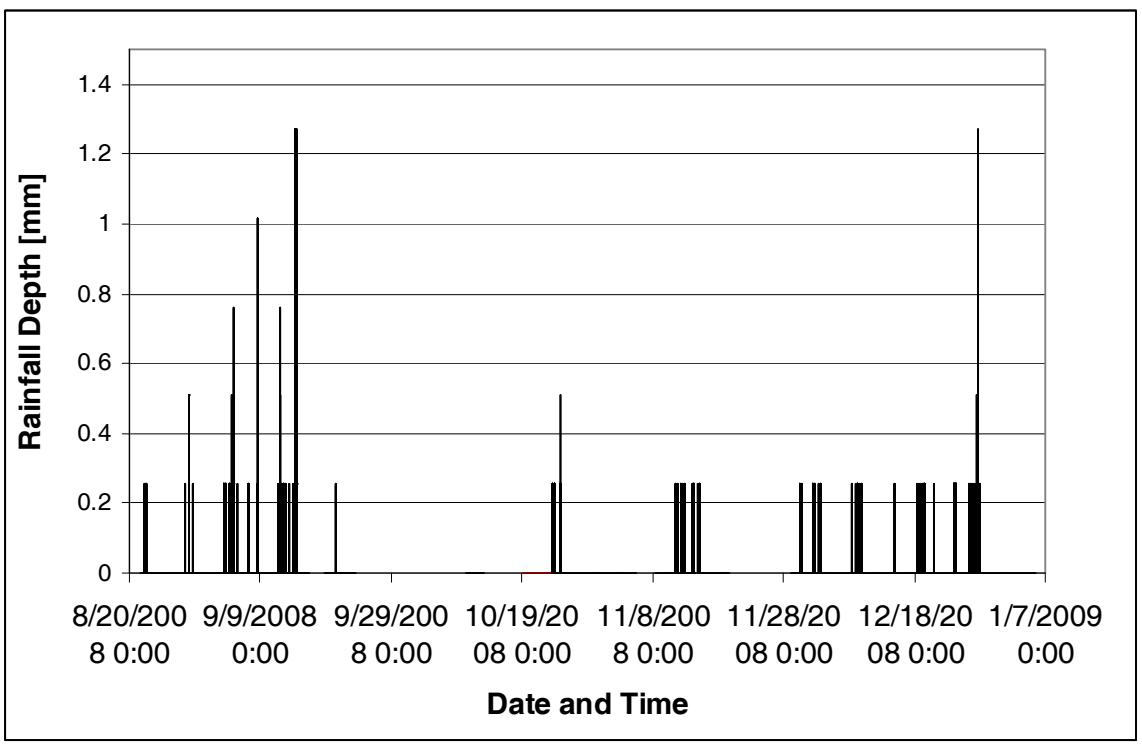

Figure 12. Entire green roof gage rainfall record

Figure 13 shows a comparison of the conventional roof raingage with the green roof raingage for a small rainfall event. Table 7 shows the duration and rainfall depth for the two gages, it can be seen that there is very little difference between the two. This is most likely due to the magnitude of the event. Unfortunately, due to data loss larger storm events were not able to be compared.

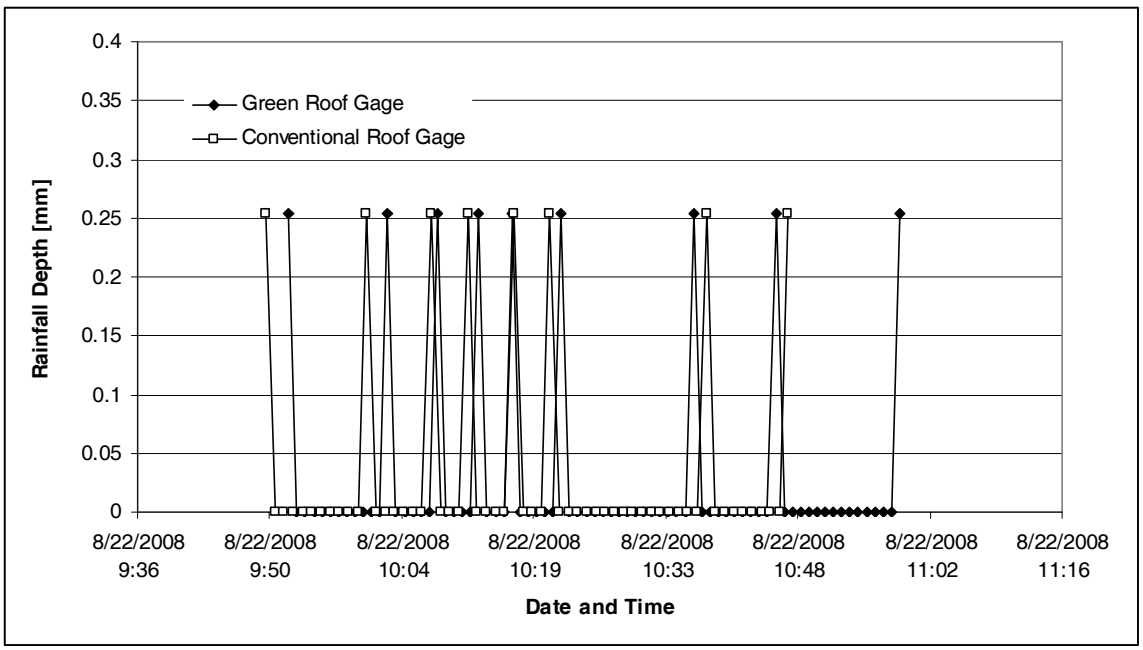

Figure 13. Comparison of gages for small rainfall event

Table 7. Comparison of rainfall events

Gage	Duration [min]	Rainfall Depth [mm]
Green roof	67	2.286
Conventional roof	57	2.032

Air Temperature and Relative Humidity

Figure 14 shows a comparison of lower air temperature at the green and conventional roofs. It can be seen that the temperature above the green roof is less than that above the conventional roof. This may be an indication of the insulating properties of the green roof, but more analysis is required. Figure 15 shows a comparison of RH at the green and conventional roofs. This plot shows the RH at the green roof is higher during the daytime, possibly indicating evapotranspiration.

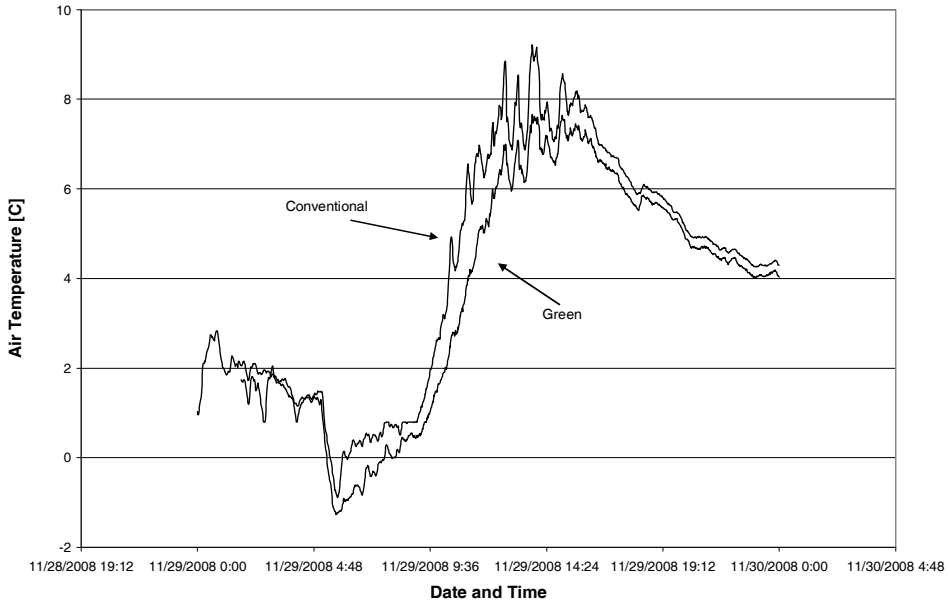

Figure 14. Comparison of lower air temperature at green and conventional roofs

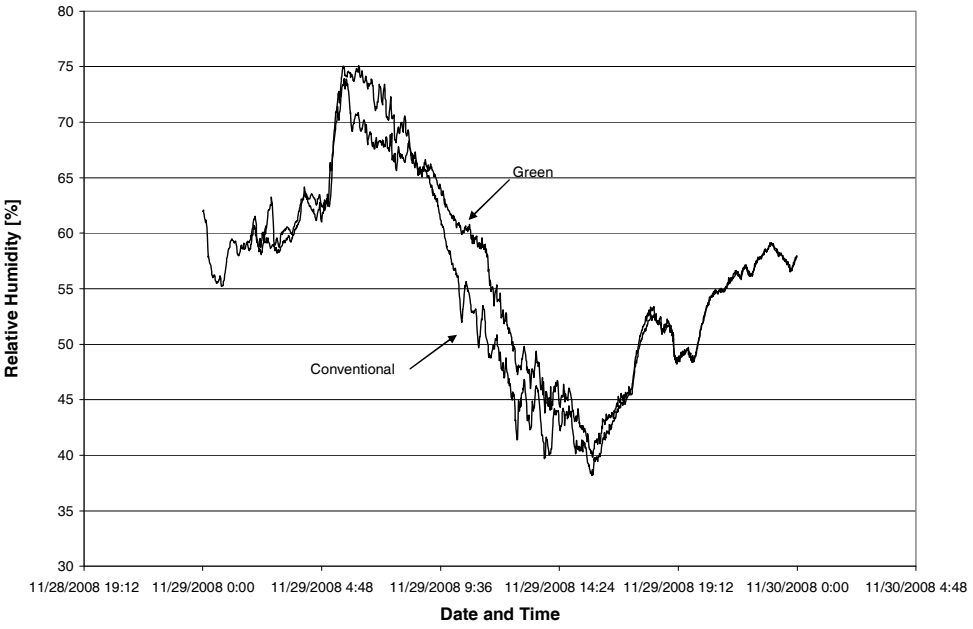

Figure 15. Comparison of lower RH at conventional and green roofs

Solar Radiation

Figure 16 shows a comparison of the up-looking pyranometers at each station. The plot illustrates the difference in shading the two roofs receive. Beyond the shading there is

little difference in the incoming solar radiation. Figure 17 shows a comparison of the down-looking pyranometers. Interestingly, these results show the effect of the smaller albedo of the green roof. The brown growing media reflects far less solar radiation than the white roofing membrane on the conventional roof.

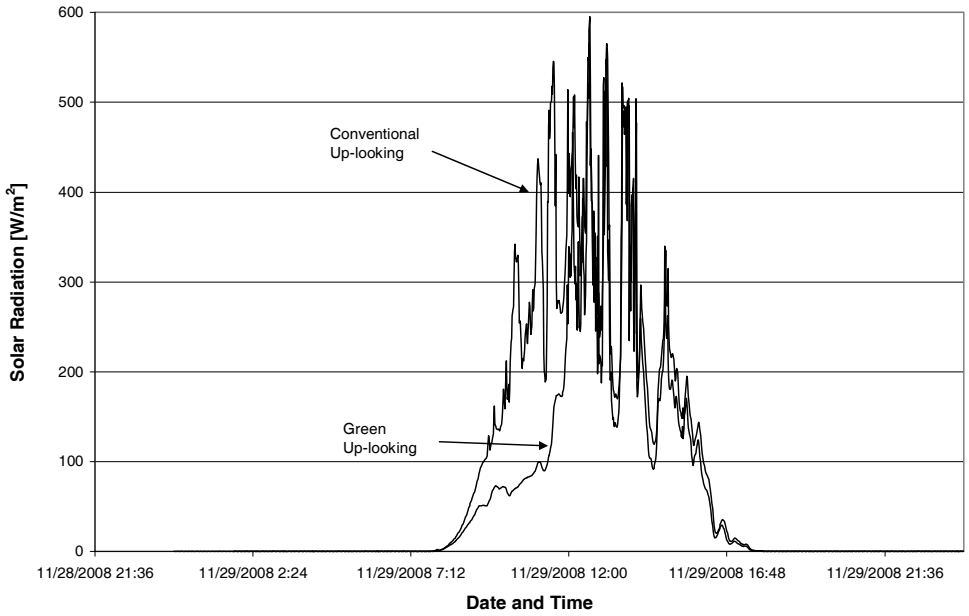

Figure 16. Comparison of up-looking pyranometers

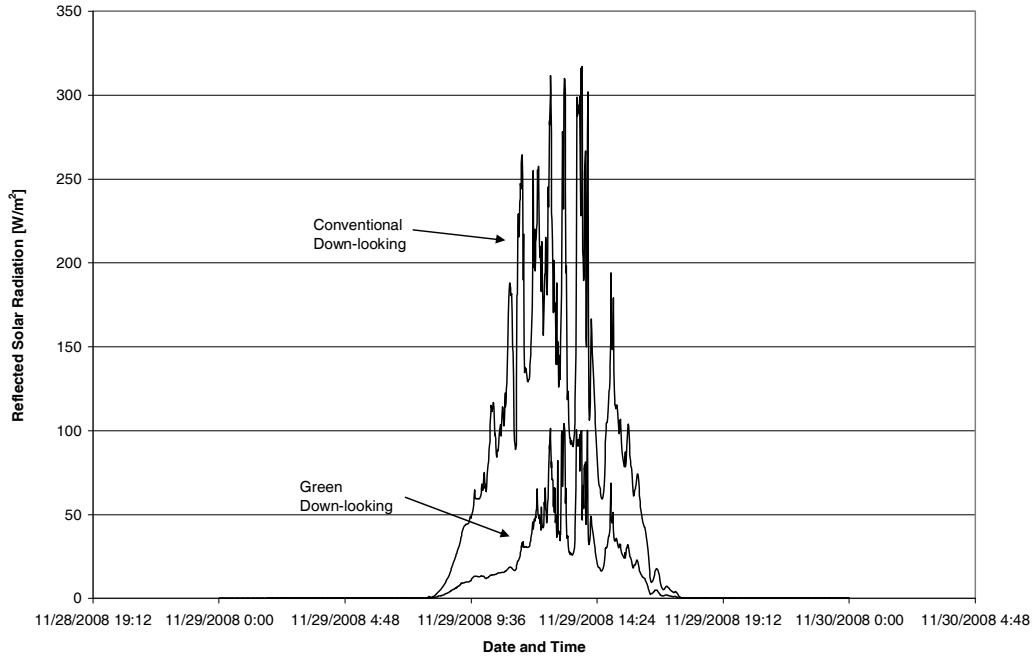

Figure 17. Comparison of down-looking pyranometers

Soil Moisture

Changes in soil moisture due to a 6 hour, 25 mm rainfall event can be seen in Figure 18. The most intriguing results show the response of the bed is relatively fast for higher intensities of rainfall. However, once the rainfall has ceased, detention of the water in the pore spaces can be seen. The green roof effectively detains some of the runoff and releases it slowly.

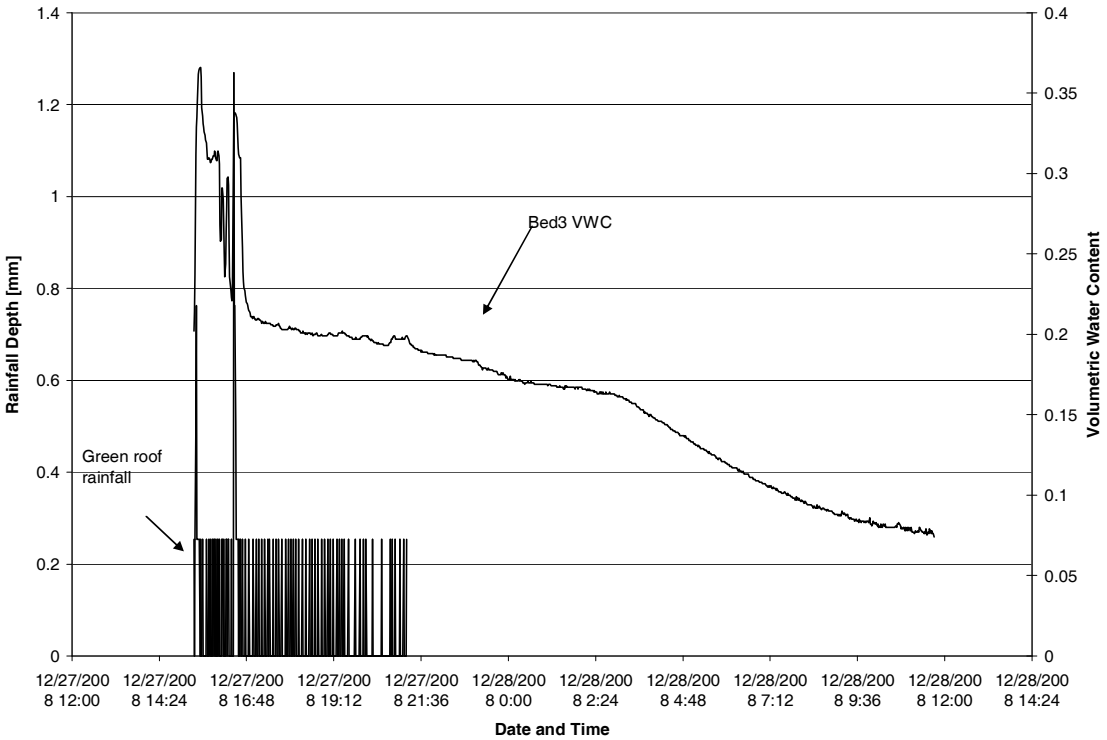

Figure 18. Effect of 6 hour, 25 mm storm on VWC in green roof Bed3

Wind

Wind data from the anemometer were analyzed, finding the prevailing wind direction is South-Southwest at an average speed of 3 m/s. Gusts up to 53 m/s (120 mph) were recorded; gusts strong enough to blow the top off of the raingage causing damage and loss of precipitation data for the conventional roof station.

Conclusions and Future Work

The current dataset contains data for atmospheric conditions and soil moisture and temperature for 20 rainfall events. Indications of differences in insulating properties can be seen, however more rigorous analysis of the data can be complete when the under roof temperature sensors are installed. Furthermore, evaporation and infiltration processes can be seen. However, few strong conclusions can be drawn without the aid of runoff data.

In the near future: the flow meters will be deployed, the passive and water quality samplers will be installed, the under roof temperature probes will be installed and the wireless communications network will be set up. Moreover, once a suitable dataset is obtained for the current configuration of soil moisture sensors, a new configuration of sensors will be implemented. The new configuration will place the sensors horizontally at different depths to collect process scale data to investigate the soil moisture profile. Ultimately, the goal is to provide real-time monitoring and control of the sensors and dataloggers, with real-time data being uploaded to a website.

Multiple Watershed Scales Approach for Placement of Best Management Practices in *SUSTAIN*

Fu-hsiung Lai,[1] Jenny Zhen,[2] John Riverson,[2] Khalid Alvi,[2] and Leslie Shoemaker[2]

ABSTRACT

Since 2003, the U.S. Environmental Protection Agency has been developing a decision support system for placement of best management practices (BMPs) at strategic locations in urban watersheds. This system is called the **S**ystem for **U**rban **S**tormwater **T**reatment and **A**nalysis **IN**tegration (*SUSTAIN*).

One dominant technical requirement for *SUSTAIN* is the ability to place management practices at multiple scales. To manage the complexity of larger watershed scale applications, *SUSTAIN* uses a tiered approach to evaluate both individual and multiple nested watersheds. In addition, for distributed BMPs in residential parcels of a new development or an existing neighborhood, *SUSTAIN* uses an optional *lumped* approach to aggregate BMPs by two generic BMPs, representing infiltration and storage processes. This paper describes the procedures for performing a tiered evaluation of BMPs at various spatial scales and aggregation of distributed BMPs. It illustrates framework features and performances through selected examples that are typical of the conditions and scenarios of watershed stormwater management.

The tiered optimization implemented in *SUSTAIN* provides an efficient and manageable means for large watershed scale decision makings and allows users the flexibility in placing assessment points throughout a watershed where flow and pollutant load reduction goals are to be met.

KEYWORDS

Stormwater management, decision support, watershed scale, best management practices (BMPs), cost optimization, tiered approach, aggregation, distributed BMPs.

INTRODUCTION

In 2003, the U.S. Environmental Protection Agency (EPA) initiated development of a decision support system that is based on sound science and engineering for selection and placement of best management practices (BMPs) and low impact development practices (LIDs) at strategic locations in urban watersheds. The BMP/LID assessment tools would help develop, evaluate, select, and place BMP options on the basis of cost and effectiveness. Called the **S**ystem for **U**rban **S**tormwater **T**reatment and **A**nalysis **IN**tegration (*SUSTAIN*), it provides a means for objective analysis of management alternatives among multiple interacting and competing factors. The desired outcome from the system application is a thorough, practical, and informative assessment of BMP/LID placement options considering the significant water quantity

[1] U.S. Environmental Protection Agency, Office of Research and Development; E-mail: Lai.Dennis@epa.gov; Urban Water Management Branch, Woodbridge Avenue, Edison, NJ 08837
[2] Tetra Tech, Inc., 10306 Eaton Place, Fairfax, VA 22030

and quality factors in urban watersheds and associated restoration or mitigation costs. The tool is designed for experienced watershed and stormwater practitioners to develop, evaluate, and select optimal BMP options for various watershed scales on the basis of cost and effectiveness. The beta version of *SUSTAIN* is to be released in 2009.

SUSTAIN is intended to support local and county government engineers and planners, federal and state regulatory reviewers, private consulting engineers, concerned citizens, stakeholders, and academicians in developing watershed-based stormwater management plans. The users are expected to have a fundamental understanding of watershed and BMP modeling processes.

SUSTAIN is being developed in phases because of its comprehensive scope and budgetary constraints. The Phase 1 work was completed in 2005, and the Phase 2 work is underway and scheduled to be completed in 2009. *SUSTAIN* has seven key components: ArcGIS framework manager, BMP siting tool, watershed module, BMP module, optimization module, post-processor, and BMP cost database. They are integrated under a common ArcGIS platform. In Phase 1, a conceptual framework design was developed, and major components were programmed and preliminarily tested. The systematic development of the framework through a critical review of modeling needs, current and emerging data management technology, and available watershed and BMP models has been previously presented (Lai et al. 2003; Lai et al. 2004; Riverson et al. 2004; Lai et al. 2005; Lai et al. 2006; and Lai et al. 2007). The systematic design process ensures that *SUSTAIN* provides a platform that satisfies the needs of environmental managers with technical sophistication consistent with current and emerging technology. The Phase 1 work adopted the then existing BMP module and parts of the optimization module in the Prince George's County BMP evaluation model (Tetra Tech 2001). The ongoing Phase 2 work expands the capabilities and functionalities of the system. Key enhancements include a preprocessor to facilitate selection of placement sites, more tightly integrated and flexible post-processors, expanded cost-estimating functions, and additional BMP types and improved BMP simulation processes. The optimization module is significantly expanded to incorporate an additional solution technique—the Non-dominated Sorting Genetic Algorithm II (Deb et al. 2002)—and provides a means to perform a multi-tier evaluation of individual or multiple, nested watersheds. The Phase 2 work also includes an aggregated BMP approach to represent regionalized distributed BMP/LID practices.

TIERED OPTIMIZATION APPROACH

A relatively large watershed can usually be subdivided into several smaller subwatersheds or subareas. For each subarea, users select an appropriate suite of feasible BMP options (types, configurations, and costs) at strategic locations. *SUSTAIN* generates time series rainfall-runoff data from BMP drainage areas and routes them through BMPs, in parallel or in series, and predicts quantity and quality at selected locations. For each subarea, *SUSTAIN* produces output for deriving optimal cost-effectiveness curves that relate flow or pollutant load reductions with

their associated costs as shown in Figure 1. Each point on the cost-effectiveness curve represents an optimal combination of BMPs that will collectively remove the targeted amount of pollutant load at the least cost.

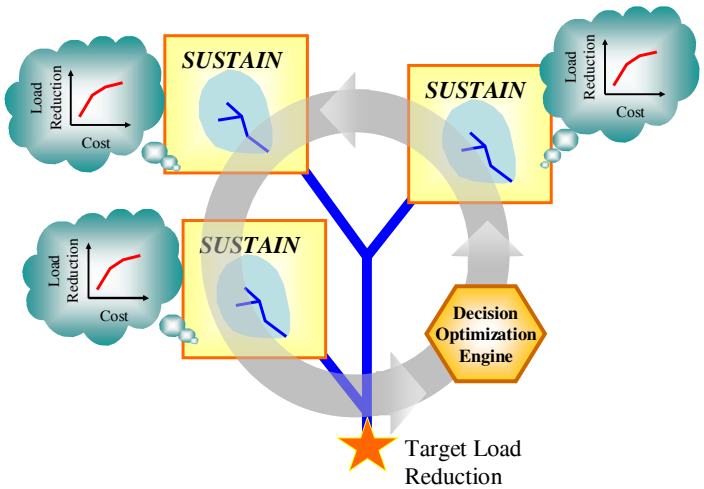

Figure 1. Tiered application of *SUSTAIN* for developing cost-effectiveness curves.

One important requirement in developing *SUSTAIN* is the ability to place management practices at multiple scales. This is because placing BMPs at different spatial levels, i.e., on-site, subregional, and regional, affects the overall cost-effectiveness of the stormwater control system (Zhen et al. 2004). In an urban setting, the on-site scale can be exemplified by building lots or neighborhoods with a drainage area in the range of 10–100 acres. LID technologies are normally applied on this scale. Other BMPs collect runoff at hydrologic junctions further downstream, at a level typically associated with the township scale with a drainage area of approximately 100–5,000 acres. At the larger, regional scale, the benefits of management are often measured by effects on receiving streams, lakes, or other larger waterbodies. The regional scale usually represents a watershed on a county level with a drainage area greater than 5,000 acres. Management plans often need to reflect the cumulative benefit of management practices at multiple scales on downstream water quality in rivers, lakes, or estuaries. Detailed simulation can be performed at the site scale or small watershed scale to evaluate the effects of various combinations of practices and treatment trains on localized water quantity and quality. For evaluation and placement at a larger scale watershed, there could be hundreds or thousands of individual management practices that compose the aggregated treatment. To manage the complexity of larger-scale applications, *SUSTAIN* uses a tiered evaluation approach conceptualized in Figure 1 that allows for evaluation of both individual watersheds and multiple, nested watersheds.

As the first step of the tiered optimization analysis, cost-effectiveness curves for each subwatershed (tier 1) are generated by performing multiple optimization runs for the defined incremental flow/pollutant reduction targets. The second step is to construct

the search domain for a combination of subwatersheds (tier 2). The search domain contains the discrete solutions on the tier-1 cost-effectiveness curves at various assessment points *i* and *j* in the watershed. Figure 2 illustrates the search domain construction process.

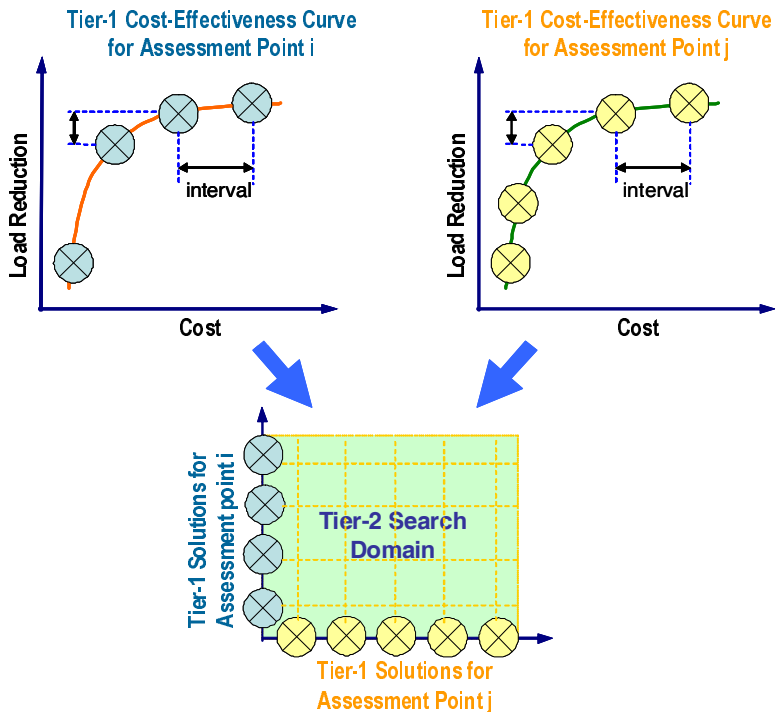

Figure 2. Construction of the tier-2 search domain using tier-1 results.

The third step is to perform the tier-2 optimization on the search domain. The optimization engine is designed to strategically sample within the search domain. The cost-effectiveness of each sample is measured, stored, and analyzed to guide the next search direction. Figure 3 illustrates the simulation process that generates the results used for measuring each iteration run's cost-effectiveness. The simulated time series output for each set of tier-1 solutions (assessed at smaller location point ★) are stored and used every time the solution is sampled. Similarly, the watershed area that is not covered by the tier-1 assessment points can either be represented by a pre-simulated time series or by real-time simulation during the tier-2 search process (assessed at larger location point ★). Because tier 2 typically represents modeling at a larger watershed scale, time of concentration is an important factor that must be incorporated into the solution approach. For every iteration run, the transport module can be used to route the time series data from the tier-1 subwatersheds and the watershed area between the tier-1 and tier-2 assessment points. The tiered approach is flexible and can apply to both large watersheds that contain several subwatersheds and small watersheds that require a BMP/LID plan at a street block or a parcel level.

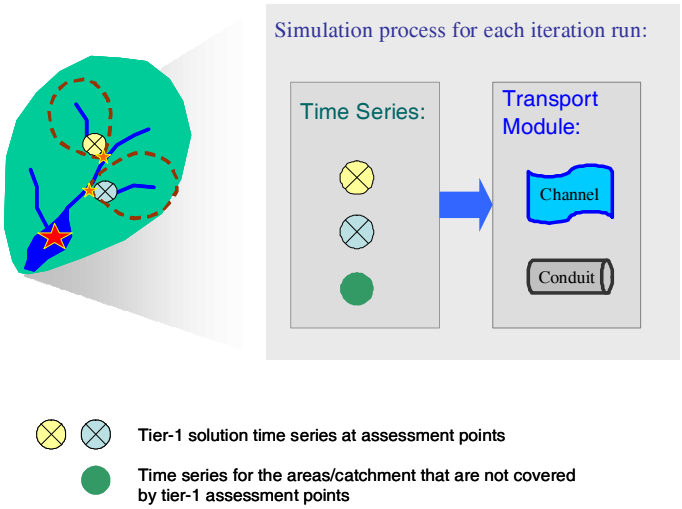

Figure 3. Simulation process for every iteration run.

A hypothetical exercise was carried out to further demonstrate the tiered optimization approach. The objective of this optimization search was to find the lowest cost combinations of BMP options for the desired total phosphorous (TP) load reductions at the specified assessment points. The hypothetical watershed consists of two tier-1 subwatersheds (subwatersheds A and B in Figure 4 below), each with three sets of BMP treatment trains. Each train has an infiltration facility and a detention pond in series. Subwatershed A directly drains to the watershed outlet, while subwatershed B is further upstream and drains to the watershed outlet through a conduit. Figure 4 depicts the entire watershed layout.

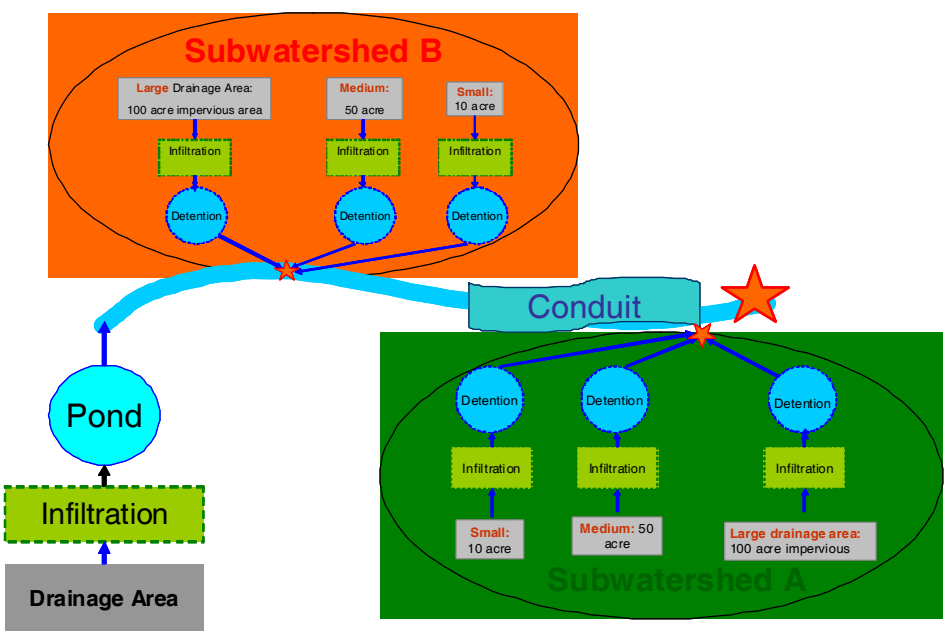

Figure 4. Tiered watershed schematic.

For the tier-1 optimization analysis, the decision variables are the sizes of the infiltration and detention ponds. The outcome of the tier-1 optimization analysis is the identification of optimal solutions along the cost-effectiveness curves shown in red and green diamonds in Figure 5.

Each optimal solution on the tier-1 cost-effectiveness curve contains a combination of decision variables that achieve the desired load reduction at the lowest cost. For the tier-2 optimization, the decision variables included the sizes of the BMPs corresponding to the discrete optimal solutions on the two tier-1 cost-effectiveness curves. The search engine is used to find the tier-2 optimal solutions shown as blue squares in Figure 5. Figure 6 shows the decision variable values (normalized by the maximum value) for each optimal solution along the tier-2 cost-effectiveness curve. For example, at the 18 percent tier-2 TP load reduction target, the tier-1 solutions with 20 percent reduction for both subwatersheds A and B were selected, while the upstream infiltration facility and detention pond were not chosen. As the target tier-2 TP load reduction increases, the tier-2 solutions tend to allocate more TP load reduction to the subwatershed A, which directly drains to the watershed outlet. The upstream pond and infiltration facility were selected only at significantly high load reduction targets, preferring pond over infiltration facilities.

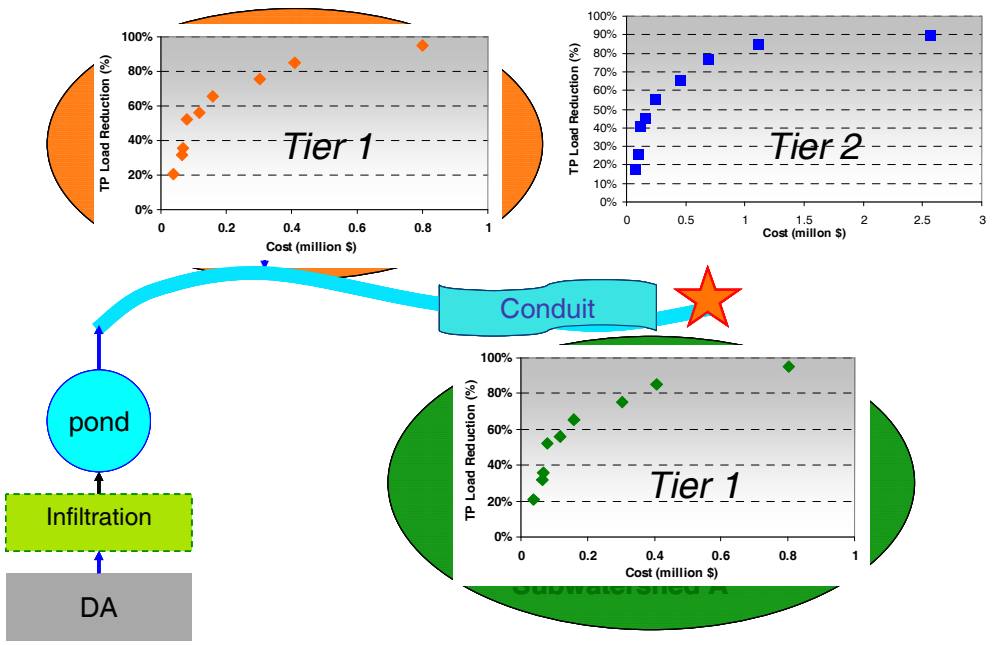

Figure 5. Tier-1 and Tier-2 cost-effectiveness curves.

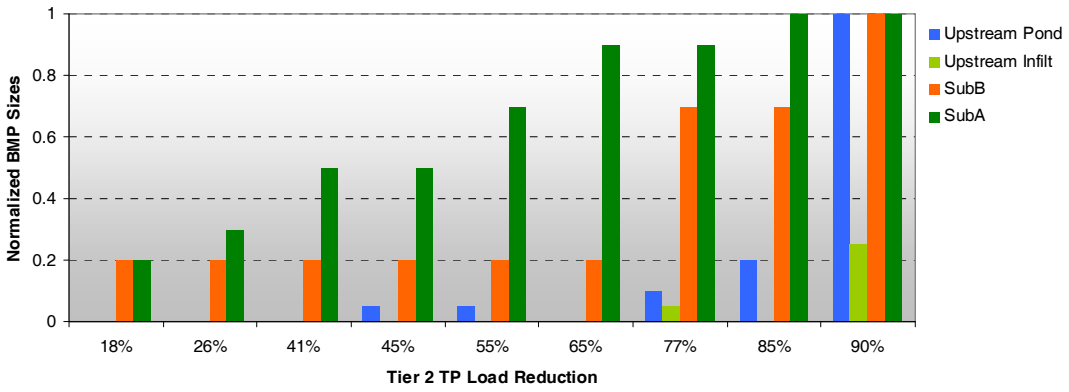

Figure 6. Breakdowns of the tier-2 optimization solutions.

One advantage of the tiered optimization approach is that it significantly improves search efficiency. For this hypothetical case, the total number of solutions for each tier-1 subwatershed is 5^6 (each BMP has 5 possible sizes, and there are 6 potential BMPs in each subwatershed). The possible number of solutions for the tier-2 run is 10^2 x 5^2 (10 tier-1 discrete solutions for both subwatersheds and 5 possible sizes for the two upstream BMPs). The total number of possible combinations using the tiered approach is $5^6 + 5^6 + 10^2 \times 5^2 = 33{,}750$. In comparison, if the optimization is performed in a single run, the total number of combinations of decision options that need to be evaluated would be $5^{14} = 6{,}102{,}515{,}625$ (for the 14 potential BMPs in the entire watershed with five possible sizes for each BMP). This is approximately 180,000 times more searches than that required for the tiered approach. As shown in Figure 3, a tiered optimization can involve transport routing, which can be computationally time consuming. Hence, the reduction of needed search by the tier-approach would also significantly reduce the computational efficiency.

AGGREGATE BMP APPROACH

The BMP module in *SUSTAIN* performs explicit simulation of individual BMP practices for a defined management area. For larger-scale watershed applications, there could be hundreds, even thousands of BMP units scattered throughout the landscape. This poses a challenge in evaluating the collective benefits of distributed BMP units. The required simulations and cost comparisons of these distributed options could significantly burden the modeling effort and require a compromise between the accuracy of the results and computer time required. Hence, an aggregate BMP modeling approach to represent the characteristics of distributed BMPs was developed in *SUSTAIN* aiming at the reduction of computational effort while providing comparable time series data output.

As illustrated in Figure 7, a typical aggregate BMP consists of a series of optional components, including on-site interception, on-site treatment, routing attenuation, and regional storage/treatment. Each component can be used to represent a number of individual BMPs. For example, on-site interception can be represented as a cistern, rain barrel, or green roof, while on-site treatment can be bioretention, porous

pavement, or an infiltration trench. Each individual component can be enabled or disabled on the basis of the desired functionality and can use the BMP template to input the sizes and parameters. Users are asked to input the gross drainage area and the number of units for each aggregate BMP components. For example, as illustrated in Figure 8, one unit bioretention cell with the size of 10 feet long by 10 feet wide is designed to treat runoff from a 0.1-acre drainage area.

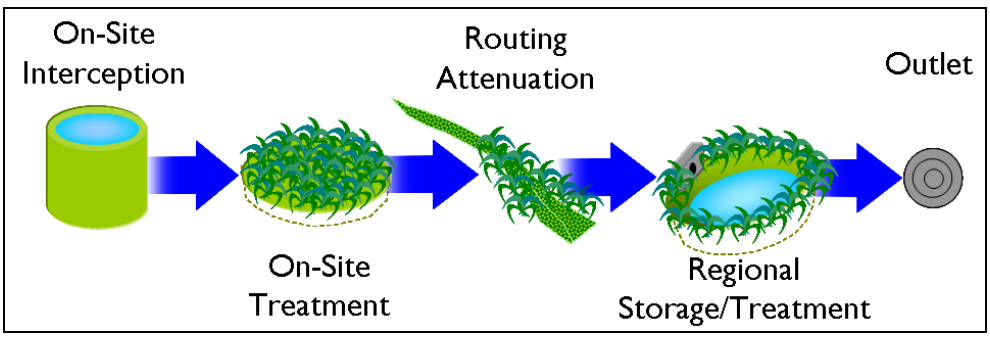

Figure 7. Generic aggregate BMP schematic.

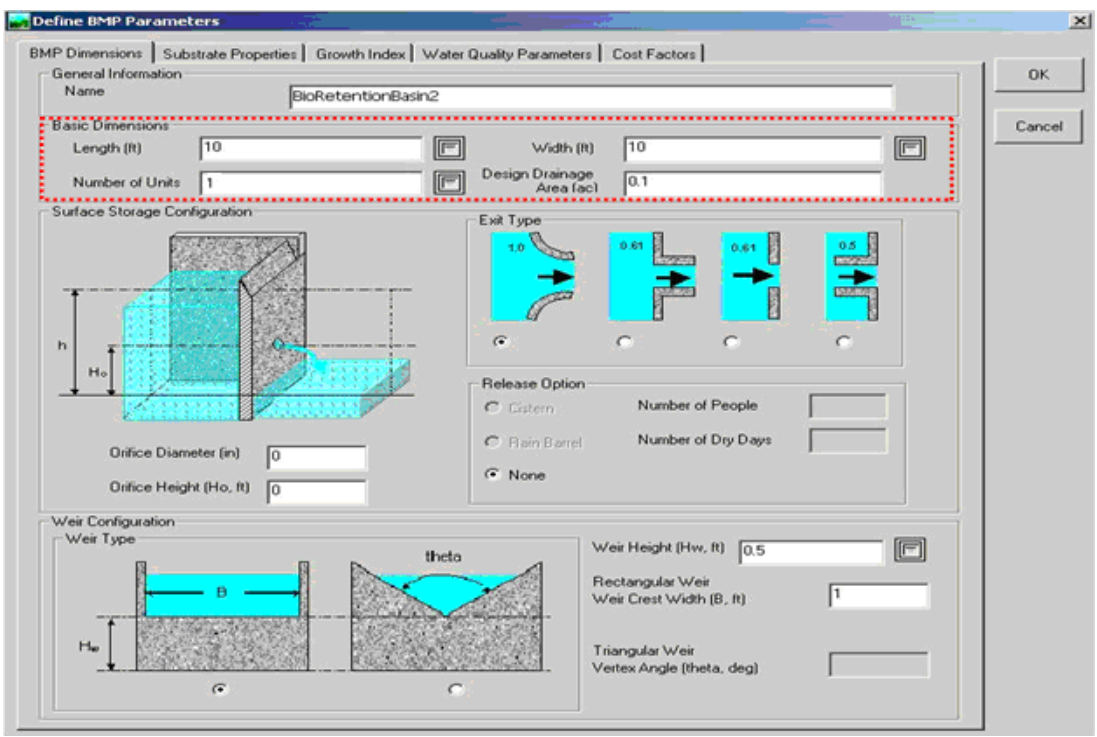

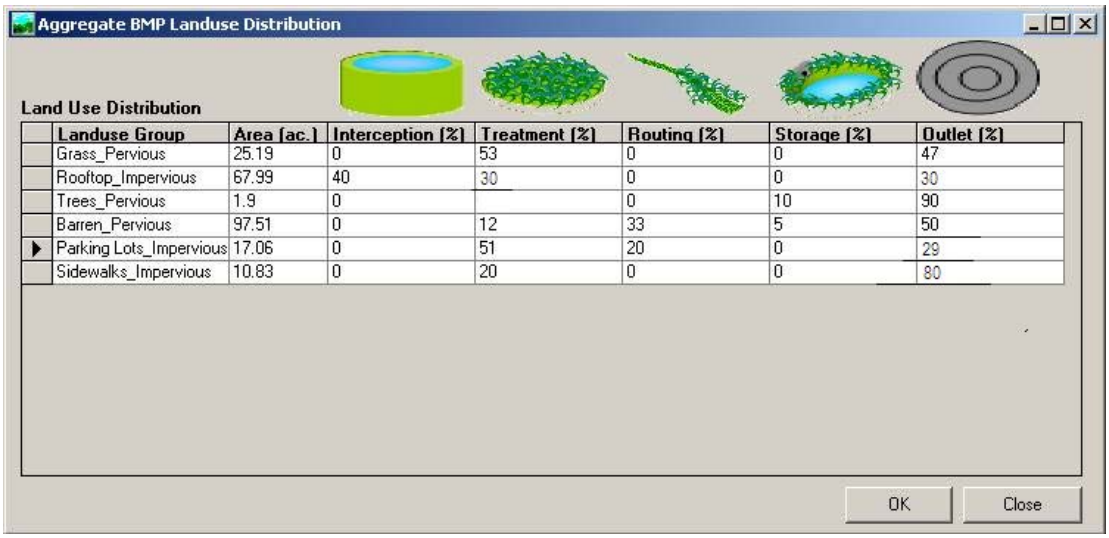

Figure 8. Aggregate BMP sizing interface.

To apply the aggregation procedures, the land use distribution of the drainage area shown in Figure 9 is calculated on the basis of the land use map. Users then assign the percentage of each land use group that could drain to each of the aggregate BMP components (Figure 9). Runoff and pollutant loads from the total drainage area of

each component is lumped and routed through the respective component, preserving the overall routing order shown in Figure 9. The relative scales and sizes of individual BMPs are preserved in the aggregate representation. For the example shown in Figure 8 where one unit bioretention cell with the size of 100 ft^2 is assumed to treat runoff from a 0.1-acre drainage area, one lumped bioretention representing 500 units of bioretention cells with the size of 50,000 square feet would be used to treat runoff from a watershed area of 50 acres.

Landuse Group	Area (ac.)	Interception (%)	Treatment (%)	Routing (%)	Storage (%)	Outlet (%)
Grass_Pervious	25.19	0	53	0	0	47
Rooftop_Impervious	67.99	40	30	0	0	30
Trees_Pervious	1.9	0		0	10	90
Barren_Pervious	97.51	0	12	33	5	50
Parking Lots_Impervious	17.06	0	51	20	0	29
Sidewalks_Impervious	10.83	0	20	0	0	80

Figure 9. Example of land use area assignment to aggregate BMP components.

CONCLUSIONS

The tiered optimization procedures implemented in *SUSTAIN* and described in this paper provide an efficient means for developing cost-effective stormwater management solutions in multiple-scale watersheds. The described aggregate BMP modeling approach to represent distributed BMPs at a larger scale has been separately tested, though not described in the paper, and shown to result in a significant reduction of computational effort while providing a comparable time series data output. Both the tiered optimization and aggregate approach are being applied to two watershed case studies and the results will be reported in the near future.

Nexus Projects in Kansas City's Suburban Watersheds

Brian Rast, PE, CFM, PMP[1]

[1]Planning Branch, U.S. Army Corps of Engineers, Kansas City District, 700 Federal Building, 601 East 12th Street, Kansas City, Missouri 64106-2896; PH (816) 389-3337; FAX (816) 389-2025; email: brian.t.rast@usace.army.mil; Member American Society of Civil Engineers (ASCE) and Association of State Floodplain Managers (ASFPM).

ABSTRACT

Two studies in Kansas City will benefit from the U.S. Army Corps of Engineers' emphasis on multipurpose plans and focus on systems. The Upper Turkey Creek and the Brush Creek Basin are both watersheds facing complex circumstances with many stakeholders. The studies are *nexus projects*, or planning efforts, using the watershed perspective to address the array of interrelated water resource issues through solutions that involve Federal, state, and local programs and projects. These nexus projects are defined by several characteristics, especially the strong integration uniting local, state, and Federal initiatives and recommendations for future stormwater management goals in the watersheds, including water quantity and water quality. An important characterization of nexus projects is the establishment of helpful processes in the watersheds, ranging from communication techniques to a decision process for evaluating best management practices and stream corridor restoration measures. The studies are providing forward looking, collaborative planning efforts to assemble multipurpose alternatives to address flood risk management, environmental degradation, and even recreation. The paper shows how nexus projects in an urban setting can lead to watershed management plans that establish useful processes, integrate the cities in achieving the goals of a shared watershed vision, and get the right projects implemented by first building strong partnerships.

INTRODUCTION

No one can live in a vacuum, and similarly, the work in the discipline of planning cannot be done by one. The water resource planners at the U.S. Army Corps of Engineers (Corps) achieve their best planning alternatives for solving water resource problems when these planners include input from the many relevant disciplines affected by a potential construction project. Planning studies include the effort to write a good report that acts as a decision document on the most feasible alternatives. To do this, water resource planners must integrate the ideas from many stakeholders, whether local, state, or Federal agencies, or simply individuals. Only then can the selected plan best represent a balance between human development and environmental sustainability. To do this, planning leaders must fully understand the missions of other agencies that are affected.

In April 2007, floodplain and stormwater managers met to discuss how two Federal agencies coordinate their programs. In their joint recommendations, those floodplain

and stormwater managers sought "to improve flood risk management with the specific focus on the nexus between Corps and FEMA programs" (ASFPM 2007). That simple word, *nexus*, is defined as a means of connection; tie; link; or the core situation. The word can serve to widen our awareness to other programs that planners should be aware of. This paper coins the phrase *nexus projects* to refer to projects that are defined by their need for using a systems approach, requiring interagency cooperation, transcending political boundaries, seeking a multipurpose solution, and/or integrating local, state, and Federal initiatives.

The Corps addresses nexus projects in many mission areas. As an example, look at the great river, the Missouri River, also known as the Big Muddy. The Missouri River Recovery Program seeks to address a nexus with a budget that now rivals the Everglades. The Missouri River has many interests and uses, all of which are considered in the river's recovery program. They include social, economic, historical and cultural uses such as agriculture, commerce, conservation, energy, environmental, natural resources, navigation, recreation, residential, urban uses, and water supply. These uses have resulted in significant impacts to the Missouri River ecosystem. This example involves many states and agencies and is very large nexus project. Nexus projects can be found on smaller scales, such as the situation in two small, tributary watersheds to this river.

The word nexus goes further than acknowledging systems. Nexus projects require an understanding of other agencies' missions, roles, and capabilities. Nexus projects reach beyond the confines of political boundaries, seeking to integrate initiatives. This describes the essence of collaborative planning, as described by the Corps Engineering Circular, *Planning in a Collaborative Environment* (Corps 2005). Projects that apply collaborative planning involve many stakeholders. Since watershed-level projects also require these considerations, they are good case studies for nexus projects.

As further constraints on water resources funding occur at all levels, the need for thought out approaches, or addressing nexus projects, is becoming more important for decision makers dealing with our water resources. Coordinating efforts, leveraging resources, and avoiding duplication are critical. This means the watershed perspective is one system approach that water resources planners must improve at. In 2008, the Corps completed Five Pilot studies on a watershed basis. The large scale watershed studies that the Corps fully funded began in 2006 with the purpose of determining how that type of study assists stakeholders and the Nation. The Five Pilot studies involve multiple states, multiple stakeholders, and one involves Canada. Figure 1 presents the five studies as either states with cross hatching or a large star. The findings of the Five Pilot studies and the two studies appearing in this paper point at the benefits of presenting nexus projects to decision makers for prioritizing funding choices.

Urban areas are another setting where nexus projects can occur. Many Federal agencies are actively addressing urban watersheds. For several years, one of the fastest growing parts of Corps' Civil Works budget has been the restoration of streams in urban environments (Fischenich 2001). This paper presents two studies in Kansas City as examples of nexus projects.

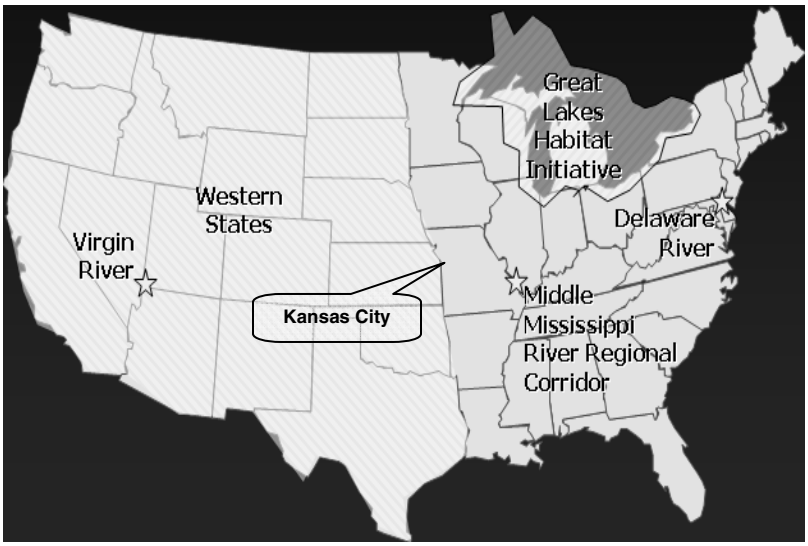

Figure 1. Five Pilot Watershed Studies.

TWO NEXUS PROJECTS

The Brush Creek Basin project and Upper Turkey Creek project are two studies that are nexus projects. Each has a watershed about 30 square miles in area. Their needs are best visualized by a watershed map that both de-emphasizes political boundaries, as shown in Figure 2, and captures the complexity of the situation, later, in Figures 3 and 4. Both creeks flow northeasterly towards Downtown Kansas City, Missouri, which is shown with a star in Figure 2. Nexus projects, like these, do not need to have big watersheds that cover multiple states, as the Five Pilot watershed studies did. Smaller, urban watersheds also face complex circumstances.

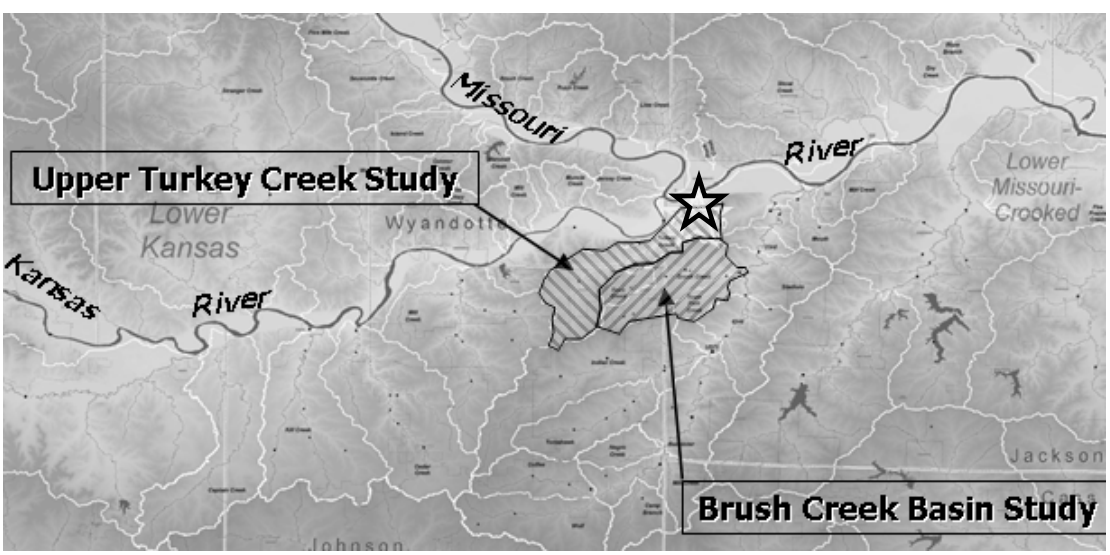

Figure 2. Corps Studies Using Watershed Perspective in Kansas City Metro-Area.

Upper Turkey Creek. This project is an investigation, referred to as a study, that is in the feasibility phase, which is a planning phase. The sponsors who are cost sharing on this project are the City of Merriam, Kansas and the Unified Government of Wyandotte County, Kansas and the City of Kansas City, Kansas. Notable stakeholders include the Downtown Merriam Partnership, the Merriam Drainage District, and the Turkey Creek Coalition. The historical circumstances include a significant flood in 1998 that both cause flood damages and endangered lives as water overtopped Interstate 35. $12 million in flood damages occurred in Merriam's downtown reach, and Interstate 35 overtopped in five spots. Downstream, the Corps is currently constructing the Lower Turkey Creek flood project, consisting of a diversion tunnel, over 20-feet in diameter and a channel widening and bridge project. Those sites are not part of the Upper Turkey Creek (UTC) work. The current feasibility study is authorized to address flooding with structural (i.e. channels, floodwalls) and non-structural (i.e. flood warning systems, relocations, buyouts) recommendations. Under the watershed perspective, the study can also address ecosystem restoration, as found acceptable in an urban situation.

UTC is a nexus project because the study involves several small cities in Johnson County and the Unified Government in Wyandotte County. The planning efforts must integrate local efforts and address a variety of stormwater infrastructure. As an example, the study established one contiguous hydraulic model that can evaluate existing conditions and proposed work within both counties as a system.

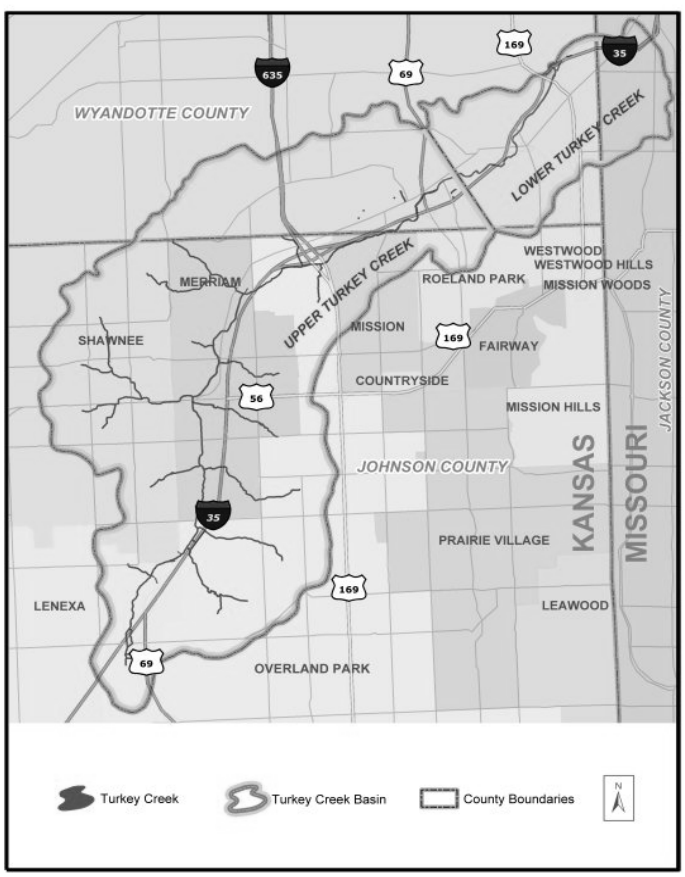

Figure 3. Watershed Map for Turkey Creek.

Another reason this is a nexus project is that the UTC watershed has several agencies and levels of government active here. Activity includes the Corps, the Environmental Protection Agency (EPA), the U. S. Geological Survey (USGS), the Federal Emergency Management Agency (FEMA), and the State of Kansas. EPA has proposed a special area management plan. USGS has been helping Johnson County with studies addressing watershed contaminants, and under the National Flood Insurance Program (NFIP) FEMA is receiving updates to Flood Insurance Rate Maps (FIRMs) for all of Johnson

County. The State has expressed concerns with water quality in a Use Attainability Assessment. All of the technical planners from many disciplines and from the many agencies must work openly, so the need is to provide a framework for interagency cooperation.

Brush Creek Basin. This project is also an investigation in feasibility phase. The sponsors sharing the cost are Johnson County, Kansas and the City of Kansas City, Missouri. Stakeholders include the Brush Creek Community Partners. The history of Brush Creek is well known in this region for the flood of 1977, which unfortunately resulted in the deaths of 25 people. Over $66 million in flood damages resulted, including damages in the Country Club Plaza shopping district. In 1996 the Corps and Kansas City completed construction of a $48 million channelization project.

Figure 4. Watershed Map for Brush Creek.

However, in 1998 the creek flooded again and 8 people died downstream of the project. The feasibility study has a multipurpose authorization, addressing flooding and allied purposes, possibly water quality and recreation. This planning effort recognizes the combined sewer overflows and the non-point source problem identified by the USGS in a recent study of the Blue River watershed, of which Brush Creek is a sub-basin of (Wilkison 2006).

The Brush Creek Basin (BCB) study is a nexus project, because this project involves two states, and this means the need is to overcome this separation and integrate the fractured local efforts. Additional complexities include the need to recognize the

water quality goals that must address not only combined sewer overflows and sanitary sewer overflows, as regulated by the EPA, but especially the non-point sources throughout the watershed. USGS specifically pointed out the degree of impairment of the streams and the effects on water quality, explaining that half of the problem is non-point sources. Best management practices (BMPs) are being implemented by many of the cities, and the Corps has assisted in planning some using the funding program, Planning Assistance to States, within the Rock Creek tributary for the City of Mission, Kansas. Johnson County's strong stormwater management program has aided smaller cities in implementing some BMPs. The watershed's planners understand the need to look beyond their own jurisdictions to implement solutions. All of these are evidence of the presence of a nexus project.

CHARACTERISTICS OF NEXUS PROJECTS

Developing Characteristics. The idea of nexus projects is characterized by water resource initiatives that develop by

- acknowledging the systems approach
    - transcending political boundaries
    - managing stormwater comprehensively
- integrating efforts by local, state, tribal, & Federal agencies
    - avoiding repetitive efforts or combining initiatives
    - leveraging funds & grants
    - requiring interagency cooperation
- considering multipurpose solutions
    - pursuing sustainable projects
    - addressing environmental conditions with creative and compatible alternatives that balance with economic development
- establishing useful processes to aid in achieving long-term goals
    - engaging in collaborative planning
    - applying processes that will find and evaluate alternatives that meet agreed objectives

The planners at local governments, the state level, the tribes, and the Federal agencies must be aware of when there is a significant nexus. A nexus among their mission statements. A nexus for water quality goals. For the Corps planners, this means realizing that urban water quality cannot be trivialized. For planners in EPA, this means realizing flood hazards overlap with local environmental priorities. For all, this may mean re-examining transportation to enhance multipurpose alternatives. Planners must be aware of the nexus surrounding infrastructure to find the most sustainable alternatives. In pursuing this concept of the nexus among cities, states, tribes, or agencies, the many disciplines involved in solving water resource planning

problems should strive to lay down a process to implement best practices in any system.

A closer look will explain why BCB and UTC have prominent nexus project characteristics. The two watersheds are experiencing the same prevalent problems, flooding concerns and environmental degradation associated with urbanization. These nexus projects are developing because planners are acknowledging the main characteristics. The cities are reaching out from their political boundaries. Cities are interested in stormwater management alternatives. Stakeholders are voicing their desire to improve the environment. Collaboration is happening. Tax payers are happier seeing an interest in reducing repetitive efforts, and they realize that funds can be invested better by applying multipurpose measures and by wrapping these studies into comprehensive watershed management plans or floodplain management plans. In fact, the studies call for defining and pursuing specific processes inside watershed management plans that are proving very valuable.

Systems As a Characteristic. The Corps' acknowledgement of nexus projects has grown and is leading to more guidance about using a systems approach. In the mid-1990s, a priority mission for the Corps' budget became restoring the environment. Planning procedures show increasing concern for watersheds and ecosystem restoration between the late 1990s and the current Water Resources Development Act of 2007. Within the Corps, the ecosystem restoration mission now has a recognized Planning Center of Expertise. The Corps understands the need for having the planning discipline address nexus projects. More recently, the Chief of Engineers has emphasized the need for a systems approach, and for these two studies in Kansas City, this means applying a watershed perspective. Systems appeared specifically in first of four themes in the Chief's *Actions for Change* (Corps 2008), which enhances the version that first appeared in August 2006:

Theme 1: Comprehensive Systems Approach. In space, time, and function: Use a flexible and adaptive system in conjunction with all stakeholders/partners to facilitate collaborative planning, design, and construction.

> *Action 1 -- Employ an integrated, comprehensive, systems-based approach.*
>
> *Action 5 -- Employ adaptive planning and engineering systems.*
>
> *Action 6 -- Focus on sustainability.*

This idea of a systems approach, or watershed perspective, is in harmony with this concept of nexus projects. The relevance of nexus projects and systems continues to mature.

When Congress authorizes investigations by the Corps, the degree to which a study examines watershed level work may be described in several degrees. In the first degree, a study, or "investigation," may use a watershed perspective, as explained in *Policy Guidance Letter #61* (Corps 1999). In the second degree, pure watershed planning work produces a watershed study and sometimes a watershed management plan. A draft engineering circular (EC) for these true watershed studies is due to come out in the spring of 2009 (Corps 2007). The EC explains that the Corps may lead the study or may be simply a team member in the effort. The Federal

government shows an incentive for addressing such planning needs with an additional 10% cost share, or 75% total cost share that a true watershed planning effort is eligible for, versus the normal 65% for most studies. These first two degrees of watershed level work can be compared to what occurs frequently at the local level: Stormwater master plans attempt to provide a city or county with a watershed perspective. However these local master plans often are constrained by political boundaries and stop short of reaching out to the watershed borders. In this third degree, what results is a list of capital improvement projects, prioritized by some criteria other than the needs of a watershed. Often the focus is on very localized problems that get just a band aid, even though overall watershed health is at stake.

Watershed planning is an efficient and effective way to address the problems of urban stormwater management, which are sometimes nexus projects. Since the 1990s, much has developed at the Corps for nexus projects that are in the watershed planning arena. More recently, the science for detecting water quality parameters has also been refined. This is important in stormwater management as this allows engineers and scientist to test implementation with better water quality sampling and use adaptive management to improve. Both of these facts are relevant for these watershed projects.

The Multipurpose Characteristic. This is another strong characteristic of nexus projects. An urban stream corridor is a good example for examining multipurpose alternatives. The Corps now recognizes benefits in combining missions, for example, the "marriage" of business lines, unifying corrective measures from ecosystem restoration mission and the flood risk management mission into a suite of alternatives that would address a given water resources problem. Recreation is another, albeit more minor, consideration, and recreation may be used to address transportation in the multipurpose nexus characteristic.

As an example, consider transportation in terms of bike trails. As Gilbert White, one of the fathers of floodplain management, observed: Do not put the parks on the hilltops, put them in the stream corridors. Planners have observed this since the 1960s. If they can serve as parks, the stream corridors can serve as linear parks, including hiking and biking trails. In harmony with this, the Mid-America Regional Council (MARC) established a master plan, called their *MetroGreen* trails system, and Johnson County and associated cities have embraced the idea with their *Streamway Parks*. This concept is even more important when you consider other facts and what might encourage use by bicyclists that might commute. Streamway trails have a less variable, lower grade compared to the roads laid out in a grid that inevitably include a roller-coaster ride on hills and valleys. Not to mention all the intersections requiring starts and stops. As far as efficiency in moving, the lowest demand for force is in the valleys, which is what the railroads have known for more than a century. The point is that the communities could amplify the amenity of a stream corridor, when they include hike and bike trails in combination with flooding and environmental issues, and they can establish a much more biker friendly area than the current situation, where bikers on UTC must brave two lane roads with trucks supporting the industrial road traffic. Who knows how popular enabling such a corridor along UTC would be considering the fact Turkey Creek parallels the main

interstate connecting the county having the highest income in the State of Kansas with both Kansas Citys' downtowns. A final thing worth mentioning is how the stream corridors could double as utility corridors too, as many do already with sanitary sewers, and the trails could double as equipment paths for comprehensive maintenance. Multipurpose projects extend beyond water quantity and water quality, as transportation issues also are relevant when striving for sustainable solutions, considering the need to reduce our carbon footprints and basically just survive the high cost of gasoline.

The Corps is attempting to unite the efforts in these watersheds with these nexus projects in light of multipurpose needs. For the BCB study, the planners are recognizing that the alternatives identified in the planning phase may be either implemented in the short-term with local funding or constructed later with Corps assistance. Issues span the stormwater spectrum, from water quantity to water quality, while touching on transportation and recreation. The issues and players make these nexus projects.

The UTC study is further along in feasibility phase. Planners have taken the hydraulic and hydrologic models used for the FEMA FIRM updates and expanded their use to evaluate a variety of alternatives that reduce flood hazards for several reaches. The current set of alternatives for urban stream corridors, in Merriam's downtown reach and in the vicinity of the Unified Government's Roe Lane Industrial Park, could be levees or floodwalls measures to protect property. Another alternative could be channel widening with minor ecosystem restoration of habitat and possible buyouts or relocations, as compatible with stream corridor restoration mentioned earlier. State flood hazard mitigation funding has been available for that alternative; however, the local residents and/or businesses must be willing to go forward with this. In the short-term, this would be a very big step for those affected by such an extreme alternative. Planners are pointing out the trade-off on UTC: gaining a channelized reach similar to the current Brush Creek Federal project with little environmental value and ignoring possible improvements that might address urban degradation. For UTC structural alternatives, more likely is that a combination of channelization and floodwalls may be most feasible. Although in the long-term, say 50 to 100 years out, planning goals for reclaiming land along the stream corridor throughout the watershed could be identified.

Both studies are looking at the possibility of multipurpose stream corridors. These multipurpose, nexus projects can include recreation in the form of trails. The Corps can include recreation for up to 10% of the total project cost. With the cost of alternatives currently averaging a million dollars, asphalt biking trails would be a small addition that could be covered in the cost sharing agreement. Again, a nexus project addresses complex circumstances and uses collaborative planning to find similar, acceptable multipurpose projects.

In Figure 5, the case for a multipurpose project is made on UTC. The variety of beneficial functions of stream corridors or floodplains, in alignment with the missions of many agencies, could be addressed by ecosystem restoration. The benefits are shown as the arbitrarily chosen symbols of fish, birds, or turtles, representing the respective amount of aquatic habitat restored, as reasonably acceptable for the urban

stakeholders that need these. Multipurpose alternatives have the most maximized benefits, as shown in the final column at the bottom.

Named Alt.s	Measure	Mission Area	Cost	Benefits
Alt. 1	Channelization Only	Flood Risk Management.		
Alt. 2	Levees & Flood Walls Only	Flood Risk Management.		
Alt. 3	Combo: Channelization with Levees & Flood Walls	Flood Risk Management.		
Un-named	Bank Stabilization	Ecosystem Restoration		
Un-named	Restore Streamway (Native Vegetation, Wetlands)	Ecosystem Restoration		
Un-named	**Combo (channel benching), Relocations, & Streamway Restoration**	**Multipurpose** FRM, ER, & Recreation		

Figure 5. Initial Planning Alternatives for Upper Turkey Creek.

The finalize details about both planning projects' multipurpose analysis will appear in their respective decision documents, the feasibility reports, but much public involvement work remains. Producing these products takes time because of the interaction needed among many stakeholders. Funding comes intermittently. Both facts can delay planning projects. The UTC feasibility report will be finalized after significant public involvement occurs in 2009 and will likely see design work on acceptable alternatives in late 2010. BCB is about a year or so behind UTC, however planning work is introducing useful tools for the local cities and counties to use, as described below. Similar to UTC, the BCB planners are seeking feedback via various public involvement techniques to gage acceptability of alternatives.

THE PROCESSES AS A CHARACTERISTIC OF NEXUS PROJECTS

The most prominent characteristic that allows nexus projects to develop are the various processes that contribute to wise planning and development. These processes include communication tools: maps, geographic information systems, on-line maps, websites, collaborative web tools like e-rooms, and especially documents such as watershed management plans or floodplain management plans. Another process is getting a group to reach consensus on the right organizational structure for the area, whether a floodplain or a watershed. A final process that is needed is one that evaluates, and sets the priority for, water resource measures that provide the most benefits per dollar of investment.

Communication Processes. As a first example, the damage to property and the threat of loss of life due to flooding leads to useful communication process found in

the flood insurance rate maps (FIRMs) under FEMA's National Flood Insurance Program. Both BCB and UTC are affected by Johnson County's county-wide revisions to the FIRMs. From year-to-year for the same frequency of storm, rising water surface elevations at any one location on a stream comes with the development of any upstream land to more impervious conditions. Many downstream creeks have serious flooding concerns. ASFPM points out this serious issue with one of their mottos, "Today's floodplain is not tomorrow's floodplain." The revised FIRMs show continuous reaches of homes and business inundated by the base flood's water surface extents, and this helps define the first set of opportunities. If the base flood is the extents of inundation that the public agrees to use as a screening tool for achieving some objectives, then several reaches of streams are already identified for possible Federal interest-multipurpose project sites. However, FIRMs are just one communication process to be aware of.

These nexus projects develop because several communication processes contribute to their momentum. Communication techniques, such as web tools and geographic information systems share information quickly and transparently. However, creating and using a watershed management plan (WMP), or a floodplain management plan, allows them to unite and begin to achieve long-term goals. A WMP is a living document that looks at a vision associated with a specific planning horizon, such as 50 to 100 years. The WMP documents all processes for identifying the best project sites for environmental improvements and for resolving real estate issues. This alone is not enough.

Processes & Organizational Structure. Additional processes must be addressed, especially the need for an organizational structures for managing any WMP. Without identifying an organizational structure, the WMP would be simply one more study that collects dust on a shelf. This group must be funded locally to have any endurance. The organizational structure will manage communication techniques, such as web tools, maps, on-line forums and calendars for communicating meeting dates. The Corps' Five Pilot watershed studies have shown that going through these processes and funding these types of collaborative software tools yield benefits, including active participation and contributions from stakeholders to build consensus, facilitate implementation, and head in the direction of the goals agreed upon. Also, the Five Pilot studies have shown that these nexus projects need Federal investment to establish these processes.

Both the BCB and UTC studies are striving to establish vision, mission, goals & objectives shared among the stakeholders in the watersheds, and this is a process that requires patience. Figure 6 below illustrates the Three-Prong Approach, which is the process that the BCB project is using. The figure shows a conceptual timeline for these three prongs. The Corps, represented in the figure with the hatched boxes, is working through a planning effort and identifying nexus projects that can be either implemented by the locals or other projects that may be cost shared with the Federal government. The Three-Prong Approach is being launched under the coordination of Johnson County, Kansas, the City of Kansas City, Missouri, and the Mid-America Regional Council (MARC), with assistance from the Corps. The success that they have had can be attributed partially to the forum they are using, called the Brush

Creek Coordinating Committee (BCCC). The BCCC has convened many stakeholders and captured a vision. This is a framework of collaboration, which is the heart of the integrated effort. Throughout 2007 and 2008, the BCCC has met monthly to gradually establish the vision and mission statements. Kansas City, Missouri launched the BCCC in the 1980s. The BCCC has a diversity of technical people involved, ranging from biologists, to parks staff, to engineers. MARC has acted to facilitate the meetings and help the BCB study establish needed management measures and processes, although the formation of the BCCC was a needed process in itself.

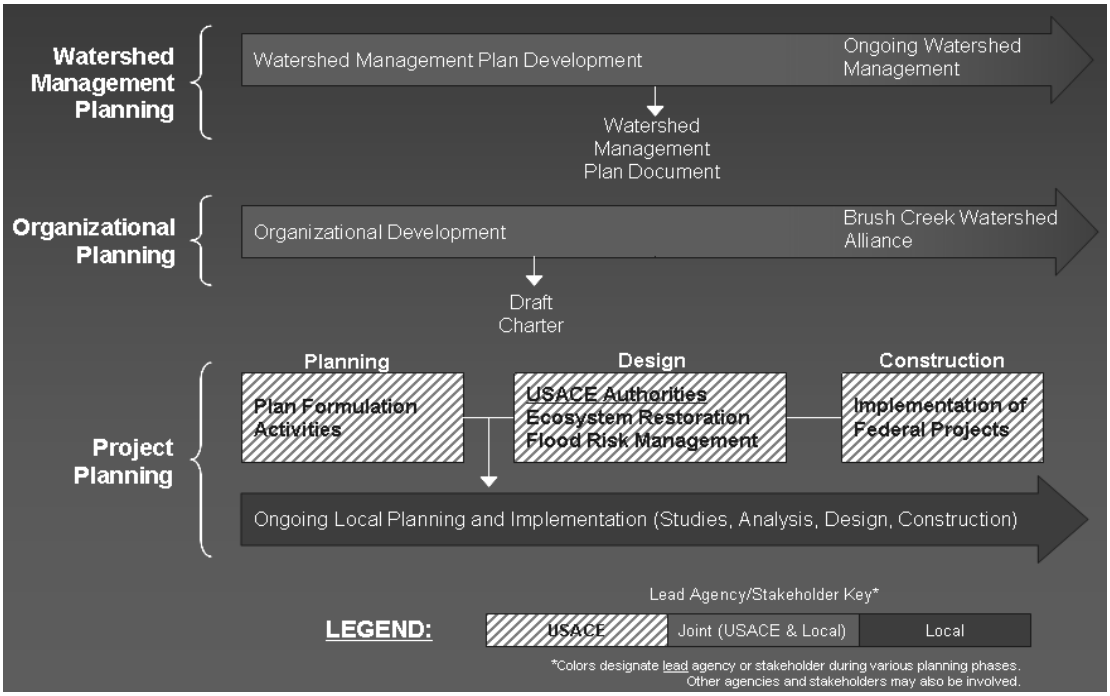

Figure 6. Brush Creek's Process: The Three-Prong Approach.

The persistence of the planners that have given time to the collaborative effort on the BCB planning work has allowed them to create meaningful vision and mission statements and goals:

Vision Statement: *A healthy, sustainable Brush Creek Watershed, where communities work together to protect, restore, and enhance resources in a cost effective manner.*

Mission Statement: *Create a sustainable watershed employing a balanced approach to manage resources and infrastructure while building a healthy community.*

Goals: Manage flood risk; improve water quality; preserve, enhance, and restore riparian and aquatic ecosystems; promote and enhance recreational opportunities; establish and implement organizational framework for watershed management; increase public education, understanding, and participation in watershed stewardship; promote sustainable economic development. Goals have also been sorted to these themes: *Environmental Design & Construction, Advocacy & Education, Integrated Collaborative Management, Economic Development.*

Objectives: The BCCC has identified only qualitative objectives at this time.

The Ultimate Characteristic of Nexus Projects: A Decision Process. A decision process is the most valuable process that defines nexus projects. For BCB and UTC, evaluating the urban environmental nexus can address the Federal interest and unite the constituents in the watersheds. The biggest process that defines these as nexus projects is the one that helps identify the water resource solutions with the most benefits for urban stormwater.

This means addressing not just flooding but also water quality conditions, which currently has the attention of many. In parts of each watershed, combined sewers are being addressed as the cities seek to comply with the Clean Water Act. Kansas City, Missouri is preparing to spend billions of dollars to address combined sewer overflows, or CSOs, with their Wet Weather Program and KC-ONE. USGS studies indicate a large part of the water quality issues are non-point sources, though. A significant effort went into the USGS reports on stream health on the Blue River (Wilkison 2006). The stormwater program under Johnson County, Kansas Public Works has several on-going USGS studies for Johnson County watersheds (Rasmussen 2008). On UTC, EPA proposed special area management plan, or SAMP, which could begin to establish firm guidelines to start to address water quality. On a National scale, EPA released a green infrastructure memo (Grumbles 2007) that acknowledges the structural BMPs, such as Kansas City's *10,000 Rain Gardens* and also including those the Corps planned for Mission, Kansas, as appropriate solutions to water quality challenges. The situational awareness continues: American Public Works Association (APWA) and MARC released a *BMP Manual*. Even the U.S. Department of Agriculture, through the Forest Service, contributes to addressing physical component of water quality: In the *2006 Ten-year Action Plan National Urban & Community Forestry Advisory Council* the goal is to offer grants and to recognize "urban and community trees and forests are vital parts of America's infrastructure and essential to the well-being of our individual human health and welfare." Communities addressing urban forest will see improved urban environments, where benefits include cooler summer air, warmer homes in winter, cleaner air and water, quieter streets, peaceful neighborhoods, healthy and productive local economies. Finally, a situational awareness identifies good changes in regional real estate practices to address water quality. Setback ordinances are being implemented by several cities in developing areas. Similar to APWA's *Stormwater Design Criteria* stream setback details, one by one, cities in the Metro-Area have adopted stream setback ordinances for the developing areas of Overland Park, Lenexa, and Kansas City, Missouri. However, the areas already developed are the real challenge, and land trusts, generally not accepted in the area in the past, may be a useful measure to solve the problems in these nexus projects. Within the Kansas City Metro-Area, the interest in stormwater is clearly a part of needed situational awareness.

The state of watershed protection for both watersheds begs the question where is the most cost effective place to begin? Downstream stakeholders bear the flood waters that runoff of sites upstream. Development has been degrading urban water quality gradually overtime. A helpful step is to establish a decision process for addressing these issues. A good process that does a good job of telling the story, and as a result, can unify the stakeholders, is a characteristic of nexus projects.

The planners at the Corps can offer at least two decision processes. Flood damage analysis is one, and the process uses projected water surface profiles and a thorough economic analysis of flood damages. This is the most well known strength that the Corps offers in the flood risk management mission area. The process that is less well known is the ecosystem restoration mission. This may be the process that can help stakeholders unify and want to stand behind a given set of water resource improvements.

But first, what is urban ecosystem restoration? The idea of restoring the ecologic conditions to pre-settlement time is not realistic. The definition of urban ecosystem restoration is not an easily defined thing. This is a grey area of many different opinions, and none are perfect. The definition also varies with location, and views vary depending on which lenses of the various groups or agencies are used to see it. That definition of how to balance economic development and environment is needed, and time must be spent collecting input.

For the Kansas City Metro-Area, two areas of focus in addressing a decision process that involves urban ecosystem restoration are BMPs and wise floodplain management. First, consider BMPs. Land use practices across the Nation have increasingly acknowledged a practice of keeping rain where it falls over the past 40 years. Low impact development, or LIDs, curb-cuts, and rain gardens are examples of BMPs. Secondly, consider the wise use of floodplain management in light of the condition of the urban stream. These streams are characterized by highly eroded banks with the channel cut-off from the floodplain. A sustainable condition in the stream corridors is needed. A nexus of many cities, states, and agencies exists in the stream corridors. Ecosystem restoration priorities for the Nation typically center on endangered resources, where significance can be addressed, and these are not found in urban areas. However, when sustainability is considered, the question becomes what are we not doing that could reduce adverse anthropogenic effects to the environment? Also relevant, urban ecosystem restoration brings back the intangible socio-economic benefits of having a natural retreat in the proximity of stakeholders in urban areas. Looking at the mission statements of more than one single agency again shows the nexus: EPA's sustainable watersheds and Multi-Objective Management, the FEMA NFIP concept behind Beneficial Functions of floodplains, states like Kansas and Missouri that use EPA's 319 grants, and the Corps' variety of programs, including Regional Sediment Management. A decision process might help integrate all these initiatives.

Without a guiding decision process on both BMPs and stream corridor measures, determination of what achieves a watershed vision can be a vague and wandering search, but consider the stream corridors more closely. Alternatives in the stream corridors have the multipurpose opportunity to address flooding and erosion. Over a 50 or 100 year timeframe, the re-establishment of stream buffers in these developed areas would open the door to more sustainable solutions to the erosion of stream banks. Opportunities have been revealed with the recent FEMA FIRM updates showing continuous reaches of properties subject to flooding from the 1% event. Restoration of a contiguous reach is of more significance than a single property. Within watershed management plans, the cities could gradually, over many years,

reclaim at risk properties in these floodplains and use those lands to address the water quality challenges. A helpful step is to establish a decision process for addressing these stream corridors and BMPs.

To define a decision process, consider the nexus of all the agencies and cities on BCB and UTC (see Figure 7) and reflect on the variety of mission statements each has. The Corps cannot ignore urban water quality. For the Corps, water quality measures fit best under ecosystem restoration. If you are a municipality that shares a watershed with others, how do you make the decision for whether to apply BMPs or whether to apply bank stabilization for eroding creek banks? A process is needed that juxtaposes these and describes what output you would get for some land based BMPs versus the improvements to establish a sustainable stream corridor. Maybe a combination is the best approach?

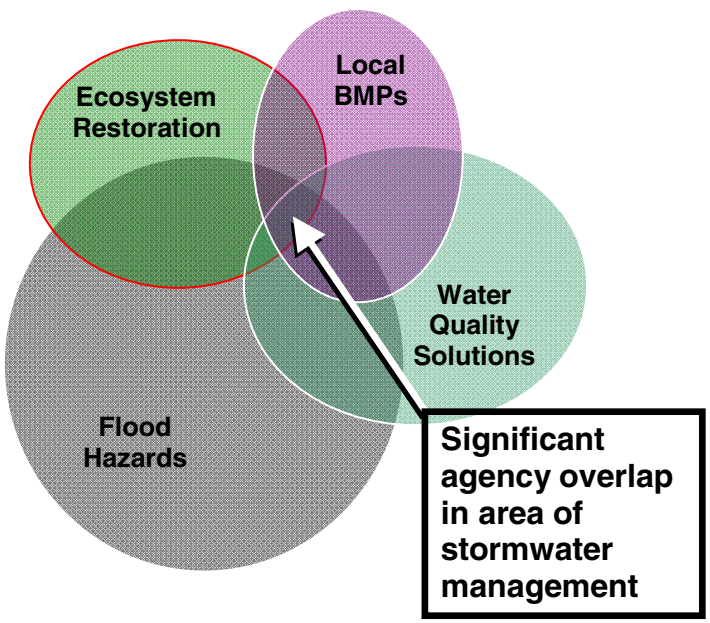

Figure 7. Relevant Water Resource Funding Nexus

The most prevalent water quality contaminant is sediment, because the sediments serve to transport the remaining pantheon of water quality offenders. In urban watersheds, this comes from the changed conditions caused by land development that goes from pervious conditions, such as native planted ground, to impervious conditions, like roofs and pavement. This change increases rainfall runoff. That moves streams out of balance, specifically in how flows and sediment react (Lane 1955). Indeed, the rate of loss of sediment in urban watersheds can be ten times greater than agricultural watersheds. Therefore, any management measures that can address this will help.

The Decision Process. A process for evaluating which alternatives provide the most benefits for the buck exists. The measures must be chosen based on how well they address both water quality and water quantity problems. If the stakeholders know which measures provide the best results, they can make informed decisions about the alternatives that include combinations of these measures. A process that tells the whole story of the watershed is missing from simple capital improvement programs that ignore watershed boundaries. A good process is presented in the principles behind cost effective analysis (Robinson 1995). So to answer the question on how to juxtapose the various BMPs on the UTC project, the Corps offers a process that applies two tools to address environmental degradation in the urban watersheds.

First, from the ecologic or biologic disciplines, a conceptual model is needed that describes the environmental degradation in terms of aquatic habitat. A conceptual model is a tentative description of a system that serves as a basis for intellectual organization and represents the modeler's current understanding of the relevant system processes and characteristics (Fischenich 2008).

This would be a habitat model that could satisfy the Corps' ecosystem restoration mission requirements and characterize water quality conditions. The habitat model chosen is going to make the difference. For the Corps, the habitat model must tie to the aquatic habitat. The model should also be based on watershed variables. Finally, the model should be locally accepted. The UTC planners are proposing the Kansas Department of Wildlife and Parks' habitat model, *Subjective Evaluation of Aquatic Habitat* (KDWP 2004). Combining this with the economic discipline is the step that makes the process begin to take shape.

In 2004 UTC planners began juxtaposing watershed protection measures in an interim report, *Upper Turkey Creek Basin Environmental Restoration Report Feasibility Phase* in August 2004. The report presents a medley of BMPs and stream corridor restoration measures. In 2009, funding will allow the Corps to complete the feasibility report, which will use these initial plan formulation measures and compare them to bank stabilization measures. The planners will show the cost effectiveness of the various alternatives, extending the study beyond the single purpose of flood damage reduction.

The ecosystem restoration measures could be a menu of measures that includes recommendations for treating streambank erosion, or the ecosystem restoration measures may be watershed-wide BMPs that meet the water quality needs under the Clean Water Act. This has been of increasing concern since EPA has begun enforcing rules that apply to municipal separate storm sewer systems (MS4s), and operators of these MS4s must comply with the National Pollutant Discharge Elimination System. Below in Table 1 is a short list of possible measures, or features, which could be formulated into appropriate alternatives and then built to treat the spectrum of stormwater problems, whether attributed to water quantity or water quality.

Second, a cost effectiveness and incremental cost analysis (CE/ICA) is needed for the subject process, and CE/ICA can answer the question of which measures are most effective to achieve an urban watershed's vision. On the UTC feasibility study, the Corps proposes combining the Kansas aquatic habitat model with the CE/ICA done within the IWR-PLAN software. These processes allow the Corps to satisfy the *Principles and Guidelines*: "Efficiency is the extent to which an alternative plan is the most cost effective means of alleviating the specified problems and realizing the specified opportunities, consistent with protecting the Nation's environment." (U.S. Water Resources Council, 1983). At the same time the Corps satisfies the Federal Objective: "The Federal objective of water and related land resources planning is to contribute to national economic development consistent with protecting the Nation's environment, pursuant to National environmental statutes, applicable executive orders, and other Federal planning requirements."

Table 1. Measures for Improving Water Quality.

Streambank Treatments (Corps 1998)	Instream Practices (Corps 1998)	Best Management Practices (BMPs) (APWA 2003)
Bank Shaping and Vegetation	Bank toe stability measures	Filter Strip
Branchpacking and Brushlayering	Bendway Weirs	Native Landscaping (rain gardens)
Coconut Fiber Roll	Boulder and Log Weir	Open Space
Dormant Posts or Dormant Cuttings	Channel Block	
Gabions and Gabion Mattress	Channel Constrictor	Engineered Swales
Hedge - Brush Layering	Cross Channel Log and Revetment	Sand Filters
Joint Planting or Vegetative Riprap	Deflectors	Infiltration Trench
Live Fascines and Wattlings	Grade control structure	Bioretention Filters
Live Siltation	Log Cover (Whole, Half and Slab)	
Live Staking	Longitudinally Peaked Stone Toe Protection (LPSTP)	Extended Detention Wetlands
Log, Rootwad and Boulder Revetment (Native Material Revetment)	Lunker Structure	Wetland Treatment Systems
Overhanging Bank Cove	Newbury Rock Riffle	Pervious Pavement
Riprap	Rock and Wood Spur Dikes	Wet Ponds
Rootwad/Rootball	Tree Drop Deflector and other Midchannel Deflectors	
Stream Debrushing, Brush Bundles and Brush Mats	Vortex Rock Weir with Floating Logs	
Vegetation/Revegetation	"W" Rock Weir	
	Water Control Structure	

This process is the essence of the role that economics has in environmental planning. As with flood damage reduction, CE/ICA seeks to maximize the net benefits, and helps to answer the decision makers' question of whether the level of output is worth the investment. If improved water quality means better habitat, then decision makers should focus on the units of habitat restored in a watershed, not just the levels of contaminants. A good habitat model applied with a watershed perspective could be a valuable tool for decision makers.

The decision makers typically get an analysis summarized in the graph in Figure 8. Each alternative is compiled of compatible measures that establish a coordinate composed of cost and habitat output. Each proposed alternative has a horizontal component, or environmental output, determined by multiplying the area of the project site by the associated habitat index. This index can be either the U.S. Fish & Wildlife's Habitat Suitability Index from the Habitat Evaluation Procedure, or in the case of the two Kansas watersheds, the Kansas habitat model provides a similar habitat index via the R-value. The area is tied to the width of the stream corridor and the length of stream deemed to be affected directly by the proposed measures. The cost of those measures is the vertical component. A certain stream corridor with proposed measures can be grouped as a single alternative, which would be a single point on the graph. BMPs used throughout the watershed would be assessed by looking at the beneficial affect to a reach of stream that lies downstream from the BMP alternative, in terms of affected area. Together, the graph would include both types, where the BMPs are the solid dots in the Figure 8 example. With the graph complete, some alternative points end up on the cost effective frontier and some are best buys. Both streambank treatments and watershed-wide BMPs address water quality challenges. This process would then capture the intended watershed

perspective, and decision makers, whether local or Federal, could begin focusing first on the measures with the most benefits for aquatic habitat.

Good environmental planning ought to look at the whole problem. Urban stream corridors have disconnected habitat due to erosion and channel incisions. BMPs address a host of other contaminants. The Corps' economic process for evaluating ecosystem restoration measures could be very useful in this case.

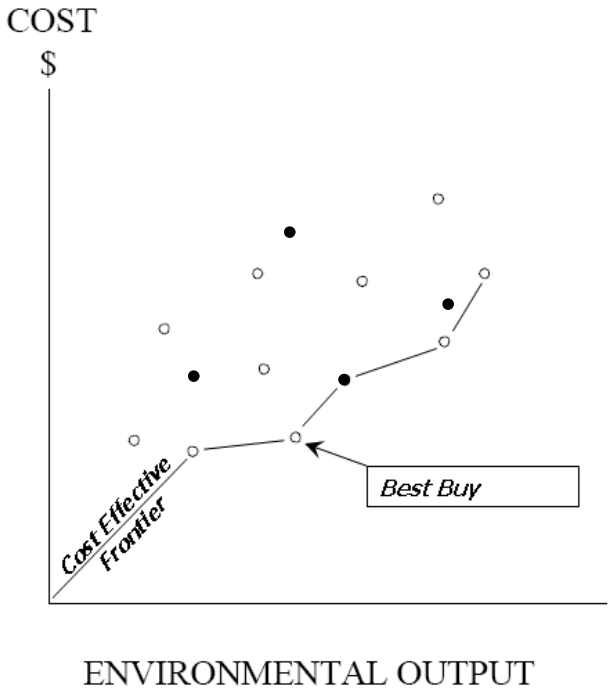

Figure 8: Concept of Cost Effectiveness and Incremental Cost Analysis.

The process described above is needed for nexus projects. As far as the Corps' feasibility study goes, the process defined by the CE/ICA has to be done anyways to evaluate alternatives. When the CE/ICA is done to integrate the efforts in an entire watershed, the reward is a decision tool that provides a means for focusing and coordinating the efforts of local stakeholders. The next process may be an even grander plan that looks at the long-term identification of the easements or property needed for the alternatives. In this regards, the use of geographic information systems could be used to identify needed acquisitions and track the status. As properties become available over 50 or 100 years, they could gradually be acquired.

These two watersheds are recognized as nexus projects, and the stakeholders will benefit from the planning work that will improve the degraded environmental state and reduce flood hazards as well. This is how the Corps can provide planning assistance to show a way to integrate stakeholders and to achieve more sustainable stream corridors throughout the urban watersheds in Kansas City Metro-Area.

CONCLUSION

Water resource planners should recognize the characteristics of nexus projects. They must understand the commitment they require, and they must be patient in taking the time needed for collaboration. They should consider all facets of stormwater management. In doing this, all those involved in the nexus project should see the importance of long-term planning that addresses gradual processes that will achieve the objectives and attain the shared vision. The nexus projects are these watershed studies that are showing how to solve problems for their shared water resources.

The BCB and UTC projects are providing forward looking collaborative planning efforts to the Kansas City Metro-Area. They are establishing and applying a process

for restoring stream corridors is a central theme, and they are defining what urban ecosystem restoration is. Planners are realizing the importance of looking at the 50 to 100-year planning horizon and documenting the goals with a systems approach. A key realization is that urban stream corridors that could be restored are wise floodplain management, and that is also a best management practice. Even without a cost shared project, the Corps will have provided a way forward, allowing locals to work towards their agreed upon vision for sustainable stream corridors. The studies will reduce redundant efforts and leverage funds.

Planning studies are requiring planners to think about the nexus of many things. The decision makers they serve continue to encourage the acknowledgement of the concept of nexus projects. Nexus projects develop because they have characteristics that build strong partnerships during the planning work. The reward from this synergy can benefit many down the road.

NON-POINT SOURCE NUTRIENT LOADING IN AN URBAN WATERSHED

Eric Gurr and Fidelia (Ola) Nnadi

University of Central Florida, Civil and Environmental Engineering Department, Orlando Florida; PH: (407) 823-2105; email: egurr@mail.ucf.edu

ABSTRACT

The United States Environmental Protection Agency (EPA) passed the Federal Clean Water Act (CWA) in 1972 which set the framework for the water quality standards for the entire United States. As a result of the CWA many point sources were eliminated, but in the process it became apparent that non-point source loads represented even more of a threat. To further study the physical and chemical characteristics of urban runoff the Nationwide Urban Runoff Program (NURP) was established in 1978. This lead to series of management options, named Best Management Practices (BMPs) which proposed various structural and non-structural methods to reduce nutrient loads.

The present study attempts to generate accurate and effective water quality and quantity data that future stormwater management decisions can be based upon. The main objective of this study is to determine the nutrient loadings into the tributaries of Lake Tohopekaliga, using automatic monitoring sites established throughout the City of Kissimmee, Florida. These monitoring sites were located to monitor subbasins within the watershed such that inflows from outside the city limits can be isolated and external pollutant loads quantified. Additional internal monitoring sites were established to determine the pollutant loads of sections within the city.

The nutrient removal efficiency was performed using both the event mean concentration method and the summation of loads method to check for seasonal variation. Analysis was based on 25 discrete grab samples collected on a bi-monthly basis over a twelve month period. The concentration levels of total nitrogen did not seem to vary significantly from its mean value of 0.90 mg/l throughout the year, while there were some relatively lower values in late spring. The study found that concentration levels of total phosphorus ranged from 0.02 mg/l to 0.48 mg/l, but not in relation to either season or flow volume fluctuations. The wet pond showed no net removals of total nitrogen and was actually found to be releasing total phosphorus to the downstream receiving waters.

Background

Florida is surrounded by water, and its many internal lakes and rivers have long been recognized for their excellent fishing and boating. This notoriety draws land developers to the lake shores to establish residential and commercial infrastructure. The altering of the natural environment during the urbanization of watersheds can cause harmful side effects such as decreased infiltration of rainfall, increased runoff volumes and increased occurrences of flooding. These hydrologic factors lead to streambank erosion which is the main transport mechanism for pollutant export to receiving waterbodies (Schueler, 1987). The influx of these nutrients carried by the runoff from developed watersheds can lead to algae blooms which reduce water quality levels.

The United States Environmental Protection Agency (EPA) passed the Federal Clean Water Act (CWA) in 1972 which set the framework for the water quality standards for the entire United States. As a result of the CWA many point sources were eliminated, but in the process it became apparent that nonpoint source loads represented more than 65 percent of pollutants entering our nation's waterbodies (Rushton and Dye, 1993, Livingston, 1985). Research that began prior to the adoption of the CWA documented that a large source of nonpoint pollution is the runoff from urban and industrial areas (Whipple and Hunter, 1977). The Nationwide Urban Runoff Program (NURP) was established in 1978 to collect basic data on the physical and chemical characteristics of urban runoff across the country (EPA, 1983).

A series of management options, named Best Management Practices (BMPs) were developed to control the pollutants transported in urban runoff (Schueler, 1987). These BMPs can be either maintenance or development practices that do not include the construction of a permanent stormwater management structure like street sweeping or Low Impact Development (LID) which are referred to as "non-structural" or they can be actual ponds, swales or physical processes which are referred to as "structural". The effectiveness of each of these BMPs varies according to the targeted pollutant, pollutant concentration, and site conditions.

Scope and Objectives

The study area encompasses approximately twenty (20) square miles of surface area with a relatively flat topography and poorly drained soils. A mixed land use of residential, commercial and agricultural can be found throughout the City of Kissimmee. Stormwater runoff in the city is conveyed to Lake Tohopekaliga by six (6) distinct tributaries which receive flow from the runoff of their respective watersheds.

The goal of this study is to generate accurate and effective water quality and water quantity data to aid in future stormwater management decisions. Specifically, this study aims to establish automatic monitoring sites throughout the City of Kissimmee, Florida to determine the pollutant loadings into the tributaries of Lake Tohopekaliga. These monitoring sites were located such that inflows from outside the city limits were isolated and external pollutant loads quantified. Also, additional internal monitoring sites were established to determine the pollutant loads of internal sections of the city. These internal monitoring sites were used to determine the variable pollutant removal efficiencies and hydraulic fluctuations of natural, irregular riverine systems.

The objective of this paper was to create a pilot study to verify the results of a nationwide urban runoff program conducted by the Environmental Protection Agency which rated permanent wet pool detention basins as very effective in reducing nutrients from urban runoff (EPA 1983). This objective was met by collecting nutrient data at the inflow and outflow points of an in-line, wet detention lake to provide more information on effectiveness of essential nutrient removal.

Discrete grab samples in tandem with the continuous hydraulic and hydrologic data from monitoring stations were gathered on the man-made lake. The data were analyzed to determine if there are any seasonal variations in pollutant loading or removal efficiencies. For the purpose of this study, only total nitrogen and total phosphorous were examined.

The man-made lake selected for the pilot study has an area of 15 acres and ranges from 3 to 8 feet deep with an average depth of approximately 5 feet. This lake receives an average annual flow of 3.5 cubic feet per second, which results in a residence time of 11 days with no littoral zone. Monitoring stations are located at the influent and effluent sections of the lake which provided data on the hydraulic and hydrologic parameters.

Methodology

The essential chemical compounds that all plants require to grow and flourish are nitrogen and phosphorus. Nitrogen compounds are primary constituents of concern in surface waters due to their limiting role for plant growth. The most important forms of inorganic nitrogen in surface waters are ammonia, nitrite, and nitrate. Organic nitrogen is also an important constituent of surface waters and occurs in both dissolved forms and in particulate organic matter. Nitrogen is the critical element required for protein synthesis and, hence, is critical to life of all plants.

Phosphorus occurs as soluble and insoluble complexes in both organic and inorganic forms in aquatic systems. The principal inorganic form is ortho-phosphate and is the preferred form for plant (macrophyte) growth. Dissolved phosphorus includes both phosphate and dissolved organic phosphorus. Particulate phosphorus includes biological matter such as plankton (microbiota) and phosphorus sorbed on biotic and abiotic suspended particles. Dissolve organic phosphorus and insoluble forms of organic and inorganic phosphorus are generally not biologically available until they are transformed into soluble inorganic forms.

Phosphorus may be permanently or semi-permanently lost from aquatic ecosystems to the sediments and to a lesser extent as phosphine gas to the atmosphere. Because organic phosphorus can be transformed and used by plants, it is generally sufficient to consider the ambient concentrations of total phosphorus in natural water bodies to anticipate ecological effects. Naturally occurring inputs of phosphorus originate from surface inflows, groundwater inflows, leaching from soils, and atmospheric deposition. Anthropogenic inputs are typically from the use of inorganic phosphorus fertilizers for agriculture and landscaping, the use of animal feeds rich in phosphorus, and from discharges of phosphorus in wastewaters and stormwaters.

Wet detention ponds use permanent pool of water to achieve nutrient removal. To maintain a permanent pool it is important to have sufficient surface runoff, fairly impermeable soils, and an adequate base flow to the pond. The effectiveness of these permanent pools at removing nutrients depends on the inflow rate and detention time, which are both functions of the storm intensity, runoff volume, and pond size (Gurr, 2007). These parameters determine the fraction of nutrients captured in the pond for treatment, especially during quiescent periods between events (Woodward-Clyde, 1986)

The influent-effluent approach is the most effective method for estimating the pollutant removal efficiency of a structural BMP. This is because pollutant removal efficiencies are based on calculating the difference between influent and effluent loads (Urbonas, 1994). Since the locations of the sampling points are immediately upstream and downstream of the BMP, it makes it possible to isolate the pollutant loads for the mass balance calculations.

The nutrient load transported at any time interval is determined by mass balance. The United States Environmental Protection Agency proposed two different mass balance methods for computing nutrient removal efficiency in a lake. The first method, called the average event mean concentration efficiency ratio (E_{emc}), uses an average of the event mean concentrations from all of the samples distributed over the sum of the sample volumes. The E_{emc} expressed as percentages is computed as follows:

$$E_{emc} = (1 - E_{emc\ (ave)out} / E_{emc\ (ave)in}) \times 100$$

where $E_{emc\ (ave)in}$ is the averaged inflow E_{emc} and $E_{emc\ (ave)out}$ is averaged outflow E_{emc}. The loads are computed as the product of event mean concentrations and the associated volume. Since the average event mean concentration efficiency method averages all of the event volumes, it gives equal weight to each storm event.

The second method, which is the summation of loads efficiency ratio (E_{sol}), sums the product of each sample volume multiplied by its corresponding event mean concentration. The E_{sol} expressed as percentages is computed as follows:

$$E_{sol} = (1 - SOL_{out} / SOL_{in}) \times 100$$

where SOL_{in} is the summed inflow loads and SOL_{out} is the summed outflow loads. Loads are then computed as the product of event mean concentrations and the associated volume. However, unlike the average event mean concentration method, sample data is required for each events input and output loads.

Although, both of these methods are independent of the number of samples collected and assume that their results represent the storms that normally occur in the region, the summation of loads method however assumes the collected samples represent all significant input and output loads (Martin, 1986). Even though the average event mean concentration method is capable of providing efficiencies of BMPs, the summation of loads method was found to be a better measure of the overall efficiency of a BMP (Martin, 1986). Additional research on BMPs found that where there is a permanent pool, computing pollutant removal effectiveness for individual storms may not be meaningful since the outflow typically has limited relationship to the inflow. For wet detention ponds, it may be more appropriate to use total loads over the monitored period to compute removal efficiencies (Strecker, 1992).

Data Results and Analysis

The physical data to fulfill the goal of the study were gathered by continuous monitoring equipment installed at nineteen permanent sites located within the six tributaries of Lake Tohopekaliga. Two of these monitoring sites were located at the upstream and downstream channels of the pilot study lake (Figure 1). The multi-parameter water quality instrument used to measure temperature, dissolved oxygen, pH, Chlorophyll, conductivity, salinity, turbidity and total dissolved solids was the YSI 6600 EDS Component. While Sontek Argonaut (SW) instrument was installed along the bottom of the channel to measure water level, velocity and temperature. The automatic samplers were not in place during some of the initial water quality sampling so the data used in this study were limited to a twelve-month data period.

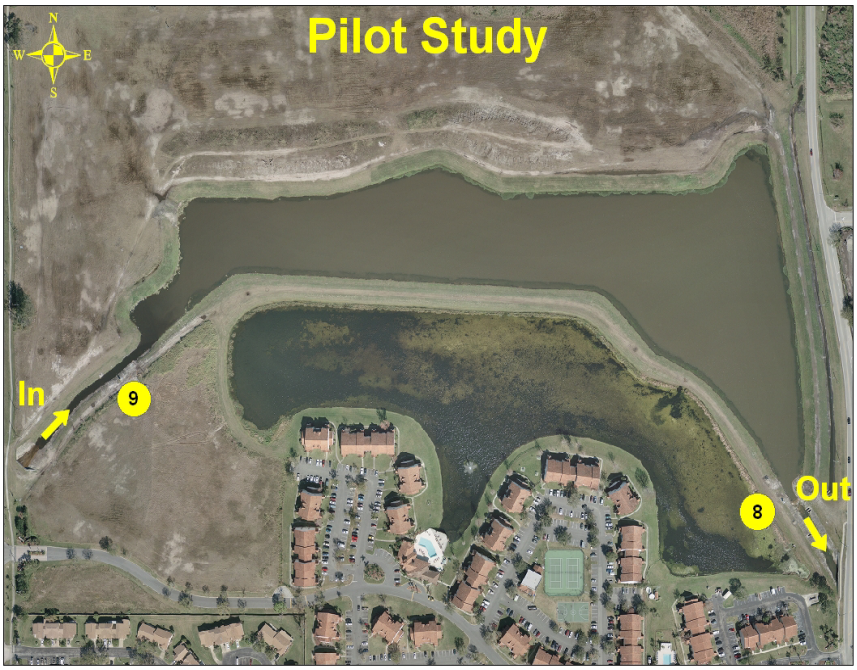

Figure 1: Study site location

Frequency of sample collection and the level of detail for the water quality analysis were within budgetary constraints. Water quality sampling protocols were established to cover field sampling procedures, sample labeling conventions, sample transit and laboratory result verification. All analysis of water quality samples were required to be conducted by laboratories certified in the state of Florida and the continuous field monitoring equipment needed to be maintained on a daily basis by personnel licensed by the equipment manufacturers.

The laboratory results from the collected grab samples in the pilot study lake show little variation of total nitrogen concentration levels from their mean value of 0.90 mg/l whereas the concentration levels of total phosphorus ranged from 0.02 mg/l to 0.48 mg/l during the year-long study period. The levels of total nitrogen and total phosphorus in the lake were within the range for algae bloom generation of 1.5 mg/l and 0.15 mg/l for total nitrogen and total phosphorus, respectively. During the study period, only two minor algae blooms were observed and they only lasted a few days each.

Both E_{emc} and E_{sol} approaches were used to compute the mass balance for nutrient loads. The E_{sol} approach was performed on a bi-monthly and monthly basis whereas the E_{emc} approach was performed for the entire year. Figures 2 and 3 represent the

seasonal nutrient loads flowing into and out from the lake for total nitrogen and total phosphorus, respectively.

CONCLUSIONS AND RECOMMENDATIONS

The laboratory results from the collected grab samples show slight variation of total nitrogen concentrations and moderate variation of total phosphorus concentrations throughout the year. The concentration levels of total phosphorus ranged from 0.02 mg/l to 0.48 mg/l, but not in relation to either season or flow volume variations.

A review of the data shows that the E_{emc} and E_{sol} methods yielded approximately the same results. This is mostly because the study period was short duration of only one year. It is interesting to note that the magnitude of total nitrogen loads coming into the lake were basically identical for either pollutant load analysis method. In contrast, the total phosphorus levels increased at the outlet of the lake, which suggests that the study lake was actually releasing total phosphorus into the downstream receiving waters.

The nutrient loads flowing into and out from the lake were evaluated for wet and dry cycles, but no significant variation of nutrient concentration levels nor removal efficiencies were found with respect to season. The only nutrient that showed any seasonal variation was nitrogen and it only showed slightly lower values towards the later part of spring and early summer.

LIMITATIONS

Resuspended pollutants from the lake floor were not accounted for in the analysis since sediment data was not collected during this study. Atmospheric contributions of pollutants to the lake were expected to be insignificant, but the data was not available to verify this assumption. The initial and final pollutant loads within the lake were not measured, so an assumption was made that it remained unchanged from year to year. Also, any contribution from waterfowl was not accounted for even though there is a rather large roust of birds along the maintenance berm of the lake.

Abstract

Pervious pavement is a low impact development stormwater control. The Urban Watershed Management Branch of the U.S. Environmental Protection Agency in Edison, NJ, is evaluating concrete pavers as a popular implementation. The pollutant removal of a bench-scale permeable interlocking concrete paver system was evaluated using urban stormwater runoff from a 9 ¾-acre drainage area. Stormwater was delivered to the pavement system twice daily to accelerate aging of the system, while monitoring clogging and long-term pollutant removal. The role of microbial communities within the pervious pavement system in pollutant removal is also being examined. It is important to evaluate stormwater quality after filtration through pervious pavement systems to see if the exfiltrate has improved sufficiently for release to surface or ground waters. The bench-scale phase of this study examined materials and system hydraulics to optimize for the full-scale experiment. The project evaluated system performance with the presence of a geotextile between gravel layers using both woven and nonwoven fabrics along with control systems with no geotextile.

Background

Permeable interlocking concrete pavement is a stormwater best management practice (BMP). The pavers themselves are not permeable, but the spaces in between the pavers allow water to infiltrate. The gaps are filled with washed, graded stone that allows infiltration and also provides structural support for the pavers. Recent

literature has shown that the concentration of stressors in exfiltrate is substantially lower than the infiltrate for other pervious pavement systems partly because the gravel layers under the surface provide some filtration (James and Thompson 1997, Rushton 2001, Clausen and Gilbert 2003, Ellis et al. 2004). Studies showed that annual pollutant export in runoff from driveways was 86% less for paver driveways than impervious asphalt driveways (Clausen and Gilbert 2003, Gilbert and Clausen 2006). The system can also potentially reduce the urban heat island effect because the pavers reflect sunlight rather than absorbing it (James and Thompson, 1997).

Objectives

The overall objective of this ongoing project is to assess the long-term pollutant removal performance of a pervious pavement system receiving parking lot runoff. A bench-scale hydraulic study determined the flow rates and materials necessary for the full-scale experiment. A separate bench-scale microbial study will examine the role of microbial colonies in pollutant removal performance of this pervious pavement. Results from these two bench-scale experiments will be used to refine the full-scale investigation.

This paper focuses on the hydraulic bench-scale study. The primary objectives of the hydraulic bench-scale study are to:

(1) Determine the flow rate of stormwater through the system;
(2) Compare the total suspended solids (TSS) of the influent stormwater with that of the effluent; and
(3) Determine the performance effects of the presence/absence of a permeable geotextile in the system and to determine performance differences between a woven and nonwoven geotextile.

Secondary goals of this hydraulic study are to:

(1) Determine the discharge volume of the system;
(2) Determine the breakthrough time of the effluent discharging from of the system; and
(3) Monitor clogging of the system as the study progresses.

Experimental Design

Four small-scale pervious paver systems were constructed in 60cm x 60cm x 90cm HDPE bins. Pavers of a minimum of 7.6cm thickness were placed on a 2.5cm layer of 1-cm diameter crushed stone. The 1-cm crushed stone also fills the gaps between the pavers. These pavers were surrogates for the interlocking pavers and were spaced accordingly. There is a maximum of 1.27cm space between the pavers. Below the 1-cm layer is a 12.7-cm deep layer of 1.6-cm diameter angular crushed stone, and a 3.8-cm diameter slotted PVC pipe is positioned near the bottom of the bin that routes discharge through the bin wall. The bins are placed at a 1% longitudinal slope, the same as that of the full-scale pervious pavement design. Two

systems were installed with a woven permeable geotextile (manufacturer reported apparent opening size = 0.425mm, flow rate = 204 L/min/m^2) between the gravel layers, while the other two systems have no geotextile (Figure 1). The permeable geotextile separates the gravel layers to prevent migration and possibly increases the solids removal from the stormwater infiltrate.

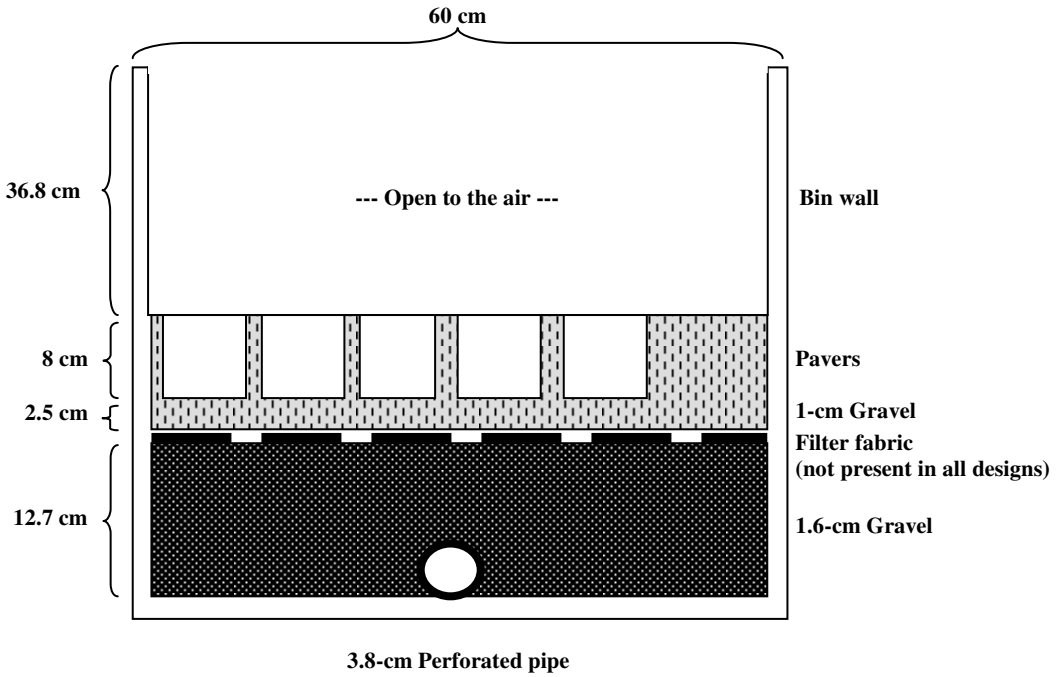

Figure 1. A schematic of the bench-scale pervious pavement system. This schematic is not drawn to scale.

Approximately 17L of collected, homogenized, stormwater were "rained" over each bin every workday, twice daily, for 12 weeks. The stormwater gravity-drained from a 19-L bucket through 5-mm holes drilled in the bottom. The bucket was positioned over the center of each bin to ensure that the water landed on the pavers and did not flow down the sides of the bin (Figure 2). The stormwater drained from the influent bucket in less than 1 hour. The 17L stormwater introduction is the equivalent of a 3cm rain event for the bench-scale paver system (90cm x 60cm). After 12 weeks the study boxes received the equivalent of 380 cm of rain, which is 3 times the mean annual precipitation for New Jersey (124 cm/year) (Robinson 2007). By simulating 3 years of rainfall/runoff (introduced as collected stormwater), the solids loading on the system was accelerated and the effects on the hydraulic and pollutant removal performance on the system were observed.

The discharge from the bins was collected. The depth changes with time in both the influent and effluent bucket were recorded using water level loggers (Global Water, Inc.). Both the influent (stormwater) and the effluent were analyzed for TSS according to Standard Method 2540 D (Clesceri et al, 1999).

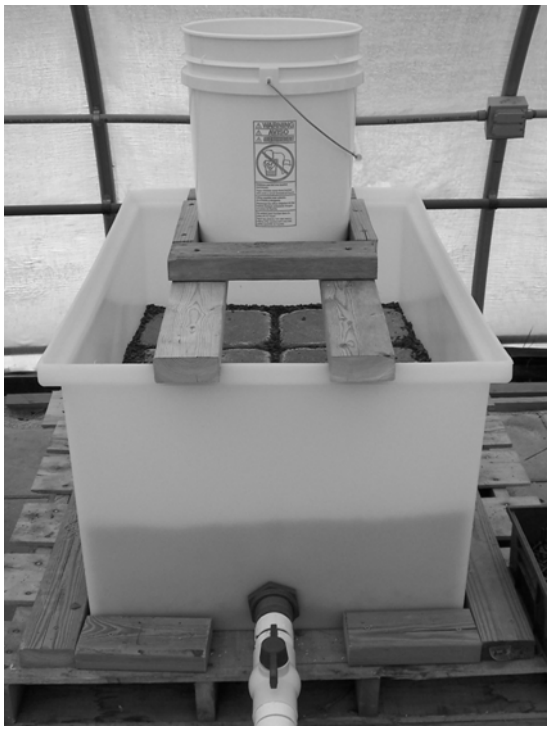

Figure 2. Bench-scale pervious pavement system demonstrating stormwater delivery method.

A second four-bin study was run with two boxes containing a nonwoven geotextile (manufacturer-reported apparent opening size = 0.212mm, flow rate = 6095 L/min/m^2) between the gravel layers, and two bins were used as controls with no geotextile. This allowed a performance comparison between the two geotextile types. The woven geotextile has a grid-like polypropylene weave, the apparent opening size is relatively large, and the flow rate is relatively low, while the nonwoven geotextile is made up of needle punched, polypropylene staple filaments, has a smaller apparent opening size, and has a relatively high flow rate.

The first four-bin study (woven geotextile) was run for 12 weeks and then extended an additional 12 weeks for a total of 24 weeks (Six years of equivalent New Jersey rainfall). The second four-bin study (nonwoven geotextile) was run for 12 weeks concurrently with the second 12 weeks of the first set of bins. Stormwater introductions were made twice daily for the studies.

Preliminary Results and Discussion

The TSS removal for both the woven and nonwoven pervious pavement systems was 89% ($R^2 > 0.96$) (Figure 3).

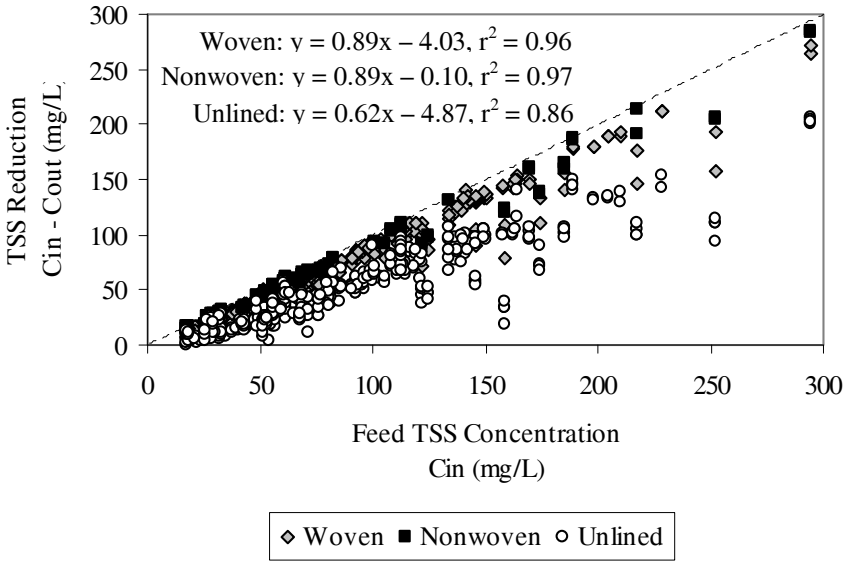

Figure 3. TSS concentration reductions compared to feed concentrations for woven, nonwoven, and unlined systems.

The unlined systems removed 62% of solids, indicating that the gravel and block paver system, with no geotextile, does provide some TSS reduction. The performance of the unlined control systems was more variable than the systems with geotextiles. The presence of a geotextile in pervious block systems increased TSS removal efficiency ($p < 0.01$), but the two geotextile types are not statistically different ($p = 0.06$).

The effluent flow rates from the woven and nonwoven systems were statistically different ($p = 0.04$) and both differ from the unlined systems ($p<0.01$, $p <0.01$ woven and nonwoven, respectively). The unlined bins had the largest effluent flow rates. The nonwoven bins had larger mean flow rates than the bins with the woven fabric, which was expected given the manufacturer's geotextile flow rate differences (constant head test) (Figure 4).

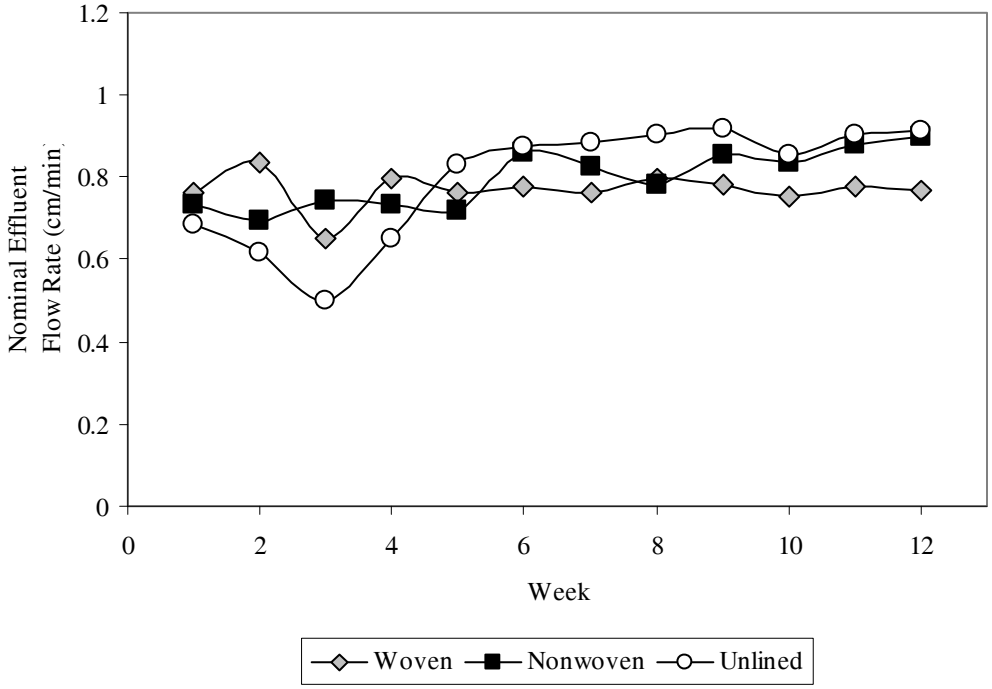

Figure 4. Effluent flow rates for woven, nonwoven, and unlined systems during the first 12 weeks of operation.

The experiment simulated the rainfall/runoff from an equivalent of six years of New Jersey rainfall. The effluent flow rates from the lined and unlined bins at the start of the experiments showed no statistically significant difference from the flow rates at the end of the experiment. This suggests that the systems had no measurable clogging during the experimental period.

Future Work

Once the hydraulic studies are complete, the microbial bench-scale study will begin to examine the role of microbial communities on the performance of the pervious pavement systems. Microbial removal of pollutants can be an effective method for reducing concentrations at contaminated sites (Hutchins et al. 1998, Ellis et al. 2000, Townsend et al. 2003, Shi et al. 2005).Therefore, pollutant removal in pervious pavement systems may be enhanced by expediting the establishment of microbial colonies in the gravel layers. Microbial growth effects will be observed with respect to the following variables: inoculation of microbes on the geotextile, the presence and location of a carbon source in the system, and the detention of stormwater in the system.

The full-scale parking lot construction has started and monitoring study is expected to start in the summer of 2009. The full-scale study, in cooperation with EPA's Region 2, will focus on a 1-acre parking lot with 110 parking spaces that will have three pervious pavement systems: pervious asphalt, pervious concrete, and pervious pavers. The roadways of the parking lot will be conventional asphalt and the parking islands will be pervious. The pervious asphalt parking area will be installed

to the specifications of the National Asphalt Pavement Association, the pervious concrete will be constructed following Standard 522.1 of the American Concrete Institute, and the pervious pavers will be installed to the specifications of the Interlocking Concrete Pavement Institute.

The subsurface of the pervious pavement parking areas of the lot will have both lined and unlined sections. The lined sections will have impermeable liners and underdrains to collect the infiltrate and the unlined sections will drain to the underlying soil. There will be four lined and five unlined sections for each pervious pavement type to allow for comparisons.

The exfiltrate from the lined sections of the pervious parking areas will be collected and monitored for volume, rate, and environmental stressors (e.g., solids, pathogens, nutrients, metals, and semi-volatile organic compounds). Instruments are being installed in the parking lot to record a variety of other parameters such as: sub-grade moisture, sub-grade temperature, water depth, ambient temperature, meteorological conditions, and parking lot usage (car counter). The lot will be maintained (sweeping, vacuuming), but schedules will be varied to determine maintenance recommendations for these types of pervious surfaces. The parking lot will also be observed for signs of aging, surface degradation, clogging of surfaces, and system failure. The parking lot lifetime is projected to be 20 years, but it may last longer if it is well-maintained. This project is being undertaken because there has not been a definitive, long-term, multi-stressor, statistically-valid investigation on multiple pervious pavement systems at the same site.

Conclusions

The hydraulic bench-scale study yielded results that are critical for achieving success in the full-scale parking lot study. Both lined and unlined systems removed TSS, and the lined systems showed 89% relative TSS removal, on average. The systems with the woven and nonwoven geotextiles were not statistically different from each other for TSS removal, but the nonwoven systems had statistically larger flow rates than the woven ones. Both woven and nonwoven systems were different from the unlined for both TSS removals and effluent flow rates. After six years of New Jersey rainfall, no measurable clogging of the systems was seen and solids removal was still robust. The success of the full-scale parking lot is dependent on proper design and these bench-scale studies will help direct those design decisions.

Planning for Sustainable Growth and Water Resources in the Chesapeake Bay Watershed

Thomas E. Dumm, PE[1]

[1] O'Brien & Gere, 8401 Corporate Drive, Landover, MD 20785; PH (301) 731-1160; FAX (301) 577-4737; email: dummte@obg.com

ABSTRACT

Over the past several decades, a multitude of strategies, policies, and programs have been formulated and implemented in an effort to protect the quality of a most precious resource – the Chesapeake Bay. In 2006, Maryland passed a new law known as House Bill (HB) 1141 which directly addresses the relationship between planned growth and water resources. The Water Resources Element of HB 1141 ensures that future county and municipal comprehensive plans reflect the opportunities and limitations of the local and regional water resources.

Situated on a peninsula in the Chesapeake Bay, Kent County, Maryland is nationally recognized for its rural character and serene beauty. Less than a two hour drive from Philadelphia, Baltimore and Washington DC, growth and development pressures have the potential to impact the sustainability of the water resources of the County. This paper includes a discussion of the following topics related to the update of the County's Water & Sewerage Plan which incorporates the Water Resources Element of HB 1141:

- Overview of the Water Resources Element of HB 1441.
- Tools and data sources (i.e., Source Water Assessments, TMDL's, land use plans, Chesapeake Bay Critical Areas, etc.).
- Water resources limitations (i.e., infrastructure, susceptibility of potable water sources to pollutants, point source nutrient load caps, and TMDLs).
- Methods for managing growth where there is limited resource availability (i.e., building permit limitations, down zoning, etc.).

INTRODUCTION

A multitude of strategies, policies, and programs have been formulated and implemented in an effort to protect the quality of the Chesapeake Bay. In 2006, Maryland passed a new law known as House Bill (HB) 1141 which requires counties and municipal jurisdictions to complete a Municipal Growth Element and Water Resources Element. In 2008, Kent County retained O'Brien & Gere to prepare its Water Resources Element including information that could be used by elected officials and decision-makers as a roadmap for addressing the sustainability of planned growth and water resources.

OVERVIEW

Situated on a peninsula on the eastern side of the Chesapeake Bay, Kent County, Maryland is nationally recognized for its rural character and serene beauty. Less than a two hour drive from Philadelphia, Baltimore and Washington DC, growth and development pressures have the potential to impact the sustainability of the water resources of the County. The Water Resources Element of HB 1141 requires that counties and municipal jurisdictions answer the following questions related to sustainability:

- Is there adequate water supply to meet current and future needs?
- Is there adequate wastewater and septic capacity to meet current and future needs?
- How much development can the watersheds accommodate before the nutrient load thresholds is exceeded?

The answers to these questions are intended to link land use decisions and water resources and ultimately improve the health of the Chesapeake Bay. One key aspect of this linkage is the prediction of pollutant loading which is dependent upon a variety of factors, including point sources of pollutants (i.e., wastewater treatment plants) and non-point sources of pollutants (i.e., stormwater, septic, agriculture, etc.). Water quality regulations have traditionally focused on point source pollutants because they are easier to define, test and control; however in the Upper Eastern Shore Basin which includes Kent County point sources constitute only six percent of the total nutrient loading. To address both point and nonpoint source pollution, Maryland has developed the Tributary Strategy Implementation Plan which consists of a comprehensive list of river-specific cleanup strategies that detail the "on-the-ground" actions needed to reduce the amount of nutrients and sediment flowing into the Chesapeake Bay. The Tributary Strategy Implementation Plan includes a multitude of programs within each of the following strategies:

- Point Source
- Growth Management
- Onsite Sewage Disposal System
- Agricultural
- Urban Sources
- Stormwater
- Air Deposition

The overall goal of the Tributary Strategies is to achieve roughly a 50 percent reduction in nitrogen and phosphorus from the Agricultural Strategy and 50 percent from the remaining strategies. In the Upper Eastern Shore Basin which includes Kent County, approximately 70 percent of the nitrogen and phosphorus pollutant load is from agriculture and 5 percent is from point sources.

NUTIRENT LOADING METHODOLOGY

The Maryland Department of Planning developed a non-point source nutrient loading analysis to determine how growth trends and land use decisions could impact future nutrient loading. The expectations for the loading analysis were three-fold: (1) simple

non-point source analysis for nutrient loading, (2) reasonable assurance that future land use scenarios have been considered, and (3) discussions of future steps for running analyses and tailoring the analyses for Kent County. The loading analysis was in the form of an MS Excel spreadsheet and was intended to be applied on a county-wide basis using the loading rates provided by the State for a multitude of land uses (i.e., development, agriculture, forest, wetlands, etc.). Baseline simulations for loading (lbs/yr) were conducted using nitrogen and phosphorus loading rates (lbs/acre/year) and 2002 and 2030 land use (acres). These baseline results can be compared to alternative land use scenarios to assess the loading impacts associated with changes in land use.

FINDINGS

The methodology for conducting the loading analyses outlined in the Water Resources Element was developed to provide counties and municipal jurisdictions with a means for generating a simple and technically defensible prediction of the non-point source loading. For the Upper Eastern Shore, approximately 70 percent of the nitrogen and phosphorus loading is attributed to agriculture. However, in Kent County, the non-point source loading analyses conducted in this study indicated that because of the large quantity of agricultural land in the County the percentage of nitrogen and phosphorus pollutant loads from agriculture were significantly higher (greater than 95 percent) than the Upper Eastern Shore. Although the loading analyses is simplistic, it illustrates that the improvements in water quality will in large part be driven by the ability to achieve the reductions in nutrient loads associated with the Agriculture Strategy. This challenge is one faced by jurisdictions throughout the Chesapeake Bay Watershed.

CONCLUSIONS

Numerous strategies can be implemented to address point and non-point source loading and the improvement in water quality will be defined, in part, by the overall reduction in pollutant loading achieved by a combination of strategies. At this time, the County will initially focus its efforts on the following areas:

- On-site Sewage Disposal Systems
- Capacity Management Plans for Water and Sewer
- Wellhead Protection and Aquifer Recharge Areas
- Stormwater

Implementation of the Agriculture Strategy will likely be directed by the Natural Resources Conservation Service and is paramount to achieving the pollutant loading reductions outlined in the Tributary Strategy Implementation Plan and improving water quality. The challenges involved in moving forward and implementing the tributary strategies will likely be significant and will require the cooperation of a number of organizations. However, recognizing that the Water Resources Element is in its infancy and needs further refinement, the State of Maryland has taken a bold first step toward linking land use decisions with sustainability of water resources in the Chesapeake Bay Watershed.

Pollutant Transport within the Vadose Zone: Interactions of Soil Horizon Chemistry on Water Quality

ABSTRACT

Hydrologic cycle restoration is the primary objective of stormwater management. Infiltration and biofiltration systems composed of engineered soils have become a preferred tool for obtaining this objective while also providing pollutant removal. It is desirable, though, to limit soil disturbance and incorporate native soils. The use of native soils requires a fundamental understanding of their behavior towards water transport and pollutant treatment. Their structure is not homogeneous but instead contains several layers, or "horizons," each with differing pollutant removal capacity. The ability of the various horizons to treat runoff was investigated over 40 simulated storm events in two soil types, a Wharton silt loam and Leetonia loamy sand. Effluent water results showed leaching of total nitrogen and removal of total phosphorus by all soil horizons of both soil types. Potassium leached from the organic horizons of both soils, the silt loam showed removal by lower horizons while the loamy sand did not. All soil horizons of both soil types lowered the pH of influent stormwater and increased conductivity, turbidity, color, and hardness.

INTRODUCTION

Urban sprawl has created large areas of impervious surfaces, increasing surface stormwater runoff peak rates and volumes which amplify erosion rates and flood occurrences. Along with increased surface runoff, the urban environment creates increased levels of pollutants that are washed into steams at levels that may deleteriously impact recreational usage, and aquatic life and habitat, as well as increasing the cost of drinking water treatment. Infiltration units have become a preferred method for reducing runoff rates, volumes, and pollutant loads. Clark et al. (2006) provides an extensive literature review on water quality passing through the infiltration device and the International BMP Database provides results regarding improvements in surface runoff quality after passing over or through an infiltration basin. To maximize the benefit of infiltration as a stormwater management tool, understanding of the biogeochemical processes that control both the quantity and quality of water passing through a soil (natural or engineered) is required.

Because natural soils have transitional layers, called horizons, of varying biological activity, chemical reactions and physical qualities, it is important to understand the properties and interactions of these individual horizons when evaluating a soil's pollutant removal capacity. Most soils have five basic horizons: O, A, B, C, and R. The O-horizon, or organic horizon, consists of vegetative matter that is still in a recognizable condition. Once this organic matter decays beyond recognition of its origin and begins to mix with mineral particles, an A-horizon, commonly called topsoil, is defined. Below the A-horizon, minerals and metals leached from above accumulate and form a B-horizon. Similarly, the C-horizon is a mineral layer formed from material raised by groundwater from the consolidated bedrock of the R-horizon.

This study tested the ability of two natural, undisturbed soil columns representing both the entire available horizon and the individual soil horizons to treat local stormwater runoff. In addition, soil horizons samples were periodically removed from the study and will soon be tested to measure accumulation of pollutants and release of exchangeable ions over time. In the end, correlations between soil parameters and pollutant migration will be studied and the results incorporated into design guidance for determining the proper application, predicted lifespan, and maintenance requirements of infiltration devices. This research, in particular, focuses on the pollutant removal capacity below the organic horizon of the soil where it is believed that much removal occurs but that has historically been ignored. This information is crucial to providing an accurate picture of the movement of pollutants in the subsurface, regardless of the infiltration method used (Clark and Pitt 2007).

MATERIALS AND METHODS

Ten-centimeter diameter columns of two soil types, a Wharton silt loam and Leetonia loamy sand, were vertically encased in PVC pipe and removed intact from two central Pennsylvania sites. The descriptions of the columns are given in Table 1. The Wharton silt loam contains four test groups of soil horizons: O, A, AB, or OAB. The Leetonia loamy sand columns also contain four test groups of soil horizons: O, A1, A1A2, or OA1A2. Control columns of each soil type, representing pre-infiltration conditions, were also collected for soil analysis.

Table 1. Collected soil column descriptions

Soil Type	Horizon(s)	# of Columns	Depth (cm)
Wharton silt loam	O	5 study	5
	A	5 study	15
	AB	5 study	32
	OAB	5 study,1 control	37
Leetonia loamy sand	O	5 study	10
	A1	5 study	11.5
	A1A2	5 study	20.5
	OA1A2	5 study, 1 control	30.5

The Wharton silt loam columns come from a sloped field with a shallow soil that is less than one meter to bedrock. Currently, the land is maintained as a lawn but there has been agricultural activity in the past and plowing may have occurred; the O-horizon is barely three centimeters deep but was slightly exaggerated in the O-horizon columns to keep the soil intact. The A and B-horizons are moderately rocky.

The Leetonia loamy sand columns come from a wooded section of state gameland about 15 meters from a timber harvest landing and 100 meters from abandoned strip mines. Also present are the remains of the village of Dougherty; the small average size of the trees in the area and the presence of a concrete spring water containment structure suggest that the collection site was once part of the village. The O-horizon is fairly deep and consists almost entirely of forest canopy leaf litter. The A-horizon is very sandy and mostly rock free. Impenetrable compaction was encountered at a depth of about 30 centimeters, before a B-horizon was reached, so the obtained section of A-horizon was divided into two sub-horizons in order to make observations similar to the Wharton columns. Also the creation of two depths of the A horizon will enable comparisons to be made of removal as a function of depth.

Roughly 3800 liters of stormwater runoff was collected from the Penn State Harrisburg campus during Fall 2007 and kept in an indoor storage tank. This stormwater includes runoff from copper or tar rooftops, campus roadways/parking lots, and lawns. Approximately once a week, the stormwater was circulated inside the tank for 30 minutes, 135 liters pumped into a barrel, and 600 ml distributed into each column. The 600 ml volume is equivalent to a 7.5 mm storm event on a site where the infiltration system occupies 10% of the surface area. Each soil type received a total of 40 simulated storm events. Effluent was collected from each column weekly and volumes recorded.

A 500 ml bottle of water was collected from the barrel each week for influent water quality analysis and the effluent samples of the soil columns were analyzed bi-weekly on an alternating schedule. Water quality analysis was performed for the effluent of each column; the columns represent true replicates and the error bars on the graphs represent ± 1 standard deviation.

Water quality tests included pH and conductivity (indirect measure of dissolved salts); total hardness (calcium/magnesium); turbidity, color, total nitrogen, total phosphorus (phosphate), potassium, and sulfur (sulfate). Samples for future heavy metals analysis by graphite furnace were passed through a 0.45µm filter and preserved with a 2% addition of 67-70% nitric acid solution; copper, lead, and zinc are planned for testing early Spring 2009. Samples for future total organic carbon analysis by TOC analyzer were preserved with a 2% addition of 5N sulfuric acid.

At the start of the research and in intervals of 8-storm events, a column of each representative test group of each soil type was sacrificed for future soil testing at the Penn State College of Agricultural Sciences Agricultural Analytical Services Lab. Each sacrificed column is subdivided into ~3 inch segments and will be tested for

water pH, buffer pH, soluble salts, total carbon and total nitrogen through combustion, and phosphorus, potassium, magnesium, calcium, zinc, copper, and sulfur. Sieve analysis for soil texture has been completed and the soil analysis at State College is expected to be complete in early Spring 2009.

The initial plan was to have undisturbed natural soil columns, but the Wharton columns showed preferential flow along the pipe, with stormwater not flowing through the soil. It was decided that these columns would be removed from the PVC, divided into three-inch sections, broken apart, air dried, and then the sections repacked in their initial order. The Leetonia columns performed as intended and were left intact. Results for the Wharton silt loam are post-disturbance and may reflect the interaction of the soil type and the soil disturbance.

RESULTS

Results of water analysis reveal leaching of total nitrogen by all soil horizons of both soil types. While the leached concentrations of the Wharton soil started high (> 100 mg/L) and then sloped towards the influent (< 10 mg/L), the total nitrogen concentrations leached from the Leetonia soil started near the influent and then gradually increased to 20 – 30 mg/L (Figure 1). Two questions are raised by this data. First, did disturbing the Wharton soil expose parts of the soil where nitrogen was readily release? Second, what differences exist between the two soils that lead to the differences in stable effluent concentrations?

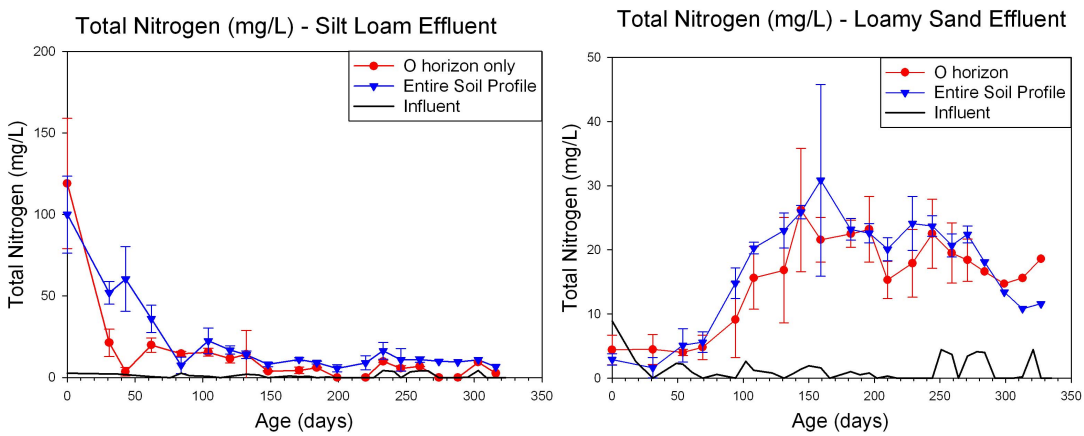

Figure 1. Effluent Total Nitrogen: Wharton silt loam and Leetonia loamy sand

The O-horizon had no impact on the total phosphorus concentration, after the elevated O-effluent concentration during the first two events (Figure 2). This elevated phosphorus concentration that decreased rapidly may be an artifact of the soil disturbance, especially since it correlates well with the elevated nitrogen concentrations from the Wharton soil. The less-organic soil horizons remove the phosphorus from the influent water, and as seen during the two earliest events for the Wharton soil, the lower mineral horizons remove the phosphorus that is released from the organic horizon. This indicates that an increasing mineral concentration and/or a

decreasing organic concentration, where phosphorus content is less likely to be bioavailable and more likely to be bound into soil minerals, can improve phosphorus removal in infiltration systems.

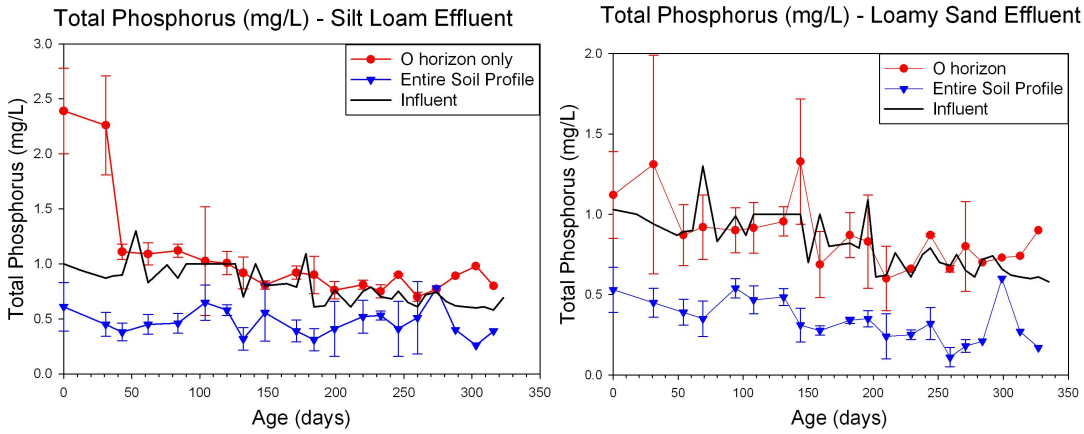

Figure 2. Effluent Total Phosphorus: Wharton silt loam and Leetonia loamy sand

Since potassium carries a +1 valence charge, it is likely to have limited competition in a media where the sorption/ion-exchange locations prefer a polyvalent cation. Interestingly, the potassium was not leached from the Wharton silt loam, although it was leached from the loamy sand (Figure 3).

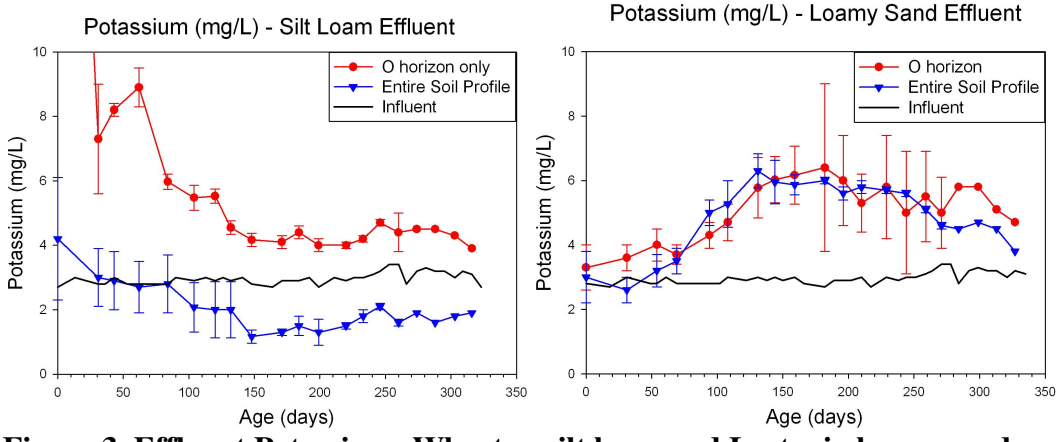

Figure 3. Effluent Potassium: Wharton silt loam and Leetonia loamy sand

Sulfate removal would require the soil to have a substantial anion exchange capacity (AEC). However, our observations indicate that the AEC of these two soils is small (Figure 4).

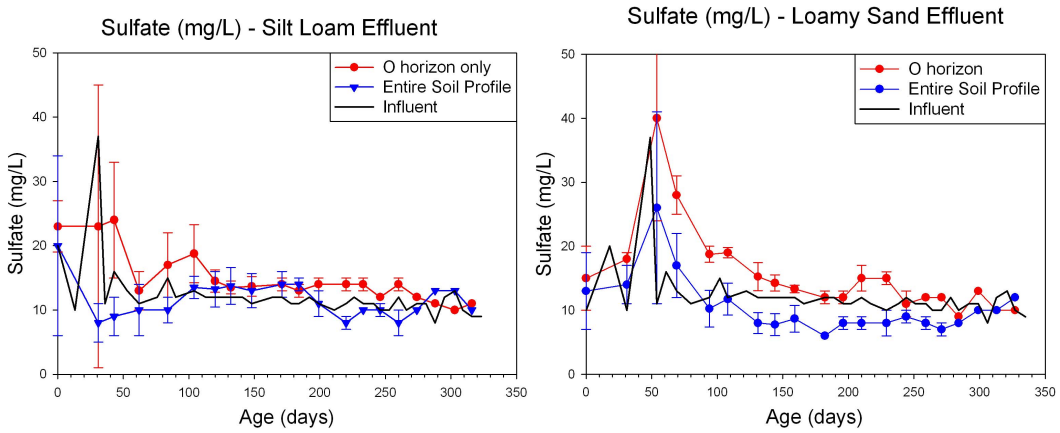

Figure 4. Effluent Sulfate: Wharton silt loam and Leetonia loamy sand

All soil horizons of both soil types lowered the pH of influent stormwater (Figure 5). Effluent pH was slightly lower for the Leetonia loamy sand. The Wharton silt loam has a slight upward trend in the effluent pH for the O and A horizons, indicating a potential loss of acidity. However, the acidity of the AB horizons together and the entire profile increase the acidity of the effluent water. For the Leetonia loamy sand, no change in pH has been observed. Until soil analysis is complete, the question remains as to whether changes in pH will herald changes in soil chemistry that affect removal.

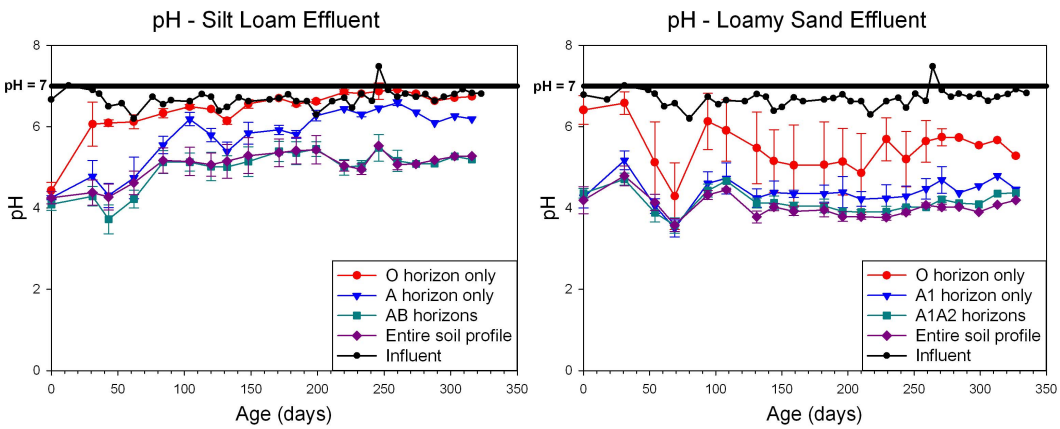

Figure 5. Effluent pH: Wharton silt loam and Leetonia loamy sand

All horizons increased conductivity, hardness, turbidity, and color of the passing stormwater. The hardness results (Figure 6) show a distinct contrast between the soils. The Wharton silt loam, the disturbed soil, had concentration trends similar to those of total nitrogen. The initial concentration of the hardness components was elevated compared to the influent and, after the first few filtering events, the effluent concentrations resemble the influent. This indicates that over time, a slight release of calcium and magnesium from the media is occurring, agreeing with what is known about calcium and magnesium's participation in ion-exchange reactions with other polyvalent cations. In general, if the passing water has a polyvalent cation that will

sorb to the soil stronger than calcium or magnesium, then the calcium or magnesium is released into the flowing water and is replaced by the polyvalent cation (typically heavy metals). This appears to be occurring in the Wharton soil. The early elevated concentrations may be an artifact of having to disturb the soil. Later in the soil's lifespan as a filtering media, it appears that the hardness increases through the soil profile, indicating potential sorption/ion-exchange sites for the polyvalent cations.

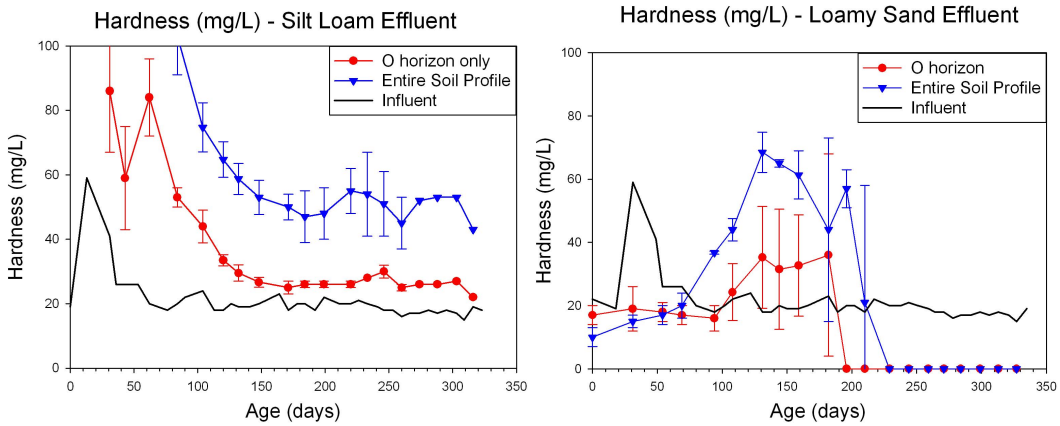

Figure 6. Effluent Hardness: Wharton silt loam and Leetonia loamy sand

The Leetonia loamy sand results are different. First, likely because the soil column was not disturbed during construction, hardness components such as calcium and magnesium were removed from the stormwater, indicating that removal sites existed for the entire group of polyvalent cations. However, after approximately eight weeks (four filtering events), hardness was released from the column. One explanation for the sudden leaching of hardness is that the sorption/ion-exchange sites were full, but that the calcium and/or magnesium were loosely bound. When a polyvalent cation with a stronger affinity for that soil component was near enough to the site to react and replace the calcium or magnesium, then the replacement occurred, washing out calcium and/or magnesium. What is unexpected is the decrease to zero hardness in the effluent near the end of the filter run – first for the organic horizon and then for columns containing the entire soil profile. This indicates that soil chemistry in the column has changed sufficiently to make removal of calcium and magnesium competitively favorable. It is unknown why this occurs.

DISCUSSION

The initial drastic leaching of some tested parameters by the Wharton soil columns, which had to be air-dried and repacked, may resemble what occurs after construction of infiltration units. The release of nitrogen especially is of concern because of the attention that nutrient pollution receives. The nitrogen release of the Wharton soil columns quickly reduced but the nitrogen release of the Leetonia soil columns slowly increased. This increase in nitrogen release by the Leetonia may be a result of decaying organic matter. These results are in contrast with those of Hsieh and Davis (2005), who found that nitrate removal increased with increased organic matter

(Hsieh and Davis, 2005). Additionally, field removal of nitrogen by infiltration units has also been observed (Hunt et al., 2006).

In contrast, a neutral impact on phosphorus content by the O-horizon columns of both soil types was observed and removal of phosphorus was seen by all other soil horizons of both soil types. The influent concentration of phosphorus in this study started around 1.0 mg/L and slowly decreased to 0.70 mg/L. Phosphorus removal has also been seen with influent concentrations of 3 mg/L but may or may not be independent of organic matter (Hsieh and Davis, 2005). In this study, the neutral interaction of the O-horizon and slightly greater removal of phosphorus by soil columns containing a B or A2 horizon suggest that phosphorus removal is independent of organic matter and is dependent on one or more components of the mineral matter. A limit to the phosphorus removal capacity of soils has been observed before in a groundwater recharge study (Schneider et al., 1987) and it is unknown whether removal would continue long term for infiltration applications.

In addition to the created nitrogen pollution, all soil horizons of both soil types lowered the pH of influent stormwater and increased the conductivity, hardness, turbidity, and color of effluent. The O-horizon columns of the Wharton soil had little impact on pH, but an influent pH of 6.7 was been reduced to 5-6 in the effluent of other Wharton columns. The Leetonia soil reduced pH to 4-5 in the effluent of all horizons. An influent conductivity of 40 µS/cm steadily increased in the effluent of all Leetonia columns and reached levels of around 150 µS/cm in the effluent of OA1A2 columns. The conductivity of Wharton column effluent leveled out at 60-90 µS/cm. Hardness slowly decreased in the effluent of the Wharton columns while it increased from the Leetonia columns, perhaps because of Leetonia's sandy composition. Until soil analysis has been completed, the cause of these changes can only be speculated. Despite low turbidity and color present in the influent, 4-7 NTU and 50-100 PtCo respectively, both the Wharton and Leetonia produced greatly increased levels in the effluent of their columns; especially the Wharton, which was air-dried and repacked.

CONCLUSIONS

Infiltration units may or may not be helping the stormwater dilemma but with continued research and changes in design they could definitely be a proper solution. Although only half completed and still in the process of obtaining some key data, this study has already provided interesting data for insight into the functions of individual soil horizons and their impacts on the suitability of infiltration units. The phosphorus removal shown by horizons with little organic matter is of significance and will be further researched. It is believed that the results of planned soil analysis will help answer some unknowns. A closer look at pollutant loadings and the influence of the outflow to inflow volume ratio upon pollutant removal will also be required since a connection has been seen before (Hunt et al., 2006). Finally, analysis of heavy metals is in progress and may help complete the picture.

ABSTRACT

Evaluating the performance of manufactured BMPs on a consistent and scientifically sound approach is beneficial for both the service provider and the services recipient. To do this properly, it is important that these devices need to be tested under a standard set of protocols. The testing data must be collected, reported, and validated prior data analysis. The testing, data collection, data reporting and validation will be addressed under a separate ASCE/EWRI subcommittee. The focus of this paper is to address the data analysis and performance evaluation of manufactured BMPs.

To address this issue the existing statistical data analysis methods and performance evaluation that potentially could be used for manufactured BMPs have been examined in this paper. Special attention was devoted to the data distribution and the issue of normality since that will influence the selection of suitable data analysis approach. In general, it has been concluded that the stormwater data is log-normally distributed. The existing BMP performance evaluation has also been evaluated and the effluent probability plot has been recommended to determine the performance evolution of manufactured BMPs.

INTRODUCTION

Background. Since the passage of the United State Clean Water Act in 1972 and consequently through NPDES amendment in 1983, many local, state and industry are obligated to treat the stormwater runoff before discharging them to a receiving water. Initially with Phase I, the regulatory compliance was only applicable to communities with population higher than 100,000. Since as early as 2002, Phase II extended the same regulatory framework to communities with population of 10,000 or higher and to areas along the urban fringe that together have a residential population of at least 50,000 and an overall population density of at least 1,000 people per square mile. For this reason, demand for the use of compact treatment systems has increased and as a result numerous manufacturers responded and developed wide ranges of structured best management practices (BMPs) to remove different pollutants. These treatment systems are defined as manufactured treatment devices (MTDs). Some organizations such as Caltrans, who had the technical capability and financial resources tried to develop their own treatment systems that is more suitable on their right-of-way facilities (http://www.dot.ca.gov/hq/env/stormwater/special/newsetup/index.htm#new_technology). In recent years, however, the use of MTDs are rapidly increasing in order to meet escalating water quality regulatory requirements; particularly in re-development and new development areas where land space is limited and potential use of other BMPs are not practical. As the use of MTDs has been increased, the demand for some type of certification for their effectiveness in pollutant removal and meeting water quality standard has also been increased on national level. Several attempts have been made on

state and regional level (TAPE, TARP, ETV). However, no consistent protocol has been established for national use.

In response to this national demand, a manufactured BMP certification committee was established under the EWRI's stormwater infrastructure committee of water, wastewater, and stormwater council (WWSC) and the wet weather flow technology committee of the urban water resources research council (UWRRC) (Guo et al., 2007). In addition, parallel efforts are being undertaken by ASTM and WERF. To avoid inconsistencies between the organizations, liaisons from the task committee were established for these other groups. To develop the certification guidelines, several subcommittees were established and each subcommittee was responsible for specific task to develop the final certification guidelines document. The subcommittees to tackle specific tasks include: data reporting, data analysis and performance evaluation, lab testing, field monitoring, scaling, and maintenance. Deliverables from each sub-committee will be a technical guidance manual that will be published by EWRI. The work of each sub-committee will be presented at the annual ASCE/EWRI Congress conference meeting and finally will be published as a peer reviewed ASCE journal paper.

This effort has been broadened to be consistent with the reporting requirements for the International Stormwater BMP database (BMPDB) developed by a broad coalition of partners including the Water Environment Research Foundation (WERF), ASCE Environmental and Water Resources Institute (EWRI), USEPA, Federal Highway Administration (FHWA) and the American Public Works Association (APWA). The purpose of the BMPDB is to provide scientifically sound information to improve the design, selection and performance of BMPs. Continued population of the database and assessment of its data will lead to a better understanding of factors influencing BMP performance and help to promote improvements in BMP design, selection and implementation.

Focus of the paper. The objective of this paper is to summarize the data analysis and performance evaluation task and to prepare a conference manuscript to be presented at the ASCE/EWRI Congress conference at Kansas City, 2009. The specific objectives of this manuscript are to present (1) the potential data analysis approaches, and (2) to evaluate potential methodologies for assessing manufactured BMP performances. From this preliminary work, there will be an opportunity to recommend consistent protocol to evaluate the performance of manufactured devices.

POTENTIAL DATA ANALYSIS APPROACHES

Data Quality and Reporting Prior Statistical Analysis. The central goal of a BMP verification program is first to collect scientifically defensible data in fulfillment of the verification objectives. Statistical methods may be used in the design of the lab, pilot, or field testing to determine data quality objectives (DQOs). DQOs are an important and useful step to ensure that the data produced by laboratory or field testing is sufficient, both in terms of quality and quantity, to establish meaningful confidence levels for the BMP performance evaluation.

The use of standardized procedures to collect BMP performance data and reporting them is essential for successful verification program – not just from one BMP to another, but also from project to project, region to region, year to year. If consistent methods are not applied, it may be difficult to perform data comparisons, and the value of the data may be diminished. For instance, flow can vary significantly throughout a runoff event, and rainfall intensity and runoff volume (Kayhanian et al., 2007). Flow-proportioned composite samples are therefore considered to be the most representative sampling regimen for runoff monitoring. The preferred set-up for water quality evaluation in BMPs is to employ automated monitoring equipment to collect an equal sample volume (aliquot) for every increment of a pre-set runoff flow volume. The composite sample ideally needs to cover the full event hydrograph and accounts for variation in flow and/or runoff quality throughout the runoff event. Grab sampling, or even time-proportioned compositing, by contrast, may generally produce data that are not representative of any given runoff event. Grab sampling provides no information on the contaminant mass load, which in many cases is the ultimate goal. Depending on the sample timing and the nature of the events monitored, this can lead to a substantial bias in the reported results. However, grab samples

are typically needed for collecting solid samples (including sediment and litter) where automatic samplers may be impractical.

Regardless of method of sampling collection, the verification protocol should provide a series of steps to be taken both in the field and in the lab to ensure the overall quality of data. The product of hard work related to representative sample collection, analytical testing method, and proper QA/QC will still be a relatively useless pile of data reports if there isn't consistency in and an established protocol for data reporting. The data reporting protocols help ensure that data from all tested BMPs will be reported in consistent format – and that the data records will include sufficient information to permit their full use within a common database. For instance, if half of data for total suspended solids are reported as TSS and the remaining half as "Total Suspended Solids", extracting the data from a database may not include all dataset. Similarly, reporting inconsistent unit for TSS as PPM or mg/L may create similar problem on data extraction and data analysis. In addition, a well-designed database having a user-friendly interface feature can be developed to provide an efficient and uniform data storage and data retrieval as an important and essential component of a successful verification program.

Performing detail statistical analysis and performance evaluation of manufactured BMPs will require additional data collection such as flow, physical characteristics of the manufactured device, monitoring site characteristics, and storm event characteristics. These data can be included as part of the same database. The principal data components potentially to be collected under each category are summarized in Table 1. Fields and content guidelines for each of these categories will be described in detail by the Data Reporting subcommittee.

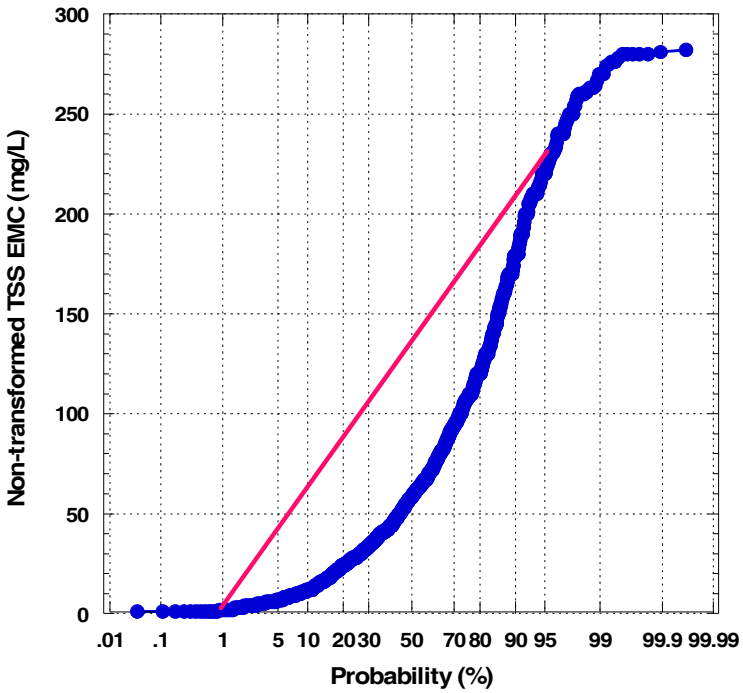

Table 1. Summary of potential data to be collected as part of the manufactured BMP verification.

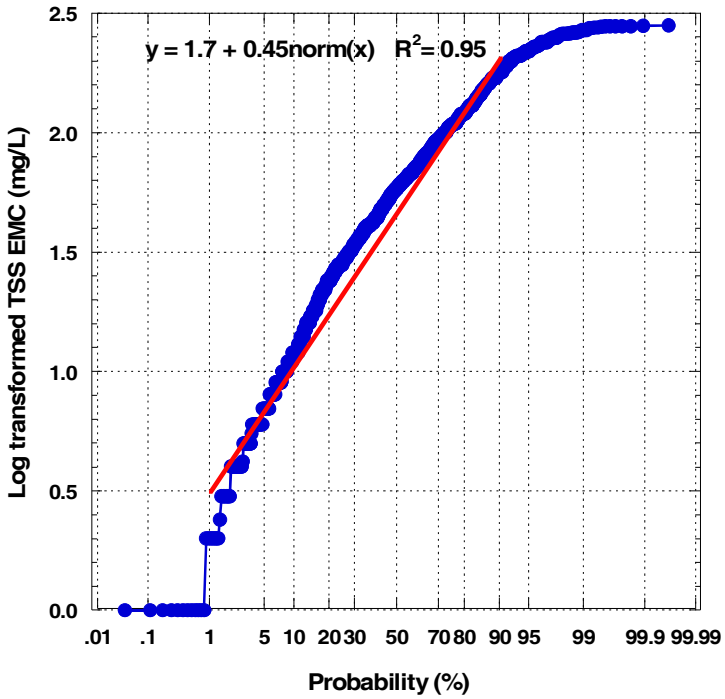
Data collection category	Data component collected under each category
WQ Parameter and solids characteristics	*Water Quality:* conventional, nutrients, aggregate organics, metals (total and dissolved) PAHs, etc…… *Solids:* trash, total suspended solids (TSS), total dissolved solids (TDS), suspended solid concentration (SSC), particle size distribution (PSD)
Storm event and hydraulic characteristics	Storm event starting and ending time, rainfall characteristics, inflow and outflow volume, antecedent dry period, etc…….
Device physical characteristics	Device name, principal pollutant removal mechanism, design characteristics, size, etc…….
Monitoring site characteristics	Drainage area, imperviousness, number of lanes for highway, AADT, etc…….



Statistical Analysis. This section of the paper is organized to deal with some of the basic statistical analysis that can be performed to address specific question. General questions and statistical approach that are commonly used to address them are summarized in Table 2.
Detail discussion of each topic presented is beyond the scope of this paper and will be presented in final certification guidelines documentation. An overview of recommended statistical analyses for BMP performance monitoring can be found in the recently updated EPA manual (EPA, 2009). The selection of an appropriate statistical test based on the distribution of data (e.g., normality verification) is further discussed below.

Testing the Normal Distribution of Data. Various methods are available to test the normality of data distribution. The best method to verify normal distribution of stormwater runoff data is the probability plot of the original data and transformed data. Based on the past experience, the majority of the environmental data including stormwater runoff characterization and BMP performance data typically are not normally distributed. Log transformation is commonly the most suitable method to verify the normal distribution of data. A sample distribution of stormwater data for TSS prior to transformation

and after log-transformation is shown in Figure 1. As shown, the data distribution before transformation resembles an exponential function. After log-transformation of the data, the majority of the data plots linearly (at least between 10 percentile and 90 percentile range) and hence assumption of log-normal distribution is appropriate. The assumption of log-normally distributed data is important when performing a comparative statistical analysis (Shumway et al, 2002; Kayhanian et al, 2002).

(a) non-transformed TSS data

(b) Log-transformed TSS data

Figure 1. Probability distribution of TSS EMC before and after log-transformation.

Table 2. Summary of Statistical Approach Addressing Specific Question in BMP Testing.

Statistical topic	Question to be addressed	Statistical approach
Sample size	How many samples are needed to achieve desired confidence? After a few years of field sampling or number laboratory testing, how would we decide whether we need more samples than initially planed?	USEPA statistical methods for practitioners: EPA QA/G-9S
Selection of an appropriate statistical test	How do we verify whether data are normally distributed? How do we very that the data variability of two or more groups is similar? This question is specifically useful when preparing the BMP probability plots.	Graphical data presentation using histogram, box plot, normal probability plots. Numerical evaluation through Shapiro-Wilk W test
Addressing non-detect in data set	How do we account for non-detect results?	Regression on order statistics (ROS)
Examining outlier in data set	How do we prepare graphical and numerical data summaries to identify potential outliers?	Histogram, box plot, standard and log-transformed probability plots, and scatter plot
Probability of meeting water quality requirements	How do we estimate how often the average BMP effluent concentration would meet a water quality standard or regulatory discharge limit? How do we estimate the BMP percentage removal of a pollutant with a specified confidence level?	This should be available directly from the effluent probability plot of laboratory or field testing data, assuming the field data sample is large enough to be representative.
BMP effectiveness for specific pollutant removal	In an influent-effluent approach or before-after approach, how do we decide whether a given BMP is effective in removing a pollutant?	Hypothesis testing through null hypothesis (H_0) or alternative hypothesis (H_A). Statistical test performed include student's t-test with equal variance and t-test with unequal variance. Both tests assume a particular probability distribution.
Comparing effectiveness of two or more BMPs	How do we compare the effectiveness of two or more pilot BMPs under similar test condition or under a given geographic location?	Paired t-test comparing the mean of effluent concentration for normal or log-normally distributed data. Comparing three or more BMPs use the analysis of variance (ANOVA). Specific analysis include: parametric ANOVA (equal variances), Welch ANOVA (unequal variance).
Developing a linear regression equation	How does BMP effectiveness vary as a function of factors such as storm event characteristics, BMP design variables, operational, maintenance practices?	Multiple linear regression using the following form: $y = \beta_0+\beta_1x_1+\beta_2x_2+\ldots\beta_mx_m+\varepsilon$ where, y=response variable, x=model variable, β = model parameters, and ε random error
Effectiveness of BMPs over time	How can we tell if the effectiveness of a BMP is changing over time within a year or multiple years?	Graphic representation using time-series plot or Mann-Kendall test.

The normality can further be tested using goodness of fit test applying the Shapiro-Wilk W test. For example the data presented in Table 3 can be tested for normality using graphical representations of data using standard probability, histograms, or box and whisker plots. The results of the Shapiro-Wilk W test for the previous data set are shown in Table 3 and illustrates that the original data did not fit the normal distribution but was log- normally distributed. The brief discussion presented here could justify the log-transformation of manufactured BMP data and may be used as a basis to perform other statistical analysis.

Table 3. Summary of Shapiro-Wilk W test to verify the normal distribution of a typical data.

Test #	BMP effluent	Shapiro-Wilk W test result
1	10.9	*Parameter estimate prior transformation:*
2	4.3	*Parameter* *Estimate* *Lower 95%* *Upper 95%*
3	6.9	μ 11.84 8.75 14.94
4	0.7	σ 13.90 12.03 16.47
5	2.9	
6	79.6	*W test result:*
7	9.6	*W = 0.642* *Prob<W = <0.0001*
8	4.0	
9	4.8	*Since the probability is less than 0.05, we can conclude that the assumption of normal distribution is not reasonable.*
10	14.3	
11	14.5	
12	4.4	*Parameter estimate after log- transformation:*
13	12.2	*Parameter* *Estimate* *Lower 95%* *Upper 95%*

MANUFACTURED BMP PERFORMANCE EVALUATION

Review of the historical approaches. During the past ten years numerous methods have been applied to evaluate the performance of constructed and manufactured BMPs. These methodologies are summarized in Table 4. A few of the performance evaluations shown in Table 4 (e.g., influent and effluent concentration or load basis) are more commonly used while others are less common. The approach for using the performance evaluation in most cases is straight forward. Two other methods specifically the "lines of comparative performance" (Minton, 1999) and "performance expectation function" (Lenhart, 2007) have also been introduced and their application have not universally been adapted. However, among all performance evaluation the probability method may be the most comprehensive way to evaluate manufactured BMPs and it is gradually being recognized as method of choice as it has been recommended by the USEPA/ASCE (2002). The potential application of this technique is further discussed below.

Table 4 Summary of Methodologies used for BMP Performance Evaluation.

Method	BMP Performance Evaluation Method	Approach/Formula	Applicable certification program
1	Pollutant EMC reduction for single test or storm event	$\text{Efficiency} = 100 \times (1 - \frac{\text{Effluent EMC}}{\text{Influent EMC}})$	ETV, TARP, TAPE, EPA
2	Pollutant load reduction for single test or storm event	$\text{Efficiency} = 100 \times (1 - \frac{\text{Effluent load}}{\text{Influent load}})$	ETV, TARP, TAPE, EPA/ASCE
3	Pollutant load reduction for multiple tests of storm events	$\text{Efficiency} = 100 \times (1 - \frac{B}{A})$	ETV, TARP, TAPE, EPA/ASCE
4	Mean pollutant concentration removal efficiency	$\text{Efficiency} = 100 \times (1 - \frac{\text{Average effluent Conc.}}{\text{Average influent Conc.}})$ This technique does not require flow measurement and it might be useful for pollutants with grab sampling where no flow weighted data is available.	EPA/ASCE BPM performance monitoring
5	Regression of loads (ROL)	Compute effluent and influent load same as method 2; perform linear regression based on outflow and inflow load and determine the R^2 and slope of regression line. Under special circumstance, the regression lines may be forced through (0,0) as it may produce a more realistic lead removal.	EPA/ASCE BPM performance monitoring
6	Relative to achievable	$\text{Efficiency} = 100 \times (1 - \frac{\text{Attainable limit Conc.}}{\text{Average influent Conc.}})$	EPA/ASCE BPM performance monitoring
7	Relative to water quality standard	$\text{Efficiency} = 100 \times (\frac{\text{avg. infl. conc.} - \text{avg. effl. conc.}}{\text{avg. infl. conc.} - \text{WQ standard conc.}})$	EPA/ASCE BPM performance monitoring
8	Effluent probability method	This method provides comprehensive BMP performance evaluation by presenting the standard parallel probability plot of both influent and effluent EMCs for all storm events or performance tests.	EPA/ASCE BPM performance monitoring

Effluent load = effluent EMC × effluent volume
Influent load = influent EMC × influent volume

$$B = \left[\sum (\text{effluent EMC}_1 \times \text{flow V}_1) + (\text{effluent EMC}_2 \times \text{flow V}_2) + \ldots\ldots\ldots (\text{effluent EMC}_n \times \text{flow V}_n)\right]$$

$$A = \left[\sum (\text{influent EMC}_1 \times \text{flow V}_1) + (\text{influent EMC}_2 \times \text{flow V}_2) + \ldots\ldots\ldots (\text{influent EMC}_n \times \text{flow V}_n)\right]$$

Effluent Probability Method. Effluent probability method is probably the most comprehensive method that could be used to determine the performance evaluation of manufactured BMPs. Under this approach, a standard probability plot is prepared for both inflow and outflow pollutant EMC or load. Before, preparing the probability plot, however, non-parametric (or if applicable parametric) statistical tests should be conducted to indicate if the difference between influent and effluent are statistically significant. In addition, the log normality should be checked and the probability plot may be prepared based on log transformed data. If the log transformed data deviates significantly from normality, other transformations can be explored to fit the data distribution. Three example of log-normally distributed probability plots are shown in Figures 1 through 3. Figure 1 shows the probability plot for TSS data for a BMP that there is a clear difference between influent and effluent event mean concentration. Figure 2, shows the TSS data for another BMP that there is no distinct difference between influent and effluent EMC. Under this situation, no removal efficiency can be expected. Figure 3 shows the results for TSS data for a condition when a BMP performed fairly well when influent TSS concentration was high but achieved no removal when TSS concentration was low.

One problem associated with the probability method is the lack relationship with direct influent and effluent measurement. For instance, a BMP performance is much higher under correlated data shown in 2 vs. 1 (see top Figure). Ideally, the BMP performance can remain within a narrow range with high probability of meeting effluent requirement regardless of influent concentration or testing condition. For example, the sample probability plots could be used to determine if BMP could meet certain regulatory or standard effluent quality requirement. As an example, under ideal BMP performance (see top Figure 3), the probability plot shows that effluent TSS quality of 30 mg/L can be met at all time. Multiple probability plots can also be produced under a single plot to compare the performances of two or more BMPs.

Another issue that worth to discuss with respect to BMP performance is that the pollutant removal generally decreases as influent concentration decreases. This may not be a practical problem since the point where BMP performance starts to decrease is often close to the point where the influent concentration is low enough that is does not exceed the discharge requirement and hence a high level of treatment is not needed. Similarly, if majority of pollutants are associated with smaller particle size, some manufacturer devices may not be able to sufficiently meet the discharge load requirement at full capacity flow rate. However, it has been shown that this phenomenon is largely dependent on the dominant unit process used in certain MTDs and as such filtration systems do not exhibit much variability in removal (Roseen et al, 2006). Nevertheless, there is value in requiring BMPs to report performance even at low concentrations, recognizing that removal may not as important if discharge limits are being met. At the other extreme, discharge limits may exceeded at very high influent concentrations even though the BMP were capable of removing 80% of influent concentration. Therefore, testing the manufacture BMPs under wide ranges of influent flow and pollutant concentration is essential in order to determine the true performance characteristics.

SUMMARY AND CONCLUSIONS

Generally, the manufactured BMP performance data collected over a range of flow rates is not normally distributed. This can impact the choice of statistics used to describe performance. Log transformation found to be a good choice for normal distribution and hence the statistical data analysis should be performed accordingly. The choice of statistical method usually related to question to be addressed and must be performed on consistent basis throughout the verification program.

Consistent, data collection, data management, data retrieval, and data analysis is an important and essential integrated component of a successful manufactured BMP verification program. This may apply to both laboratory and field testing; although it is more realistic for laboratory generated data so lab data collection should be a requirement. For proper performance evaluation, the manufactured BMP may be tested at 25, 50, 100 and 125 percent of designed flow. BMP testing at or above 100 percent of designed flow rate is especially useful to assess scouring.

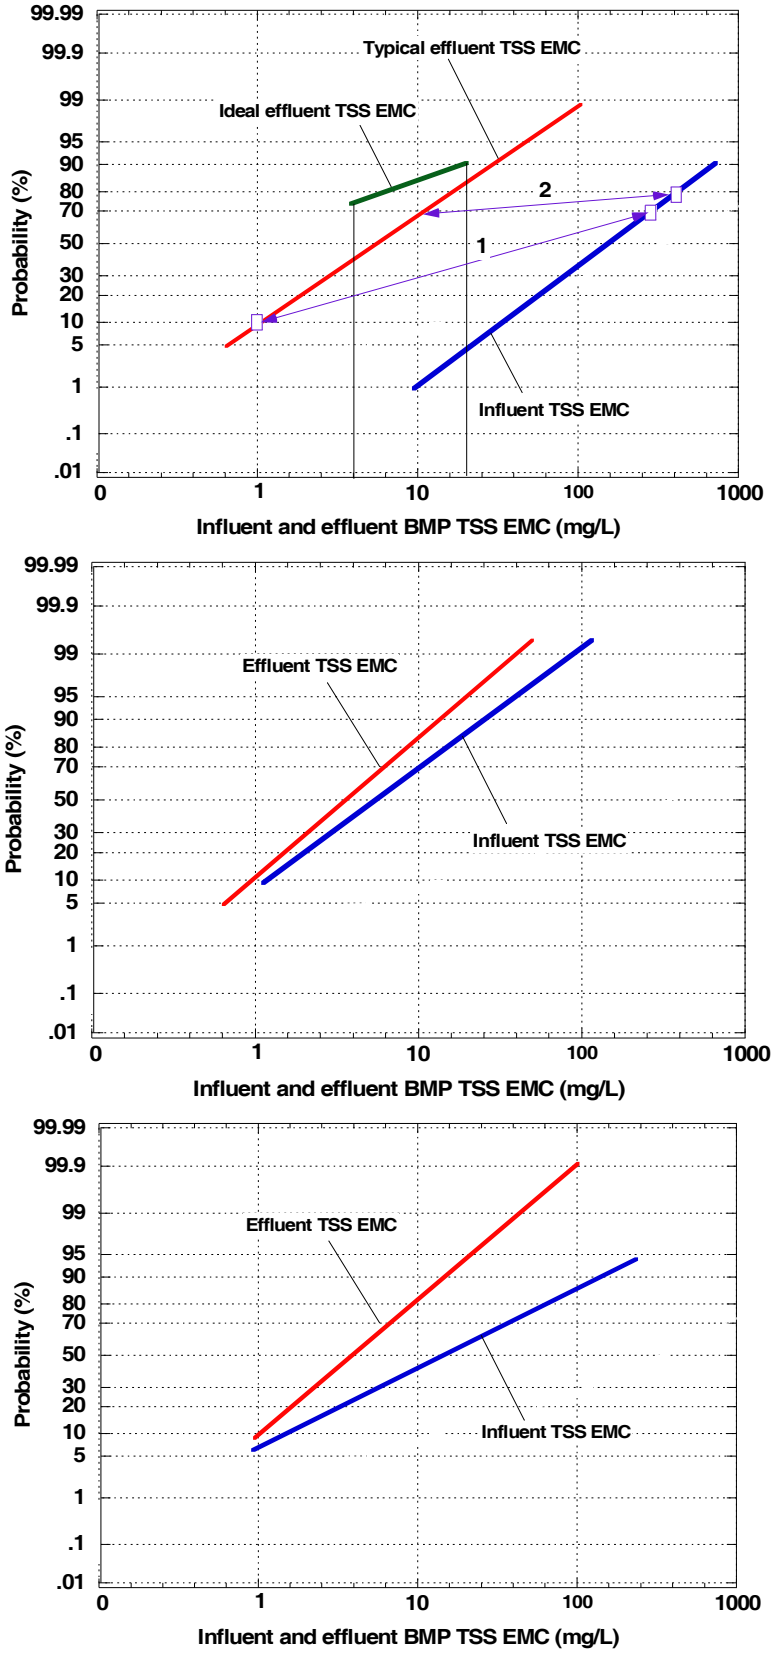

Figure 3. Probability plot for influent and effluent BMP TSS EMC under three different performance conditions.

ACKNOWLEDGEMENTS
The lead author greatly acknowledges the contribution of Robert Roseen, Jim Lenhart, and Greg Williams for their valuable comments and suggestions. This paper will be presented at the EWRI congress conference at Kansas City and the travel expense for the paper presentation will partially be supported by the ASCE/EWRI task force committee.

Proposed scaling relations for manufactured stormwater BMPs

John S. Gulliver, Qizhong Guo, John J. Sansalone, Gregory Williams, and J.S. Wu
for the Scaling Sub-Committee,
Guidelines for Certification of Manufactured Stormwater BMPs Task Committee

Manufactured stormwater best management practices (BMPs) generally apply one or both of two unit operations to remove particles from stormwater runoff: hydrodynamic separation and filtration. Hydrodynamic separation is best used to remove sand particles, while filtration is used to remove organic particles as well as silt and clay. Many manufactured stormwater BMPs also have a chamber designed to remove floatables, or particles that are lighter than water. The numerous designs and multiple sizes of these manufactured stormwater BMPs suggest the need for scaling criteria to size and apply designs in the field. This paper reviews the scaling criteria research that has been completed, the research that may be adopted from other areas, and the needs for developing scaling criteria in manufactured stormwater BMPs.

KEYWORDS

Best Management Practices, Unit Operations, Unit Processes, Stormwater, Particulate Matter, Particle Size Distributions, Dimensionless Numbers, Scaling

Introduction

Most manufactured stormwater BMPs (M-BMPs) function as either hydrodynamic separators or filters. Hydrodynamic separators utilize the difference in density to settle suspended solids into the bottom of the device and to retain floatables, such as hydrocarbons and trash at the surface of the device, while the effluent flows through an intermediate elevation. Filters use a media to retain particles of a given size while the effluent flows through the filter. These devices are generally placed below ground, and therefore are suited for high density locations and retrofits to existing infrastructure. There is a great need for these underground devices, and manufacturers have responded to this need. M-BMP units supplied by each vendor are manufactured with specific capacity/size categories. Scaling criteria help in developing performance specifications for various sizes of M-BMP and in utilizing model-scale tests to develop performance specifications. However, an industry-wide, uniform methodology to scale and size these devices does not currently exist. This paper will review the need for scaling criteria in M-BMPs, and propose scaling criteria for head loss and flow, particle separation, scour and filtration.

Need for Scaling Relations

Because of interaction with a complex flow field, the need for scaling criteria is probably greatest in hydrodynamic separators. The vertical velocity relative to water causes separation while the turbulence of the flow field tends to mix the media that is being separated back into the water. There are three issues that need to be addressed: 1)

settling of heavier-than-water particles out of the flow, 2) rise of lighter-than-water compounds such as oils and trash out of the flow field, and 3) the tendency to entrain both after separation has been accomplished in high flow. Experimental tests are possible on model-scale or full-scale devices, but these tests will need to be scaled to another size of device in order to meet demand. In addition, if an accurate scaling procedure can be developed and verified, it will be possible to perform smaller-scale model studies on each device which can be scaled to full device size with a known accuracy.

A filter media can be tested through column studies. However, the parameters that need to be controlled (e.g., grain size versus column diameter) and scale-up to full scale filters needs to be documented. In addition, many filters are partially self-cleaning, utilizing turbulence in the flow field to remove caked material from the filter. The scaling relations developed in item 3) above may be sufficiently general to apply to this case as well. Tests would still be required on the devices to demonstrate and measure the self-cleaning properties. To apply the results of such tests to a multiple of device sizes would require scaling criteria.

Dimensionless Numbers and Scale Effects

One goal of scaling is to have one dimensionless number that represents the important processes of the device. This is not generally possible at all scales, so criteria are developed on the appropriate model scale. These criteria include a critical Reynolds number value that must be exceeded to assure that turbulent flow occurs:

$$\mathbf{Re} = \frac{Q}{\nu d} \geq \mathbf{Re_C} \tag{1}$$

and a critical Weber number that must be exceeded to assure that surface tension does not alter the flow field:

$$\mathbf{We} = \frac{\rho Q^2}{\sigma d^3} \geq We_C \tag{2}$$

where Q is discharge through the device, ν is kinematic viscosity, ρ is density of the liquid, σ is liquid surface tension, g is the acceleration of gravity, and d is the smaller of the important length scales in the flow field, such as the diameter of the device or depth of water. It is also common practice to enhance the wall roughness in a physically-scaled model to result in a similar relationship of wall shear stress to flow velocity (similar friction factor or drag coefficient) as in the full scale.

Fenner and Tyack (1997) reviewed the scaling criteria for removal efficiency and head loss of hydrodynamic separators and, in addition to geometric similarity, came up with the following dimensionless similarity criteria:

Removal Efficiency: Hazen number = $\mathbf{Ha} = \frac{AV_s}{Q}$ (3)

$$\text{Froude number} = \mathbf{Fr} = \frac{Q}{\sqrt{gd^5}} \quad (4)$$

Pressure loss:

$$\text{Euler number} = \mathbf{Eu} = \frac{\Delta P d^4}{\rho Q^2} \quad (5)$$

$$\text{Friction factor} = \mathbf{f} = \frac{u_*}{V} \quad (6)$$

where A is the plan area of the separator, V_s is the settling velocity of the particles, V is a mean flow velocity, g is the acceleration of gravity ΔP is pressure drop, ρ is the density of the fluid, and $u_* = (\tau_{wall}/\rho)^{1/2}$ is the shear velocity at the walls. The Hazen number is designed for similarity of settling in a quiescent flow field, Froude number similarity is required for fluid flow driven by gravity, Euler number similarity will appropriately scale up pressure loss and friction factor similarity is required for the influence of turbulence in the flow field. Friction factor similarity would also be important for removal efficiency, because of the impact of turbulence on particle settling.

Based upon previous experience with settling of suspended sediments in lakes (Dhamotharan, et al. 1981), the Peclet number (**Pe** = $V_s L /D_t$) and a dimensionless time, are appropriate and sufficient dimensionless scaling parameters to explain sediment deposition rates. In the definition of the Peclet number V_s is particle settling velocity in quiescent water, L is settling depth, and D_t is a vertical eddy diffusion coefficient. Peclet number is defined as the ratio of convection to diffusion: in this case the convective, settling process is opposed by eddy diffusion in the system tending to keep solids in suspension. Similar to the approach taken for lakes and reservoirs, Wilson, et al. (2007, 2008) scaled convection with the settling velocity (V_s), used the settling depth (h) as a vertical length scale L, and a flow velocity times a length scale for the vertical diffusion coefficient (D_t). When the diameter is the shortest dimension of the flow, $D_t \sim Ud$, and by continuity $D_t \sim Qd/A$. In most hydrodynamic separators, flow enters the chamber from above and turbulence is stronger where plunging occurs. Therefore, if A is taken as the horizontal projection of the chamber (the cross-sectional area of mixing) which is proportional to d^2, then $D_t \sim Qd/d^2 = Q/d$. The Peclet number for the stormwater treatment device therefore becomes;

$$\mathbf{Pe} = V_s\, h\, d/Q \quad (7)$$

If the smallest dimension of the device is its height, or settling distance, as is the case for detention ponds, then inflow is relatively horizontal and thus A becomes the cross-section of the pond, hd. Therefore $D_t \sim Qh/dh = Q/d$ and **Pe** = $V_s\, h\, d/Q$. In both cases, one obtains the same equation for the Peclet number. The resulting Peclet number resembles the Hazen number, $V_s\, d^2/Q$, which is the ratio of settling velocity to overflow rate and was not developed to scale eddy diffusion.

Scaling of Removal Efficiency for Hydrodynamic Separators

Fenner and Tyack (1997) investigated the performance of a 1.6 m and 0.3 m diameter hydrodynamic separators with plastic beads of specific gravity equal to 1.04. They found that Froude scaling was most accurate at low removal efficiencies and Hazen

scaling was more successful at higher removal efficiencies. They proposed a hybrid scaling formula which incorporates the impact of each dimensionless number:

$$\frac{Q_{prototype}}{Q_{model}} = \eta_m L_r^{\,2} + (1-\eta_m) L_r^{\,2.5}\left(1+\frac{d_p}{3mm}\right) \tag{8}$$

Where η_m is the fraction of removal in the model, d_p is the mean particle diameter in mm and L_r is the length ratio (prototype/model). To be used in practice, Eq. (8) should be adjusted for the specific gravity of the particles, which typically will differ from those used in Fenner and Tyack's experiments, or arranged to use the settling velocity of the particles. The latter was performed on Fenner and Tyack's data to result in:

$$\frac{Q_{prototype}}{Q_{model}} = \eta_m L_r^{\,2} + (1-\eta_m) L_r^{\,2.5}\left(1+\frac{V_S}{25mm/s}\right) \tag{9}$$

where V_S is settling velocity of the particles in mm/s.

A relationship for settling velocity has been developed by Ferguson and Church (2004)

$$V_s = \frac{gRd_p^{\,2}}{18\nu + \left(0.75CgRd_p^{\,3}\right)^{1/2}} \tag{10}$$

where v is kinematic viscosity of the fluid, d_p is particle diameter, g is the gravitational acceleration, R is the specific gravity in water (1.65 for silica sand) and C is a constant equal to 0.4 for spheres and 1 for typical sand grains. Equation (10) becomes Stokes law at small particle diameters and results in a constant drag coefficient for large particle diameters.

A criticism of Eq. 8 is that it mixes flow scaling with particle settling into one equation. The result is that Eq. (8) and (9) will be applicable only to the particles that Fenner and Tyack tested. This is not necessary, and it is possible to separately scale settling velocity and flow. One proposal for scaling is outlined in the following sections.

Flow and Head Loss in Hydrodynamic Separators

Flow in most hydrodynamic separators is controlled by gravitational forces. The field of physical hydraulic models has been performing this type of scaling for many years. The criteria are as follows:

1. The model should be sufficiently large that surface tension (Weber number effects) does not alter performance and scaling of the model.
2. Reynolds numbers in the model should be sufficiently large such that the flow is not close to laminar. For open channels this is Re = 2,000 and for closed conduits, Re = 8,000 is recommended.
3. The friction factor in the model should be close to the prototype value. This often means adding some roughness to the model. This will make the ratio of turbulence to flow velocity similar in the model and prototype.

4. Froude number scaling is now possible:

$$Fr_p = Fr_m \tag{11}$$

where subscripts *p* and *m* indicate prototype and model scales, respectively. Then,

$$\frac{Q_p}{Q_m} = \left(\frac{L_p}{L_m}\right)^{5/2} \tag{12}$$

Settling and Rise in Hydrodynamic Separators

Scaling for settling with both retention (Hazen number) and turbulent mixing (Peclet number) result in a similar scaling parameter for settling of solids in hydrodynamic separators. Froude number scaling, Eq. (12), should also be followed. The final result is:

$$\frac{Q_p}{Q_m} = \frac{V_{Sp}}{V_{Sm}}\left(\frac{L_p}{L_m}\right)^2 \tag{13}$$

It is possible to satisfy both Eqs. (12) and (13) because of the addition of settling velocity to equation (12). Although model-prototype tests are needed to verify this scaling technique, the fact that both mixing and retention result in the same scaling parameters is encouraging. In addition, rise velocity for floatables should follow the same scaling parameters as settling.

Scour in Hydrodynamic Separators

Collected solids in hydrodynamic separators, if not cleaned, will eventually reach the height where scour of the collected solids will occur. In addition, some hydrodynamic separators are exposed to higher flows, beyond the design flow, and are therefore subject to potential scour of collected solids. Scour is physically modeled by equating (dimensionless) Shields stress, the presumed bottom stress where sediment begins to move off of the bottom, divided by parameters of the sediment. Shields stress is given by:

$$\tau^* = \frac{u_*^2}{gRd_P} \tag{14}$$

where $u_* = \sqrt{f/8}V$ is shear velocity.

Equating Shields stress for model and prototype results in

$$\frac{Q_p}{Q_m} = \sqrt{\frac{f_m d_{pp} R_p}{f_p d_{pm} R_m}}\left(\frac{L_p}{L_m}\right)^2 \tag{15}$$

As with settling, Froude number scaling, Eq (12) should also be followed. The process of scour in a Hydrodynamic separator is a combination of lifting sediment off of the bed and settling of that sediment back to the bed. Thus, scour similarity needs to simultaneously satisfy Eqs. (13) and (15). To get similarity relations (13) and (15) to both be satisfied, relatively large sediment is necessary, such that Eq. (10) becomes

$$V_s = \sqrt{\frac{gRd_p}{0.75C}} \tag{16}$$

This is often difficult to achieve.

Removal Efficiency for Filters

The particle trapping of a filter is a local phenomenon, dependent upon the characteristics of the media and the particle size distribution of the suspended solids. This can be relatively well simulated with a bench-top column test, where the media filtration efficiency is tested with the particle size distribution of interest. The scaling parameters of most interest are the media Reynolds number,

$$\boldsymbol{Re} = \frac{Q}{\varepsilon^{1/3} A^{1/2} \nu} \tag{17}$$

and the suspended solid-media size ratio:

$$L_s = \frac{d_p}{d_{med}} \tag{18}$$

where ε is the porosity of the filter media and d_{med} is the equivalent spherical diameter of the media. Then, scaling of discharge and media would follow the relations:

$$\frac{Q_p}{Q_m} = \left(\frac{\varepsilon_p}{\varepsilon_m}\right)^{1/3} \frac{L_p}{L_m} \frac{\nu_p}{\nu_m} \tag{19}$$

and

$$\frac{d_{med,p}}{d_{med,m}} = \frac{d_{p,p}}{d_{p,m}} \tag{20}$$

The scaling of one particle size distribution to another, and scaling with filter flow rate is of interest because it would reduce the required filtration tests. In addition, filters are often placed in the turbulent flow field of the device, resulting in differential pressure drop across the filter that varies spatially.

In the application of filters, one needs to also consider the fouling that will occur at the filter surface. Fouling will increase the frequency of cleaning and could reduce the filter life. The cleaning of particle cake which has accumulated on the surface of the filter, however, cannot be simulated with column tests because cleaning is often provided by turbulence generated in the chamber of the filter device. This would require a scaling

analysis similar to high flow scour, since both are based upon the resuspension of collected material.

Conclusions

1. Scaling laws have been proposed for head loss, settling, scour and filtration. These laws need to be tested with combined model and prototype studies of manufactured BMPs.
2. The scaling relation of Fenner and Tyack is not recommended, because it combines settling and head loss similarity and is applicable only to the type of spheres used in their experiments.
3. Froude number scaling, with approximately equal friction factors, should be used in all model studies.
4. Settling can be modeled with Peclet number or Hazen number scaling. They are equivalent, and encompass the important processes of settling.
5. Scaling for scour should follow Shields stress and Hazen (Pecltet) number scaling. This will be difficult, but is possible if the sediment is sufficiently large, such as with plastic beads.
6. The scaling of filtration units is dependent upon the size of the particles relative to the size of the media and the pressure distribution in the filtration chamber. Froude scaling with equal friction factors should be sufficient for pressure distribution. In addition, cleaning of a filter unit is similar to scour, such that the scour scaling parameters should also be followed to simulate cleaning of the filter fouling. While bench tests are acceptable to test the filter media, the operation of the filter as a whole deserves a full scale prototype test, because of the complexities of pressure distribution and fouling. Model scaling relations would help in determining the performance of manufactured filtration units.

The ability to scale the performance of manufactured stormwater BMPs through similitude relationships will help size and design these products for municipalities. In addition, it will focus the research and experiments on items that are truly essential to performance. The result will be more focused research, improved quality of tests, and better manufactured stormwater BMPs. Although there is much work to be completed in improving scaling relations for these devices the committee believes that the benefits will outweigh the costs.

ABSTRACT

Sustainable stormwater management involves ensuring that site runoff not exceed the pre-development peak flow rate and volume, typically accomplished through the use of water retention, infiltration, and reuse onsite through rainwater harvesting. Certain roofing materials, however, may be a pollutant source, thus, influencing the runoff's potential for harvesting. This project focuses on the first year of roof life for several traditional roofs and an extensive green roof. Substantial and significant releases of zinc and copper originated from an uncoated galvanized roof and from two treated woods, respectively. Roof runoff concentrations during early life indicated potential toxicity concerns for zinc and copper both in the water and from the potential buildup in the soil. Periodic elevated nutrient concentrations also were seen. Additionally, periodic spikes in pollutant concentrations after periods of low water concentrations indicated that elevated pollutant levels simply were not a result of washoff from excess preservative remaining on the surface of the material at installation.

INTRODUCTION

Impervious surfaces, such as rooftops and pavements, occupy a large part of the urban landscape. They often are directly linked directly to urban receiving waters through the storm drainage system. It is common, for example, in older cites in the northeastern United States to have the roof drains directly connected to the storm sewer or combined sewer system. This direct transport system for impervious-area-

generated pollutants has led to quantifiable degradation in urban receiving waters. Prior research links either total impervious area or directly-connected impervious area (as a percent of total urban land) to stream degradation with threshold values of no alteration/degradation typically found at approximately 10 – 15% impervious surfaces (Klein, 1979; Schueler, 1994; U.S. EPA 2002; Wang and Kanehl, 2003; Wang et al., 2001; Wang et al. 1997; Walsh and Breen 2001). Roofing is a substantial fraction of the urban impervious surface area (Akbari et al., 2003; Bochis et al., 2008).

Laboratory studies of common construction materials have demonstrated the potential for many construction materials to leach pollutants into the environment (Clark, 2000, Clark et al., 2004). Other studies have confirmed the important role played by roofs, paved surfaces, treated woods, and other construction materials to wet weather flow pollutant contributions, with primary emphasis on metals' release from these materials (Clark et al., 2008; Boller, 1997; Good, 1993; Brown and Peake, 2006; Adeniyi and Olabanji, 2005; Athanasiadis et al., 2006; Tobiason et al., 2004; Khan et al., 2006; Bailey et al., 1999; Davis and Burns, 1999; Kingette Mitchell, 2003; Wallinder et al., 2007). Clark et al. (2008) also have investigated nutrient contributions from these roofing materials. Extensive green roofing, where the media depth is shallow and the plants are typically drought and heat tolerant alpine-types, has been examined as a means of reducing the volume of and improving the quality of stormwater runoff (Berghage et al., 2007a,b; Berghage et al., 2008; DeNardo et al., 2003; Emilsson et al., 2007; Kohler and Schmidt, 2003; Moran, 2004; Teemusk and Mander, 2007; Long et al., 2008; Wanielista et al., 2007). In general, green roofs have been shown to remove metals from runoff, with nutrient releases being mixed and potentially dependent on the form and content of nutrients in the growing media.

Although pollutant releases can occur at any point in time, generally, it is thought that there are two periods of concern for pollutant release – early and late life. During the early life (such as within the first few months to one year), excess sealants and potential surface contamination wash off. This release decreases over time with environmental exposure. The second time of concern is the end of life where the material has degraded so greatly that the subsurface/subbase materials are exposed and pollutants released.

Green roof lifespans are currently estimated at 30 – 50 years, based on functioning installations in Europe approximately 30 years in age. For green roofs, the early stage encompasses plant establishment and washout of fines in the media mix. Also, depending on the growth media or substrate used, initial runoff may have excess nutrients leached out before stabilizing. For other materials, this lifespan is typically approximately the same or smaller. For example, asphalt shingle roofs often are guaranteed for approximately 15 – 20 years.

The purpose of this research is to compare the runoff quality from several types of roofing early in their life spans (defined for this research as approximately 4 months): galvanized (uncoated) steel roofing, asphalt shingles, cedar shakes, and green roofing with an expanded shale and peat moss media. The underlying question for this research is whether the green roof improved runoff quality compares to the traditional

roofing materials investigated here. If improved runoff quality is seen, then the follow-up question to be answered is whether the green roof actually "cleaned" the rainfall or whether its presence, in place of a traditional material, prevented the release of pollutants.

METHODS

This paper compares the results from two projects – one focusing on commercially-available roofing materials and one focusing on green roofing – as the materials aged over the first twelve months of operation, defined here as the early life of a roof. This designation is arbitrary. It is the time of initial aging and includes the period where washoff of excess surface coatings or cross-contamination due to storage near fertilizers at the retail location would occur for traditional roofs. For the green roof, this time period incorporates the early plant establishment phase and potential aging of the organic growth substrate. The data reported herein for the traditional roofs was collected from August 2005 through July 2006 (results from the first two years of testing is reported in Clark et al., 2008). Green roof samples were collected June 2007 through May 2008 (full test results since installation can be found in Clark et al., 2008). With the exception of the green roof materials, all roofing materials were purchased from Lowes Home Improvement Stores in Harrisburg, PA. The description of the green roof materials and their sources can be found in Long et al. (2008).

These roofing materials were installed on test frames on the Penn State Harrisburg campus. The roof frames for traditional roofs were designed to mimic residential roofs; both installation practices and materials mirrored those used in the field to the maximum extent practicable. The treated woods, cedar shakes, uncoated galvanized metal, asphalt shingles, and a plexiglass control panel were installed in August 2005.

The extensive green roofs were installed in late May 2007. The roof slope was 1:4, which is near the upper slope range for non-baffled roofs. The green roof consisted of a drainage layer of coarse expanded shale, topped by a geotextile layer, and finally the media mix (42.5% medium-grade expanded shale, 42.5% fine-grade expanded shale, 10% peat moss, and 5% granular activated carbon). The media mix was determined through the laboratory testing reported in Long et al. (2008).

Samples were collected from almost every storm for both roofs within each respective early lifespan except when the forecast was for less than 0.05 inches of rain. Samples were collected and analyzed for pH, nutrients (nitrate, ammonia, total nitrogen, and total phosphorus) and heavy metals (lead, copper, cadmium, arsenic, nickel, iron and zinc) using methods outlined in APHA (2005). The lists of analytical methods were described in Clark et al. (2008) and Long et al. (2008). The HDPE and plexiglass roofs were used to measure atmospheric deposition and their results were background subtracted from the runoff concentrations of the other materials. With the exception of pH, for which background subtraction would not be valid, the results shown in this paper were corrected for atmospheric contributions and reflect only the contributions from the materials themselves.

Statistical analysis was performed for each parameter using a multivariance one-way analysis of variance (MANOVA) on ranks in SigmaStat 3.5 (SPSS, Inc.) with the post-hoc Dunn method for pairwise comparison. The MANOVA on ranks was used because the assumptions of normality and/or equal variance were not met for each parameter. The MANOVA on ranks used a significance level of 0.05.

RESULTS AND DISCUSSION

All pollutant concentrations have been background corrected for atmospheric deposition, allowing for direct material comparisons. pH values presented here are direct measurements without any background corrections. Only total pollutant concentrations are presented. Although more bioavailable, dissolved species of pollutants have not been analyzed for this dataset.

Figure 1 shows the results for pH. The pH of the control was included in this figure to highlight the pH of the rainwater after it was returned to the lab. It ranged between approximately 4 and 6, slightly acidic. Periodic samples of rainwater pH also were collected and analyzed in real-time at the test site. Rainwater pH was occasionally slightly lower than that measured in the lab in the samples, ranging from 3.7 to 6.0. The results showed that the green roof was able to neutralize the acidic rainwater to above 7.0. Neutralization also occurred with both the galvanized and shingle roofs from the traditional roofs.

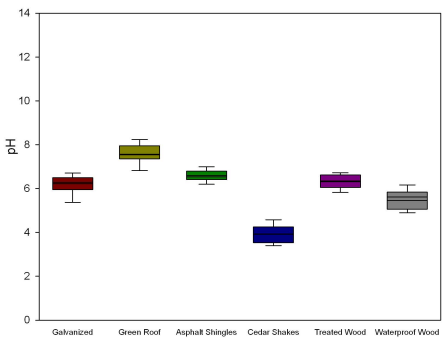

Figure 1. Runoff pH from roofing materials and control (rainfall pH range between 3.9 and 6).

For pH, the three categories statistically different categories were high (pH > 6), middle (pH = 4 – 6), and low (pH < 4). The highest pH group included the green roof, the galvanized metal, and the asphalt shingles. The middle group was comprised of the treated and waterproof woods plus the control. The low pH group contained the cedar shakes. Compared to the control and the rainwater samples, the cedar shakes consistently acidified the samples and were statistically different from the other materials.

Figure 2 highlights the nutrient release for nitrate. The results for ammonia and total nitrogen are similar to those seen for nitrate. All materials had several storm events for which no measurable nitrate was found in the runoff water. The nutrient runoff

concentrations for the galvanized metal and green roofs never exceeded 1 mg/L. The galvanized metal was not a source of total phosphorus (data not shown), in contradiction to other work performed by this research team on galvanized metal, which found measurable concentrations of total phosphorus in the runoff water. Of these materials, the cedar shakes were the greatest source of nitrate, potentially due to the degradation of the surface of the wood and the splitting of the shingles as the materials age. The asphalt shingles were the greatest source of phosphorus. Unlike for nitrate, the green roof was a source of phosphorus. It has been hypothesized that the phosphorus results from the release of nutrients in the peat used to supply organic matter to the green roof. Research by Hunt et al. (2006) on bioinfiltration media, which is currently under investigation for applicability to green roof media, indicated that if a low-phosphorus organic media is used and maintenance on the roof can be managed to add only the phosphorus required for the plants, phosphorus content in the runoff may be reduced to levels that are not an aquatic concern.

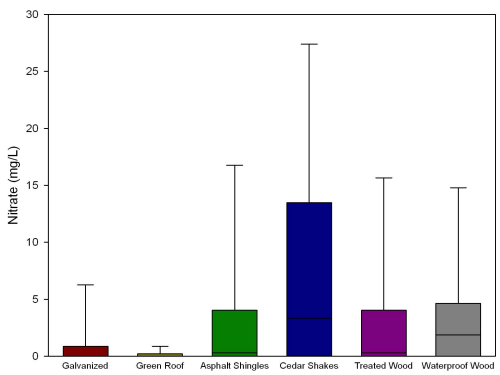

Figure 2. Runoff nitrate concentration from roofing materials (background corrected).

The statistical analysis for both nitrate and phosphorus found that the roofs were not distinguishable from each other, with the exception of the difference in runoff nitrate concentrations between the cedar shakes and green roof. This likely was due to the large variabilities seen in the runoff data and several non-detections of nitrate and phosphate in the runoff from the woods and shingles. The concern was whether surface contamination existed on the roofs at the beginning of testing that washed off during subsequent storms. Sources of this contamination could be excess surface sealants or fertilizer potentially stored nearby at the home improvement store. The runoff concentrations were graphed as a function of material age (Clark et al., 2008 contains the graphs for all roofing materials but the green roof) to examine any potential temporal trends. No trends were noted for the green roof. For the other roofing materials, spikes were seen during the testing period; however, a general trend of decreasing concentrations was noted for total phosphorus (but not for the nitrogen compounds).

The results for the metals are shown in Figures 3 and 4 for copper and zinc, respectively. The results for lead, cadmium, chromium, nickel, and arsenic are not shown because the concentrations were regularly near or below the method detection limit. Iron results are not included because they mirror the results seen for zinc, with elevated concentrations associated with the galvanized metal roof. Several materials had small releases of copper: galvanized metal, green roof, asphalt shingles, and cedar shakes. The median runoff concentrations were < 25 µg/L, which were well below the caution level for terrestrial plant toxicity. This concentration, however, is in the toxic range of certain aquatic plants (US EPA, 2007). Large variabilities were seen in the runoff concentrations for the cedar shakes and asphalt shingles. Figure 4 shows the upper ranges for the runoff copper concentrations and the large range of runoff concentrations for the two treated wood products. Statistically, the roofs could be divided into two groups – high (treated woods) and low (galvanized metal, green roofs, cedar shakes, and asphalt shingles) runoff concentrations.

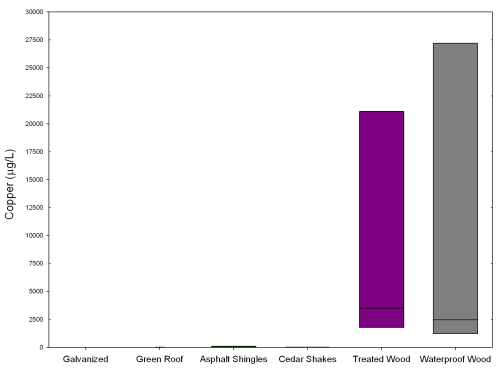

Figure 3. Runoff copper concentrations from roofing materials (high runoff concentration materials, background corrected).

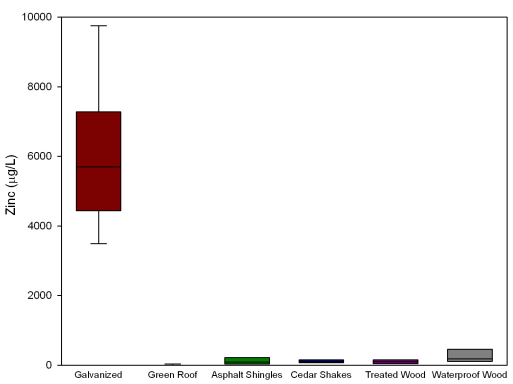

Figure 4. Runoff zinc concentration from roofing materials (background corrected).

For zinc, statistically, the materials were separated into high concentration (galvanized metal) and low concentration (green roof, asphalt shingles, cedar shakes, and the treated woods) materials. The high zinc concentration in the runoff from the uncoated galvanized metal was not surprising since zinc is added in the hot-dip galvanizing process as the sacrificial cation and may have been released as the roof captures the hydronium ion and neutralizes the acid rain. Comparison of the runoff concentrations from the uncoated galvanized metals to the aquatic toxicity criteria established by the U.S. Environmental Protection Agency (120 µg/L) showed that the median runoff concentration was approximately 1,400 times greater than the criteria.

The underlying hypothesis of this research was that there were two periods in the life-span of these materials that were of concern environmentally. The first, and the focus of this investigation, was the early life, when excess surface coatings and surface contamination from storage would wash off into the runoff. In the case of the green roof, this early life coincided with plant establishment and aging of the organic materials in the media mixture, likely characterized by nutrient release. The second would be when substantial visible degradation occurred. It was assumed that this degradation would expose to the atmosphere substrates that were not designed for environmental exposure.

This research does not focus on the fate and transport of these pollutants. However, the discharge location of the roofing runoff may affect whether these compounds are receiving water concerns. The runoff concentrations, particularly of zinc and copper from the galvanized metal and treated woods, respectively, may be problematic for rainwater harvesting for landscape irrigation. Concerns are raised not only because of the water quality itself but also because of the potential for metal buildup in the uppermost soil layer. The uppermost soil layer typically has a relatively high organic content, which often results in strong binding of the metals to the soil. Treese et al. (unpublished data) has shown a substantial buildup of copper in the upper 5 cm of the soil profile after approximately 1 year worth of rainfall. This rapid rate of soil buildup may be an exception since the runoff source was primarily a roof with substantial copper flashing. However, metal accumulations in the root zone must be considered when selecting a roofing material appropriate for rainwater harvesting.

Future research, in addition to developing models of degradation and resultant runoff concentrations as a function of the environmental parameters causing degradation, also should focus on whether a first flush exists, which would require treatment prior to reuse and possibly prior to discharge. It also should focus on the speciation of the pollutants in the runoff. This research analyzes only the total pollutant concentrations and does not analyze for the fraction that was dissolved and likely more bioavailable.

CONCLUSIONS

These results show that during the early life of a roofing system, several of the traditional roofing materials (shingles, cedar, galvanized) release pollutants into the

rainwater. These pollutants may then be transported in the storm drain system to receiving waters. Green roofs have been advocated as a means to control the volume of the runoff, but limited information is available about their water quality contributions. This research tests an extensive green roof along with several traditional roofing materials. Based on these early-life results, it appears that, while the green roof may not clean up relatively clean rainwater further, with the exception of acidic rainfall, it may be a roofing system that contributes few pollutants to the runoff water.

Sustainability initiatives typically focus on rainwater harvesting for landscape irrigation. This research highlights the water quality concerns, and potential need for treatment, in the runoff from several common building materials advocated for harvesting. Further research will be required to determine whether the pollutants seen in this research are bioavailable. Based on this research, exposed treated woods and uncoated galvanized metals appear to be inappropriate for rainwater harvesting, and possibly for direct receiving water discharge as well, during their early life (measured to date as four months in the U.S. Mid-Atlantic region).

ACKNOWLEDGMENTS

The authors would like to express their gratitude to Dr. Robert Pitt, Betsy Graham, and Noboru Tagawa of the University of Alabama for their assistance in digesting and analyzing the metals samples. Additionally, the authors would like to thank the following Penn State Harrisburg undergraduate and graduate students for their assistance in constructing and maintaining the test set-ups: James Elligson, J. Bradley Mikula, Daniel Treese, and Natasha Nicholson. Funding for this research was supplied by the Penn State Harrisburg Graduate Research Council and the School of Science, Engineering, and Technology.

Redesigning Constructed Stormwater Wetlands: an integrated modeling approach to optimize form and function

G.D. Jones[1], K.A. Mogavero[1], and B.M. Wadzuk[1]

ABSTRACT

Constructed stormwater wetlands (CSWs) have tremendous potential in managing stormwater runoff. These systems are shallow marsh environments that are built to minimize both peak flow rates and contaminant loads to aquatic ecosystems following storm events. In order to meet these goals, CSWs are constructed with few guiding principals. Despite these principles, little research has been conducted to optimize the biological, chemical, and physical processes involved in stormwater mitigation.

A four tiered modeling approach is underway to redesign Villanova's CSW, however, this paper focuses on MIKE 11 a hydraulic model. Four plan view designs were created which included a one pond, two pond, one pond and meander, and continuous meander design. Using the same inflow data, a modeled outflow hydrograph was simulated. Three parameters were obtained from this hydrograph: peak flow rate, time to discharge, and time rate of change of flow.

The best performing design was the continuous meander design which had the lowest peak flow rate, longest stormwater discharge time, and lowest mean change in flow rate. The second best performing design was the one pond design. As a general rule of thumb, increasing the length to width ratio increases the hydraulic performance. Although this may be true, the single pond design had the lowest length to width ratio but was the second best performing model. Based on these results, volume storage was the best predictor of model performance.

INTRODUCTION

Constructed stormwater wetlands (CSWs) are shallow marsh systems planted with emergent vegetation that are designed to treat stormwater runoff (PADEP 2007). Because of their high capacity to reduce pollutant loads, CSWs are becoming increasingly popular for mitigating stormwater runoff (Koob et al. 1999; PADEP 2007). Furthermore, CSWs are capable of reducing peak flow rates associated with stormwater runoff. Despite their benefits, their large size requirements are a limiting factor in their implementation (PADEP 2007). Therefore, in order to maximize their efficiency in the smallest available space, having an understanding of how the features of a CSW affect its performance is critical.

When designing CSWs, stormwater managers have few design criteria to aid in creating the most efficient system for their needs. Walker (1998) found that the residence time of

polluted stormwater was the key factor in treatment efficiency of wetlands. Persson et al (1999) concluded that large length-to-width ratios, wide uniform depths, and wide wetlands with transverse baffles were the key characteristics that made an efficient wetland. These design suggestions were also corroborated by Conn and Fiedler (2006). Although the body of literature on CSWs is growing, Scholz and Lee (2005) concluded that detailed processes within constructed wetlands contributing to the treatment performance is lacking. Furthermore, it appears that good performance designs are obtained through trial and error instead of applying mathematical principles to maximize the performance at a particular location.

Because creating an optimum design for CSWs is critical for meeting stormwater regulations, and because little research exists for understanding the mathematical relationship between CSW features and their affect on performance, the ultimate goals of this research are two-fold. First, an optimum redesign will be created for CSW on Villanova University's campus. This design will incorporate hydrodynamic designs using MIKE 11 in addition to biochemical designs using ECOLAB (Danish Hydraulic Institute, Hørsholm, Denmark). Second, multivariate statistical techniques, such as linear regressions or discriminate function analysis, will be used to understand the relationship between physical CSW parameters and design performance. This paper focuses on the results for creating an optimum hydrodynamic redesign using MIKE 11 for Villanova's CSW.

METHODS

Site Description

Villanova's CSW is a mature wetland system that is located on Villanova University's campus in Villanova, Pennsylvania (Figure 1). It was originally a detention basin that was retrofitted in 1999. During base flow conditions, a steady flow of water enters the system from two pipes that drain Villanova University's campus. These pipes serve as the primary inputs of water into the system. Additionally, a single pipe allows water to leave the system. The drainage area is approximately 56.6 acres, and of this area, 57%, 31%, and 12% of the surfaces are impervious, semipervious, and pervious respectively.

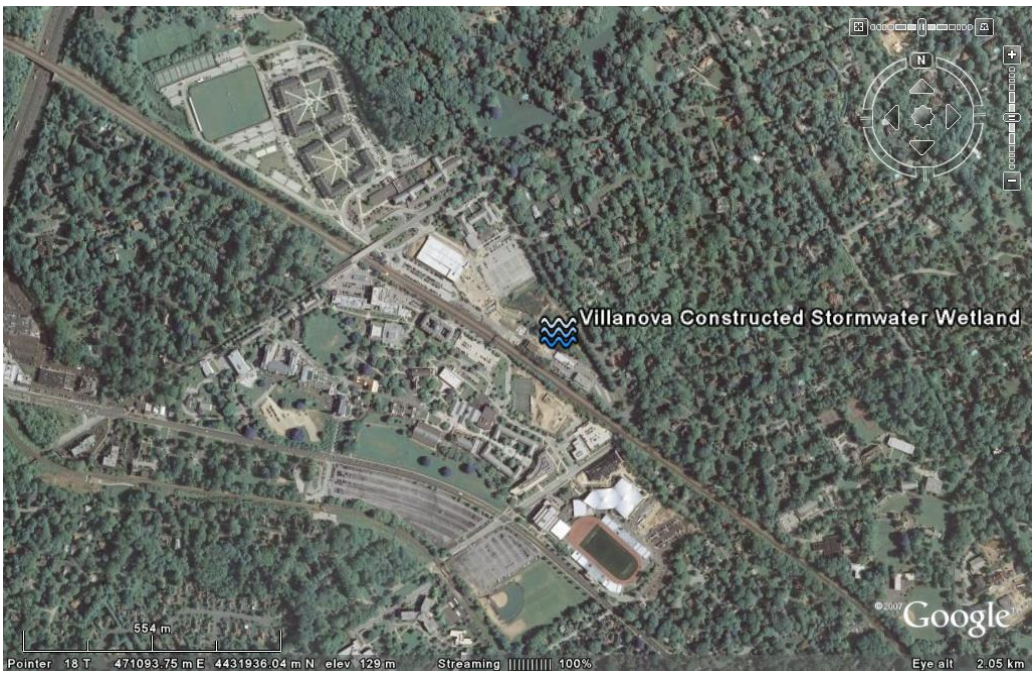

Figure 1. Aerial photograph of Villanova University and the Villanova University Constructed Stormwater Wetland. Image was obtained from Google Earth.

Simulated Designs

The physical design of a CSW – the shape, depth and length – affects the hydraulic and biological and chemical optimum performance. The hydraulic performance was evaluated for four CSW designs, which included one large pond, two equal sized ponds, one pond followed by meanders, and continuous meanders (Figure 2). The total plan view surface area of each of design and the position, elevation, and orientation of the inflow and outflow structures for all designs were identical. These designs were chosen because they represent a broad range of typical hydraulic features.

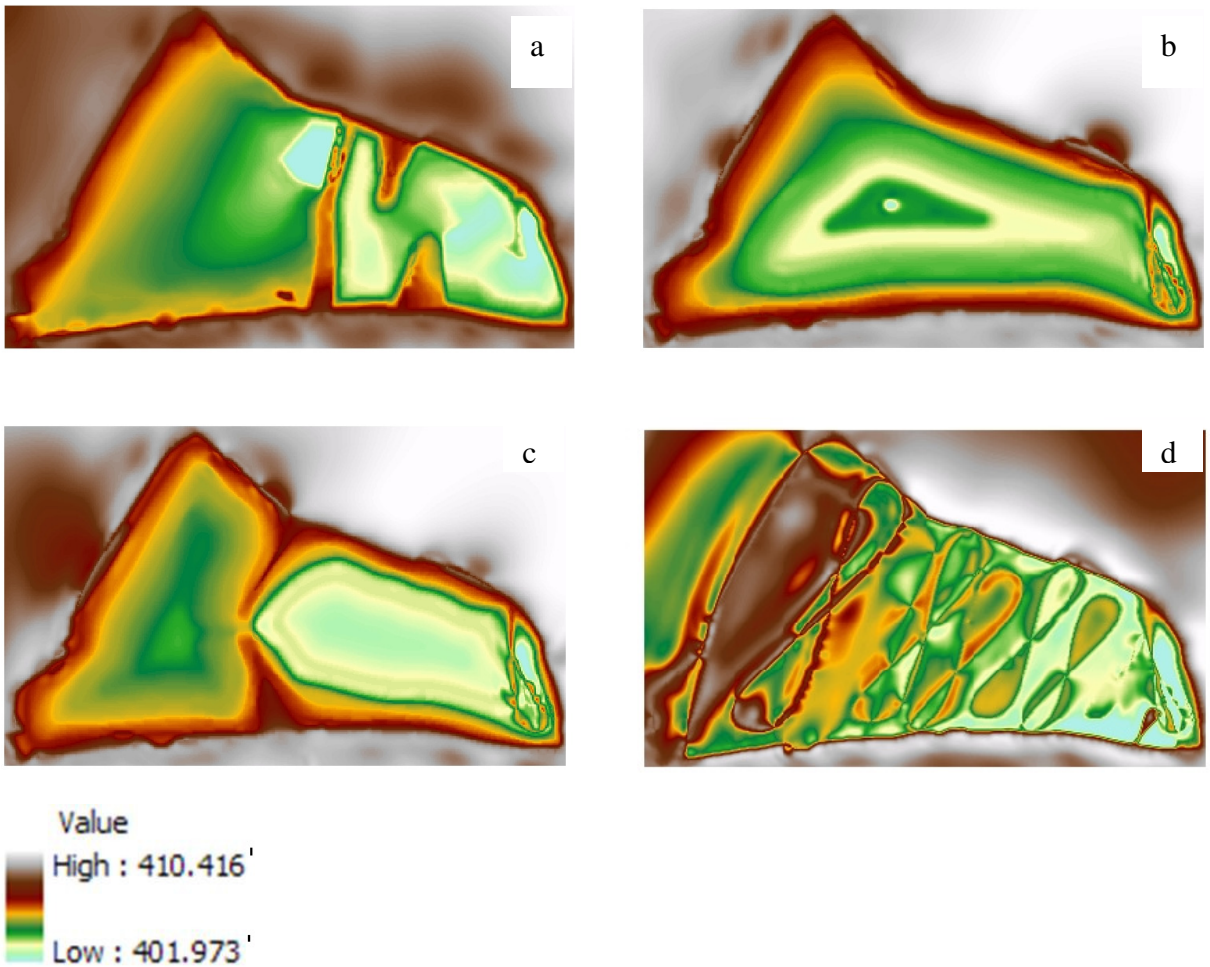

Figure 2. A 3-D digital elevation model (DEM) was created for each of the four designs (a= pond and meander, b= 1 pond, c= 2 ponds, and d= continuous meander).

Design Performance

The performance of each CSW design was evaluated based on 1) the maximum peak flow rate, 2) stormwater discharge time, and 3) flow rate of change. The design(s) with the lowest peak flow rate, longest stormwater discharge time, and lowest flow rate of change was ranked the best design. The performance of each design was compared to the inflow hydrograph which served as a no treatment or control design. By minimizing peak flow rate, maximizing discharge time, and minimizing change in flow rates, the energy carried in the stormwater would be minimized which would minimize scour and erosion within and downstream from the wetland channel.

Peak flow rates were determined by finding the maximum flow of the hydrograph. The stormwater discharge time was evaluated as the time difference between the initial increase in

flow due to stormwater runoff and the time for the system to return to baseflow conditions (~0.3 ft^3/s) at the outlet of the CSW. The flow rate of change was determined by averaging the absolute value of the slope for the entire hydrograph. The absolute value of the flow rate of change was used since positive changes in flow rate (before peak flow) and negative changes in flow rate (after peak flow) would average to zero. Differences among the mean change in flow rate were evaluated using a One-way analysis of variance (ANOVA). Analysis of variance can determine if at least one mean value is statistically different from another. In order to determine which value(s) are statistically different, a post hoc test is used to determine which mean(s) is (are) different. For this analysis, Tukey's HSD post hoc test was used to determine which designs had statistically higher and lower flow rates of change (Lomax 2001). All statistical significance values were evaluated at an alpha (α) level of 0.05.

MIKE 11

Performance metrics for each CSW design were obtained from MIKE 11 simulations, which is a one-dimensional hydrodynamic modeling package based on the complete dynamic wave formulation of the Saint Venant equations for open-channel flow. The Mike 11 model simulated flow and water level through Villanova's CSW. The model operates from four basic data inputs: network, cross section, boundary, and hydrodynamic parameters.

In 2007, a ground surface elevation survey was conducted of Villanova's CSW. This survey served as the base map for the pond and meander design. The survey topographic lines were imported into MIKE 11 GIS, an extension of ArcMap 9.2, and a 3-D digital elevation model (DEM) of the surface of the CSW was created (Figure 2a). The network and cross section files needed in Mike 11 were created from the DEM. The network, or thalweg, was created by following the path of lowest elevation from the inlet to the outlet. Cross sections were taken along the network at approximately 20 meter intervals. Each cross section extended the width of the CSW or to the width of a limiting structure, such as a berm. The roughness coefficient for weedy streams with underbrush range from 0.075-0.15 (Mays 2005); for this simulation, the lower extreme was used. Subsequent models were created in AutoCAD, and network and cross section files were created in a similar manner (Figure 2 b-d).

The upstream and downstream ends of the CSW were modeled as open boundaries. The input data for the model was the inflow (ft^3/s) entering the CSW from the two pipes previously described. The flow exiting the system was calculated by MIKE 11 using a Q-h curve that was previously established for the outlet of the system. The total duration of the simulation was 24 hours, and included 40 minutes of base flow conditions prior to a 0.71 inch rain event that lasted 3.5 hours in May 2007. The time preceding this storm was considered base flow conditions (>36 hours without rain).

Finally, Mike 11 has various hydrodynamic parameters that can be used for setting supplementary data for a simulation. These parameters include flood plain resistance factors, sand bars, wind conditions, wave approximations, etc. Default values for all parameters were used which are sufficient for obtaining satisfactory simulation results in most cases (DHI 2008).

RESULTS

Peak Flow Rate

When comparing the inflow hydrograph to the modeled results, the inflow had the greatest maximum flow rate, followed by the pond and meander, 2 ponds, 1 pond, and continuous meander designs (Table 1.) Overall, the modeled designs reduced the peak flow rate by 46-58%.

Table 1. Performance results for the four designs and the control (Inflow). Flow units were cubic feet per minute (cfs). Mean flow rate of change represent absolute values.

	Peak Flow (cfs)	Time to Discharge (hr)	Mean Change in Flow Rate (Δcfs/min)
Inflow	4.48	4.42	0.62
1 Pond & Meanders	2.40	4.25	0.15
2 Ponds	2.26	4.50	0.10
1 Pond	2.16	4.58	0.10
Continuous Meanders	1.87	5.58	0.03

Time to Discharge

The pond and meander design had the shortest time to discharge, followed by inflow, 2 ponds, 1 pond, and the continuous meander designs (Table 2, Figure 3). With the exception of the pond and meander design, each modeled design increased the time to discharge by 2-26%.

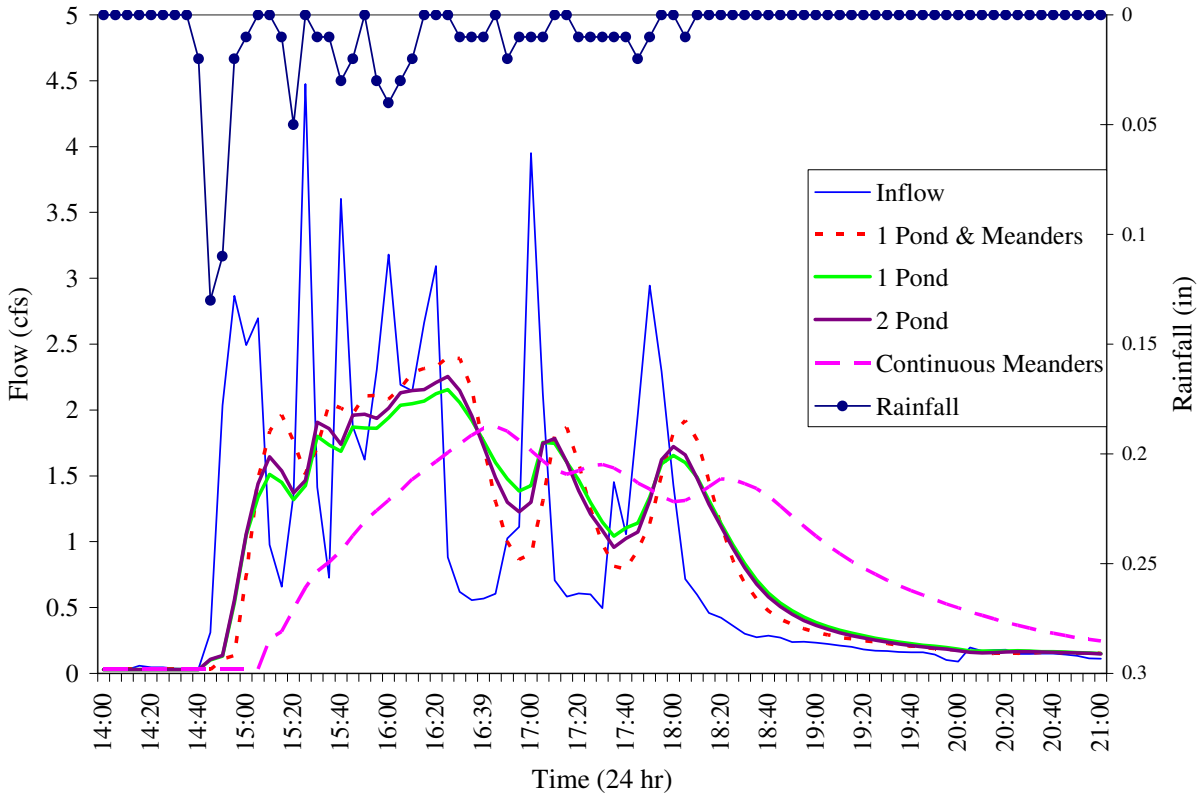

Figure 3. Modeled hydrographs were used to evaluate each model. Only seven hours were plotted to highlight flows during and immediately following the modeled storm event.

Flow Rate of Change

The inflow had the greatest mean change in flow rate, followed by the 1 pond and meanders, 2 ponds, 1 pond, and continuous meanders designs (Figures 3 and 4, Table 1). Overall, the modeled designs decreased the mean change in flow rate by 76-95% from the inflow. Based on the One-way ANOVA, a statistical difference existed among the means of the four designs and the inflow control ($df=4$, $F=24.32$, $P<0.001$). Using Tukey's HSD post hoc test the inflow's mean flow rate of change was statistically greater than all other designs, while the continuous meander's mean flow rate of change was statistically lower than all other designs (Figure 4). The 1 pond and meanders mean flow rate of change was statistically greater than those of the 1 pond and continuous meander designs (Figure 4).

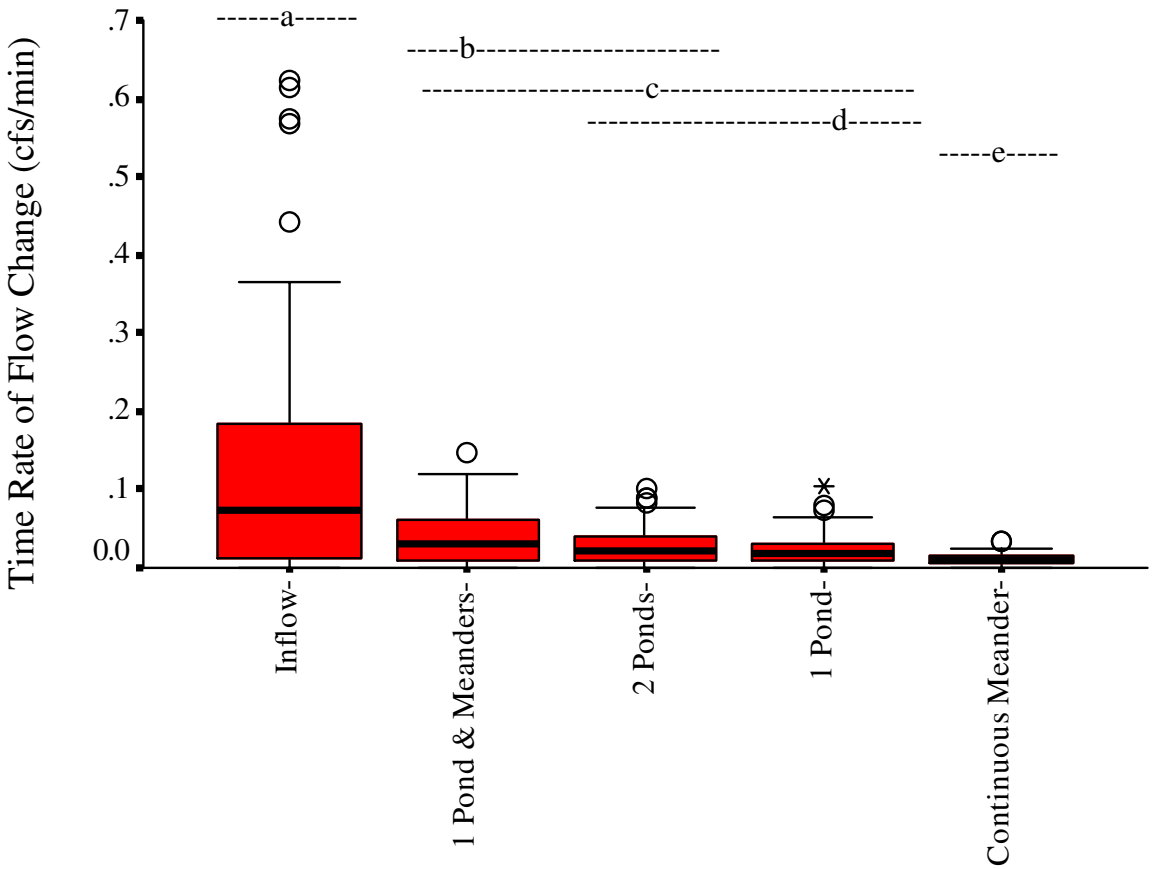

Figure 4. Box and whisker plots of the four wetland designs and control (no treatment). Letters above plots correspond to treatment (a=no treatment, b=2 ponds, c=current design, d=1 pond, and e =continuous meander). Bars above each boxplot represent statistical differences among boxplots. Bars that do not span other boxplots were statistically different ($P<0.05$). No difference in means was detected for bars that span other boxplots.

DISCUSSION

The continuous meander design outperformed all other designs in the three categories. Both pond designs performed similarly while the pond and meander design was consistently the worst design. All models outperformed the inflow model in most categories, which was expected since any treatment is likely better than no treatment (Table 1). Only the pond and meander design had a shorter time to discharge than that of the inflow hydrograph. The pond and meanders design represents the current state of Villanova's CSW and was the only model to contain a sediment forebay. It is possible that the small storage capacity of the sediment forebay caused a temporary backwater as stormwater initially entered the CSW. Early stormwater inputs would have been temporarily retained before water levels increased enough to negate the storage effects. Therefore, the temporary storage in the sediment forebay could have caused an accordion effect shortening the time to discharge. To verify this, future research will compare the current pond and meander system to one where the sediment forebay is removed.

The continuous meander design had the greatest length to width ratio while the single pond design had the shortest. It is surprising then that these two designs were the best hydraulic designs and that the composite designs (two ponds and pond with meanders) performed worse. These results are somewhat contrary to previous literature in which the general conclusion is that increasing the length to width ratio also increases the performance (Walker 1998, Person et al. 1999, Conn and Fiedler 2006).

The difference between the observed results for the continuous meander and single pond designs and the composite designs are likely explained by increased storage capacities within the single pond and continuous meander designs; however, the underlying mechanism is different for both. The mechanism controlling the continuous meander design is the longer length, leading to the longer travel time through the CSW that dampens the hydrograph. The mechanism controlling the single pond model is that there is a large volume to absorb the inflow and damp the outflow hydrograph. For example, consider the volume of two sphere systems. One system is composed of a single sphere with a radius of two while the second contains two spheres each a radius of one. The total volume of the single sphere system is four times greater than the total volume of the composite system. For a unit increase in water depth in either the single of two pond designs, the single pond design would store more volume. Therefore, it is not surprising that the composite systems have less storage volume than the non-composite systems.

In addition to geometry, storage was affected by vegetation (modeled as roughness) within the CSW itself. Although the roughness coefficient was held constant (0.075) for all models, the length to width ratio varied and was greatest for the continuous meander model. Within each design, vegetation acted as a regulating device, causing water to pond locally behind it. With a high length to width ratio, the total volume of water must pass a greater proportion of vegetation thereby causing and increase in localized ponding throughout the system. This increase in localized ponding would result in greater storage volume.

The dynamics of stormwater runoff are complex and are unlikely to be fully described using the analysis within. For example, if high resistance and high length to width ratio was the best practice for decreasing peak flows generated from stormwater management, than the pond and meanders model should have performed better since it has the second greatest length to width ratio. But it is shown by the performance of the single pond design that increasing the storage volume is one way to mitigate stormwater runoff. The conventional wisdom of CSW has been to extend the travel path. The present research shows, however, that while a high length to width ratio will improve hydraulic performance, it is necessary to understand all the mechanisms that are driving volume storage and peak flow rate reduction.

CONCLUSIONS

The continuous meander design had the best performance; however, the metrics do not identify which variables inherent to each design have the greatest contribution to the performance to each design. Furthermore, there is a qualitative element in interpreting and evaluating performance metrics for each design. Are the differences among the models meaningful? For example, will a 0.10 cfs difference in peak flow rate between the two and one pond design impact biochemical processes within the system? The next step of this research will be to derive mathematical relationships between design parameters, such as length to width ratio

or roughness, and the other performance variables. Future research should focus on determining the variables that are most important to mitigate the effects of urban stormwater runoff. This can be done through discriminate function analysis, or other multivariate statistical analyses. Optimizing the physical aspects is only one part of the solution to minimizing the required area of constructed stormwater wetlands. In addition to modeling various physical parameters, optimizing the biological and chemical processes is an area for future research that needs to be investigated, and questions like, "what physical dimensions optimizes biological removal or chemical degradation of nutrients?", should be addressed.

Research of Hydrologic and Water Quality Performance of 4 Linear Wetlands in Eastern North Carolina

J. D. Wright[1], W. F. Hunt[1]

Abstract. *The North Carolina Department of Transportation is charged by an agreement with the North Carolina Department of Environment and Natural Resources to treat stormwater from NC DOT facilities across North Carolina. One heretofore unaccounted treatment is hundreds of miles of right-of-way swales in eastern North Carolina. It is possible that these serendipitous practices are improving runoff quality along theses highways. If so, an assessment of their performance is needed.*

Four existing right-of-way linear swales along I-40 east of I-95 will be monitored to determine their hydrologic and water quality effectiveness. Two different treatments are being examined: one swale that is unaltered and one that has been allowed to establish wetland conditions. There are two examples of each. Monitoring will also address the impact of the vegetated filter strip between the shoulder and the edge of the swale. Monitoring began in August of 2008. Samples are being collected from 18 events and analyzed for TN, TKN, NH_4-N, NO_{2-3}-N, TP, and TSS.

Keywords. Stormwater, BMPs, road side swales, Wetlands, Permeable Pavement

Introduction

The North Carolina Department of Transportation (NC DOT) is charged by an agreement with the North Carolina Department of Environment and Natural Resources (NC DENR) to treat stormwater runoff from NC DOT facilities across North Carolina. To date, NC DOT has installed scores of retrofits across North Carolina and has researched the hydrologic and water quality function of several. One unaccounted for treatment is hundreds of miles of right-of-way linear wetlands in eastern North Carolina. It is possible that these serendipitous practices are improving runoff quality along these highways. If so, an assessment of their performance is needed.

A research team in Northern Sweden studied several different grassed swales (Backstrom 2003). They found that the swales retained significant amounts of particulate matter during high pollutant loading events. However, when the swales received low pollutant concentrations, some of the swales released pollutants. Disssolved pollutants did not receive any perceptible treatment. The swales studied were regarded as facilities that even out pollutant peak loads, but were not able to consistently reduce pollutant loads. In eastern North Carolina where nitrogen deposition is an important issue, a standard dry swale, such as those studied in Sweden may not provide ample treatment.

[1] Department of Biological and Agricultural Engineering, North Carolina State University, Campus Box 7625, Raleigh, NC 27695

Another study conducted in Florida examined a series of dry grass swales in a low impact parking lot (Rushton, 2002). The swales were associated with permeable pavement applications. The system, which included a pond, permeable pavement, and sand filters was able to reduce pollutants and reduce runoff. The swales that were individually examined often added phosphorus to the pond, where the phosphorus was later removed. Evaluated alone, the dry swales were not a very effective practice. Perhaps this was due to high amounts of phosphorus present in the swale or inadvertent fertilization. It is apparent that the swales studied in Florida and Sweden would not adequately treat nutrients associated with North Carolina. Both of these swales were designed to be dry.

Stormwater wetlands, however, have repeatedly been shown to reduce nitrogen and phosphorus concentrations and loads from small watersheds. Some wetland studies have been conducted in highway interchanges (Farrel and Scheckenberger 2003) and have shown promising pollutant removal. A pair of wetlands was recently studied in North Carolina for approximately two years; each treating relatively small watersheds (Johnson 2007). One wetland in Charlotte was able to reduce the nitrogen concentration by 40% and phosphorus concentrations by 55%. A less sophisticated study in Smithfield showed nitrogen removal rates exceeding 80% and phosphorus removal rates higher than 70% at a high school in Johnston County. These studies indicate that wetlands have a significant potential to reduce nitrogen and phosphorus. To date no research has been conducted of either existing wetland swales or standard swales in the NC DOT linear right-of-way.

The goal of this research is to examine whether linear swales will significantly reduce nutrients and solids from highways and the impact of allowing swales to develop wetland conditions. Four linear swales in the right-of-way of interstate 40 between interstate 95 and mile marker 360 were identified for study.

Methods

Four linear swales were monitored along the right of way of interstate 40. Two swales with wetland vegetation (Figure 1) were each paired with a swale that was not vegetated (Figure 2). The first non wetland vegetated site is along the east bound lane of I-40 around mile marker 332. This site is paired with a wetland vegetated site located along the shoulder of the east bound lane between mile marker 332 and 333.

Figure 1 Wetland Vegetated Swale

Figure 2 Non Vegetated Swale

The next wetland vegetated site is located along the east bound shoulder between mile marker 353 and 354 in Sampson County and is paired with a non wetland vegetated site near mile marker 360 at the boundary between Sampson County and Duplin County (Figure 3). Samples were also collected to quantify the effect of the shoulder between the edge of the pavement and the wetland (referred to as the filter strip). A section of the swale approximately 100 feet long was monitored. Monitoring required a slot drain be installed along the shoulder at the edge of the pavement (Figure 4) and at the edge of the filter strip (Figure 5).

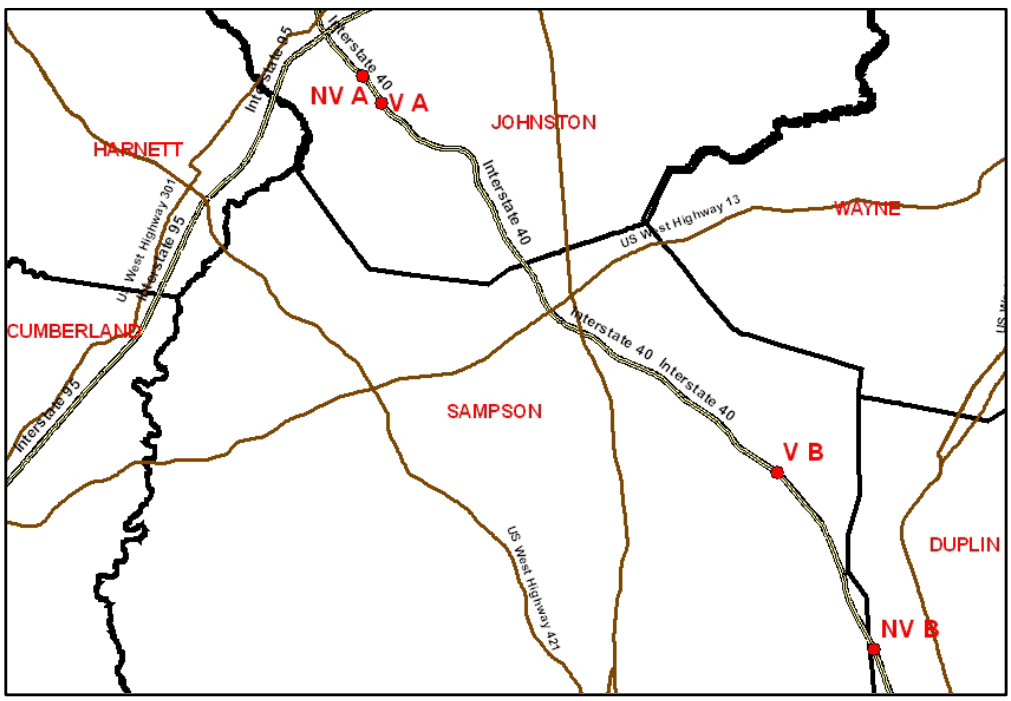

Figure 3 Swale Locations

Figure 4 Pavement Slot Drain

Figure 5 Filter Strip Slot Drain

Figure 6 shows the monitoring set up. An outlet structure with a 30^{o} v-notch weir was installed in the swale to measure the flow rate and to be able to collect water quality samples (Figure 7).

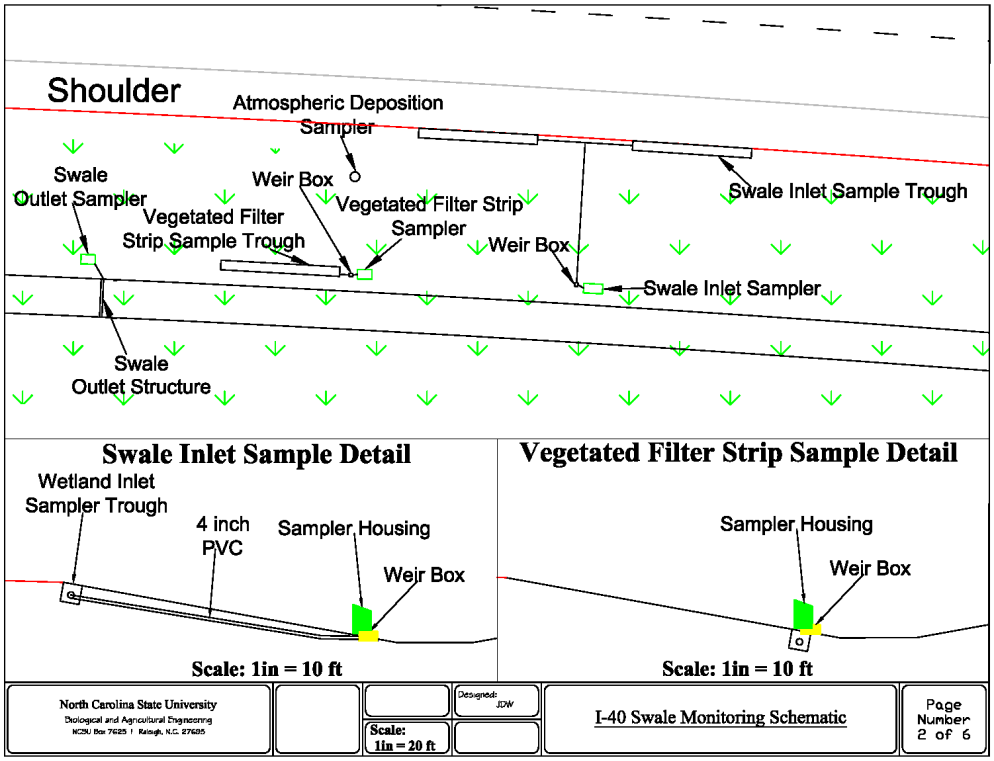

Figure 6 Monitoring Layout

Figure 7 Outlet Structure

Weir boxes with 30^{o} v-notch weirs were used to measure the volume of water that passed through the slot drains at the edge of the pavement and the filter strip (Figure 8). ISCO 730 bubbler modules were used to measure the depth of flow over the weirs and calculate flow rate. The bubblers triggered ISCO 6712 automatic samplers to take flow-weighted composite samples for the storm. The sampler received pulses from the bubbler each time a pre-defined volume of water passed over the weir and then took a sample. Runoff from storm events up to 37.5 mm (1.5 inch) in size was expected to be fully captured by the bioretention cells. Rain fall samples are being collected to determine the impact of atmospheric deposition at each site.

Figure 8 Weir Box

Results and Discussion

Data collection began in September of 2008. Seven storms have been collected to date with data from three of those storms presented in Table 1. After samples from one storm at NV B and three storms at the other sites have been collected, initial analysis indicates some reduction in nitrate and nitrite nitrogen between the inlet and outlet at each swale and a reduction in NH_3 at each swale with the exception of NV B. The filter strip at NV A showed a reduction in nitrate and nitrite nitrogen. There was an increase in TSS at each swale. It is possible that the sites have not had a chance to stabilize after the equipment was installed causing sediment to wash into the swales. Further analysis will be possible after more storms are collected.

Conclusions

NC DOT has hundreds of miles of swales throughout the state of North Carolina. It is important to adequately characterize how much treatment these swales are providing in their current state. Additionally, if a slight modification of linear wetlands that would allow them to develop wetland vegetation improves nutrient and other pollutant removal, NC DOT may be able to provide simple retrofits to improve performance. This research may allow for NC DOT to account for thousands of pounds of nitrogen and phosphorus removal in eastern NC. In addition to pollutant removal the NC DOT may be able to save a substantial amount of money by justifying reduced maintenance practices along the right of way and and in the swales by not mowing or spraying and allowing wetland vegetation to establish.

Acknowledgements

The authors would like to thank the NC DOT for their support financially and logistically. We would like to specifically thank the Sampson County Maintenance crew for their support in installing the monitoring equipment.

Abstract

To a certain extent, all reservoirs are subjected to the problem of sediment deposition universally. Depending on the amount of material deposited the shortening of reservoir capacity and useful life result in several unpredictable consequences. To determine the total quantity of deposition, as well as the pattern and distribution of deposits in a reservoir, hydrographic survey is the only direct measurement method. These hydrographic survey methods are being considered as expensive, time consuming and cumbersome. In the present study, an attempt has been made to employ genetic programming (GP) soft computing technique to estimate the volume of sediment retained (S_v) in the Pong Reservoir, India. It was found that GP model captured the trend and magnitude of S_v very well. Moreover, GP model provided input-output relationship in the form of computer programs which may be easily used by end user. Also, GP can be effectively used to capture the non-linear relationship between the input and output with short length of data.

Introduction

Hitherto, humankind has been trying to harness the available surface water resources by creating reservoirs. Reservoirs have well known primary purposes such as water supply, irrigation, flood control, hydropower and navigation. The total storage capacity of reservoirs in the world has been estimated by various sources. One of the estimation is 4000 to 6000 x 10^9 m^3, and another is 5 per cent of the total runoff in the world (38830 x 10^9 m^3), i.e. 2 000 x 10^9 m^3 (Yang, 2003). While according to Siyam et al. (2005), the potential quantity of water that can be controlled through reservoirs in the future varies between 9000 and 14000 km^3 annually. Thus reservoirs are key infrastructures for humankind survival and well being.

Despite the benefits realized, reservoirs are also having some drawbacks. Reservoirs are often threatened by loss of capacity due to sedimentation. Globally, the overall annual loss rate of reservoir storage capacity due to sedimentation is estimated as 1 to 2 per cent of the total storage capacity (Yoon, 1992; Yang, 2003). In India, many

reservoirs have been subjected to reduction in their storage capacities due to sedimentation. Analysis of sedimentation survey details with respect to 43 major, medium and minor reservoirs in the country indicate that the sedimentation rate varies between 0.34 – 27.85 ha m/100 km^2/ year for major reservoirs, 0.15 – 10.65 ha m/ 100 km^2/ year for medium reservoirs and 1.0 – 2.3 ha m/ 100 km^2/ year for minor reservoirs (Shangle, 1991). Thus, the accuracy in prediction of the volume of sediment deposited in a reservoir is very important for planning, design and operation of reservoirs. In the present study, an attempt has been made to simulate the volume of sediment retained (S_v) in the Pong Reservoir at Beas Dam on Beas River, Kangra district, Himachal Pradesh, India using Genetic Pogramming (GP) soft computing technique. It was observed that the GP model captured both the trend and magnitude of S_v with small set of data easily.

Study Area

To study the suitability of the GP model for estimating the S_v of a reservoir in India, Pong Reservoir has been selected as a case study. Pong Reservoir is located on Beas Dam, a multipurpose river valley project commissioned in 1974, on Beas River at village Pong in Kangra district of Himachal Pradesh, India. The Beas catchment along with location of Pong dam is shown in Figure 1. The catchment area of river Beas is fan shaped.

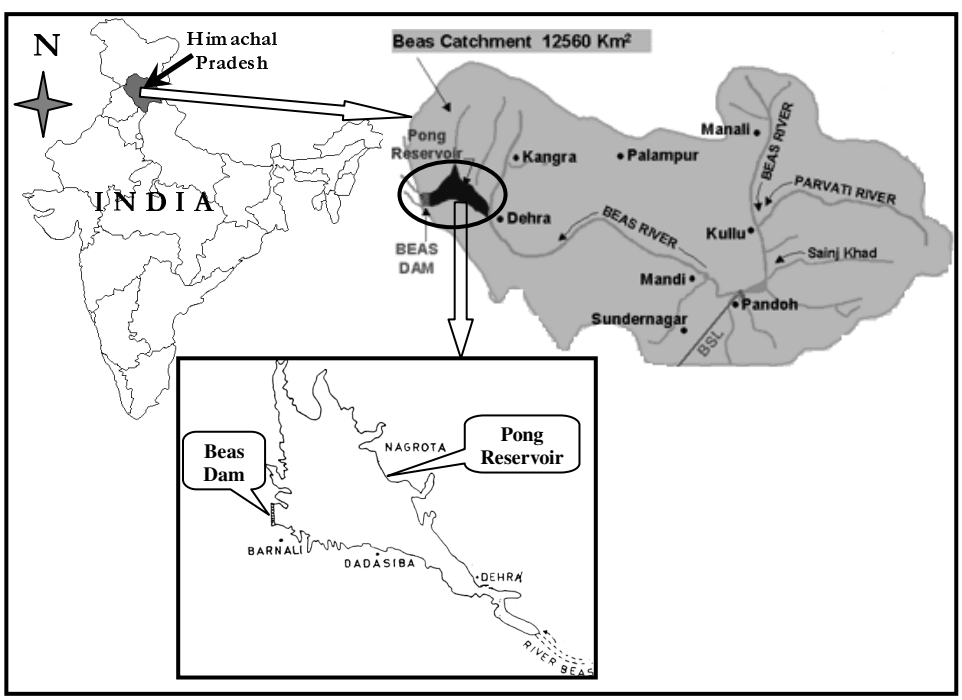

Figure 1. Location of Pong Reservoir on Beas River

It has an enormous water-spread of 260 km^2 at full reservoir level and impounds 8578.99 x 10^6 m^3 of water with spread length of 42 km and maximum width 16 km at normal storage. The live storage of the reservoir is 7291.22 x 10^6 m^3 and the dead storage is 1287.773 x 10^6 m^3. The total catchment area above the dam site is 12,562 km^2 out of which only 777 km^2 is under snow and rest of the area is covered by forests, degraded forests, cultivated land and uncultivated withered rocks (BBMB, 2006). The annual yield of the catchment is about 10,720 x 10^6 m^3. Pandoh dam, constructed about 140 km upstream of Pong Dam, diverts the normal flow of river to River Satluj (Beas-Satluj Link Project) and intercepts an area of 5278 km^2. With the construction of Pandoh Dam the sediment contribution of river has reduced by a large percent, as major sediment load brought in the river upto Pandoh gets deposited in the Pandoh reservoir. Thus, the Pandoh Dam acts as a check dam for Pong Reservoir.

Methodology

The Darwin's natural selection theory of evolution based GP, is a relatively new technique and member of the evolutionary algorithm family (Koza 1992). The generalized form of Genetic Algorithm (GA), GP, operates on parse trees structures composed of function and terminal sets, rather than on bit strings as in a GA. GP is an inductive form of machine learning as it evolves a computer program to perform a underlying process defined by a set of training samples (Whigham and Crapper, 2001). It approximates the solution that best describes the input-output relationship. The algorithm considers an initial population of randomly generated programs, derived from the random combination of input variables, random numbers and functions, which include arithmetic operators (+, -, *, /), mathematical functions (sin, cos, exp, log), logical/comparison functions (OR, AND) etc., appropriately chosen based on some understanding of the underlying process. This population of potential solutions is then subjected to an evolutionary process and the fitness measures of the evolved programs are evaluated. The individual programs that best fit the data are then selected from the initial population, discarding no-so-fit programs. The programs that best fit are selected to exchange part of the information between them to produce better programs through crossover (exchanging the parts of best programs with each other) and mutation (randomly changing programs to create new programs). This evolution process is repeated over successive generations and is driven towards finding best solution describing the process. It has been successfully applied to complex non-linear hydrological problems by various researchers like Savic et al. (1999); Whigam and Crapper (2001); Khu et al. (2001); Liong et al. (2002); Dorado et al. (2002); Harris et al. (2003); Babovic (2005); Drunpob et al. (2005); Jayawardena et al. (2006); Makkeasorn and Chang (2007); Sivapragasam et al. (2007); Parasuraman et al. (2007); Singh et al. (2007); Wang et al. (2007); Aytek and Kisi (2008); Sivapragasam et al. (2008). The detailed description of the GP method can be seen in Koza (1992); Babovic Keijzer (2000); Babovic et al. (2001).

Results and Discussion

The GP soft computing technique, which provides input-output relationship in the form of computer program, has been employed to estimate S_v. In the present study, the Discipulus Pro Version Lite 4.0 has been used for implementing GP. The available capacity (C_t), annual rainfall (R_t) and annual inflow (I_t) data for 33 years (1974-2006) were considered as input parameters. The S_v was considered as output parameter for the same period. For analysis, first 70% (1974-1996) and remaining 30% (1997-2006) of the available data length has been chosen for training and testing respectively. The objective function was to find the minimum mean square error of the estimated S_v. The relevant GP parameters and their chosen values, which provided the best input-output relationship, are shown in Table 1. It has been noticed that the large population size provides high search space for GP solution. The parameter "initial program size" and "maximum program size" indicate the maximum size of the program of the initial population and of the population from subsequent generations, respectively.

Table 1. Values of GP Control Parameters

Parameter	Value
Population Size	500
Mutation Frequency (%)	95
Crossover Frequency (%)	50
Program Size	
Initial	80
Maximum	512
Total runs started	53
Cost function	MSE
Set of functions	+,-, ×, ÷, √, sin, cos, exp, log, x^2

The large initial program size of 500 leads to good initial exploration of the search space and provides better result after 53 numbers of runs for this problem. The evolved GP computer program is presented in Appendix I. The performance of the present GP model has been evaluated by common statistical parameters such as coefficient of correlation (R); root mean square error (RMSE); mean absolute error (MAE); Nash and Sutcliffe (1970) efficiency (E) as presented in Table 2. The R value for training and testing are obtained as 0.991 and 0.896 respectively. This correlation analysis shows an outstanding performance of GP model.

The results of the GP model are presented in form of scatter plot in Figure 2. The results in terms of trends of observed and estimated S_v during the testing period are shown in Figure 3. From these figure, it can be seen that not only the pattern, but also

the magnitude of S_v was well captured by the proposed GP soft computing techniques. These figures confirm the good performance of the ANN model.

Table 2. Performance Statistics of the S_v Estimation Models

Performance Criteria	Value	
	Training	Testing
R	0.991	0.896
RMSE ($10^6 m^3$)	1.441	2.413
MAE ($10^6 m^3$)	1.071	1.786
E	0.991	0.762

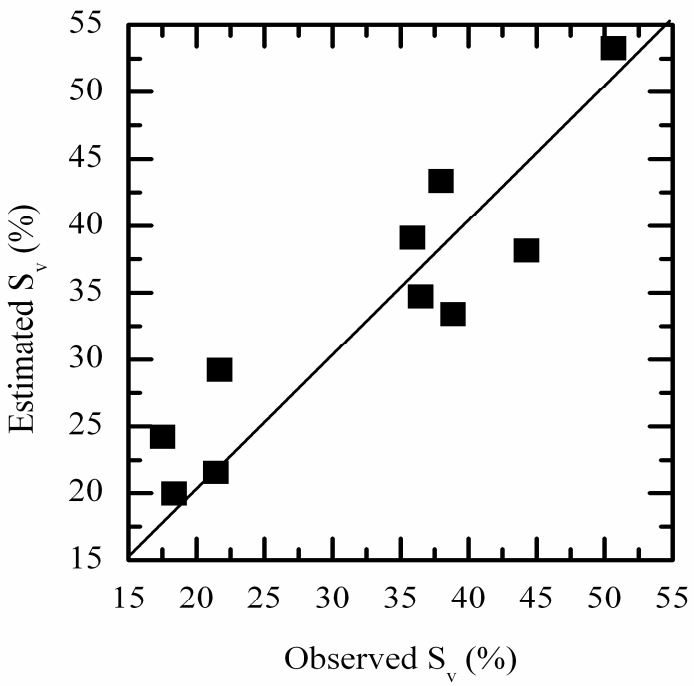

Figure 2. Scattered Plot of Observed vs Estimated S_v using GP

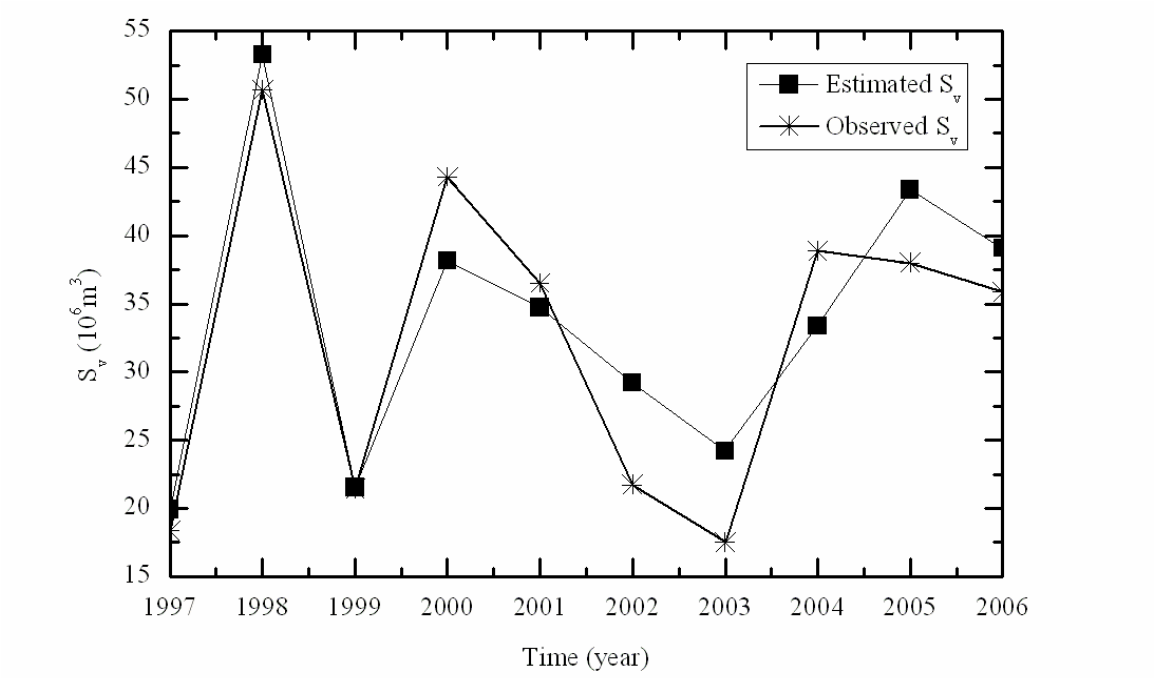

Figure 3. Comparison Plot of Observed and GP Estimated S_v for Pong Reservoir

The impact of each input parameter was analyzed by taking into account the number of times an input appears in a way that contribute to the fitness of the programs containing them (as presented in Table 3). A value of 1.00 in the frequency column indicates that the particular input variable appeared in set of all best programs. The average and maximum effect of removing all instances of a particular input from each best program is also presented. The results are scaled between 0 and 1.0. A value of 1.0 represents the largest impact value possible (Francone, 2001)

Table 3. Relative Impact of Input Parameters (GP)

Input Parameter	Frequency	Average Impact	Maximum Impact
C_t	1.00	0.77	0.96
R_t	0.33	0.23	0.61
I_t	0.67	0.35	0.64

The impact analysis of input parameters shows that C_t is the most important input parameter in estimating S_v of Pong Reservoir.

Conclusions

The volume of sediment retained (S_v) in Pong Reservoir on the river Beas in Kangra district, Himachal Pradesh, in the foothill of Himalayas, India has been estimated using GP soft computing technique. It was observed that GP model captured the trend and magnitude of S_v estimation very well. It was realized that the emerging soft computing techniques such as GP can estimate S_v easily. The outperforming GP model provided input-output relationship in the form of computer programs which may be easily used by end user. It was also found that GP can be effectively applied to capture the relationship between input and output with short length of data. This study shows that the use of soft computing tools can improve the accuracy of estimation significantly as compared to the conventional cumbersome hydrographic survey method.

ABSTRACT

A field study was conducted to assess biases of suspended sediment concentration (SSC) analyses (ASTM standard D 3977-97) performed on discrete samples obtained by auto-sampler in comparison with actual sediment concentrations from whole volume sampling. Research results indicate that the biases attributed to monitoring of sediment event mean concentration (EMC) and particle size distribution (PSD) in parking lot runoff by automated samplers (non-isokinetic) can be insignificant. Large volume samples (~15,000 L) of the full pipe cross-section were taken from a stormwater sewer system for eighteen storm events over two years to monitor for EMCs and PSDs. Concurrently, flow weighted grab samples were obtained by automatic samplers throughout the entire large volume sampling period. Thus characteristics of sediments were compared from a "whole storm" sample with that of "sub-samples" obtained by an autosampler using non-isokinetic sampling. SSCs and particle size distributions were compared for the two respective field sampling methods. The two methods showed a strong correlation for median sediment EMCs (R^2=.9801, n=18). Biases to particle size distributions were found to be largely confined to the large particles (>160 um) representing less than 25% of the load by mass. Moreover, sediment particles captured by the whole volume sampling and autosampler were not significantly different (α=0.05) for D_{50}'s=0.067 and 0.047 microns respectively (particle size at which 50% of the sample mass is less).

INTRODUCTION

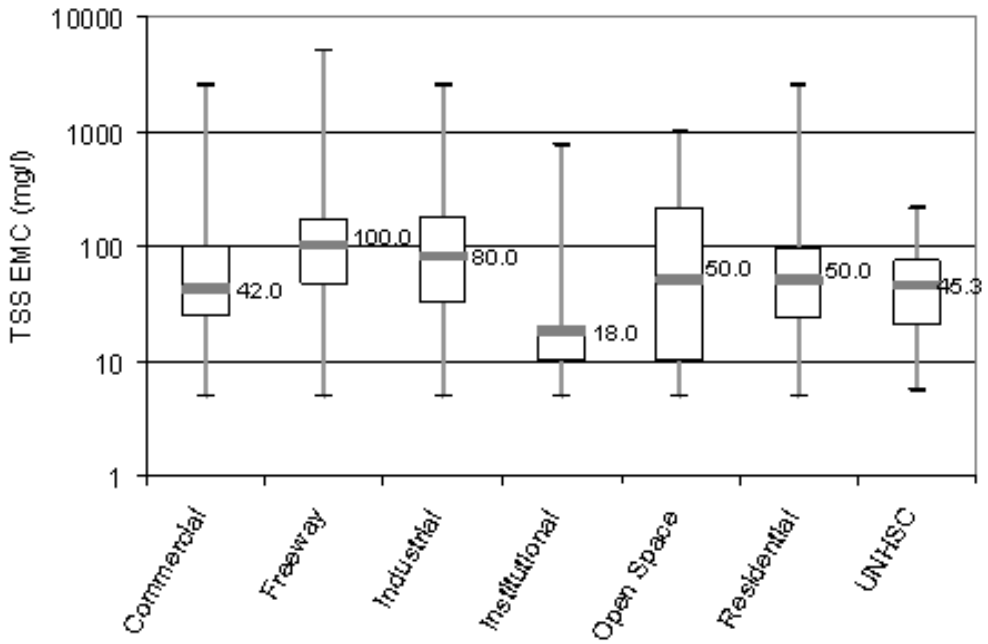
Stormwater has been identified as the greatest threat to surface water quality (EPA, 2002). Sediment concentration is the pollutant that most regulating bodies have identified as a surrogate pollutant to measure stormwater quality. (EPA, 1993, TARP 2003). Several guidelines have been developed to standardize the protocol for monitoring sediment concentration in stormwater runoff through the use of automatic samplers and their deployment in: storm sewer systems, swales, or other effluent discharge infrastructure (EPA, 1992, TARP 2003, TAPE, 2008). These guidelines also provide insite into the location of the sampling probe in the water column and the method of extracting water samples.

However, the type of automatic sampler used in stormwater monitoring can bias results. A review of the protocol for sampling suspended sediment in surface water, suggest isokinetic samplers are necessary to accurately collect sand size particles and correctly calculate sediment concentrations (USWQ, 1998, Horowitz, 2008). An isokinetic sampler possesses the ability to adapt its sampling intake velocity to the velocity of the incoming discharge. In order to obtain an accurate sample of particles with varying specific gravity

and momentum characteristics, the samples should be withdrawn at the same velocity as the discharge (Othmer, 2002).

The majority of automatic samplers used in stormwater monitoring programs are non-isokinetic samplers. A non-isokinetic sampler does not possess the ability to create a velocity within the sampling tube that mimics the incoming velocity of the stormwater. Another potential bias with sediment monitoring is the location of the sampling probe intake itself. The location of the intake could influence the reporting accuracy of sediment concentration (Horowitz, 2008). If the intake is located on the invert, it might draw in more sediment and overestimate sediment concentration (ISCO, 2001).

This research followed federal and state guidelines to monitor sediment concentration in stormwater runoff and evaluated its utility. This was accomplished by monitoring effluent from a stormwater sewer system with non-isokinetic automatic samplers whose sampling intakes where located at the storm sewer invert. The results from these effluent samples were compared to the data obtained by capturing the entire volume of effluent passing by the samplers, to determine the actual sediment concentration.



Site Description. This research characterized sediment concentration in stormwater runoff at the terminal end of a storm sewer that drained a curbed and guttered 10-acre commuter parking lot built in 1996 (Roseen et al., 2006). The West Edge parking lot is located on the University of New Hampshire campus in Durham, NH and is at nearly 80% capacity eight months of the year. The lot is plowed, sanded, and salted regularly during the winter months. The climate is temperate and the 42 inches of annual precipitation is typically evenly distributed throughout the year.

The time of concentration for the parking lot is 22 minutes with land slopes between 1.4-2.0%. At the terminal end of the drainage system, a distribution box was built, in order to distribute this stormwater to a system of ten 15-inch pipes, configured to each receive equal parts of the runoff (Roseen et al, 2006). The sediment pollutant concentration in the stormwater runoff at this site is typical for this type of land use, Figure 1.

MATERIALS AND METHODS

Equipment Description. A removable seal in the distribution box controlled flow into one of the 15-inch pipes. At the terminal end of this pipe were two ISCO 6700 samplers with intakes set along the pipe invert, 12-cm behind a 15-inch Thel-mar compound weir. The location of the intakes, flow measurement method, and rainfall collection data followed regulatory guidelines (EPA, 1992, EPA, 2002). The suction head for the automatic samplers was 13.0 ft. Downstream of the 15-inch weir, a sedimentation forebay of a sand filter was used as the initial collection area for the stormwater that passed by the sampler intakes. This basin was lined with two tarps: a 2.5 mm, 30-ft by 20-ft polyethylene tarp, which could be removed and cleaned; and larger 2.0 mm thick multipurpose polyethylene liner underneath.

Figure 1: Total Suspended Solids (TSS) Event Mean Concentration (EMC) for varied land uses and at the UNH Stormwater Center (UNHSC) (NSQD 2005). Data in (mg/L).

Sample Collection. Generally a storm a month was targeted for capture. As soon as runoff began to flow out of the 15-inch weir, water was allowed to fall onto the tarp and the sampling programs were turned on. One sampling intake collected 1L flow-paced grab samples at short time intervals during the entire time the sedimentation bay filled. This sampling approach followed regulatory sampling guidelines, (EPA, 2002). The second intake took a "Constant Volume - Time Proportional to Flow Volume Increment", single composite sample, also following EPA guidelines. Depth of flow (ft) was measured using an ISCO 730 bubbler and a Global Water WL400 pressure transducer located at the intakes and was subsequently converted into discharge (gpm) using the stage-discharge rating curve provided by Thelmar for their 15-inch weir, an acceptable flow measurement procedure within EPA recommendations.

Once the sedimentation forebay filled, water was diverted away from tarp, the programs were shut off and the seal in the distribution box closed

Analytical Method. Generally, 20-24 1L flow-paced samples were collected by automatic sampler per storm event. Eight to nine of these samples were selected for sediment analysis in order to develop an Event Mean Concentration (EMC).

The EMC calculation used for this study split the mid-point between two consecutive concentration samples which is standard practice (Charbeneau, 1998 and Stenstrome, 2005). These samples were kept at 4ºC temperature and sent to an analytical lab for analysis following EPA recommendations for sample preservation and holding. These samples were analyzed for sediment concentration using the Suspended Sediment Concentration analysis (SSC) following ASTM D397 protocol (ASTM 2000) for each sample. The use of the SSC method was used instead of the traditional Total Suspended Solids (TSS) analytical test because of the influence sand-size particles have on the reporting accuracy of TSS (Gray, 2000).

The single composite sample was kept at 4ºC temperature and sent to a lab for Particle Size Distribution analysis using Tri-laser photo-detection. The usual time lapse between collection and analysis was 24-30 hours.

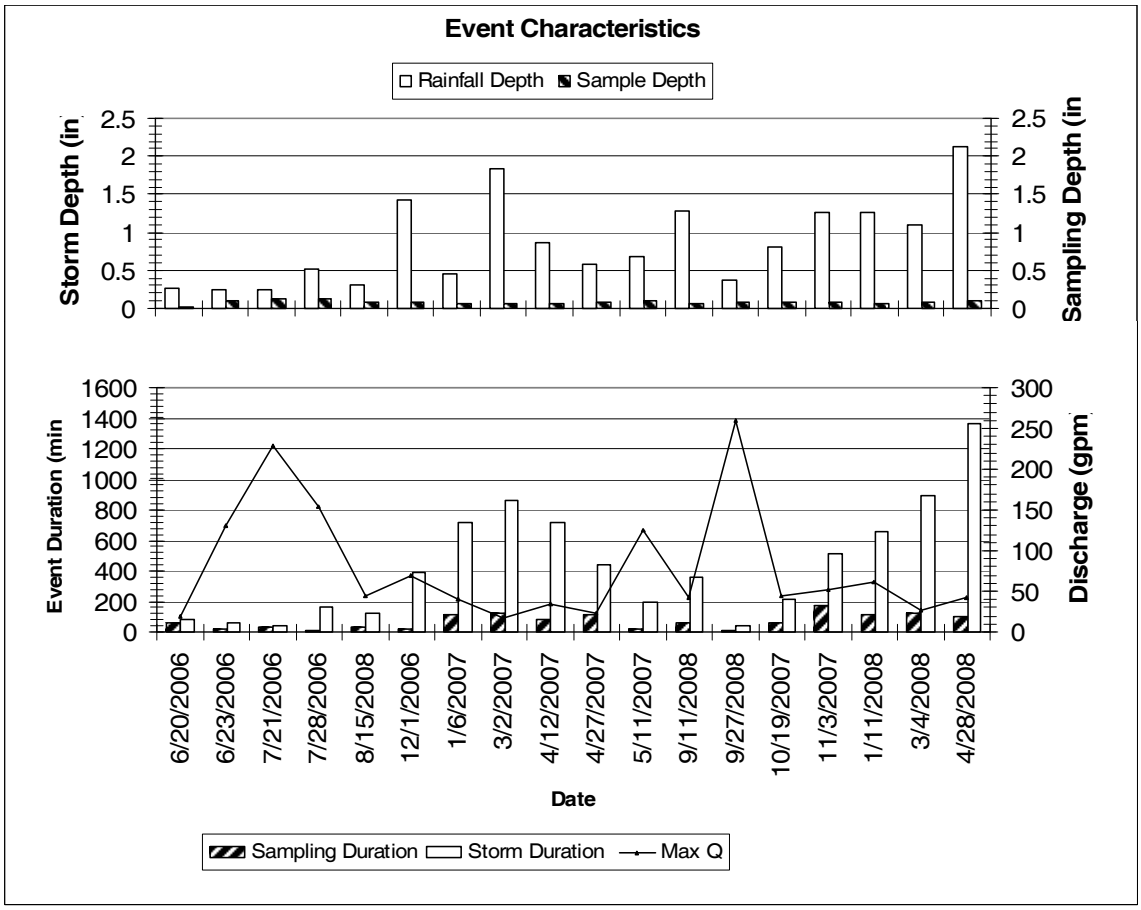
The water captured in the tarp-lined basin was allowed to settle for 48 hours and followed with a volume-measured decant of the upper half of the water in which grab samples were collected. The remaining water, and any remaining sediments on the liner, were transferred into a 13,000 liter tank. After another 48 hours of settling, another volume-measured decant with grab samples was completed and the remaining 37-55 liters of slurry was recovered. This slurry was wash sieved (sieve sizes 2.5 mm-0.075 mm) and a hydrometer test was completed on sediments less than 0.075mm following ASTM D422D.

Reporting Method. Flow weighted event mean concentrations (EMC) were developed using discrete sample analyses from the automatic samplers. (EPA, 2002, Huber, 1993). Sediment concentrations for the total capture (TC) sample was determined by totaling the mass of the sediments divided by the total volume of runoff.

Table 1: Analytical Experimental Design for Sediment Characterization

Method of Sample Collection	EMC	PSD
Total Capture (TC)	Measured Decant Volume/Weight of Recovered Sediments	Wash Sieve and Hydrometer
Automatic Samplers (AS)	SSC analysis of 1L Discrete Samples	Microtrac Tri-Laser Device

RESULTS



Sampling and Event Characteristics. Eighteen events, over the course of two years were monitored. Figure 2 shows the depth of rainfall over the watershed compared to the effective precipitation captured for the Total Capture (TC) sample. The rain captured occurred during the first flush of rain events. During this first flush, the pollutant concentration is assumed to be highest (Li 2006, Aryal 2006,). High discharge rates reduced sampling time, as seen in Figure 2 and usually occurred during summer thunderstorms.

The intake velocity in the sampling tube of the automatic sampler, with 13.0 ft suction head, is 2.8 ft/s. The range of velocities in the stormwater pipe during these events can be seen in Table 2. Three of 18 storms that occurred exceeded the intake velocity of the sampler. The remaining storms were less than the sampler intake capacity.

Table 2: Pipe Velocities (ft/sec) Observed During Storm Events.

Storm Profile	# of Storms	Median Velocities (ft/s)	Max (ft/s)	Min (ft/s)
I	5	0.01-0.50	0.47	0.09
II	8	0.51-1.00	0.81	0.51
III	3	>1.01	3.52	1.3

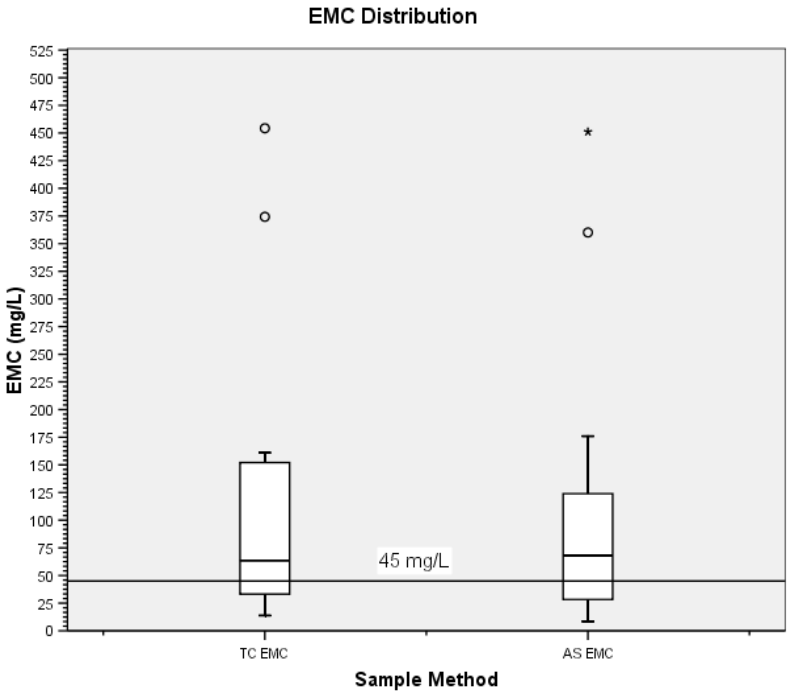


Figure 2: Sampling and Event Duration and Depth with Maximum Discharge

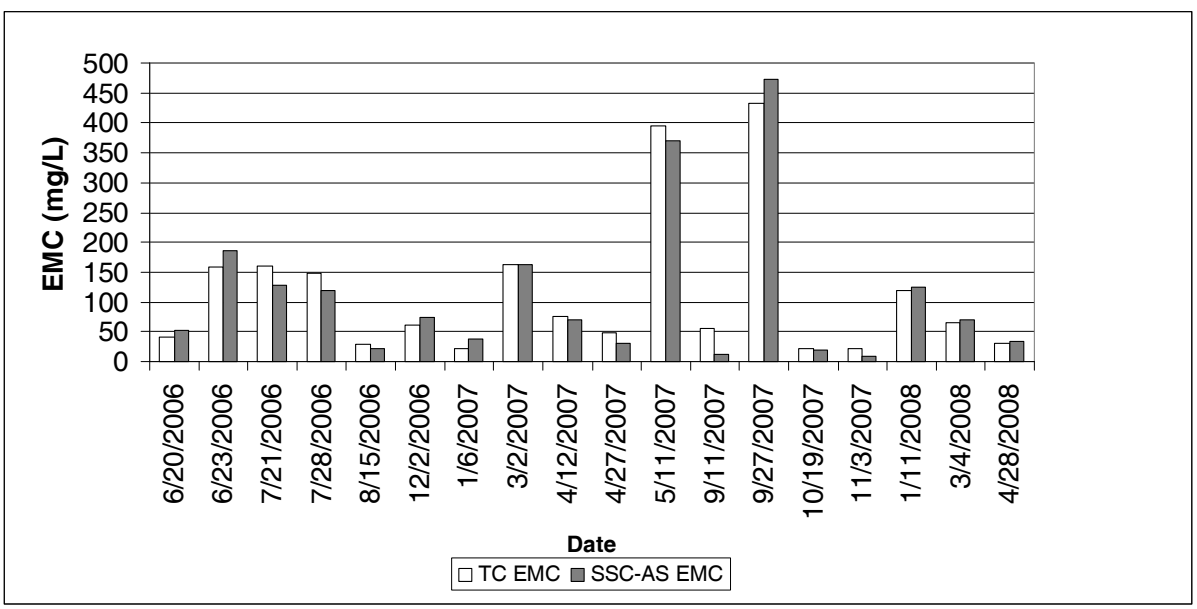
Total Capture and Sampling Methods. The median sediment EMCs from the total capture (TC) and suspended sediment concentration (SSC) b y autosampler (AS) are 69.0 and 70.1 mg/L, respectively, as seen in Figure 3. The median concentration for both methods is higher than what is expected for the this land use type as would be expected for first flush sampling. In Figure 1, the values for sediment EMC were determined using the TSS analytical method which previous research has shown to have inaccuracies (Gray 2000).



Typical median sediment concentration values for light transportation land use (45mg/L) are illustrated in Figure 3 by the reference line. The distribution of the sediment concentration for TC and SSC-AS are similar to each other as illustrated in Figure 3. The box represents the interquantile range (IQR) of the distribution, An extreme outlier "*" exists in the AS PSD and is more than three times the IQR from the end of the box. This outlier occurred during the 9/27/07 event. The greatest outlier from the TC method also occurred during this event but was not outside 3 times the IQR. Figure 4 present the comparison of sediment concentrations by the 2 methods by date and illustrates the range of observations.

Figure 3: Sediment EMC for Total Capture (TC) Versus SSC by Auto-Sampler (AS) (mg/l)

Higher sediment concentrations typically occurred during storms in the summer months, which experience events with large discharge rates.

Figure 4: Sediment Concentration by Date for Total Capture (TC) Versus SSC by Auto-Sampler (AS)

Correlation between Methods and Sediment Concentration Results. The correlation between the sediment EMCs for the two methods, SSC by auto-sampler and the TC is strong (R^2=.974) as observed in Figure 5. The results of sediment concentration for each method

were normally distributed and the two methods were found not to be significantly different at a 95% confidence level (Table 3).

Figure 5: Correlation between Sediment Concentration by Total Capture (TC) Versus SSC by Auto-Sampler

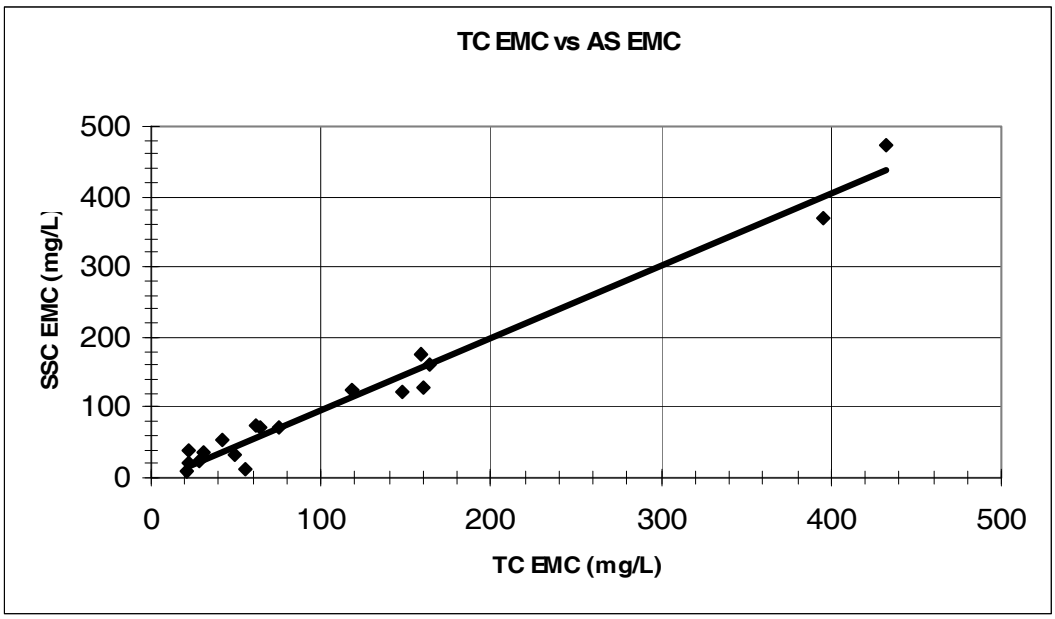


Table 3: T- Test for Significance of Sampling Methods: TC vs SSC

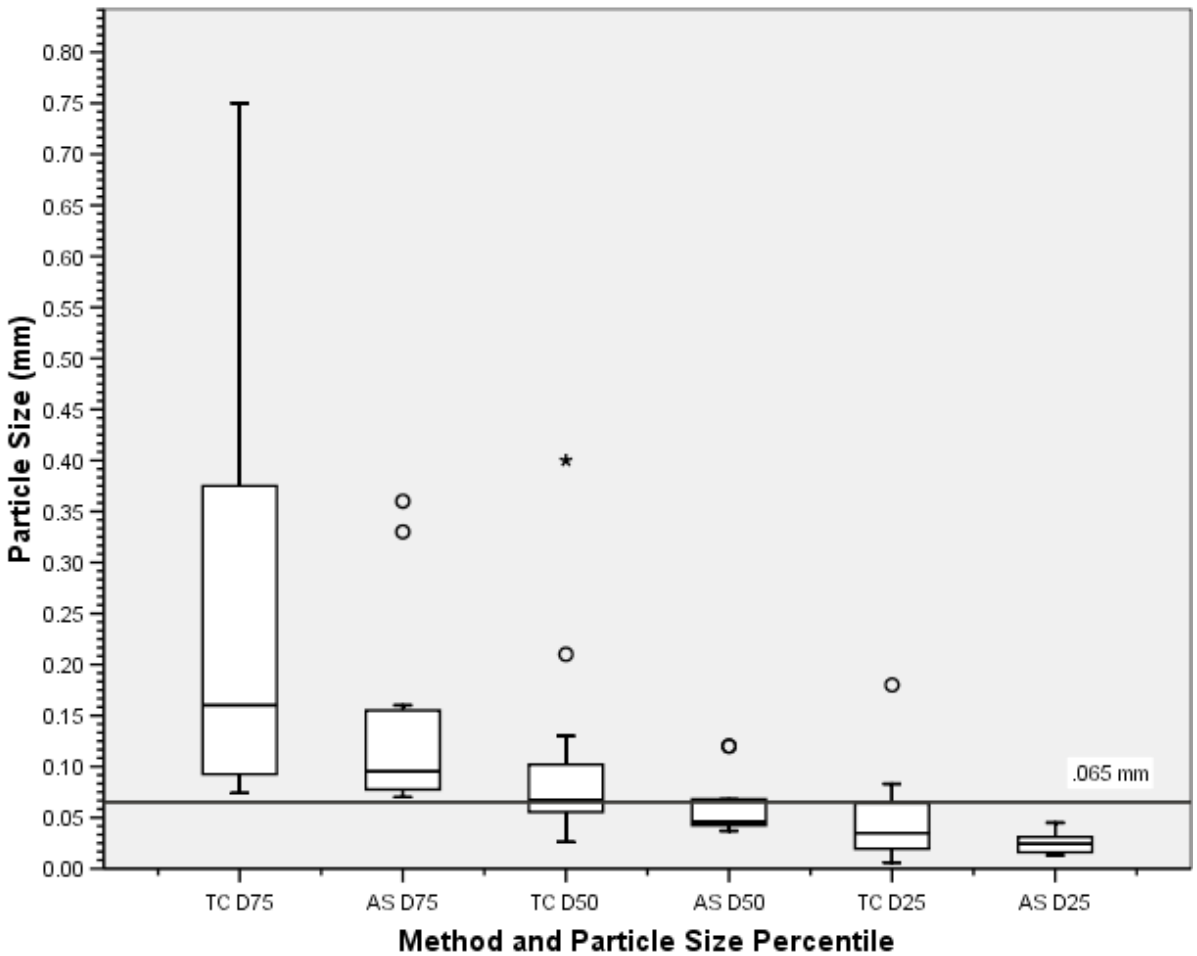

N	Mean (mg/L)	St. Dev.	95% Confidence Interval		Signifigance
			Lower	Upper	
18.00	7.40	18.40	-1.77	16.50	0.11

Suspended Sediment Particle Size Distribution (PSD). The range of particle sizes found in stormwater runoff varies significantly with land use however the presence of sand size sediments or coarser are commonly found in stormwater. (Sansalone, 1999) The median value of all D_{50} values for sediments recovered in the total capture samples and SSC samples taken by auto-sampler is 0.067 mm and 0.046 mm respectively. The distribution of three particle size percentiles is illustrated in Figure 6 (n=11). This size distribution fits well within the range for PSD of sediments from this type of land use (Fumari, 2002, Li, 2005). PSDs were not completed on sediments captured by automatic samplers for every event. A sand size reference line can be seen in this figure and all values above this line are sand size or coarser.

CONCLUSION

This study demonstrated that the use of auto-samplers combined with the suspended sediment concentration (SSC) method was an effective means for determining actual measured sediment loads (TC). This was for a site where the median particle size was in the 46-67 micron range (depending on method), common of stormwater sediments. Much press has been given to the notion that auto-samplers are fundamentally ineffective at sampling

Figure 6: Distribution of PSD Fractions by Method

sediment loads. However, most of these studies have focused on the use of total suspended solids (TSS) with auto-samplers.

There are a source of potential errors when measuring sediment concentration, including samplers, sediment concentration methodology (TSS, TS, TVS, SSC, turbidity), sample splitters (cone and churn splitters), to name a few. For the combination of SSC with auto-sampler, there was no significant difference from the actual sediment load. Biases to particle size were observed, especially for the larger particles above 65 micron. The D_{75} particles were substantially underrepresented by the auto-sampler. For the range of 18 storms studied, only 3 storms had pipe velocities that exceeded the sampler intake velocity at 2.8 ft/s, another potential source of error. A sediment concentration monitoring method that employs a non-isokinetic automated sampler can provide an accurate measure of sediment concentration in a common stormwater sewer system.

ABSTRACT

Central Florida's population is growing at a rapid pace and is approaching the limits of its available groundwater supplies. Considering this fact, the South Florida Water Management District (SFWMD), St. Johns River Water Management District (SJRWMD), and Southwest Florida Water Management District (SWFWMD) foresee that additional groundwater withdrawals in Central Florida to meet future water demands beyond 2013 will be restricted. The objective of this initial feasibility study is to evaluate the availability of surface water in the upper Kissimmee River basin as an alternative supply source for Central Florida. As part of the Upper Kissimmee Basin Regional Water Feasibility Study, 28 integrated water supply options were identified and evaluated by developing a reservoir optimization model that minimizes both capital and O&M costs of various water supply components, such as intakes, reservoirs, water treatment plants, pumps, pipelines, and groundwater withdrawals, and so forth, and satisfies necessary physical constraints.

The optimization approach appropriately sized the various water supply system components from both surface and groundwater sources to meet a desired yield target while addressing the primary environmental performance measures identified for the Kissimmee River restoration effort. In addition to minimizing water supply cost, reliability was also maximized using a multi-objective genetic algorithm. A key component of the feasibility study is to provide a planning-level estimate of surface-water availability and reservoir sizing for one or more project locations within the study area. This work was completed in August 2008 using interim operational criteria for the Upper Kissimmee Chain of Lakes. Additional refinements to the estimates of water availability and reservoir sizing are anticipated in the future as the current environmental criteria and operation schedules of the lake structures are modified in 2009.

INTRODUCTION

The three Florida Water Management Districts that border each other in Central Florida (SFWMD, SJRWMD, and SWFWMD) have determined that additional groundwater from current wellfields in Central Florida will be restricted beyond 2013 unless it can be demonstrated that the additional withdrawals do not add to the cumulative affects of current withdrawals. The Districts have indicated to the water utilities that alternative water supplies are needed to meet their future demands (beyond 2013). The Upper Kissimmee River Basin surface water has been identified as a potential source of alternative water supply.

In recent years, several water resource management issues have emerged as competing for the water resources in the Upper Kissimmee Basin (UKB). Four specific items that have come to light include: 1) meeting hydrologic requirements for the Federally-authorized Kissimmee River Restoration Project (Water Resources Development Act, 1992), 2) meeting the hydrologic requirements for the health of the upper basin lakes, 3) finding alternative storage to reduce flows to Lake Okeechobee, as directed in the Northern Everglades and Estuaries Protection Program (Section 373.4595 Florida Statute), and 4) finding water supply alternatives to the Floridian aquifer as a source of water to meet municipal consumptive uses in the upper basin.

CH2M HILL assisted SFWMD by conducting this feasibility study for developing a new surface water supply in the UKB to provide alternative supplies to Central Florida utilities consistent with the Central Florida Coordination Area (CFCA) plans and agreements. The study area for this project is the drainage basin of the Kissimmee River upstream and including the S-65 spillway structure at the discharge of Lake Kissimmee. Key components of the feasibility study was to provide a planning-level estimate of surface-water yield given a pre-defined surface water availability after environmental and programmatic needs of the watershed are met and reservoir sizing for one or more project locations within the study area. Figure 1 presents a map of the study area.

OBJECTIVE

In a previous study CH2M HILL (2008a) developed a reservoir spreadsheet model for the UKB System to evaluate the relationship between reservoir sizing and water yield based upon the surface-water availability information provided by the District. The reservoir spreadsheet model was used to determine the size of reservoirs to meet a given target yield via a water balance analysis. This study illustrated that the surface water for alternative supply may not be available constantly. So in addition to available surface water supplies the optimization model included the use of supplemental groundwater sources that may be needed to improve the reliability and increase the potential quantity with which future water demands can be met from this system.

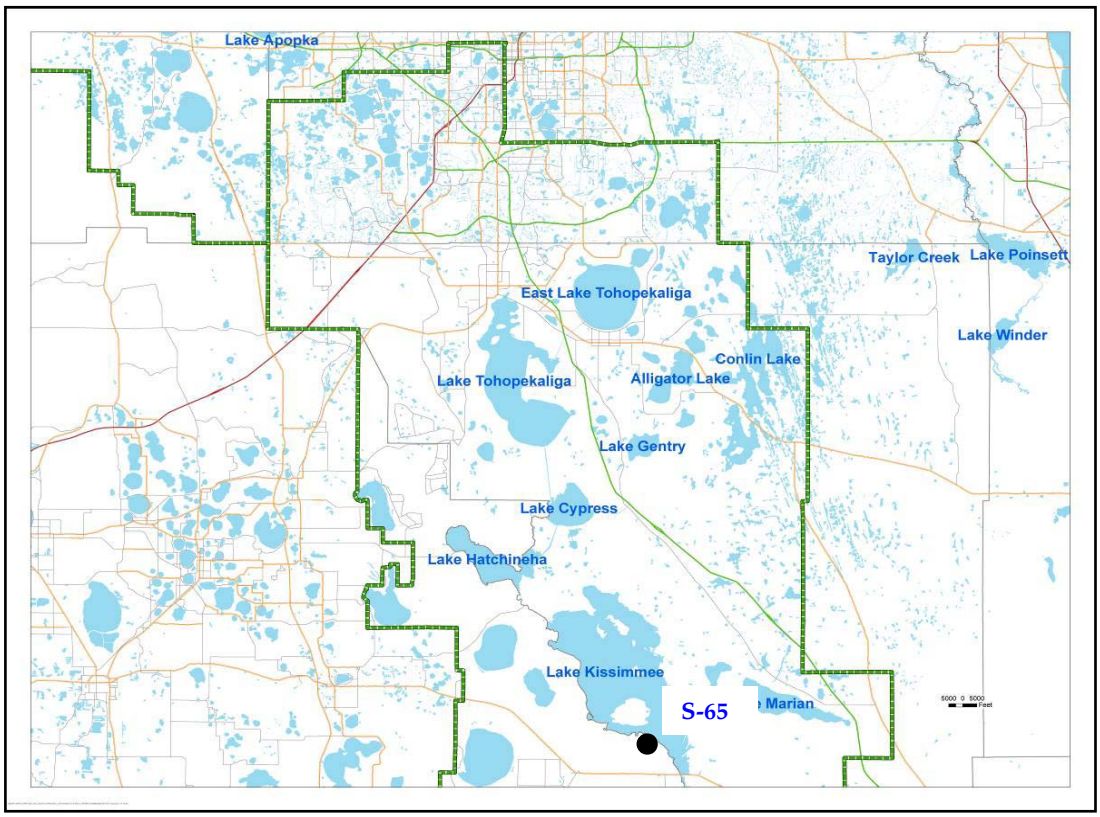

Figure 1. Upper Kissimmee Basin Water Supply Feasibility Study Area.

The objective of follow-up study was to develop an optimization model and apply it to a broader UKB water supply infrastructure system. To identify the best combination of pre-identified candidate project configurations that meet the project objectives, an optimization approach was applied around the reservoir spreadsheet model to incorporate the sizing of pumps and pipelines need for the UKB water supply system. For a given scenario, the optimization model identified an optimal solution that both minimizes costs and satisfies necessary physical constraints.

INTEGRATED WATER PLANNING SCENARIOS

Targeted water supply yields included for this analysis are 10, 20, and 40 million gallons per day, annual average daily flow (mgd, AADF). These target supply quantities are less than the expected cumulative water supply deficit between 2013 and 2025 of the stakeholders which is greater than 80 mgd, AADF (CH2M HILL, 2007). These smaller supply quantities were considered because the preliminary work concluded that only 20 mgd of water was available 50 percent of the time from Lake Kissimmee. Therefore to meet supplies greater than about 10 mgd additional sources other than solely surface water are needed to provide even the modest rates studied here.

A preliminary strategy regarding the locations of water supply system components within the UKB was developed based on the local knowledge of CH2M HILL and SFWMD. Figure 2 provides an overview of the system components including surface water inlets, transmission pipelines, groundwater withdrawal points, storage reservoirs, and points of connections (POCs). Water storage is believed to be an important component required to utilize "water of opportunity" to the fullest degree so storage reservoirs are also central in the water supply scenarios. For purposes of this study, the identification of water-storage options is conceptual in scope. SFWMD identified publicly-owned land areas to be initially considered as potential locations for surface storage impoundments until more detailed available land assessments can be conducted.

Once the potential water supply system layout was developed, a variety of scenarios capable of meeting target water yields of 10, 20, and 40 mgd at four potential connection points to utilities were identified. Twenty-eight scenarios were selected for evaluation because these would include most potential alternatives. The associated water supply sources, treatment alternatives, delivered water quality, transmission routes, and delivery points were specified for each scenario. The development of these scenarios and the formulation of model objectives and constraints were coordinated with the SFWMD. Table 1 provides a list of the 28 water planning scenarios selected for evaluation.

SYSTEM COMPONENTS AND OPTIMIZATION LAYOUT

As shown in Table 1, multiple sources from which one or two points of connection must be supplied are specified for each model scenario. Figure 3 shows a schematic of a typical path from supply source to point of delivery. Supply system components include surface water intakes, reservoirs, pump stations, treatment plants, and transmission booster pump stations and pipes. The size of the system's physical components determines the system's ability to meet yield targets and minimize costs. For a given scenario, the optimization model determines the cost of the withdrawal, treatment, and delivery of surface water and groundwater supplies to a particular POC.

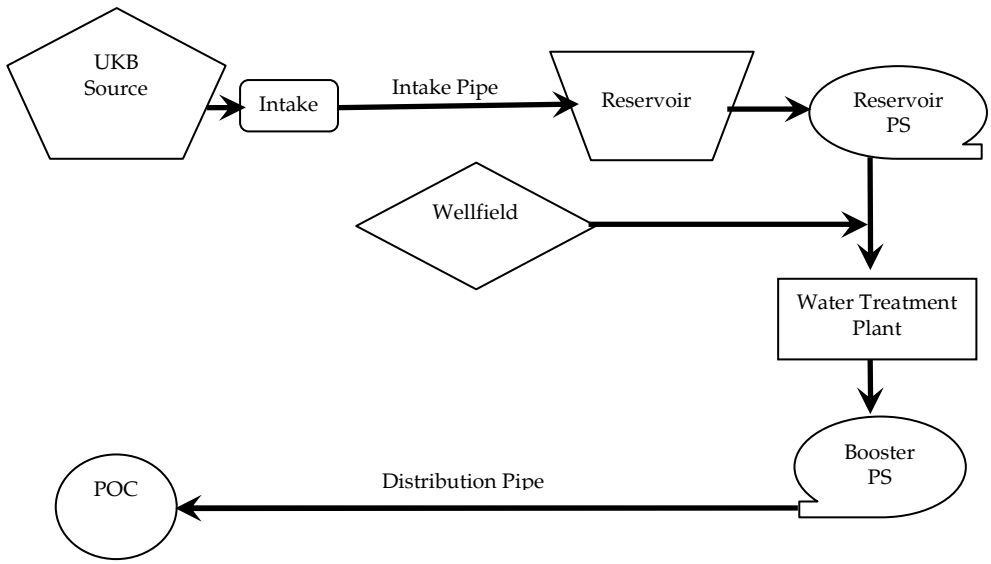

Figure 3. Water Delivery Schematic for the Upper Kissimmee Basin

Optimization Model Approach. The UKB optimization model was developed to size water supply components, such as intakes, reservoirs, water treatment plants, pumps, pipelines, and groundwater withdrawals to meet a given target yield. In addition to minimizing the cost-based objective function, the optimal solution must also meet certain assumptions and physical constraints which are described below. For this study, the model was run on a daily time step over the period of January 1, 1970, through December 31, 2005 using the time series of available water that provided the greatest yield identified in the previous reservoir study. This time series of available water was provided to CH2M HILL by the SFWMD. This data stream represented the then-best estimate of surface water available at S-65 that would meet environmental objectives for the multiple projects in the basin. However, since then the District is moving forward on additional evaluations to better refine the objectives and available surface waters from the UKB (to be completed in approximately 2010).

Objective Function. The optimization model determines the optimal supply system configuration by minimizing the following objective function:

*Total Performance Cost = Capital Cost*PF1+ O&M Cost*PF2 + GW Penalty*PF2*

Where: *Capital Cost* = Capital cost of Intake, Intake Pipe, Reservoir, Booster Pump Station, & Distribution Pipeline*; O&M Cost* = O&M cost of Intake Pumps, Reservoir Pumping, Groundwater Pumping and Distribution Pumping*; PF1 & PF2* = Present worth factors, *PF1* = 1.0 assuming interest rate equals inflation rate*, and PF2*= $(1+NIR)^t$; NIR = Nominal Inertest Rate based on the annual interest rate of 5%, t = no. of days; *Penalty* = A penalty is applied to discourage groundwater use

While the cost of groundwater withdrawals is presented in the final results, this cost was not incorporated in the objective function because surface water is the preferred supply source at all times, regardless of treatment costs. Groundwater supply will be less expensive than surface water so it would always be the preferred low cost solution. However, by adding groundwater use as a penalty cost, this forces the model to minimize groundwater use.

Cost Functions. The optimization model requires cost to be included to evaluate the least-cost solution as part of the objective function. To satisfy this requirement, appropriate capital and O&M cost equations were determined for the physical components of the water supply system. The cost functions used included surface water intakes, transmission pipe, reservoirs, pump stations, wellfields, water treatment plants, and booster pumps.

Except where otherwise noted, these functions were based on reported costs that were originally developed in February 2008 (Black and Veatch, 2008). These cost opinions were based on an Engineer News Record Construction Cost Index equal to 8,005 and are appropriate for planning-level evaluations. The "capital costs" listed below do not include all potential owner project costs (management, engineering, permitting, land and easements, etc.). The purpose of these opinion-of-cost functions is for developing order-of-magnitude scenario comparisons like was done for this evaluation.

Physical Constraints. Certain assumptions have been incorporated into the model to provide boundaries, such as maximum size and peak withdrawal rates from the reservoir and each well. In addition to minimizing the objective function, selection of an optimal solution is subject to the following physical constraints:

- $\sum$ (Supply – Demand) $\geq$ 0 for the study period (1970 – 2005)
- Daily groundwater supply $\leq$ an assigned Maximum Groundwater Capacity
- Maximum Groundwater Capacity $\leq$ Demand per scenario
- Surface Water Storage $\leq$ an assigned Maximum Reservoir Capacity
- Reservoir Capacity $\leq$ 9.38 Billion Gallons each (about 3 mi^2)

- Intake Capacity = Maximum Allowable Lake Withdrawal
- Maximum Allowable Lake Withdrawal ≤ 600 mgd (±1,000 cfs).
- Maximum reservoir depth = 16 ft
- Reservoir initial depth = 8 ft
- Supplies from Inlet A ≤ 24% of S-65 flows
- Supplies from Inlet B ≤ 60% of S-65 flows – Supplies from Inlet A
- Supplies from Inlets C, D, & F ≤ S-65 Flows – Supplies from Inlets A & B

MODEL RESULTS

Figures 4 through 7 provides a summary of the results for the 28 scenarios which includes the amount of surface and groundwater used; capital and O&M costs; and the size of the reservoirs. Figures 4 and 5 show the estimated capital and average annual O&M costs associated with each scenario. Figure 6 depicts the distribution of supplies from surface and groundwater sources, while Figure 7 shows total reservoir storage capacity for each scenario. In each figure, the scenarios are grouped by their specified target yield: 10, 20, 30, or 40 mgd, AADF, respectively.

The capital costs of most of the scenarios varied from $550 to $800 million. The capital cost per mgd delivered was more cost-effective for the larger yields. However, the scenarios with higher yield also used a greater fraction of groundwater (Figure 6), as expected. The overall scenario costs are generally affected by the cost of the pipelines because the reservoir costs did not vary greatly except for the few where the costs are much higher (Scenarios 3, 26, 27, and 28; Figure 7). Therefore, scenarios that reduced the pipeline costs had somewhat smaller capital costs. The O&M costs generally increased with the increase in yield, but not in direct proportion so the larger yield projects again would have lower unit O&M costs.

A maximum reservoir size of approximately 3 square miles was used in the model because increasing the size only provided small increases in yield (CH2M HILL, 2008a). The optimization model picked the largest size reservoir in most cases because of the penalty function applied to the groundwater to discourage its use. In practice there will be real-world limitations on the reservoir size.

These results are consistent with the previous results utilizing the preliminary estimates of "available water." A different data stream for available water will likely provide different results but these estimates provide an idea of the scale of projects required to develop a surface water supply in the UKB**.**

CONCLUSIONS

The SFWMD conducted a feasibility study for the purpose of developing a new surface water supply in the UKB to provide a new source of water supply to stakeholder utilities in Central Florida. As part of the Upper Kissimmee Basin Regional Water Feasibility Study, 28 integrated water supply options were identified and evaluated using a reservoir spreadsheet optimization model.

The optimization model was applied separately for each scenario to identify a solution that both minimizes costs and satisfies necessary physical constraints by appropriately sizing supply system components to meet a given target yield. In addition to available surface water supplies, the optimization model considered the use of groundwater supplies that may be needed to improve the reliability with which future water demands can be met, but only after surface water was used first. The overall conclusions of this study are listed below.

- The capital cost per mgd of delivered water was more cost effective for the larger yields. However, the scenarios with higher yield used greater fraction of groundwater, as expected.
- Consistent with previous analysis, the amount of surface water that could be applied to a constant demand will be limited with the given "available water" used in this evaluation.
- Integrated water supply planning is a complicated mix of alternatives that includes engineering, environmental, and policy decisions to be incorporated into the planning effort. The optimization model was very effective in finding integrated water supply systems given a set of physical constraints. Additional issues have been highlighted through this work, like the potential size of storage reservoirs.
- A different flow record of available water may provide significantly different results, thus additional work is being focused on improved estimates of excess water from the UKB. Environmental and programmatic water needs are being established by the SFWMD. In addition, the SFWMD is in the process of a Kissimmee Basin Modeling and Operations Study (KBMOS) that includes a detailed, linked groundwater and surface-water model that is being concurrently developed for the Kissimmee River Restoration Project and adapted for water supply assessments.
- The predicted overall cost of a potential surface water supply infrastructure gives the utilities and districts better information to use in their overall planning efforts.

The results of this optimization study are meant to serve as a precursor to an improved analyses that will jointly review water supply and restoration goals in future water supply evaluations.

SIMPLIFIED SOLUTION FOR GROUNDWATER MOUNDING UNDER ROUND STORMWATER INFILTRATION FACILITIES

Kaveh Zomorodi[1]

ABSTRACT

A study was conducted to derive new groundwater mounding equations that are simple in their structures but produce reasonable values for conditions most commonly found in stormwater infiltration facilities. This paper presents the new simplified equations and their theoretical development. The equations apply to Steady–uniform recharge rate to infinite homogenous aquifers with initially horizontal water table and bedrock surfaces. Separate sets of equations were derived for recharge strips (infiltration channels/trenches) and infiltration basins (round or square facilities). The equations for recharge strips were published previously. This paper presents the equations for round or square facilities. The new equation sets require minimum input data in terms of the size and shape of the facility, the properties of the saturated layer and the recharge rate and are convenient for routine engineering calculations. Example applications of the new equation sets for conditions typical in New Jersey are presented.

INTRODUCTION

Excessive groundwater mounding under an infiltration facility could cause various problems including water logging, structural instabilities, wet basements, declined recharge rates, groundwater quality problems by reduction or loss of the unsaturated layer under infiltration facilities, and the possibility of interflow or surface water discharge leading to untimely or undesirable contribution to baseflow. Both the maximum rise of the central mound and the areal extent of the mound are important for the above concerns.

Low Impact Development (LID) quantitative calculation tools have been developed for the State of New Jersey that deal both with surface water and groundwater (Zomorodi, 2003, and Dewberry, 2002). The New Jersey regulations encourage infiltration practices mainly to help maintain groundwater recharge under post-development conditions. In the design of any infiltration facility, the potential for excessive groundwater mounding must be checked. However, the existing methods for evaluation of groundwater mounding are complex and usually difficultto apply.

[1] Ph.D., P.E., CFM, M. ASCE, Dewberry, 8401 Arlington Blvd., Fairfax, VA 22031, 703.849.0336 (P); 703.849.0104 (F); E-Mail: kzomorodi@dewberry.com

This paper presents new simplified equations that can be used for a general approximation of mounding under stormwater infiltration facilities. Separate equations were derived for recharge strips (infiltration channels/trenches) and infiltration basins (round or square facilities). The equations for recharge strips have been published previously (Zomorodi, 2003). The author has since received many requests for the second set of equations applicable to round (and with approximation to square) facilities. This paper presents the derivation and application of the equations for round and square infiltration facilities.

Limitations in Application of the Existing Solutions to Stormwater Infiltration

There are a number of issues and considerations that limit the applicability of current groundwater mounding calculation methods in everyday design of a stormwater infiltration facility. One issue is the fact that these methods require knowledge of the local groundwater system and its various hydrogeological parameters. The water resources engineers who traditionally work on BMP design are not familiar with groundwater issues and data sources. Moreover, local groundwater studies are typically not available and the regional groundwater studies (if they are available) do not accurately apply to micro-scale urban drainage conditions. Some studies indicate a need for even a larger information base that is required in application of most of the existing equations. For example, a recent study by Gua (2001) suggests that the hydraulic conveyance capabilities of not only the saturated layer but also that of the unsaturated layer must be considered in estimating the groundwater mounding.

A number of researchers such as Swamee and Ojha (1997) have tried to simplify existing solutions, but the resulting equations are still too complicated for routine applications in stormwater management design and require an iterative solution methodology.

Besides the relatively accurate estimates of groundwater parameters, most existing solutions require knowledge of the boundary conditions. Boundary conditions must satisfy assumptions of the formulas. These assumptions include factors such as an infinite aquifer extent or known head at a known distance. Bouwer et. al. (1999) and Bouwer (2002) presented simplified mounding equations. However, these equations predict only the central mound rise and not the mounding depth at a given distance from the facility and they require the depth and distance of the controlled saturated zone. The controlled saturated zone is the water table that is held constant by regional recharge/discharge activities. This means that the boundary conditions have to be prescribed and constant. Therefore, these equations may be applicable

to large artificial recharge facilities that are integrated into regional groundwater pumping plans, but they are not usable for small stormwater recharge facilities. In most cases the radius of influence of a stormwater facility on the water table is what we need to estimate and not a given parameter of the problem. The simplified equations we developed (presented later) are based on the general approach of Bouwer (2002) but they overcome the problem of controlled prescribed boundaries by the use of additional equations.

Another major issue is that the traditional groundwater mounding equations are valid for steady state recharge subject to uniform and constant recharge rates and the effect of the unsaturated zone is ignored. The few existing unsteady mounding equations typically entail other application restrictions. For example, Youngs (1977) presented an equation for unsteady groundwater mound but it assumes no water table prior to recharge. An infiltration facility receiving stormwater runoff would cause unsteady intermittent recharge in which the rate of infiltration and recharge is variable and the mound actually dissipates between recharge operations. Typically groundwater mounds below recharge basins are one to six feet after a rain event and the mound usually disappears within five days of a heavy rainfall. Zomorodi (1988, 1991) studied the response of water table to intermittent-variable rate recharge and showed that the mounding under a variable recharge rate could be quite different from mounding under a constant recharge rate even with an equivalent recharge depth for both cases. The proposed solution method in that study, however, was for artificial recharge ponds receiving water in regular cycles that allow a repeating predictable cycle of recharge. This condition is not satisfied with recharge of stormwater that occurs on an irregular time basis. Manglik and Rai (2000) presented an analytical solution for modeling of water table fluctuations in response to a variable recharge and withdrawal rate. However, this equation is too complex for routine use in stormwater management studies. Zomorodi (2002) developed a numerical model on a spreadsheet that can predict mounding due to unsteady infiltration rate and considers the effect of the unsaturated zone. The model predicts the position of the central mound and so, conceivably it can be used in verifying stormwater regulation requirements of a given minimum thickness of unsaturated layer under a recharge facility. However, to provide the shape and extent of the mound the model in Zomorodi (2002) model must be combined with another technique that provides the typical shape of the mound.

A number of complicating factors preclude development of general solution charts for groundwater mounding. For example, according to Vauclin et. al. (1979), because of the shape of the soil suction curve, it is not possible to use a series of nomographs

to predict the time of transfer (time it takes for the infiltrated water to reach the water table) for a given soil, even if the infiltration rate and depth to water table are known.

There have been attempts to develop coupled surface water-groundwater models to address the problem of a retention pond operation and its interaction with underlying aquifer. However, these models are usually integrated into proprietary software packages and their application is very data and labor intensive and is possibly justified only for the final design of large retention ponds.

Development of New Equation for Round Recharge Facilities

If the recharge area is circular or approximately square or has an irregular shape that can be interpolated to an equivalent circle, then the flow out of the facility can be simulated by assuming radial flow. Figure 1 shows the general layout and configuration of the problem. Due to symmetry of the system only the layout on one side of the pond is shown in Figure 1.

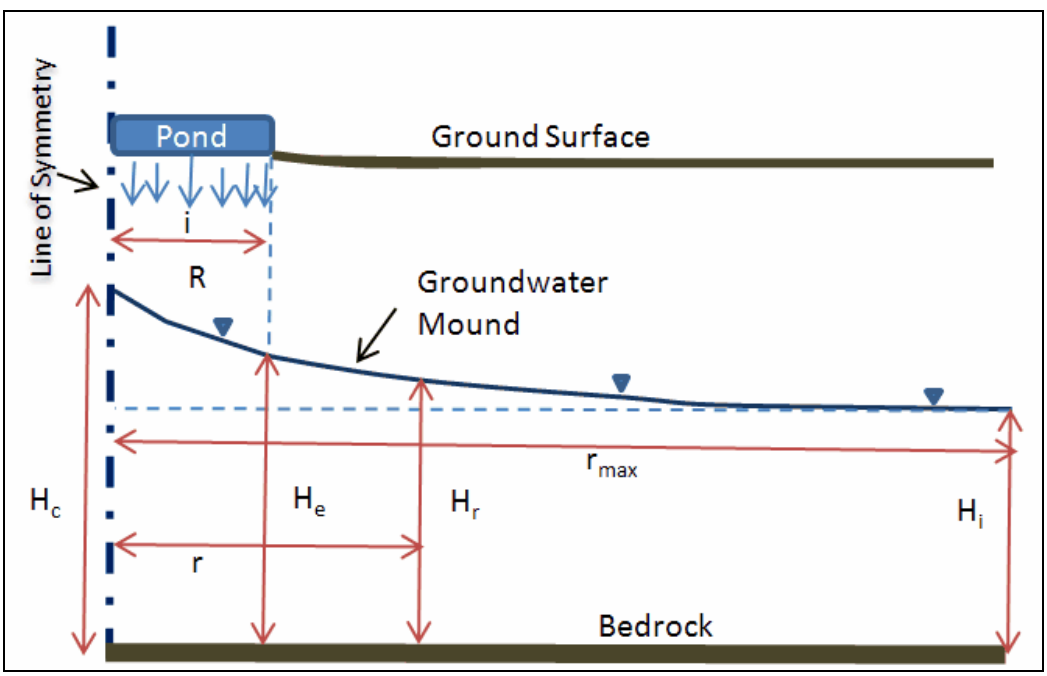

Figure 1. Circular Recharge Area Problem layout and Parameters.

Several assumptions need to be made to allow derivation of the required solution:

- Steady – uniform recharge rate from a circular recharge source (pond),
- Average recharge rate is smaller than the horizontal saturated hydraulic conductivity of the aquifer,

- Infinite aquifer extent with horizontal initial water table and bedrock,
- Horizontal flow in the aquifer,
- Homogenous aquifer,
- No source/sink terms outside of pond boundaries,
- Effective transmissivity is approximated by hydraulic conductivity times pond diameter.

The last assumption above may be justified based on review of several sources in Zomorodi (1988) that led to the conclusion that the active (effective) thickness of the saturated layer in transmitting the recharged water away from the pond is not larger than the pond width. This means that the rate of mound rise does not depend on saturated thickness of the aquifer as long as this thickness exceeds the width of the basin. Under a given design condition, whether these assumptions are valid or not depends on local conditions. The solution methodology developed here does not require an exact knowledge of the initial saturated thickness of the aquifer. As long as a rough estimate of this thickness indicates that it is larger than the pond diameterthe equations apply and an arbitrary value can be used in the equations. The effective transmissivity may be assumed to be equal to hydraulic conductivity multiplied by the basin diameter.

Assuming a constant uniform recharge rate from the circular pond which is equal to the average infiltration rate "i" in the pond, the flow from the pond to aquifer at a distance "r" from the pond center (but still under the pond) can be written as:

$$q = i\pi r^2 \qquad (1)$$

From Darcy's equation the flow away from the pond in the underlying aquifer at a given distance "r" would be:

$$q = 2\pi r K H\left(\frac{-dH}{dr}\right) \qquad (2)$$

Combining Equations 1 and 2 and rearranging the terms allows integrating the equations for limits between the pond center and the pond edge:

$$\int_0^R i\pi r\, dr = \int_{H_c}^{H_e} 2\pi K H\,(-dH) \qquad (3)$$

Based on the assumption of the effective transmissivity being equal to hydraulic conductivity times pond diameter, "H" can be replaced in the above equation with 2R as long as $H_i > 2R$. Making this substitution and simplifying the equation leads to an equation that relates the maximum saturated thickness at the edge of pond (H_e)

to the maximum saturated thickness under the pond center when the stable mound is fully formed (H_c):

$$H_e = H_c - \frac{i\,R}{8\,K} \tag{4}$$

To equate the total flow out of the pond to the total flow moving radially away to a distance "r" from the pond center in the aquifer when equilibrium is reached we can write:

$$i\,\pi\,R^2 = 2\pi\left(\frac{r}{2}\right)K\,H\left(\frac{-dH}{dr}\right) \tag{5}$$

We can write the flow balance for up to the maximum radius of influence of mounding r_{max}:

$$i\,R^2\int_R^{r_{\max}}\frac{dr}{r} = -2\,K\int_{H_e}^{Hi} H\,dH \tag{6}$$

Using the assumption of the effective transmissivity being equal to 2R x K and integrating both sides and rearranging terms we can express the natural logarithm of the mound's maximum radius of influence by:

$$\ln(r_{\max}) = \frac{4\,K(H_e - H_i)}{i\,R} + \ln(R) \tag{7}$$

Replacing H_e by its equivalent from Equation 4 yields:

$$\ln(r_{\max}) = \frac{4\,K((H_c - H_i) - \frac{i\,R}{8\,K})}{i\,R} + \ln(R) \tag{8}$$

H_c and r_{max} are both unknowns of the above equation and a second equation will be needed to solve the problem.

Bouwer (1962) proposed the following equation for the groundwater flow rate moving away from a recharge facility,

$$q(t) = \frac{K\,h'(t)Q'}{1 + h'(t)Q'} \tag{9}$$

Q' is an intermediate flow parameter. Under steady state equilibrium q (t) = i and h' (t) = H_c – H_i, and so the above equation can be used to yield:

$$H_c - H_i = \frac{i}{Q'(K-i)} \tag{10}$$

Bouwer (1962) used an analogue model to generate curves that related Q' to the two factors of the width of the infiltration bed and the original thickness of the aquifer. Zomorodi (1991) fitted an equations to the original Bouwer data or Q' which is valid as long as the width of the infiltration bed is smaller than half the original thickness of aquifer, a condition easily satisfied under most common field conditions. Modifying the equations in Zomorodi (1991) for Q' for the case of radial steady-state flow yield to:

$$Q' = \frac{12.8/(2R)}{10 + \left(\frac{2R}{H_i}\right)^{2.2}} \tag{11}$$

Substituting Q' from Equation 11 into Equation 10 and rearranging the terms yield to the equation for the final central mound rise:

$$H_c - H_i = \frac{0.156\, i R \left(10 + \left(\frac{2R}{H_i}\right)^{2.2}\right)}{(K-i)} \quad for\ i < K\ and\ 2R < H_i \tag{12}$$

Equation 12 gives the stable central mound rise and is valid as long as i < K and 2R< H_i. However, the use of Equation 12 requires a good estimate of the original saturated thickness of the aquifer. Note that in the equations developed for long strip recharge (Zomorodi, 2005) the exact value of the original saturated thickness of the aquifer is not needed as long as it is larger than the width of the recharge strip (infiltration channel). In derivation of Equation 12, it was assumed that the effective thickness of the aquifer is not larger than the diameter of the pond. However, this does not mean that the initial thickness of the aquifer may be simply replaced by the pond diameter. In fact, replacing H_i on the right side of Equation 12 with 2R would yield an inaccurate equation. In order to make the system of equations independent of the original aquifer thickness an analysis was made in which the rise was calculated by Equation 12 for various values of $2R/H_i$ and K and i. It is generally known that beyond a given thickness of the aquifer, the effect of any additional depth of the saturated layer on the mound rise is nominal. The idea here was to define the limiting value (the largest quantity) of $2R/H_i$ as a function of K and i (both of which are known parameter). For different values of K and i the values of $2R/H_i$ were identified where the calculated central mound rise would only change by a

nominal value (0.01 inch or 0.00083 ft) when the value of $2R/H_i$ changed by 10% . The results for the critical value of $2R/H_i$ were recorded for a range of K and i values and are presented here as the data points in Figure 2.

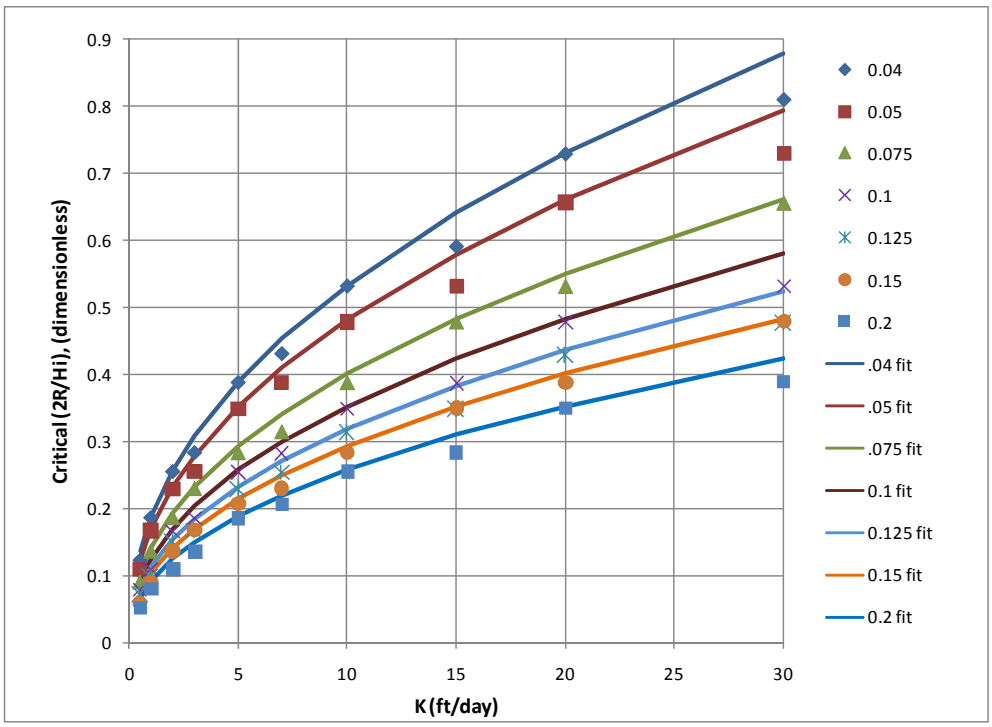

Figure 2. The Critical Values of $2R/H_i$ as a Function of K and i.

The number next to each data symbol in Figure 2 legend is the i value in ft/day. A power curve can well represent the data points for each i value in Figure 2. However, one equation was derived to represent all data points in Figure 2 and at the same time allow simplification of Equation 12:

$$\frac{2R}{H_i} = 0.0434\left(\frac{K}{i}\right)^{(1/2.2)} \qquad (13)$$

The fit curves produced by Equation 13 to the data points in Figure 2 are shown as solid curves in Figure 2. Equation 13 implies that as long as $(2R/H_i)$ is equal to or smaller than the value calculated by Equation 13 a change of $2R/H_i$ by more 10% does not appreciably impact the calculated value of the central mound rise and we don't need to know the exact value of the original thickness of the aquifer. This presents an opportunity to simplify the problem formulation. For example, if K= 15 ft/day and i= 0.069 ft/day, then the pond diameter should be no more than half of the aquifer thickness. Only a rough knowledge of aquifer thickness is required to verify this. In this example if the actual thickness of the aquifer is less than half of

the pond diameter we would expect errors in estimating the central mound rise equal to or larger than 0.00083 ft. For many stormwater management applications (especially Low Impact Development provisions) the value of 2R would be relatively small and this condition would be easily satisfied and so we could use Equation 13 to simplify Equation 12. This leads to the following equation for the central mound rise:

$$H_c - H_i = \frac{0.156\, i\, R\,(10 + 0.001\frac{K}{i})}{K - i} \qquad (14)$$

Note that even for large values of K compared to i, the term (0.001 K/i) is relatively small. Samplecalculations showed that this term can be disregarded without significantly changing the values calculated by Equation 14. This leads to the final form of the equation for the central mound rise under a round infiltration basin:

$$H_c - H_i = 1.56\frac{i\,R}{K - i} \qquad (15)$$

The maximum radius of influence of mounding can be found by calculating the rise from equation 15 and using the resulting value in Equation 8. An equation to directly calculate r_{max} can be found by combining equations 15 and 8, simplifying like terms, and taking exponential of the two sides of the equation which yields:

$$r_{\max} = e^{\left(\frac{5.74\,K + 0.5\,i}{K - i}\right)} \times R \qquad (16)$$

Where r_{max} represents the radial distance from the pond center beyond which mounding is negligible.

Having the value of the central mound rise, the rise of the mound at the pond edge can be found by using the value of the rise in Equation 4. Alternatively a direct equation for the mound height at the pond edge it can be derived by using Equations 15 and 4:

$$(H_e - H_i) = (\frac{1.56\,K}{K - i} - 0.125)\frac{i\,R}{K} \qquad (17)$$

The water table position at any radial distance between the pond center and the pond edge can be simply estimated by linear interpolation.

The water table rise at any point between the edge of the pond and r_{max} can be found by writing Equation 7 for an arbitrary “r” and subtracting the original

thickness of the saturated layer from H_r which is the thickness of the saturated layer including the mound at a radial distance "r" from the pond center:

$$(H_r - H_i) = (\frac{1.56K}{K-i} - 0.25\ln(\frac{r}{R}) - 0.125)\frac{iR}{K} \qquad (18)$$

As "r" approaches r_{max} , the value of the rise calculated by Equation 18 approaches zero and when r= r_{max} the rise drops to zero. This can be verified by replacing r in Equation 18 by its equivalent formula for r_{max} from Equation 16.

Example Calculation for Mounding under an Infiltration Pond

In this example let us consider a hypothetical infiltration pond in New Jersey. The pond is roughly circular in shape with a surface area 25 feet in radius and it overlays a homogeneous aquifer with a horizontal water table and a horizontal bedrock. The aquifer horizontal hydraulic conductivity is 3 ft/day. The exact thickness of the aquifer is not known, however, there are indications that it is at least 100 feet thick, allowing us to assign an arbitrary value of 100 feet to its lower limit estimate. There are no other major sources or sinks either recharging or discharging the aquifer in the vicinity of the pond. Calculations through New Jersey main Recharge Spreadsheet (Zomorodi, 2004) have shown that during a typical year, the total recharge depth from the pondto the aquifer is about 547 inches. The dimensions of the stable mound under and around the pond need to be estimated.

First, we must check the three conditions for equation application as explained under Equations 12 and 13:

1) Check $2R \leq H_i$: 2R = 50 ft which is smaller than the lower estimate of the aquifer thickness (100 ft).

2) Check i < K, the average recharge rate over a year would be 547/ (12 x 365) or about 0.125 ft/day which is smaller than hydraulic conductivity of 3 ft/day.

3) Check $2R/ H_i$: from Equation 13 the critical value of $2R/H_i$ is calculated to be 0.184. Assuming a value of at least 100 ft for the initial aquifer thickness, the value of 2R should be less than or equal to 100 x 0.184 or about 18 ft. But in our example, the value of 2R=50 ft. Therefore, if the aquifer thickness in reality is only about 100 ft, the central mound rise calculated here could be slightly underestimate. The required thickness of the aquifer for no errors would be 50/0.184 or about 270 ft. Note that in this example the value of K=

3 ft/day is relatively small. The larger the value of K the more relaxed the above restrictions would be. If K= 27 ft/day the 100 ft aquifer thickness would be sufficient for our estimates to have no errors.

The solution steps for this problem are as follows:

1. For the pond center use Equation 15:

$$H_c - H_i = 1.56\frac{i\,R}{K-i} = \frac{1.563\times 0.125\times 25}{3-0.125} = 1.70\,ft$$

2. At the pond edge where r=R=25 ft, the rise ($H_e - H_i$) can be calculated by Equation 17:

$$(H_e - H_i) = (\frac{1.56\,K}{K-i} - 0.125)\frac{i\,R}{K} = (\frac{1.56\times 3}{3-0.125} - 0.125)\frac{0.125\times 25}{3} = 1.57\,ft$$

For any radial distance from the pond center to pond edge the rise may be estimated by linear interpolation. For example 10 ft away from the pond center the rise would be about 1.64 ft.

3. For all points between the pond edge and r_{max}, apply Equation 18. For example 75 ft from the pond center (50 ft from the pond edge) the mound would be 1.28 ft as calculated by:

$$(\frac{1.56\,K}{K-i} - 0.25\ln(\frac{r}{R}) - 0.125)\frac{i\,R}{K} = \left(\frac{1.56\times 3}{3-0.125} - 0.25\times\ln(\frac{75}{25}) - 0.125\right)\left(\frac{0.125\times 25}{3}\right)$$

4. The maximum radius of influence is calculated from Equation 16:

$$r_{\max} = e^{\left(\frac{5.74\,K+0.5\,i}{K-i}\right)}\times R = e^{\left(\frac{5.74\times 3+0.5\times 0.125}{3-0.125}\right)}\times 25 = 10{,}200\,ft$$

For all distances beyond r_{max} assume no mounding. In this case r_{max} is rather large distance. Application of a groundwater recharge Software to this example also indicates very large radius of influence. Note that this is the limit of radial distance around the pond where there will be any rise. In practice, a certain amount of rise at a given distance may be acceptable. For example, suppose that the lowest foundation elevation of a proposed residential house is to be set 1 foot above the maximum water table. At least how far away from the pond center should this structure be located to keep the mound level below the foundation level? This

question can be answered by solving Equation 18 for the "r" value that would make $H_r - H_i = 1$ foot. The answer is r = 223 ft which, given the 25-ft radius of the pond suggests a minimum distance of about 200 ft between the structure and the edge of the pond. Figure 3 shows the mounding under the pond and its vicinity as calculated for this example by the new equations (due to symmetry only half of the pond and one side of the aquifer are shown).

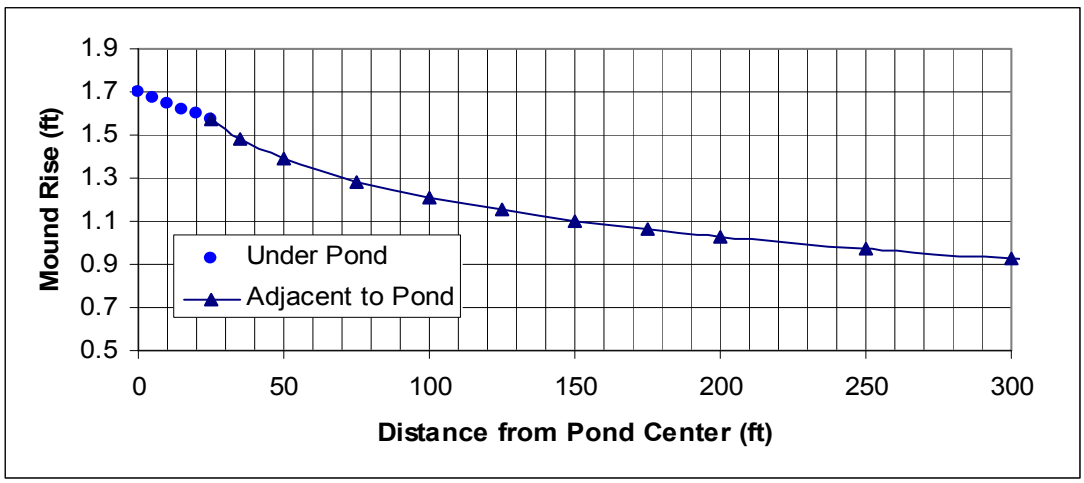

Figure 3. Mounding under the Pond of Example Calculation.

Notice that the results are sensitive to the value of hydraulic conductivity. The value of K used in this example K= 3 ft/day is expected to be exceeded in most field conditions where large scale infiltration BMPs are implemented. For example, if the value of K is increased to 6 ft/day the central mound rise drops to 0.83 ft and 223 ft from the pond center the rise would be only about 0.48 ft.

Comparison of Results with an Existing Solution

In order to check the performance of the equations derived above a couple of example cases were solved by these new equations and by the Sunada Software "Artificial Recharge" which is an artificial recharge mounding program developed by Molden et. al. (1984a and 1984-b). This software package uses the well-known analytical solution by Glover (1960) for rectangular basins. The equations implemented in this package cannot be easily solved by manual calculations. The input values and assumptions of the example calculation as laid out in the previous section were used in this comparison. Sunada Software is a specialized computer program and its use requires parameters additional to the requirements of our simplified equations. To make sure that we are solving an almost equivalent problem using both methods several provisions had to be made. While for the new equations a circular pond with a radius of 25 feet was used, in the Sunada Software

a square pond with an equivalent area of the circular pond was used. The value of transmissivity used in the Sunada Software was calculated by multiplying the K value by 2R. The Sunada Software also needed a value for Specific Yield, a parameter not appearing in our equations. For this parameter the default program value of 0.1 was used. Sunada software is provides the shape and size of the mound for various time period after a constant recharge rate is initiated. Figure 3 compares the values of the central mound calculated by Sunada (labeled Sunada K=3) as a function of recharge period in years to the central mound value calculated by the new equation. Sunada software predicts a central mound value that rises in time and for 100-years of recharge approaches the value calculated by the new equation. The central mound rise continues to slightly increase beyond 100-years but more or less stabilizes in time. The results by the two methods are also compared in Figure 3 for a K value of 6 ft/day. In this case due to larger hydraulic conductivity of the aquifer the rise of the central mound is milder. In this case, the value calculated by the new equation corresponds to the calculated central mound rise by Sunada software calculated for almost 50-years of recharge. In general, Figure 3 shows that the new equation provides a good estimate of the long-term central mound rise when compared to the results of the Sunada Software.

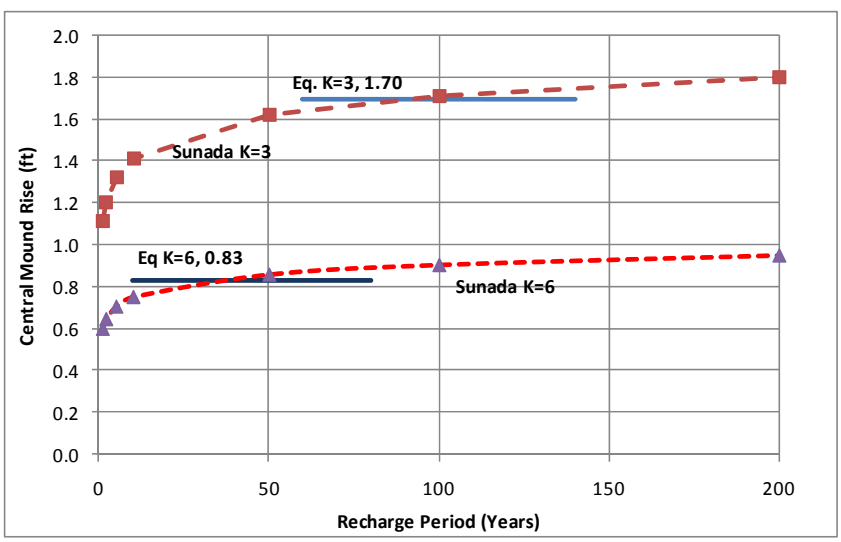

Figure 3. Comparison of the Central Mound Rise Calculated by the New Equation and the Sunada Software.

Figure 4 compares the shape of the mound calculated by the new equations to the values calculated by Sunada Software for a recharge period of 100-years. For K=3, the two sets of results are almost identical. For K=6, the new equations slightly under predict the values calculated by Sunada software but the results follow the

same shape of the curve. The values calculated by the new equations in this case more closely correspond to Sunada values calculated for 50-years of recharge.

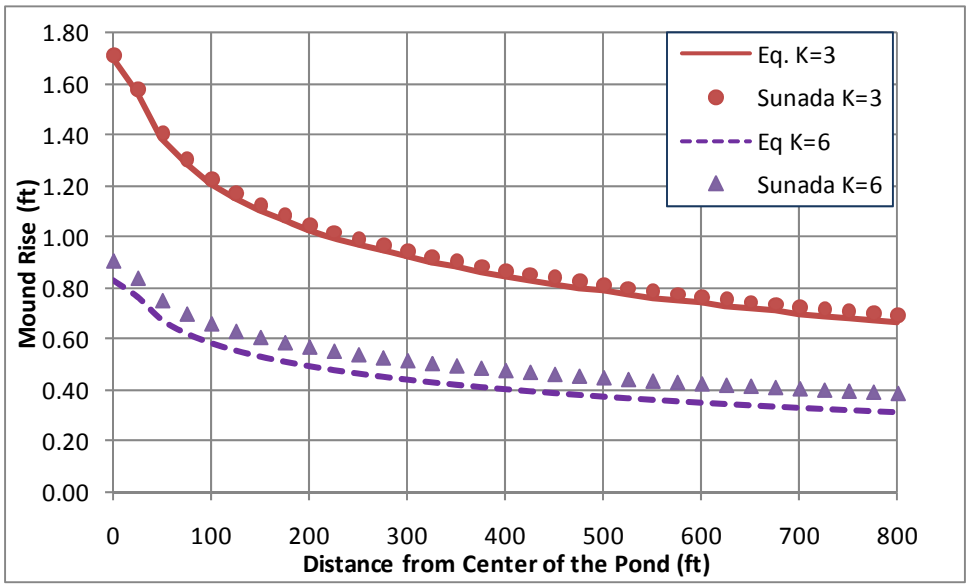

Figure 4. Comparison of the Mound Shape by Sunada Software (for 100-years of recharge) and by the New Equations.

CONCLUSIONS

The new equations developed and presented in this paper provide a simple means of predicting the rise of the groundwater mound under a round or square stormwater infiltration facility or recharge basin. The equations apply to steady–uniform recharge rate to infinite homogenous aquifers with initially horizontal water table and bedrock surfaces. The new equations require minimum input data in terms of the size and shape of the facility, the properties of the saturated layer and the recharge rate and are convenient for routine engineering calculations. Example applications of the new equation sets for conditions typical in New Jersey showed that the new equations are easy to use and provide reasonable results. The results obtained by the new equations were shown to generally agree with the results from a more elaborate analytical solution implemented in a software package.

NOTATION

The problem parameters as used in this paper are as follows:

C= a constant equal to the slope of linear relationship between $2R/H_i$ and K, (day/ft),

h’ (t)= Rise of the mound above the original aquifer thickness at time “t”, (ft),

H_C = Maximum saturated thickness (original aquifer thickness plus mound rise) under the centerline of the facility under the stable mound condition, (ft),

H_e = maximum saturated thickness at the edge of pond under the stable mound condition, (ft),

H_i = Initial thickness of the saturated layer (aquifer), (ft),

H_r= Thickness of saturated layer under the stable mound condition a radial distance "r" from the pond edge, (ft),

i = Average Infiltration from pond (assumed to be also equal to Recharge Rate to aquifer), (ft/day),

K = Horizontal Saturated Hydraulic Conductivity of the saturated layer (ft/day),

q(t)= Downward flux of groundwater at water table at time t, (ft/day),

Q'= a flow parameter that depends on the two factors of the width of the infiltration bed and the original thickness of the aquifer, (ft^{-1}),

r= an arbitrary radial distance from the pond center, (ft),

r_{max}= Maximum radius of influence of the mound beyond which mound rise is zero, (ft),

R= Radius of Pond (for non circular shapes the radius of an equivalent circle may be used for "R"), (ft).

ACKNOWLEDGMENTS

This project has been wholly funded by a 319(h) Grant to the New Jersey Department of Agriculture. The author would like to thank Mr. Charles Kuperus, Secretary of Agriculture, and Mr. Hunter Birckhead, State Erosion Control Engineer, State Soil Conservation Committee, NJDA.

ABSTRACT

The South Lake Park Bioretention Garden project consists of a survey, layout, design, and plans for parking lot reconstruction and bioretention grading and underdrain system. The layout and grading for both the parking lots and bioretention cells were challenging aspects for the following reasons: matching the existing grade for adjacent constraints, regulating the amount of water that each cell received, and taking special care to evenly distribute how the water flowed into the cells to minimize erosion and possible cell damage. Applied Ecological Services, Inc. (AES) was asked to design alternative BMPs as demonstration projects at two parks in Overland Park, KS. AES was selected because of its expertise in natural systems and ecological restoration. Understanding that failure of poorly designed BMPs has resulted in public doubts, AES anchored their design by conducting infiltration tests of engineered bioretention soils. The attention the team gave to the site layout, construction sequence, and native plant selection has lead to successful results.

INTRODUCTION

A bioretention cell is a shallow basin filled with a soil media and planted with native grasses, trees, and shrubs. Bioretention cells collect stormwater and hold it for a short period of time, allowing water to infiltrate into and be stored in the soil. The pollutants in the water are removed through various plant and soil processes. The bioretention cell design includes a subsurface perforated drainage pipe that allows subsurface drainage to flow to the storm sewer and nearby water bodies.

The project goals for the bioretention cells at South Lake Park included reducing stormwater discharge volume, improving water quality, enhancing natural beauty of park setting, and reducing erosion activity of the feeder streams and overflow channel that cause deposition of silt in the lake

The bioretention cells at South Lake Park function by retaining and treating storm runoff from the nearby roads, parking lots and buildings at the site. The site is located

south of W. 86th street and Valley View drive in Overland Park, KS. The site serves as an educational site and field experience for the community at South Lake Park and for adult education and demonstrations on the design, construction, and function of bioretention cells. The project was designed and constructed by Applied Ecological Services, Inc. an experienced ecological consulting firm that has demonstrated knowledge and skill at creating ecologically valid and functional natural wetland and native habitat areas. The education and demonstration programs will be supported by the Parks and Recreation Department of Overland Park as part of the city park system. The Parks and Recreation Department will provide appropriate public notice of the availability and opportunity of the site through their established public outreach efforts.

The site is designed as a functional natural area with locally valid ecological groupings of native plant species. Native landscape concepts will be used to demonstrate the approach to combining ecological functionality and an attractive park amenity. Design elements are included that allow public access to specific educational aspects such as particularly notable native or historic species, important or essential ecological processes of the site, or specific construction aspects that are important to successful retention and natural treatment.

INFILTRATION CAPACITY AND HYDRAULIC CONDUCTIVITY OF ENGINEERED BIORETENTION CELL SOIL

A simple benchscale study was conducted to determine the most effective soil matrix to facilitate water infiltration and permeation, as well as holding capacity, in bioretention cells and similar alternative best management practices for stormwater. There has been substantial discussion about the "best" soil mix to use in bioretention cells, including the type of material and amounts of different constituents. For this study, it was determined that an engineered soil matrix of sand and compost would be evaluated. Sand was chosen because it will not foul as a result of fine soil particles being translocated in the profile during the initial year of bioretention cell operation. Compost was selected because it increases water-holding capacity of the engineered soil and because of its nutrient holding capacity.

Methods

The benchscale study was completed using packed columns and measuring the rate of falling head of water at the top of the column. Infiltration was measured into unsaturated and saturated media, followed by measurement and calculation of hydraulic conductivity by rate of falling head into saturated media.

Sand and compost were obtained from Missouri Organic Recycling in Kansas City, Missouri, and staged in the AES workshop in separate piles. Sand and compost in mixes of 30% sand/70% compost, 50% sand/50% compost, and 70% sand/30%

compost (volumetric measurements) were homogenized in a plastic tub using a wide mixing spatula for several minutes to assure consistent media texture. After homogenizing the representative sand/compost mix, the soil media was placed into 4-inch (inner diameter) PVC pipe (27 inches long). The soil was placed in approximate 9-inch lifts and packed using a wooden rake handle before the next lift was added. The finished column was 24 inches of packed sand/compost media with approximately 3 inches (7.5 cm) of void space at the top of the column. A series of three columns was used, providing three replicates of each treatment. The PVC column was prepared prior to packing by placing screen material underlain by a paper coffee filter affixed (with rubber bands) to the bottom of the PVC pipe. After each column was packed, it was placed on an elevated holding platform, with metered collection buckets below each column. Water was placed into a graduated measuring cup in 600 ml increments. The volume of water was verified by weighing on a balance to assure 600 grams of water were placed in the cup (assuming 1 g/cubic centimeter (cc) density of water). Each 600 ml increment provided a hydraulic head of 7.0 cm at the top of the column. Infiltration was measured for movement into the dry column, and with each subsequent 600 ml increment of water, with four increments added to each column. The fourth increment of water reflected wet, and assumed saturated, conditions. The rate of falling head was measured as the time it took for water to infiltrate into the soil mix from the moment of placement into the column until the instant that no water remained on the soil mix surface.

The amount of water collected after infiltrating and passing through the column was measured for each column. After equilibration of each column after 6 hours, the amount of water collected was subtracted from the amount of water poured through the column. The packed column volume (approximately 4,970 cc) was multiplied by the calculated bulk density (see below) to obtain an approximate weight of the material in the soil column. Water holding capacity could then be calculated as the amount of water remaining in the column after equilibration (in grams) divided by the weight of the soil media in the column. The soil water holding capacity is measured as grams of water per gram of soil.

After four increments of water were added to each column and measured for infiltration, we assumed saturated conditions existed. Saturation was assumed to be achieved after water was allowed to equilibrate in the column for a period of 18 to 24 hours. To measure hydraulic conductivity in the profile as a reflection of falling head, 600 ml increments were again added to the top of each column and the rate of falling head recorded, with the first measurement being the last measurement of the infiltration tests.

To measure porosity of the soil mixes, each soil mix as packed into a 500-ml vessel (measuring cup). The packed cup was weighed, and the weight of the empty cup was subtracted to obtain the weight of the soil mix. Bulk density of the sand/compost mix was calculated as the weight of the soil media divided by 500 ml (or cc's) to obtain an approximate density measurement of the engineered soil. This value was used for estimating water holding capacity.

Water was slowly added to the packed soil mix, allowing time for displacement of gasses and saturation of the soil pores. Trapped air was removed by repeatedly inserting a narrow rod into the mix to release gasses. After the saturated soil mix was allowed to equilibrate, the soil/water weight was measured. The weight of the water equals the weight of the soil/water mix minus the weight of the soil mix and cup. Because water density is assumed to be 1.0 gm/cc, the volume of pore space was assumed equal to the weight of the water in the soil mix, and measured as cc per cc of soil, or as a percent of the soil volume.

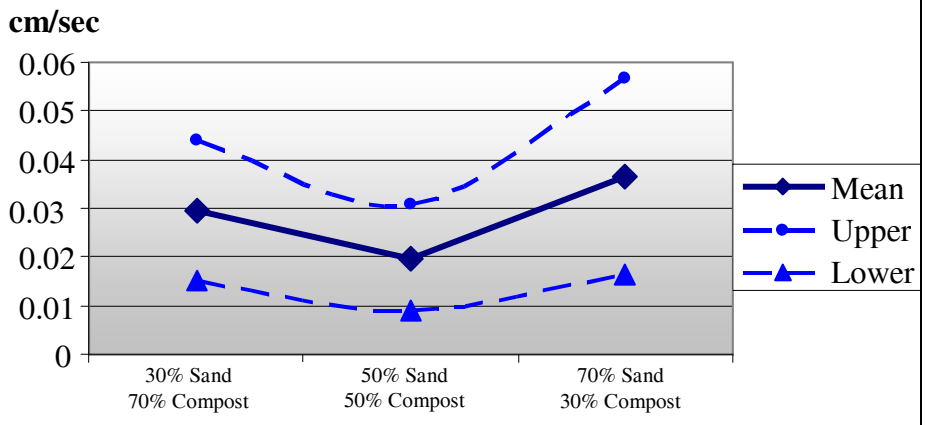
Results

Results of the benchscale study are summarized in Table 1. A discussion of the measurements of each of the parameters examined is provided below.

Table 1: Mean Values for Measured Soil Parameters

	30% Sand 70% Compost	50% Sand 50% Compost	70% Sand 30% Compost
Water Holding Capacity (gm water/gm soil)	0.18	0.14	0.18
Soil Bulk Density (gm/cc soil)	1.15	1.30	1.26
Porosity (percent)	35	35	30
Infiltration Rate (cm/sec)	0.029723	0.019821	0.03663
Hydraulic Conductivity (cm/sec)	0.006459	0.007693	0.009599

Water Holding Capacity and Bulk Density



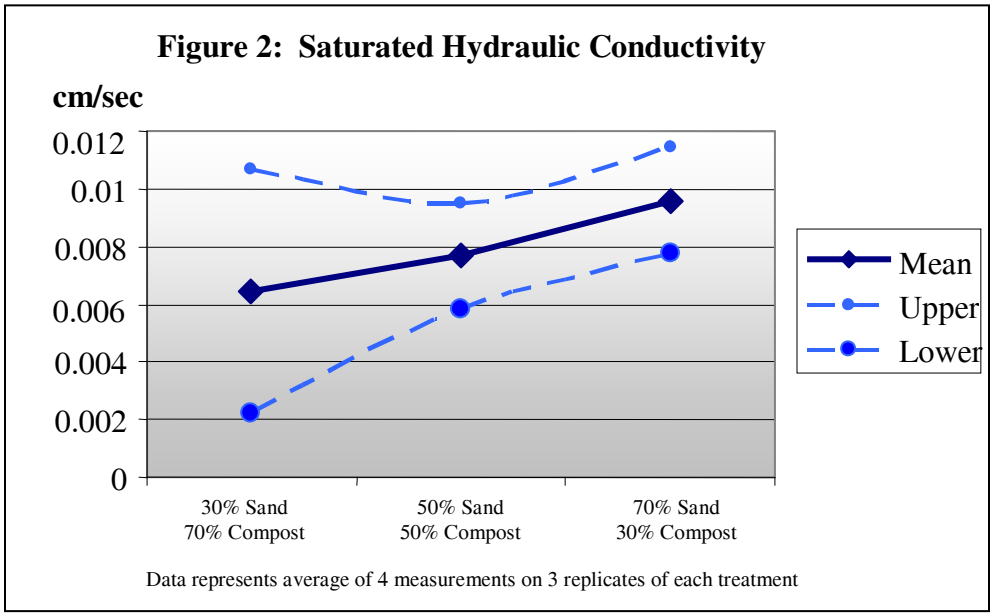
The calculated water holding capacity of the soil mixes appears to be reasonably consistent between all soil mixes, ranging from 0.14 to 0.18 gm water per gram of soil. The lower water holding capacity in the 50% sand/50% compost mix should not be interpreted as indicative of conditions, and more data is necessary to determine the true water holding capacity of these soil mixes.

Bulk density was measured and estimated to aid in determining the water holding capacity of the soil mixes. As with water holding capacity, the bulk density appears to vary little, with the lowest density being in the mix with 70% compost, as would be expected. Variability in the degree of packed media in the columns and in other vessels probably contributes to the relative uniformity in the data.

Infiltration Rate

Infiltration rate, from the measurements collected, projected a trend as demonstrated in Figure 1 (with upper and lower standard deviations). Figure 1 demonstrates relatively consistent infiltration of water into each of the soil mixes, with slower movement into water into the 50% sand/50% compost mix.

Figure 1: Infiltration Rate into Sand/Compost Soil



Data represents average of 4 measurements on 3 replicates of each treatment

The decrease in infiltration rate in the 50/50 soil mix appears to be a function of the higher bulk density and lower water holding capacity, indicating greater compaction for this treatment Overall trend, if this would be examined as a linear regression, would indicate relatively uniform infiltration, with a slight upward capacity with increased sand content. On the whole, the expected infiltration rate of water into any of the sand/compost mixes would be expected to be between 0.02 to 0.04 cm per second. The data of first infiltration measurements into the dry soil mixes indicates that infiltration is expected to be between 0.03 to 0.06 cm per second when the soil mix surface area is dry.

Hydraulic Conductivity

Hydraulic conductivity, from the measurements collected, projected a trend as demonstrated in Figure 2 (with upper and lower standard deviations). Figure 2 displays a more notable trend of water movement through the soil, with increasing movement of water through the mix with increasing sand content.

The upper and lower standard deviations of the data indicate more variability in hydraulic conductivity measurements with the increased amounts of compost (treatment 1). This is not unexpected, as increased compost will likely have more varied density depending on the degree of packing into the columns. This may be reflective of what could also occur under field conditions.

Summary

The benchscale measurement of water infiltration into and hydraulic conductivity through engineered soil provides a preliminary indication of expectations of flow dynamics for bioretention cells and similar stormwater best management practices. In general, with a sand and compost mix for the treatment media of bioretention cells, movement of water through the cell can be expected to be at a rate between 0.006 and 0.01 cm per second (6×10^{-3} to 1×10^{-2} cm per second) under saturated conditions, and faster under dryer conditions.

Because of the apparent relative uniformity in the data, with a trend of increasing hydraulic conductivity with increased sand content, it would be appropriate to recommend that a moderate approach be utilized for obtaining the appropriate sand/compost mix for the design of bioretention cells. Therefore, from the data obtained, it is appropriate to designate a soil mix of 50% sand and 50% compost for the bioretention cell. The 50/50 sand/compost mix offers the most positive attributes of both the sand and the compost by providing adequate infiltration of water through the bioretention cell, good water holding capacity, strong nutrient holding capacity in the compost, and a very good root-growing medium. Too much compost in the mix (such as at the 70% level) could result in excessive subsidence as compost decays.

Too little compost (such as at the 30 % level, or less), may not provide adequate water holding and/or nutrient holding capacity, and water treatment through biological actions, as desired for the treatment unit.

DESIGN AND CONSTRUCTION

Site Inventory and Analysis and Infrastructure Design Support

AES staff and associates prepared basemaps including all applicable and available site information for use in constructing the selected BMPs. Available topographic surveys, boundary surveys, and park layout were compiled in AutoCAD format. AES's ecological site design team visited the site to become familiar with the opportunities and constraints of the specific property and to become familiar with its surroundings. An AES soil scientist conducted a preliminary soils assessment and survey to determine the appropriateness of certain native plants and sustainable stormwater elements. Compilations and conclusions were documented for use in site design.

AES received technical support from BHC Rhodes for the design of the parking lot and associated infrastructure in consideration of elements that could affect the bioretention cells.

Initial Planning Meeting and Design Charette

An initial planning and concepts meeting was held to start the project work. The meeting was necessary to finalize contracts, clarify tasks and schedule, obtain any additional data, and begin the project coordination process. The Design Charette was an interactive, collaborative process with the goal of achieving a consensus schematic/conceptual design. Participants included members of the design team, BHC Rhodes, the Owner, and appropriate City personnel.

Preparation of Conceptual Landscape Plans

AES refined schematic drawings of recommended design solutions developed during the charette process and prepared Draft Conceptual Plans for the bioretention cell, including soil treatment, planting areas, stormwater flow, and other elements. The Draft Conceptual Plan consisted of a plan view drawing of the bioretention cell layout and surrounding park areas and features, and was presented to BHC Rhodes for review, input, and approval. A memorandum describing project elements, a Conceptual Plant List, and Conceptual Opinion of Probable Construction Cost was prepared for dissemination with the Draft Conceptual Plan. AES incorporated BHC Rhodes comments into the plan for presentation to the City. AES incorporated revisions requested by the BHC and the City to create an approved Final Design Documents.

Design Documents

AES prepared the design documents defining the improvements shown on the Draft Conceptual Plan in sufficient detail to obtain City approvals and proceed with project implementation. The following documents were provided by AES:

Design Drawings: AES prepared five sets of design drawings for use in permitting and construction that included: summary sheet, design plan, planting plan (Figure 3), erosion control plan, and construction details.

Specifications: AES staff prepared specifications to supplement and clarify the design drawings as necessary for communication to the General Contractor, any subcontractors, and to the City for necessary approvals.

Opinion of Probable Construction Costs: AES staff prepared a final Opinion of Probable Construction Cost for the proposed design.

Design Calculations: AES staff reviewed and incorporated engineering calculations demonstrating stormwater runoff and water quality improvements for City approvals.

PROJECT APPROVALS, PERMITTING, AND MEETINGS

AES prepared necessary ecological, environmental, and stormwater management regulatory submittals and secured project approval from the City of Overland Park and other governing agencies. These included stormwater management permits and approvals, water quality certifications, and erosion and sedimentation control plans, among others. BHC Rhodes kept abreast of requirements and progress. The City had a standard permit guidance and format that was closely followed for this process, and permits were completed with minimal comment from the City.

Participation in public meetings helped to educate locale public offices, residents, neighbors, etc. on the project design, methods, and philosophy. This proved to be very effective in alleviating public discontent and dispelling misconceptions.

CONSTRUCTION OVERSIGHT

AES oversaw construction of the final design. Complexity of the final design determined the Lead Designer's involvement in construction observation. However, construction oversight required that an AES restoration supervisor to visit the site daily during construction to review progress and conduct construction quality assurance. Construction quality assurance was necessary to verify that the design was being built and vegetation established according to design specifications. During each site visit progress was examined, quality of workmanship and materials was evaluated, and a CQA checklist was completed.

CONSTRUCTION AND FUNDING

AES completed these projects as design-build programs. The contracting division of AES provided constructed bioretention garden cells as specified in the design plans and specifications. Funding for the project included a City of Overland Park & Johnson County Stormwater Management Advisory Council (SMAC) Partnership, a research and development grant to evaluate BMP performance for the region, and a cost share for design construction and monitoring – SMAC 75% City 25%.

EDUCATION PROGRAMS AND OUTREACH

The City Parks and Recreation Department will provide the resources for maintaining the site and accommodating tour groups and education classes. Announcements of the availability of the site appeared in school resource materials, city catalogs, activity calendars and other public information materials. Coordination and response to requests for field trips, tours, workshops and other educational experiences was provided as needed. The site will be maintained as an educational area that is safe, has informative signs in place, and displays healthy natural elements.

CONCLUSION

AES successfully designed a series of bioretention gardens as alternative stormwater best management practices (BMPs) for reducing peak stormwater discharge and creating ecologically functional units that sustain native habitat. These biorention cells also allow some of the stormwater to infiltrate and recharge the natural water cycle. A measure of success of the project is that the community of Overland Park, KS appreciates the site for its benefits to the environment. It continues to serve as a local example of a successful bioretention cell.

State of the Practice of Wet Weather Flow Analysis

Mitchell Heineman, P.E., M. ASCE, D.WRE

CDM, 50 Hampshire Street, Cambridge MA 02139; HeinemanMC@cdm.com

ABSTRACT

Engineers analyze wet weather flow in collection systems using a variety of computer tools and analytical techniques. Tools and data available for performing these analyses have greatly advanced since software for this purpose was first standardized in the 1970s. The practicing engineer today has access to GIS-based modeling software, high-resolution land cover and elevation datasets, and enormous hydrologic databases. Methods used for typical engineering work have advanced quite modestly by comparison. Furthermore, there is little standardization of how analyses of drain, combined sewer, and sanitary sewer collection systems are carried out, despite considerable commonalities among their wet weather performance.

This paper reviews the state of the practice of collection system modeling, considering software availability and selection, model complexity, calibration criteria, and simulation methods. Urban modeling protocols for drain, combined, and sanitary sewer systems are discussed. Uniform approaches for model calibration are suggested. Finally, the paper identifies research and development needs where the state of the practice is limited by current technology.

INTRODUCTION

Engineers analyze wet weather flow in collection systems using a variety of computer tools and analytical techniques. Tools and data available for performing these analyses have greatly advanced since initial development of software such as USEPA's SWMM and USACE's HEC models in the early 1970s. Today's engineer has access to GIS-based modeling software, high-resolution digital land cover and elevation datasets, and enormous precipitation, streamflow and groundwater databases. However, methods used for typical engineering work have advanced quite modestly by comparison. There is little standardization of how analyses of drain, combined sewer, and sanitary sewer collection systems are carried out, despite considerable commonalities among these systems in wet weather performance.

Analysis of existing collection systems today often uses dynamic models, but construction and application of these models remain rooted in historic methods which were constrained by limited flow data availability and computer resources. Many models are still developed with minimal calibration and validation datasets, only weakly emulate key components of system hydrology, and are applied with design

storms that do not represent local meteorology and bear limited statistical relevance to design standards they are intended to inform. The UK *Wastewater Planning Users Group Code of Practice for the Hydraulic Modelling of Sewers* (2002) defines standards for model calibration and verification that are rooted in an historical approach where it was not practical to simulate more than a few storms. USEPA's *Combined Sewer Overflows: Guidance for Monitoring and Modeling* report (1999) states little more than that, "…calibration and validation are frequently done with two to three storms each."

Whereas urban runoff models originally focused on combined sewer overflows and drain system flooding, sanitary sewer systems are now a principal focus of many studies, and key components of most combined sewer studies. Various methods have been identified to simulate sanitary sewer rainfall-derived infiltration and inflow (RDII), such as described in Bennett *et al.* (1999), and recently discussed by Lai (2008). However, the state of practice generally remains based in event simulation, whereas RDII in many sewer systems depends on longer term processes that are only well-represented via continuous simulation.

This paper reviews the state of the practice of collection system modeling with regards to software availability and selection, model complexity, calibration criteria, and simulation methods.

MODEL SELECTION

Engineers today are faced with many choices in software selection. While good engineering design should not depend on computer software choices, the software used has important implications for the engineering approach ultimately used and the design of facilities.

Two important distinctions affect software selection and, ultimately, facilities design. First, available software is generally segregated into steady state versus dynamic models. Second, for dynamic modeling, some engineers favor design storm analysis while others favor multi-storm and/or long-term analyses. A third, lesser distinction, also divides collection system modeling software and engineers: some software packages are linked to CAD programs and environments, some to GIS software/environments, and some use schematic or non-visual interfaces.

Many state-of-the-art wet weather flow analyses use dynamic collection system modeling software. However, many engineers use steady-state analyses, as this is a common norm and software for these analyses are generally easy to use. Typically, new sewer and stormwater systems designs are based on steady-state models; engineers plan systems that conform to a standard based on peak runoff and/or inflow/infiltration rates. These rates are typically driven by local or state guidelines that dictate use of a peak runoff rate determined using rational method or comparable methodologies.

Dynamic collection system modeling for analysis of combined and sanitary sewer systems in the US commonly uses models based on USEPA SWMM, Wallingford Software's InfoWorks CS, or DHI's MIKE URBAN CS. InfoWorks is a comprehensive package that uses its own proprietary modeling engine and GIS. Its beginnings date to 1980, corresponding with development of the UK Wallingford Procedure. MIKE URBAN CS is a GIS-based modeling framework built around MOUSE. MOUSE was developed by the Danish Hydraulic Institute (now DHI Water & Environment) in 1983. MIKE URBAN also supports SWMM 5 within the same interface.

SWMM was first released in 1971. It was completely reprogrammed by USEPA in 2004. SWMM 5 is available free from EPA, or via commercial packages that incorporate it in various ways. Vendors offering products built around SWMM 5 include Bentley Systems (SewerGEMS and CivilStorm), BOSS International (StormNET), Computational Hydraulics International (PCSWMM.NET), DHI (MIKE URBAN), and MWHSoft (InfoSWMM and H2OMap SWMM). Additionally, XP Software offers xpswmm, which was derived from USEPA SWMM 4 in the 1990s. InfoWorks incorporates algorithms adapted from SWMM 4 among its various hydrologic methods. While all the dynamic models can model single storms or continuous simulations, the ease and speed of performing long-term or multi-storm simulations differs greatly among packages. Similarly, there is a wide range of connectivity and interoperability with CAD and GIS among these programs.

MODEL COMPLEXITY

Until early in this decade, computer models of existing urban sewer systems were typically built by assembling design drawings, record drawings, and sewer maps and then digitizing critical data into text files. This approach, combined with limitations on computing power, necessarily yielded parsimonious models that incorporated the minimum detail needed to reasonably model collection systems. Today, many existing systems models are developed in part from GIS collection system asset databases. This shift, combined with greatly increased computing power, has resulted in many models being built with much higher levels of detail. Whereas a decade ago, a one thousand pipe model was considered large, collection system models with many thousands of pipes are now becoming common.

There is a strong drive to implement models that bear close resemblance to their prototype systems. However, growth in model size has not been matched by corresponding growth in the use of models to perform long-term simulations, or process model sophistication. The design storm approach, coupled with simple surface hydrology, remains favored by most engineers for facilities analysis and design.

The balance between model network realism and parsimony is driven in part by vendors touting their software's ability to store large databases and run faster than competitors' products. There remains a significant gap in the demonstrated accuracy

of models as a function of their level of detail, and there is little movement or understanding of the use of approaches that require more than single storm simulation for facilities analysis.

Model complexity has also grown in recent years, although many models today still omit processes that may be of considerable import in identifying engineering solutions. Many dynamic sewer models traditionally focused on simulating inflow peaks and, to a lesser extent volumes, during and immediately after rainfall. Sanitary flows were often modeled as an averaged constant, and minimal attention was paid to infiltration and baseflows, which have lesser bearing on management of peak inflows. Today's more powerful computers and database management tools facilitate detailed simulation of wastewater flows. Many engineers now model diurnally varied flow, as this is relatively easy to specify, and bears directly on calibration of dry weather flow. However, little attention is devoted to understanding and simulating sewer and drainage baseflows; these flows are beyond the scope of existing calibration standards, and have a less recognized bearing on facilities design for peak flow management. While the major dynamic collection system models can simulate pipe infiltration and stream baseflow as a function of groundwater conditions, few models are built that account for this major contributor to the overall water balance in many collection systems.

CALIBRATION CRITERIA

Standards for collection system model calibration differ widely and generally lag the modeling state-of-the-art. USEPA's 1999 *Combined Sewer Overflows: Guidance for Monitoring and Modeling* report states little more than that, "calibration and validation are frequently done with two to three storms each." The UK Wastewater Planning Users Group (WaPUG) *Code of Practice for the Hydraulic Modelling of Sewers* has clearly defined standards for model calibration and verification, but these standards are rooted in an historical approach whereby it was not practical to simulate more than a few storms. Whereas the WaPUG standards identify acceptable tolerances for calibration to two days of dry weather flow and three wet weather events, it is today practical to calibrate models to much broader datasets. Temporary flow metering programs accompanying model development typically are deployed for three months, while many cities now have long-term sewer metering data that may be available for a year or longer. Long-term urban drain system metering is less widely available than sewer system data, but numerous local studies exist, as do extensive long-term USGS streamflow records.

Some US communities and regulatory agencies today refer to the WaPUG standards when identifying criteria for model calibration. However, these standards are primarily appropriate for traditional CSO (combined sewer overflow) studies, and lack relevance for SSO (sanitary sewer overflow) or stormwater studies. Even for combined systems, the WaPUG guidelines are inadequate for evaluating calibration of models to the large datasets and broadly scoped models that are now being routinely developed.

The WaPUG guidelines identify criteria for model calibration based on:
- two days of dry weather
  - timing of peaks and troughs
  - peak discharge
  - flow volume
- wet weather calibration to three events
  - timing of peaks and troughs
  - peak discharge
  - flow volume
  - surcharge depth
  - unsurcharged depth at key points

Given the many advances in computing technology since the initial version of these criteria was promulgated in 1993, it is appropriate that more rigorous standards be developed today. Some areas for consideration include:
- dry weather flow calibration to two seven-day periods
- dry and wet weather velocity
- comparison of volumes, peak discharge, peak velocity, and peak depth for all storms over an extended flow metering period
- if seasonal baseflows variation is modeled, it should be measured via assessment of discharge distribution frequency
- for combined sewer systems, models should be calibrated to long-term records of overflow frequency
- for all sewer systems, models should be checked against long-term treatment plant flow records
- conformance of calibration to statistical goodness-of-fit criteria
- sensitivity and uncertainty analysis

DESIGN SIMULATIONS

Design storms. Despite the exponential growth of computing power, single design storms remain a primary basis for many facilities studies. Synthetic design hyetographs using standard distributions are commonly used for facilities assessment. Hyetographs developed following the NRCS (formerly SCS) TR-55 methodology (Natural Resources Conservation Service, 1986) are often used in US rainfall-runoff modeling. NRCS hyetographs are 24-hour events that exhibit nearly the same recurrence frequency at all durations. Thus a 10-year NRCS storm ideally nests a 10-year 15-minute rainfall within a 10-year 24-hour depth. Since only four hyetograph shapes identified for the entire United States, NRCS hyetographs only approximate this ideal in many locations.

NRCS-type hyetographs have several limitations that restrict their applicability:
- NRCS hyetographs are not realistic in locations where short-duration convective storms cause short duration extrema whereas long-duration cyclonic storms drive long-duration extrema

- NRCS hyetographs are centrally peaked, whereas extreme rainfall is typically front- or back-loaded in many locations
- An n-year rainfall likely does not yield an n-year runoff response. This is especially true where baseflow is important, such as in sanitary sewer systems where seasonal infiltration can contribute as much excess flow to a system as direct inflow.
- Synthetic hyetographs are more difficult to explain to the public than historic events.
- In some areas and for certain types of facilities, a 24-hour storm may not be sufficiently long to analyze performance
- Single event analysis does not consider effects of consecutive storms
- In tidally-influenced areas and other locations where a time-varying tailwater condition must be considered, the modeler must develop an appropriate tailwater to accompany the design storm that yields the intended recurrence frequency

The use of synthetic hyetographs shapes other than NRCS can mitigate or eliminate some of these restrictions. Use of selected historical storms as design events potentially offers several advantages, but poses its own difficulties. For example, data analysis identified 21 storms in Norfolk, Virginia from 1948 to 2006 that were a 5-year or larger event at three or more durations at select durations from 1 to 96 hours. For a study where 5-year, 10-year, and 25-year storms were needed for design analyses, one possible solution would be to select the 15 June 2001, 23 August 1990 and 27 July 1969 events listed in Table 1 to represent the respective recurrence periods. While the 1990 storm is larger than the 2001 storm at nearly all durations, and the 1969 storm is similarly generally larger than the 1990 storm, none of these events conforms to the characteristic return period across a range of durations.

A further limitation is encountered when applying a single hyetograph over a large area. Proper correspondence of areal total rainfall with return period may require substantial reduction of the rainfall totals, with differing reduction factors applied at different durations, as discussed by Huff and Angel (1992).

Table 1. Norfolk, Virginia rainfall depths for select storms

Date	1-h	2-h	3-h	6-h	12-h	24-h	48-h	96-h
27 July 1969	2.9	3.5	3.8	4.2	4.7	5.6	6.7	7.8
23 August 1990	1.7	2.8	3.5	4.2	4.3	4.3	4.7	5.0
15 June 2001	1.1	2.1	3.0	3.7	4.1	4.4		
25-year depth	2.8	3.6	3.9	4.8	5.7	6.8	7.8	8.4
10-year depth	2.4	3.0	3.2	3.9	4.7	5.5	6.3	6.9
5-year depth	2.0	2.5	2.7	3.2	3.9	4.6	5.3	5.8

Frequency estimates from "Precipitation-Frequency Atlas of the United States" NOAA Atlas 14, Volume 2, Version 3 reported for Virginia 36.872 N 76.209 W (Norfolk)

Other constraints challenge modelers when selecting design storms:

- In many parts of the US, 1960s and 1970s-era rainfall atlases remain the official National Weather Service precipitation frequency publications. These atlases are based on much more limited datasets than are now available
- Rainfall atlases usually assume stationarity of datasets. Collection system planners should ideally incorporate climate change uncertainty into their designs.
- Most rainfall atlases do not report precipitation estimates for recurrence intervals shorter than one year, while some facilities designs, such as for combined sewer overflows, must examine performance in more frequent events

Event versus continuous simulation. Approaches used for assessing collection system performance differ widely. Many sewer and stormwater design studies evaluate steady-state peak discharge only. This approach is common for design of new sewer and stormwater development and for flood studies. Many large-scale urban collection system analyses use single event design storm approaches. Representative, or "typical", year simulations are used for some urban combined sewer systems, while five-year simulations have been used in other studies. True long-term simulations are rarely used. An approach where select large storms are simulated and performance statistics tabulated from model results offers many advantages for extreme event analysis, but is not commonly used.

Steady-state peak discharge computation remains the most common basis for designing new sewer and drain facilities. This approach has the advantage of simplicity, but typically yields more conservative (i.e. larger) facilities design than would be obtained from dynamic simulation. Steady state analyses can be performed using a wide variety of spreadsheet methods and software.

Single-event design storm simulations using a dynamic collection system model can today be performed on very large models with most of the complexity of the prototype system incorporated into the model. This approach remains limited in that it may not yield a design flow commensurate with the intended recurrence frequency. It is further compromised where factors other than rainfall-driven inflows, such as infiltration or tailwater, affect system performance.

Representative year simulations have been used in many communities to assess combined sewer overflows. Some investigators use historic precipitation data directly, while others adjust historic data by adding and removing events to obtain a record closer to a statistical ideal (Tsay *et al.*, 2007). The representative period may be one year or a longer period such as five years. When true historic data are used, this approach can be used realistically in conjunction with other environmental data. Examples of these situations are where a large river influences local system hydraulics but is statistically independent of the local system, or where temperature data is used to simulate snow processes. When complex collection system models are used, representative year simulation is restricted by limits on computing power and speed, computer storage capacity, and post-processing of large datasets. InfoWorks and MOUSE have built-in functionality for speeding long-term simulations and

controlling output size; SWMM has no comparable inherent capabilities, although some vendors have added some functionality in this area.

A one to five year representative period simulation is useful for combined sewer system analysis, where design criteria have return periods of one year or less; it has limited use for analyzing system performance in extreme events. Selection of a representative period from a long precipitation record requires considerable analysis, although the process becomes less critical as longer representative periods are used (Yeboah and Heineman, 2004).

True long-term simulation relies on the availability of long-term precipitation data. Most major US airports today have continuous digital hourly datasets dating to 1948. This enables statistically robust assessment of system performance for events with recurrence frequencies of 5 to 100 years. There are important constraints limiting adoption of long-term simulation:

- There is minimal demand for its use; most communities and regulatory agencies accept and understand the use of design storms for facilities planning
- Long-term simulations using complex models strain computational resources and are time-consuming to analyze
- Many engineers are not familiar with appropriate statistical techniques for assessing system performance based on results from long-term simulation
- Most collection system models omit seasonal and long-term variability; results from short simulations of select storms thus yield the same results as true long-term simulations

Long-term simulations are especially useful for extreme event analysis (e.g. flood or SSO) where the extreme events cannot be identified *a priori*. Thus, in a sanitary sewer system that is equally influenced by both rainfall-driven inflow and groundwater-driven infiltration, which is in turn controlled by long-term precipitation, it may not be possible to identify the most extreme events in a long record other than by simulation. Long-term dynamic collection system simulations may be performed by reducing model complexity. This can be achieved by, for example, simplifying the collection system, simulating rainfall-runoff without conduit hydraulics, or using a simpler model such as STORM (Heineman, 2004).

Many of the benefits of long-term simulation can be achieved by identifying select large rainfall events and developing statistics for those select events. For instance, a facilities design for 10-year performance could be developed from a 50-year precipitation record by simulating 20 pre-screened storms expected to yield the largest responses and identifying the conditions which fall at a 10-year plotting position (approximately the fifth largest event in the 50-year record) or along a fit of the results to a log-normal or other appropriate statistical distribution. InfoWorks and MOUSE have built-in capabilities for performing the batch-type simulations needed for this type of analysis; some of the commercial SWMM packages have similar capabilities.

Use of long-term simulations must be based on quality datasets. Where precipitation is the only external data, good long-term datasets are available for major US cities. However, these datasets must be assessed for stationarity and evaluated against potential climate change impacts. Similar attention must be paid to other external boundary data such as temperature and river and ocean levels.

RECOMMENDATIONS

While it is the engineer's responsibility to select appropriate software and engineering methods, there is little formal guidance available for design of collection system modeling studies. WaPUG's standards are somewhat dated and are primarily oriented towards combined systems. New standards that address all types of urban collection systems and consider the range of available datasets will help align contemporary studies with current technology.

USEPA SWMM is the most commonly used model for US dynamic collection system modeling. While SWMM was originally designed for combined sewer systems, it has long been used for sanitary and stormwater system analysis worldwide. The hydraulic aspects of SWMM have continually evolved throughout its history, and are much stronger in SWMM 5 than in older versions. However, the model's hydrology is constrained by limited scientific inquiry and by a lack of demand for more rigorous approaches. Some areas where the model's hydrology could be improved are listed below.

- The groundwater infiltration module works well for natural streams. It is usable for simulating pipe system infiltration, but does not simulation a complete sub-surface system where groundwater can enter pipes and streams or flow laterally.
- Raster-based drainage models have been developed, but have had limited application to urban collection systems. The catchment and inlet paradigm used in SWMM, InfoWorks, and Mouse works at many scales, but advances in computer technology warrant re-assessment of runoff simulation fundamentals.
- SWMM 5.0.14, released in January 2009, implements a seasonal soils recovery parameter that has not been experimentally tested. SWMM's surface infiltration models were originally designed for single event analysis, and were later modified for continuous simulation. They have not previously been adapted to simulate seasonal variation in infiltration processes.
- SWMM's surface water and groundwater components are not well-coupled. While surface water infiltration influences groundwater conditions, the water table has no impact on surface infiltration.
- SWMM's process models were not designed to simulate the complexity of sanitary sewer RDII processes. These processes are generally simulated by manipulating the process models in ways that make it difficult to translate field data into model parameters. For instance, representing sump pumps in SWMM requires either considerable aggregation and many assumptions or a highly detailed model.
- The principal dynamic collection system models are deterministically driven by rainfall. Adding a stochastic component to runoff hydrology or to dry weather

flow processes may yield more realistic models in some cases. This may be especially valuable in sewer systems with minimal RDII where random wastewater load variation is a significant stressor.

This paper has reviewed current practice in urban collection system modeling, identifying the state-of-the-art, opportunities for standardization, and research needs. The currently strong national interest in civil infrastructure projects creates an opportunity to address the issues associated with the advanced age of many US urban collection systems. Modest investment in research and development of updated guidance protocols for this field will yield great return in the value of the models used for urban facilities planning, improving the science of collection system modeling and yielding strong returns in reliable public works.

The application of Environmental Site Design Processes to design a residential subdivision

Steven D. Trinkaus, P.E., CPESC, CPSWQ; Trinkaus Engineering; Southbury, CT

ABSTRACT:

Strategies of Low Impact Development (LID) are best known as alternative treatment systems to reduce the impact of storm water runoff on the environment. A more important aspect of LID is the implementation of Environmental Site Design (ESD). ESD is a design process to evaluate the environmental conditions on a parcel of land prior to the creation of a land development project. This process is most important for residential developments. While ESD can work with any land use regulations, the most environmentally sound developments will occur in those communities, whose land use regulations that permit "cluster" or "open space" designs.

This paper will explore the strategies and steps necessary to create a residential subdivision utilizing ESD.

THE KEY CONCEPTS OF ENVIRONMENTAL SITE DESIGN:

The strategies of ESD are designed to achieve certain benchmarks during the development process for all types of development. The overall benchmarks are as follows:

a) Establish Increased on-site recharge rates and Volumetric Reductions for Runoff,
b) Establish Nutrient-Based Storm water Loading Criteria,
c) Conservation of Forest Area,
d) Protect wetlands, watercourses, including zero-order streams and provide minimum width buffers for these systems,
e) Map and preserve the most permeable soils on the site,
f) Utilize Site Fingerprinting and define maximum limits of site clearing,
g) Utilize well defined and effective construction phasing plans,
h) Utilize decompaction and reaeration of soils following the construction period to restore infiltrative capacity.

For lower density development, the following are additional benchmarks for the application of ESD:

a) Allow the cluster or open space designs that reduce lot sizes in exchange for the conservation of natural areas,
b) Reforest turf areas to maximize area covered by tree canopy,
c) Conserve forests, wetlands and other natural areas with a goal of 65% of the site area being preserved,
d) Utilize restrictions on clearing and grading, implement filter strips and natural vegetation to disconnect impervious areas,
e) Maximize controlled sheet flow to naturally-vegetated area,
f) Limit residential street width to 22',
g) Disconnect rooftop runoff and direct to rain gardens, cisterns or filter strips,

h) Keep total site imperviousness to 10% or less. Design drainage systems to prevent direct connections to streams from the impervious areas,
i) Consider alternative road design standards to facilitate the use of grass swales in lieu of conventional curb/gutter systems.

ZONING REGULATIONS:

In this particular community, the zoning regulations permit Open Space subdivisions by Special Permit under Section 4.3 – OPEN SPACE SUBDIVISIONS. The goals of this regulation are as follows:

a) Permit flexibility in land development by allowing fro a variation in the lot sizes in all residential zones except R-4 without increasing the density permitted with the zone in which the property is located,
b) Provide open space, conservation and recreation areas (both active and passive),
c) To the extent practicable, preserve the natural and scenic qualities of the site and its surrounding neighborhood, including wetlands, watercourses, ridge tops, existing stands of mature vegetation, rock outcrops, scenic and historic sites,
d) Protect water quality, natural drainage systems and areas affording housing in conformance with the policies set forth in the plan of development.

SUBJECT PROPERTY:

The subject property comprises 104.5 acres and is located on the east side of Platt Hill Road, west and significantly above Highland Lake in Winchester, CT.

THE PROCESS OF ENVIRONMENTAL SITE DESIGN:

The following are the steps necessary to obtain the base mapping to create a residential subdivision using ESD:

1) Obtain field delineation of inland wetlands and watercourses on the site by a Certified Soil Scientist. In Connecticut, wetlands are solely determined by the presence of low chorma coloring within the upper 20" of the soil. The soil scientist will also approximate the boundaries and types of upland soil types on the site. These boundaries are typically sketched on a preliminary map of the site.
2) Obtain a boundary survey of the site along with the field location of all delineated inland wetlands and watercourses.
3) Obtain a topographic base map of the property based upon current aerial photographs which will provide existing contours at a 2' interval.
4) Investigate the presence of 100-year flood boundary limits on the site from the available mapping by the Federal Emergency Management Agency (FEMA).
5) Obtain an inspection of the site by an environmental consultant to determine the presence of vernal pools or other high quality wetland/watercourse areas.

Create an initial base map showing the information obtained above. This base map is used to begin the site assessment/analysis process.

A. Soils: Utilize local soil manuals or information from National Resource Conservation Service (Website: www.websoilsurvey.nrcs/usda.gov/app/) to determine the range of infiltration rates for soils on the site. Highlight those soils with the highest infiltration rates on the plan. Test pits may be necessary to verify the location of the infiltrative soils on the site.

Hydrologic Patterns: Determine watershed boundaries on the site tributary to wetland or watercourse systems. Verify in field if necessary.

Vegetation: Determine and highlight different types of forest cover.

Wetland/Watercourse/Floodplains: Determine on the map those wetland areas which are of high quality or possess unusual biological habitat.

Slopes: Determine all slopes on the site in excess of 25% and highlight on plan.

ACTUAL SITE FOR ESD ANALYSIS:

The site contains 104.5 acres and was farmed until the mid 1950s'. Wetlands were delineated by soil scientist. There are three intermittent stream/wetland corridors and a large Red Maple Swamp. Two isolated wetland areas were determined to be small vernal pools by environmental consultant.

The majority of the soils on the site are Paxton and Woodbridge. There are two large areas of Charlton soils as shown. While the soil permeability of the A horizon for all three of the soils range between 1.26 ft/day to 12.6 ft/day. The permeability of the B horizon for the Paxton and Woodbridge soils is significantly less at 0.4 ft/day, while the range for a Charlton is 4.0 ft/day to 12.6 ft/day. Clearly, most of the proposed development should occur on the Paxton and Woodbridge soils, thus saving the Charlton areas for use as infiltration areas or for low intensity residential use.

With the exception of two small meadow meadows, the majority of the site is densely wooded. The brush areas are in succession from meadow to woods and are also found along the intermittent stream corridors on the site. The site does contain a good mixture of Red & Black Oak, Sugar & Red Maple, Silver Beech, Black Cherry and some Northern White Pine. The pines are concentrated in the area of the Charlton Soils in the south central portion of the site.

The 25% slopes were delineated using the two foot topographic mapping. These slopes are primarily located above the eastern wetland system. In general development should not occur on these soils due to concerns of erosion during the construction period and these soils pose difficulties with stabilization after construction due to their fine grained nature.

Figure 1 shows the topography, wetlands/watercourses/vernal pools, watershed divides and soils.

Figure 2 shows 25% slopes, soil types and generalized vegetative cover.

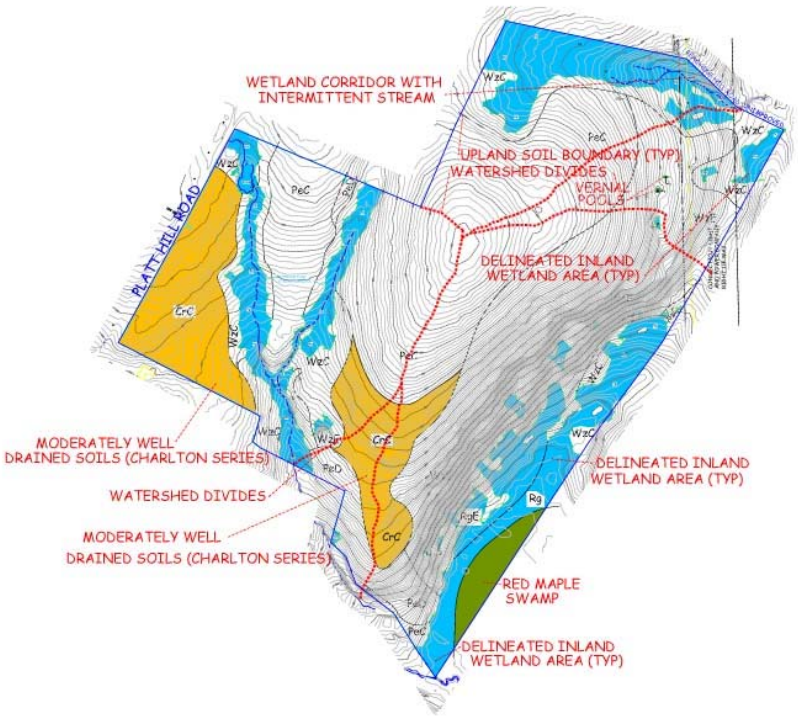

Figure 1 - Wetlands/Soils/Watersheds

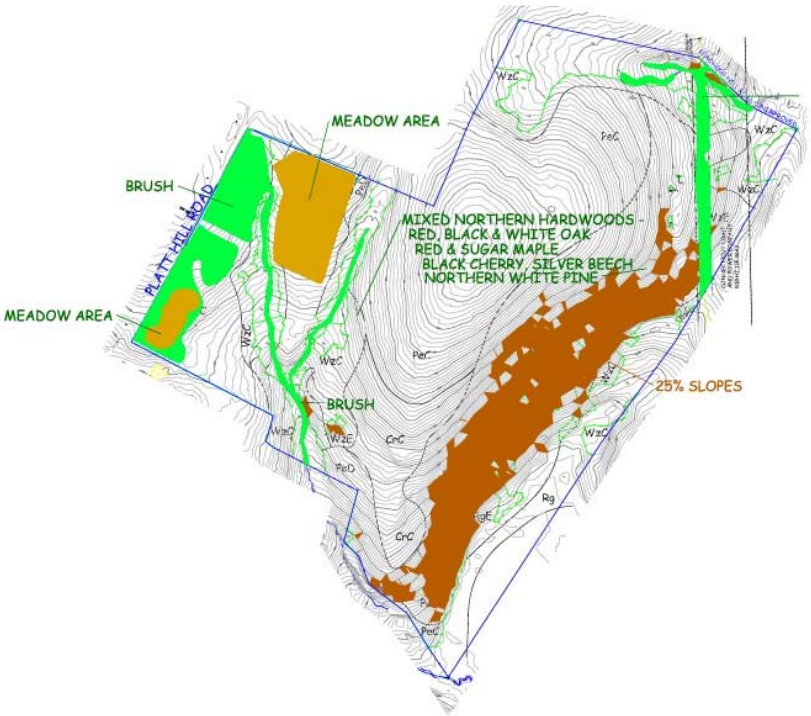

Figure 2 - 25% slopes/Vegetation Types/Soils

DEVELOPABLE AREA:

Of the total 104.5 acres, slightly over 49 acres is available for development. This area is shown in Figure 3 below. The next step is to determine the suitability of the site for the installation of subsurface sewage disposal systems (SSDS) for each proposed lot. The local health district required a 75' separation from a SSDS to a wetland or watercourse, so those areas were excluded from the developable areas. Over 150 deep test pits were excavated on the site. In general, the testing was done on the lower portions of the site to permit gravity flow systems to be utilized on each lot.

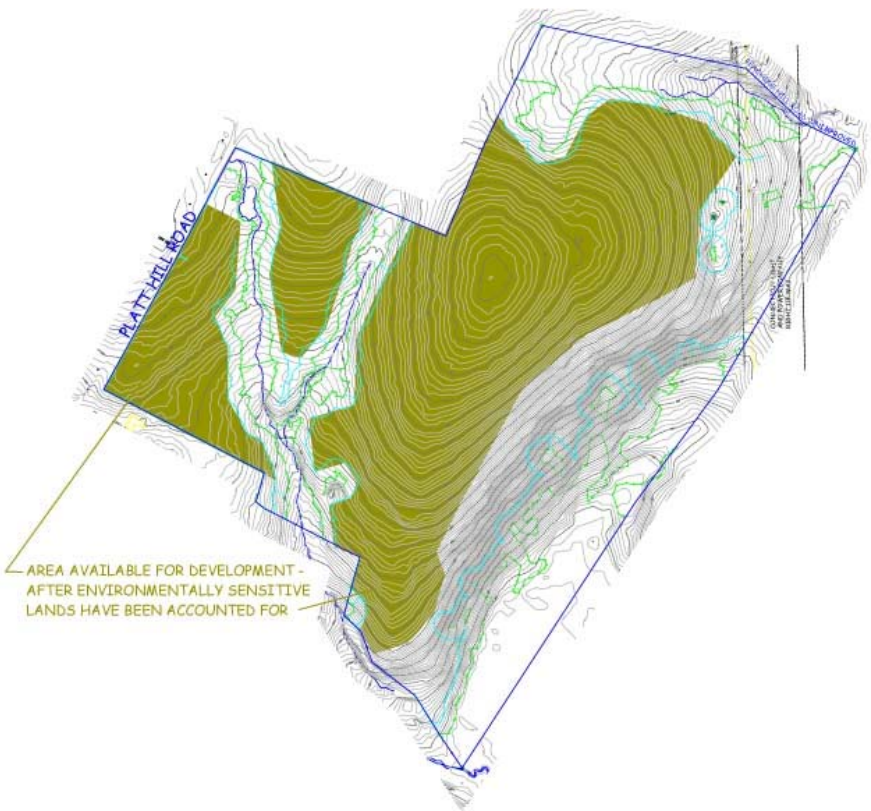

Figure 3 - Area available for development

The next step in this process was to compute the maximum allowable density permitted on the site in accordance with the town's regulations.

Density Calculation: For all residential zones, the total land area must be reduced as follows to determine the Developable Land Area (DLA). You must exclude 50% of all lands with inland wetlands soils, land subject to flooding, water bodies or watercourses, or land with slopes in excess of 25%. Once this calculation is done, Section 4.3 has further requirements to be met. First, 15% of the total land area must be taken out to for future street rights of way. Next, any land subject to utility easements must be taken out. Once these calculations have been done, the DLA shall be divided by the minimum lot requirements for the zone to determine the maximum number of lots permitted on the tract.

The calculation is as follows:

Total Site Area:	104.50 acres
- 15% (roads):	- 15.67 acres
- Utility Easement:	- 5.12 acres
- 50% of wetlands:	- 10.83 acres
- 50% of 25% slopes:	- 6.12 acres
Net Area:	66.76 acres
Current zoning: 1 house/1.9513 acres	
Max. Allowable density:	66.76/1.9513 = 34.2 lots

A layout conforming to current zoning is prepared to determine if ESD strategies can be implemented under this scenario. Figure 4 shows the conventional plan, while it appears feasible, many of the environmentally sensitive areas are not protected and a significant amount of road must be constructed, including reconstruction of 700'+ of an unimproved road to the north. This plan does not conform to the benchmarks of ESD. In order to achieve the ESD benchmarks, a reduction in density is necessary as is the consideration of an Open Space Design.

Figure 4 - Conventional Design

SITE DESIGN AND ACCESS:

Zoning regulations in this community permitted the use of an Open Space subdivision concept, where lots areas could be reduced from 85,000 sq.ft. to 40,000 sq.ft.

Septic soil test results were evaluated to determine the carrying capacity of the land to disperse the anticipated effluent loads. Based upon this analysis, a density of about 25 – 27 lots would be appropriate on the site. A conceptual layout of the road and lots is then prepared for the previously defined Developable Area. The following design elements need to be considered:

a) Road alignment should follow existing contours to the maximum extent possible in order to minimize site disturbance and limiting of grading.
b) Building lot should be sited with an eye toward providing easy access to the proposed residences with minimal changes in grade.
c) Use common driveways where practical to reduce impervious areas.
d) Subsurface sewage disposal systems are generally located below the proposed residences in order to facilitate gravity flow.
e) How will storm water from the impervious area be handled? It is very important that storm water be evaluated early in the design process to achieve ESD goals.

ENVIRONMENTAL SITE DESIGN STRATEGIES THAT CAN BE APPLIED ON THE SITE:

a) Preserve a large portion of the site as permanent Open Space,
b) Cluster Development Utilize Site Fingerprinting to minimize the extent of clearing for each lot,
c) Utilize rain gardens for the roof drains,
d) Utilize filter strips for overland flow prior discharge into natural areas,
e) Encourage the disconnection of impervious areas such as driveways from road,
f) Infiltrate runoff from impervious areas where the soil is suitable,
g) Implement storm water treatment systems to remove common pollutants from runoff,
h) Require soil tilling (min. 12” deep) of the disturbed soils around the house and yard area prior to the installation of topsoil to increase the infiltration ability of the soil.

Due to the regulations of the this community, conventional structural drainage systems had to be utilized for the road conveyance system. To provide enhanced settlement of coarse grained particles, 48” deep catch basin sumps are to be installed on the last catch basin prior to discharge. All other catch basins have 24” sumps. However, there was the opportunity to utilize LID storm water Best Management Practices (BMPs) to treat the runoff after it left the road right of way.

WHAT ESD STRATEGIES WERE APPLIED ON THIS SITE?

1. Cluster twenty four lots proposed on 104.5 acre site,

2. 64.1 acres preserved as Open Space, including ridge top,
3. Road design follows existing contours, minimizing site grading,
4. All roof drains are directed to rain gardens,
5. Runoff from driveways downhill of road discharged as overland flow across vegetated areas,
6. Installation of wildflower meadow strip with 3" micro-berm at edge of lawn area prior to natural area,
7. Four common driveways were used to reduce impervious areas,
8. Storm water treatment systems consisted of Subsurface Flow Gravel Wetlands, Constructed Shallow Marsh Wetlands, Linear Vegetated Level Spreader, Stone Infiltration Trenches, Vegetated Swale with Gravel Filter Berms.

Figure 5- Final Site Design

HYDROLOGIC ISSUES:

The site has two major drainage divides, one goes to the south to Taylor Brook (a perennial stream) and the north goes to Sucker Brook (an intermittent stream). For pre-development conditions, the RCN was 71 for Taylor Brook and 70 for Sucker Brook. Without the disconnection of impervious areas, the RCN values increased to 72.3 for Taylor Brook and 74.9 for Sucker Brook.

The preservation of over 60% of the land in its natural state has a significant positive effect on the Runoff Curve Numbers (RCN) for post-development conditions.

When the roof areas and those driveways downhill of the road system are removed from the total impervious area, the RCN's are reduced. For Taylor Brook the RCN is reduced to 71.2 (virtual match to pre-dev value of 71) and is reduced to 70.1 for Sucker Brook (virtual match to pre-dev value of 70).

Total impervious cover on the site is 4.4%, well below the desired 10% threshold. When the effective impervious area is considered, only 3.2% will be impervious. This minimization of impervious cover is best way to minimize impacts of development on water quality.

All of the storm water treatment systems are designed to contain the required Water Quality Volume (1" of rainfall). This applies to the subsurface flow gravel wetlands, constructed shallow marsh wetland, vegetated level spreader, rain gardens and infiltration trenches.

Because of the necessity of using conventional storm water conveyance system on the road, there will be increase of the Time of Concentration to the treatment systems. However, this initial increase of the Tc will be mitigated by the long residence times within the treatment systems, so that the Tc to the design point on the property line will match or exceed the pre-development Tc.

In addition, the preservation of significant natural areas below the proposed lots will also help to maintain pre-development times of concentration for overland flow from the individual lots.

The rain gardens, infiltration trenches and the preservation of over 60% of the site will allow the pre-development recharge rate to be maintained on the site. The other storm water treatment systems will also remove significant pollutant loads, especially the subsurface flow gravel wetlands and constructed shallow marsh wetlands so water quality goals will easily be achieved.

CONCLUSION:

The application of ESD early in the design phase and the application of LID strategies and treatment systems clearly demonstrate how land can be developed in an environmentally friendly manner. These strategies not only protect sensitive environmental areas, but also create a very livable community for future residents.

Abstract

Although it has been established that thermal pollution from urban stormwater can negatively impact the aquatic ecosystem, there are few mechanisms available to reduce the temperature or urban stormwater runoff. A monitoring study was conducted at 4 bioretention areas in western North Carolina, located along the southeastern extent of United States trout populations, to examine the effect these systems have on runoff temperature and identify any design criteria pertinent to temperature reduction. Median runoff temperatures leaving the pavement surfaces, based on storm events, exceeded the 21°C upper avoidance temperature of trout at all sites during the months of June through September. Of the bioretention areas studied, the two systems that covered an area smaller than 10% of their contributing watershed were able to significantly ($p<0.01$) reduce both maximum and median storm temperatures between the inlet and outlet. At the two bioretention areas that were larger than 10% of their contributing watershed area, maximum effluent temperatures were significantly ($p<0.01$) cooler than influent temperatures; however, there was no significant ($p<0.05$) difference between median influent and effluent temperatures. Despite reductions in temperature, effluent temperatures were not significantly ($p<0.05$) cooler than the upper avoidance temperature for trout at any of the monitoring locations. There was evidence that substantial reductions in runoff volume occurred at all bioretention areas, especially the systems that were larger than 10% of their contributing watershed. Overall, monitoring results indicated that bioretention areas served as effective treatment mechanisms for reducing, but not eliminating, the thermal impacts associated with urban stormwater runoff.

Introduction

As advances in aquatic ecology have coincided with increased urbanization, it has become evident that warm stormwater runoff can negatively impact coldwater stream environments. Due to the thermal properties of asphalt, pavement surfaces can reach temperatures in excess of 60 °C, with much of the heat concentrated near the surface (Asaeda et al., 1996). During a storm event, runoff collects this heat and distributes it throughout the watershed. Although water temperature in streams naturally fluctuates in response to changes in solar radiation and the ambient air temperature, temperature changes are typically limited to a 0.6-0.8°C temperature increase for every 1°C increase in air temperature (Morrill et al., 2005). The discharge of stormwater runoff into coldwater creeks can raise stream temperatures above normal levels, with runoff temperatures elevated even during the night and early morning (Kieser et al., 2004; Lieb and Carline, 2000).

Heated stormwater runoff is a concern because of the negative impact it can have on the aquatic ecosystem. Because many aquatic organisms lack the ability to regulate their body temperature, temperature increases in the aquatic environment can impair major biological functions. Increases in stream temperature can negatively impact the behavior, metabolism, reproduction, growth, and vulnerability to disease of many aquatic organisms. Moreover, because various organisms respond differently to elevated temperatures, thermal pollution can have substantial impacts on community structure. Trout and salmon, which serve as important game fish in many parts of the United States, are among the fish most sensitive to elevated water temperatures. Due to a variety of complex factors, it is difficult to predict the specific effects of elevated temperatures on fish behavior and survival (Hocutt et al., 1980). In spite of these complexities, it has been determined that trout generally avoid water temperatures in excess of 21°C (Coutant, 1977).

Despite evidence that the thermal impacts or urban stormwater runoff have a negative effect on the aquatic ecosystem, there are few mechanisms available to cool stormwater runoff. Stormwater best management practices (BMPs) have been installed throughout the United States in order to reduce the impacts of sediments, nutrients, metals, and other pollutants; however, the effect of these systems on runoff temperature is not well understood. A study of a wet pond found that temperatures increased between the inlet and outlet (Kieser et al., 2004). Because wet ponds are not typically shaded, solar radiation can heat the water within the pond above the temperature of the ambient air. A stormwater wetland has been shown to reduce runoff temperatures when well shaded, with the net heat reduction attributed to evapotranspiration and infiltration (Kieser et al., 2004).

Although bioretention areas have been shown to reduce runoff flows, their effect on runoff temperature has not been thoroughly examined (Hunt et al., 2006). Soil temperature is largely governed by radiation and convective heat transfer near the soil surface. Because thermal conduction through a soil column is relatively slow, deeper layers of soil are able to maintain relatively stable temperatures over long periods of time (Mohseni et al., 2002). During irrigation with warm water, it has been shown that water temperature approaches the temperature of the surrounding soil as it infiltrates, resulting in minimal temperature variations at soil depths greater than 100 cm (Wierenga et al., 1970). At shallow drain depths, heat exchanges between the soil and infiltrating water may have little impact on water temperatures. For example, seasonal mean water temperatures between rooftop runoff and underdrain outflow were not significantly different at a relatively shallow (60 cm) bioretention area in the northeastern United States (Dietz and Clausen, 2005).
In order to examine the effect of bioretention areas on runoff temperature, a monitoring study was conducted at 4 locations in western North Carolina, along the southeastern extent of United States trout populations. Effectively managing thermal pollution is important in this region, since many coldwater stream environments approach the temperature limits of trout under natural conditions.

Methods

The monitoring sites consisted of bioretention areas in Asheville, Lenoir, and two adjacent bioretention areas in Brevard, North Carolina. Monitoring was

conducted during the summer months, generally from May through mid-October. Data were collected at all monitoring sites during 2006 and 2007.

To measure outflow at all bioretention areas, pulley-float stage recorders were used in conjunction with v-notch weirs. Pulley-float stage recorders with v-notch weirs or measured rainfall were used to estimate inflow at all monitoring sites. Due to complications with the flow monitoring equipment, flow data were primarily used to identify periods of flow over the temperature sensors. Rainfall data were collected for each monitoring location using tipping bucket rain gauges with a resolution of 0.25 mm. HOBO™ Water Temp Pro (H20-001) and HOBO™ 4 channel loggers (H08-008-04 & U12-008) with temperature sensors attached (TMCX-HD), which were all manufactured by Onset Computer Corporation, were used to collect temperature measurements. All temperature and flow measurements were logged at a 5 minute interval.

Statistical analysis was conducted using SAS® software, Version 9 (SAS Institute Inc., Cary, NC). The potential thermal impact to trout populations was ascertained by comparing water temperatures to 21° C, the temperature at which trout begin to experience thermal stress, using a signed rank test. Comparisons of influent, effluent, and soil temperatures were conducted using the Wilcoxon Rank Sum test (Wilcoxon, 1945). Storm medians and maximums were used in the analysis of BMP influent and effluent temperatures. Statistical significance was established within a 99% confidence interval ($p<0.01$), unless otherwise noted.

Site Description

The Asheville bioretention area (35°36'46"N, 82°33'54"W) covered 45m² and received runoff from 280 m² of asphalt parking lot. During the summer of 2005, when the bioretention area and contributing parking lot were constructed, a light colored chip seal was applied to the parking surface in an attempt to reduce pavement temperatures. The bioretention area was located approximately 6 m from the parking lot and runoff was routed into the BMP within an asphalt channel. Perforated PVC pipes, 10 cm in diameter, were used to drain the bioretention area and 38 cm smooth walled corrugated plastic tubing (CPT) discharged the bioretention effluent into nearby Reed Creek. The bioretention area did not contain mulch and naturally progressed from no vegetative cover in June of 2005 to an estimated 55% vegetative cover in late August, 2006. Temperature probes were installed at the inlet channel, inside the outlet weir box, and at 5 evenly spaced depths within the soil column from the surface to the underdrain depth of 135 cm.

The Lenoir bioretention area (35°55'20"N, 81°31'24"W) covered a 30 m² area. Runoff originated from a 675 m² asphalt parking lot and two sections of concrete sidewalk, which covered a combined area of 95 m². The bioretention surface was covered by hardwood mulch and vegetation within the BMP shaded 79% of the area, while the bioretention area and adjacent parking surface were shaded by a mature tree canopy. A network of 12 cm perforated CPT underdrains located 95 cm below the ground surface collected infiltrating runoff and discharged the water onto a street curb located approximately 10 m away. Temperature probes were installed in the inlet pipe, outlet weir box, and at 4 evenly spaced depths within the soil column from the

surface to the underdrain depth. Soil temperatures were only monitored at this site during the summer of 2007.

Adjacent bioretention areas were monitored in Brevard, NC (35°14'20"N, 82°43'52"W). Water from these bioretention areas, as well as others in the parking lot, was routed by an underground drainage network to Kings Creek, which was adjacent to the property. Both systems were mulched with pine straw. The Brevard east bioretention area covered a 37 m² area and received runoff from approximately 525 m² of asphalt parking lot (Fig. 4). Water left the bioretention area through a 12 cm perforated CPT underdrain network located approximately 48 cm below the soil surface. An estimated 43% of this bioretention area was shaded by low-lying plants. Temperature probes were located in the inlet weir box and outlet pipe. Soil temperature was measured at a depth of 48 cm during the summer of 2007.

The Brevard west bioretention area covered a 36 m² area and received runoff from approximately 325 m² of asphalt parking lot. Water left the bioretention area through a 12 cm perforated CPT underdrain network located approximately 43 cm below the soil surface. An estimated 43% of this bioretention area was shaded, primarily from 2 maple trees. Periods of inflow and outflow were identified with weir boxes mounted at the inlet and outlet, where temperature probes were also located.

Results and Discussion

Runoff temperatures directly leaving the parking surfaces were significantly ($p<0.05$) warmer than 21°C during the months of June through August at all monitoring sites. Runoff temperatures were typically warmest at the beginning of a storm event and cooled as the storm progressed. The coolest runoff temperatures were observed leaving the parking surface at the Asheville bioretention area, likely due to the presence of a light colored chip seal on the parking surface. Over the course of the monitoring period, runoff temperatures at the Asheville bioretention area were not significantly ($p<0.05$) different from those measured at a nearby parking lot that benefited from an older asphalt surface and shading from a perimeter of mature trees.

At the Asheville bioretention area, there was no significant ($p<0.05$) difference between median effluent temperatures and the 21°C threshold when examining the entire monitoring period; however, median effluent temperatures were significantly ($p<0.05$) cooler than 21°C when the month of August was excluded. There was no significant ($p<0.05$) difference between median influent and effluent temperatures at the Asheville bioretention area, indicating that the bioretention area was not able to consistently reduce runoff temperatures over the course of an entire storm (Figure 1). Although maximum effluent temperatures were not significantly ($p<0.05$) different from the 21°C threshold, maximum effluent temperatures were significantly ($p<0.05$) cooler than the maximum influent. A reduction in maximum water temperatures suggests that the bioretention area was able to reduce the initial runoff temperature spike, but unable to convey the benefits of cooler runoff as a storm progressed.

Median and maximum effluent temperatures at the Lenoir bioretention area were both significantly lower than influent temperatures, which indicated that the bioretention area was able to reduce the thermal impact associated with the

stormwater runoff. Despite the reduction in water temperature resulting from bioretention treatment, median effluent temperatures were not significantly ($p<0.05$) different from 21°C and maximum effluent temperatures were significantly warmer than 21°C. Although thermal impacts were reduced, the effluent from this bioretention area still posed some risk to the thermal environment of trout waters. At the Brevard east bioretention area, median and maximum effluent temperatures were significantly cooler than influent temperatures; however, effluent temperatures were also significantly warmer than 21°C. Similar to the Lenoir bioretention, the Brevard east bioretention was able to reduce, but not eliminate the thermal impact to a coldwater stream environment. At the Brevard west bioretention area, there was no significant ($p<0.05$) difference between median influent and effluent temperatures; however, there was a significant difference between maximum temperatures. Similar to the Asheville bioretention area, these temperature results suggest that the bioretention area was able to reduce the initial spike in runoff temperatures, but could not convey the benefit of cooler runoff temperatures later in a storm. Median and maximum effluent temperatures were both significantly warmer than 21°C, indicating potential thermal impacts to a coldwater stream environment. Seasonal trends in influent and effluent temperatures were not as well defined during 2007, possibly due to the impact of the drought throughout the region.

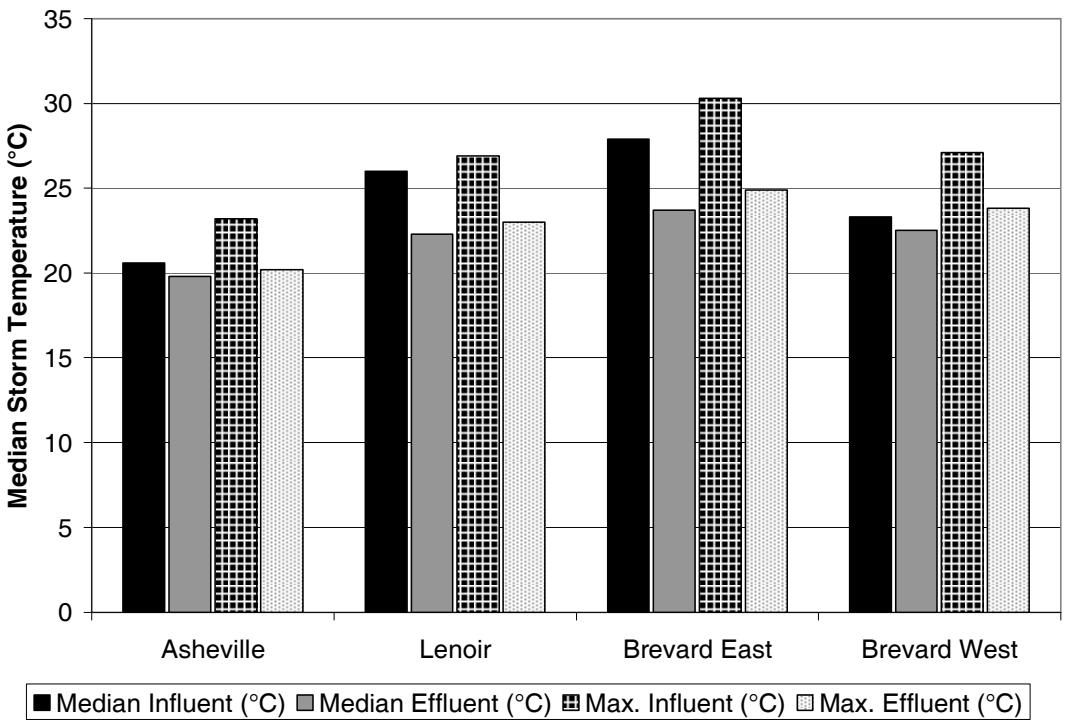

Figure 1. Median storm temperatures observed at each bioretention area for 2006

Despite significantly warmer median influent temperatures at the Brevard east bioretention area, there was no significant ($p<0.05$) temperature difference between median effluent temperatures at the Brevard east and Brevard west bioretention areas. The primary difference between these bioretention areas was the size of the contributing watershed, since they shared immediately adjacent locations, similar soil

properties, drain depth, and bioretention size. The area occupied by the Brevard east bioretention area was equivalent to 7% of the contributing watershed, while the area of the Brevard west bioretention was equal to 11% of the contributing watershed. Based on temperature results alone, there appears to be minimal thermal pollution benefits associated with moderately oversizing a bioretention area. One major benefit of a proportionally larger bioretention area that does not directly relate to effluent temperatures is the ability of a larger system to infiltrate runoff without generating outflow. When water exfiltrates, or leaves the bioretention area through the underlying soil and not the drainage pipes, the thermal impact from that runoff is effectively eliminated. Although the adjacent bioretention areas received the same rainfall, measurable outflow occurred in response to 76% of rainfall events at the Brevard east bioretention area, but only 27% of rainfall events at the Brevard west bioretention area. A similar outflow reduction finding was made by Li et al. (2009).

Analysis of temperature trends at specific soil depths provided insight into optimum underdrain depths. With the exception of nighttime surface temperatures, soil temperatures were coolest at the bottom of the bioretention soil column during the summer months. Soil temperatures at the bottom of the bioretention areas also exhibited the smallest fluctuations in response to storms or diurnal and seasonal temperature changes. However, the stability of soil temperatures at greater depths poses a potential risk of increasing the temperature of infiltrating water during later portions of a storm when cooler runoff prevails. Although there were several exceptions during late night storms, soils at a depth of 90 cm or greater remained cooler than soils at shallower depths for most storms. Beginning in September, soil temperatures were often warmest at the bottom of the bioretention areas, which raises potential concerns of warm effluent from deep bioretention areas during spawning seasons in the fall when temperature preferences are cooler.

Conclusion

Based on monitoring results, it appears that bioretention areas were able to effectively reduce the thermal impacts of urban stormwater runoff. Thermal load reductions can be attributed to initially warm runoff dissipating heat within the cooler soil depths of a bioretention area, and the ability of these systems to reduce runoff volumes. Although these systems effectively reduced thermal pollution from urban stormwater runoff, thermal impacts were not eliminated, since effluent temperatures were often warmer than the 21°C trout temperature threshold. Results of this research show that when runoff temperature is considered in BMP design, it should be possible to reduce thermal loads or minimize temperature increases, while maintaining the water quality and quantity benefits of bioretention.

Abstract

Lawrence Technological University is a private university located on a 120-acre campus in highly urbanized Southfield, Michigan (Detroit Metropolitan Area). The campus was primarily developed over the last several decades with limited or no stormwater controls as was customary with regulations of the time. However, the opening of a student services center in 2005 provided the opportunity for the campus to commit itself to green design and the use of low impact development (LID) techniques. The 40,000 square-foot A. Alfred Taubman Student Services Center (Center) is a Leadership in Energy and Environmental Design (LEED) Silver Certified green building that features a 10,000 square foot green roof; geothermal heating and cooling; cistern water harvesting; a bioswale, and other energy efficient technologies. As such, the Center provides a living laboratory for Lawrence Tech architecture and engineering students, local municipal officials, community planners, and design engineers to learn about LID techniques and LEED certification.

Of specific interest to stormwater management, the building features a 10,000 square foot Hydrotech Garden Roof™ and gray water cistern that recycles roof water. The presence of the green roof provided an unique opportunity to compare and contrast the hydrologic performance of a full-scale greenroof with other more traditional roofs on campus. This was accomplished by outfitting three separate roof drains (a traditional blacktop asphalt roof, a rock ballasted roof, and the green roof) with water quality and quantity sensors. Objectives of the Greenroof Performance Evaluation Project include the overall volume of precipitation retained and detained by the green roof compared to the other roofs on campus; the peak discharge and run-off coefficient reduction of the greenroof for various storm events, the nutrient loading attenuation capabilities of the greenroof; the reduction in ambient temperature associated with the greenroof; and the educational benefit of establishing a long-term monitoring station capable of determining the temporal performance of the green roof that could be integrated into the curriculum.

Introduction

A green roof, or vegetated roof, is a roofing system that includes a layer of engineered soil planted with vegetation. The two basic varieties are extensive and intensive with extensive roofs being lighter and more commonly used to treat stormwater runoff. The green roof at Lawrence Technological University is an extensive HydroTech Garden Roof™ (Figure 1). Green roofs represent a type of stormwater best management practice (BMP) that focuses on volume reduction and water quality in addition to water quantity and peak discharge attenuation

(Hutchinson et al., 2003; Hunt et al., 2005; Hunt et al., 2004; Moran et al., 2005; Liptan, 2003; Carter and Rasmussen, 2005 and Kolb, 2004). Green roofs have been used as a stormwater BMP for decades in Germany and are gaining in popularity in the United States. However, common acceptance of green roofs as a structural stormwater BMP has been slow in many communities. One reason is the lack of published full-scale performance data on their performance in a variety of climatological settings. Regional differences in hydrology, climate, plant material, and background water quality make the transference of results from one region to another questionable. Finally, there are numerous green roof design configurations and data is needed to evaluate the effectiveness of different designs. All of these factors indicate the necessity of more research studies on green roof performance.

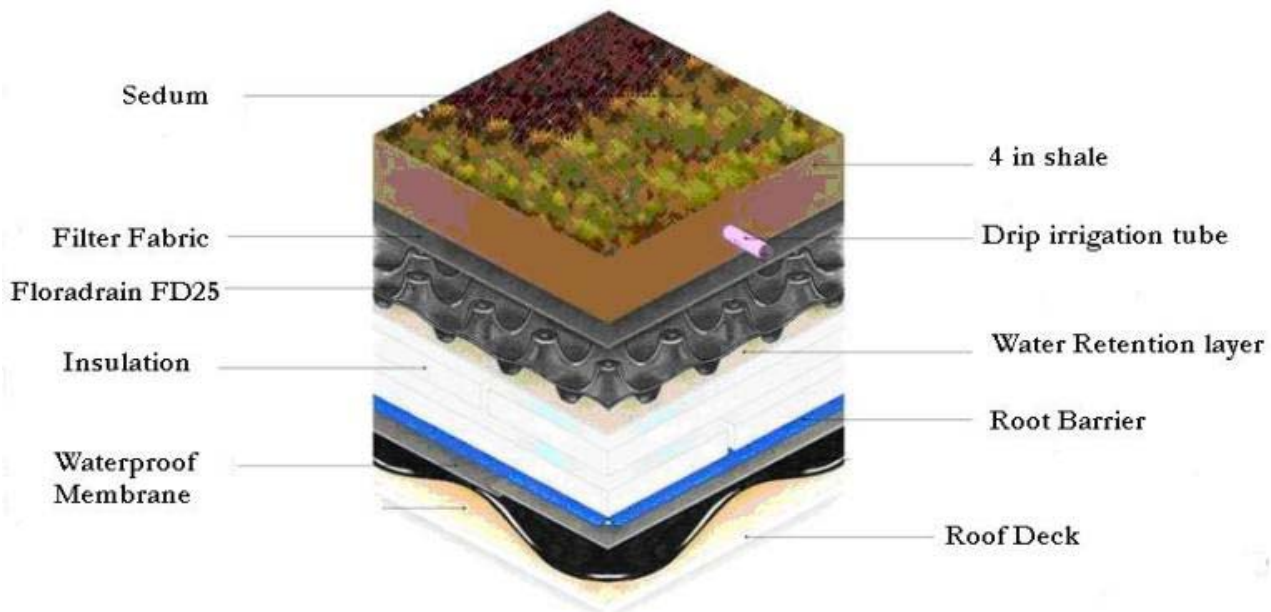

Figure 1: Cross section of HydroTech Garden Roof™ (schematic courtesy of HydroTech).

Project Objectives

The green roof constructed at Lawrence Technological University (LTU) was designed as a stormwater BMP in an urban environment (Figure 2). It was constructed over the A. Alfred Taubman Student Services Center (SSC) and was designed to retain approximately 60 percent of the annual rainfall while the remainder drains into a 10,000 gallon cistern to be used as "gray" water for sanitary purposes. To evaluate the performance of the greenroof, it is compared with runoff data collected from two additional full-scale roofs on Lawrence Tech's campus adjacent to the SSC - a rock ballast roof and a black asphalt roof. The black asphalt roof also acts as the control station from which to compare the green roof too.

The goals of this research and demonstration project are as follows:

1. Determine the overall percent of precipitation retained and detained by the green roof (water quantity).

2. Determine the peak discharge reduction of the green roof (water quantity)
3. Determine the nutrient loading attenuation capabilities of the green roof (water quality).
4. Determine the reduction in ambient temperature associated with the green roof (air quality).
5. Establish a long-term monitoring station capable of determining the temporal performance of the green roof as well as provide data that can be integrated into the curriculum (water quantity and education).

Figure 2: Green roof on the A. Alfred Taubman Student Services Center.

Monitoring Equipment

To monitor discharge from the roof, three Palmer-Bowlus flumes of 4 inch diameter were installed into existing roof drains at the three locations (Figure 3). The flumes were inserted into existing roof drains. When runoff from the roof reached a certain level in the flume, water was siphoned from the flume into the Avalanche Sampler which has a refrigerated compartment with a 14 bottle configuration for discrete collection of water samples. A second tube connected the flume to a 730 Bubbler Flowmeter, which measured the level of the runoff in the flume based on the pressure necessary to release a bubble air. The runoff discharges were calculated based on the water level readings in the flumes using Equation 1.

$$Q = 1.68 \times H^{1.9} \qquad \text{(Equation 1)}$$

where, Q = Flow in ft^3/sec (cfs),
H = Level reading in flume (ft).

The discharge rate from Equation (1) was integrated over the entire time runoff was observed to obtain volumes of the runoff was observed to obtain volumes of the runoffs:

$$V = \int_0^t Q(t)dt \qquad \text{(Equation 2)}$$

where, V = Volume of runoff (cubic feet)
Q = Runoff discharge (cfs),
t = Time (seconds)

The percent retained was then determined using the equation:

$$\%\ \text{Retained} = \frac{\text{Amount retained (inches)}}{\text{Total rainfall (inches)}} \times 100\% \qquad \text{(Equation 3)}$$

where the total rainfall was measured via the rain gauge and the amount retained is the volume from Equation (2).

Water Retention

One of the objectives of the green roof research was to determine the water retention capabilities of the green roof. Precipitation is retained on the greenroof and then stored in the soil media and the drainage layers below until moisture goes back into atmosphere via evapotranspiration. Percent retained on the green roof is calculated as the difference between rainfall depth and runoff depth on green roof as determined by Equation (3). Data was collected for six months from April to September 2008. During that time there were a total of twenty one measurable rainfall events for a total precipitation of 13.40 inches. The green roof retained 9.14 inches of rainfall depth, which represents a 68.24% retention rate. The total percent retained on the LTU green roof is comparable to a green roof study in Portland 69% of 44 inches was retained over a 15 month period (Hutchinson et al., 2003). It is also comparable to a study conducted at Michigan State University where 66% rainfall retention was reported over 24 rainfall events (Rowe et al., 2003).

Table 1. Summary of monthly water retention for LTU greenroof.

Period	Rainfall (inches)	Runoff (inches)	Amount Retained (inches)	Percent Retained %
Apr-08	0.68	0.09	0.59	86.59
May-08	2.12	0.11	2.00	94.40
Jun-08	3.52	0.66	2.85	81.01
Jul-08	2.55	0.60	1.94	76.30
Aug-08	0.29	0.00	0.28	99.44
Sep-08	4.24	2.77	1.47	34.66
Total	13.4	4.25	9.14	68.24

Table 1 provides a summary of monthly water retention values where monthly retention percentages varied from approximately 35% to 100%. A similar range of water retention was recorded for individual storm events. This variation represents the various factors that affect the

rainfall retention including rainfall intensity/duration/frequency, initial soil moisture, and evapotranspiration. For example, the green roof is able to retain more water from smaller rainfall events. When the soil media on the green roof is already saturated from a previous event, it was unable to absorb additional water. In addition, when there was a longer time period between storm events, evapotranspiration played a role and water temporarily stored in the soil media and drainage layer was either evaporated or transpired by the vegetation. For example, May exhibited a total recorded rainfall of 2.12 inches over four events that were at least 4 days apart. Whereas in the month of June, the total rainfall was 4 inches over six events with several events occurring two or three days apart. For June, the green roof retained 81% of the total precipitation compared with 94% for May.

A similar analysis was conducted for the other two roofs and compared against the green roof. The percent retained and total rainfall depth retained for each month is shown in Figure 3. In total, the black asphalt roof retained 1.4 inches for a retention percentage of 10.44% with the rock ballasted "stoneroof" retaining 6.88 inches for a retention percent of 48.58%.

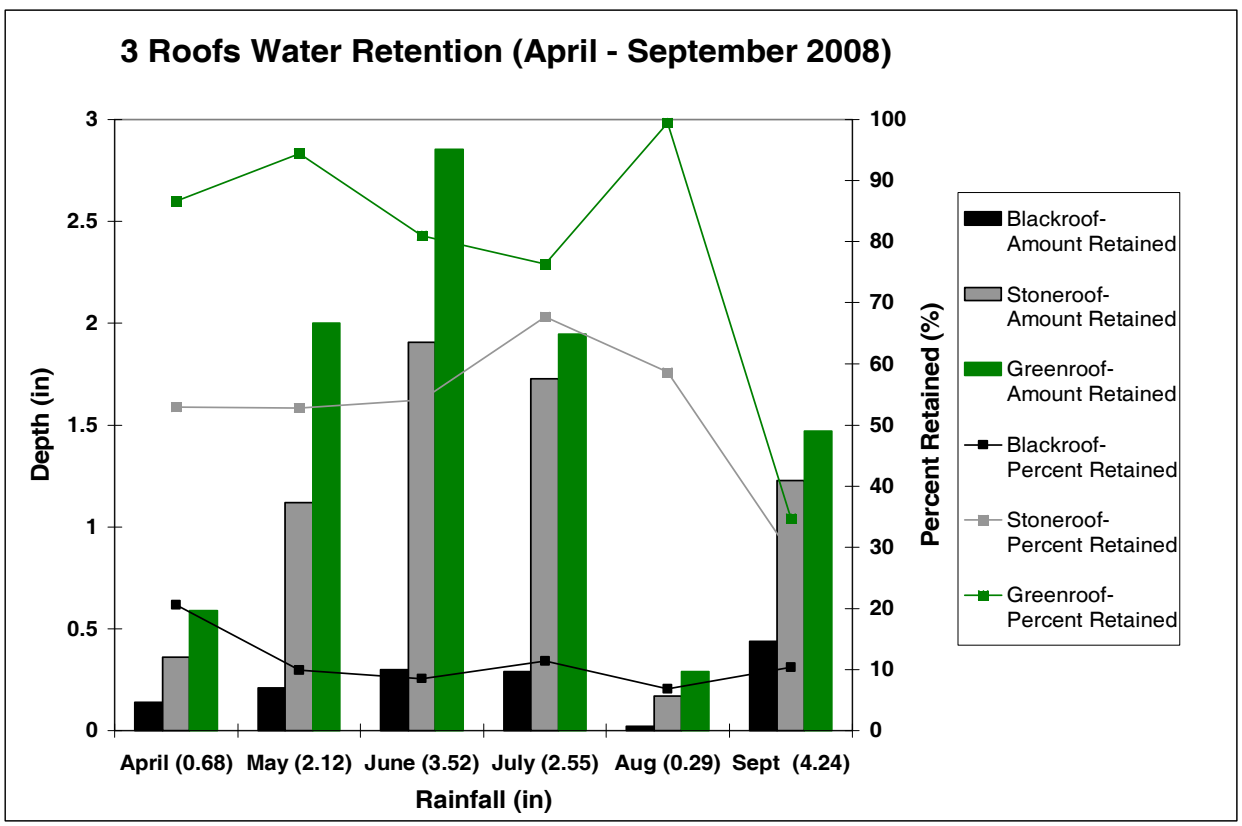

Figure 3. Display of monthly retention for the three roofs.

A rational coefficient (C) is a dimensionless number that is used to determine the peak discharge of an area for a given rainfall intensity. The rational coefficient is often used in hydrologic calculations and is included in many stormwater ordinances which rely on the rational formula for determining peak discharge for small watersheds. The rational coefficient can be calculated based on volume:

$$C = \frac{\text{Volume of roof runoff (cu.ft)}}{\text{Volume of rainfall (cu.ft)}} \qquad \text{(Equation 4)}$$

To demonstrate the impact rainfall intensity has on the runoff coefficient of a green roof, the rainfall events from April to September 2008 have been categorized into three sizes: rainfall intensities that varied between 0.1 inch to 0.5 inch were considered as of small size, intensities with a range of 0.5 inch to 1 inch were categorized as medium events and rainfall amounts greater than 1 inch were termed as large events. Table 2 displays the range of runoff coefficients for the types of rain events. From the table it is clearly seen that the runoff coefficients for the green roof increase with increasing rainfall intensities. The black asphalt roof and the stone roof have similar runoff coefficients values regardless of rainfall intensity.

This effect can clearly be seen in Figure 4 which plots measured runoff from the three roofs versus rainfall for all storms of less than 1 inch total depth. Statistical best-fit trend lines indicated a linear relationship for the black roof and the stone roof (although the stone roof had significant variability) whereas the green roof exhibited a power relationship indicating increased run-off with increasing rainfall.

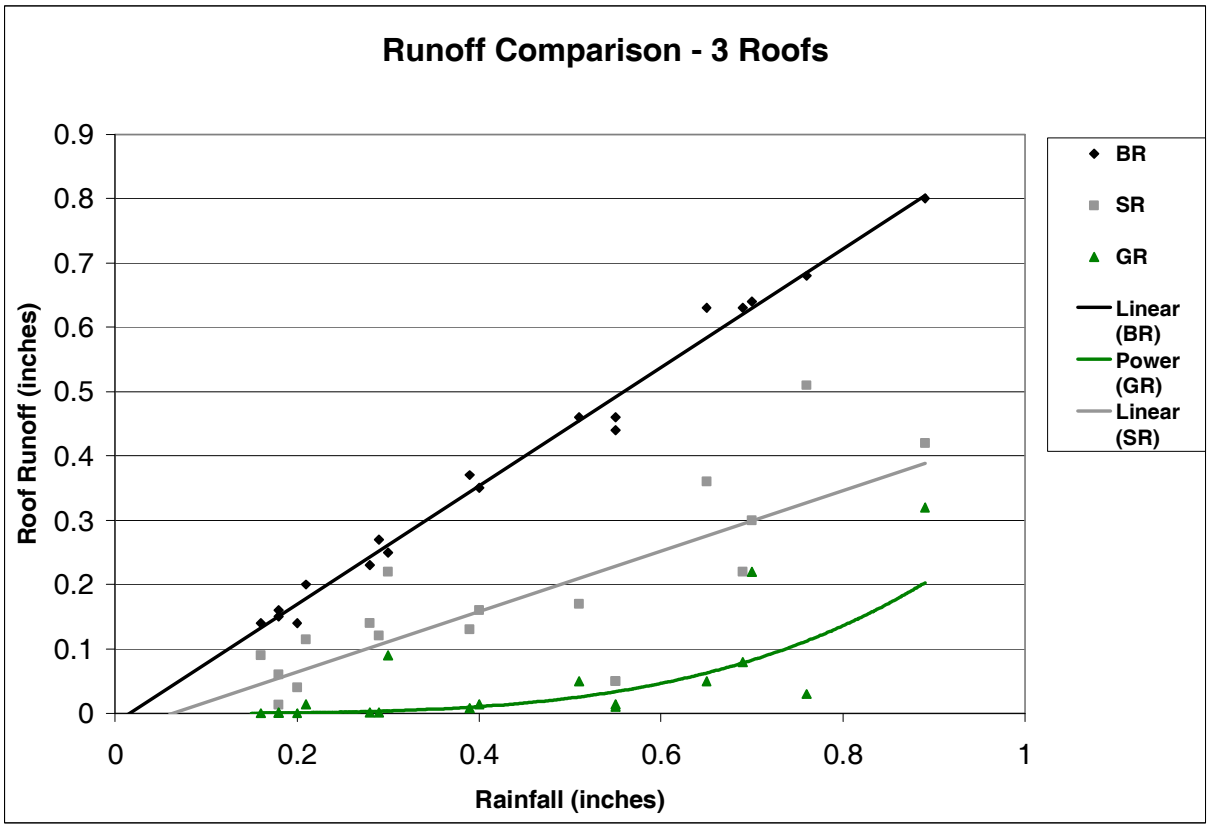

Figure 4: Display of runoff comparisons for the three roofs, less than 1 inch.

Table 2. Rational coefficients for the three roofs based on selected storm sizes.

Size Category	Storm Size	Number of Observations	Green roof	Black roof	Stoneroof
Small	0.1 -0.5 (in)	9	0.037	0.88	0.44
Medium	0.5 – 1 (in)	8	0.13	0.91	0.36
Large	> 1 (in)	3	0.55	0.92	0.62

Peak Discharge Attenuation

Reduction of peak discharge is another major benefit of green roofs and was included in the LTU greenroof research's objectives. The soil media and the drainage layer on the greenroof absorb rainwater and runoff occurs after the soil is saturated and drainage layer is at capacity. This process causes a delay for the runoff to occur and thus a time delay is observed between the time when the rainfall begins and the time when the greenroof exhibits measured runoff. This difference can vary from several minutes to several hours depending upon the initial conditions of the green roof media and the intensity/duration/frequency of the rainfall event. To compare the three roofs, which were different in size, the flows were normalized per 1000 square feet of the corresponding roof areas and represented as hydrographs based on Equation 1.

Figure 5 is an example of one of the 21 hydrographs measured in this investigation. The graph shows time (hours) on the x-axis and discharge (cfs) on the y-axis along with 15-minute rainfall data. For this example, the green roof observed a delay of 2.5 hours from the start of the rainfall event until discharge was measured. During this time the soil media was getting saturated and the drainage layer was filling. In addition, runoff from the greenroof was observed for 1.5 hours after the precipitation ended. Finally, all of the initial peaks measured on the black roof are not captured on the green roof discharge record. The green roof peak discharge occurs around 3.75 hours and is significantly less than the corresponding black asphalt roof peak measured around 2.5 hours into the storm record. Overall, the green roof showed significant reduction of flow rates for the entire study from April to September 2008. Individual reductions in peak discharge varied from 99.9% for the smallest 0.1 inch of rainfall to 54.23% for the largest single measured rainfall event (2.54 inches of rain) with an average percent reduction of 84.06%.

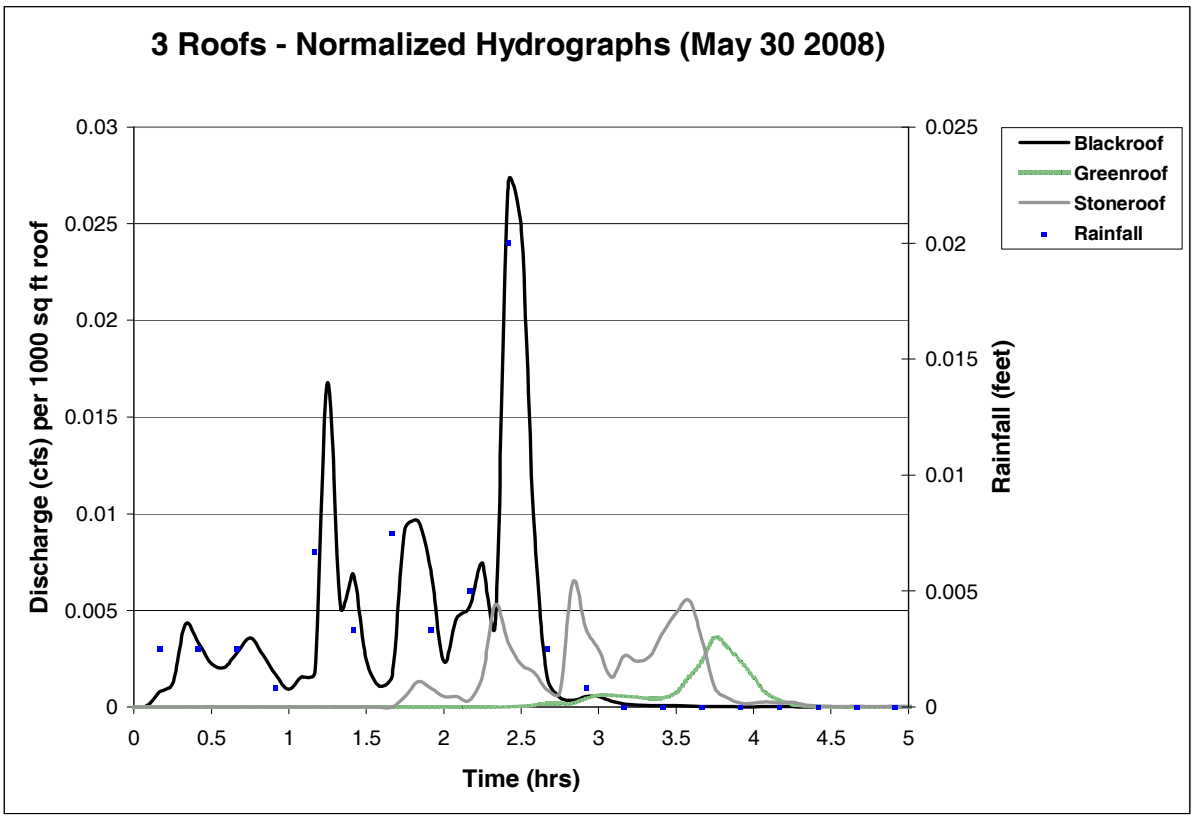

Figure 5. Peak flow hydrograph of three roofs (May 30 2008).

Laboratory Study – Water Quality Data

The water quality tests were conducted on nutrients that included total phosphates (TP) and Nitrates (NO_3^--N), and also total solids (TS). Data is available for a total of five rain events from May 2008 to September 2008. The Avalanche Samplers installed at the three sites have collected water samples required for the water quality tests. Equal amounts of water were then taken from the samplers, composited into a container, and then were utilized for the pollutant testing using procedures found in Water Quality with Computers (Johnson et al., 2008). A summary can be found in Table 3. Overall, there was significant variability between individual rainfall events and the nutrient removal and water quality performance portion of the investigation is inconclusive. However, given the significant reduction in discharge associated with green roofs, the mass loadings are significantly better than the concentrations.

Table 3. Average pollutants derived on the 3 roofs.

Type of Pollutant	Average Rainfall (inches)	Greenroof Concentrations (mg/L)	Blackroof Concentrations (mg/L)	Stoneroof Concentrations (mg/L)
Total Solids	1.19	190	108	152
Total Phosphates	1.19	0.12	0.18	0.10
Nitrates	1.19	0.41	0.37	0.80

Ambient Temperature Reduction

The temperature difference between the urban areas and the surrounding natural areas is called as urban heat island effect and this is found to be significantly reduced by green roofs. Three temperature sensors (Microlite USB from Fourier Systems) were used as the temperature measuring devices on the three roofs. Temperature data was collected starting from the month of December 2007 to June 2008 and daytime average temperatures were calculated. Table 5 shows the values calculated for the three roofs which indicate the green roof was always cooler than the other two roofs. However, the temperature sensors failed on several occasions and the quality of the temperature data collected is questionable. That said, the ambient temperature reduction of green roofs has been well documented in other investigations (Getter and Rowe, 2006; Liu and Baskaran, 2003; Tan & Sia, 2005; Liu, 2004; Oke, 1987; Scholz, 2001 and Laberge et al., 2004).

Table 5. Average daytime temperatures of three roofs for selective months.

	Average Daytime Temperature °C		
Month	Blackroof	Stoneroof	Greenroof
February 2008	2.28	1.30	1.74
March 2008	11.97	9.95	9.10
May 2008	28.02	27.12	21.0

Education

The final goal of the LTU Green Roof Performance Evaluation Project was the ability of the green roof to provide educational benefits to university students, municipal engineers and planners, and the general public. This goal was definitively met. Research data from the green roof has been utilized by two Master students for their thesis (Kaluvakolanu, 2009; Biman, 2009) and has been incorporated into undergraduate and graduate level engineering and architecture courses. The roof has been the subject of many regional presentations and tours in an effort to

inform the populace on the benefits of green roofs. In addition, the University is setting up partnerships with regional public school districts and community colleges to assist them in implementing green roofs on their campuses as well as to utilize the green roof as part of their curriculums. Finally, the LTU green roof served as a case study for the new Michigan Low Impact Development Manual.

Summary

Water quantity data was collected for six months from April to September 2008, with a total of twenty one rain events. A total precipitation of 13.40 inches was observed for which the greenroof retained 9.14 inches, which accounted to 68.24% of retention. The retention observed at the blackroof was 10.44% and stoneroof showed total retention of 48.55%. The variability of rainfall retentions on the greenroof ranged from 33% to 100% for monthly data and this was dependant on the rainfall patterns. The greenroof also showed significant reduction of peak flows with an average of 84.06% for the total rain events. Average Rational Formula runoff coefficients were developed from the runoff flows observed on the greenroof. For storms ranging from 0.1 inch – 0.5 inch, the coefficient was 0.037, for storms in the range of 0.5 inch to 1 inch, coefficient of 0.13 and 0.55 was observed for storms greater than 1 inch; typical rooftop runoff coefficients range from 0.75 to 0.95.

Water quality samples were collected from the three roofs for five selected rain events. Laboratory tests were conducted to determine the concentrations of total phosphates (TP), nitrates (NO_3^--N) and total solids (TS). Greenroof showed higher concentrations of total solids and nitrates compared to the other two roofs, while it showed lower concentrations of total phosphates.

Temperature data was collected on the three roofs from December 2007 to June 2008. The results showed that greenroof was efficient in reducing rooftop temperatures in summer when compared to the black and stoneroofs. The average daytime temperatures of summer were 28.45 °C on greenroof, 32.55 °C on blackroof and 31.6 °C on stoneroof.

The Road to LID Plan Approval in Coastal North Carolina

Development of a Spreadsheet Modeling Tool for LID Based Designs

by Hunter Freeman P.E.
Withers & Ravenel, Cary, NC

Introduction

North Carolina has an abundance of natural resources and a climate that has helped make it one of the fastest growing states in the nation. With the growth and the jobs, comes the challenge of protecting the environment and quality of life that makes it such a desirable place to live. This is especially true for the 20 coastal counties, where stormwater policies are being updated to protect shellfish habitats and enhance water quality.

In theory Low Impact Development (LID) practices are one means to achieve high water quality standards, but until recently guidance for implementing this type of program at any level has been scarce. To that end the North Carolina Coastal Federation (NCCF) with National Oceanic and Atmospheric Administration (NOAA) grant funding and contributions from three jurisdictions: the City of Wilmington, New Hanover County, and Brunswick County, spearheaded the development of LID specific stormwater design manuals and a spreadsheet based modeling tool for each local government. The model was developed to assist engineers and developers with the permitting and approval of LID stormwater management plans as well as act as a tool for the reviewing agencies to use in the approval process.

Withers & Ravenel worked with the NCCF and the three local governments to tailor the model to meet specific requirements of each jurisdiction, combining the governmental needs with the calculation requirements of the engineer.

A Background on Stormwater Regulations in NC

While the current emphasis of North Carolina's LID initiative is to reduce the impact of runoff from new impervious surfaces, challenges to North Carolina's water quality are hardly new or limited strictly to urban development.

Virtually none of the North Carolina's coastal plains resemble the natural habitat the early settlers found when they arrived. The practice of draining wetlands to establish fertile cropland was commonplace. The conversion of North Carolina's pristine forest to agricultural use impaired nearly 50% of the estimated 8 million acres of natural coastal wetlands. These impacts deprived coastal habitats of their natural system for pollutant removal – functional wetlands.

Today, land development represents the greatest environmental impact from non-point source pollution in North Carolina, and sedimentation pollution, primarily from construction sites, is the largest non-point source pollutant by volume.

In 1974, North Carolina was one of the first States to enact statewide Erosion and Sedimentation Control regulations. North Carolina moved to protect water supply watersheds and other sensitive waters from non-point source pollution in the late 1980's with water quality regulations primarily targeting total suspended solids (TSS).Nonetheless some of North Carolina's river basins, in addition to the majority of the coastal estuaries, have proved to be more sensitive to pollution than others and needed more protection.

In the early 1990's fish kills in the Neuse River were traced to the proliferation of an organism which flourishes in nutrients from fertilizers, waste water discharges and runoff from impervious surfaces. In 1997, the State passed some of the nations strictest regulations for the Neuse River Basin. These rules were followed by Tar-Pamlico River Basin Rules, Randleman Lake Watershed Rules, and now the Jordan Lake Watershed Rules which are currently in development. The goals remained constant – reduce pollutant loading rates resulting from wastewater treatment processes and new development.

While new impacts to the water quality have been greatly reduced due to these regulations, the quality of coastal waters and habitat continues to degrade, due largely to the explosion of development within North Carolina's Inner Banks – the mainland development adjacent to the estuaries themselves.

The Challenge of Coastal Development

The natural amenities of the southeastern North Carolina coast have attracted new residents on a daily basis. Coastal North Carolina has been one of the fastest growing regions of the nation over the past 30 years. The number of housing units has increased by 127% in that time period, ranking the area as 5th in national growth. More specifically, Brunswick County, located between Wilmington, NC and Myrtle Beach, SC, was recently ranked as the 17th fastest growing county in the nation (source: US Census).

With the influx of development, and the increased impervious cover that accompanies it, stormwater runoff has become a major contributor to the pollution of North Carolina's sensitive coastal waters. The NCCF estimates that over 100,000 acres of shellfish habitat has been contaminated due to pollution from all sources, but principally stormwater runoff.

In July 2008, the North Carolina Senate passed a bill modifying stormwater regulations in the 20 coastal counties. The previous regulations, originally adopted in 1988, have remained unchanged since 1995. The recent efforts to revise the rules were met with significant opposition from developers and local governments alike. The newly revised regulations lower density thresholds for sensitive watersheds, require permitting for small projects previously exempt from regulations, and also

allow for a wider variety of stormwater treatment facilities, and best management practices (BMPs) including Low Impact Development techniques.

The Road to LID

In 2005, the NCCF, using EPA grant funding, formed the Lockwood Folly Roundtable in Brunswick County, NC. Water quality experts from a number of State agencies presented the Roundtable with evidence that demonstrated a long-term deterioration of water quality in the Lockwood Folly River. These presentations showed that between 1980 and the present, widespread areas in the Lockwood Folly failed to meet State water quality standards set for shellfishing. As a result, the percentage of the river's shellfishing areas that are closed increased from 18% in 1980 to the current level of 55%.

The group of eight stakeholders spent 18 months identifying key strategies in an attempt to protect, preserve and possibly restore local shellfish habitats. From the roundtable eight strategies were accepted by the County Commissioners in February 2007. Included among them were plans to "*Incorporate low impact development (LID) technology into county site design and development policies. The strategy will include methods to integrate this tool into the County's existing development management program."* In addition, a second strategy was to coordinate "*State, local, and federal regulatory programs with Brunswick County taking lead enforcement role and fostering inter-local cooperation,"* and to "*Suggest policy changes and financial plan to accomplish."*

Technical Advisory Committees

In 2006, the NCCF received grant funding from the NOAA to develop LID based ordinances for Brunswick and New Hanover counties, and the City of Wilmington.

Beginning in January 2007, the two counties organized Technical Advisory Committees consisting of local government staff, engineers, planners, developers, and local stakeholders. The Coastal Federation also contracted with Larry Coffman, a widely recognized LID expert, and implementer of a successful LID program in Maryland. He offered a wealth of knowledge and assistance in writing the ordinances, resolutions, and design manuals being used by both counties. With one of the largest obstacles being how to engineer and regulate LID in the fast moving pace of land development, Mr. Coffman's experience proved invaluable. The committees immediately began working towards drafting resolutions to encourage Low Impact Development practices; writing LID design manuals for use by engineers and developers; and identifying obstacles to LID implementation.

The three jurisdictions are highly motivated to get the necessary tools in place to encourage LID developments within their boundaries. While having similar overall

objectives, development patterns in the two counties are very different, and thus each of the three tasks mentioned above took on slightly different structures during the development process.

Development Patterns and LID

Brunswick County is largely undeveloped, and while it is a quickly growing area there is still the latitude to implement plans to manage growth, protect open space, and create watershed management strategies for areas such as the Lockwood Folly River. Conversely, New Hanover County is relatively densely developed. With much of the county being incorporated within the city limits of Wilmington, the county as a whole is rapidly becoming an urban area.

Brunswick County is tailoring their resolution and design manual to emphasize strategies to incorporate LID within new development. The county is projecting that development will involve more large scale master plans rather than individual single lot residential or commercial developments. In keeping with those projections, LID practices can be employed over large tracts of land with planners and developers starting from an essentially clean slate.

New Hanover County and the City of Wilmington are more inclined to focus their LID efforts on retrofit opportunities, small scale new developments, and urban infill projects. While there are some large tracts within the county which still remain undeveloped, there is a higher premium on redevelopment and infill projects closer to the center of Wilmington. .

The challenges of implementing LID practices in each county were had considerably more in common than differences stated above might suggest. It became apparent during these discussion that the overall development patterns and future land use goals of the two areas was less critical in identifying challenges to LID implementation. The list of recognized issues could be generally categorized as development, but one primary focus area became the ability, or lack thereof, to obtain necessary stormwater permits.

Identification of the Problem

The ability of any project to gain permit approval is a vital component of all successful designs, stormwater management plans, and developments. While the technical advisory committees were looking for ways to promote and encourage LID designs, one challenge to LID design which was identified by nearly every stakeholder was that the permit process timetable would increase exponentially unless a process was created specifically for LID designs. The root of the issue was simply the number of BMPs being used. Conventional designs used small numbers of large BMPs, while LID designs used large numbers of small BMPs. This meant that

preparation of calculations, reports, and supplemental worksheets in addition to permit reviews, would all take more time simply because there were more structures to review, not to mention more structures to operate and maintain

It is important to note that in these communities, as well as across most of coastal North Carolina, the stormwater permitting process is implemented by the North Carolina Division of Water Quality (DWQ). The water quality regulations are also set by the State, and then often supplemented with local flood control ordinances which are regulated by each individual jurisdiction. So at the very least, two stormwater permits are required for most projects.

On the whole, the regulations themselves posed little or no problem for LID implementation; it was the design and review process that needed to change. Moreover, for the permit process to work efficiently, projects would need to begin preparing for LID permit submittals from day one, long before the permit reviewer would ever see the first submittal. Conceptually, if the stakeholders could agree on revised standards for engineering calculations and reporting, then this could be used as the foundation of the revamped permit process. Withers & Ravenel, with the support of the NCCF, involved the State of North Carolina as a stakeholder in this process, putting them on an equal playing field with the local jurisdictions.

Regulatory Cooperation

In a separate initiative, State officials in North Carolina are spending considerable effort developing LID standards, policies, and a State LID design manual, scheduled for publication in late 2008. Past efforts by the State have opened the door for LID. The most recent version of the State stormwater BMP design manual included references to LID and had some allowances and guidance information for LID projects. In 1995, the DWQ developed their first stormwater BMP design manual in response to Clean Water Act amendments. Recently, the DWQ has made significant revisions to the manual, reflecting improved technologies and updated construction practices. The major focus of the manual is to spell out required design parameters for structural BMPs.

In 2007, Withers & Ravenel participated in a second set of stakeholder meetings with the City of Wilmington, New Hanover and Brunswick counties, the NCCF, and the State DWQ to discuss the methodologies, assumptions, and equations which would be accepted for LID designs.

The goal of this second set of stakeholder meetings was to involve the State permit reviewers in the discussions related to the technical requirements of LID. Once those general principles were in place, the group could move on to discussing possible changes to the LID permit review process. In a limited number of meetings, the group was able to thoroughly examine the technical aspects of LID, as well as a myriad of

areas within the design and approval processes where current policies posed a challenge for LID implementation.

It was apparent in these stakeholder meetings that to facilitate LID designs in the short term, the LID permitting process in North Carolina would need to closely align with the current permit process for conventional designs. Larry Coffman's experience with LID permitting in Maryland was relevant and valuable during these discussions. With LID permitting, Brunswick and New Hanover counties and the City of Wilmington were blazing a new trail for stormwater permitting in the State, and that created numerous decision points that required concurrence from all regulatory stakeholders before any permitting plan could take shape.

The regulatory stakeholder meetings centered on calculation methods for LID submittals. In an effort to promote LID as well as standardize the calculation methods, Withers & Ravenel was contracted by the NCCF to develop a spreadsheet based computational tool for the calculations, which was later dubbed LID-EZ.

Developing LID-EZ

Withers & Ravenel, using experience in writing analytical tools for Wake County's volume based stormwater ordinance, stepped in to help remove the calculation obstacle from LID permitting. LID-EZ is a spreadsheet based program developed to aid in the implementation of Low Impact Development stormwater management strategies on residential and commercial development projects. LID-EZ utilizes basic pre and post development land use and storage device design information input by the user, combined with established engineering methods, to quantify the impact of proposed development on stormwater runoff rates, volumes, and pollutant loads. The calculations and results are presented in an easy-to-read format and can be tailored to include specific site and stormwater data to address compliance with specific local stormwater regulations.

The engineering equations and methodology used in LID-EZ are based on the Soil Conservation Service Curve Number Method (described in Part 630 of the Natural Resources Conservation Service (NRCS) National Engineering Handbook), Technical Release 55 (TR-55) also published by NRCS, and TR-20 for time of concentration calculations. A number of current State policies and recommendations are also used in the software.

Above and beyond the calculations, LID-EZ's value is that it is customized to the individual preferences and policies of the four regulatory agencies involved in this project. The discussion during the regulatory stakeholder meetings was instrumental in delivering a spreadsheet that could actually be completed by the engineer, reviewed by a permit reviewer, and checked for regulatory compliance in less time than it took to perform the same tasks for a conventional design.

The Uses of LID-EZ

LID-EZ has two distinct uses. The first is a quick calculator, which is a single sheet form design to compute preliminary estimates of required storage volumes to meet State regulations. This sheet is completely independent of the remainder of the program. Because the sheet is not intended for use with final permit submittals, there are significantly fewer input requirements, warning messages, and data verification tools. The objective of incorporating this sheet was to provide a tool for engineers and planners who wish to determine the total required storage volumes for development sites at the time of sketch plans or preliminary submittals. Because land planning is such a critical aspect to successful LID design, having the ability to quickly evaluate numerous site plans using only the information typically known at the sketch plan stage (land area, soil types, and basic residential or commercial site data) is helpful in optimizing land use and maximizing the benefit of LID devices.

The second function is the detailed computational tool. This section of LID-EZ requires more detailed user input necessary and the results are intended for permit submittals and review. The user entry data is divided into three main input forms. One each for pre-development conditions (land use, soil types, time of concentration), post development (with the same inputs are pre-development) and the third for BMPs and storage devices. After completing the first two sheets, LID-EZ will report accurate values for required storage volumes, pre and post development curve numbers and time of concentrations, total runoff volumes for numerous storms, and estimated peak flows for each storm event.

The storage input sheet requires four critical inputs: the type of device being used, the impervious area draining to the device, the volume provided, and the downstream BMP (if applicable). Using those three inputs, in combination with the results already reported after filling in the land use data, LID-EZ computes and reports all the remaining data required for permit review. Other than reporting the storage volumes required and provided, the results include summary data on the size of each BMP relative to the upstream drainage area, estimated pollutant removal efficiencies for the entire site, and anticipated post development curve numbers for each storm event after accounting for the storage volume.

The curve number output is critical because of the local flood control requirements. The regulatory stakeholder group realized that it may be difficult to achieve flood control for larger storm events using only LID devices. The curve number reported (calculated using methods established by the Maryland Department of the Environment) reflects post development land use as well as the impact of the numerous LID techniques and devices used in other areas of the watershed. This allows the developers to reduce the size of required flood control devices in proportion to the extent to which they apply LID practices to their site.

Specific Limitations in North Carolina

In using the curve number method, which is included in the current version of the State BMP manual as an allowable method for computing runoff volume from LID projects, calculation methods were being used which had not been widely used in North Carolina for permit approval. Although the core equations have been previously published and generally accepted, restrictions were needed on the limit to which certain variables could be employed.

These areas of the curve number method were discussed during the regulatory stakeholder meetings. In establishing allowable input ranges, we consulted papers from many experts on the curve number method, used our experience from the Wake County stakeholder meetings, and consulted with staff from the Soil Conservation Service. The information we gathered was used throughout the regulatory stakeholder meeting. The stakeholder discussions were, to our knowledge, the first in depth analysis of how to take LID from a conceptual planning tool to a viable permitting option in North Carolina.

Some unique aspects of LID-EZ were included in the program to simplify input parameters. These included restricting pre-development land use to woods, pasture, or impervious area, and restricting post development land use to woods, open space, residential lots, connected impervious area, and disconnected impervious area. A separate input section includes information on the residential lots, such as proposed impervious area and preserved woods on each lot, resulting in computations which generate a composite curve number for residential areas.

Other decisions were made to assist with permit review and reduce the number of potential errors in the submittals. This included limits on sheet flow length, restrictions on the use of impervious area in pre-development conditions, and inclusion of multiple warning and error messages to alert the applicant of potential errors. The programming behind LID-EZ includes numerous checks for consistency between pre-development and post-development land areas, composition of soils, and calculators to assure that adequate storage volumes are provided to meet State standards.

Recent Updates to LID-EZ

The original development of LID-EZ was limited to holistic calculations for entire tracts of land. After consulting with State regulatory officials, we identified the need for more detailed information, resulting in the addition of input fields for the impervious area drainage to individual BMPs and the identification of downstream BMPs. In this case, two simple inputs significantly increase the potential for high quality LID designs.

Conventional stormwater permitting in North Carolina requires detailed information about each structural BMP to ensure that minimum design requirements are met for volume control and pollutant removal. Using the two additional inputs, we were able to add computational checks to ensure that the storage volume provided was proportional to the impervious area draining to the device. Impervious area was also used to compute pollutant loading figures for total suspended solids, nitrogen, phosphorous, fecal coliform and temperature. Combining pollutant removal data previously published by the State with the user input of the downstream BMP, we could reconstruct the treatment train effect of multiple BMPs in series and report the anticipated pollutant removal rates for the entire site.

In addition, we are updating the spreadsheet with tools enabling the user to receive credit for pervious pavement installations in accordance with DWQ guidance, and we are developing a separate program targeted specifically at the analysis of retrofit opportunities.

Withers & Ravenel is currently in the process of preparing a presentation and an intensive day long training session for regulators from the Division of Water Quality. We hope to educate permit reviewers about the equations and methods being used, and establish a permit application process specifically for LID projects in coastal North Carolina.

The current version of the spreadsheet has been distributed on a case by case basis to a limited number of engineers. The revised spreadsheet, with added functionality, will be released for use in late September 2008 in conjunction with publication of LID design manuals for Brunswick and New Hanover counties.

Conclusions

The end result of the stakeholder and task force meetings was multi faceted. On one level, we achieved concurrence between all the local agencies, as well as buy-in from the State regulators on all of the issues known at the time. On an entirely different level, but perhaps even more importantly, we had initiated a long term dialogue between State regulators, local officials, and the development community which continues today and is a key component in establishing a more complete approach to LID design and permitting

Since the conclusion of the stakeholder meetings, it has become easier to achieve consensus on key decision points in development of LID tools, largely due to the fact that each stakeholder in the regulatory meetings was open minded and believed that Low Impact Development would lead to a better living environment, and had a willingness to make LID happen.

While we are still in the process of product development, we look back with satisfaction on the accomplishments of the past 18 months. Significant progress has been made on LID resolutions in each community, which is a key step in promoting

LID for new developments. The design manuals are nearly complete, and the spreadsheet program is already in its second version. We continue to increase the number of tools and resources available to local developers and are looking forward to the day when LID designs become the standard for high quality stormwater management plans in North Carolina.

ABSTRACT

In 2008, the Center for Watershed Protection and the Chesapeake Stormwater Network developed the Runoff Reduction Method. The method was developed as part of a project to research and update best management practice (BMP) performance and, in particular, ascertain the ability of various BMPs to reduce post-development runoff volumes. The method focuses on the capability of conventional and innovative stormwater management practices (e.g., permeable pavement, green roofs, rainwater harvesting, bioretention, downspout disconnection, etc.) to reduce runoff, as well as remove pollutants, and incorporates built-in incentives for environmental site design, such as forest and open space preservation. Because of the high runoff reduction capabilities of various site design and innovative stormwater practices, implementing these innovative practices at a site reduces the overall number and size of structural BMPs required. This approach helps put innovative stormwater management practices on a level playing field with conventional stormwater management practices, such as wet and dry ponds.

Currently, various state programs are in the process of using or adopting the Runoff Reduction Method as part of regulatory and non-regulatory programs. The Virginia Department of Conservation and Recreation (DCR) is integrating the Runoff Reduction Method into proposed stormwater management regulations and an updated stormwater management handbook. The Georgia Department of Natural Resources is modifying the method for a new Coastal Stormwater Management Manual Supplement. The State of Delaware is using the concept of runoff reduction in proposed statewide regulations. With the incorporation of the Runoff Reduction Method into these programs, communities are poised for the wide-spread implementation of low impact development and innovative stormwater management practices on development sites.

Keywords: Runoff reduction, volume, nutrients, site design, BMPs, LID, regulations, Virginia

INTRODUCTION

The Runoff Reduction Method was developed in early 2008 by the Center for Watershed Protection (CWP) and the Chesapeake Stormwater Network (CSN) in order to promote better stormwater site design and as a compliance tool for Virginia's proposed stormwater regulations. The method focuses on the capability of both conventional and innovative stormwater management practices (e.g., permeable pavement, green roofs, rainwater harvesting, bioretention, downspout disconnection, etc.) to reduce runoff and remove pollutants, and incorporates built-in incentives for site design approaches that preserve forest and open space.

Runoff reduction is defined as the average annual reduction in stormwater runoff volume. Various BMPs are capable of reducing the overall volume of runoff based on the post-development condition. Runoff can be reduced via canopy interception, soil infiltration, evaporation, transpiration, rainfall harvesting, engineered infiltration, or extended filtration. Depending on the BMP or series of BMPs, runoff reduction processes can be combined with processes that remove pollutants through settling, filtering, adsorption, biological update, or other mechanisms. The Runoff Reduction Method includes BMPs that achieve runoff reduction (RR), pollutant removal (PR), or both.

The field of stormwater management has recently seen many new terms being adopted to describe related and overlapping approaches and philosophies. Runoff reduction describes a process or function of BMPs. As such, it is an important components of other stormwater terms, such as low impact development (LID), environmental site design (ESD), and green infrastructure. For the purposes of this paper, the term runoff reduction will be used, but the other terms are also applicable. Independent of what it is called, the suite of practices and site design techniques that reduce runoff volumes has the potential to reduce the size and number of structural or conventional best management practices (BMPs) and put innovative practices on a more level playing field with the commonly used wet and dry ponds.

The Runoff Reduction approach also moves beyond managing stormwater solely for peak rate and water quality treatment by attempting to replicate a more natural (or pre-development) hydrologic condition. More specifically, it moves towards a more comprehensive approach that addresses runoff volume, duration, velocity, frequency, groundwater recharge, and protection of stream channels. When used in conjunction with site pollutant limits, the approach can help meet the pollutant reduction goals (i.e. nutrient strategies, TMDLs) of the larger watershed.

THE METHOD

The Runoff Reduction Method relies on a three-step compliance procedure, as described below:

Step 1: Reduce Stormwater Runoff by Design

Step one focuses on implementing better site planning and design techniques during the early phases of site layout. The goal is to minimize impervious cover and mass grading, and maximize retention of forest cover, natural areas and undisturbed soils (especially those most conducive to landscape-scale infiltration). The Runoff Reduction Method assigns runoff coefficients for forest, disturbed soils, and impervious cover to calculate a site-specific target treatment volume.

Step 2: Reduce Volume of Post-Construction Stormwater Runoff. In this step, a designer uses combinations of small-scale, distributed and conventional practices that are effective at reducing runoff from the site. In each case, the designer estimates the area to be treated by each runoff reduction practice to incrementally reduce the required treatment volume for the site. The designer is encouraged to use these practices in series within individual drainage areas (such as rooftop disconnection to a grass swale to a bioretention area) in order to achieve a higher level of runoff reduction.

Step 3: Capture and Treat Remaining Stormwater Runoff.
In this step, the designers apply pollutant reduction values to the runoff reduction practices used in Step 2. If the target pollutant limits are not reached, the designer can select additional, conventional BMPs - such as filtering practices, wet ponds, and stormwater wetlands - to meet the remaining pollutant reduction requirements.

Figure 1. Practices Included in the Runoff Reduction Method

In reality, the process is iterative for most sites. When compliance cannot be achieved on the first try, designers can return to prior steps to explore alternative combinations

of site planning, site design, runoff reduction practices, and pollutant removal practices to achieve compliance. A possible Step 4 would involve paying an offset fee (or fee-in-lieu payment) to compensate for any pollutant load that cannot feasibly be met on particular sites. A related, but simpler option would be to allow a developer to conduct an off-site mitigation project in lieu of full on-site compliance. **Figure 1** includes a list of site design and stormwater practices that can be used for each step.

RUNOFF COEFFICIENTS AND TREATMENT VOLUME

The negative impacts of increased impervious cover (IC) on receiving water bodies have been well documented (CWP 2003, Walsh et al. 2004; Shuster et al. 2005; Bilkovic et al. 2006). Due to widespread acceptance of this relationship, IC has frequently been used in watershed and site design efforts as a chief indicator of stormwater impacts. More recent research, however, indicates that other land covers, such as disturbed soils and managed turf, also impact stormwater quality (Law et al, 2008). Numerous studies have documented the impact of grading and construction on the compaction of soils, as measured by increase in bulk density, declines in soil permeability, and increases in the runoff coefficient (OCSCD et al, 2001; Pitt et al, 2002; Schueler and Holland, 2000). These areas of compacted pervious cover (lawn or turf) have a much greater hydrologic response to rainfall than forest or pasture. Further, highly managed turf can contribute to elevated nutrient loads. Typical turf management activities include mowing, active recreational use, and fertilizer and pesticide applications (Robbins and Birkenholtz 2003).

An analysis of Virginia-specific data from the National Stormwater Quality Database (Pitt et al. 2004) found that runoff from monitoring sites with relatively low IC residential land uses contained significantly higher nitrogen concentrations ($\alpha = 0.05$) than sites with higher IC non-residential uses (CWP & VA DCR, 2007). This suggests that residential areas with relatively low IC can have disturbed and intensively managed pervious areas that contribute to elevated nutrient levels.

The failure to account for the altered characteristics of disturbed urban soils and managed turf can result in an underestimation of stormwater runoff and pollutant loads generated from urban pervious areas. Therefore, the computation and compliance system for stormwater runoff should take into account impervious cover as well as other land cover types.

The runoff coefficients provided in **Table 1** were derived from research by Pitt et al (2005), Lichter and Lindsey (1994), Schueler (2001a), Schueler, (2001b), Legg et al (1996), Pitt et al (1999), Schueler (1987) and Cappiella et al (2005). As shown in this table, the effect of grading, site disturbance, and soil compaction greatly increases the runoff coefficient compared to forested areas.

The Runoff Reduction Method uses runoff coefficients to calculate a site-specific target treatment volume (Tv). A site's Tv is calculated by multiplying the "water quality" rainfall depth by the three site cover runoff coefficients (forest, disturbed

soils, and impervious cover) present at the site, as shown in **Figure 2**. The "water quality" rainfall depth is often defined as the rainfall depth associated with 90 percent of runoff-producing storm events on an average annual basis. Use of this depth as a design requirement for stormwater BMPS ensures that 90% of all storm events will be completely treated, as will the first portion of all larger storm events. The 90% storm event approach to defining the treatment volume is widely accepted and is consistent with several state stormwater manuals (MDE, 2000, ARC, 2002, NYDEC, 2001, VTDEC, 2002, OME, 2003, MPCA, 2005).

Table 1. Site Cover Runoff Coefficients (Rv)

Soil Condition	Runoff Coefficient
Forest Cover (R_{vF})	0.02 to 0.05*
Disturbed Soils/Managed Turf (R_{vT})	0.15 to 0.25*
Impervious Cover (R_{vI})	0.95
*Range dependent on original Hydrologic Soil Group (HSG) Forest A: 0.02 B: 0.03 C: 0.04 D: 0.05 Disturbed Soils A: 0.15 B: 0.20 C: 0.22 D: 0.25	

$$T_v = \frac{P \times \left[\left(R_{vI} \times \%I \right) + \left(R_{vT} \times \%T \right) + \left(R_{vF} \times \%F \right) \right] \times SA}{12}$$

Where
T_v = Runoff treatment volume in acre feet
P = Depth of rainfall for "water quality" event
R_{vI} = runoff coefficient for impervious cover[1]
R_{vT} = runoff coefficient for turf cover or disturbed soils[1]
R_{vF} = runoff coefficient for forest cover[1]
% I = percent of site in impervious cover (fraction)
%T = percent of site in turf cover (fraction)
%F = percent of site in forest cover (fraction)
SA = total site area, in acres
[1] R_v values from **Table 1.**

Figure 2: Determining the Stormwater Treatment Volume

The proposed treatment volume has several distinct advantages when it comes to evaluating runoff reduction practices and sizing BMPs. In effect, Tv provides an objective measure to gage the aggregate performance of runoff reduction practices and conventional BMPs together using a common currency (runoff volume). Calculating the Tv explicitly acknowledges the difference between forest and turf cover and disturbed and undisturbed soils, which creates incentives to conserve forests and reduce mass grading. Further, runoff is a direct function of impervious cover and disturbed soils, which provides designers incentives to minimize both at a

development site. Additionally, the Tv captures approximately 90% of the annual runoff volume from the site, and partially captures for larger storms. Managing this volume through the Runoff Reduction Method provides effective treatment of pollutants for a range of storm events, which is important since the first flush effect has been found to be modest for many pollutants (Pitt et al 2005).

DOCUMENTING BMP PERFORMANCE

After implementing environmental site design and site planning techniques to minimize the site treatment volume generated, the next steps of the Runoff Reduction Method involve the selection of BMPs to reduce Tv, and in effect, the pollution load of a site. CWP and CSN made a significant effort through an extensive literature search to identify the capabilities of various BMPs to reduce overall runoff volume (*runoff reduction*) in addition to pollutant concentrations (*pollutant removal*). Historically, BMP performance has been evaluated according to the pollutant removal efficiency of a practice. In some cases, this underreported the full capabilities of BMPs to reduce pollutant loads. Depending on the method used to calculate pollutant removal, reported removal efficiencies of stormwater best management practices (BMPs) can vary widely and are often inconsistent. Further, removal efficiencies do not always address runoff volume reductions in BMPs (Strecker et al, 2004; Jones et al, 2008). More recent BMP performance research has focused on runoff reduction as well as overall pollutant removal. In order to isolate the pollutant removal mechanisms of a BMP apart from runoff reduction, EMC based pollutant removal efficiencies were researched.

For several practices, there were a limited number of studies available that reported runoff reduction or EMC based nutrient removal efficiencies. As a result, some of the values listed in the tables below will be subject to change as more studies and data become available. The values represent the authors' best judgment based on currently-available information. Further documentation on the derivation of these values can be found in Hirschman et al, 2008.

RUNOFF REDUCTION PRACTICES

As described earlier in this paper, various BMPs are capable of reducing the overall volume of runoff based on the post-development condition. Runoff can be reduced via canopy interception, soil infiltration, evaporation, transpiration, rainfall harvesting, engineered infiltration, or extended filtration. Extended filtration includes bioretention or dry swales with underdrains that delay the delivery of stormwater from small sites to the stream system by six hours or more.

Runoff reduction data were limited for most practices. However, many recent studies have started documenting runoff reduction performance. Based on the research findings, runoff reduction rates were assigned to various BMPs, as shown in **Table 2**. A range of values represents the median and 75th percentile runoff reduction rates based on the literature search. Several BMPs reflected moderate to high capabilities

for reducing annual runoff volume. Others – including filtering, wet swales, wet ponds, and stormwater wetlands -- were found to have a negligible affect on runoff volumes, and were not assigned runoff reduction rates. The accuracy of these runoff reduction numbers can depend upon the characteristics and BMP geometry of specific sites, so specific design criteria are associated with each BMP to ensure that the runoff reduction numbers are appropriately applied.

Table 2. Runoff Reduction for various BMPs (based on average annual rainfall in the Virginia Piedmont area)

Practice	Runoff Reduction (%) *
Green Roof	*45 to 60*
Rooftop Disconnection	*25 to 50*
Raintanks and Cisterns	*40*
Permeable Pavement	*45 to 75*
Grass Channel	*10 to 20*
Bioretention	*40 to 80*
Dry Swale	*40 to 60*
Wet Swale	*0*
Infiltration	*50 to 90*
ED Pond	*0 to 15*
Soil Amendments	*50 to 75*
Sheetflow to Open Space	*50 to 75*
Filtering Practice	*0*
Constructed Wetland	*0*
Wet Pond	*0*

*Range of values is for median (Level 1) and 75th percentile (Level 2) designs

POLLUTANT REMOVAL PRACTICES

In order to isolate the pollutant removal mechanisms of a BMP and offer a better approach to assessing BMP pollutant removal performance (as distinct from runoff reduction), EMC based pollutant removal rates for nitrogen and phosphorus were researched. EMC based pollutant removal is accomplished via processes such as settling, filtering, adsorption, and biological uptake. This does not account for changes in the overall volume of runoff entering and leaving the BMP.

Based on the research findings, EMC-based pollutant removal rates were assigned to various BMPs, as shown in **Table 3**. A range of values represents the median and 75th percentile runoff reduction rates based on the literature search. It should be noted that the data used to estimate pollutant removal were derived from practices in good condition; most studies focused on BMPs that were constructed within three years of monitoring. Further, the actual EMC pollutant removal performance can be strongly influenced by the influent quality. As with runoff reduction, since pollutant removal rates are dependent on site characteristics and BMP geometry, these EMC-based pollutant removal numbers are associated with specific design criteria.

Table 3. EMC-based pollutant removal for various BMPs

Practice	Total Phosphorus Pollutant Removal (%)*	Total Nitrogen Pollutant Removal (%)*
Green Roof	*0*	*0*
Disconnection	*0*	*0*
Raintanks and Cisterns	*0*	*0*
Permeable Pavement	*25*	*25*
Grass Channel	*15*	*20*
Bioretention	*25 to 50*	*40 to 60*
Dry Swale	*20 to 40*	*25 to 35*
Wet Swale	*20 to 40*	*25 to 35*
Infiltration	*25*	*15*
ED Pond	*15*	*10*
Soil Amendments	*0*	*0*
Sheetflow to Open Space	*0*	*0*
Filtering Practice	*60 to 65*	*30 to 45*
Constructed Wetland	*50 to 75*	*25 to 55*
Wet Pond	*50 to 75*	*30 to 40*

*Range of values is for median (Level 1) and 75th percentile (Level 2) designs

ACCOUNTABILITY FOR BETTER BMP DESIGN

A range of performance values associated with design are introduced in the Runoff Reduction Method (see **Tables 2 and 3**). A standard, or Level 1 design can be expected to achieve the median value of Runoff Reduction and Pollutant Removal from the research), while an enhanced, orLevel 2 design achieves the 75th percentile values.

Based on the evaluation of BMP performance in the literature, design factors – such as sizing, pretreatment, flow path geometry, vegetative condition, and treatment processes – that enhance nutrient pollutant removal and runoff reduction of BMPs were isolated. These design factors were then applied to Level 1 and Level 2 BMPs. In order to achieve established RR and PR rates, the specific design factors associated with these levels must be met.

The scientific rationale and assumptions used to assign sizing and design features to the standard and enhanced BMP levels involved identifying the "standard" design features that should be included in all designs (i.e., not directly related to differential nutrient removal or runoff reduction rates), a review of individual BMP studies, and the modification of design point tables in the *Stormwater Retrofit Manual, Appendix B* (Schueler et al, 2007) to reflect the more specific goal of reducing runoff and nutrient removal for BMPs.

Importantly, it should be understood that the assigned rates are based on the assumption that BMP designs will meet certain "eligibility criteria." That is, the BMPs will be located and designed based on appropriate site conditions and limitations with regard to soils, slopes, available head, flow path, and other factors.

The specific design factors and eligibility criteria for various BMPs are detailed in the Runoff Reduction Technical Memo (Hirschman et al, 2008).

TRANSFERABILITY OF THE RUNOFF REDUCTION CONCEPT

While the Runoff Reduction Method was originally developed in tandem with the Virginia Department of Conservation and Recreation (DCR) efforts to update the stormwater regulations and handbook, the concept is widely applicable to other state and local stormwater planning procedures. The focus on runoff volume as the common currency for BMP evaluation is gaining wider acceptance across the county (U.S. EPA, 2008). Currently, various state programs are in the process of using or adopting methods similar to the Runoff Reduction Method as part of regulatory and non-regulatory programs. With the incorporation of the Runoff Reduction Method into these programs, communities are poised for the wide-spread implementation of runoff reduction practices on development sites.

- *Virginia* – The Virginia DCR is integrating the Runoff Reduction Method into proposed stormwater management regulations and an updated stormwater management handbook. The method focuses on compliance to meet site-based pollutant load limits, aimed at limiting the total nutrient load leaving a new development site. A site design compliance spreadsheet was developed to ensure runoff reduction and nutrient loading requirements for the site are met.

- *Georgia* - The Georgia Department of Natural Resources is modifying the Runoff Reduction Method for a new Coastal Stormwater Management Manual Supplement. The manual requires that the stormwater runoff volume from the 1.2" rainfall event (85^{th} percentile event) be retained, reused, or reduced to the maximum extent practical, on a new development or redevelopment site. A runoff reduction volume is calculated based on site impervious cover, and volume reduction "credits" are given to green infrastructure and stormwater management practices that reduce overall runoff.

Additional efforts to incorporate the concept of runoff reduction into updated stormwater regulations and design manuals are underway in the States of Delaware, Maryland, and the District of Columbia (Capiella et al., 2007; DeBlander et al., 2008; MSC, 2008). The *Pennsylvania Stormwater Best Management Practices Manual* (PA DEP, 2006) already incorporates standards for volume control achieved by structural and nonstructural BMPs.

CONCLUSION

Clearly, the concept of runoff reduction marks an important philosophical milestone that will help define the next generation of stormwater design. The promise of runoff reduction is that the benefits go beyond water quality improvement. If site and stormwater designs can successfully implement runoff reduction strategies, then they will do a better job at replicating a more natural (or pre-development) hydrologic

condition. This goes beyond peak rate control to address runoff volume, duration, velocity, frequency, groundwater recharge, and protection of stream channels. Important future work will involve integrating the runoff reduction concept with stormwater requirements for channel protection and flood control, so that stormwater criteria can be presented in a unified approach.

Unit Process Modeling of Stormwater Flow and Pollutant Sorption in a Bioretention Cell

Zhuangxiang He and Allen P. Davis
Department of Civil and Environmental Engineering,
University of Maryland, College Park, MD 20742

Abstract

Bioretention is a mulch/soil/plant-based low impact development facility employed to collect, store, infiltrate and treat urban stormwater runoff. This work focuses on modeling to describe the fate of stormwater and the adsorption of pollutants in bioretention facilities. A two dimensional Variable Saturated Flow and Transport Model is developed based on partial differential equation modes in COMSOL Multiphysics, in which both fluid flow and solute transport are under transient analysis. Model results indicate that the outflow volume is less than the inflow due to the storage and the extent of initial unsaturation in the media. The outflow volume from loamy sand media (with larger K_s) is larger than that from sandy loam media. The flow peak is reduced. Concentrations of naphthalene (NP) and pyrene (PY) in runoff vary with depth and most NP and PY (> 90%) is removed within about 3 cm media depth.

1 Introduction

Bioretention, also known as rain gardens, is a low-impact development (LID) best management practice (BMP), providing a mulch/soil/plant-based trapping media to collect, store, infiltrate and treat urban stormwater runoff. A diagram of a bioretention cell is presented in Figure 1. Besides a thin mulch layer on the top of the cell, the primary media consists of a sand/soil/organic matter mixture with high hydraulic conductivity, surrounded by native (possibly less permeable) soils. A vegetative layer provides evapotranspiration, pollutant uptake, and enhanced porosity of the planting soil. A ponding area serves as a storage reservoir, and thereafter extends the time for water to infiltrate into the media.

Bioretention was developed to improve post-development hydrology. Field studies have demonstrated the ability of bioretention to increase the lag time and reduce the peak flow rates as well as the total volume of effluent water (Dietz and Clausen 2005; Hunt *et al*. 2006; Davis 2008). A variety of numerical models, describing variably saturated flow by Richards' equation, have indicated that the primary factors influencing the hydraulic performance of infiltration systems similar to bioretention are initial water content, characteristics of infiltration media and surrounding soils, stormwater loading and duration (Duchene *et al*. 1994; Harada and Ichikawa 1994; Li *et al*. 1999; Sansalone and Teng 2004, 2005). However, limited modeling work is available to show the impacts of these factors on the performance of a bioretention cell.

Recently, bioretention was found to improve the quality of stormwater runoff before discharge to receiving waters. Pollutants in runoff are removed mainly through physical and chemical mechanisms during rainfall events, such as adsorption. After rainfall events, captured pollutants continue to be impacted by chemical or biological processes. Laboratory and field work have been completed indicating that bioretention is a promising management practice for controlling several urban pollutants, including total suspended solids (Hsieh and Davis 2005a, 2005b), nutrients (Davis *et al*. 2006; Hsieh *et al*. 2007), heavy metals (Davis *et al*. 2001, 2003; Li and Davis 2008), and polycyclic aromatic hydrocarbons (PAHs) (Hong *et al*. 2006). However, in order to continue the maturation of BMP research, comprehensive modeling ventures must be undertaken to complement ongoing experimental and monitoring programs. This work focuses on modeling to describe the fate of stormwater flow and the adsorption of two common PAH compounds, i.e., naphthalene (NP) and pyrene (PY), in a bioretention cell.

2 Methodology

2.1 *Geometry*

Figure 2 shows the geometry of a bioretention cell with width of 3.6 m and height of 0.8 m. Water is ponded above the surface layer when the media is saturated. The circle within bioretention media subdomain represents the underdrain with a diameter of 0.3 m. The height of the ponding space is 0.3 m, as bioretention practices are often designed to treat ponding water no higher than 0.25 m. Because the boundary conditions between the soil media and surrounding soils are unclear, a large modeling geometry is generated by extending the surrounding soil subdomain for 4.2 m wide on each side and 1.2 m deep under the bioretention media. The mulch and vegetated layers are not included in this simple representation.

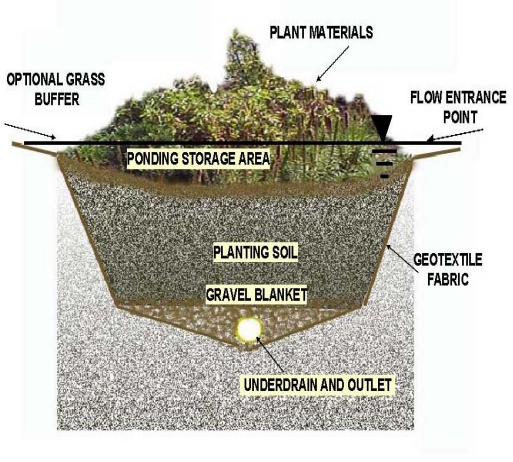

Figure 1. Typical bioretention cell (DER, 2001)

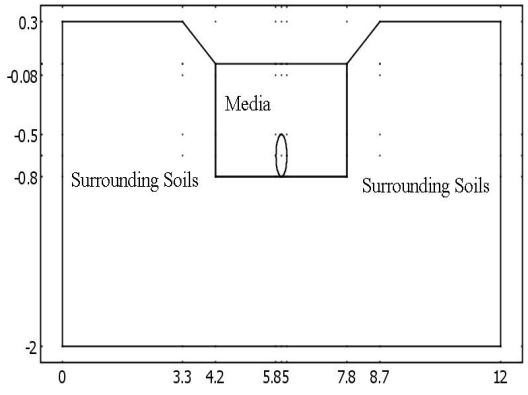

Figure 2. Geometry of a bioretention cell (Unit: meter)

2.2 Governing Equations

A two dimensional Variable Saturated Flow and Transport Model is developed based on partial differential equation modes in COMSOL Multiphysics (formally named FEMLAB). Richards' Equation Application Mode and Solute Transport Application Mode in the Earth Science Module are employed to simulate both subsurface flow and pollutant fates (COMSOL AB, 2005), using a unit operations approach to consider mass balances under unsteady state conditions.

Subsurface flow and solute transport are linked by fluid velocities from Darcy's law.

$$\mathbf{u} = K_s k_r \nabla(H_p + D) \tag{1}$$

Here, **u** is a vector of directional velocities (m/d). In the two dimensional modeling, *u* and *v* represent the x- and y- velocity, respectively. *D* represents vertical elevation (e.g., *x* or *y*).

The Richards' equation application mode uses the Richards' equation interface to describe the nonlinear relationship between retention and permeability properties according to van Genuchten. Richards' equation governs the saturated-unsaturated flow of water in soil.

$$[C + \mathrm{Se}S]\frac{\partial H_p}{\partial t} + \nabla \cdot [-K_s k_r \nabla(H_p + D)] = Q_s \tag{2}$$

Here, *C* represents specific moisture capacity (m^{-1}), Se is the effective saturation of the soil, *S* is a storage coefficient (m^{-1}), and Q_s represents fluid sources and sinks (d^{-1}). $S = \theta_s - \theta_r$, where θ_s and θ_r are water volume fraction at saturation and after drainage, respectively.

Equation 3 is implemented in the Solute Transport application mode, describing advection, dispersion, sorption, volatilization, and decay of solute in soil.

$$\left[\theta + \rho_b \frac{\partial c_p}{\partial c} + a_v \frac{\partial c_G}{\partial c}\right]\frac{\partial c}{\partial t} + \left[(1 - k_G)c\frac{\partial \theta}{\partial t}\right] + \nabla \cdot [-\theta D_{LG} \nabla c + \mathbf{u}c] = R_L + R_P + R_G + S_c \tag{3}$$

On the left side, the first bracketed term shows the change of liquid-, solid-, and air-phase concentrations with time. The second term explains changes in storage because water content in the soil media varies in time. The third term represents the overall solute flux due to dispersion, diffusion, and advection with moving water. The right side represents reactions (liquid phase, solute attached to soil particles, and air phase) and sources. In this work, adsorption is assumed as the main pollutant removal mechanism and the reactions in three phases are not considered.

2.3 Boundary Conditions

The surface boundary of bioretention media is crucial as it is not easy to handle the varying rainfall boundary. Non-steady state flow and pollutant concentration

conditions typical of urban stormwater runoff are input. Specifically, the inflow rate is modeled as a Gaussian distribution and coefficients a, b and c in the Gaussian equation are employed to represent the peak, density and duration of rainfall, respectively. The influent concentration of PAHs is assumed as 120 *u*g/L (Pitt *et al*. 1995). The concentration decreases exponentially and the minimum pollutant concentration in runoff after a decay period is assumed to 10% of the highest concentration.

The boundary of the underdrain is also important. The water from a bioretention cell enters a drainage system though holes on the top of the drainage pipe. The boundary conditions at the top half circle are set to be atmospheric pressure in the fluid flow mode and convection in the solute transport mode. The boundary conditions of the under half circle are described as no flux. All boundary conditions for surrounding soils are set to no flux for both water flow and solute transport.

2.4 Parameters

Simulations are run to evaluate the impacts of inflow rate, input concentrations, and some key parameters of bioretention performance and design, such as the soil types and properties for both cell media and surrounding soils (K_s, θ_s, θ_r, α, n, and ℓ). Some important parameters for bioretention performance and design are listed in Table 1. The impact of the linear partition coefficient (K_p) of NP and PY is also evaluated. This parameter is determined based on solubility and media organic matter content (foc). K_p of PAHs is calculated by the following equations:

$$K_p = f_{oc} K_{oc} \quad (4)$$

$$\text{Log } K_{oc} = 0.4057 \log K_{ow} - 0.4155 \log S + 2.3739 \quad (5) \quad \text{(Gao } \textit{et al}. \text{ 1996)}$$

Here, K_{oc} is the partition coefficient of pollutant in the organic fraction of the soil. K_{ow} is the partition coefficient of organic matter between octanol and water. S is the PAH solubility in water.

Table 1. Important Parameters for Bioretention Performance and Design

Parameters	Definition	Units	Values	Comments
$\mathbf{K_s}$	Saturated hydraulic conductivity	m/d	*	
$\mathbf{\theta_s}$	Saturated volume liquid fraction	-	*	
$\mathbf{\theta_r}$	Residual volume liquid fraction	-	*	
α, n, ℓ	Parameters for Van Genuchten	**α**: m^{-1}.	*	$\ell = 1\text{-}1/\mathbf{n}$
$\mathbf{H_p}$	Pressure head of ponding	M	0 ~ 0.25	
$\mathbf{H_{p0}}$	Initial pressure head in soil	M	**	
$\mathbf{K_p}$	PAH partition coefficient	m^3/kg	***	
$\mathbf{f_{oc}}$	Fraction of organic matter in soil		1 ~3%	
$\mathbf{C_0}$	Initial concentration in soil	Kg/m^3	0	

* Values of K_s, θ_s, θ_r, α, n, and ℓ of media and surrounding soils are listed in Table 2.

** H_{p0} is defined using expressions in which initial pressure head varies with soil depth.

*** K_p of PAHs is calculated using equation (4) and (5).

Table 2. Hydraulic Parameters of Bioretention Media and Surrounding Soils (Li *et al*. 1999)

Soil Type	K_s[m/d]	θ_s	θ_r	α [m^{-1}]	n	ℓ
Media						
Sandy Loam [a0]	1.0627	0.41	0.065	0.075	1.89	0.471
Loamy Sand	3.450	0.41	0.057	0.124	2.28	0.5614
Surrounding Soils

[a0]: standard soil type of bioretention media

[b0]: standard soil type of surrounding soils

3. Results and Discussion

3.1 Hydrology performance

The Bioretention media is a sandy loam with a saturated hydraulic conductivity, K_s, of 1.06 m/d, surrounded by sandy clay loam with a smaller K_s of 0.314 m/d. Flow volumetric flux (m^2/d) is used in the results of this two dimensional model instead of flow rate (m^3/d). Under the assumed Gaussian distribution influent (solid line), the dashed line in Figure 3 shows that the peak of the effluent from the underdrain was delayed and reduced. The total volume of outflow is much less than that of inflow.

Davis (2008) employed three metrics to quantify the hydrological benefits of two field bioretention facilities with lined bottoms in Maryland, including the peak flow rate ratio of effluent to influent $R_{peak} = q_{peak\text{-}out}/ q_{peak\text{-}in}$, the effluent/influent volume ratio $f_{V24} = V_{out\text{-}24}/V_{in}$, and the peak discharge time ratio of effluent to influent $R_{delay} = t_{q\text{-}peak\text{-}out} / t_{q\text{-}peak\text{-}in}$. An $R_{peak} < 1$ indicates peak reduction. An $f_{V24} < 1$ indicates runoff volume reduction and ground water recharge. The target f_{V24} value proposed is $f_{V24} <$ 0.33 with the same rationale for R_{peak}. Peak delay ($R_{delay} > 1$) is expected for 75-88% of rainfall events at field bioretention facilities (Davis 2008). In this simulated event, f_{V24}, R_{peak} and R_{delay} are 0.086, 0.08 and 1.67, respectively, which all indicate good hydrological performance of this bioretention cell.

3.2 Water quality

Figure 4 shows the influent concentration of NP and the concentration at the depth of 0.5 m, at the top of the underdrain. The effluent NP concentration is nearly zero and hence the removal efficiency is nearly 100%, mainly due to the high adsorption of NP by the organic matter in the media. In this model, adsorption is considered as the primary removal mechanism. Figure 5 shows that the NP concentration varies with depth (negative values of depth indicate depths beneath the surface). Most NP (>90%) is removed within about 3 cm depth. Similar results are also obtained for PY, although the PY has a larger K_p than NP. This is probably due to the very high K_p values of both NP and PY, calculated as 0.023 and 1.311 m^3/kg, respectively.

These simulation results of PAH concentrations agree well with the field data collected by DiBlasi *et al* (2009), reporting that the PAH event mean concentration reduction ranged from 31 to 99%, with a mean discharge EMC of 0.22 μg/L at a Maryland bioretention cell. Also, the intercepted PAH compounds penetrated only a few centimeters vertically beneath the surface. Similarly, laboratory, field and modeling studies showed high metals removal within the top soil layers (first 20 cm), significantly decreasing with media depth (Davis *et al*. 2001, 2003; Li and Davis 2008). This suggests that a shallow bioretention cell design may be recommended when PAHs and heavy metals are the pollutants of interest.

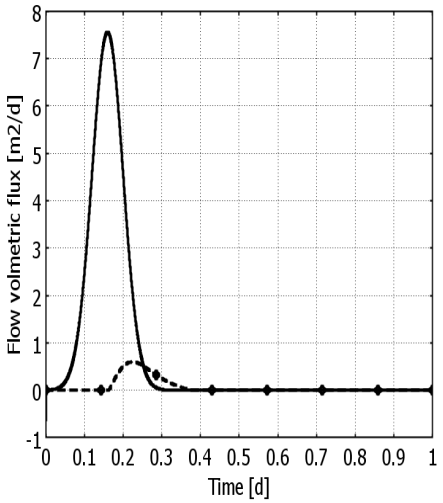

Figure 3. Gaussian Distribution Influent flux (solid line) and effluent flux from underdrain (dash line)

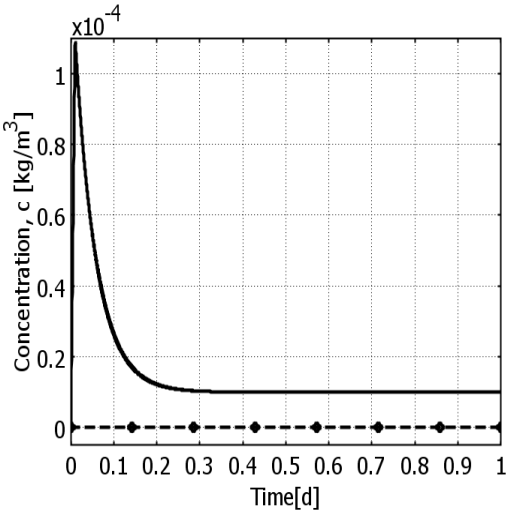

Figure 4. Influent NP concentration (solid line) and effluent NP concentration (dash line)

3.3 Soil types for media and surrounding soils

For the same hydraulic loading, the outflow volume varies for different media types. Figure 6 shows the effluent flow from sandy loam media, and from loamy sand media (with larger K_s), surrounded by the same surrounding soils of sandy clay loam. Media with higher K_s (i.e., loamy sand) generates higher flow peak, larger total volume, and shorter lag time.

Figure 7 shows that, under the same hydraulic loading and with the same sandy loam media, the outflow also changes for different characteristics of surrounding soils. Surrounding soils with higher K_s, such as sand, generate lower discharge peak and less total volume. Two-dimensional modeling of the partial exfiltration reactor (PER) by Sansalone and Teng (2005) supports the results in Figure 7, except that in Figure 7 the time to peak flow does not change much with surrounding soils.

In Figure 8, for sand with K_s of 7.1 m/d, the peak flow rate is 3.5 times that of clay loam with K_s of 0.0624 m/d. With the more permeable surrounding soils (larger K_s),

more water enters into surrounding soil layer, resulting in less effluent discharge from a bioretention cell. Therefore, total outflow volume decreases.

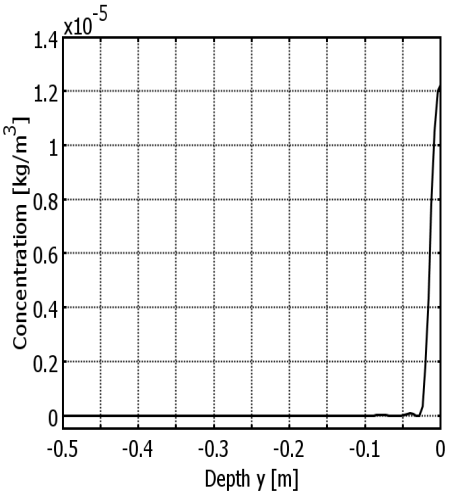

Figure 5. Concentrations of NP vary with depth when t = 0.2 day.

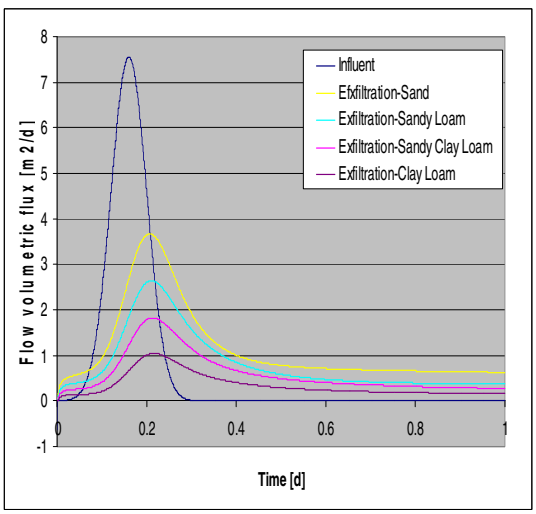

Figure 8. Exfiltration for different soils

Conclusions

In this study, a two dimensional Variable Saturated Flow and Transport Model is developed based on application modes in COMSOL Multiphysics. This model is tested under transient hydraulic and pollutant loading. Model results indicate that the outflow volume is less than the inflow. The flow peak is reduced and delayed. Concentrations of NP and PY in runoff vary with depth and most NP and PY (> 90%) is removed within about 3 cm media depth. This suggests the possibility of a shallow bioretention cell design.

Different soil types with different hydraulic properties in both media and surrounding soils impact the outflow from a bioretention cell. The outflow volume from loamy sand media (with larger K_s) is larger than that from sandy loam media. However, surrounding soils with larger K_s, such as sand, produce less outflow volume than those with smaller K_s. This suggests that careful consideration of the soil types of both media and surrounding soils is important in the design and function of a bioretention cell.

Continuing work evaluates more complicated geometry such as multi-layer soil media including the mulch layer and vegetative layer. Other mechanisms of pollutant removal in bioretention facilities such as biodegradation will be considered in order to evaluate long-term performance.

Use of the Basin Development Factor to Evaluate Urban Watershed Response

Shiva Sunder[1], Theodore G. Cleveland[2], and David B. Thompson[3]

1. ABSTRACT

The Basin Development Factor (*BDF*) is a reasonably straightforward categorical variable that has promise for estimating urban hydrologic response. The objective of this study is exploratory — the goal is to learn whether the *BDF* improves the explanation of the rainfall and runoff responses of watersheds. This particular metric is attractive as an alternative to other metrics in use.

The *BDF* was determined for more than 100 watersheds in Texas and then used to generate estimates of unit hydrograph timing characteristics and peak discharge characteristics. Simulated responses using these values are compared to both observed and prior simulated responses for the same watersheds.

Inclusion of *BDF* as an explanatory variable in the regression analyses in this study to generate hydrologic responses did not materially reduce, or enhance performance in models of selected watersheds. This finding indicates that use of *BDF* cannot make estimates worse, but does not improve estimates either (and thus *BDF* as implemented here could be ignored). The result was discouraging, but the particular effort overlooked that the regression models used could estimate zero discharges, when, in fact, the actual database did not contain zero values.

Despite the discouraging result, the authors believe that the BDF bears further study and suggestions for such studies are offered.

2. INTRODUCTION

Hydrologic response of a watershed is controlled in large part by its topography, storage properties, and loss (or runoff generation) properties. The study reported herein was motivated by an observation that topography is relatively unchanged in urban watersheds as they develop, but hydrologic response certainly changes — no doubt in some proportion to changes in storage, runoff generation, and conveyance efficiency to the outlet.

Liscum and Massey (1980), Liscum et al. (1996), and Liscum (2001) in a series of studies addressed the effect of change by a variety of watershed properties as explanatory variables

in rainfall-runoff regression models of the Houston area. One promising explanatory variable was the Basin Development Factor (*BDF*) (Sauer et al., 1983). The *BDF* is a measure of runoff transport efficiency of the drainage systems in a watershed, and thus indirectly addresses the storage and transport components of a watershed's runoff signal. *BDF* is a categorical variable, whose value is assigned based on the prevalence of certain drainage conditions that result from urbanization of a watershed.

Cleveland et al. (2008) used a particle tracking approach for parametrizing unit hydrographs from topographic information for selected watersheds in Texas. That work demonstrated that topographic information explained a large portion of variability in response, yet the use of a binary categorical variable for developed and undeveloped watersheds was insufficient to capture the spectrum of change as a watershed urbanizes; the *BDF* potentially extends the range of responses by 11 categories.

Southard (1986) examined an alternative urban basin characteristic, called the percentage developed area, to simplify the computation process of evaluating the percentage of impervious area within a basin. At the time, he speculated that the field reconnaissance of a watershed with an area of 20 square miles would take 1 to 6 hours but computation of percentage of developed area would take less than 2 hours for basins with area 22 square miles or less. Field reconnaissance necessary to determine BDF would be impractical if the user is located a considerable distance from the basin, however since that time tools like Google Earth make the prospect of computing a BDF as practical as percentage impervious area.

This study examines the *BDF* on urban hydrologic response. The objective of this research is to determine how the *BDF* explains the rainfall and runoff responses of watersheds and if this metric is a useful alternative to other metrics in use. The BDF is applied to more than 100 watersheds in Texas and the results compared to prior efforts on these watersheds.

3. METHODOLOGY

The database used for this research contains rainfall and runoff values, physical and dimensional parameters of 133 watersheds in Texas. The database combined the contents of Asquith et al. (2004) with recent computations of BDF using Google Earth, as well as recent additions to the original rainfall-runoff database.

The Basin Development factor is computed from analyst interpretation of the presence or absence of the following physical features, of which three (of four) are detectable using aerial imagery. Borrowing from Sauer et al. (1983) the four components and their meanings are:

(1) Channel Improvements: The improvements are noted by taking into consideration the phenomenon of straightening, deepening, clearing and enlarging. If all or any of the above phenomena are present in at least 50% of the main channel and its

tributaries, then, a value of one is given to the third of the watershed taken into consideration; else it takes the value zero.

(2) Channel linings: If more than 50% of the main channel length is lined with an impervious material like concrete, then a value of one is given to the third of the watershed under study, else the value of zero is assigned. Usually, if the drainage channel is lined with an impervious material, it will have a good channel improvement. Hence this aspect is an added factor to portray a highly developed drainage system.

(3) Storm drains or storm sewers: the enclosed drainage structures (usually pipes) that are used on the secondary tributaries, that collect the drainage from the parking lots, streets etc., and drain into open channels in most cases or into channels enclosed as pipe or box culverts are called storm drains. So, when over 50% of the secondary tributaries are found to have storm drains, then a value of one is given else zero value is given.

(4) Curbs and gutters: this factor reflects the actual urbanization of the watershed area. If more than 50% of the area is industrially developed or used in constructing residential or commercial buildings and if streets and freeways are constructed using curbs and gutters, then the value one is assigned. Else the value zero is given. Curbs and gutters take drainage to storm drains.

The authors acknowledge that storm sewers are likely undetectable from Google Earth imagery and thus there is considerable subjectivity in these last two components of the BDF, nevertheless the analysts proceeded using their best judgement to arrive at a defendable value.

The computation of BDF for one watershed is illustrated as an example. Figure 1 is a screen capture of a Google Earth image with a watershed delineated. The boundaries are approximate which is sufficient for this task.

The watershed is divided into three approximately equal parts that are examined for channel improvements, channel linings, storm drains and curbs and gutters. The component scores for the watershed are listed in Table 1. The upper portion of the watershed has no visible channel, thus these two components are scored zero. Storm sewers probably exist and are scored one on this conjecture and the obvious curb and gutter component is scored one in this portion. The middle portion has visible channels, and there is some evidence of improvement (there are linear features when the image is zoomed), but there is no visible evidence of lining. Hence the channel improvement is scored one, as is the curb and gutter, and storm sewer. The lower third has all components and each is scored one, for a total $BDF = 9$.

As an observation (from several dozens of urban watersheds) a $BDF = 9$ is a reasonably developed watershed. Several different analysts will arrive at different values of BDF but

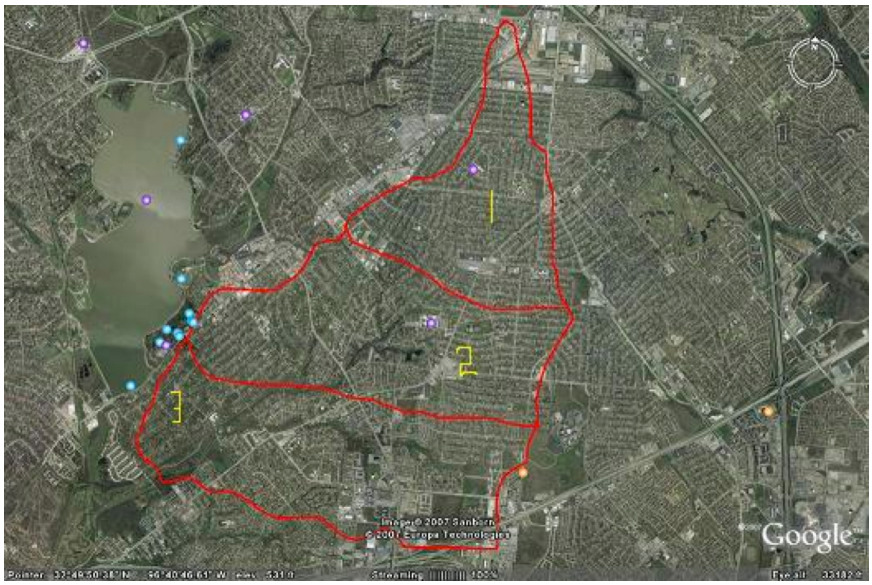

FIGURE 1. Station 0807320 Ashcreek Watershed, Dallas, Texas. Boundaries are approximate.

TABLE 1. Ash Creek BDF component scoring

Area	Imp. Channel	Lined Channel	Storm Drain	Curb and Gutter
(1) Upper $\frac{1}{3}$	0	0	1	1
(2) Middle $\frac{1}{3}$	1	0	1	1
(3) Lower $\frac{1}{3}$	1	1	1	1

generally will be within a score of one, thus the subjectivity is not so large that two analysts will score at opposite ends of the scoring range.

Figure 2 is a plot of the relationship of a characteristic time, T_p, and a characteristic spatial dimension, A/S_o, for each watershed examined. The figure exhibits considerable variability, but when these results are segregated by *BDF* value, the watersheds with greater *BDF* value plotted closer to the lower envelope of the marker cloud (i.e. along the lower line in the figure), while the watersheds with lower *BDF* plotted along the upper envelope. This result is anticipated and important for the potential use of *BDF* as an explanatory variable[4].

The values of T_p were determined from the observation data using methods described in Thompson et al. (2007) and Asquith et al. (2006) and can be considered metrics of the actual watershed response (as opposed to estimates obtained by regressions). The differences in the characteristic time were found to be meaningful enough to consider *BDF* as an explanatory, categorical variable. These values of *BDF* were then used to generate regression equations

[4]The differences are visible when the figure is plotted in color. The authors were unsure of the manuscript would be in color, so the text was written as if only black and white were available.

to estimate values of initial abstraction, I_a, loss rate, C_l, characteristic time to peak, T_p, and a peak rate factor, Q_p. The meanings of these values are analogous to the same terms used in the collective works of Cleveland et al. (2008), Thompson et al. (2007), Asquith and Roussel (2007), and Asquith et al. (2006).

Of particular importance, to reduce the effort required to analyze the database, station median values were used to generate the estimation equations that were used to generate the responses to rainfall input in the cases where *BDF* was considered as an exploratory variable, while the other results presented herein were computed on a storm-by-storm basis.

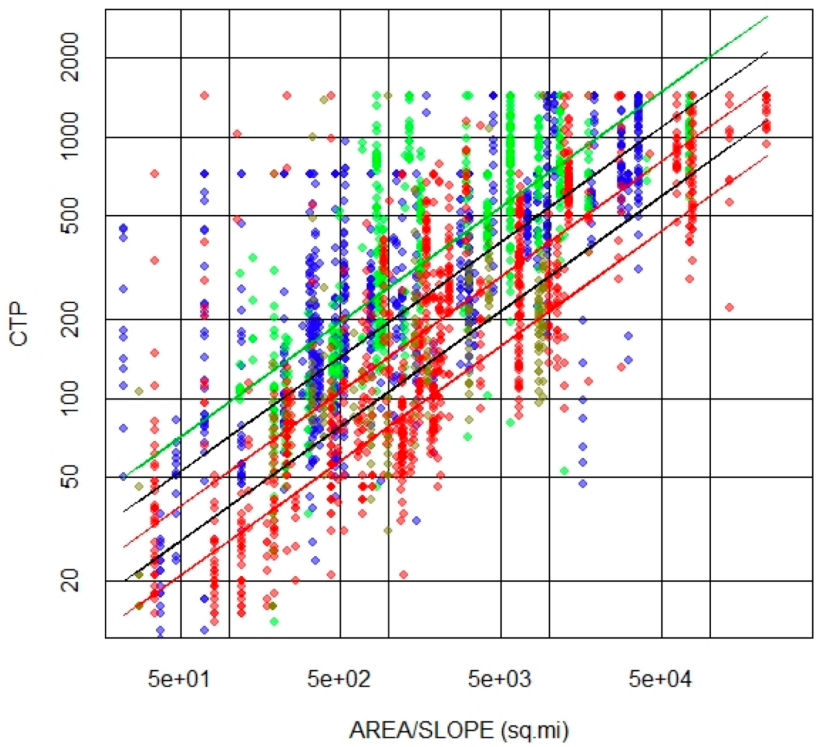

FIGURE 2. Observed characteristic time, T_p, and ratio of watershed area to slope (a characteristic spatial dimension) for all storms all watersheds. Markers indicate individual rainfall-runoff paired events. Marker density is indicative of relative number of markers in a particular location. Color is segregation by *BDF* value.

Once these regression equations were generated, estimated responses from these regressions were compared with those of Asquith and Roussel (2007) where similar analysis was performed on a subset of these watersheds and Cleveland et al. (2008) where only a minimal set of categories related to basin development was examined. The desirable result would be

a measurable reduction in variability explained by the additional categories; an undesirable result would be added variability, and a null result would be acceptable (but not particularly useful).

4. RESULTS

The *BDF* results presented here incorporate the loss model of Asquith and Roussel (2007), and only the characteristic time is different when comparing these two estimation procedures. The *NO_BDF* model uses the results from Cleveland et al. (2006), and represents storm-fitted unit hydrographs. The Digital Terrain Runoff Model (*DTRM*) results are from Cleveland et al. (2008) which incorporated a proportional loss model.

Figure 3 is a plot of the peak discharge values computed using the three different models. Ideally all models would plot along an equal value line. The markers representing the *BDF* model exhibit more variability than anticipated, but are still within reasonable values for most of the storms simulated.

Figure 4 is a plot of the time of peak discharge values computed using the three different models. Ideally all models would plot along an equal value line. Of particular note in this plot is the significant number of zero times in the *BDF* model. These values are attributed to the choice of loss model used in these simulations — and initial abstraction constant loss model that for some storms simulated zero runoff (when, in fact, actual runoff was non-zero). The markers representing the *BDF* model exhibit about the same variability as the prior efforts[5], and could be argued to reduce variability slightly.

The upper panel of Figure 3 is a boxplot of the information depicted in the scatterplots of Figure 3. The boxplots (and associated non-parametric tests) indicate that all the models perform the same when compared to each other or to their associated observations. Likewise the lower panel of figure 4 is a boxplot of the same information depicted in the scatterplots of Figure 4. These boxplots (and associated non-parametric tests) also indicate that all the models perform the same when compared to each other or to their associated observations.

5. DISCUSSION AND INTERPRETATION

Inclusion of *BDF* as an explanatory variable in a regression analysis to generate hydrologic responses did not materially reduce, or enhance performance in models of selected watersheds.

The implementation here was essentially an application of the loss models of Asquith and Roussel (2007) with an adjustment for the value of *BDF*, without re-analysis of the entire database — thus the method admits zero discharge cases when, in fact, such cases were not

[5]the zero values being ignored for this statement

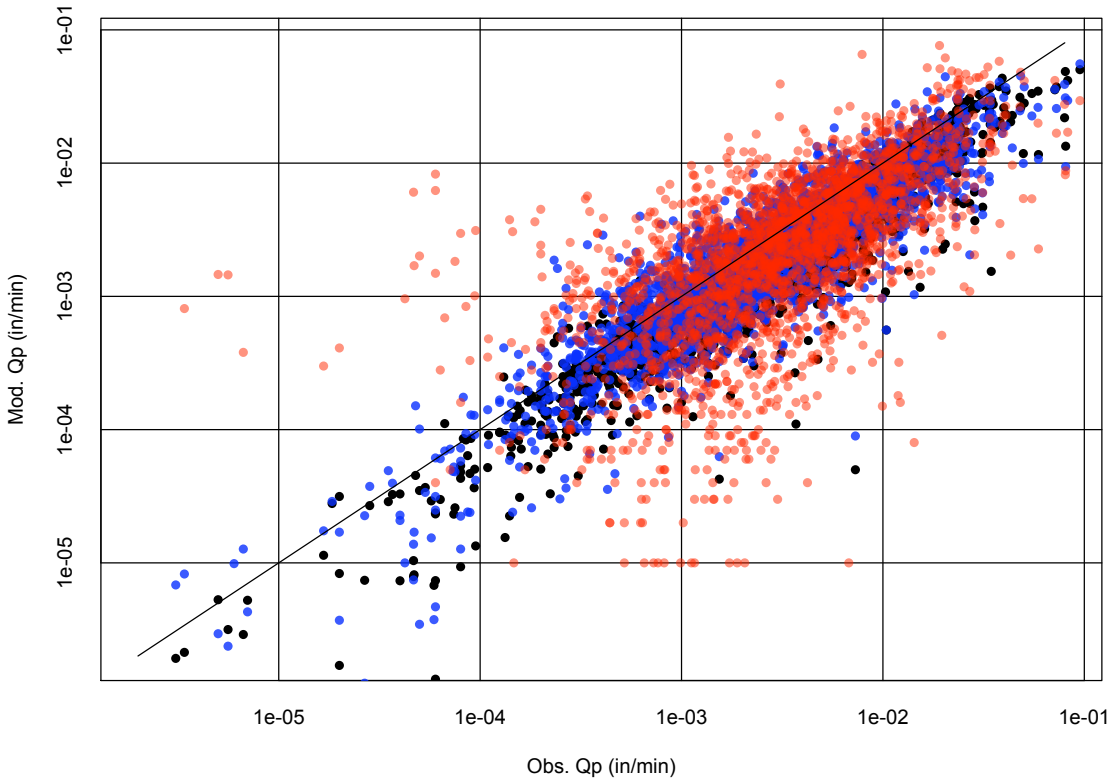

FIGURE 3. Plot of observed and model peak discharge values for individual storms on the study watersheds. Black markers (narrow marker cloud) are storm-optimized (storms fitted to unit hydrographs), blue circles are terrain-based unit hydrographs (Cleveland et al., 2008), and red markers are results estimated using a regression model that incorporates *BDF*.

in the original data, and this substantial difference is an issue needing further clarification. Furthermore, the authors did not re-analyze the entire database, instead choosing to apply regression to the station median values to incorporate the effects of *BDF* on response. This particular conceptual error is why the *BDF* did not perform as well as anticipated[6].

The simulated characteristic times, if the zero-discharge cases are censored, qualitatively reduces the variability in the responses, weakly supporting the original conjecture that *BDF* could confer additional accuracy in such modeling. Once loss (runoff generation) processes are accounted for, the simulated responses are sensitive to values of *BDF*.

[6]Or the BDF is simply not useful as an explanatory variable — yet its value in other venues suggests the conceptual error is a better explanation

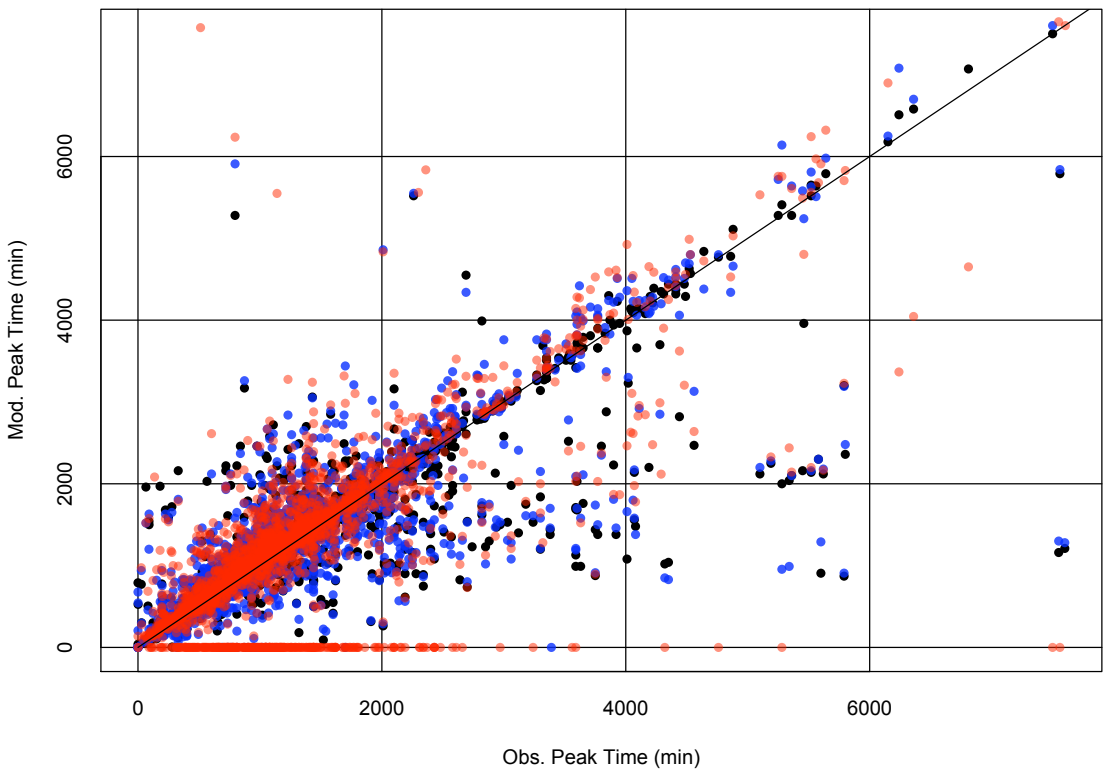

FIGURE 4. Plot of observed and model time of peak discharge values for individual storms on the study watersheds. Black markers (narrow marker cloud) are storm-optimized (storms fitted to unit hydrographs), blue circles are terrain-based unit hydrographs (Cleveland et al., 2008), and red markers are results estimated using a regression model that incorporates *BDF*.

Future efforts would be to re-analyze the entire database with *BDF* as an explicit explanatory variable (instead of a de-coupled analysis done in this work) and combine this effort with the terrain based model to determine if the inclusion of *BDF* improves the simulation value of that model. Additionally, the issue of runoff generation appears to be the crux of these kind of simulations and this issue is not adequately addressed in this work.

6. ACKNOWLEDGEMENTS

The research reported herein was supported in part by the Texas Department of Transportation and the Harris County Flood Control District. Their financial support is greatly appreciated and acknowledged.

ABSTRACT

The objective of this study is to document the water quality benefits and the hydraulic properties of PFC. Stormwater runoff from a four-lane divided highway in Austin, Texas, USA was monitored at the edge of pavement at two sites before and after the installation of a PFC. Observed concentrations of total suspended solids and pollutants associated with particulate material were much lower in the runoff from the PFC than that derived from the conventional asphalt surface. Significant concentration reductions were observed for total suspended solids, total lead, total copper, and total zinc. The reduction in TSS concentration is about 90 percent and the average discharge concentration is less than 10 mg/L. Concentrations of dissolved constituents were not significantly different at either site. These results are generally consistent with findings of research conducted in Europe.

Results of this study indicate that PFC performs as well as many types of structural controls for reducing the pollutants in highway runoff. Consequently, this material that has historically been used primarily for safety benefits should also be considered where reduction in pollutant discharge is desired. This material incorporates runoff treatment within the pavement itself, which facilitates its use in retrofit situations where additional right-of-way may not be available for stormwater treatment.

In addition, to the water quality measurements, cores of the pavement have been collected at a number of sites of different ages and traffic densities to determine porosity and hydraulic conductivity. Laboratory measurements of the hydraulic conductivities of the cores indicate that the testing regime commonly used results in conditions where Darcy's Law is no longer valid.

INTRODUCTION

Porous asphalt overlays are used increasingly by state transportation agencies in the U.S., including those in Georgia, Texas, California, and Utah, to improve drivability in wet weather conditions and to reduce noise from highway traffic. Acknowledged benefits include reduced splash and spray, better visibility, better traction, reduced hydroplaning and less noise (Stotz and Krauth, 1994; Berbee et al., 1999). These pavements also may reduce the runoff volume and peak runoff velocity, as well as increase the lag time between rainfall and runoff, especially for smaller storm events.

The impact of PFC on stormwater runoff quality has been evaluated in only a few scientific studies; however, improved runoff quality has been consistently observed by researchers (Berbee et al., 1999; Pagotto et al., 2000; Stotz and Krauth, 1994) There are several reasons to think that improved water quality may result from the installation of this material. PFC might be expected to reduce the generation of pollutants, retain a portion of generated pollutants within the porous matrix, and impede the transport of pollutants to the edge of the pavement.

It has been reported that the concentrations of selected constituents in highway runoff were affected by the number of vehicles passing the site during a storm event (Irish et al., 1998). These constituents included oil/grease, copper, and lead. Spray generated from tires was assumed to wash pollutants from the engine compartments and bottoms of vehicles. It is reasonable to expect that the amount of material washed off vehicles while driving in the rain will be reduced since PFC reduces splash and spray. This reduction in the amount of material washed from vehicles is expected to decrease the concentrations of these pollutants in the runoff generated from roads paved with PFC. In addition, the porous structure of PFC also may act as a filter of the stormwater. Runoff enters the pores in the overlay surface and is diverted towards the shoulder by the underlying conventional pavement. Pollutants in the runoff can be filtered out as the water flows through the pores, especially suspended solids and other pollutants associated with particles.

In order to properly maintain the benefits of the PFC layer, stormwater runoff must be contained within the pore space. Several researchers have addressed the issue of flow in porous pavements. Jackson and Ragan (1974) were among the first to model flow through an entirely porous pavement. They developed numerical solutions to the Boussinesq equation for a pavement with zero slope in order to determine the effect of underdrain spacing on discharge rates. Ranieri (2002) was the first researcher to model water depths specifically within PFC. He developed a runoff model to determine the required PFC thickness necessary to contain the entire runoff within the pore space based on the roadway geometry, rainfall intensity, and PFC hydraulic

conductivity. The theoretical model was validated with a laboratory experiment that simulated rainfall on PFC and measured the water depth within the pore space. Ranieri (2007) expands on the earlier work and provides some minor corrections to the original model.

Tan et al. (2004) used a three-dimensional finite element model to determine the effects that roadway geometry (slopes and widths), design rainfall, and PFC thickness have on the water depth within the PFC. Finally, Charbeneau and Barrett (2008) provide analytic solutions to the governing equations of flow through PFC for a variety of boundary and rainfall conditions. In addition, Charbeneau and Barrett address the issue of completely saturated PFC flow with the addition of surface runoff, and suggest a method for determining the spacing of underdrains.

In order to model flow within PFC knowledge of the hydraulic conductivity of the pavement is required. There are two main obstacles to direct measurement of hydraulic conductivity: 1) the high permeability may result may result in a non-Darcy flow regime, and 2) in-situ measurement results in two dimensional flow patterns, rather than the one dimensional regime commonly associated with most permeability testing.

OBJECTIVES

The main objective of this study was to compare the water quality of stormwater runoff derived from a PFC overlay with that from a conventional hot mix asphalt pavement. This comparison was made by collecting runoff samples at the same location along a highway in the Austin, Texas area before and after a PFC overlay was applied. The second objective was to determine a method to accurately characterize the hydraulic properties of the PFC.

METHODOLOGY

Stormwater runoff quality was monitored at two sites located on Loop 360 in Austin, Texas, USA during the period from February 2004 through December 2007. Loop 360 is a four-lane state highway in the western part of Austin. The original monitoring site is adjacent to the two southbound lanes of the highway, while the second site is located a short distance away on the northbound lanes. The average daily traffic count is estimated at 48,000 (Campo, 2005).

GKY FirstFlush Samplers were installed to collect the runoff from a site on Loop 360. In October 2004, TxDOT implemented a PFC overlay project at this location. The overlay was applied on top of the existing conventional asphalt according to TxDOT specifications. New instrumentation was installed at the site in November 2006 including an H-flume and an automatic sampler. Consequently, at this site there has now been collection of runoff samples since the initial installation of the PFC more than 4 years ago.

In February 2007, two GKY First Flush samplers were installed about 1.5 km away adjacent to the northbound lanes. When the overlay was initially installed, conventional pavement was retained at stop lights along the highway because of fears that the PFC might be damaged by the acceleration/deceleration of vehicles at the lights. The samplers were placed about 60 m apart, one located adjacent to the PFC portion and one adjacent to the conventional pavement. This allowed comparison of the water quality from the same events for the two pavement types.

At the original site, five samples of runoff were collected from the conventional pavement and 36 samples of runoff were collected after the PFC overlay, while a total of 13 storms have been monitored at the site with paired samplers.

PFC cores were extracted by saw cutting from pavement surfaces. Typical coring will recover the PFC layer along with part of the underlying conventional pavement. The laboratory test specimen thus has a circular shape with an open PFC surface and impermeable base. This research has used PFC core samples with diameters of 15.1 and 21.8 cm taken from three locations around Austin, TX. The small diameter cores were extracted in March 2007, and the large diameter cores were extracted in February 2008. The impermeable conventional pavement base is removed from the PFC layer resulting in core thicknesses of 2.5 to 5 cm. The cores are analyzed in the laboratory to determine hydraulic conductivity using constant head tests and porosity. In addition, a falling head test protocol developed for the field is proposed to determine the in-situ hydraulic conductivity. Determination of in-situ hydraulic conductivity is necessary to easily evaluate the drainage potential of the PFC throughout its life cycle without the extraction of core samples.

RESULTS

The EMCs measured during the sampled storm events at the two monitored sites are shown in Table 1. Concentrations of TSS, total phosphorus, and total lead, copper, and zinc are significantly lower in runoff generated from the PFC surface than in runoff generated from the conventional asphalt surface. A negative sign on the removal efficiency indicated that an increase in concentration was observed; however, these differences were not statistically significant.

The data indicate that the runoff generated from the PFC surface has consistently lower concentrations of particles and particle associated pollutants than that from the traditional asphalt surface. This difference in water quality also was noted upon visual inspection of the runoff samples collected at the edge of pavement. The concentrations of nitrate/nitrite, dissolved copper and zinc, and total and dissolved phosphorus did not exhibit a significant difference between the two road surfaces. These data indicate that the PFC has little to no effect upon the concentrations of dissolved constituents in the stormwater runoff.

Table 1 Constituent EMCs for Conventional Asphalt (HMA) and PFC

	Original Site			Second Site		
Constituent	HMA	PFC	Removal %	HMA	PFC	Removal %
TSS (mg/L)	117	9.0	92	159	17	89
TKN (mg/L)	1.13	1.03	9	1.12	0.93	17
NO3/NO2 (mg/L)	0.43	0.40	9	0.17	0.28	-65
Total P (mg/L)	0.13	0.08	40	0.15	0.06	60
Dissolved P (mg/L)	0.06	0.07	-12	0.04	0.04	0
Total Copper (ug/L)	27	14	49	30	13	57
Dissolved Copper (ug/L)	5.9	10.6	-78	5.9	9.3	-58
Total Lead (ug/L)	12.6	1.5	88	11	1.4	87
Dissolved Lead (ug/L)	<1.0	<1.0	NA	<1.0	<1.0	NA
Total Zinc (ug/L)	167	31	82	132	21	84
Dissolved Zinc (ug/L)	47	23	51	16	11	31
COD (mg/L)	64	62	3	77	62	19

After more than 3 years of monitoring, no significant correlation between discharge concentrations at the edge of pavement and time since installation or cumulative rainfall volume has been observed. As an example, Figure 1 presents the concentrations of total suspended solids for each of the monitored events at the original site. The measurements prior to 8/1/04 were of runoff from the conventional pavement. The measurements made after 10/06 were from flow weighted composite samples and the average concentrations from this sampler were all lower than those collected with the passive sampler, but not by a large amount. To date, no significant relationship has been ascertained between time and concentration. The dramatic difference in TSS concentrations for each of the monitored events at the second site is illustrated in Figure 2.

A critical component in the assessment of the water quality benefits of PFC is whether the relatively low pollutant concentrations observed in this study is a function of removal of pollutants within the pavement, reduced generation of pollutants through reduction in washoff from vehicles, or the lack of accumulation of pollutants on the new road surface. It is unlikely that the latter is the cause of the low observed concentrations since this research has shown that 4-year old PFC pavement still had better runoff quality than a conventional asphalt roadway. As particles and particle associated pollutants accumulate within the pore structure it seems likely that more runoff will travel on the surface of the pavement resulting in concentrations that might not be significantly different from those observed in runoff from conventional asphalt pavements unless maintenance is performed to remove the accumulated material.

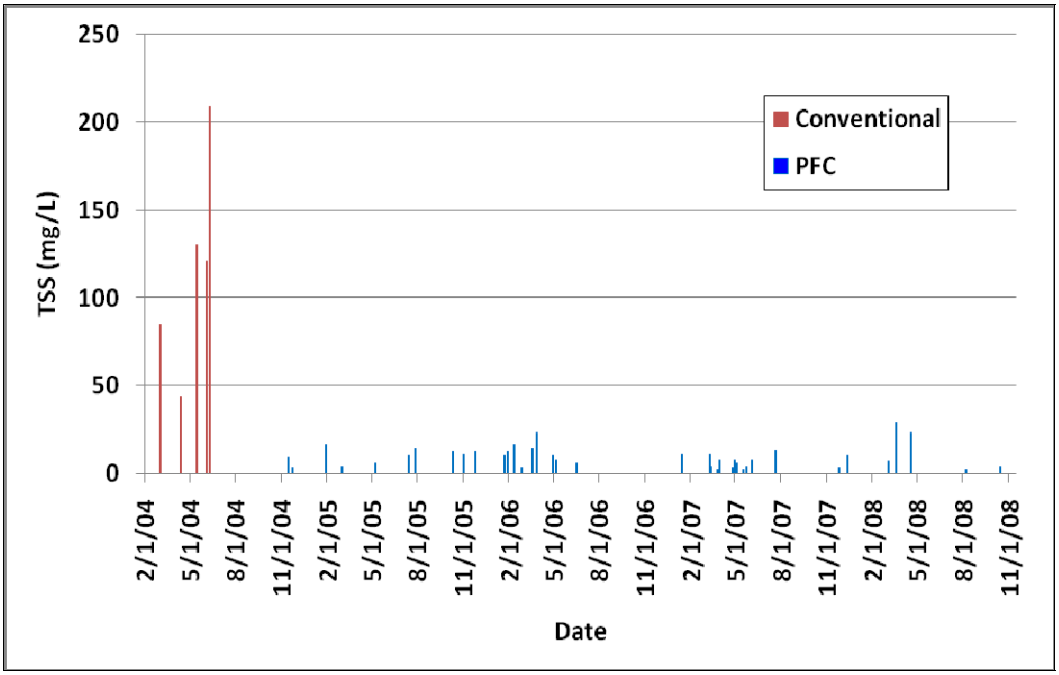

FIGURE 1 TSS concentrations for monitored events original site.

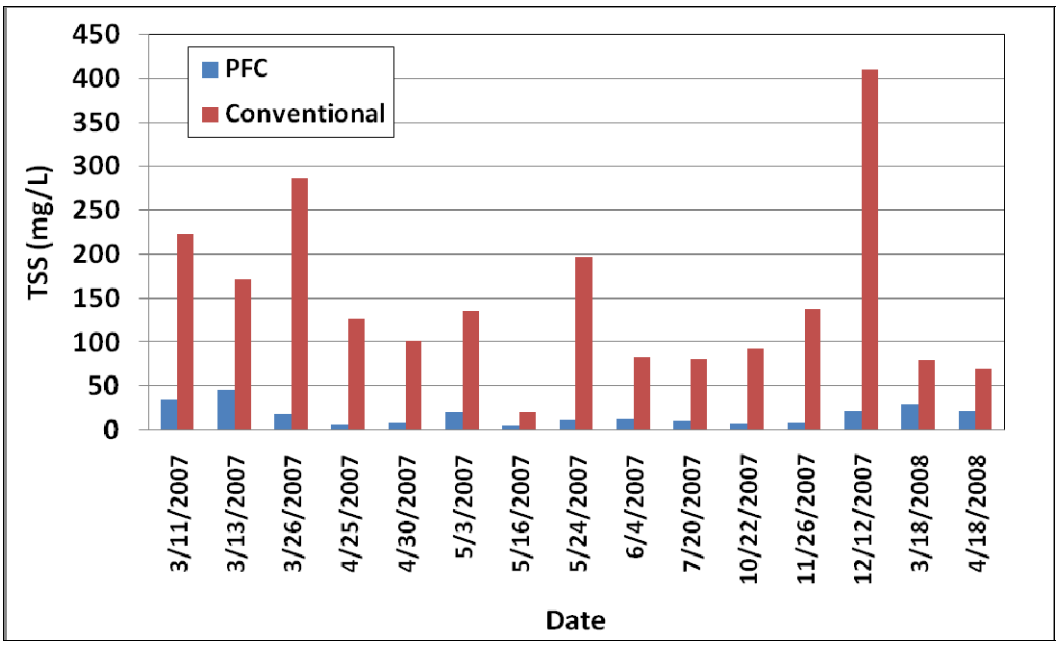

FIGURE 2 TSS concentrations for paired events at new site.

Laboratory analysis of the porosity and hydraulic conductivity of PFC core samples were conducted for both the small diameter and large diameter cores. Analysis of the porosity showed a decrease in effective porosity between the two core samples (taken within a year of each other). This decrease in porosity suggests the trapping of particles within the pore space as a removal method.

Determination of the PFC hydraulic conductivity is conducted by a series of constant head tests. Testing consists of submerging the PFC core in a water tank and placing the core between two pliable rubber membranes which create no flow boundaries on the top and bottom surfaces. A standpipe centered on the top surface of the PFC core serves as the inflow boundary. The outflow boundary is the circumference of the core. Therefore, flow enters the core in the vertical direction, and exits the core radially. A constant flow rate is established in the standpipe using a peristaltic pump. Steady state conditions are established, and the head in the standpipe is measured with an ISCO bubbler with the datum taken as the water elevation in the tank. Multiple flow rates are tested in order to create a curve of the standpipe head as a function of flow rate.

The Forchheimer equation can be modified for the global conditions of the core, since the hydraulic gradient and specific discharge cannot be easily measured for two-dimensional flow.

$$h_s = \alpha Q + \beta Q^2 \tag{1}$$

Equation (2) is the modified Forchheimer equation used for this research. The specific discharge has been changed to the total volumetric discharge, Q. The hydraulic gradient is taken as the head on the standpipe, h_s. These changes from the original Forchheimer equation alter the Forchheimer coefficients to the modified Forchheimer coefficients, α [T/L^2] and β [T^2/L^5]. Experimental data can be fit to Equation (2) for measured values of h_s and Q in order to determine α and β for each core. Figure 3 shows the results for a typical core. The data shown is in good agreement with the constant head equation using the modified Forchheimer equation, and shows a clear nonlinear relationship. In anticipation of the use of a falling head test in the field, a falling head test was conducted in the laboratory. The falling head curve shown in Figure 3 closely matches the constant head curve, particularly for the low flow rates which are more likely to be observed in the field.

In order to determine a representative core hydraulic conductivity, we must examine the equations governing flow in cylindrical coordinates. Carslaw and Jaeger (1959, pg. 215) provide an equation for the flow rate through an "infinite" core using a linear Darcy-type flow. The use of the method of images and the addition of a shape factor can be included to incorporate the finite core dimensions. The modified solution of Carslaw and Jaeger for a finite core is:

$$Q = 4Kh_s R_s F \tag{2}$$

Equation (3) relates the flow rate to the hydraulic conductivity K, the head on the standpipe, the radius of the standpipe R_s, and the shape factor F. If only the linear portion of the modified Forchheimer Equation (2) is considered, a representative

hydraulic conductivity can be obtained as a function of the core and standpipe geometry (F and R_s), as well as the modified linear Forchheimer coefficient given in Equation (4).

$$K = \frac{1}{4\alpha R_s F} \tag{3}$$

The resulting hydraulic conductivity obtained in the lab is on the order of 0.5 to 2.0 cm/s.

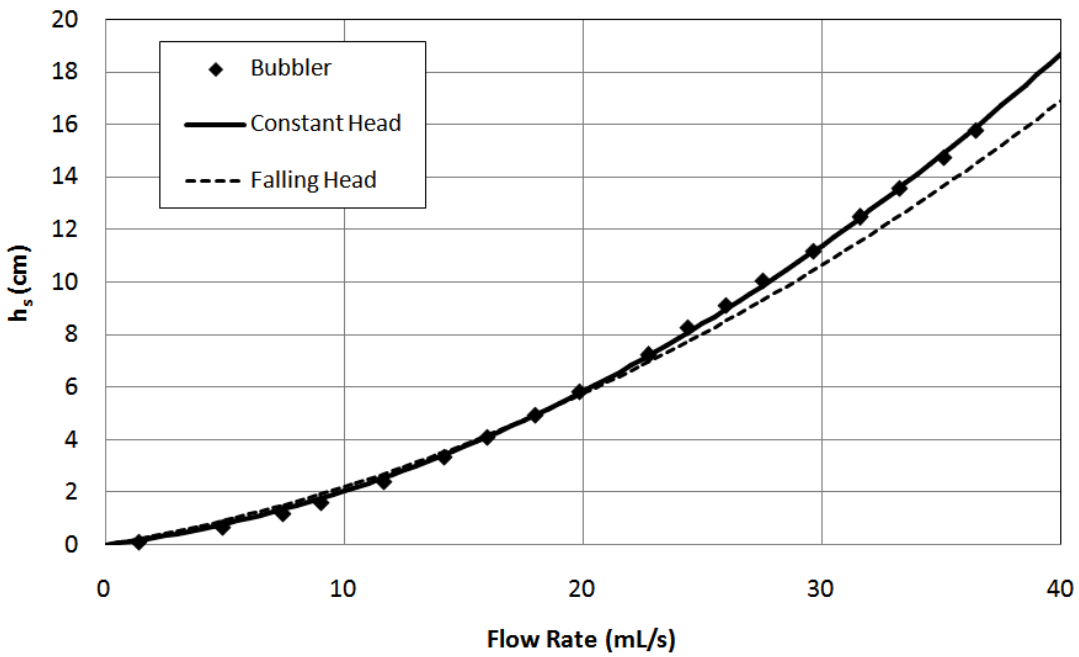

FIGURE 3 Head versus flow rate data and model fit for typical PFC core

Falling head tests are analyzed by solving the modified Forchheimer equation for the flow rate. Laboratory tests have shown that constant head and falling head tests result in approximately the same relationship, particularly at low flow rates, when a set of three time-head measurements are taken. Therefore, falling head tests in the field should provide an adequate alternative method for obtaining the in-situ hydraulic conductivity throughout the life of the PFC overlay. Current in-situ hydraulic conductivity test results are of the same magnitude as those obtained in the lab.

CONCLUSIONS

This research examined the quality of runoff from a conventional asphalt pavement and a permeable friction course. This research was unique in that it provides a direct comparison of the two surface types at the same research sites, and analyzes runoff produced during discreet storm events over a 4-year sampling period.

Concentrations of TSS, total metals and total phosphorus were found to be significantly lower in runoff generated from the PFC surface than in the runoff from the conventional hot mix asphalt surface. Average concentrations of TKN, COD, nitrate-nitrite and the dissolved forms of lead, zinc, and phosphorus show little change between the two surface types. From these results it is evident that the runoff generated from the PFC surface is of better quality than that from the traditional asphalt surface. Many regulatory agencies in the US require an 80 percent reduction in the amount of TSS discharged from new developments. The TSS removal observed during this project easily exceeds this threshold; consequently, this type of overlay may be considered a Best Management Practice (BMP) for highways in lieu of ponds, filters, or other structures commonly constructed to treat stormwater runoff. This improvement may be the result of several factors. Fewer pollutants may be derived from the bottoms of vehicles since splash and spray are reduced. In addition, these pollutants could be retained in the pores of the overlay and thereby prevented from leaving the paved area.

Core samples can be extracted from a layer of PFC and analyzed in the laboratory through a series of constant head tests to determine a representative hydraulic conductivity. The hydraulic conductivity depends on a shape factor which incorporates the geometry of the core assuming linear Darcy-type flow through the core. Laboratory testing has shown that nonlinear flow occurs in PFC for the large head values experienced during the constant head tests. The nonlinear effects can be modeled using a modified Forchheimer equation for the global conditions of the core. With the experimentally determined modified Forchheimer coefficients and the linear shape factor, a representative hydraulic conductivity can be calculated.

Additional research is needed in order to fully incorporate the nonlinear effects of flow through PFC. The approximations used here for determining the linear head distribution through a PFC core and the linear shape factor do not precisely represent the nonlinear flow observed in the lab constant head tests or field falling head test, nor the necessary boundary conditions. However, this provides a good first approximation for characterizing the hydraulic properties of PFC as well as a defined test procedure.

ACKNOWLEDGMENTS

The Texas Department of Transportation provided funding for this project under projects #0-4605 and 0-5220. Special thanks to Gary Lantrip of TxDOT's Austin Division. He has been a consistent proponent for the use of porous pavements and is currently overseeing continued research by TxDOT on its water quality benefits.

Abstract

When measure of the device performance is based on laboratory data, NJCAT calculates the average annual removal efficiency using the NJDEP-specified weighting factors. In this study, ten years of precipitation records were used to quantify frequency distributions of runoff volumes/depths as well as runoff peak flow rates. The SWMM model was used to simulate the runoff events produced by the given precipitation events. The model results indicate that the weighting factors, based on frequency distribution of the peak runoff rates normalized by the peak runoff rate generated by the uniform-intensity water quality design storm, are close to the NJDEP-specified weighting factors. The impact of using two different water quality design storms, uniform vs. non-uniform intensity distribution, to size an interim-certified hydrodynamic separator was also evaluated. The SWMM model was used to continuously simulate solids loading to the treatment device. The lab-measured relationship between flow rate and removal efficiency was used to specify the removal rate of solids within the storm event. The model results also indicate that sizing with the uniform-intensity design storm would achieve a removal efficiency close to the one verified. Sizing with the non-uniform intensity design storm, although could be taken as a conservative approach, would achieve the removal efficiency considerably higher than the one verified.

1. Introduction

In the State of New Jersey the Stormwater Management Rules (NJDEP 2004a) require Stormwater Best Management Practices (BMPs), for major new developments, to achieve an annual average of Total Suspended Solids (TSS) removal efficiency equal or greater than 80%, and for major re-developments, 50% TSS removal. Regulations require this efficiency as an annual average. Therefore, the treatment devices do not have to be designed to achieve 80 or 50 percent of TSS reduction for every individual storm event that occurs in a year.

The rules (NJAC 7:8-5.5) also specify a “water quality design storm” which consists of 1.25 inches of rainfall falling non-uniformly over two hours. This design storm substituted the one specified in NJAC 5:21-7.6 and 7:13-2.8(b), defined as 1.25 inches of rainfall falling in two hours with a uniform intensity of 0.625 in/hour. According to the proponents of the non-uniform quality storm, although the previous one provided “sound basis for the design of stormwater

quality treatment facilities that require an estimate of the total runoff volume that will flow to the facility" it did not provide information for the design of those facilities that required an accurate estimate of the runoff peak flow rate that would flow through them. The non-uniform water quality storm provides estimates of total runoff volume as well as peak runoff rate for the same storm event.

Based on the described regulations the New Jersey Best Management Practices Manual (NJDEP 2004b) indicates that the design of flow-through devices, such as the hydrodynamic separators, must be based on the runoff peak flow rate generated by the current non-uniform water quality design storm. Therefore under such specification, project engineers will size the devices to achieve the required solid removal efficiency when the treatment flow rate, in the drainage area, equals the runoff peak flow rate generated by the water quality design storm, with non-uniform intensity distribution.

This study intends to compare the hydrodynamic separator sizing methodology based on the uniformly distributed quality design storm with the sizing methodology based on the non-uniformly distributed design storm.

Two approaches were taken to determine the removal efficiency that a hydrodynamic separator could achieve when sized with different design storms. The first approach consisted of calculating the removal efficiency of the device using weight factors which are based on the frequency distribution of the runoff depths and peak runoff rates generated by precipitation over 10 years. The second approach consisted of continuous simulation of the solids removal performance of a hydrodynamic separator during 10 years of precipitation events.

2. Methodology

2.1. Curve Fitting of Hydrodynamic Separator Performance

Many hydrodynamic separator manufacturers have tested the solid removal performance of their devices at full scale and under laboratory controlled conditions. The results from many of those tests have been submitted to the New Jersey Corporation of Advanced Technology (NJCAT) for verification and performance of many devices has been certified by the New Jersey Department of Environmental Protection (NJDEP).

When this study was started, the NJCAT verification report most recently available corresponded to the FloGard® Dual-Vortex Hydrodynamic Separator (model DVS-48), manufactured by Kristar Enterprises Inc. Therefore, the FloGard® was the device selected for evaluating the impacts of using different water quality design storms to size the hydrodynamic separators.

The removal efficiency of the device was tested following the Total Suspended Solids Laboratory Test Procedure developed by NJDEP (2003). Tests were run at flow rates of 25, 50, 75, 100 and 125 % of the FloGard® DVS-48 treatment flow rate (280 gpm) (NJCAT 2007).

Figure 1 shows the TSS removal efficiencies measured at all the five tested flow rates and at three TSS influent concentrations (100 mg/L, 200 mg/L, and 300 mg/L). TSS was measured as Suspended Sediment Concentration (SSC). It can be observed that the solids removal efficiency

of the device decreases as the operating flow rate increases and the removal efficiency does not vary significantly with the influent concentrations. An exponential regression of the measured removal efficiencies vs. the operating flow rates yields the following mathematical expression for the model DVS-48:

$$RE = 100e^{-0.00299Q}$$

where

RE = removal efficiency (%)

Q = operating flow rate (gpm)

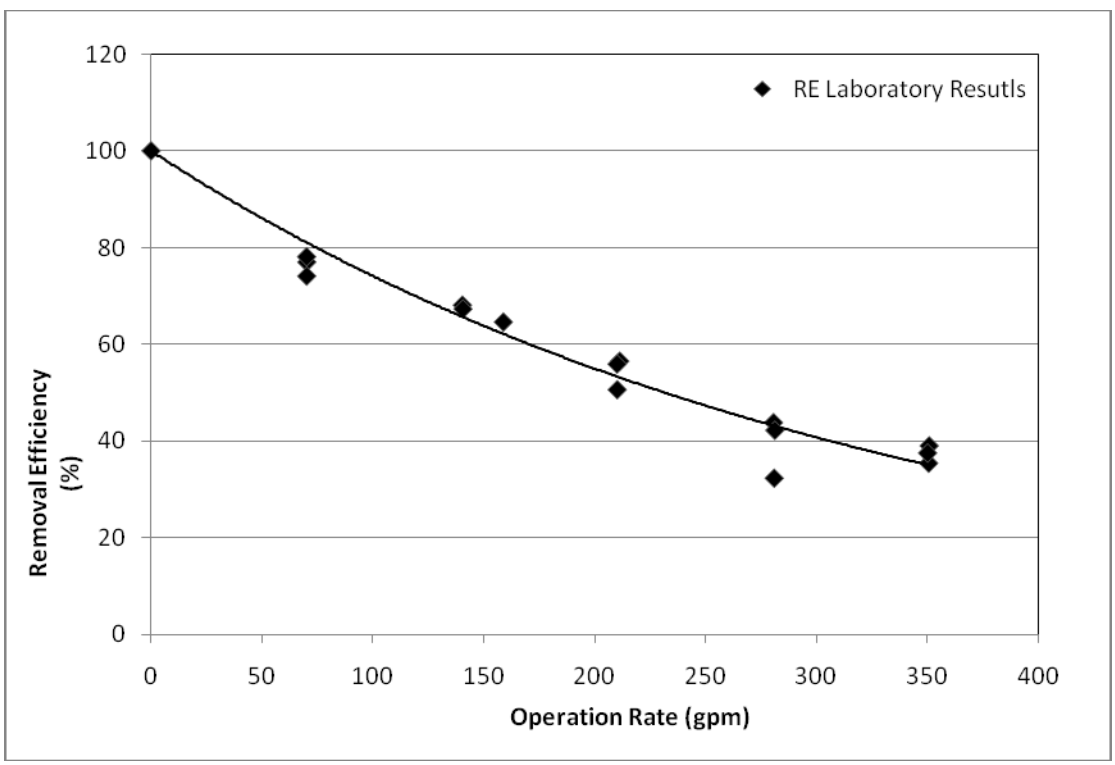

Figure 1. Measured FloGard® SSC Removal Efficiencies vs. Operating Flow Rates

2.2. Collection of Precipitation Data

Hydrodynamic separators on site receive stormwater runoff under non-uniform flow rates that change in small time steps. Such variations affect the removal efficiency of the device since the removal performance of the device depends on its influent flow rate, as discussed above. For that reason precipitation data with small-time-interval readings was needed for the intended simulation. The National Climatic Data Center (NCDC) reports precipitation readings every 15 minutes, for 19 stations in New Jersey. At the time of this study, reliable readings with even smaller time steps were not available from national or regional climatologic services.

Trenton, New Jersey was the meteorological station selected to collect 10 years of precipitation data from the NCDC website since New Jersey Rainfall Intensity-Duration-Frequency Curves were developed from Trenton rainfall data between 1913 and 1975 (NJDEP 2004b). The available data at the mentioned website covered the period between 1977 and 2001.

The daily data of each year was summed in order to calculate the annual precipitations to select 10 years in a row with an annual precipitation close to the long term annual mean precipitation in New Jersey, which is 40.24 inches, according to the Office of the New Jersey State Climatologist. Years 1981 to 1990 were selected, with annual rainfalls of 45.0, 37.1, 46.2, 46.1, 27.4, 37.0, 50.9, 33.5, 49.4, and 42.2 inches, respectively. Average annual precipitation during the studied period was 41.48 inches, close to the long term average.

2.3. Determination of Weighting Factors

Stormwater Runoff Continuous Simulation

EPA Storm Water Management Model (EPASWMM), version 5.0, was used to simulate the peak flow rates generated by the collected precipitation data over a defined subcatchment. The properties of the subcatchment introduced in SWMM intended to represent highly impervious drainage areas, such as parking lots, where hydrodynamic separators are usually installed. The subcatchment was defined as having 80% of impervious area, 20% of pervious area, evaporation of 0.1 in/day, impervious depression storage of 0.1 inches, pervious depression storage of 0.2 inches and slope of 0.1%. The infiltration loss was calculated in SWMM using the Horton Method.

The drainage area of the subcatchment, which would be an input to SWMM, was calculated assuming that the runoff peak flow rate, generated by the former New Jersey water quality design storm (uniform intensity of 0.625 in/hour), was equal to the treatment operating rate of the FloGard® DVS-48, i.e., 280 gpm (0.63 cfs). Applying the Rational Method and assuming a runoff coefficient of 0.8, the subcatchment area obtained was 1.26 acres. From the SWMM modeling results, the uniform design storm generated a peak flow of 0.638 cfs in a drainage area of 1.26 acre. Such peak flow was slightly higher than the FloGard® treatment operating rate. For that reason a smaller drainage area of 1.25 acre was used. This drainage area generated a peak flow rate of 0.63 cfs.

Frequency Distribution of Runoff Volumes/Depths

After providing SWMM with the collected precipitation data and defining the subcatchment area to study, the following steps were performed:

1. The model was run using the collected 10-year precipitation data.
2. A rank ordered report was obtained from SWMM. The report contained the magnitude of the total volume of each runoff event, the starting date and time, the duration, its exceedance frequency and the return period in years.
3. The runoff volume was divided by the area of the subcatchment in order to obtain the stormwater runoff depth.

4. The runoff volumes generated by the uniform and non-uniform design storms were determined by SWMM and the correspondent depths were calculated. Since the obtained depths had almost the same values, an average design storm runoff depth was calculated.
5. The runoff depths generated by the collected precipitation data were expressed as a percentage of the average depth generated by the design storms.
6. The obtained values were ranked from the lowest to the highest in order to obtain the probability (P) of values being equal to or less than the ranked one. The probability was calculated using the Weibull plotting position formula.
7. The runoff depths, expressed as a percentage of the average runoff depth generated by the design storms, were plotted versus their probability of no-exceedance.

Frequency Distribution of Runoff Peak Rates

In order to obtain frequency distribution of the peak runoff flow rates the following steps were performed:

1. The runoff peak flow rate that the water quality design storm of uniform intensity would generate over the defined area was obtained using SWMM.
2. The runoff peak flow rate that the water quality design storm of non-uniform intensity would generate over the defined area was obtained with SWMM.
3. The peak runoff flow rates generated by the collected precipitation data over 10 years were simulated by SWMM.
8. A rank ordered report was obtained. The report contained the magnitude of peak flow rates of each storm event, the starting date and time, the duration, the exceedance frequency and the return period in years.
4. The runoff peak flow rates were expressed as percentages of the peak flow rates obtained from the simulated design storm events. Two sets were obtained.
5. The obtained values were ranked from the lowest to the highest in order to obtain the probability of values being equal to or less than the ranked one. The probability was calculated using the Weibull plotting position formula.
6. The runoff peak flow rates, expressed as percentages of the peak runoff rate generated by the uniformly distributed design storm, were plotted versus their probability of no-exceedance.
7. The runoff peak flow rates, expressed as percentages of the peak runoff rate generated by the non-uniformly distributed design storm, were plotted versus their probability of no-exceedance.

Weighting Factors

Figure 2 shows the frequency distribution of the runoff depth and the peak flow rates, generated by the collected 10-year precipitation data, expressed as percentages of the average runoff depth as well as the peak flow rates generated by the uniform and non-uniform design storms, respectively.

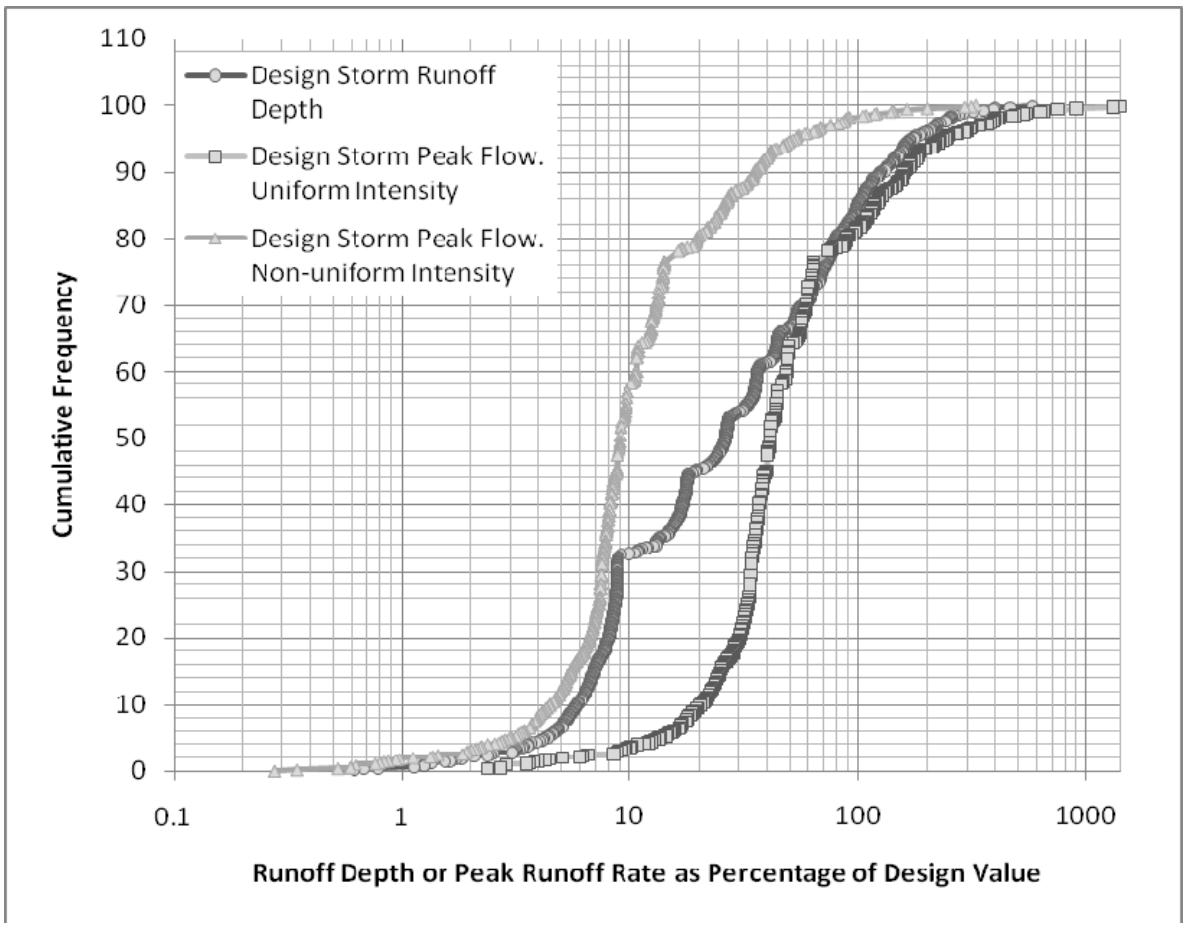

Figure 2. Frequency Distribution of Runoff Depths and Peak Flows

Table 1 shows the cumulative frequency distribution of the runoff depths produced by the collected precipitation data, expressed as percentages of the average runoff depth generated by the water quality design storms (0.930 inches). The same table also shows the frequency distribution of peak runoff flow rates expressed as percentages of the peak flow rates generated by the uniformly and the non-uniformly distributed water quality design storms (0.63 cfs and 2.85 cfs, respectively).

The difference between two adjacent cumulative frequencies is the probability of occurrence for range between two adjacent design values, and it is defined as the weighting factor. Five weighting factors for the ranges of 0-25, 25 -50, 50-75, 75-100 and 100-125 % of the design value were calculated. These ranges of flows were evaluated by the FloGard® manufacturer, as required by the NJDEP lab testing procedure. Table 2 shows the obtained weighting factors. The probability (thus the weighting factor) for the range larger than 125% of the design value was added to the probability (thus the weighting factor) for the range between 100-125%.

Table 1. Cumulative Frequency Distribution of Runoff Depth and Peak Flow Rates Generated by Precipitation over Ten Years (expressed as percentages of the design values)

% of Design Value	Cumulative Frequency (%)		
	Runoff Depth	Peak Flow Rate (uniform design storm)	Peak flow rate (non-uniform design storm)
25	48.00	13.00	84.05
50	66.81	60.00	94.60
75	78.00	78.00	96.87
100	85.75	81.50	98.00
125	90.31	83.50	98.60

Table 2. Weighting Factors of Runoff Depth and Peak Flow Rates Generated by Precipitation over Ten Years (expressed as percentages of the design values)

% of Design Value	Weighting Factors		
	Runoff Depth	Peak Flow Rate (uniform design storm)	Peak flow rate (non-uniform design storm)
25	0.48	0.13	0.84
50	0.19	0.47	0.10
75	0.11	0.18	0.03
100	0.08	0.04	0.01
125	0.14	0.18	0.02

2.4. Calculation of Weighted Removal Efficiency from Weighting Factors

The FloGard® weighted removal efficiency was calculated using each set of the weighting factors. Each weighting factor was multiplied by the removal efficiency measured from the laboratory tests at the corresponding flow rate (25, 50, 75, 100, and 125% of the device treatment rate, respectively). The total weighted removal efficiency is the sum of the five products.

2.5. Continuous Simulation of Removal Efficiency

Stormwater Runoff Simulation

The stormwater runoff from two subcatchments of different sizes was simulated using SWMM. The area of each subcatchment was specified according to two sizing criteria. The first criterion considered the treatment flow rate of the FloGard® DVS48 as equal to the peak flow rate generated by the water quality design storm with a uniform intensity of 0.625 in/hr. The second criterion considered the treatment rate of the FloGard® DVS-48 as equal to the peak flow rate generated by the water quality design storm with a non-uniform intensity distribution.

The areas were calculated using the Rational Method and assuming a runoff coefficient of 0.8. The first sizing criterion yielded a subcatchment area of 1.25 acres and the second sizing criterion yielded a subcatchment area of 0.25 acre. The subcatchments were meant to represent a typical watershed were the hydrodynamic separators are usually installed. The subcatchments were defined as having 80% of impervious area, 20% of pervious area, 0.1 in/day of evaporation, 0.1 inches of depression storage in the impervious zone, 0.2 inches in the pervious zone, and a 0.1 % slope. The infiltration loss was calculated in SWMM using the Horton Method.

Water Quality Simulation

The pollutant buildup was simulated in SWMM assuming a linear accumulation of the dust on the subcatchment surfaces (Huber and Dickinson 1988).

According to New Jersey BMPs Manual (NJDEP 2004b), an annual accumulation of 200 pounds per acre can occur in a commercial area. Dividing this value by 365 days a daily accumulation rate of 0.55 lbs/day was obtained. This value was used in the linear dust accumulation equation.

SWMM simulates the washoff process of the accumulated pollutants through the following expression:

$$C_t = C_w \times r^w \times P$$

where

C_t= pollutant washed off at time t (pounds)

P = quantity of constituent still available on the surface at time t (pounds)

C_w= washoff coefficient

r = runoff rate (cfs)

w = modeling exponent

The parameters C_w and w are inputs to SWMM by the user. The remaining material on the surface at the end of a time step is calculated by SWMM during the simulation.

In this study, three different cases were simulated by varying the values of the parameters C_w and w in order to generate concentration distributions that reflected the first flush effect (FF) during the storm event.

However there is no standard quantitative definition of the first flush effect. Different authors proposed different mass-based indicators. For this reason, three pairs of coefficients were selected to generate pollutant washoff distributions that would reflect the most common definitions of the mass-based first flush effect. Case 1 simulates a FF of 80% total pollutant load transported by the first 20% of the total runoff volume (Sansalone and Chad 2004). Case 2 simulates a first flush effect of 80% of the total pollutant load transported by the first 30% of the total runoff volume (Bertrand-Krajewski, et al. 1998) and case 3 simulates a first flush effect of 80% of the total pollutant load transported by the first 40% of the total runoff volume.

Among all the continuously simulated storm events, three were selected to evaluate distribution of the solids mass (solids concentration multiplied by runoff volume). These events were selected because their peak flow frequency exceedance was close to 50%, according to SWMM statistic report for subcatchment 1 (1.25 acres). That is, they are "average" storm events. Different exponent-coefficient combinations were tried until the desired distributions were achieved.

Table 3 shows the selected coefficients for the simulation and the resulted distribution of the solids mass.

Table 3. Study Cases of Pollutants Washoff

Case	W	C_w	% Volume at 80% mass
1	1.6	50	20
2	1.7	50	30
3	1.9	50	40

A simulation of the removal efficiency of the device was additionally performed for the case when 80% of the mass is transported by 80% of the volume, i.e., the runoff mass is uniformly distributed through the event. The washoff process was modeled using an exponent (w) equal to 2.5 and a washoff coefficient (C_w) of 2.0.

Removal Efficiency Continuous Simulation

As described above, the laboratory test of the FloGard® Dual Vortex showed that its removal efficiency depends on the flow rate. If the flow rate is less than the hydraulic capacity (560 gpm for the tested model DVS-48), the fitted relationship between the removal efficiency and the flow rate is assumed to be applicable. After the hydraulic capacity is exceeded, the removal efficiency is assumed to be zero since the removal efficiency of the treated part of the flow is small and the bypassed part will not receive any treatment. However, the use of positive and

zero removal efficiency may not be appropriate if a significant bottom sediment resuspension occurs under the flow beyond the tested maximum flow rate. The removal efficiency could actually be negative if a severe sediment resuspension occurs during high flows that would pass through an online system.

At the end of the event the total mass of pollutant that entered the device will equal the sum of the calculated influent mass during each time step of the entire storm (= the simulated flow rate multiplied by the simulated concentration and the time interval). The total mass removed from the storm water runoff will equal the sum of the mass removed during each time step of the entire storm (= the influent mass multiplied by the removal efficiency at the specific flow rate at that time step). The removal efficiency of the device for the entire event is obtained by dividing the total mass removed by the total mass that entered the device. See Fernandez (2008) for additional modeling details.

3. Results and Discussion

3.1. Calculated Weighted Removal Efficiency

The weighted removal efficiencies calculated using three different sets of weighting factors are listed in Table 4.

Table 4. FloGard® DVS-48 Weighted Removal Efficiencies based on Frequency Distribution of Runoff Depths and Peak Flow Rates, Expressed as Percentages of Design Values.

% Operating Rate	Av Removal Efficiency	Runoff Depth		Runoff Peak Rate, Uniform Design Storm		Runoff Peak Rate, Non-uniform Design Storm	
		Weighting Factors	Removal Efficiency	Weighting Factors	Removal Efficiency	Weighting Factors	Removal Efficiency
25	74.6	0.48	35.81	0.13	9.70	0.84	62.66
50	67.6	0.19	12.84	0.47	31.77	0.10	6.76
75	55.6	0.11	6.12	0.18	10.00	0.03	1.67
100	43.8	0.08	3.50	0.04	1.75	0.01	0.44
125	38.7	0.14	5.42	0.18	6.97	0.02	0.77
Total weighted removal efficiency		63.69%		60.19%		72.30%	

The results shown in Table 4 suggest that the weighted removal efficiency (63.69%) calculated from the weighting factors based on frequency distribution of runoff depths is close to that (60.19%) calculated from the weighting factors based on frequency distribution of peak runoff flow rates expressed as percentages of the peak runoff rate generated by the uniform intensity design storm. However, the weighted removal efficiency (72.30%) calculated from the weighting factors based on frequency distribution of peak runoff flow rates expressed as percentages of the peak runoff rate generated by the non-uniform intensity design storm is considerably larger than that normalized by the uniform intensity design storm (60.19%). It is approximately 12% larger in terms of absolute difference.

The weighted removal efficiency (60.19%) calculated from the weighting factors based on frequency distribution of peak runoff flow rates expressed as percentages of the peak runoff rate generated by the uniform intensity design storm is strikingly similar to that (60%) calculated using the NJDEP-specified weighting factors (NJCAT 2007).

The performance claim verified by NJCAT reads:

"The FloGard® Dual-Vortex Hydrodynamic Separator, Model DVS-48, at a flow rate of 280 gpm (0.63 ft3/s), has been shown to have a 60% total suspended solids (TSS) removal efficiency, measured as suspended solids concentration (SSC) (as per the NJDEP methodology for calculation of treatment efficiency) using NJDEP specified material with an average d50 particle size of 70 microns, an average influent concentration of 202 mg/L and 100% initial sediment loading in laboratory studies using simulated stormwater."

The weighted removal efficiency of 60% was calculated using the NJDEP-specified weighting factors.

3.2. Continuously Simulated Removal Efficiency

Tables 5 and 6 summarize the results of simulated total influent and effluent mass and the correspondent removal efficiency for two different drainage areas (1.25 acres and 0.25 acres, respectively). See Fernandez (2008) for detailed model results.

The SWMM continuous simulation indicates the FloGard® model DVS-48 can achieve an average annual removal efficiency of approximately 70%, on a drainage area of 1.25 acres sized from the peak runoff flow rate generated by the design storm with uniform intensity.

The simulation shows that the same device can achieve a removal efficiency of approximately 90% over a drainage area of 0.25 acres sized from the peak runoff flow rate generated by the design storm with non-uniform intensity. The use of uniform rainfall distribution is already a conservative criterion with the simulated approximately 70% removal efficiency that is larger than the verified 60%. The use of non-uniform rainfall distribution is even more conservative with the simulated approximately 90% removal efficiency that is much larger than the verified 60%.

Table 5. Simulated Influent Mass, Effluent Mass and Removal Efficiency for the FloGard® DVS-48 in Subcatchment 1 (1.25 acres)

	Subcatchment 1		
Case	Influent Mass (lbs)	Effluent Mass (lbs)	Removal Efficiency (%)
1	2352.78	692.09	70.58
2	2352.45	713.70	69.66
3	2352.45	765.94	67.44
Runoff mass uniformly distributed	2345.91	1042.16	55.58

Table 6. Simulated Influent Mass, Effluent Mass and Removal Efficiency for the FloGard® DVS-48 in Subcatchment 2 (0.25 acres)

	Subcatchment 2		
Case	Influent Mass (lbs)	Effluent Mass (lbs)	Removal Efficiency (%)
1	477.61	47.45	90.06
2	477.61	48.56	89.83
3	477.60	50.73	89.38
Runoff mass uniformly distributed	474.76	121.69	74.36

For the drainage area of 1.25 acres sized with the uniform-intensity design storm and in the case where the runoff mass was assumed to be uniformly distributed within the storm event, the continuous simulation yielded a removal efficiency of 55.58%, which is reasonably close to the removal efficiency (60%) calculated using the NJDEP-specified weighting factors and verified by NJCAT. This result is consistent with the assumption behind application of the weighting factors that the runoff mass is uniformly distributed through the event.

It should be cautioned that the above-described SWMM modeling results may not fully represent the field performance of the device. Size and density of the particles used in the lab testing and the lab-measured flow rate-removal efficiency relationship that was an input to the model may not accurately represent the field conditions.

4. Conclusions

The current NJ stormwater rules define the water quality design storm as 1.25 inches of rainfall non-uniformly distributed over two hours. This is a significant change from the previous definition of uniform rainfall distribution. The current definition leads to a higher peak runoff rate in small watersheds in comparison to the previous definition although the runoff volume remains essentially the same.

The runoff frequency analysis suggests that setting design treatment flow rate equal to the peak flow rate generated by the uniform-intensity water quality design storm is more consistent with the use of existing weight factors in calculating the average annual solids removal efficiency. Use of the non-uniform intensity water quality design storm to size the treatment device is probably too conservative. The SWMM modeling of the solids removal performance also suggests that sizing the treatment device with the uniform intensity water quality design storm is more appropriate than sizing with the non-uniform intensity design storm.

Water Sustainability Index: Application of CWSI for Ahwaz County

J. Attari[1] and S.A. Mojahedi[2]

[1]Assistant Professor, Water Engineering Department, Power and Water University of Technology, P.O. Box 16765-1719, Tehran, Iran; email: attari@pwut.ac.ir
[2]Expert, Water Resources Planning Department, Ministry of Energy, Valiasar and Neyayesh crossing, Tehran, Iran; email: ali.mojahedi@gmail.com

ABSTRACT

Sustainability of water resources is vital especially for developing countries such as Iran which are located in the Middle East and North Africa (MENA) region where water is scarce. To balance the high demand of water for economical growth and at the same time preserve the environment for present and future generations, sustainability of water resources should be considered by monitoring and data mining. For this purpose, several quantified indices have been proposed and applied world wide recently. In this paper, the Canadian Water Sustainability Index (CWSI) proposed by PRI, has been trailed for the case of Ahwaz County, a community located in South West of Iran fed by Karun River. Required data for the composite CWSI score which is the average of five major theme-based components (i.e. resource, ecosystem health, infrastructure, human health capacity) was collected according to the PRI evaluation method. In addition to the standardized CWSI, the final index was also calculated considering weight estimation for the five components by pair-wise comparison, using Expert Choice version 2000. Results showed that application of this index as a policy tool, with some modifications in weights, was satisfactory for the educational case study and could be replicated for other communities in Iran.

Keywords: Water Resources Sustainability, Sustainability Index, CWSI

INTRODUCTION

Sustainability of water is vital for preservation of this resource in the world. This is more prominent for developing countries and especially for those located at the Middle East and North Africa (MENA) Region, where water is scarce (World Bank 2007). Iran is one of these countries which suffers from limited renewable water supply while intends to develop its economy which highly demands water resources. To balance these two contradictory factors and at the same time preserve the environment for present and future generations, sustainability of water resources should be considered by monitoring and data mining.

Mays (2007) defines water resources sustainability as : "the ability to use water in sufficient quantity and quality from the local and global scale to meet the needs of humans and environmental ecosystem for the present and future to sustain life, and to protect humans from the damages brought about by natural and human-caused disasters that affect sustaining life." Whichever definition is used, there is a

need for measurement or quantification of water impacts on the environment for present and future generations so that plans for sustainable water resources management can be carried out accordingly.

Sustainability indicators and composite index are increasingly recognized as a useful tool for policy making and public communication in conveying information. They simplify, quantify, analyze and communicate otherwise complex and complicated information. There are currently several initiatives working on the frame works for sustainable development in different fields such as environment (Singh et al. , 2008).

The Canadian Water Sustainability Index (CWSI) has been developed by the Policy Research Initiative (PRI) for evaluating the well-being of Canadian communities with respect to fresh water resources. This index integrates a range of water-related data and information into a series of 15 indicators, classified in five major theme-based components (i.e. resource, ecosystem health, infrastructure, human health capacity). The CWSI which is the arithmetic average of scores of the indicators provides a holistic profile of a community's key water issues, allowing for comparison and analysis (PRI, 2007).

The primary objective of this paper is to assess the water resources sustainability and well being in the Ahwaz County, a community located in South West of Iran fed by Karun River. In the absence of any local index, the Canadian Water Sustainability Index (CWSI) has been trailed for this purpose.

METHODOLOGY

In the absence of any local index, the CWSI has been trialed for the Ahwaz County in Iran. Most of the water and wastewater data for calculation CWSI indicators in this community were collected form the local (AWWC, 2006) and national sources (NWWEC, 2006), while the demographic information were acquired from the latest census carried out (SCI, 2006).

In this study, the standard CWSI score which is the simple average of five major theme-based components was first calculated according to the PRI evaluation method. Furthermore, the index was also calculated considering weight adjustments. For this purpose, importances of five components relative to each other were first estimated on the basis of an internal data analysis and weights were further calculated by pair-wise comparison, using Expert Choice version 2000. In this regard, arithmetic weights were considered for the components. On this basis the final CWSI of the five components were calculated according to the following formula:

$$CWSI = \frac{\sum_{i=1}^{N} w_i \times X_i}{\sum_{i=1}^{N} w_i} \tag{1}$$

where: X_i refers to component i of the index for a particular community

w_i is the weight applied to that component.

Finally the standardized CWSI score was compared with the weighted average.

STUDY AREA

Ahwaz City is the center of Khuzestan province, located in South West of Iran (Figure 1). Ahwaz County (City of Ahwaz and subsidiary cities) has a population of 1,166,287 people (NWWEC, 2006). Karun River, the most important river of Iran, passes through this county which is located about 12 meters above the sea level (Figure 1). This river is the main source of supplying drinking water to the citizens and abstraction from the ground water resources is negligible. Total length of the water supply network is 2349 km which covers 278,000 connections (AWWC, 2006).

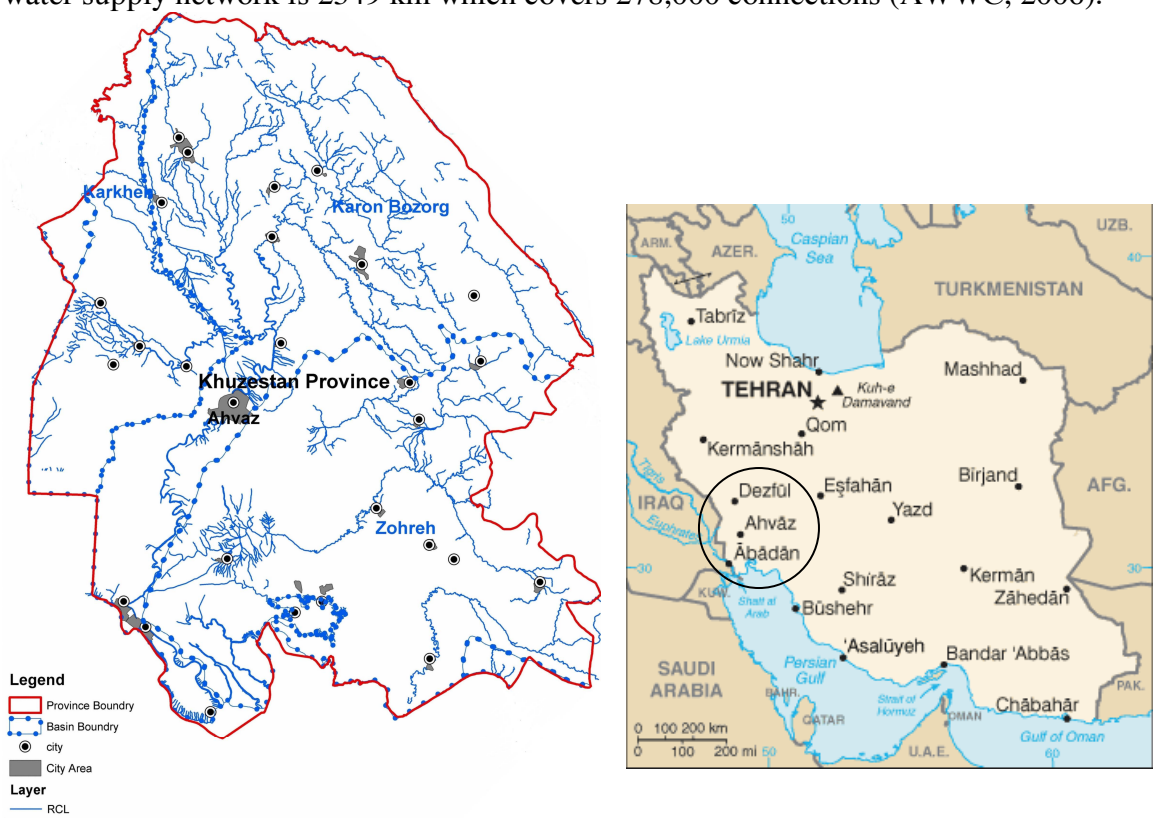

Figure 1. Location of Ahwaz County in Khuzestan Province

The flow rate of Karun river, measured at Ahwaz station, are 90 m^3/s in low water seasons, 2500 m^3/s high water season and about 5000 m^3/s in maximum floods. This River suffers from discharge of pollution loads from industrial, agricultural, agro-industrial and domestic sources. Increasing water withdrawal from and wastewater discharge to the river has endangered the aquatic life of this important ecosystem. Furthermore, the drinking and in-stream water quality standards have been violated in many instances. (Karamouz et al., 2008).

RESULTS

The indicators of CWSI for Ahwaz County were calculated according to the mentioned methodology. Results for estimation of each of the 15 sub-components, grouped in the 5 thematic components, are summarized below.

1. Resource: This component, evaluated at the river basin scale, scores the natural endowment of freshwater and comprises three indicators of Availability, Supply and Demand as follows:

1.a. Availability: This indicator assesses the annual amount of renewable fresh water available which is 21.8 BCM for the population of 1,166,287 persons for Ahwaz county. Considering the Falkenmark water stress indicator as a bench mark, the score for this component would be $R_a=100$.
1.b. Supply: This indicator considers the seasonal variability of the supply only as the ground water resources depletion does not occur in Ahwaz. Using discharge time series of the Karun River at Ahwaz location, run-offs exceeded 5% and 95% of the year are $244 m^3/s$ and $1715 m^3/s$ respectively. By dividing the last tow figures, the score for this component would be $R_s=100$.
1.c. Demand: This indicator assesses the current level demand of water on the basis of water license allocations. In Ahwaz County, the total amount of water consumed for municipal, irrigation and industrial use were 1.3 BCM in 2006. This amount in relation to the total amount of renewable freshwater (21.8 BCM), scores $R_d=94$.

2. Ecosystem Health: This component examines the health of the river basin's aquatic system with three indicators of Stress, Quality and Fish as mentioned below:
2.a. Stress: This indicator is intended to reflect the pressures imposed on ecosystem by pollution as well as excessive water use. In Ahwaz County, 20.5 BCM of water is removed from the ecosystem which leads to score of Es=*85*.
2.b. Water Quality: This indicator assesses the quality of water with respect to protection of aquatic life. For this purpose CWSI relies on the Water Quality index (WQI). This tool was also employed for the case of Ahwaz County (Mojahedi & Attari, 2009) which provided a result of $E_{wq}=85$.
2.c. Fish: This indicator reflects the health of native fish species that are economically and culturally important for the community. These fish population trends are not considered to have much influence in Ahwaz County and therefore collection of limited data for estimation of this indicator was not considered.

3. Infrastructure: This component assesses the state of water and wastewater infrastructure by combination of its ability to meet future demand, its condition and the level of treatment it provides as follows:
3.a. Demand: This indicator assesses the capacity of the water infrastructure to meet future demand due to population growth. The Water distribution network of the Ahwaz county currently covers the entire community but this would not be enough for a population growth of about 1.28% in this area and therefore $I_d=8$.

3.b. Condition: This indicator reflects the condition of water and wastewater infrastructure by considering the system losses. Unfortunately, the un-accounted for water in Ahwaz network is more than the limiting value of 25% and therefore $I_c=0$.
3.c. Treatment: This indicator focuses on the level of wastewater treatment. In Ahwaz County, 85% of populations are connected to the municipal sewers but only 28% receive secondary treatment in which insoluble matter and biological impurities and therefore $I_t=18.6$.

4. Human Health: This component considers three issues of Access, Reliability and Impact of water supply which are directly related on the health and well being of the community.
4.a. Access: This indicator measures the amount of potable water which is available to each person. In the Ahwaz County, about 230L/cap/day is available which is larger than the bench mark value of 150L/cap/day and therefore $H_a=100$.
4.b. Reliability: This indicator reflects reliability of a community's water supply in terms of services disruptions days per person. This figure for the City of Ahwaz is estimated to be 0.35 day per person which rewards a high score of $H_r=100$.
4.c. Impact: This indicator assesses the number of registered water borne incidences per 1000 people. Such an official data was not available for the Ahwaz County at the time to the authors.

5. Capacity: This component measures the capacity of the community to manage their water resources in terms of Financial Capacity, Education and Training as mentioned below:
5.a. Financial: This indicator examines the financial capacity of a community to manage water resources in relation to the communities with the highest surplus and debt in the country. Unfortunately, all of the water and wastewater companies in Iran face deficits now days as they are not functioning on a full cost recovery basis. Therefore, the companies with the maximum (-12.45$) and minimum amount of loss (-2.23$) per capita in the country were selected for the sake of this comparison. In the Ahwaz County, the amount of surplus in relation to the expenditures is -8.61$ per capita which leads to a score of $C_f=38$.
5.b. Education: This indicator considers the level of education in the community to address local water issues. In Iran, 45% (the maximum) and 18% (the minimum) of the population, aged between 20 to 64, have at least high school education. This figure for the Ahwaz County is 34% and therefore $C_E=58$.
