5.c. Training: This indicator specifically addresses the level of training that water and wastewater treatment plant operators have received. In the Ahwaz water and wastewater company, roughly about 60% of the operators have had no training, 25% had other trainings and 10% have industrial certified trainings. This leads to a score of $C_o=27.5$.

DISCUSSION

The results of estimation of the indicators as well as an average of their sub-components are summarized in Table 1. The final CWSI index was first evaluated according to standardized method and then by consideration of weights using Equation 1. Comparison of these results did not show a significant effect once weights were adjusted for this county. Therefore, application of the standardized index is more appropriate especially for intra-community comparison purposes.

Table 1. Results of final CWSI for Ahwaz County

No.	Component	Indicator	Code	Score	Component Score w_i	Component Weight X_i	Component $w_i X_i$
1	Resource	*Availability*	R_a	100	98	0.329	0.267

Final CWSI Score			*Weighted Average=63.0*			*Weighted Average=69.3*	

CONCULSION

In this paper, the Canadian Water Sustainability Index (CWSI) was trialed for the case of Ahwaz County, in the South Western part of Iran. Results showed that:

- In the absence of any local water sustainability index, the first attempt to apply CWSI index for the case study in Iran was found satisfactory, despite economical and ethical differences.
- The final standardized CWSI score, calculated for Ahwaz, were found to be in the range of the figures calculated for the six communities in Canada.
- The final CWSI score for Ahwaz County has most benefited form the large amount of resources component while the poor infrastructure component has dramatically lowered the average score. To improve this, wastewater treatment plants with large investments are currently under construction.

- Modifications of the CWSI index by weight adjustments, using pair-wise, did not show a significant effect. Therefore, application of the standardized index is more appropriate especially for intra-community comparison purposes.
- This educational case study can be replicated for other communities in Iran which further facilitates comparison of the indices.

Development of watershed management modeling system: the Los Angeles County Flood Control District's watershed based approach for urban runoff and stormwater quality

Youn Sim, Ph.D., P.E., M. ASCE

Los Angeles County Flood Control District, 900 South Fremont Ave, Alhambra, CA 91803; PH (626) 458-4314; email: ysim@dpw.lacounty.gov

ABSTRACT

Improving the quality of urban runoff and stormwater in the Los Angeles County's coastal watersheds is challenging. Thousands of separately permitted discharges with multiple Total Maximum daily Loads flow into the same receiving water bodies simultaneously. This makes it necessary and economical to address many different pollutant sources concurrently. In order to help overcome such challenges, the Los Angeles County Flood Control District is developing a watershed modeling system (WMMS) that would ultimately identify cost-effective projects through an integrated, watershed based approach. Using WMMS, collective impact of a variety of pollutant sources from point to non-point is evaluated and thereby comprehensive, long-term strategies for overall water quality improvement of the entire watershed will be planned. In addition, the WMMS will be used as an integrated watershed management tool for future planning of projects that achieve multiple benefits besides water quality such as water conservation, flood control, and open space development. This would eventually allow for an effective stormwater resource management.

Background

- **Watersheds in the Los Angeles County, California**

The Los Angeles County's coastal drainages flow from the highlands in the east to the Pacific Ocean in the west. Total size of coastal watersheds is approximately 3,100 square miles. Major surface waters originate from pristine mountains, flow through urbanized foothill and valley areas, high density residential and industrial coastal areas, and terminate at highly utilized recreational beaches and harbors. Drainages in the northern and western part of the County flow through un-developed or developing areas. Alluvial fans in low lying areas such as the San Fernando Valley, San Gabriel Valley, Oxnard Plain, and the Los Angeles Coastal Plain contain layers of sediment that form aquifers. The aquifers are important sources of ground water in the basin. The Los Angeles County's coastal watersheds include the following six watersheds. See Figure 1 for watershed locations:

1. San Gabriel River,
2. Los Angeles River,

3. Dominguez Channel,
4. Ballona Creek/Coastal,
5. Malibu Creek, and
6. Santa Clara River Watersheds.

- **Land Use**

Land use within the County varies considerably from vacant land to industrial. Overall land use in the County is dominated by undeveloped vacant land, which encompasses 64 % of the total land use. Residential areas comprise 19% of the total land use in the region, followed by commercial and public areas which comprise 6%. All other land use categories including agriculture, transportation and utilities, industrial, open space and water make up the remaining 11% of the County.

- **NPDES Permittees**

Typical artificial discharges (distinguished from stormwater discharge) regulated under NPDES program include discharges from: publicly owned treatment works (POTWs), generation stations, refineries, and other minor industrial facilities. Currently approximately 600 permits are issued under this category in the County.

The storm water program consists of three components; municipal, industrial and construction. The goal of the program is to reduce/eliminate the discharge of pollutants in storm water and dry weather flows from urban, construction, and/or industrial environments. Municipal stormwater discharge (MS4) in the County is currently regulated only by two permits while industrial and construction stormwater discharges are regulated by approximately 5,000 permits.

It should be noted, however, that among the total 5,600 permits in the County, TMDLs are enforced in only one permit, Los Angeles County MS4 permit.

- **TMDL Parameters and Source Characterization**

Stormwaters in the County include flows from mountain areas through urbanized areas, high-density residential and industrial coastal areas. The water bodies that carry the runoff have been identified as impaired for various pollutants including bacteria, metals, nutrients, and also carry trash. These water bodies are identified, listed, and updated by the USEPA under Section 303(d) of the Clean Water Act as Impaired Water bodies.

Specific pollutant sources, their transport mechanisms, and processes that influence the magnitude and patterns of pollutant distribution vary significantly depending on the locations. Controlling the impairment of these water bodies by these pollutants has been a challenge to local governments.

- **TMDLs developed**

  To date total 23 TMDLs have been developed for water bodies in the County. They include trash, metals, toxics pollutants, bacteria, nutrients, and chlorides. TMDLs of most pollutants are allocated to POTWs, MS4, California Department of Transportation (freeway owner), and industrial and construction sites. Nutrient and chlorides TMDLs mainly focus on effluents from wastewater treatment plants. Most of TMDLs have both point and non-point source components. Typical non-point sources identified in the TMDLs are aerial deposition, natural sources (forests and birds), and urban runoff. In particular, since the County's watersheds are highly urbanized, a majority of pollutants in stormwater runoff is from non-point sources.

Watershed based approach to current challenges

As indicated above, among the total 5,600 permits in the County, TMDLs are enforced only in one permit, Los Angeles County MS4 permit. TMDLs are allocated to storm drain outlets. However, since there are thousands of drain outlets into receiving waters, TMDL compliance for MS4 is typically determined based on water quality measured at receiving waters instead of quantifying total loads at all storm drain outlets. It should be noted that besides MS4, 5,600 other individually permitted discharges also impact the water quality of the same receiving waters. Therefore, it is almost impossible for MS4 dischargers to demonstrate the effect of their efforts toward TMDL compliance at the receiving waters. At any given time, deterioration of water quality can be attributed to any one of 5,600 separate discharge activities.

In order to overcome such challenges, a watershed based approach was needed to address the water quality of entire watersheds. In the watershed based approach, collective impact of a variety of pollutant sources from point to non-point is evaluated and thereby comprehensive, long-term strategies for overall water quality improvement of the entire watershed can be planned. Projects can be developed to achieve multiple benefits besides water quality such as water conservation, flood control, and open space development. This would eventually allow for an effective stormwater resource management.

- **Project goals**

  To help implement the watershed based approach to urban runoff and stormwater quality, the Los Angeles County Flood Control District has initiated a project to develop a watershed management modeling system (WMMS) that would ultimately be used to identify cost-effective pollution reduction projects. The WMMS simulates hydrologic and pollutant transport process and subsequently identifies cost-effective combinations of local scale (often referred to as LID type BMPs) and watershed scale BMPs. Identified local scale BMPs present a great option for individual cities and the unincorporated County areas to implement to

control pollution at the sources. Watershed scale BMPs treat residual runoff from the entire watershed. The WMMS and its results will be made available to all cities for their use in making decisions on how to best address pollution in runoff within their jurisdictions.

Specific goals include:

a. To develop WMMS for all major watersheds within the County boundary that simulates hydrologic and pollutant generation and transport process. See Figure 2 for illustration of WMMS.

b. To develop water quality improvement plan for the unincorporated County areas (WQIP) as a comprehensive plan for long-term TMDL implementation.

c. To provide technical guidance for LID implementation at new and re-development projects in the unincorporated County areas by quantifying water conservation and pollution reduction benefits.

d. To develop a watershed management tool for future planning of multi-benefit projects involving water quality, flood control, water conservation, and open space development components in the unincorporated County areas.

- **Project components**

1. WMMS based on USEPA's watershed models and BMP selection system based on an optimization algorithm.
2. WQIP for the unincorporated County areas that includes a thorough list of optimally selected, cost-effective BMP projects at local and regional scales and estimated pollution load reduction and associated costs.
3. Continuous update of watershed condition and subsequent BMP adjustment based on data from Countywide monitoring plan

- **Project Benefits**

1. Provides a system for phased BMP implementation with quantified pollutant load reduction to be achieved.
2. Allows for integrated watershed management with multi-benefits in addition to water quality benefit.
3. Allows for an iterative adaptive approach to water quality improvement goals through continuous refinement and improvement of the WQIP. See Figure 3 for illustration of an iterative and adaptive process using WMMS and WQIP.

Latest Progress

- **Watershed model development**

Existing watershed models for the Los Angeles County's coastal watersheds were developed by a multi-agency cooperation among the Los Angeles Regional Water Quality Control Board, U.S. Environmental Protection Agency (EPA), Southern California Coastal Water Research Project (SCCWRP), Tetra Tech, Inc., the Ventura County Watershed Protection District, the U.S. Army Corps of Engineers, and the Los Angeles County Flood Control District. The models employed a regional modeling approach that has been developed to simulate the hydrology and transport of sediment and metals. The approach is based on EPA's Hydrologic Simulation Program–FORTRAN (HSPF) and the Loading Simulation Program C++ (LSPC) (a version of HSPF, recoded into C++).

The models have mostly been used to support Metals TMDLs for Ballona Creek, the Los Angeles River, and the San Gabriel River, Dominguez Channel estuary, and and Los Angeles and Long Beach harbors, and Indicator Bacteria TMDLs for Santa Monica Bay beaches.

To provide a regional modeling approach to meet watershed planning needs, all previously developed models of the County's watersheds are currently being re-configured into a single modeling system based on the latest version of LSPC. This consistency provides a foundation for modifications for tailored applications, including representation of key watershed and pollutant source characteristics, management considerations, environmental conditions, spatial resolution, and other factors determined important for planning purposes.

- **Hydrologic Response Units**

In a watershed model, land unit representation should be sensitive to the features of the landscape that most affect hydrology and pollutant transport. In urban areas, it is important to estimate the division of land use into pervious and impervious components. In rural areas, vegetative cover is more important. Agricultural practices and crops (or crop rotations) should be well represented when present, although this component is less a factor in Los Angeles (where about 1 percent of the total sub watersheds area is agricultural) than in other areas. Depending on the goals of the model, if soil hydrologic groups are not homogenous in a watershed, it may be important to further divide pervious land cover by soil hydrologic group so that infiltration processes are better represented. Slope may also be an important factor, especially if steep slopes are prevalent; high slopes influence runoff and moisture-storage processes. The combination of land use, soil hydrologic group, and slope was used to define the HRUs. The HRU approach simplifies the selection of model parameters and provides a clear physical basis for parameter assignment.

Based on intensive analysis using nationally and locally available database for land use, soil types and slopes, the followings haven been found for HRU development:

a. The developed areas are concentrated in areas that have relatively poorly draining soils (Hydrologic Soil Group D).
b. Nearly half of the vacant land is composed of D soils, but the other half is almost evenly divided between B and C soils.
c. The developed areas are almost exclusively in areas that have slopes of less than 10 percent.
d. The highly sloped areas (> 10 percent slope) are almost exclusively vacant.

Figure 4 shows the spatial distribution of HRUs in the Los Angeles County.

Abstract

The water that surrounds us - lakes, rivers, streams, and aquifers - makes up our drinking water sources. These source waters can be threatened by a number of potential sources of contamination, such as on-site septic systems, sewer lines, hazardous chemical storage, storm water runoff, and animal wastes. The determination of the potential or risk is a key component of the source water assessment.

The Texas Source Water Assessment and Protection (SWAP) Program was promulgated as part of amendments to the 1996 Safe Drinking Water Act and consists of two fundamental aspects: Assessment and Protection. Source water assessments determine a water supply's susceptibility to contamination. Source water protection is the implementation of management strategies or practices to mitigate or eliminate risks associated with potential sources of contamination (PSOC). The assessments and protection plan are specific to each public water system, its source waters, and areas of concern which may impact source waters.

The objective of this paper is to discuss the innovative methodology used to encourage development of source water protection programs and conduct source water protection activities for selected public water systems using groundwater as the water supply. The methodology includes both technical activities as well as educational and outreach efforts to encourage active participation in the program. This paper will document the process used and present the results of these activities in multiple communities.

Introduction

The Texas Source Water Assessment and Protection (SWAP) Program was promulgated as part of amendments to the 1996 Safe Drinking Water Act and consists of two fundamental aspects: Assessment and Protection. Source water assessments determine a water supply's susceptibility to contamination. Source water protection is the implementation of management strategies or practices to mitigate or eliminate risks associated with potential sources of contamination (PSOC). The assessments and protection plan are specific to each public water system, its source waters, and areas of concern which may impact source waters.

While the Texas Commission on Environmental Quality (TCEQ) has completed assessments in the past for systems, taking action on the information contained in the assessments has been encouraged but ultimately left to the discretion of the water system. Thus, the protection component of the SWAP program is voluntary. One challenge public water systems face is managing competing demands for limited resources. Resources must be allocated to required expenditures and consequently, voluntary programs such as source water protection may not receive high priority nor have high implementation rates.

To address this problem and as part of the Source Water Protection Program, this project – the Source Water Protection Project (Project) was implemented to encourage active participation by public water systems and their customers in implementing effective source water protection programs. The goals of the Project are:

- Reduce the risk of groundwater pumped from public water supply wells of becoming contaminated
- Integrate source water assessments with source water protection activities
- Document Best Management Practice (BMP) approaches to manage PSOCs so the risk of groundwater contamination is reduced
- Demonstrate progress in the number of public water systems implementing source water protection activities.

Methodology

To address the goals of the Project, an approach was developed to engage public water systems and communities in actively participating in the source water protection process. The approach developed included technical as well as public education and outreach components. This approach builds on the existing required components of the SWAP Program by enhancing the public education and involvement facets of the program. The following multi-step process was used:

- Development of a comprehensive public education and outreach program that includes:
    - Development of a source water assessment and protection "brand" to facilitate a recognition and communication of a consistent message.
    - Identification of community "spark plugs", interested and committed individuals to lead local planning teams and to use the SWAP process to encourage stewardship of the groundwater resources in the project area.
    - Coordination of public meetings throughout the process to share information about the benefits of source water protection; obtain information about the community regarding the water supply system and its water quality issues,

PSOCs, and existing wellhead protection efforts; provide updates on the process; and discuss BMP implementation opportunities and challenges.

- Coordination of community outreach and education events

- Determination of groundwater capture zones through the characterization of local aquifer properties and groundwater modeling; in this case using version 3.2.1 of the Wellhead Analytical Element Model (W*h*AEM2000) developed by the US EPA (Kraemer et al, 2007).
- Identification and assessment of PSOCs through office and field investigation techniques.
- Development of an extensive database to facilitate selection and prioritization of BMPs to minimize the risk of contamination within the wellhead protection area using a three step process to identify appropriate BMPs, evaluate BMPs effectiveness using multiple criteria, and prioritize recommended BMP implementation.
- Identification of potential funding mechanisms to assist with BMP implementation.

The approach is presented graphically in Figure 1, beginning with a notice to proceed (NTP) for a given public water supply system.

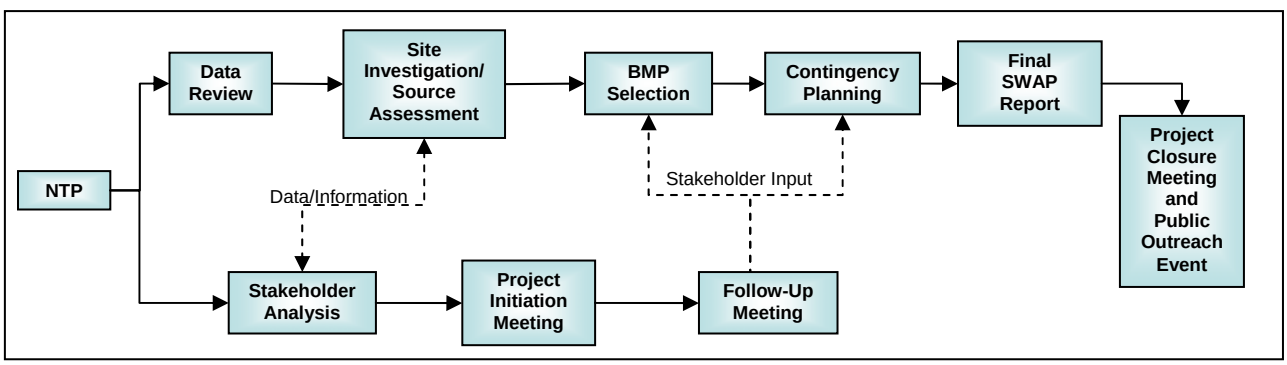

Figure 1 Source Water Protection Project Approach

Data Review

A review of available information for each project area was conducted prior to the project initiation meeting with the system. The review included a list of public water systems; previous source water assessment results, including PWS information, susceptibility ratings for each contaminant for each source; and other available information.

Stakeholder Analysis

In conjunction with data review, the stakeholder analysis of each system was essential to start the consensus building process that will lead to successful source water protection program implementation in each community. The purpose of the stakeholder analysis was to identify a

local planning team that may extend beyond jurisdictional boundaries and use the SWAP process to encourage stewardship of the groundwater resources in the project area.

The stakeholder analysis consists of identifying what activities are taking place in the area of interest, identifying property owners or who is responsible for each activity, and determining which community groups may have an interest or influence in SWAP activities. Because the source water protection program is voluntary, stakeholder identification and motivation is critical to achieving widespread community involvement. Information from the stakeholder analysis was also used to target and personalize the public outreach component of the project and educate, inform and ultimately secure stakeholder participation in the project.

Project Initiation Meeting

A project initiation meeting was held with each public water system. The purpose of the meeting was to introduce the source water assessment and protection program to the community, discuss the project purpose, identify the benefits of proactive source water protection, obtain information about the community and its land uses, answer questions, and obtain the community endorsement to participate in the project. Representatives from the public water supply were invited to attend along with the stakeholders, resources and other interested parties.

Site Investigation/Source Assessment

This task consisted of characterizing local aquifer properties and groundwater supply; conducting a field survey of the water supply system and identifying and assessing potential sources of contamination (PSOCs). Potential sources are widely varied and may range from airplane landing strips to hazardous waste generators to golf courses. Specific tasks included:

- Performing record searches of available data to obtain information such as location of septic tanks and industrial activities.
- Evaluating federal and state databases for potential contamination sources.
- Performing groundwater modeling to determine the wellhead protection area
- Performing field investigations to verify potential source of contamination (PSOC) information.

BMP Evaluation and Selection

Based on data gathered during the source assessment and stakeholder analysis, BMPs were selected to protect the source water supply where evidence of impacts were observed or a significant threat to the aquifer exists. BMP evaluation and selection was based on a prioritized list of potential contaminants, cost, the frequency and peak at which the contaminants may occur, and identification of BMPs which can be implemented and managed by the PWS. In addition, evidence of non-point source pollutant impacts or a threat to the aquifer must be present in order to make BMP recommendations for implementation. BMP selection was coordinated with the local planning team and stakeholders because of the direct economic consequences associated with BMP implementation.

Additional BMP assistance was provided to each participating system. For each BMP selected, additional resources were identified as well as an evaluation of potential funding sources to determine if financial assistance was available. Information regarding each potential funding source including type of funding (grant, loan or other), application deadlines, and other information was provided.

Contingency Planning

As part of the best management practice implementation, a contingency plan was developed for each source water protection area. The goal of the contingency plan is to ensure immediate and long-term protection of the source water supply area. For immediate problems, such as well contamination, the plan identified personnel, testing equipment, protocols (e.g., boil water advisory procedure), notification procedures and methods of containment to isolate pollutants. The plan also identified all key information regarding the water supply system, options for providing alternative water supply and location and capacity of treatment facilities

Outreach Implementation Plan

Implementation of the public education and outreach component of the project is critical to the execution of a successful voluntary SWAP program. Therefore, a comprehensive outreach implementation plan was developed to maximize community participation. The outreach implementation plan consisted of development of a SWAP "Brand," development of promotional materials, implementation of a SWAP website, implementation of a SWAP informational phone line, and coordination public outreach and education events.

The SWAP Logo (as shown in Figure 2) was developed to be included on all SWAP materials. A SWAP website (www.swaptexas.org) was developed and implemented to support the effort to enlist public water system participation in the SWAP program by consolidating source water protection information relevant to public water systems in one easy to access location; providing informative content in an easily navigable manner; providing credibility to outreach efforts; and tracking site usage as a measurement of outreach efforts. Information on the website includes a layman's explanation of source water protection and its implications; links to currently participating public water systems; the SWAP logo, short "success" stories/case studies; links to other relevant information sources, including the TCEQ and EPA SWAP websites. Figure 3 presents a screenshot of the website.

Figure 2. SWAP Logo

Figure 3. SWAP Website

All public information for the project was coordinated to facilitate consensus building, and participation in the project. All mail-outs and promotional materials were structured in user-friendly formats. Meetings were organized as discussions rather than lectures to dispel suspicions and encourage knowledge sharing. Meeting invitations were followed-up with personal phone calls to maximize attendance. Where appropriate, local media and elected officials were notified of meetings and invited to attend.

In addition to the project initiation meeting, a project follow-up meeting and project close-out meeting were conducted to keep the public water systems and their stakeholders involved in the process and informed of the results. The project follow-up meeting was held with each public water system, following the determination of the wellhead protection area, site investigation and BMP evaluation and selection. The purpose of the meeting was to review progress to-date, discuss identified PSOCs, discuss the preliminary selection of BMPs and potential funding sources, obtain system specific information that may affect BMP recommendations, and discuss possible public outreach events. Following the project follow-up meeting, the source water protection report was completed for each system. A final project meeting was conducted to present the report to the system, answer any remaining questions, schedule public outreach events. Each system agreed to participate in a follow-up survey to obtain information on BMP implementation.

Results

So far, eight public water systems have been contacted to participate in the project. At this time, six systems (75%) have agreed to participate. These systems include 26 wells and provide drinking water to over 7,000 customers. For each system the project initiation meeting has been conducted, as well as the groundwater modeling, site investigation, identification of PSOCs, BMP evaluation and selection and project follow-up meeting.

Response to the information provided to the systems and communities has been overwhelmingly positive and throughout the process a number of notable success stories have occurred. One system was able to use the source water protection report and map of the wellhead protection area to prevent a construction debris landfill from being located within the wellhead protection area. For that same system, an abandoned and deteriorated oil rig was removed from a wellhead protection area. In another instance, the project team was able to connect a public water system with a community group specifically interested in funding source water protection activities.

Additional public outreach and education events have been scheduled in three of the six participating systems, and scheduling of additional events is anticipated. The scheduled events include development and distribution of system-specific and PSOC specific information to residents to encourage protection of source water supplies through pollution prevention, participation at a community festival to distribute SWAP information and answer questions.

Based on the information regarding PSOCs within the wellhead protection areas, each system has agreed to implement some of the recommended best management practices. Future actions by each system will include development of the local planning team, investigation of potential funding sources, and implementation of the recommended BMPs. The project team will follow up at 6-months and 1-year time frames to document what BMPs have been implemented.

Conclusions

Effective data analysis and proactive consensus building are the keys to successful source water protection plan implementation. A voluntary source water protection program can be successful in encouraging participation. The development of a comprehensive public outreach and education plan combined with an effective technical approach are the keys to success for this project. Public water systems and their customers are interested in having a proactive role in protecting public water supplies. Technical information provided in a non-threatening, consistent, easy to understand manner provides the catalyst needed for communities to take ownership of protecting public water supplies. The source water protection approach used for this project ultimately resulted in a protection plans that contain practical, protective measures to minimize and prevent undesirable impacts from land use activities on drinking water sources.

E-mail: kazy1424@yahoo.com

ABSTRACT

Nigeria lies very close to the equator (hot country) West coast Africa between latitude 4 N and 14 N degree and longitude 2 E and 15 E degree. The country is located at the Northern end of Eastern branch of west coast of Africa rift system. Nigeria geological set up comprises broadly sedimentary formation and crystalline basement complex, which occur more or less in equal proportion all over the country. The sediment is mainly Upper Cretaceous to recent in age while the basement complex rocks are thought to be Precambrian. The studied area lies between latitude 12.4" and 11.11"W and longitude 13.81" and 14.13" S. The studied area is underlain by Precambrian basement complex of southern western Nigeria .The major rock in the area is charnokite and granite rock. The granite rock which are member of the older granite suite occupy about 65% of the total area .The principal granite is petrographic variety are recognized .The fine grained biotite-granite medium-coarse, non porphyritic biotite -hornblende granite and coarse-porphyritic biotite - hornblende granite. Also three main textural type of Charnokitic rock are also distinguished are coarse grained, massive fine grained and gneissic fine grained .The mode of occurrence of rock is three (1) core of the granite rock as exemplified by study area and few smaller bodies (2) Margin of the granite bodies as seen in Ijare and Uro edemo-idemo Charnokitic bodies and (3) Discrete bodies of the gneissic fine grained Charnokitic rock within the country gneisses as seen in Ilaro and Iju and Emirin village. All the charnokite in the region are dark-greenish to greenish-gray rocks with bluish quartz and greenish feldspar.

INTRODUCTION

Water is known to be a universal solvent. It is also one of the natural resources tapped by man, animals and plants to meet their needs for life sustenance.

The world's water resources include the entire range of natural waters on earth, either in vapour, liquid or solid form. Water is classified as surface water or groundwater. Surface water include rain water collected into rivers, lakes, reservoirs and oceans while groundwater include natural springs, well and boreholes.

Groundwater is commonly understood as water occupying the voids within a geologic stratum, groundwater is free from suspend matter and bacteria. It can be said to be pure, clear and colourless. Groundwater has greater quality than surface water.

About 495,000 children die annually of various diseases due to drinking of water that are not properly safe and sanitize (sea, stream e.t.c.), even as population increases and industries required all over the world, most people generally required about 2.5 litres of water everyday for direct consumption. The average amount of water used domestically each day by every person is about 190 litres (Hamill and Bell, 1986).

Generally, industries require approximately one quarter to one third of the public water supply under normal condition the easiest and most convenient way to meet the public demand for water is to utilize surface water resources, but unfortunately, water such as river, lake, stream e.t.c. are less plentiful than can be imagined. It can be recorded that surface water resources account for less than 2 percent of the world's fresh water.

The latter fresh water available however is unevenly distributed while the sources that are available have been either contaminated or polluted. (Hamill and Bell, 1986).

Groundwater accounts for about 98 percent of the world's fresh water and is fairly evenly distributed throughout the world. It provides a reasonable constant supply which is not completely susceptible to drying up under natural condition unlike surface water (World water balance and water resources of the earth UNECO Copyright 1978).

All over the globe, groundwater has been a very good and important source of water supply. It has been of continuous and tremendous use in irrigation industries and urban centers, as well as in rural communities. It is conveniently available at point of use and possesses excellent quality that requires little or no treatment in most cases.

OCCURRENCE OF GROUND WATER

The concept which explains the ultimate destination of rainwater is the sea either directly through run off or indirectly be infiltration and subsurface flow. A system of water movement in the atmosphere or rainfall, dews, hailstones or snowfalls over land as run off. Vertical and horizontal movement underground as infiltration or subsurface and continuous movement of all forms of water is the hydrogeology cycle. In the atmosphere, water vapours condense and may give rise to precipitation. However, not all this precipitation will reach the ground surface; some are intercepted by vegetation cover or surface of building and other structures and then evaporate back into the atmosphere.

The precipitation that reaches the ground surface may flow in to stream, lake and ocean, where it will either be evaporated or form seepages intruding in to the ground likewise soil moisture and further percolate downward to underline aquifer where it may be held for several years longer.

Groundwater in Nigeria is restricted by the fact that more than half of the country is underlain by crystalline basement rock of pre-cambian era.

The main rock types in this geological terrain include igneous and metamorphic rock such as migmatites and granite gneisses.

Generally in their unaltered form, they are characterized by low porosity and permeability. Porosity in basement rocks is by induction through weathering while secondary permeability induces by tectonic activities which manifest in form of that often act as conduct path facilitating water movement.

In other words, aquiferous zones in the basement terrain include fractured/weathered rocks. The yielding capacity of well, drilled within such rock are always very enormous.

RESEARCH METHODOLOGY.

I. Literature Review: All available geological/hydrological information were collected through the reading of journal, reference seminar paper (Olorunfemi M.O., 1990)
II. Data Gathering: All vertical electrical sounding data were collected from water section of the Federal Ministry of Agriculture and Water Resources Abuja, Wenner array was used in collecting the date.
III. Data Analysis: The data were interpreted by using partial curve matching technique. Computer was then used to interpret the results, from the result obtained geoelectric sections were generated.
IV. Interpretation of Results: Result obtained from each VES station were completed and interpreted in order to determine the best location for groundwater development in the study.

GEOLOGY OF THE STUDY AREA

Akure south Local Government falls within the basement complex region of Nigeria. The studied area lies between latitude 12° 04° and 11° 11° W and 13° 81° and 14°13°. and is underlain by precambian basement complex rocks of South Western Nigeria.

Several part of Africa is underlain by crystalline basement complex rocks. The major types of rocks in Akure are granite rocks and charnokite.

The granite rocks which are member of the older granite suit occupy about 65% of the total area of Akure. Three principal petrographic varieties are recognized, the fine-grained biotite granite, medium to coarse grained, non-porphyritic biotite – hornblende granite and coarse – porphyritic biotite- hornblade granite.

The classification is based largely on the textural characteristics. Also three main textural types of charnockitic rocks are also distinguished in Akure.

These are the coarse-grained variety, massive fine grained and the gneissic fine-grained types. Unlike most of the older granite, the charnokite rocks do not occur in form of smooth rounded boulders and only a few low hills all forming oval to sub-circular and elongated bodies.

The charnockitic rocks appear to have three modes of occurrence in the area, the first occurrence is within what seems to be the 'core' of the granite rock as exemplified by Akure body and few smaller bodies.

The second is along the margins of the granite bodies as seem in Ijare and Uro Edemo-Idemo charnockitic bodies. The first two modes of occurrence are mainly shown by the coarse-grained charnockitic variety. The last mode of occurrence is represented by the discrete bodies of the gneissic fine-grained charnockitic rocks within the country gneisses as seen in Ilara and also near Iju and Emirin villages.

All the charnockitic in the region are dark-greenish to greenish-gray rocks with bluish quartz are greenish feldspars (V. O. Olarewaju, 1997).

HYDROGEOLOGY OF THE STUDY AREA

The major river in Akure in Ondo State is Ero River,this river originates from Igbara Oke road, about 16-18km distance to Akure town.

Osun River is the major source of water runoff in Akure town, there are other smaller rivers such as Owuruwu River which is about 60m distance from Apex Nursery and Primary School, Oba Adesida, which is the Ves location. This river flows to meet Osun River at Akure road, the other rivers such as Otenre River, Omi Atamo, are smaller rivers that serve as runoff in the town; they meet Osun River at a point known as Osun Amon.Osun River flows from the Eastern part to Western part of the town and then flows to Ise town to meet a bigger river called Ogbese in Ondo State.

RESULT AND DISCUSSION

The interpretation of field resistivity data are in terms of resistivities and dept to the bedrock and interfaces across which a strong electrical exists.

The analysis and interpretation of the surveyed data shows four geoelectric layers. These layers are top soil which consists of the various rock types from clayey sand to sandy clay to compact sand. The second is the fresh/highly resistive basement. The fresh basement is characterized by high and infinite resistivity value and could not be contended on for groundwater, but the weathered zone and fractured basement which have lower resistivity value constitute good water zone

GEOELECTRIC SECTION

The quantitative interpretation of the VES data resulted in the production of numbers of geoelectric section. The section provides composite information along lithologic depth, the geoelectric section revealed four subsurface geoelectric layers.

The top layer which consists of (clayey sand and sandy clay) has resistivity value ranging from 70^0hm-m to 580^0hm-m, the maximum layer thickness is 3.0m. The top soil contributes to the development of groundwater, this layer is called the layer of aeration, and the water in this layer is called sub-surface water or zone of aeration. This zone is subdivided into three namely; soil water, intermediate belt and capillary belt.

The water that inf`iltrate into the soil from precipitation and in general ranges to all water present in the sub soil, or (in lithosphere). It may be evaporated from the soil, may be absorbed by plant root (soil water) and then transpired or may percolate downward to groundwater reservoir (intermediate). It occurs in a zone extending from the ground surface to the lower limit of porous water bearing rock formation (capillary) and designated s zone of the rock fracture.

The difference in compaction of the clayey sand is responsible for the variation in the resistivity values.

The resistivity of the second layer (Weathered zone) ranges from 30^ohm-m to 193^ohm-m while the thickness varies between 3m to 15.0m^2. The third layer is the fractured basement which has layer thickness varying from 17.5m – 29m with resistivity value ranging between 90^ohms-m to 240^ohms-m. The layer will be good for groundwater accommodation if the fractures are interconnected and permeable.

The fresh basement which is the fourth layer is characterized by high resistivity value up to 6650^ohm-m. The fresh basement is made up of infinitely resistivity rock in all the stations which form the bedrock.

The rock in this zone is hard, with no permeability and no water bearing. In fresh, non-fractured rock, the porosity is often less than 2%, as a result, run off is high and infiltration rate is very low in this zone.

The geoelectric section shows that the depth to the bedrock varies across the sounding station.

OVERBURDEN LAYER

The thickness of the overburden is an important hydrogeologic consideration in groundwater development in the basement terrain (Ajayi & Hassan 1990, Olorunfemi & Idonigie, 1992). Because water gets into the saturated zone through the overburden , the thickness of the overburden ranges from 23.30m to 36.60m in the study area. The variation in the overburden is due to degree of composition.

WEATHER LAYER

The weathered zone thickness shows the thickness of the weathered layer beneath in all the sounding station established across the study area, with VES 5 having the highest of thickness of about 13m and VES 1 having the lowest with about 2m.deriving from this, the thickness of the weathered layer here has, is sufficient enough for groundwater accumulation and therefore recommended for location of a borehole.

The variation in the weathered layer is due to the degree of weathering.

FRACTURED LAYER

The weathered layer thickness shows the thickness of the fractured layer beneath in all the sounding stations established across the study area, with VES 1 having the higher thickness of about 15m and VES 2 having the lowest with about 1.80m and the variation of this layer is due to degree of fracturing.

VES 5 and VES 1 are the location that will be recommended for groundwater, because they have the highest thickness of both weathered zone and fractured zone respectively which are good for groundwater accumulation.

VES 5 is recommended as priority location for sitting borehole, because it has thick

sequence of both weathered zone and fractured basement, which are good for groundwater accumulation.

If the fractured are interconnected and hence permeable, the thickness of the weathered zone in this section confers advantage on this over others.

The location will be good for optimum groundwater development, because of its availability in the study area; it will also be the only safe source of untreated water in Akure and also the cheapest source of good quality water supply, and its development can take in small crement rather than with relatively large scale financial investment which is the case of dams.

VES 5 has an advantage over VES 1, because the cost of drilling through VES 5 (weathered zone) will be cheaper than drilling through VES 1 which is of harder rock (fractured basement) and more difficult to drill.

VES 1: This location will be good for groundwater development if the fractures in this zone are interconnected and have permeable. The problem with this section is that to drill through fractured basement is very difficult and hard, it can damage the drilling bit.

VES 2: In this location, groundwater yield could be high bit, will not be up to that of (VES 1 and VES 5) so it can not be recommended for groundwater because the dip of the location and also the thickness of the area could affect its yield.

VES 4 will produce minimum groundwater yield, because of its dip and thickness of weathered zone which is small, it ranges between 1.70m to 7.0m.

VES 3: This location has the lowest thickness and the lowest probable groundwater yield, this location could be poor for groundwater yield and it is not recommended because of the thickness and dip as it can be seen in the geoelectric section.

CONCLUSION

The result of a quantitative interpretation of the VES data obtained in a geophysical survey over part of Akure, on a location opposite Apex Nursery and Primary School, Oba Adesida Road, Akure in Ondo State.

The interpreted results obtained from the study area are represented by a geoelectric section which shows the sequence and relationships between the subsurface lithologies.

The weathered layer and the fractured zone have been identified as the aquiferous in the area. The weathered layer is thicker in VES 5 and lowest in VES 1, while the fracture basement is thickest in VES 1. The 2 VES stations have been identified as the most suitable location for groundwater development in the area, with VES 5 being more prolific than others.

SPECIFIC PROBLEMS RELATED TO PARTIALLY PENETRATING WELLS IN CONFINED AQUIFERS

Ahmad Wagdy, Hany G. Radwan, Sherif M. El-Didy,
Irrigation and Hydraulics Department, Engineering, Cairo University,
Giza, Egypt., Fax. 202 5732949

Abstract

Partial penetration, especially for confined aquifers, may significantly affect the associated well(s) hydraulics due to the incidence of vertical flow in the vicinity of the well. This induces additional head losses, affects the potential pumping rate, and the related peizometeric head distribution around the well. Closed form analytical solution is beyond manual computations due to complicated integrations and summations in addition to dealing with a large number of variables. The main objective of this paper is to provide engineers with a simplified, yet accurate, solution to three specific problems, of common occurrence. Defining the effective aquifer thickness, in case of partial penetration for confined aquifers, is one problem. In case of unknown aquifer thickness, the performed analysis recommends to define the effective thickness as a multiple of the screen length, which in turn, is time dependant. Multiple values of 2, 3, and 4 are found to correspond to pumping periods of 1, 3, and 10 days, regardless of the pumping rate. Determining the optimum screen length for maximum well yield is a second problem. A screen design chart has been prepared while taking into consideration empirically-derived well capacity equation. Detecting the zone of influence of a partially penetrating pumping well is the last studied problem. The peizometric head at any radius can be estimated from proposed influence zone charts that require the pre knowledge of five well and aquifer parameters. All results are postulated based on programming of Hantush equation for partially penetrating wells.

1. Introduction

Partial penetrating wells are of common occurrence incase of unknown aquifer thickness, which causes the flow to have vertical components in the vicinity of the well leading to additional head losses around the well. Figure (1), following Wagdy et al (2009), shows a typical example in a confined aquifer. The differential equation representing the partially penetrating system, Hantush (1957) and Batu, (1998), is as follows:

$$\frac{\partial^2 s}{\partial r^2} + \frac{1}{r}\frac{\partial s}{\partial r} + a^2 \frac{\partial^2 s}{\partial z^2} = \frac{S}{T}\frac{\partial s}{\partial t} \qquad (1)$$

Where:

$$a^2 = \frac{K_z}{K_r}\ , \quad T = K_r b \quad , \ S = S_S b \qquad (2)$$

s : Drawdown at distance r (L) r : Distance from the well (L)
b : Thickness of aquifer (L) S : Storage Coefficient.
T : Transmissivity of the aquifer ($L^2 T^{-1}$) S_s : Specific Storage (L^{-1})
K_r, K_z : Horizontal and vertical hydraulic conductivity of aquifer (LT^{-1})

The solution of Equation (1) for confined aquifer is given by Hantush, (1961, 1964), (Batu, 1998) as follows:

$$s = \frac{Q}{4\pi T}\left\{W(u) + f\left(u, \frac{ar}{b}, \frac{d}{b}, \frac{L}{b}, \frac{z}{b}\right)\right\} \quad (3)$$

Where:-

$$f\left(u, \frac{ar}{b}, \frac{d}{b}, \frac{L}{b}, \frac{z}{b}\right) = \frac{2b}{\pi(L-d)} \sum_{n=1}^{\infty} \frac{1}{n}\left[\sin\left(\frac{n\pi L}{b}\right) - \sin\left(\frac{n\pi d}{b}\right)\cos\left(\frac{n\pi z}{b}\right) W(u, X_n)\right] \quad (4)$$

$$X_n = \frac{n\pi a r}{b} \quad , \quad W(u) = \int_u^{\infty} \frac{e^{-y}}{y} dy \quad (5)$$

$W(u)$: Theis well function.

The first part in Equations (3) represents the case of fully penetrating well, while the term represents the effect of partial penetration.

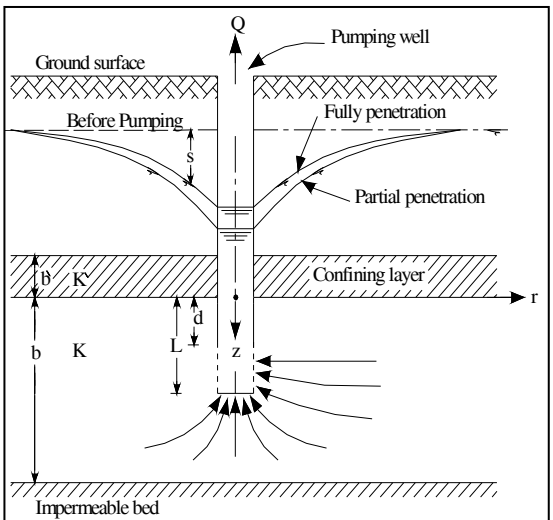

Figure (1): Flow Field for a Partially Penetrating Well in a Confined Aquifer.

2. Effective Aquifer Thickness

In many dewatering processes in the field, the thickness of the aquifer may be unlimited (too large). Common practice, considers the thickness of the aquifer equals 2.5 times of the screen length. Beyond this limit, the effect of the thickness may be neglected as shown in Figure (2). To study the effect of aquifer thickness, the term (b) in Equation (2) must be isolated. This problem will be studied for fine, medium, and coarse sand. The values of (K, S_S) for these soil types will be determined in the following sections.

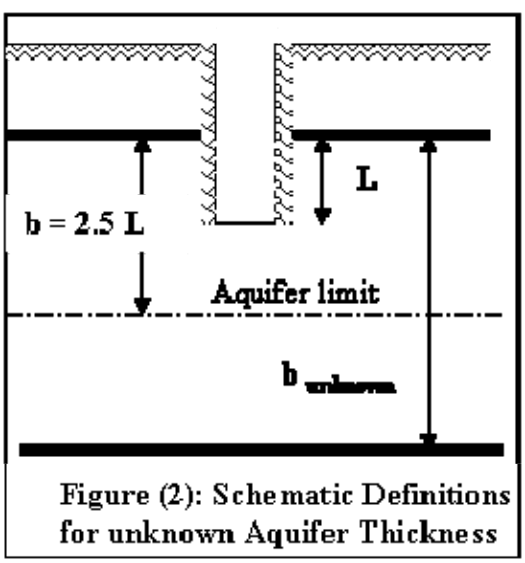

Figure (2): Schematic Definitions for unknown Aquifer Thickness

2.1 Specific Storage (S_S) of sand.

The specific storage is given by (Batu, 1998) as :

$$S_s = \gamma(\alpha + n\beta) \quad (6)$$

Where

γ : Specific weight of water.

α : Compressibility of the aquifer skeleton ($1/(ML^{-1}T^{-2})$.

n : Porosity.

β : Compressibility of water ($1/(ML^{-1}T^{-2})$.

The compressibility of aquifer skeleton (α) depends on the elasticity of the aquifer:

$$\alpha = \frac{1}{E_S} \tag{7}$$

Where E_S is the modulus of elasticity of the solid skeleton. The factor ($\gamma n \beta$) of Equation (6) gives the fraction of storage derived from expansion of water, while the product ($\gamma \alpha$) gives the fraction derived from compression of aquifer (Batu, 1998).

The average void ratio for fine, medium, and coarse sand are 0.62, 0.59, 0.55, respectively. By using the previous values of void ratio for each soil type, the values of modulus of elasticity, will be 23500, 39300, 39300 KN/m^2 for fine, medium, and coarse sand, respectively. The values of n, γ, β,and α=(1/E_S), can be used to calculate the specific storage (S_S), by substituting in Equation (6) as shown in Table (1).

Table (1): Specific Storage (S_S) for Types of Sand Soils.

Soil type	Specific storage (S_S) m^{-1}
Fine sand	4.1939×10^{-4}
Medium sand	2.5138×10^{-4}
Coarse sand	2.5138×10^{-4}

2.2 Horizontal Hydraulic Conductivity (K_r) of sand.

The properties of soil, which affect on groundwater flow are specific storage (S_S), and hydraulic conductivity (k). Ranges of hydraulic conductivity values for unconsolidated sediments are presented in Table (2), following Batu(1998).

Table (2): Arithmetic Mean Average Hydraulic Conductivity K_{av} of Porous materials.

Material	K_{av} (cm/s)	K_{av} (m/d)
Sand (fine)	2.28×10^{-3}	1.96
Sand (medium)	165×10^{-2}	14.3
Sand (coarse)	5.20×10^{-2}	44.93
Gravel	4.03×10^{-1}	348.19

2.3 Hantush's equation in a dimensionless form .

In most common processes in field, the screen extends from the top of aquifer, i.e. d =0, and all measurements occurring at z =0, therefore Equations (3, and 4) will reduce to:

$$s = \frac{Q}{4\pi T}\left\{W(u) + f\left(u, \frac{ar}{b}, \frac{L}{b}\right)\right\} \tag{8}$$

Where

$$f\left(u, \frac{ar}{b}, \frac{L}{b}\right) = \frac{2b}{\pi L}\sum_{n=1}^{\infty}\frac{1}{n}\sin\left(\frac{n\pi L}{b}\right) W\left(u, X_n\right) \tag{9}$$

New parameters, will be defined as follows:-

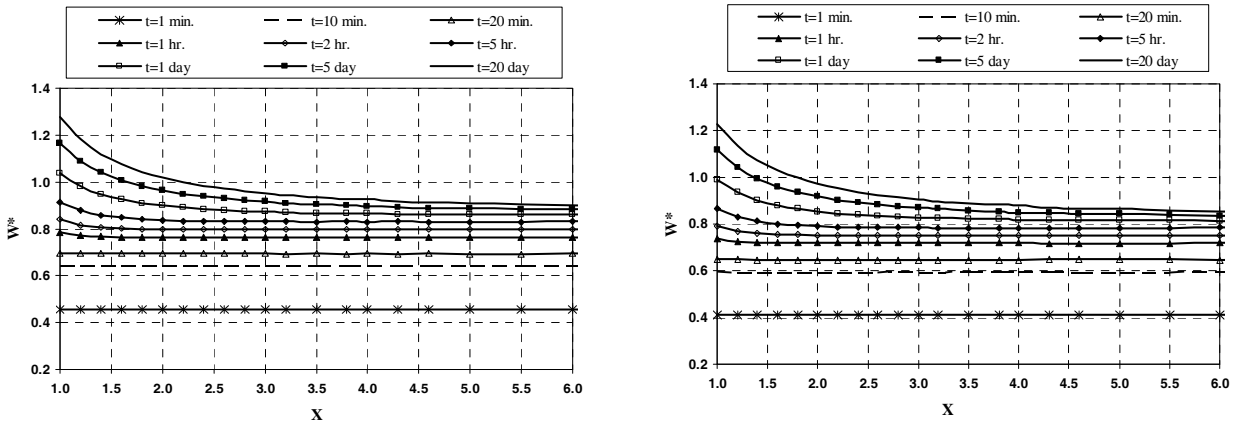
$$x = \frac{b}{L},\quad y = \frac{r}{L},\quad v = \frac{L^2 S_S}{K t},\quad W^* = \frac{s K L}{Q} \tag{10}$$

By using the previous dimensionless relations, the parameters in Equation (3) can be expressed as follows:-

$$u = \frac{y^2 v}{4} = \frac{r^2 l^2 S_S}{4 l^2 k t} = \frac{r^2 S_S}{4kt}\frac{b}{b} = \frac{r^2 S}{4Tt} \tag{11}$$

$$\frac{ar}{b} = \frac{ay}{x} = \frac{arl}{lb},\quad \frac{l}{b} = \frac{1}{x} \tag{12}$$

Then, Equation (8) will take the form:-

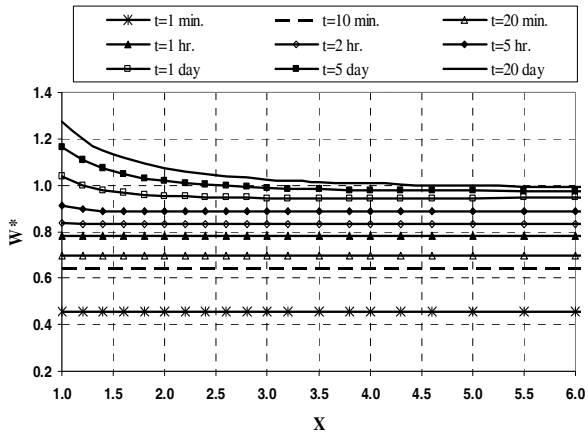


$$W^* = \frac{1}{4\pi x}\left\{ W\left(\frac{y^2 v}{4}\right) + f\left(\frac{y^2 v}{4}, \frac{ay}{x}, \frac{1}{x}\right)\right\} \tag{13}$$

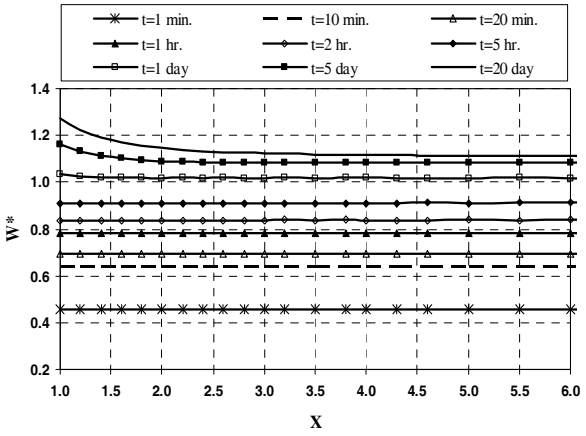
To study the problem of effective aquifer thickness, nominal screen lengths of (L) = 20, 40, 60, 80, 100m will be used, and the common values for well radius r_W = 6, 7, 8 inch.

2.4 Detection of Effective Aquifer Thickness.

This section deals with the effect of aquifer thickness (b) on the drawdown. According to Equation (13), the aquifer thickness (b) is included in the parameter (x), and the drawdown is included in the parameter (W^*). The following curves for each soil type are prepared for variable distances from well; y = (r / L). Each soil type will be discussed separately by using the corresponding values of (S_S), and (K). For the same screen length (L) the only remaining variable in (v) ratio will be the time (t). Thus, (v) will varied by considering: 1.0 min < time < 20 days, after initiation of pumping.



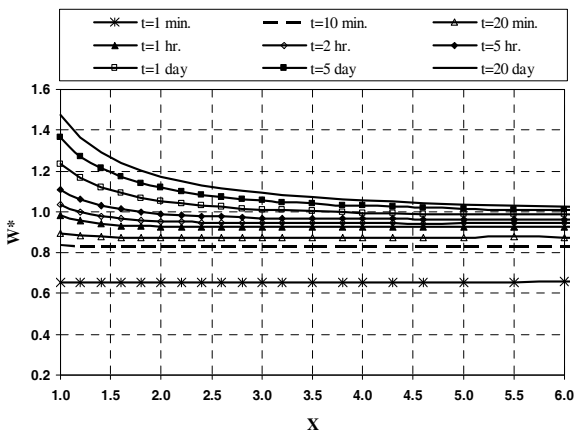
(a) Fine Sand Soil.



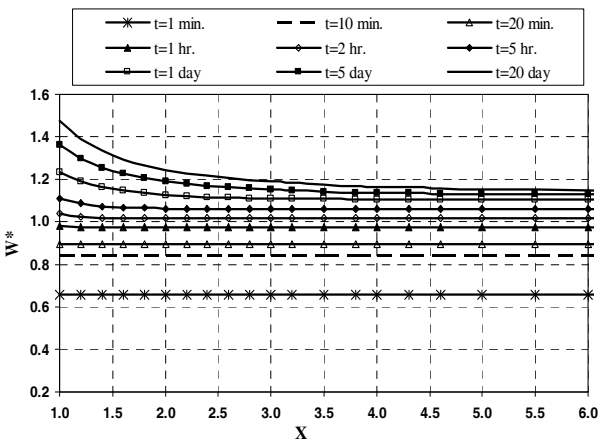
(a) (b)

Figure(3): Detection of the Effective Aquifer Thickness, for Fine Sand at L=20 m. (a) r_w = 6 inch, (b) r_w = 8 inch

Figure (3) shows that, there is no significant influence for well radii. Thus, analysis will proceed for the case of r_w = 6 inch, and screen lengths of 40, and 100 m.



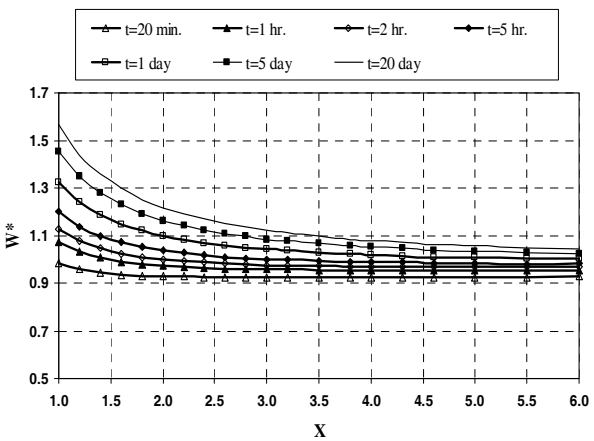
(a) L = 40 m



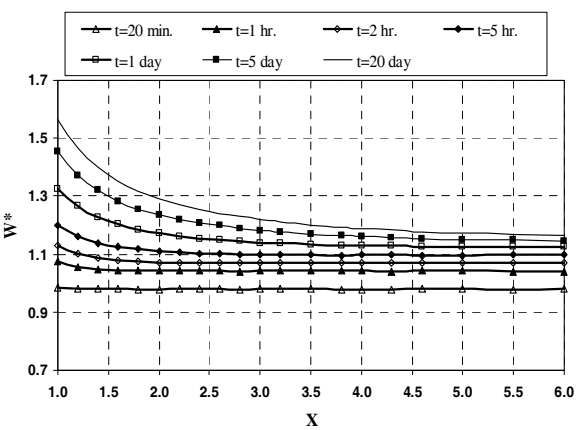
(b) L = 100 m

Figure(4): Detection of the Effective Aquifer Thickness, for Fine Sand at r_w= 6 inch.

(b) Medium Sand Soil.



(a) L = 40 m



(b) L = 100 m

Figure (5): Detection of the Effective Aquifer Thickness, for Medium Sand at r_w= 6 inch.

(c) Coarse Sand Soil.

(a) L = 40 m

(b) L = 100 m

Figure (6): Detection of the Effective Aquifer Thickness, for Coarse Sand at r_w= 6 inch.

From Figures (4, 5, and 6), the following points can be concluded:-

(1) For the first 20 minutes of pumping, flow is derived from the aquifer in the vicinity of the screen as represented by horizontal lines. This means that, the well may be literally considered as if fully penetrating the layer adjacent to the screen only.

(2) For the same value of penetration ratio (1/x), as time increases, the well is affecting larger part of the aquifer. The values of W^* increases which means that, drawdown increases beyond hypothetical full penetration case (x = 1.0).

(3) For the same screen length, as the thickness of the aquifer increases, the drawdown will increase beyond the case of full penetration.

(4) A limiting, time dependant, effective value exists beyond which the aquifer thickness has no additional influence on drawdown. These are as follows:

$$b = \begin{cases} 2.5\,L & t \le 1.0 \quad day \\ 3.0\,L & 1.0 \le t \le 3.0 \quad days \\ 4.0\,L & 3.0 \le t \le 10.0 \quad days. \end{cases} \tag{14}$$

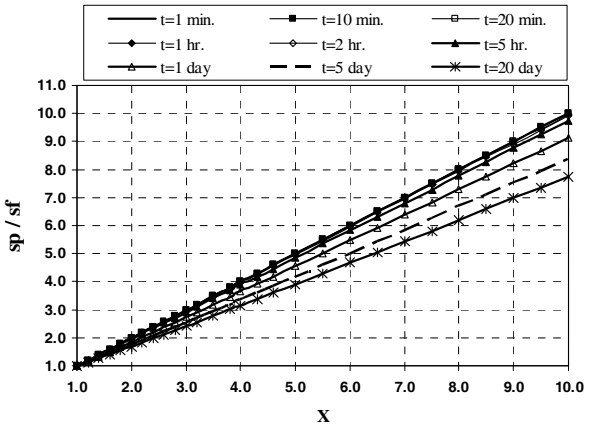
Aquifer extent is gradually reflected at the well as time passes. The common practice of setting b =2.5L is only acceptable for pumping (recovery) tests lasting less than 24 hours. Should the latter extend beyond 1-day, values from equation (14) are recommended to avoid misleading drawdowns.

(5) For the same screen length and penetration ratio, the drawdown of fine sand will be greater than medium sand which in turn will be greater than coarse sand. According to Equation (10), the following relation may be obtained:

$$s \,\alpha\, W^* \,\alpha \left(\frac{1}{K}\right) \tag{15}$$

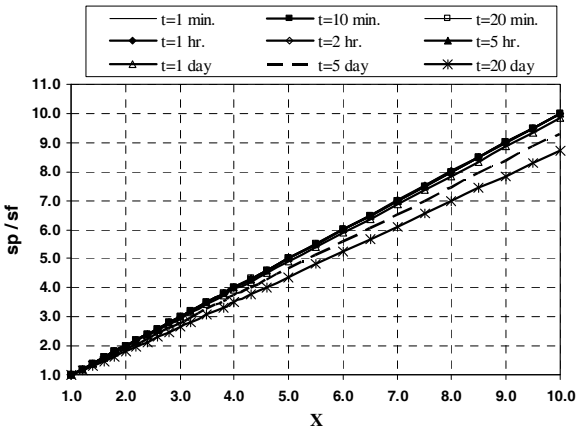
2.4 Ratio of the increase in drawdown due to partial penetration.

The values of W* for any penetration ratio (1/x) are drawn in Figures (3 to 6) during detection of effective aquifer thickness. These data will be used for each soil type to determine the increase in drawdown due to partial penetration using :



$$\frac{s_p}{s_f} = \left[\frac{W^*_P}{W^*_f}\right]\left[\frac{b}{L}\right] = \left[\frac{W^*_P}{W^*_f}\right] X \tag{16}$$

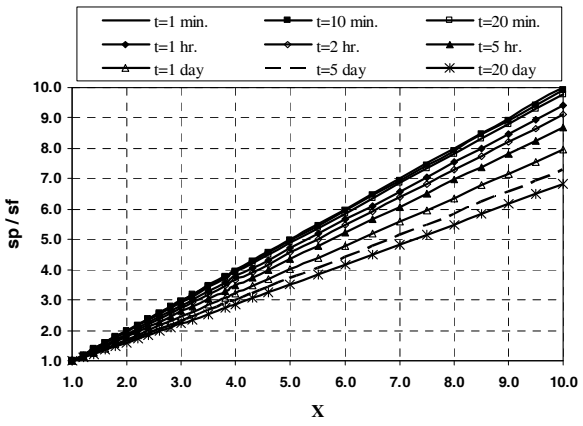
The following figures (7, 8, and 9) for the three types of soils, are drawn between (s_p/s_f) and x, for the case of r_w =6 inch. Some interesting points need to be highlighted:



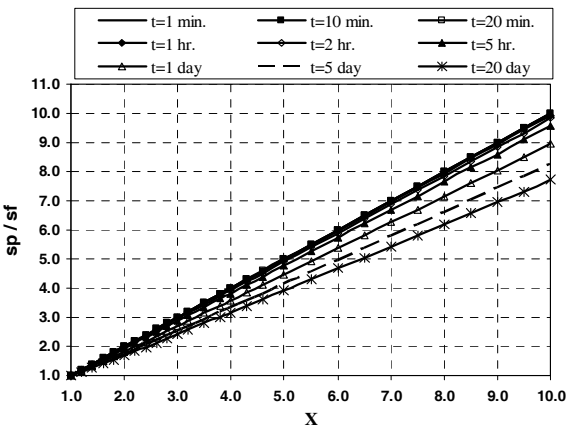
(1) The relation between the ratio of partial penetration drawdown to full penetration drawdown s_p/s_f, and inverse penetration ratio x for the same pumping rate, is linear. The dependence of s_p/s_f on pumping time is insignificant during the first hour of the pumping. However, a recovery in drawdown ratio s_p/s_f of up to 30% may occur at a 10% penetrating well (L/b = 0.1), but after 20 days of operation! (due to enhanced aquifer contribution)

(2) The maximum drawdown ratio s_p/s_f is equal to the ratio (b/L) during the first few minutes after initiation of pumping, then decreases with time.

(3) The variation in the range of the drawdown ratio s_p/s_f at any given penetration ratio is more pronounced for short screens wells (L = 40m) as compared to longer screens (L = 100 m). The effect of soil type is more pronounced at prolonged pumping periods, where s_p/s_f decreases as soil gets coarser.

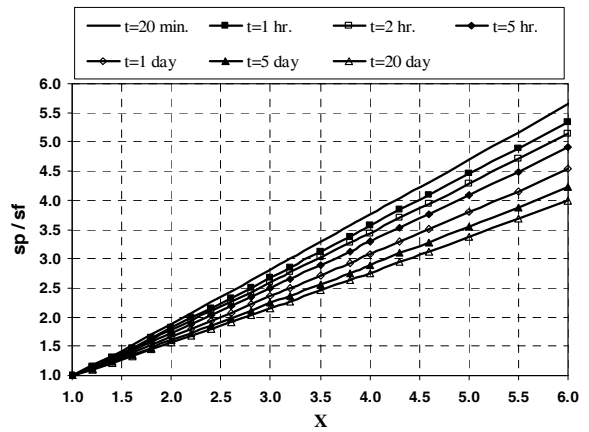


(a) L = 40 m

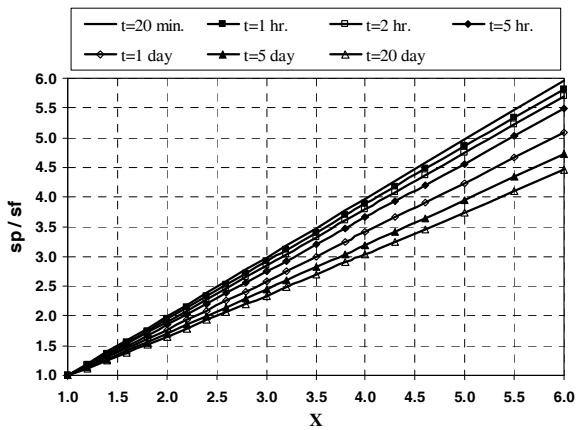


(b) L = 100 m

Figure (7): The ratio of increase in drawdown due to partial penetration, for Fine Sand at r_w= 6 inch.



(a) L = 40 m



(b) L = 100 m

Figure (8): The ratio of increase in drawdown due to partial penetration, for Medium Sand at r_w= 6 inch.

(a) L = 40 m

(b) L = 100 m

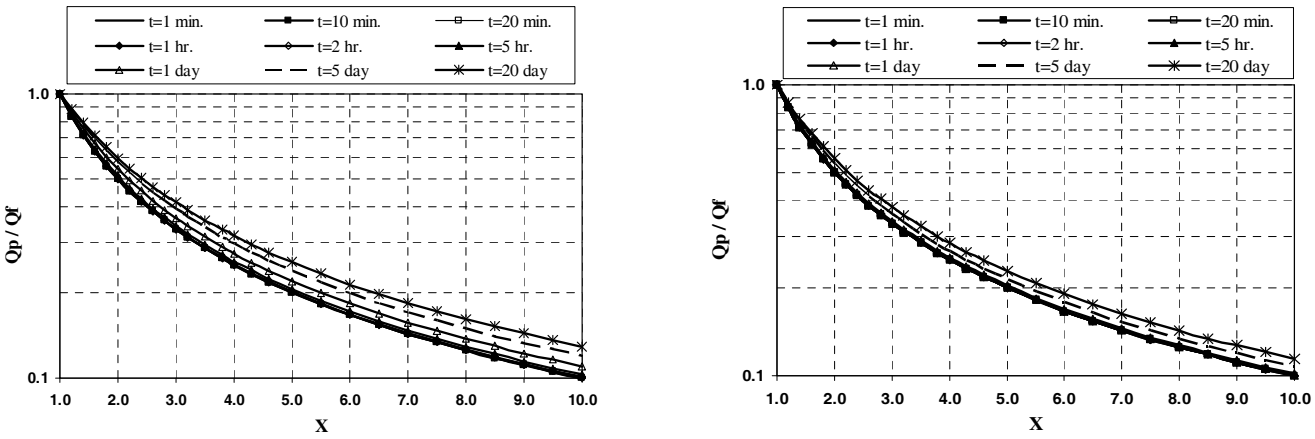


Figure (9): The ratio of increase in drawdown due to partial penetration, for Coarse Sand at r_w= 6 inch.

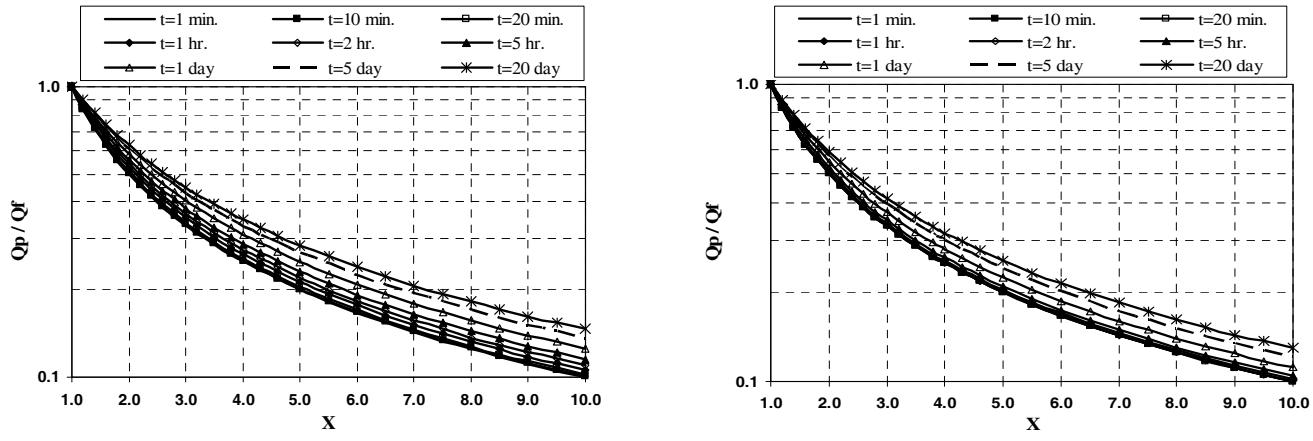
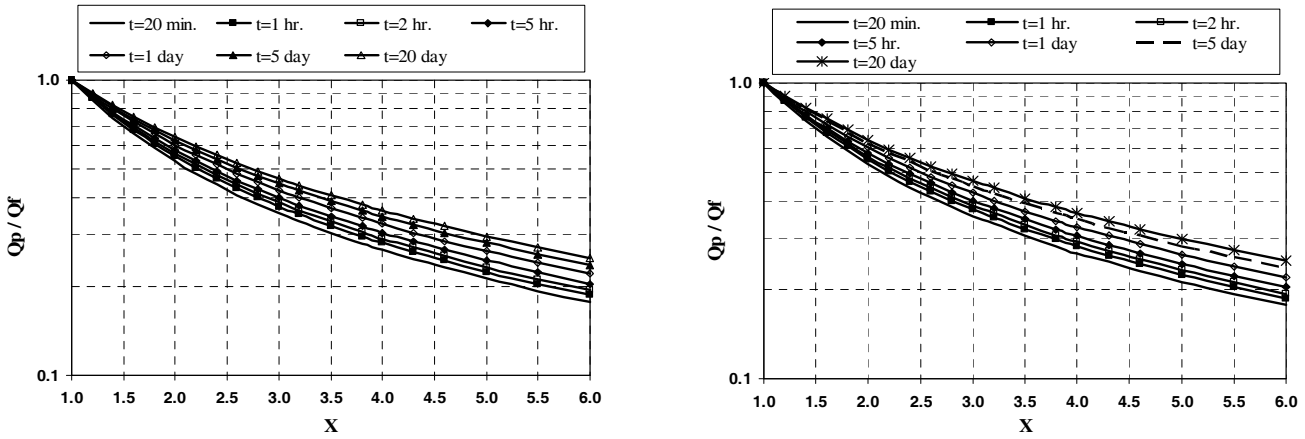
2.5 Reduction in the yield due to partial penetration.

For the same drawdown at the well face, the well yield falls beyond that under full penetration. The following relation can be used to determine the ratio between the discharge from partially to fully penetrating, as follows:-



$$\frac{Q_p}{Q_f} = \left[\frac{W^*_f}{W^*_P}\right]\left[\frac{L}{b}\right] = \left[\frac{W^*_f}{W^*_P}\right]\frac{1}{X} \qquad (17)$$

The following figures (10 to 12) for the three types of soils, are drawn between the ratio (Q_P /$Q_{f)}$) , and the ratio x for case of r_w =6 inch.



(a) (b)

Figure (10): The ratio of decrease in discharge due to partial penetration, for Fine Sand at r_w= 6 inch.
(a) L = 40 m, (b) L = 100 m

(a) (b)

Figure (11): The ratio of decrease in discharge due to partial penetration, for Medium Sand at r_w= 6 inch.
(a) L = 40 m, (b) L = 100 m

(a) (b)

Figure (12): The ratio of decrease in discharge due to partial penetration, for Coarse Sand at r_w= 6 inch.
(a) L = 40 m, (b) L = 100 m

From Figures (10, 11, and 12), the following points can be concluded:

(1) Ratio of partial to full well yield $\boldsymbol{Q_p/Q_f}$ increases gradually with time.
(2) Higher ratios of $\boldsymbol{Q_p/Q_f}$ happen in short screen wells.

3. Optimum screen length for maximum well yield from a confined aquifer of unknown thickness

When the aquifer thickness is not known, the following empirical equation of well capacity of confined aquifer can be used, following Jumikis (1971):

$$Q_{\max.} = \frac{2\pi r_f l_f \sqrt{K}}{15} \tag{18}$$

Where: Q_{max} : Capacity of confined aquifer (L^3/T), l_f : Length of filter (L)

K : Hydraulic Conductivity (L/T), r_f : Outer radius of filter (L).

Length of the filter is commonly used as the distance from groundwater level to the end of the well. The filter consists of two parts; first, the length between the groundwater level and the top of the aquifer which is variable from case to another and the second is the screen length which is required. Equation (18) can be rewritten in another form by getting the aquifer's capacity per filter's length as follows:-

$$\frac{Q_{\max.}}{l_f} = \frac{2\pi r_f \sqrt{K}}{15} \tag{19}$$

Hantush's Equation (13) can be used to determine the maximum well yield related to each screen length for unlimited aquifer thickness. According to Equation (14) the effect of the aquifer thickness can be neglected after three times of screen length, yet, the aquifer thickness is taken equivalent to twenty times the screen length (x = 20) to ensure that the aquifer is very large, and the drawdown is constant. Hantush's equation is applied to the three types of sand (fine, medium, and coarse), at r_w =6 inch as shown in Figure (13). Curves in Figure (14) are to be used to determine the optimum screen length for a given well yield or determining the well yield for a given screen length

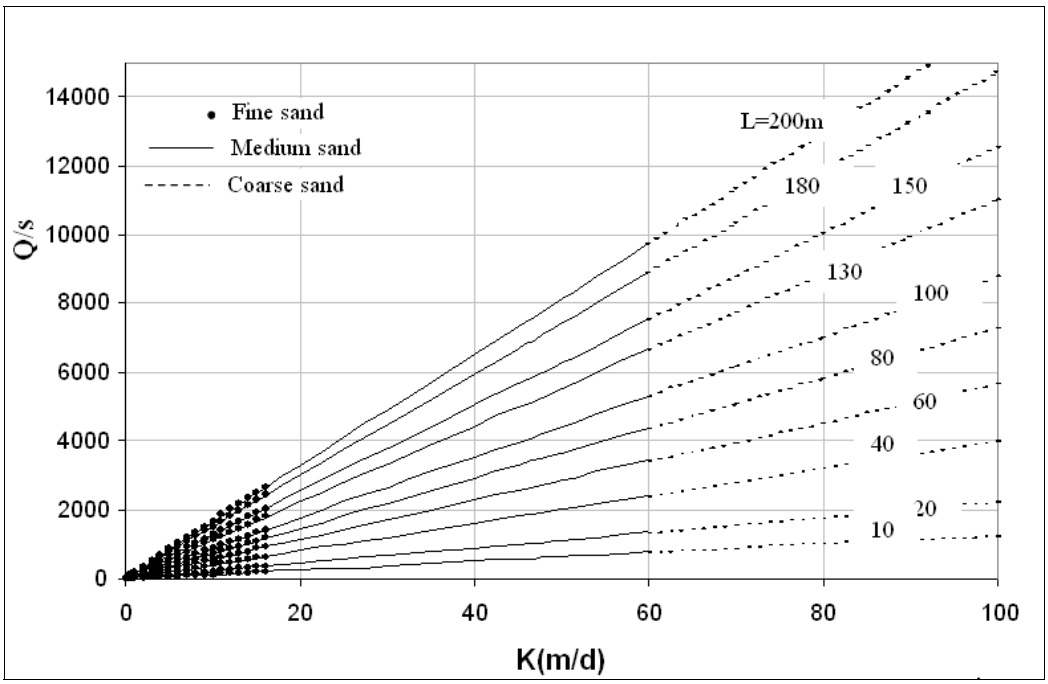


Figure (13): Variation of specific yield (Q/s) with hydraulic conductivity at variable screen lengths for three types of sands, r_w =6 in

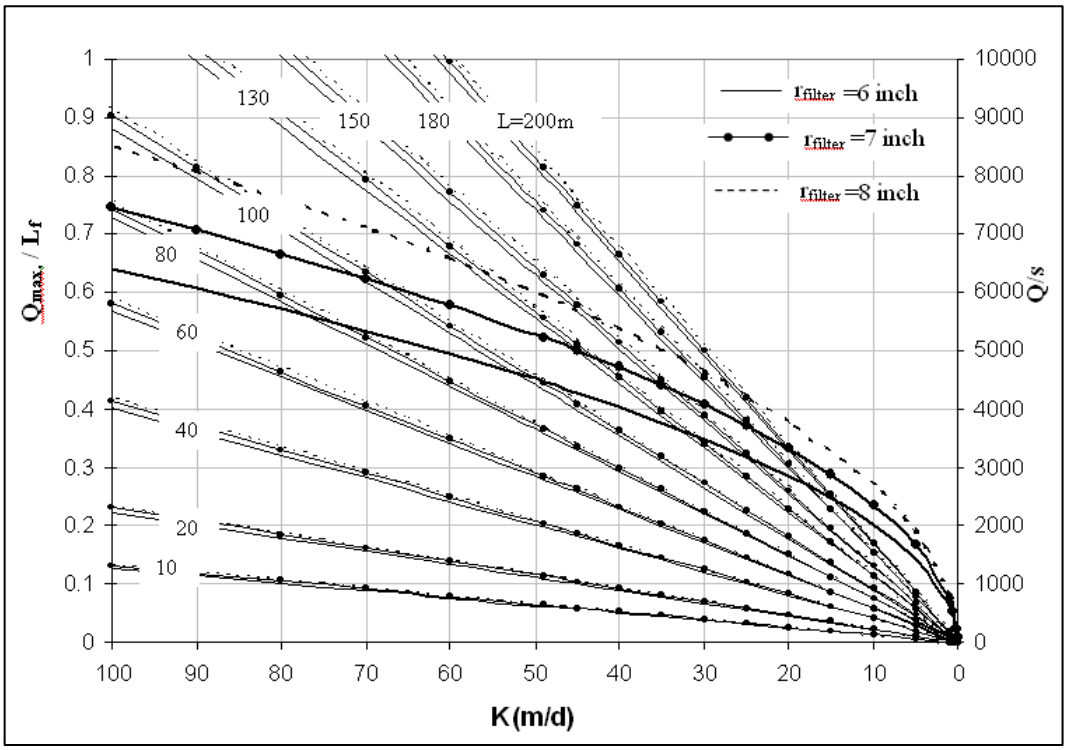

Figure (14): Detection of screen length for extracting maximum well yield from unknown confined aquifer thickness, using Analytical Solution for Hantush Equation (lines), and the Empirical Equation (curves)

4. Radius of influence for partially penetrating well in a confined aquifer at Steady state case

The general equation for a confined aquifer for partially penetrating well is represented by Equation (3). For small values of (u), u < 0.01 (steady state case) Theis equation can be approximated by Equation (-0.5772 –ln (u)) due to approximation of Cooper and Jacob. Equation (3) will be applied between two points, at the face of the well, and at the radius of influence (d/b =z/b =0.0), resulting into:

$$\frac{(s_w - s_r)K}{Q} = \left\{ \frac{1}{2\pi b} \ln\left(\frac{r}{r_w}\right) + \frac{1}{\pi^2 L} \sum_{n=1}^{\infty} \frac{1}{n} \sin\left(\frac{n\pi L}{b}\right) \left[K_o\left(\frac{n\pi a r_w}{b}\right) - K_o\left(\frac{n\pi a r}{b}\right) \right] \right\} \quad (20)$$

The right hand side of Equation (20) is solved using the MATLAB-based program, and the results are shown in Figures (15, and 16) for the two values of r_w (6 in, and 8 in)

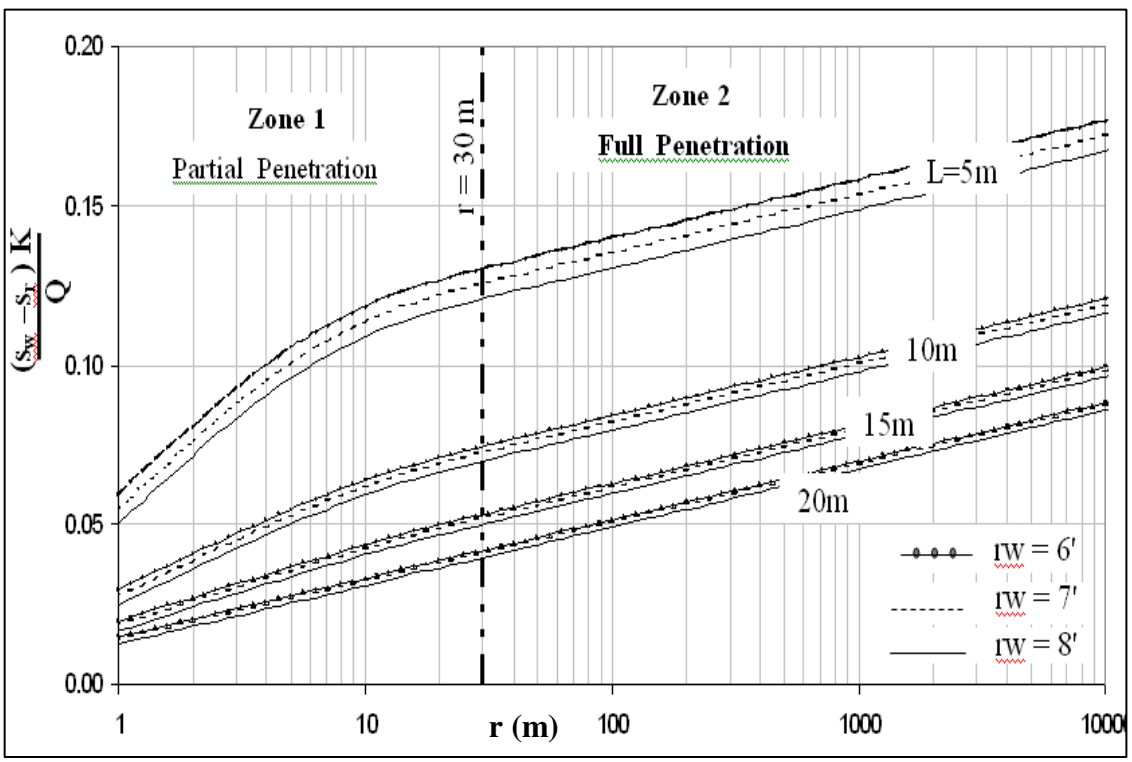

Figure (15): Relation between drawdown at any distance and properties of the Aquifer for partial penetration at b=20 m (confined, steady state).

The provided figures are recommended for calculating the following :

(1) Radius of influence by putting (s_r= 0.0) .
(2) The drawdown at any distance from a well.
(3) The distance at which the drawdown equal a certain value.

As shown from figures (15, 16), two zones exist; (i) The full penetration zone, which has straight parallel lines, and (ii) The partial penetration Zone. The point which separates between these two zones is at a radius close to one and half times of the aquifer thickness which confirms neglecting partial penetration effects for $(ar/b) \geq 1.5$ Furthermore, additional curves are provided by Radwan (2006).

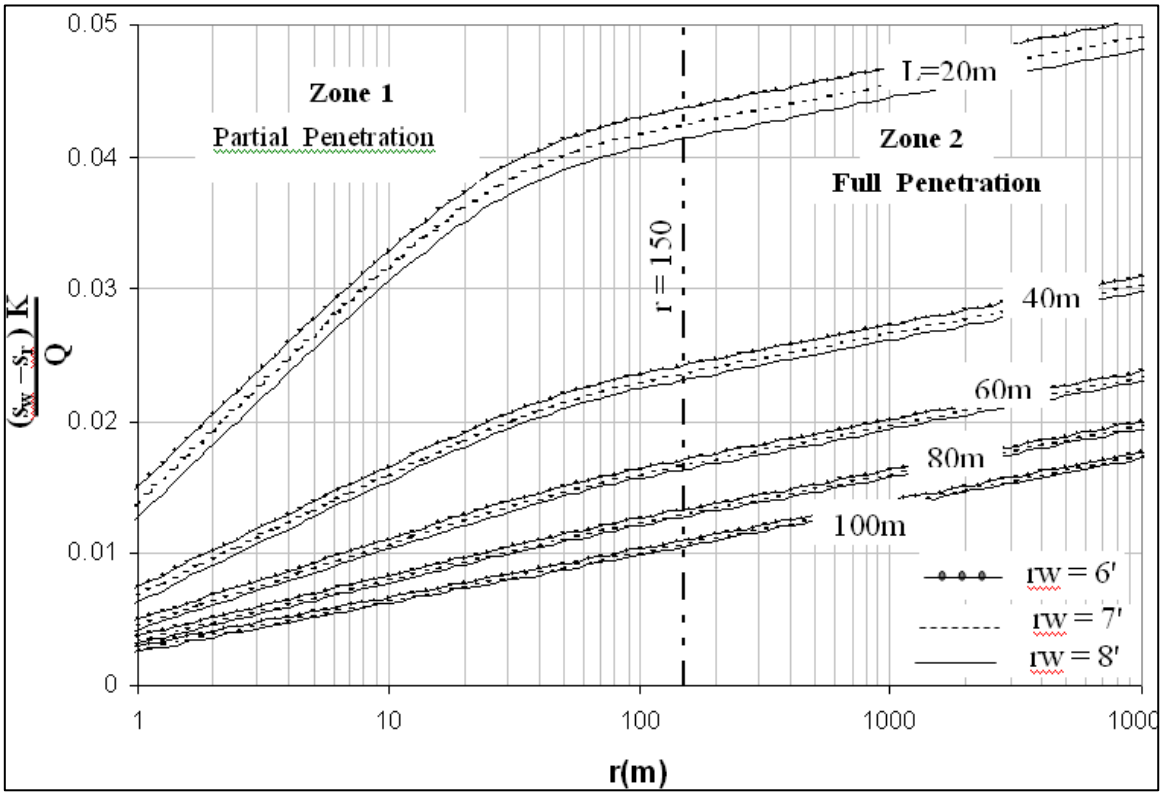

Figure (16): Relation between Drawdown at any Distance and Properties of Confined Aquifer for Partial Penetration, b=100 m (steady state)

4. Conclusion

In this work, the effect of partial penetration on three field problems for confined aquifers have been studied. First, the effective aquifer thickness is proved to be dependent on the pumping time. The commonly applied value of two and half times of the screen length, is only valid for pumping times less than 24 hours. Specific storage of three types of sand soils are calculated. Generally conditions are gradually enhanced with advance of pumping time for patial penetrating wells. Second, a chart, figure (14) is recommended for selection of optimum screen length to extract maximum well yield, taking into consideration the empirical equation of the aquifer capacity. Finally, influence zone charts are prepared for determining the radius of influence or the drawdown at any distance from a fully or partially penetrating well for steady state case, in confined aquifer.

Abstract

This paper presents a simplified approach for estimating the additional drawdown due to partially penetrating wells in confined and semi-confined aquifers. Hantush's Equation usually provides acceptable representation of the associated flow field, should this equation be properly solved. An interactive MATLAB-based computational program has been developed and verified to provide the analytical solution for the later equation. Results are projected as standard design curves which can be used to determine the total and additional drawdown due to partial penetration for semi-confined and confined aquifers, respectively. Empirical formulae, commonly used to calculate the additional drawdown in case of steady state flow for confined aquifers are also discussed, and compared with the analytical solution, showing significant differences in many cases. A proposed design chart for steady flow in confined aquifers, along with two families of curves; one for steady flow in leaky aquifers and the other for transient conditions, are thus recommended for well design purposes.

1. Introduction

Partially penetrating wells are first addressed by *Hantush* 1957. Figure (1) shows schematically a partially penetrating well in a semi-confined aquifer in which the screen interval is located at any place along the aquifer thickness (Batu, 1998). The differential equation representing this system is as follows:

$$\frac{\partial^2 s}{\partial r^2}+\frac{1}{r}\frac{\partial s}{\partial r}+a^2\frac{\partial^2 s}{\partial z^2}-\frac{K'}{Tb'}s=\frac{S}{T}\frac{\partial s}{\partial t} \qquad (1)$$

Where:

$$a^2=\frac{K_z}{K_r},\quad T=K_r b \qquad (2)$$

s : Drawdown at distance r (L).
r : Distance from the well (L).
b : Thickness of aquifer (L).
S : Storage Coefficient.
T : Transmissivity ($L^2 T^{-1}$).
b' : Thickness of confining layer (L).
K' : Hydraulic conductivity of confining layer (LT^{-1}).
K_r, K_z: Horizontal & vertical hydraulic conductivity of aquifer (LT^{-1}).

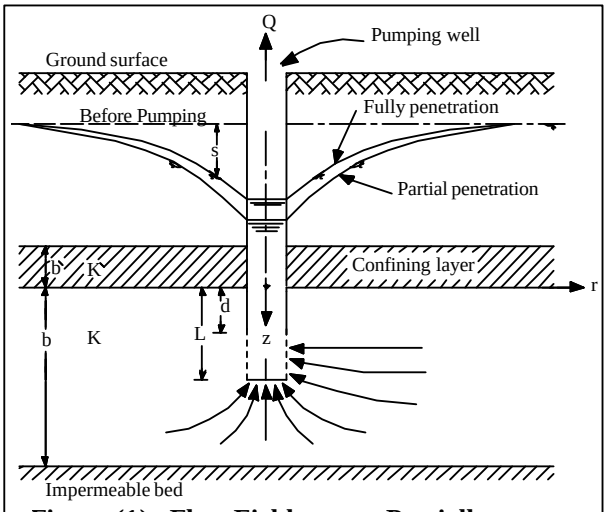

Figure (1): Flow Field near a Partially Penetrating Well in a Semi-Confined Aquifer.

1.1 Semi - Confined Aquifer. (Unsteady state).

Solution of Equation (1), for semi-confined aquifers is given by Hantush (1964), Batu (1998), and Reed (1980) as:

$$s = \frac{Q}{4p\,T}\left\{W\left(u,\frac{r}{B}\right) + f\left(u,\frac{ar}{b},\frac{r}{B},\frac{d}{b},\frac{L}{b},\frac{z}{b}\right)\right\} \quad (3)$$

Where:

$$f\left(u,\frac{ar}{b},\frac{r}{B},\frac{d}{b},\frac{L}{b},\frac{z}{b}\right) = \frac{2b}{p(L-d)}\sum_{n=1}^{\infty}\frac{1}{n}\left[\sin\left(\frac{np\,L}{b}\right)-\sin\left(\frac{np\,d}{b}\right)\right]\cos\left(\frac{np\,z}{b}\right)W(u,K_n) \quad (4)$$

$$K_n = \sqrt{\left(\left(\frac{r}{B}\right)^2+\left(\frac{npar}{b}\right)^2\right)},\quad B^2 = \frac{bb'K}{K'},\quad u = \frac{r^2S}{4T\,t}$$

$$W\left(u,\frac{r}{B}\right) = \int_u^{\infty}\frac{1}{y}\exp\left(-y-\frac{r^2}{4B^2y}\right)dy \qquad \text{Hantush well function.} \quad (5)$$

1.2 Confined Aquifer (Unsteady state).

The solution of Equation (1) for confined aquifer is given by Hantush (1961, 1964) by Letting K` equal zero, as follows (Hantush, 1961), (Batu, 1998):

$$s = \frac{Q}{4p\,T}\left\{W(u) + f\left(u,\frac{ar}{b},\frac{d}{b},\frac{L}{b},\frac{z}{b}\right)\right\} \quad (6)$$

Where:-

$$f\left(u,\frac{ar}{b},\frac{d}{b},\frac{L}{b},\frac{z}{b}\right) = \frac{2b}{p(L-d)}\sum_{n=1}^{\infty}\frac{1}{n}\left[\sin\left(\frac{np\,L}{b}\right)-\sin\left(\frac{np\,d}{b}\right)\right]\cos\left(\frac{np\,z}{b}\right)W(u,X_n) \quad (7)$$

$$X_n = \frac{np\,a\,r}{b},\quad W(u) = \int_u^{\infty}\frac{e^{-y}}{y}dy,\quad W(u)\text{: Theis well function.} \quad (8)$$

The first part in Equations (3, 6) represents the case of fully penetrating well, Hantush well function, and Theis well function, respectively, while the second part represents the effect of partially penetrating well.

2. Partial Penetration for Semi Confined Aquifers

The partial penetration term, containing integration and summation functions, is programmed using Matlab program, (Radwan 2007), and the results are shown in the following sections.

2.1 Steady State, Total Drawdown for Semi-Confined Aquifer due to Partial Penetration

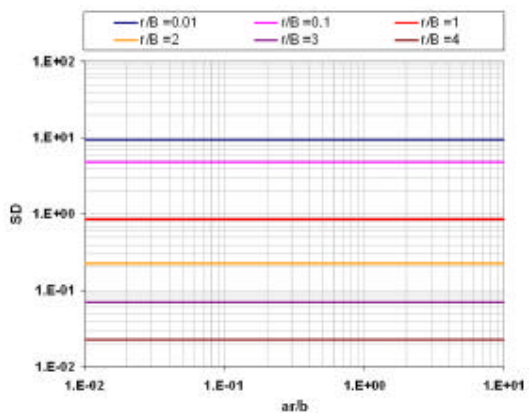
Steady state case will be reached by letting (u) approach zero in equation (3), then

$$W\left(u,\frac{r}{B}\right) = W\left(0,\frac{r}{B}\right) = 2K_o\left(\frac{r}{B}\right) \quad (9)$$

$$W(u,K_n) = W(0,K_n) = 2K_o(K_n) \quad (10)$$

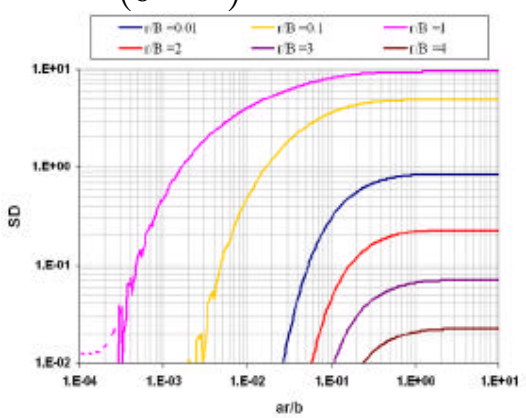
Equations (3, 4) for partial penetration, steady state, semi-confined aquifer become:

$$s = \frac{Q}{4pT}\left\{2K_o\left(\frac{r}{B}\right) + f\left(\frac{ar}{b}, \frac{r}{B}, \frac{L}{b}, \frac{d}{b}\right)\right\} = \frac{Q}{4pT}SD \qquad (11)$$



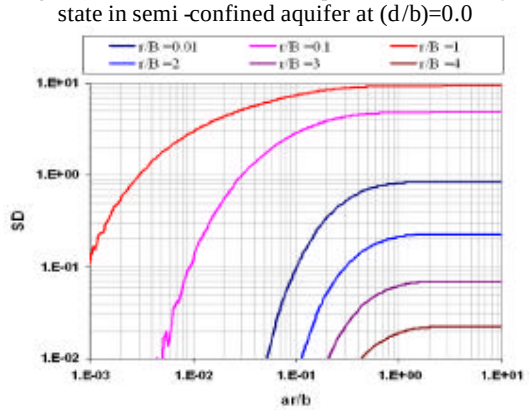
Where:

$$f\left(\frac{ar}{b}, \frac{r}{B}, \frac{L}{b}, \frac{d}{b}\right) = \frac{4b}{p\,(L-d)}\sum_{n=1}^{\infty}\frac{1}{n}\left[\sin\left(\frac{np\ L}{b}\right) - \sin\left(\frac{np\ d}{b}\right)\right]K_o\left(K_n\right) \qquad (12)$$

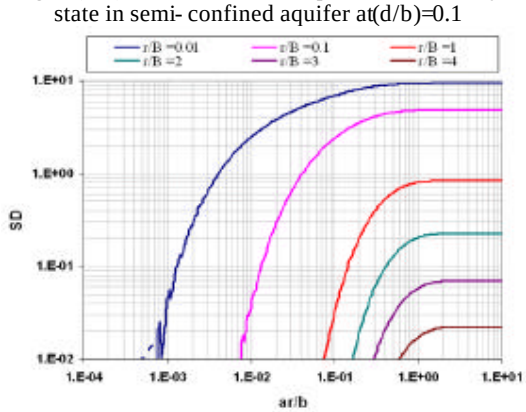


SD, the dimensionless drawdown in Equation (11), is a function of four dimensionless parameters (ar/b, r/B, L/b, d/b). General standard curves will be developed to calculate the total drawdown. First, all curves will be drawn at (L/b =1.0) (full penetration) for various ratios of (ar/b, r/B, d/b), then the effect of partially penetration will be included as a ratio of the fully penetrating well (F), for the same ratios of (d/b), where:

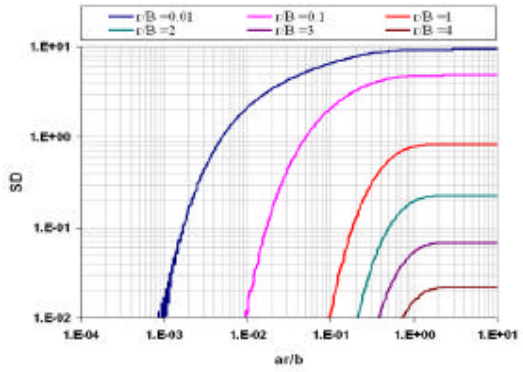
$$F = \frac{SD_{Partial-penetration}}{SD_{Full-penetration}} = \frac{s_{Partial-penetration}}{s_{Full-penetration}} \qquad (13)$$



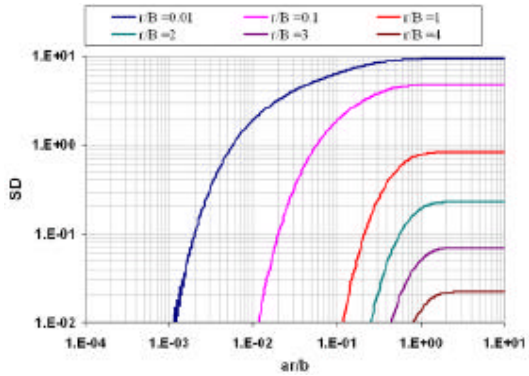
2.1.1 Standard Curves for Fully Penetrating Well $\left(\frac{L}{b} = 1.0\right)$



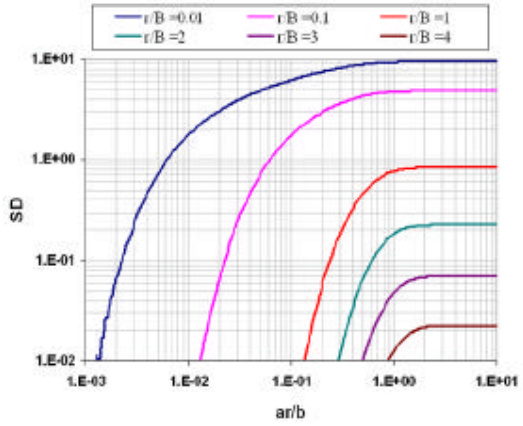
Figure(2-a): SD values for full penetration , steady state in semi -confined aquifer at (d/b)=0.0



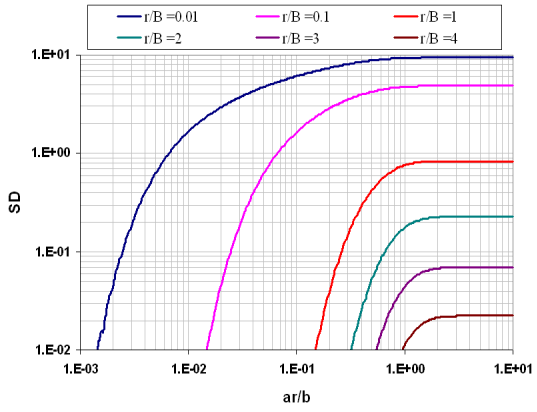
Figure(2-b): SD values for full penetration ,steady state in semi- confined aquifer at(d/b)=0.1



Figure(2-c): SD values for full penetration , steady state in semi -confined aquifer at (d/b)=0.2



Figure(2-d): SD values for full penetration ,steady state in semi-confined aquifer at(d/b)=0.3



Figure(2-e): SD values for full penetration , steady state in semi- confined aquifer at (d/b)=0.4

Figure(2-f): SD values for full penetration ,steady state in semi -confined aquifer at (d/b)=0.5

Figure(2-g): SD values for full penetration , steady state in semi- confined aquifer at (d/b)=0.6

Figure(2-h): SD values for full penetration , steady state in semi -confined aquifer at (d/b)=0.7

At full penetration, extending screen wells, the drawdown will depend on the distance from the well (r) through the ratio $[K_o(r/B)]$ ***not*** the ratio (ar/b), as shown by horizontal lines in figure (2.a). Moreover, the incremental effects of partial penetration on drawdown are restricted to a limiting value of (ar/b), marked by the horizontal part of the individual curves in figures (2.b – 2.h).

2.1.2 Standard Curves for Partially Penetrating Wells L/b [1] 1

Partial penetration effects on drawdown at any distance from the well (r) are illustrated by a family of curves, which are divided into groups as per specific screen ratios (d/b), penetration ratios (L/b), and using nominal ratios of (r/B) = 0.01, 0.1, 1.0, 2.0, 3.0, 4.0.

Figures (3.a to 4.f) reveal a factor F > 1, implying an additional drawdown in case of partial penetration as compared to full penetration case extracting the same discharge. The latter is due to an increase in the velocity of the flow, and accordingly head losses, following the reduction in flow area due to partial penetration. Furthermore, increase of screen length, significantly decreases the drawdown for the same solid part, (d/b) ratio. Moreover, the additional drawdown at any partial penetration ratio decreases as the hydraulic conductivity of confining layer increases (i.e. as r/B decreases).

(a) Group of (d/b) =0.0

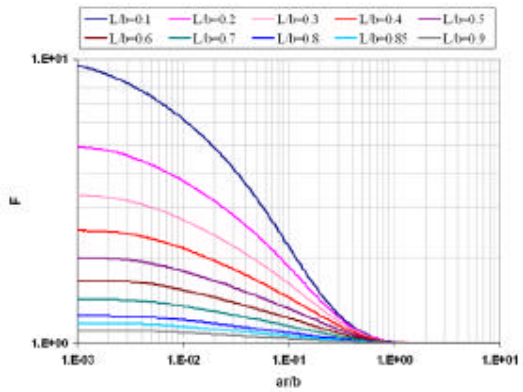


Figure (3-a): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =0.01, (d/b) =0.0

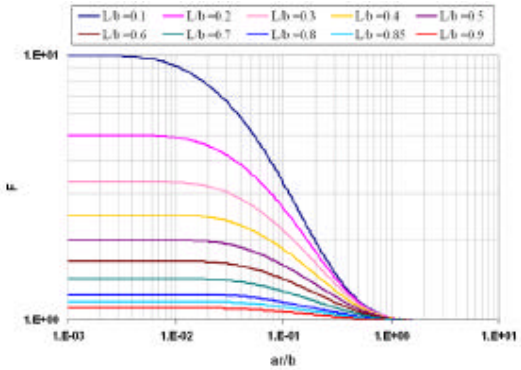

Figure (3-b): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =0. 1, (d/b) =0.0

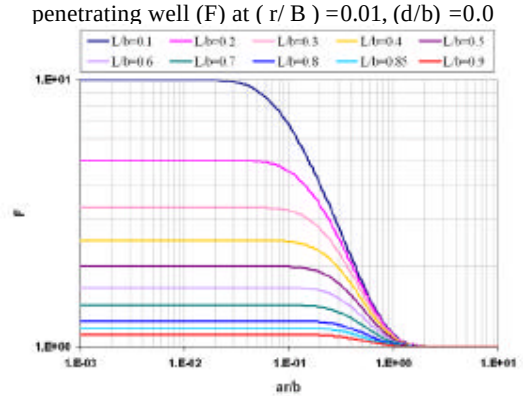

Figure (3-c): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =1.0, (d/b) =0.0

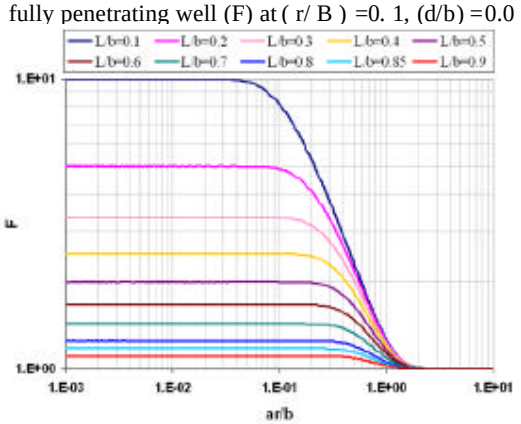

Figure (3-d): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =2.0, (d/b) =0.0

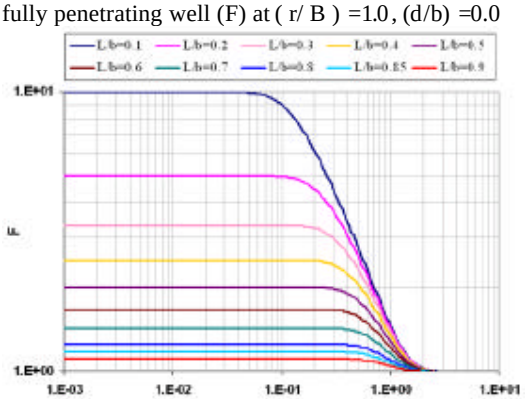

Figure (3-e): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =3.0, (d/b) =0.0

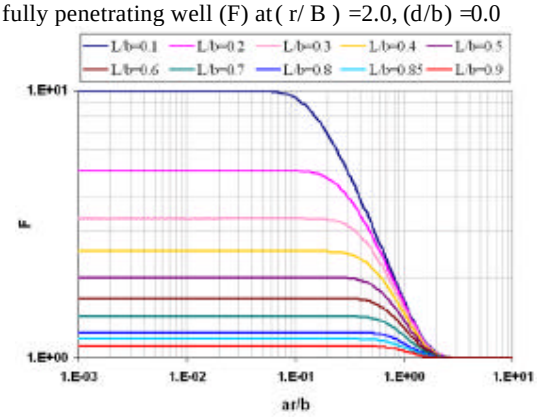

Figure (3-f): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =4.0, (d/b) =0.0

(b) Group of (d/b) =0.1 .

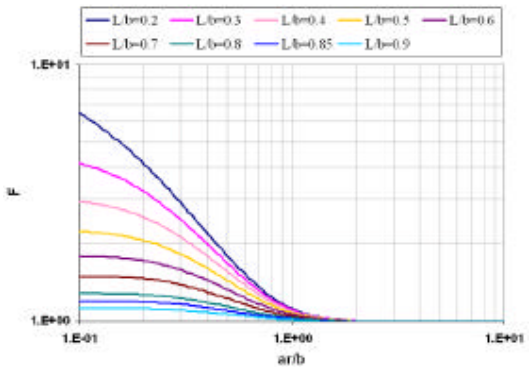

Figure (4-a): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =0.01, (d/b)= 0.1

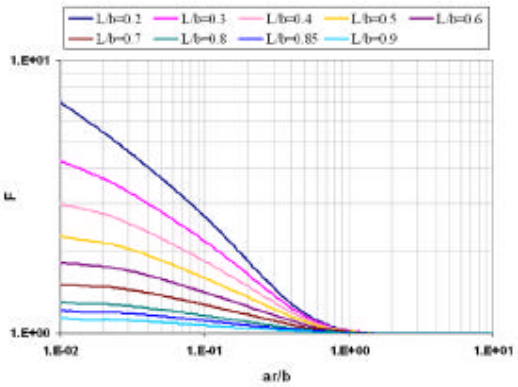

Figure (4-b): The ratio of drawdown of partially to fully penetrating well (F) at(r/ B) =0.1, (d/b) = 0.1

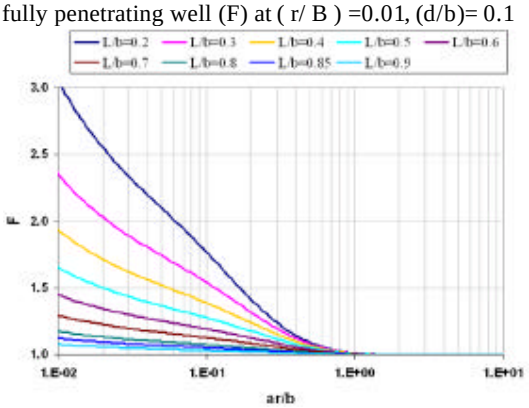

Figure (4-c): The ratio of drawdown of partially to fully penetrating well (F) at(r/ B) =1.0, (d/b) =0.1

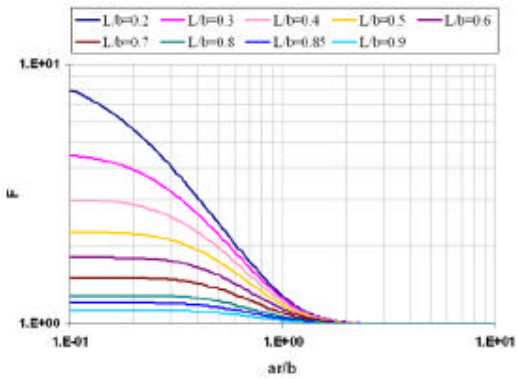

Figure (4-d): The ratio of drawdown of partially to fully penetrating well (F) at (r/ B) =2.0, (d/b) =0.1

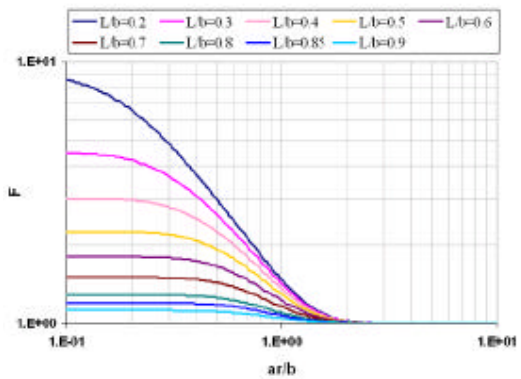

Figure (4-e): The ratio of drawdown of partially to fully penetrating well (F) at(r/ B) =3.0, (d/b) =0.1

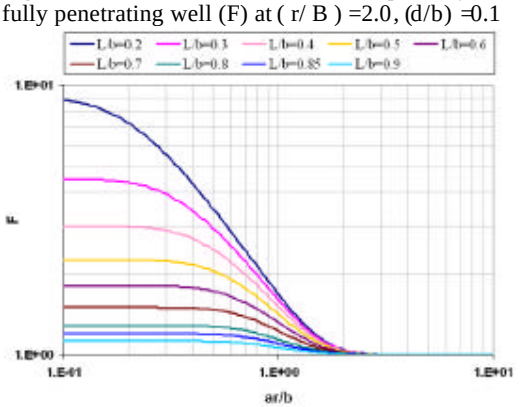

Figure (4-f): The ratio of drawdown of partially to fully penetrating well (F) at(r/ B) =4.0, (d/b) =0.1

The following procedures are recommended to estimate the effect of partial penetration:
Step(1): The well is fully penetrating; (i) compute the ratios (d/b), (ar/b), (r/B), (ii) get the dimensionless drawdown, SD, using figures (2.a to 2.h), for different ratios of (d/b), additional combinations are available at Radwan (2007), (iii) apply Equation (11), to get the drawdown due to full penetration (s_{full}).

Step(2): The well is partially penetrating; (iv) choose the required (d/b) group, then select the suitable ratio of (r/B), then get the factor (F) using figures (3.a to 4.f). (v) drawdown due to partial penetration ($s_{partial}$) finally becomes: ($s_{partial}$) = (s_{full}) * F

The effect of partial penetration may be neglected for two cases. First case follows the common practice, i.e. at the ratio (**ar/b > 1.5**) as illustrated in the former family of curves (where beyond this distance the flow field is similar to that of full penetration). Secondly, when partial penetration ratio is greater than or equal to 80% (l/b = 0.8).

3. Partial Penetration in Confined Aquifers

Several formulae are composed for predicting the additional drawdown due to partial penetration in confined aquifers. Their accuracy will be checked versus the analytical solution proposed in this work as design charts.

3.1 Steady State Flow; Visocky Formula.

Visocky (1970) solved the infinite series and an integral of exponential functions of Hantush's Equation (7), for a limited numbers of parameters and gave an expression for the additional drawdown as follows (Bouwer,1978), (Sternberg, 1973) :

$$s_{wp} = \frac{Q}{4pT}\left(\ln\frac{2.25Tt}{r^2S} + 2s_p\right) \qquad (14)$$

Where $\mathbf{s_{wp}}$ is the drawdown at the well. The first part in Equation (14) refers to Theis's Equation for fully penetrating well under the simplification of Cooper and Jacob (1946) for u < 0.01. The term ($\mathbf{2s_p}$) refers to the additional drawdown due to partial penetration. ($\mathbf{s_p}$) is given by Figure (5), prepared by Sternberg (1973), as dependant on the ratio of (L_e/b) where $\mathbf{L_e}$ is the screened length of the aquifer, but Hantush's Equation (6) depends on the ratios (d/b), and (L/b). The relation between L_e, (d/b), and (L/b) is that L_e=(L/b)-(d/b) as shown in Figure (6). By comparing Equation (14) and Hantush's Equation (6), the values of $2s_p$ should be equal the values of f{(L/b),(d/b),(ar/b)}.

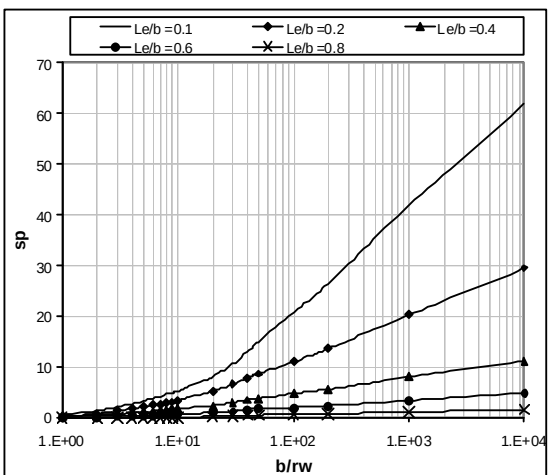

Figure (5): Graph of s_p versus b/r_w for Different Values of L_e/b

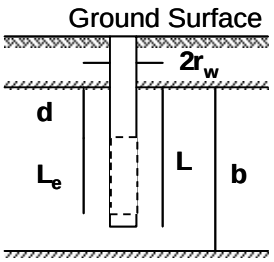

Figure (6): Partial Penetration Parameters

Figure (7) shows the values of f{(L/b),(d/b),(ar/b)} for (d/b)=0, for a homogeneous aquifer (a=1.0) which are prepared using the Matlab-based program. Figure (7) presents the results of an accurate analytical solution of Hantush equation and is recommended as a tool for estimating ***additional*** drawdown in confined,

homogeneous aquifers and fully extending well screen, (d/b)=0.0 which are features of common occurance.

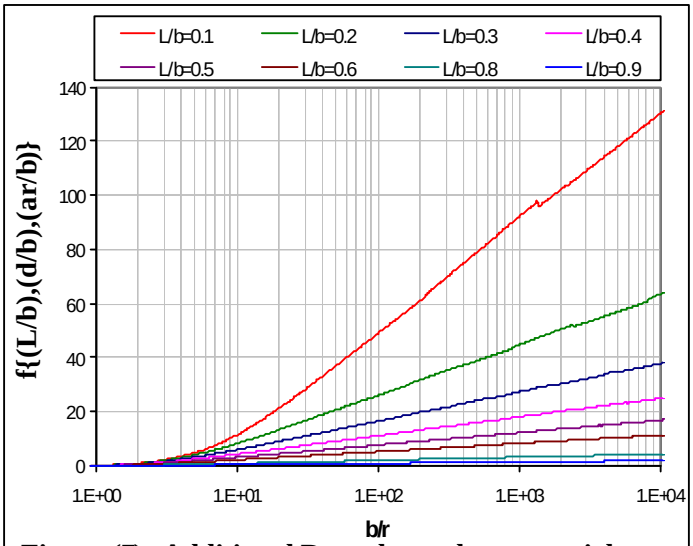

Figure (7): Additional Drawdown due to partial Penetration in Confined Aquifers at (d/b)=0, (a =1.0) for various ratios of (L/b)
Ds = f{(L/b),(d/b),(ar/b)}Q/(4pT)

The comparison between Sternberg curve and the analytical solution for Hantush equation is shown in Figure (8). This figure shows that Visocky formula, although following the same trends, yet is not accurate enough to predict the additional drawdown.

3.2 Netherlands Formula.

Netherlands generated a formula to predict the additional drawdown at the *well face* as follows (Huisman, 1972):

$$\Delta s = \frac{Q}{2\pi T}\frac{1-P}{P}\ln\frac{ah}{r_o} \qquad (15)$$

Where a is a function of the amount of penetration P= (h/b), and the amount of eccentricity (e) =(k/b) where k is the distance between the mid point of the screen and mid point of the aquifer as shown in Figure (9).

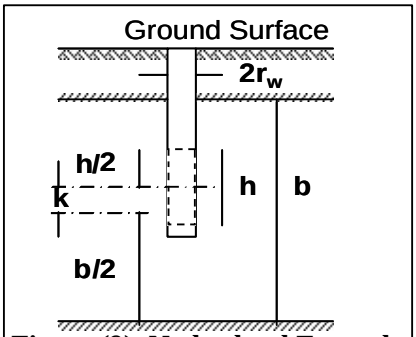

Figure (9): Netherland Formula Parameters

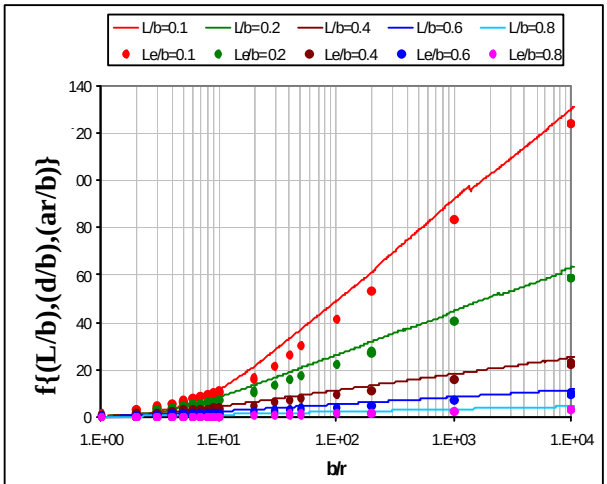

Figure (8): Comparison between Visocky's Equation (Points) and Analytical Solution (Lines) at (d/b)=0, (a=1.0)

The value of a as function of these parameters is given in **Table (1),** (Huisman, 1972).

Table (1): Values of *a* as function of e and P for Netherland Formula (Huisman, 1972).

	e = 0	0.05	0.1	0.15	0.20	0.25	0.30	0.35	0.40	0.45
p = 0.1	0.54	0.54	0.55	0.55	0.56	0.57	0.59	0.61	0.67	1.09
0.2	0.44	0.44	0.45	0.46	0.47	0.49	0.52	0.59	0.89	
0.3	0.37	0.37	0.38	0.39	0.41	0.43	0.50	0.74		
0.4	0.31	0.31	0.32	0.34	0.36	0.42	0.62			
0.5	0.25	0.26	0.27	0.29	0.34	0.51				
0.6	0.21	0.21	0.23	0.27	0.41					
0.7	0.16	0.17	0.20	0.32						
0.8	0.11	0.13	0.22							
0.9	0.06	0.12								

Netherlands Equation also deals with the ratio of screened aquifer or penetration ratio (P) =(h/b) similar to L_e in Visocky's formula, which depends on the position of the screen. The relation between P, (d/b), and (L/b) is that P=(L/b)-(d/b).

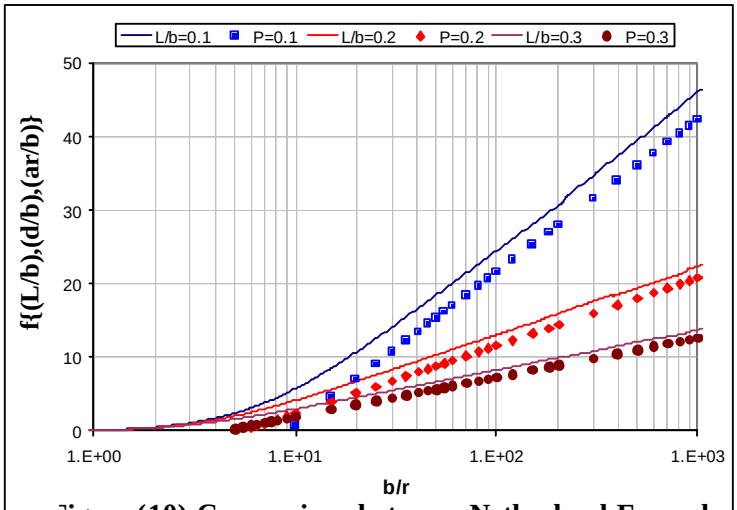

Figure (10): Comparison between Netherland Formula (Points) and Analytical Solution (Lines) at (d/b)=0, (a=1.0)

Comparison between the analytical solution of Hantush equation as proposed by Figure (7), and the half values from the former at (d/b)=0.0, and (a=1.0) is shown in Figure (10). Significant differences exist between the analytical solution and Netherlands formula. Equation (15) has a drawback of neglecting the values of Δs at (b/r) < 1.0, similar to Visocky's formula, whereas Figure (10) shows that, for every penetration ratio (P), Δs is neglected at a different ratio of (b/r).

4. Transient Flow Predictors

This section presents a group of curves for the second term of Equation (6) which concerned with the additional drawdown. Each curve has a certain ratio of (ar/b) beginning from ($1e^{-8}$) to (1.6) to determine the limit of partial penetration's effect. Only ratios of (ar/b) = $1e^{-8}$, 0.1, 1.0, 1.6 will be presented as examples. These curves are specific for the common case of (d/b) = 0.0, and homogenous aquifer (a = 1.0).

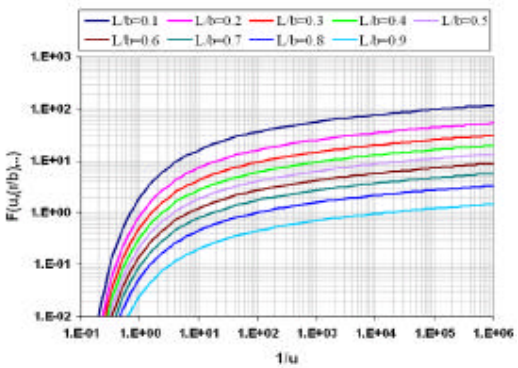

Figure (11-a): Values of f{u,(ar/b),(d/b),(L/b)} in Confined aquifer at {(d/b=0.0),(a=1.0)}, and (ar/b)=1e-8

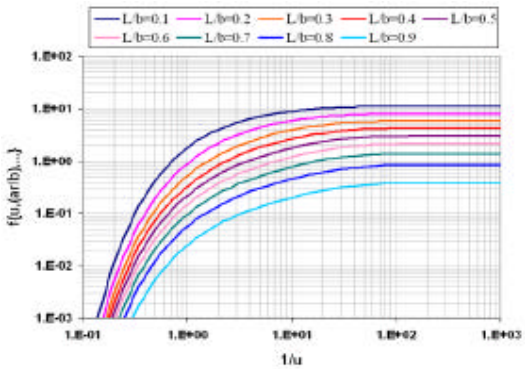

Figure (11-b): Values of f{u,(ar/b),(d/b),(L/b)} in Confined aquifer at {(d/b=0.0),(a=1.0)}, and (ar/b)=0.1

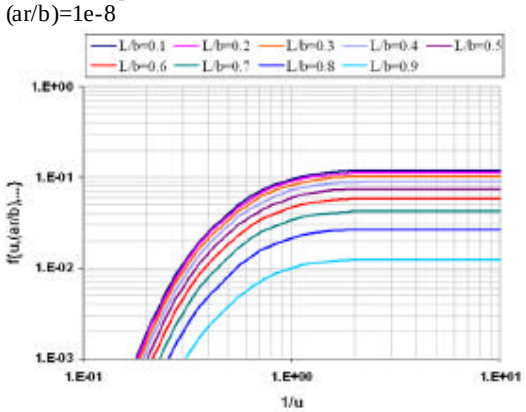

Figure (11-c): Values of f{u,(ar/b),(d/b),(L/b)} in Confined aquifer at {(d/b=0.0),(a=1.0)}, and (ar/b)=1.0

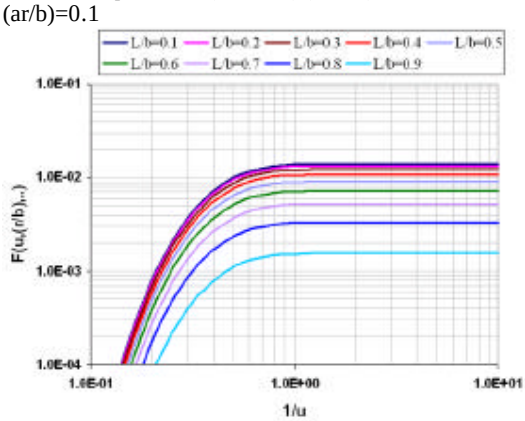

Figure (11-d): Values of f{u,(ar/b),(d/b),(L/b)} in Confined aquifer at {(d/b=0.0),(a=1.0)}, and (ar/b)=1.6

The previous figures are recommended for determining the additional drawdown term due to partial penetration at any distance from the well, and at any time. It is clear from the figures that, the term of additional drawdown may be neglected beyond the ratio of $(ar/b > 1.5)$ which confirms what has been mentioned earlier.

5. Conclusion

An interactive MATLAB-based computational program has been developed and verified to provide the analytical solution Hantush equation to quantify the effects of partial penetration for confined or semi-confined aquifers. A family of curves, figures (2.a to 4.f), have been prepared for semi-confined aquifers to predict the total drawdown due to partial penetration in case of steady state flow. Empirical formulae commonly used to calculate the additional drawdown due to partial penetration in case of steady state flow for confined aquifer are discussed and compared with the analytical solution Several errors, associated with empirical formulae are encountered. A design curve, figure (7), is thus recommended for design purposes. General curves (figs 11.a to 11.d) also are prepared based on Hantush's equation by using the analytical program, to

predict the additional drawdown due to partial penetration in case of unsteady state flow.

ABSTRACT

The hydrogeologic conceptual model is a key source of uncertainty in predictions of groundwater flow. The data used to develop the hydrogeologic conceptual model include geologic sample descriptions, interpretations of geophysical data, geochemical information et al. Frequently there is insufficient information to fully describe the hydrogeology without considerable interpretation from an expert. Existing methods for capturing this knowledge rely on the manual interpretation of hydrogeological structures. This procedure is time consuming, difficult to update and also makes it difficult to maintain alternative interpretations of the hydrogeology.

We show how hydrogeological models can be created from the 3 and 4-dimensional data sets using Radial Basis Function (RBF) models. We develop RBF models for the components in a hydrogeological model: aquifers, aquitards, boundaries, drains, and rivers. This approach has significant advantages. Firstly, the models are consistent with the known data and can be automatically updated when new data comes to hand. Secondly, the models can be influenced by both the choice of high level parameters such as anisotropy while maintaining consistency with the data. Thirdly, the user can add manual interpretations (trends or a priori information) that are maintained separately from measurements, but are then merged in the model building process to produce a model consistent with both measured and interpreted data. Once created, the model can be isosurfaced or gridded at any resolution or fitted to any mesh, a process that provides a flexible interface to flow simulators.

The methodology will be demonstrated on data from New Zealand and Denmark.

INTRODUCTION

There is an increased focus on the development of groundwater models and addressing the uncertainty that is inherent when a system is underdetermined to the degree seen in groundwater systems. A number of works show that the uncertainty associated with developing the geological model, or hydrogeological conceptual model, is a fundamental source of uncertainty in the predictions from groundwater models (Poeter 2007; Stauffer 2005). Since, uncertainty is guaranteed in a groundwater model, it is imperative to develop groundwater models in a manner that clearly exposes the uncertainty by using methods that allow this uncertainty to be explored. This, in part, can be done by applying parameter estimation (optimization)

methods such as advocated by Moore and Doherty (2006). However, those methods are not well suited to geological interpretations.

The data used to develop the hydrogeologic conceptual model includes geologic sample descriptions, interpretations of geophysical data; geochemical information et al. Existing methods for capturing knowledge from these data sets rely on manual interpretation of hydrogeological structures. This procedure is time consuming, difficult to update and reproduce as well as make it difficult to maintain alternative interpretations of the hydrogeology. Our method provides both intuitive tools to aide in capturing knowledge from data as well as separating the interpretation from data.

Radial Basis Functions's (RBF's) have been previously applied in groundwater modeling (Li et al. 2003; Shafieifar et al. 2007). We apply RBF's to develop hydrogeological models from 3 and 4-dimensional data sets processed using our knowledge capture methods. The RBF's are used to model the components of the hydrogeological system: aquifers, aquitards, boundaries, drains, and rivers based on data.

This approach has significant advantages. Firstly, the models are consistent with the known data and can be automatically updated when new data comes to hand. Secondly, the models can be influenced by both the choice of high level parameters such as anisotropy while maintaining consistency with the data. Thirdly, the user can add manual interpretations (trends or a priori information) that are maintained separately from measurements, but are then merged in the model building process to produce a model consistent with both measured and interpreted data. Once created, the model can be iso-surfaced or gridded at any resolution or fitted to any mesh, a process that provides a flexible interface to flow simulators.

The methodology will be demonstrated on data sets from New Zealand and Denmark.

METHOD

The general approach of the method is presented, then Radial Basis Functions which underpin the method are described, and finally the implementation of the method is presented.

The foundation of the method is the concept of a grid free conceptual model. This is based on a set of fundamental ideas:

- Intuitive knowledge capture from data,
- Data driven equations (RBF's) to describe individual elements of the hydrogeologic system, and
- The ability to carry out logical operations on the elements of the hydrogeologic system as well as a priori knowledge about the system.

Method overview

The general application of the method is shown in the Figure 1. The key elements of the method are the development of representations (equations) for data, (e.g. geology, topography, etc.) and a priori knowledge (e.g. structural trends). This concept can be extended to all input for model development. Special logical operators exist for geological conditions, such as erosion surfaces, so that the inter-relation of formations can be explicitly defined. Finally, state information can be added to the model in order to complete the description needed to carry out a flow simulation. This paper focuses on the stages up to and including models for formations.

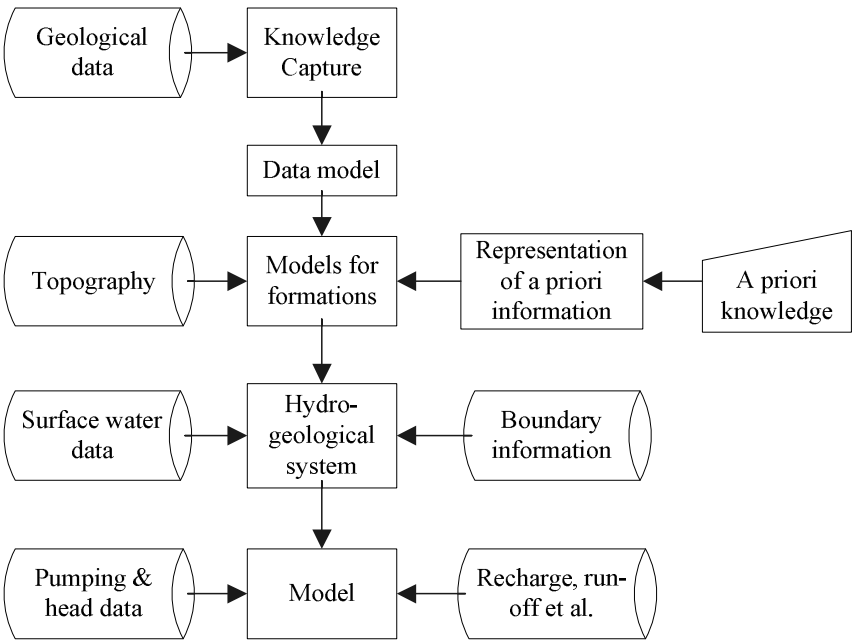

Figure 1. Flow chart for developing a groundwater model using the proposed method.

To walk through the development process:

1. A data set, say lithological well logs, is selected,
2. Grouping of formations according to hydrogeologic behavior leads to contact points that describe the contact between hydrogeologic units.
3. RBF's are fitted to these sets of points, and can be visualized.
4. A priori knowledge, or other data (e.g. dip and strike) are combined with the appropriate RBF's; which results in a description of contact surfaces
5. Formation contacts are arranged in chronological order and the relation to over- and under lying formations is provided (e.g. non-conformal relations).
6. Boundaries are added to the system description, and
7. A solid geometrical model, as RBF's, is produced for the hydrogeological system.

Surface water system features (e.g. rivers, drains, etc.) can be processed in a similar manner. As the topography is represented by an equation, elements are controlled to ensure they lie on the surface, flow down-hill and other error checking. Exterior boundary conditions are processed in a similar manner. State data is also maintained in the system, and is processed to produce input to the groundwater model.

There is in principle no limit to how information can be combined to form a hydrogeologic element, for example formations can be described by a combination of well log information, geophysical data and (hydro-) geochemical information.

Radial Basis Functions

The equations used to represent hydrogeological system elements are developed by fitting RBF's to the data set. RBF's are well established set of methods used in scattered data interpolation, signal processing and artificial intelligence methods. RBFs are real valued functions defined as:

$$y(x) = \sum_{i=1}^{N} w_i \, \phi(\|\boldsymbol{x} - \boldsymbol{c}_i\|),$$

Where, c is the ith center, $\boldsymbol{x}$ is locations in space (or space-time), w is a weight and function ϕ can be any one of a number of functions but typically is either, gaussian, quadratic, or a type of spline function. We apply a polyharmonic (thin-plate) splines function for ϕ. The key factor in the application of a RBF is the determining the weights w_i associated with centers $\boldsymbol{c}_i$, which is a straight forward optimization problem.

Implementation

The methodology is implemented into a unique computer aided modeling environment. The environment has a complete suite of tools for all of the tasks delineated in Figure 1. A prime goal in the implementation of the method is to develop an intuitive user interface. Furthermore, advanced graphics are included in the interface in order that the significance of choices on the resulting hydrogeological model.

CASE STUDIES

Two case studies are presented: a layered aquifer system from New Zealand and a till-outwash complex that overlies a chalk aquifer from Denmark. The focus of these two case studies is to demonstrate the transparency of developing the hydrogeologic frame work in the proposed manner as well as the ability to quickly develop and compare alternative conceptual models for the hydrogeology.

New Zealand Aquifer System

The aquifer system was deposited as a series of alluvial deposits from an area that is being uplifted due the pacific plate being subducted under the Tasman plate, interbedding these alluvial deposits are near shore marine and estuary fine grained sediments. In other words a classic progressive-regressive sedimentary sequence bordered to the South by a volcanic massif.

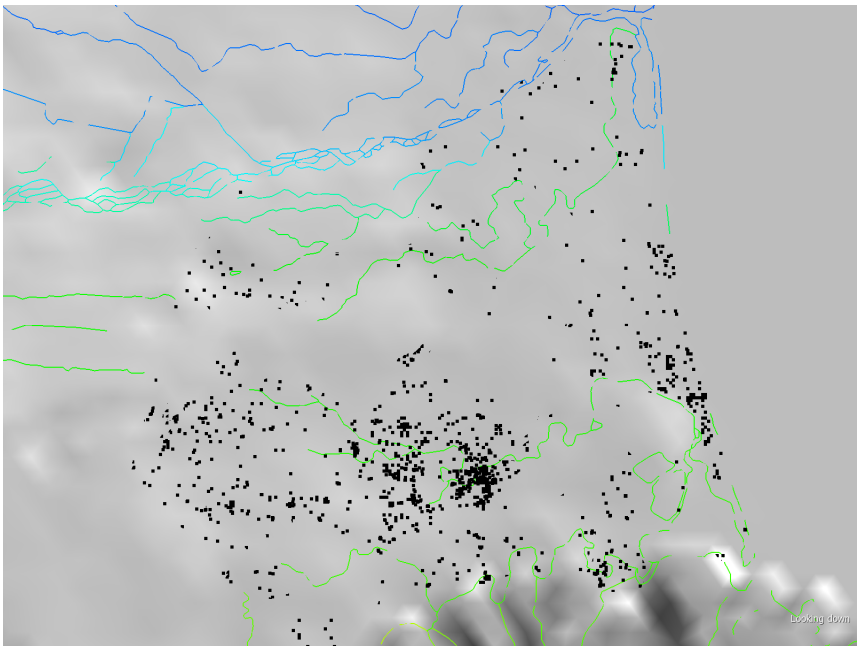

Figure 2. Distribution of wells for the New Zealand case study.

Data. The data for the development of the hydrogeologic framework are 2271 well logs of varying depth. In addition to the well logs there is a digital elevation model, GIS themes for surface water bodies, and time series data for groundwater recovery and water levels. The distribution of wells is shown in Figure 2.

Table 1. Hydrogeology for the New Zealand aquifer system.

Formation	Type	Chronology
Springston	Aquifer	Youngest
Christchurch	Aquitard	
Riccarton	Aquifer	
Bromeley	Aquitard	
Littleton	Aquifer	
Heathcote	Aquitard	
Burwood	Aquifer	
Shirley	Aquitard	
Wainono	Aquifer	
Aquifer 5	Aquifer	Oldest

There are 8 formations that need to be represented in the hydrogeological model (Table 1). A problem lies in how the interpretation of the well logs has been recorded; for example the Littleton fm. is normally denoted “LI”, but in the record one can find not only LI, but LI?, LI-1, LI-2, etc. This problem extends to the other formations as well. The knowledge capture approach we develop aides the hydrogeologist by first presenting all these variations as a group, but then providing tools that allows them to “drag and drop” into a re-classification of the data (Figure 3). Then contact points for the extremes of the group can be extracted (Figure 4).

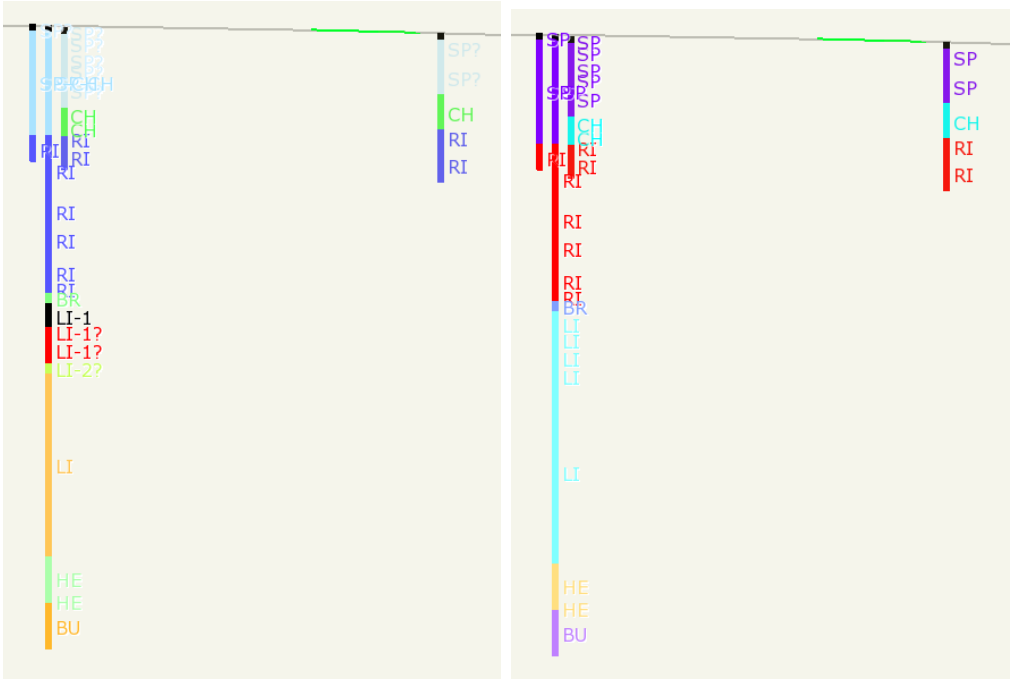

Figure 3. Well logs before (left) and after (right) applying knowledge capture tools. Note the simpler geology in the deep well on the right hand figure.

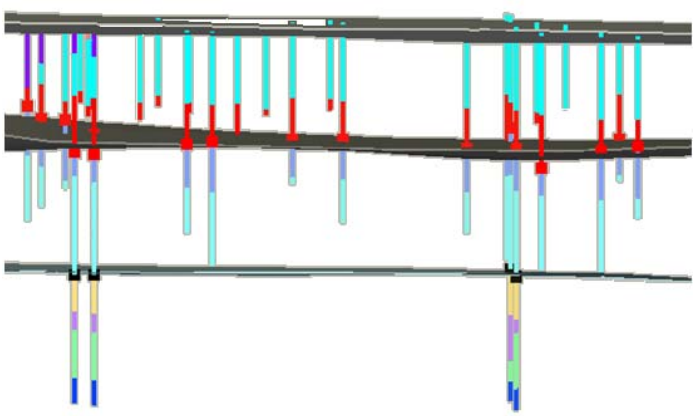

Figure 4. Well logs in 3D after processing, contact selection and 2 fitted surfaces.

Surfaces are modeled by RBF's through the contact points (Figure 4). A series of contacts surfaces are modeled that describe the hydrogeological sequence (Table 1); and used to define the hydrogeologic formations as solid volumes (Figure 5).

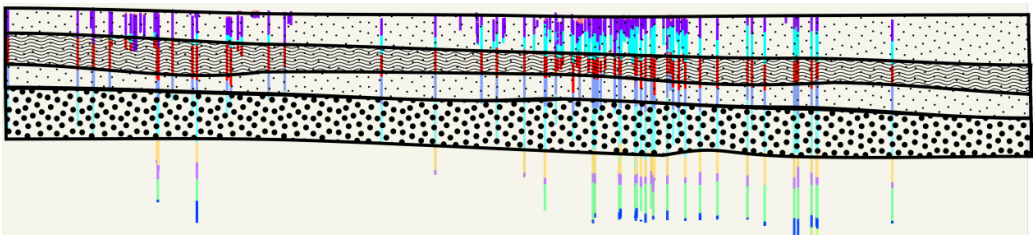

Figure 5. Cross-section of the hydrogeology developed by the complete process.

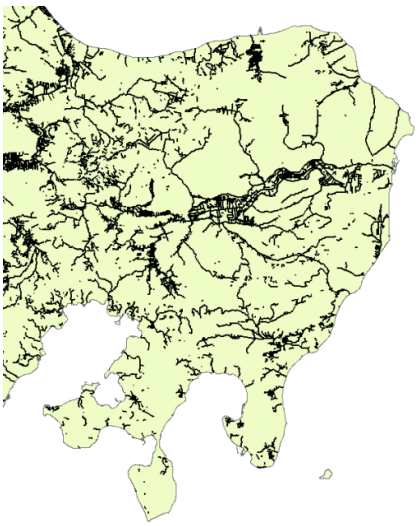

Figure 6. Map of Djursland, note this is a peninsula, the land area show is roughly 40 km wide.

Djursland Aquifer System

In Djursland, Denmark (Figure 6) there was deposited a series of glacial and postglacial sediments on top of an erosion surface which consists of chalk. The glacial sediments have been partially reworked by subsequent glaciations and Quaternary sedimentation. The result is a far more complex geological setting than what is seen in the previous example. Here we have non-layered geology (till complex) resting on an erosion surface (Table 2). The main hydrogeologic issue in the region is quality degradation due to nitrates.

Table 2. Hydrogeology for the Djursland aquifer system.

Formation	Environment	Type	Chronology
Postglacial sediments	various	mainly aquitards	youngest
Till	Glacial	Aquitard	same
Sands and gravels	Glacial	Aquifer	age
Erosion surface			
Chalk	Marine	Aquifer	Oldest

Data. The data for the development of the hydrogeologic framework are 3851 well logs of varying depth. In addition to the well logs there is a digital elevation model and groundwater chemistry data. It is very time consuming if one is to group formations by hand for 3851 well logs, though one can learn by inspecting cross-sections and from experience, which formations are hydrogeologically similar. Our knowledge extraction process quickly resolves the hydrogeological formations at the site.

The hydrogeologic problem is to define sand and gravel aquifers and specifically identify where there is good groundwater protection, i.e. thick tills overlying sand and chalk. The upper 10 – 30 meters of the chalk is a fractured aquifer, regardless of the type of chalk. The geology is simplified into hydrogeological formations in the following manner: tills and silts and other fine grain sediments form one hydrogeologic formation; while sands and gravel form a second formation; finally chalk formations are placed into a 3rd formation. The surface between chalk and the other formations is defined as an erosion surface

.

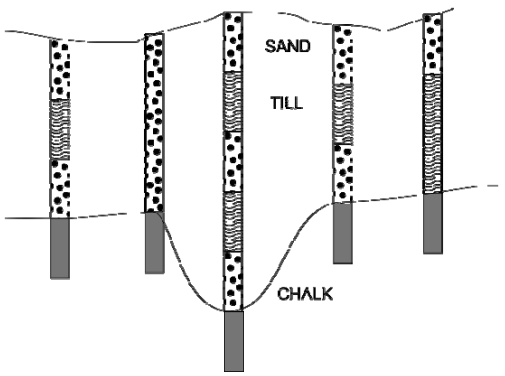

Figure 7. Conceptual problem in the Djurs hydrogeology.

Figure 7 shows the conceptual problem that is solved in the Djursland hydrogeology; that is we have a non-layered system overlying a layered system. The proposed method is ideal to addressing this type of problem because the RBF based model is not constrained to a layered system.

Another problem that needed to be addressed here is that as Djursland is a peninsula, there are no wells to the north and south. This causes a problem with the chalk surface as most interpolation routines will result in the chalk being exposed in the fjords north and south of Djursland. However, the addition of dip points just off shore for the erosion surface "forces" the chalk surface deeper, as we know is the case from wells north of the fjord.

Figure 8 shows the result of the modeling exercise for Djursland where we see a very heterogeneous system overlying the chalk surface.

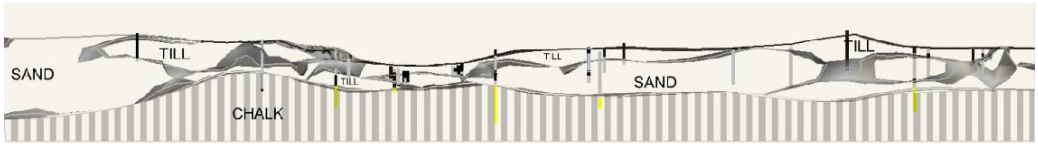

Figure 8. Cross/section modeled using the proposed RBF approach.

CONCLUSIONS

We have presented a methodology that can be applied to develop hydrogeological models in complex hydrogeological systems. We believe the method shows advantages in extracting knowledge from the data and developing grid free hydrogeological models. The method also shows advantages in clearly indicating knowledge that comes from data versus expert opinion/a priori knowledge.

A significant part of the advantage with the method is how it is employed in the implementation and is experienced carrying out the work flow in developing a hydrogeological model as well as in the collaboration between the geologist and hydrogeologist. This is difficult to demonstrate in a technical article.

The method was illustrated for 2 examples: one from New Zealand and another from Denmark. The Danish example shows advantages in modeling non-layered aquifer systems.

Abstract

Mixing is notoriously difficult in groundwater aquifers, because the Reynolds number is very small. This can limit site remediation, and inducing mixing within the groundwater aquifer could speed the chemical processes or otherwise reduce the amount of time needed to meet site remediation goals. A recent analytical model suggests that mixing in groundwater aquifers may be achieved through pulsed dipole injection and extraction from groundwater wells. Building on past work, this study uses MODFLOW, a finite-difference groundwater flow model code developed by the U.S. Geological Survey, to simulate the flow of groundwater and the movement of particles within a two-dimensional confined aquifer. The analysis shows the effects of pulsing the wells, modifying the frequency of pulsing, and changing the lag time between pulses. Mixing within the groundwater aquifer is shown graphically through the pathlines of the particles and quantified using Lyapunov exponents to determine if the flow is chaotic based on the positions and paths of particles within the aquifer. The model indicates that the pulsed dipole injection/extraction leads to increased mixing within the aquifer.

Introduction

Accelerated mixing in contaminated groundwater aquifers could reduce the required remediation time. Some groundwater remediation methods rely on the injection of chemicals, microbes, or carbon sources into the aquifer to enhance or encourage degradation. This process typically involves injection at one or more wells and the extraction of groundwater at downstream wells. For this type of in-situ remediation to be successful, it is important that the substances introduced into the aquifer spread throughout the region of concern. Unfortunately, the injected substance is likely to travel in the more conductive paths of the aquifer, leading to non-uniform mixing of the injected substance throughout the zone of intended remediation.

Several reports have demonstrated the potential for mixing in laminar flows, which are categorized under the heading of "chaotic advection" (Aref 2002). In this process, mixing occurs when the separation distance between fluid particles increases exponentially with time, which is the signature of chaotic flow. Jones and Aref (1988) analyzed mixing during pulsed injection/extraction in dipole flow, and Stremler et al. (2004) reported that pulsed injection/extraction improved mixing in microarray analysis used in biology research. Two recent studies have explored applications of chaotic advection to aquifers during injection and extraction. Sposito (2006) modeled sequential injection and extraction from a pair of wells. Bagtzoglou and Oates (2007) modeled mixing in groundwater by a system of three wells with random flow assignments. Both Sposito (2006) and Bagtzoglou and Oates (2007) focused on pulsed injection and extraction in two-dimensional, confined, homogeneous aquifers and reinjected the extracted groundwater back into the aquifer thereby forming a closed system. Sposito (2006) assumed steady-state flow during each stress period, and used a first-out-first-in particle reinjection scheme. Bagtzoglou and Oates (2007) did not specify whether their simulation was steady-state or transient during each stress period, and did not specify their reinjection scheme, but they did account for dispersion with a random walk model and for turbulent mixing in the wells. This research indicated that chaotic flow occurs, based on exponential growth of particle separation distance with time.

The present study places Sposito's (2006) conceptual model in the framework of a numerical groundwater model in order to address the following questions: (1) Can mixing be achieved just by pulsed flow, regardless of the reinjection scheme? (2) Will the predicted mixing change significantly after considering an inter-cycle recovery period in which no pumping occurs? (3) How will heterogeneity in the hydraulic conductivity affect the predicted mixing?

This paper reports on the first of these questions. Specifically, we investigate the degree of mixing resulting from pulsed dipole injection/extraction during a single pass from the injection well to the extraction well.

Methods

MODFLOW, a numerical finite difference code developed by the U.S. Geological Survey (Harbaugh et al. 2000), was used to model the flow associated with injection and extraction from a single-layer confined aquifer. In this study, MODFLOW was implemented within PMWIN (Chiang 2005). The model is a single layer, 1500 meter by 1500 meter square divided into 10,000 evenly spaced grid blocks that are 15 meters wide and 15 meters tall. Figure 1 shows a model schematic. The 10-meter thick fully-saturated confined aquifer had an initial hydraulic head of 200 meters throughout the entire model domain. The model includes one fully penetrating injection well and one fully penetrating extraction well located 345 m apart. In these preliminary tests, the model was run as a series of transient simulations corresponding to alternating injection and extraction cycles, with pumping time T = 1 d, and recovery time R = 0 d (Figure 2). The injection and extraction rates are 1.5 m^3/s. The

model was run for six stress periods in all simulations. In order to focus on mixing processes within the pulsed aquifer flow, rather than the recirculation piping, reinjection was not modeled.

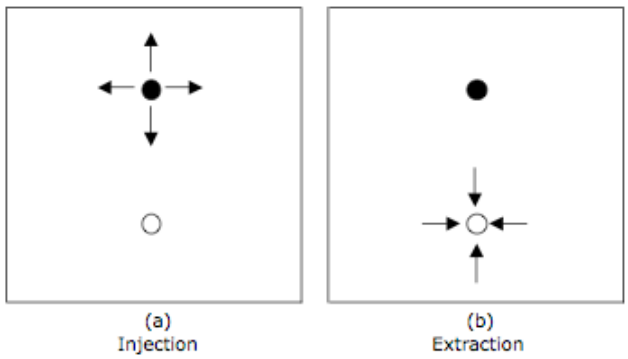

Figure 1. Schematic of pulsed dipole injection/extraction wells. Filled circles denote injection wells; open circles denote extraction wells; and arrows denote flow directions.

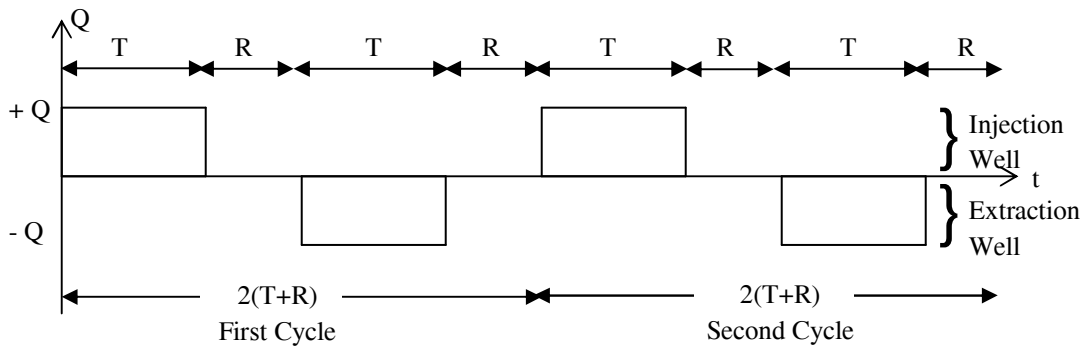

Figure 2. Plot of injection rate vs. time for two injection/extraction cycles. Each cycle comprises an injection period of length T, followed by a recovery period of length R, followed by an extraction period of length T, and a recovery period of length R for a total cycle duration of 2(T + R). Q is the injection rate and –Q is the extraction rate.

Preliminary Results

Particles within the modeled aquifer were then tracked using MODPATH (Pollock 1994), again implemented with PMWIN. Seventy-two particles, located five degrees apart, were started in a circle within the injection well grid block at t = 0. Figure 3 presents the particle locations and their pathlines through time. The pathlines of the particles do not cross.

However, a second simulation considered an additional 72 particles injected at t = T/2. In this case, pathlines did cross (Figure 4).

Initial results indicate that the pathlines of particles injected simultaneously do not cross during the injection and extraction pumping simulation, but when additional

particles are injected midway through the injection periods, the pathlines of the particles do cross. The crossing pathlines indicate that pulsed dipole injection/extraction produces mixing within the aquifer.

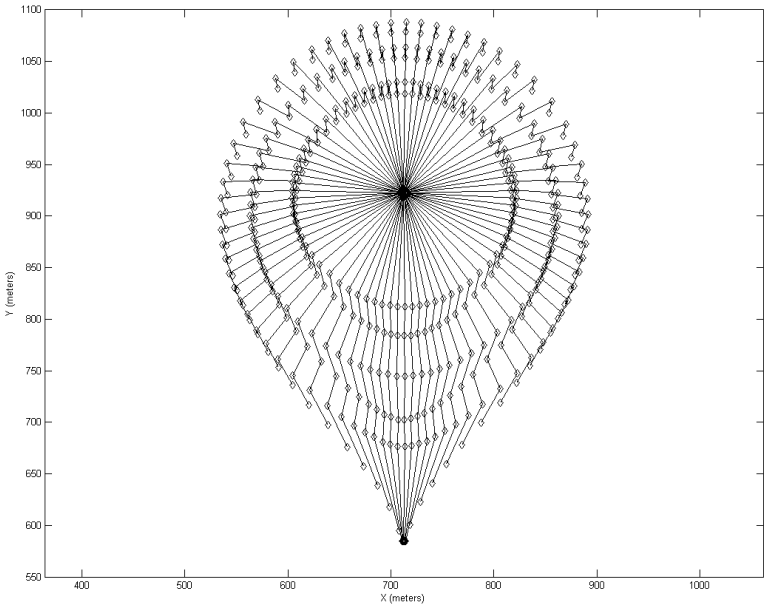

Figure 3. Pathlines for 72 particles injected at t = 0. Recovery time, R, is 0. Particles are shown by open diamonds initially and at the end of each injection or extraction period.

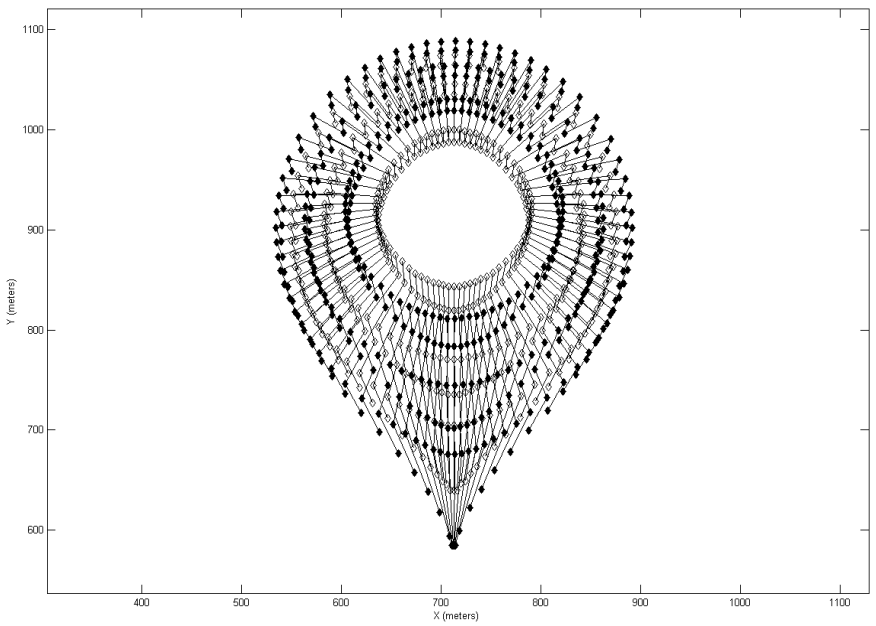

Figure 4. Pathlines for 72 particles injected at t = 0 (closed diamonds), as in Figure 3, with an additional 72 particles injected at t = T/2 (open diamonds). Recovery time, R, is 0. For clarity, the initial positions of the particles have been omitted.

ABSTRACT

Stochastic optimization has been frequently applied to groundwater management problems that involve uncertainties associated with hydrogeologic parameters. In this approach, a series of realizations are used to identify the optimal solution. However, this approach can be computationally intensive, especially for field-scale problems. To alleviate the computational burden associated with these types of stochastic optimization problems, a quantitative procedure identified as Pareto Dominance based Critical Realization Identification (PDCRI) method is developed to screen out the realizations that are most critical to the optimization results prior to the initiation of the optimization calculations. The criticalness of a hydrogeologic parameter realization on the solution is described by its Criticalness Index (CI) value, which is calculated based on a Pareto Dominance analysis. The PDCRI was applied to a hypothetical example to demonstrate its performance. The results show that the PDCRI approach can significantly improve computational efficiency without loss of reliability in optimal solutions and can also be used in other stochastic optimization problems such as optimal remediation system design or groundwater quality monitoring system design under parameter uncertainties.

1. INTRODUCTION

Uncertainties associated with the hydrogeologic input data of groundwater flow and contaminant fate-and-transport models may produce significant uncertainties in the simulation results which involve contaminant concentration and arrival time on the concentration at a point (the time for contaminant concentration to reach a certain level at the exposure point). This can seriously impact the reliability of the related epidemiologic studies. A reliable epidemiologic study sometimes may require the evaluation of extreme contaminant arrival times at an exposure point under multi-

parameter uncertainties. A possible solution to this problem is stochastic optimization.

Stochastic optimization has become a very important research area in recent years. In comparison with a deterministic optimization, a stochastic optimization considers some or all of the system input parameters as stochastic or uncertain variables [*Bakr et al.*, 2003]. The statistical method is a major approach for the solution of stochastic optimization problems. It generates a set of equally probable realizations according to the probabilistic distribution of uncertain parameters using statistical techniques to represent the effect of uncertainties. Its basic idea is that the more realizations a solution complies with, the more robust the outcome will be. This approach has been widely applied to groundwater quality management problems with uncertainties [*Aly and Peralta*, 1999; *Bau and Mayer*, 2006; *Chan*, 1994; *Hilton and Culver*, 2005; *Mantoglou and Kourakos*, 2007; *Mylopoulos et al.*, 1999; *Smalley et al.*, 2000; *Wagner and Gorelick*, 1989; *Wagner et al.*, 1992].

Usually, the reliability of the stochastic optimization results improves as the number of realizations used in the optimization process increases due to better representation of parameter uncertainties with increased number of realizations. However, this reliability improvement is associated with significant increase in computational cost, especially for field-scale problems. The previous studies on the subject have shown that although each realization is equally probable during a stochastic optimization, the effects they have on the final optimization results can be quite different – only a few realizations are really critical to the final results, which are thereby called "critical realizations" [*Mantoglou and Kourakos*, 2007; *Ranjithan et al.*, 1993]. Apparently, the application of only a few critical realizations in the optimization process instead of the whole set of realizations can dramatically improve the computational efficiency while maintaining a desired reliability level.

In *Ranjithan et al.* [1993], the critical realizations were used to improve the computational efficiency for optimal remediation design where uncertainty associated with the hydraulic conductivity parameter was considered. The level of criticalness of each realization, which was determined by the spatial distribution and the degree of variation of the hydraulic conductivity values, was identified using the pattern classification capability of neural networks. While the authors have demonstrated the reliability and efficiency of the optimal remediation design using critical realizations, this work only considered the uncertainty associated with the hydraulic conductivities. The pattern classification technique restricts the application of this method to problems with uncertain parameters showing no clear patterns, such as pumping schedule, or problems with multiple uncertain parameters. Furthermore, training of neural networks may be quite computationally intensive, and may potentially lower the efficiency of this method.

In the optimal pump-and-treat system design methodology developed by *Mantoglou and Kourakos* [2007], the objective function values of the realizations under various remediation policies were evaluated and ranked. The critical realizations were then

selected based on their ranks. Application of this method to an example problem shows that a few critical realizations could retain a comparable reliability level in optimal remediation design while reducing the computational demand significantly. However, the authors also considered the hydraulic conductivity to be the only uncertain variable.

In this study, a quantitative procedure named Pareto Dominance based Critical Realization Identification (PDCRI) was developed to screen out critical realizations under multi-parameter uncertainties by using Pareto dominance analysis, so that evaluation of extreme contaminant arrival times can be accomplished in an efficient manner – by optimization using the few critical realizations in stead of a large number of equally likely realizations can significantly reduce the computational demand while maintaining a similar level of reliability. The effectiveness and reliability of PDCRI was then illustrated by using a hypothetical example.

2. METHODOLOGY OF PDCRI

The Pareto Dominance based Critical Realization Identification (PDCRI) is a procedure that uses Pareto dominance analysis to identify critical realizations for stochastic optimization problems with single or multiple parameter uncertainties. Prior to description of the detailed procure, a few terms used in PDCRI are explained as they are defined in this study.

Realization. A realization is a set of uncertain parameters that are generated for one contaminant transport simulation. Realizations are usually generated from the probabilistic model of uncertain parameters using statistical techniques.

Critical realization. Critical realizations are realizations that can yield the extreme contaminant arrival times with high reliabilities.

Scenario. A scenario is usually a set of decision variables of the related optimization problem. For this study, a scenario stands for a pumping schedule.

Objective. Objective is the system response to a realization and a scenario. The objective in this study is the contaminant concentration at the exposure point.

Reliability. The reliability of a realization is defined as the probability that the extreme arrival time derived from a realization is the closest overall extreme arrival time considering parameter uncertainties.

Pareto dominance. The Pareto dominance is one of the key notions in multi-objective optimization problems [*Voorneveld*, 2003]. Considering two real n-dimensional vectors $\{x\}$ and $\{y\}$, if all the coordinates of vector $\{x\}$ are equal or better than the coordinates of vector $\{y\}$, with at least one coordinate being strictly better, then vector $\{x\}$ is said to Pareto dominate vector $\{y\}$, and vector $\{y\}$ is dominated by vector $\{x\}$ [*Voorneveld*, 2003]. Figure 1 illustrates the Pareto dominance in a two-objective optimization problem, where x_1 and x_3 dominate x_2, or

say x_2 is dominated by x_1 and x_3, but x_1 and x_3 are not dominated by each other. In a PDCRI application, the criticalness of a realization is evaluated by Pareto dominance analysis.

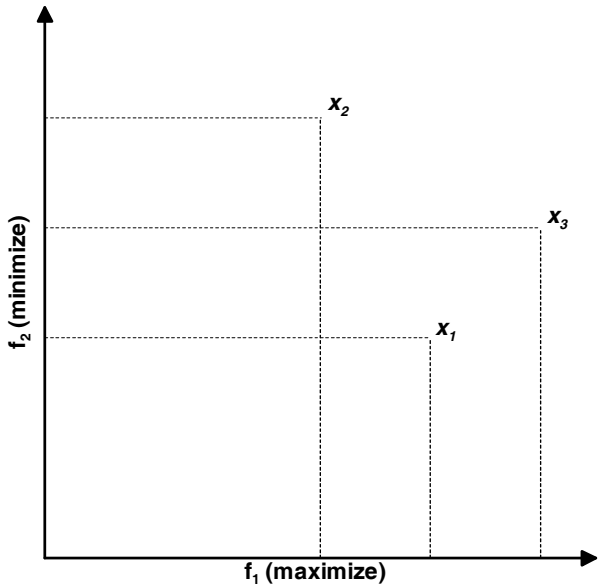

Figure 1. Illustration of Pareto dominance

The working procedure of PDCRI is illustrated in Figure 2. In the first step, a large set of equally probable realizations are generated based on the given probability distributions of uncertain parameters. Several pumping schedules (i.e., scenarios) are also randomly generated according to pumping capacities of the candidate wells. The objective value with regard to each realization under each scenario is then evaluated by using groundwater flow and contaminant transport simulation models. Assuming that n realizations and m scenarios are generated during a PDCRI application, a total number of $m \times n$ groundwater flow and contaminant transport simulations will be conducted. By using objective values obtained from the simulations, an objective vector will be formed for each realization, which consists of m objective values.

Figure 2. Flowchart of PDCRI

After the n objective vectors are obtained, a Pareto dominance analysis is conducted on these objective vectors to determine the number of times that each objective vector dominates and is dominated with respect to other objective vectors. According to the Pareto dominance analysis results, a quantitative index identified as Criticalness Index (CI) can be calculated to indicate the criticalness of a realization. The values of CI vary between 0 and 1. A realization with CI = 1 is the most critical one, and a realization with CI = 0 is the least critical one.

After the CI value for each realization is obtained, the critical realizations can be picked up for the optimization process according to CI values and reliability requirement of the related stochastic optimization problem. As can be seen in later discussions, the reliability of a realization is very close to its CI value when the CI value is close 1. In other words, if the optimization result for a stochastic optimization problem is obtained by using a critical realization with CI=α, then the probability for the result to be the "true" optimal is very close to α. Therefore, if a stochastic optimization problem desires optimal solution with a possibility of at least α, realizations with CI values of α or higher should be chosen as critical realizations.

3. DEMONSTRATION OF PDCRI APPLICATION AND DISCUSSION

To demonstrate the effectiveness and reliability of PDCRI, a hypothetical application with uncertain hydraulic conductivities was created. As shown in Figure 3, the unconfined aquifer is bounded by no-flow boundaries to its North and South. The east and west boundaries are constant head boundaries with heads of 36 feet and 40 feet, respectively. The dimensions of the site are 2,700 feet × 2,000 feet × 50 feet, which is simulated using 270 columns, 200 rows, and 1 layer in MODFLOW and MT3DMS. Each cell has the same size of 10 feet × 10 feet × 50 feet. For the groundwater flow and contaminant transport simulations, each month is simulated as one stress period. Starting from time zero, contaminant is released to the aquifer from node (100, 70) at a constant rate of 100 g/day. As indicated in Figure 3, the contaminant is then collected by the candidate wells with a pumping capacity of 3,000 ft^3/day in each well at a total water supply of 7,000 ft^3/day. The goal of the example problem is to evaluate the earliest contaminant maximum contaminant level (MCL, 20 ppb for the example contaminant) arrival time in the discharged water based on hydraulic conductivity uncertainties. The various hydraulic conductivity distributions were generated using FIELDGEN [*Doherty*, 2007]. One example realization of the hydraulic conductivity distributions is shown in Figure 3. Other properties of the site and the contaminant used in this example are given in Table 1.

For an accurate evaluation of the reliability of stochastic optimization using critical realizations, the probability distribution of the earliest MCL arrival times under hydraulic conductivity uncertainties were pre-obtained using Monte Carlo Simulation (MCS). During the MCS, the earliest MCL arrival times for 1,100 realizations were obtained via optimization. The cumulative probability distribution of these earliest contaminant MCL arrival times is very close to that of a theoretical normal distribution with mean of 8.505 stress periods and standard deviation of 0.277 stress periods, which is therefore taken as the "true" distribution of the earliest MCL arrival times.

To demonstrate the performance of PDCRI, another 1,000 realizations were generated for the example problem. For each realization, the contaminant concentrations in the discharge at the end of stress period 5 under 10 different pumping schedules (scenarios) were evaluated and then used for CI calculations as discussed below.

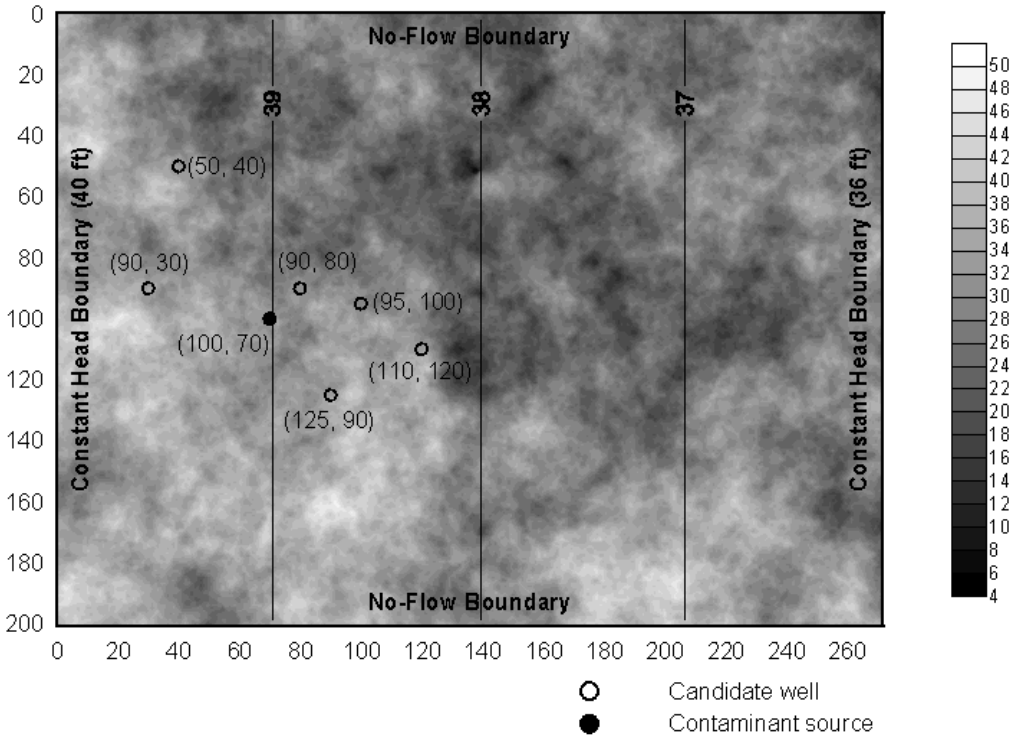

Figure 3. The candidate well locations, contaminant source, hydraulic conductivity and initial head distributions for the example problem (hydraulic conductivity unit: ft/day, head unit: ft)

Table 1. Values of parameters used in the example problem

Parameter	Value
Aquifer thickness	50 ft
Aquifer specific yield	0.05
Effective porosity	0.2
Longitudinal dispersivity	25 ft
Horizontal transverse dispersivity	2.5 ft
Vertical transverse dispersivity	0.25 ft
Diffusion coefficient	8.5×10^{-4} ft^2/day
Soil bulk density	7.7112×10^{4} g/ft^3
Distribution coefficient	5.0×10^{-6} ft^3/g
Contaminant first order reaction rate	5.0×10^{-4} 1/day

In our study, the CI values under 10 scenarios were calculated for various numbers of realizations to examine the reliability of the critical realizations with regard to the total number of realizations used in PDCRI. The obtained CI value and reliability of each realization are plotted in Figure 4 for cases with 10, 100, and 1,000 realizations, respectively. It can be seen from Figure 4 that as the CI value of a realization approaches 1, the reliability of the realization is quite close to its CI value. The higher is the CI value of a realization, the higher is the probability that the realization can yield the earliest MCL arrival time, which demonstrates the effectiveness of criticalness indication using CI.

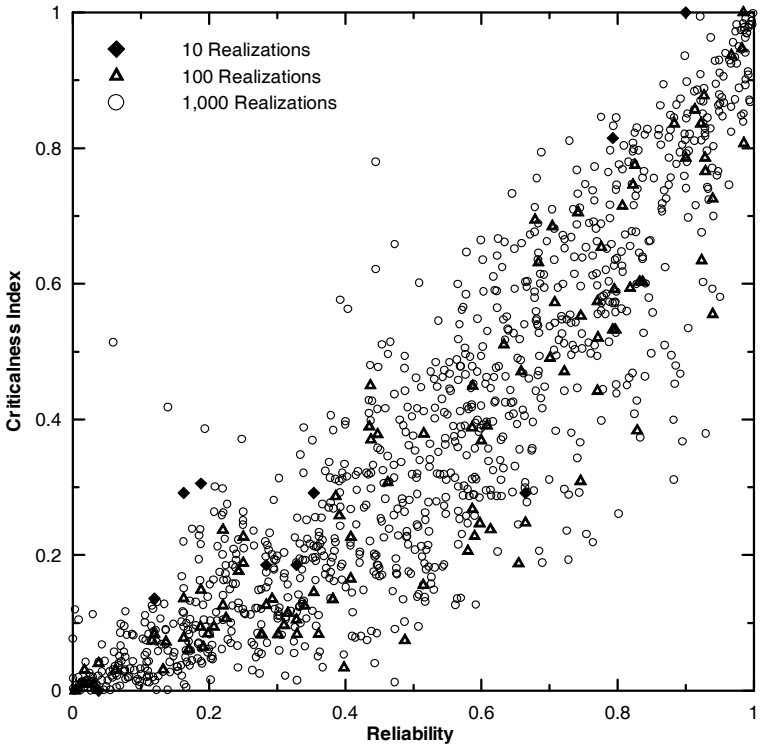

Figure 4. Criticalness Indexes vs. reliabilities of realizations used in PDCRI

4. SUMMARY

Uncertainties associated with the input data of groundwater flow and contaminant fate-and-transport models may produce significant uncertainties in the simulation results such as contaminant concentration and the arrival times, which in turn may seriously impact the reliability of the related epidemiologic studies. Therefore, a reliable epidemiologic study requires the evaluation of extreme contaminant arrival times under multi-parameter uncertainties.

Stochastic optimization, in which a number of equally likely realizations are used to represent parameter uncertainties, has been applied to solve this type of problems. Typically, the reliability improves as more realizations are used. However, the associated high computational cost restricts its application, especially for field-scale problems. To improve the computational efficiency, a few critical realizations are frequently selected to replace the large set of realizations, thus the computational requirement can be reduced to a small fraction of the original one. Several critical realization identification methods have been proposed and applied for optimal remediation design problems under hydraulic conductivity uncertainties.

In this paper, a critical realization identification procedure identified as Pareto Dominance based Critical Realization Identification (PDCRI) was developed. PDCRI can efficiently screen out critical realizations under single or multiple parameter

uncertainties. A quantitative term called Criticalness Index (CI), which is calculated based on multi-objective Pareto dominance analysis, was defined to represent the criticalness of a realization.

The effectiveness and reliabilities of the critical realizations obtained by using PDCRI were tested using a hypothetical example. Optimization results indicate that application of critical realizations in stochastic optimization problems can significantly improve the computational efficiency while maintaining a similar reliability.

Abstract

The groundwater is the major natural resources for drinking and other various purposes; however, it is under threat of degradation of its quality from concentrated and/or dispersed sources of contamination in urban area of developing countries. Therefore, contamination of groundwater has become a major concern of decision makers and water managers involved with the management of water quantity and quality and their relationship to human health in recent years. Since, groundwater monitoring and mathematical modeling is very costly in regional scale vulnerability assessment, one frequently used water quality protection strategy is to develop contamination potential maps of groundwater, and then prioritize those wells located in the potentially highly contaminated areas for testing of contaminants. However, generation of contamination potential maps is not an easy task due to lack of sufficient hydrogeologic database and inherent uncertainty. This procedure is usually carried out using GIS based overlay index method and process based model. DRASTIC model, a popular index method is used to assess groundwater vulnerability over the large geographical areas on the basis of general hydrogeological knowledge of the contaminant transport in aquifer media. DRASTIC index uses linear model to calculate the vulnerability index and the factors that influence the groundwater vulnerability must be divided into ranges and then be given ratings. This system is unable to describe a continuous transition from the easiest to be polluted to the most difficult to be polluted that is fuzzy nature of the groundwater vulnerability to contamination. Therefore, this paper aims to estimate the risk of an aquifer to be polluted from concentrated and/or dispersed sources which applies the ability of the fuzzy ruled-based system to cope with the modeling of a nonlinear system and presentation of the output of the fuzzy system in the framework of GIS. This may be possible to describe this concept with a set of linguistics rules in the form of "IF-THEN". This paper presents the fuzzy inference system benefiting from fuzzy engine and expert knowledge-based DRASTIC parameters for nonlinear mapping of the intrinsic groundwater vulnerability concept. The developed fuzzy model is applied to a shallow aquifer of Kathmandu Valley, Nepal and the result is compared with that of the DRASTIC model. This methodology has potential for facilitating groundwater vulnerability modeling at a regional scale and can be used for other regions, especially in the case of data scarcity, however, would require incorporation of appropriate input parameters and rule base suitable for the region.

Introduction

Groundwater is a globally important, valuable and renewable natural resource of water supply due to its relatively low susceptibility to contamination in comparison to surface water and its large storage capacity. However, it is under threat of degradation both by inappropriate use and by contamination, especially in haphazard urbanized area of developing countries, like Nepal. Generally, the deterioration of groundwater quality from concentrated and/or dispersed sources of contamination is mainly due to the high growth of population, unplanned growth of cities, and excessive use of fertilizers and pesticides in agriculture land, poor sewage and septic system as well as disposal of the untreated wastewater both from household and industrial activities. Therefore, contamination of groundwater has become a major concern of planners, decision makers and water managers involved with the management of water quantity and quality and their relationship to human health in recent years. In recognition of the need for effective and efficient methods for protecting ground water resources from future contamination, scientists and resource managers have sought to develop techniques for predicting which areas are more likely than others to become contaminated as a result of activities at or near the land surface (NRC 1993). This concept has been widely termed to groundwater vulnerability to contamination. It is the sensitivity of groundwater quality to an imposed contaminant load, which is determined by the intrinsic characteristics of the aquifer. To quantify aquifer vulnerability, one frequently used method is to develop contamination potential maps of groundwater, and then prioritize those wells located in the potentially highly contaminated areas for testing of contaminants. The contamination potential map is the subdivision of the area into several hydrogeological units with different levels of vulnerability, which shows the distribution of highly vulnerable areas, in which pollution is very common because contaminants can reach the groundwater within a very short time. The contamination of groundwater, however is a widespread problem and requires huge investments for remediation. Therefore, it is important to identify which aquifer systems and hydrogeological settings are most vulnerable to contamination prior to implementing groundwater monitoring and remediation programs in large geographical areas. In this context, this study aims to develop groundwater vulnerability map to identify the aquifer's inherent capacity to become contaminated benefiting from fuzzy knowledge and hydrogeological parameters in the frameworks of GIS.

In fact, groundwater monitoring and mathematical modeling is very costly in regional scale vulnerability assessment, which employs sets of extensive field measured data. In this context, the quite conceptual method like generalized knowledge base (GKB) approach may be appropriate in which decision is made on the basis of general hydrogeological knowledge of the contaminant transport in aquifer media (Afshar et al. 2007). In order to tackle the groundwater pollution and to protect its quality in a more scientific and efficient way, many different method based on GKB approach have been developed to evaluate the groundwater vulnerability to pollution such as GOD method (Foster et al. 1987); DRASTIC (Aller et al. 1987); SINTACS (Vrba and Zaporozec 1994), benefiting from the powerful

spatial analysis capability of GIS. The most typical and popular method based on GKB approach is the DRASTIC method, developed by the United States Environmental Protection Agency (EPA) (Aller et al. 1987). Because of its simple and easy to understand characteristics, this method has been adopted in the various part of world (Barber et al. 1994; Lynch et al. 1997; Babiker et al. 2005; Rahman 2008). This method is often modified to better address local issues or better represent a local hydrogeologic setting (Merchant 1994). Further, different researchers modified this methodology for mapping the intrinsic vulnerability of aquifers to better represent a local hydrogeological setting (Zhang 1996; Denny et al. 2007; Gomezdelcampo and Dickerson 2008). Recently, this popular GIS based overlay index method was introduced in Nepal to estimate the aquifer vulnerability to contamination in shallow aquifer of Kathmandu Valley (Pathak et al. 2008). Sensitivity analysis was also utilized to evaluate the relative importance of model parameters and then revised their weights to better address the local hydrogeological and terrain characteristics of Kathmandu.

Although, DRASTIC is one of the most widely used generalized knowledge base method to evaluate groundwater vulnerability, it is unable to describe a continuous transition from the easiest to be polluted to the most difficult to be polluted that is fuzzy nature of the groundwater vulnerability to contamination. Therefore, this paper aims to estimate the risk of an aquifer to be polluted from concentrated and/or dispersed sources which applies the ability of the fuzzy ruled-based system to cope with the modeling of a nonlinear system and presentation of the output of the fuzzy system in the framework of GIS. This may be possible to describe this concept with a set of linguistics rules in the form of "IF-THEN". First introduced by Zadeh (1965), fuzzy logic and fuzzy set theory have been extensively used in ambiguity and uncertainty modeling in decision making. The basic concept in fuzzy logic is quite simple; statements are not only "true" or "false" but also represents the degree of truth or degree of falseness for each input. Fuzzy sets are characterized by membership functions. Several approaches have been used to apply fuzzy set theory to groundwater vulnerability to contamination problems, including fuzzy pattern recognition and optimization technique (Zhou et al. 1999; Chen and Fu 2003), fuzzy rule-based systems (Dixon et al. 2005; Afshar et al. 2007). Afshar et al. (2007) proposed the rule base fuzzy system based on DRASTIC knowledge to evaluate the groundwater vulnerability. To illustrate the performance of the developed model, a hypothetical hydrogeological setting was assumed and results were compared with that of DRASTIC model. However, the previous studies lack to incorporate the fuzzy inference system for mapping the output of actual aquifer systems in geographical scale utilizing the powerful spatial and visual capability of GIS. This paper presents fuzzy rule based model which is developed to incorporate the non linear mapping of intrinsic groundwater concept benefiting from hydrogeological parameters used in DRASTIC method to assess groundwater vulnerability of shallow aquifer of Kathmandu, Nepal. Moreover, the developed model is validated with the result of DRASTIC methodology.

Groundwater vulnerability mapping

Study area

The total area of Valley for the study is about 350 square kilometers as shown as Figure 1, which consists of gentle hills and flat lands at elevations of 1300-1400 meters. Average annual precipitation in the Kathmandu Valley is around 1400 millimeters, about 80% of which falls in the monsoon period during June and July. Within the valley, municipal and other water supplies depend on monsoon rains and the stream and groundwater systems fed by this precipitation. Surface runoff is high during the monsoon and recharge to the shallow aquifers occurs mostly along the basin margins, directly from precipitation and by supply from many small rivers. However, recharge to the deeper aquifers is considered to be limited, due to the presence of clay beds that significantly restrict downward percolation. Because the Kathmandu Valley is a closed basin with gentle slopes toward the centre, groundwater flow is assumed to be slow, particularly in the deeper aquifers. The surface of the Kathmandu Valley is almost flat but it has buried bedrock surface with irregular shapes and high relief. The depth of the Precambrian bedrock from the ground surface ranges from tens of meters to more than 500 meters. The thick quaternary deposits consist of lacustrine and fluvial deposits, which have been eroded, however the original thickness of the deposits is unknown. Based on the engineering and environmental geological map of Kathmandu Valley (Shrestha et al. 1998), the geological setting of Kathmandu Valley with different formations is shown in Figure 2. The brief description of each formation is presented elsewhere (Pathak et al. 2008).

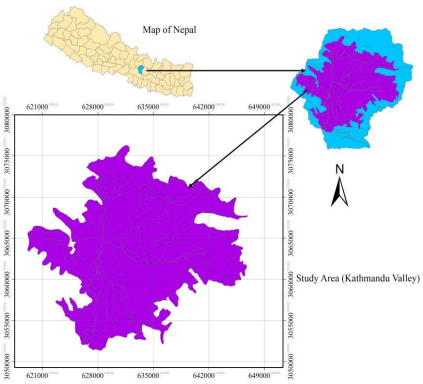

Figure 1. Location map of study area

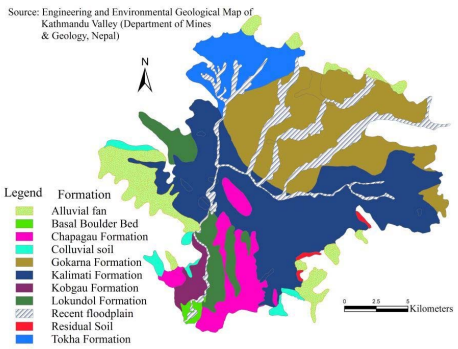

Figure 2. Geological formation map of Valley

DRASTIC and Fuzzy Inference System

Overlay and index methods, such as DRASTIC, are relatively easy to implement and require little data, but the result can be questioned because these methods rely more on the judgment of the analyst than on the actual hydrogeological processes (Frind et al. 2006). Gogu et al. (2003) reported that different overlay and index

methods like DRASTIC applied to same hydrogeological system can generate dramatically dissimilar results. Despite these criticisms due to the lack of proper validation, this method has been adopted worldwide for evaluation of aquifer vulnerability. DRASTIC index uses linear model to calculate the final vulnerability index using the following Equation:

$$VI = D_r D_w + R_r R_w + A_r A_w + S_r S_w + T_r T_w + I_r I_w + C_r C_w \quad (1)$$

The DRASTIC acronym stands for the seven hydrogeological parameters; depth to water, recharge, aquifer media, soil type, topography (slope), impact on the vadose zone media and hydraulic conductivity of the aquifer and the subscripts r and w denote the rating and the weight respectively. DRASTIC elected to use weight for each parameter based on its relative significance contributing to the pollution potential (depth to groundwater = 5; net recharge = 4; aquifer media = 3; soil type = 2; topography = 1; impact on vadose zone = 5; and hydraulic conductivity = 3) and rating value between 1 and 10 to each parameter, except R which ranges between 1 and 9 is given depending on local hydrogeological settings. Once the DRASTIC index has been computed, it is possible to identify areas, which are more likely to be susceptible to groundwater contamination relative to others. The higher the DRASTIC index, the greater is the groundwater pollution potential. In this method, the nature of the vulnerability is taken into account by dividing the values of each affecting factor into ranges and then giving to rating value to each range. However, it should be noted that if a factor value can be measured numerically, unlike the function of DRASTIC index, the fuzzy system generates a continuous vulnerability function by changing any subspace of input to the fuzzy system, which may be considered as pronounced advantage over DRASTIC method.

Fuzzy inference is the process of formulating the mapping from a given input to an output using fuzzy logic that employs the rules upon which decisions are made. A fuzzy rule based model is comprised of fuzzification of input variables, application of fuzzy operator in the antecedent, implication from antecedent to the consequent, aggregation of the consequents across the rules, and defuzzication (Figure 3). Due to the unavailability of soil attenuation type at the required scale over the entire aquifer system and the absence of spatially complete data for hydraulic conductivity, impact on vadose zone and hydraulic conductivity were excluded from DRASTIC system. Each data layer except impact on vadose zone and hydraulic conductivity was generated and/or obtained from its original source as a point, line, or polygon layer. Then, all parameters contributing to groundwater vulnerability were converted from vector (point, line, or polygon) to raster (grid) using the GIS. In raster layer, space is subdivided into discrete cells with required resolution. In this work, all five input parameters for the DRASTIC and fuzzy inference system are generated in five separate raster layers of 500 m x 500 m grid resolution. The detail of acquisition the individual data layers and method of generating input parameters were reported in earlier work (Pathak et al. 2008). The proposed fuzzy rule based model with five inputs, one output and 243 rules is shown in Figure 4. Each input domain was divided into three subdomains and output domain divided into five subdomains. The

rules were of the form "if D (depth to groundwater) is L (low) and R (recharge) is H (high) and A (aquifer media) is H (high) and S (soil type) is H (high) and T (topography) is L (low) then VI (vulnerability index) is VH (very high)," where D, R, A, S, T, and VI are linguistic variables while VH, H, and L are their linguistic values. Trapezoidal membership function, a minimum Mamdani inference and a central defuzzification method are used.

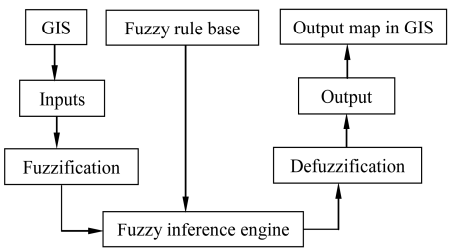

Figure 3. General structure of Fuzzy rule based system

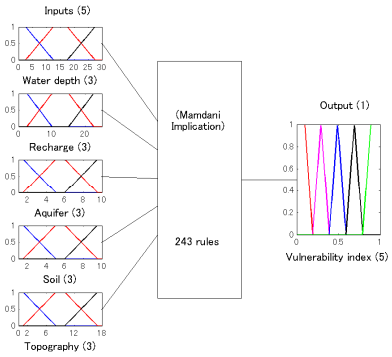

Figure 4. Proposed fuzzy rule based model

Results and discussion

Comparison of DRASTIC and Fuzzy index

The modeled results should however validate from field observations which is quite difficult and expensive in large geographical area. Hence, this study validates the model's performance by comparing the results with those of DRASTIC index. Output of DRASTIC method is first normalized to be able to compare with output of fuzzy rule based model. To compare the output of the fuzzy model with DRASTIC index, vulnerability variation resulting from fuzzy and DRASTIC model with respect to any single input variable, making other parameters constant, is computed taking the characteristics of selected hydrogeological settings of the study area. The characteristics of the five factors of the selected hydrogeological setting used for comparison study are shown in Table 1.

Table 1. Characteristics of selected hydrogeological unit to compare output of Fuzzy and DRASTIC model

Factors	Range	Rating	Weight	Normalized weight
D	4.6 - 9.1m	7	5	0.217
R	178 - 254 mm	8	4	0.174
A	Sand & Gravel	8	3	0.13
S	Sand	8	2	0.087
T	0 - 2 %	10	1	0.043

The comparison between outputs of two models indicates that the fuzzy system

has continuous nature with respect to input factors and unveils two upper and lower bound whereas the output of DRASTIC has a discrete nature as shown as Figures 5(a–c).

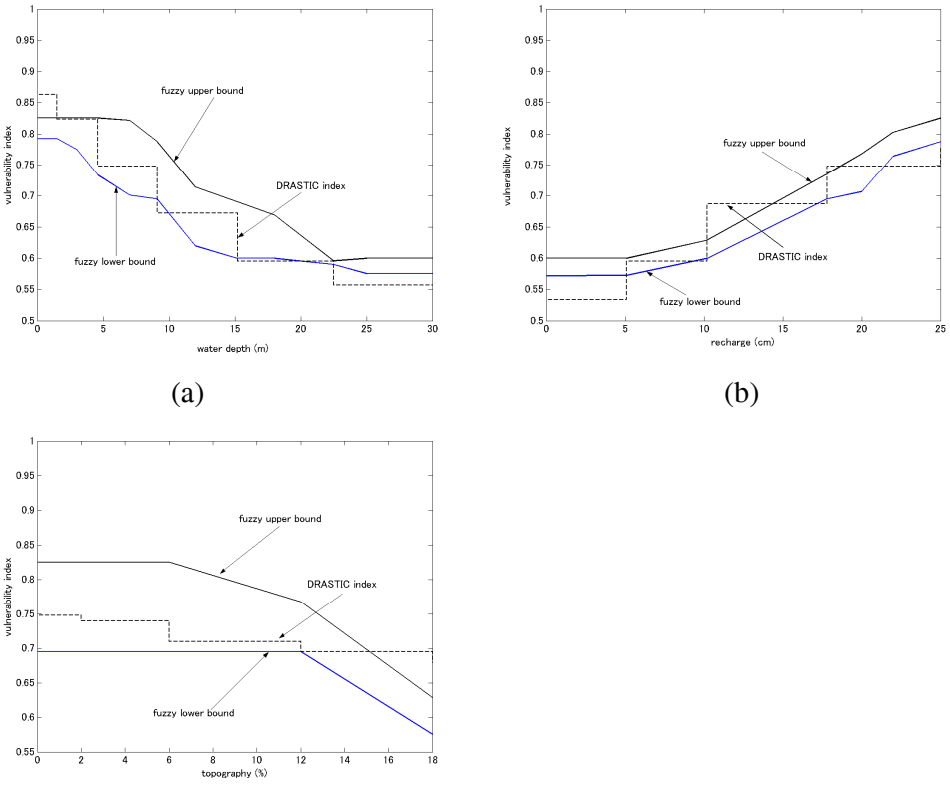

Figure 5. Vulnerability variation of (a) water depth in fuzzy and DRASTIC models; (b) recharge in fuzzy and DRASTIC models; and (c) topography in fuzzy and DRASTIC models

Application and validation

The proposed fuzzy rule based model is a decision making model which benefits from expert's knowledge hence its validation is vital. Validation of any groundwater vulnerability models based on general hydrogeological knowledge is quite difficult with field measured contaminants information in any aquifer systems due to the qualitative nature of vulnerability and inherent uncertainty. Since input parameters and knowledge base are derived from the DRASTIC system, similar results expected from both fuzzy and DRASTIC model. Hence, to demonstrate the performance of proposed fuzzy rule based model, it is applied to shallow groundwater aquifer of Kathmandu, Nepal to evaluate the intrinsic vulnerability and then output is compared with normalized index obtained from DRASTIC method. All input parameters that pertinent to groundwater vulnerability to contamination were converted to raster layer of 500 m x 500 m grid resolution using GIS. Based on defined raster layer, the

input matrix in any fuzzy subsystem is a 48 x 53 matrix covering study area. The vulnerability index in the fuzzy model is computed in each pixel of the study area. Ultimately, the output of fuzzy model is mapped utilizing the powerful spatial and visual capability of GIS (Figure 6). Output map of fuzzy vulnerability index has been compared with output map of DRASTIC method, which is presented in Figure 7. The difference of two outputs is plotted in Figure 8, which indicates that both map follow the same trends, however, the main difference is that fuzzy model has a continuous nature whereas the output of the DRASTIC has a discrete nature.

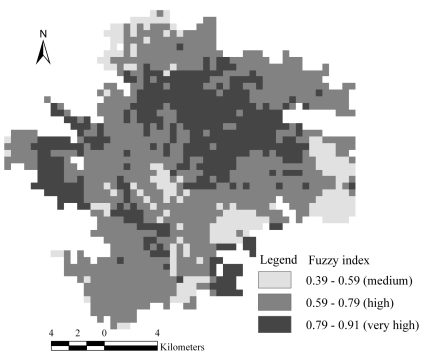

Figure 6. Vulnerability mapping of study area based on fuzzy rule based system.

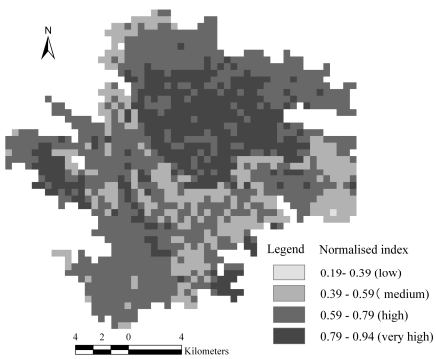

Figure 7. Vulnerability mapping of study area using DRASTIC method

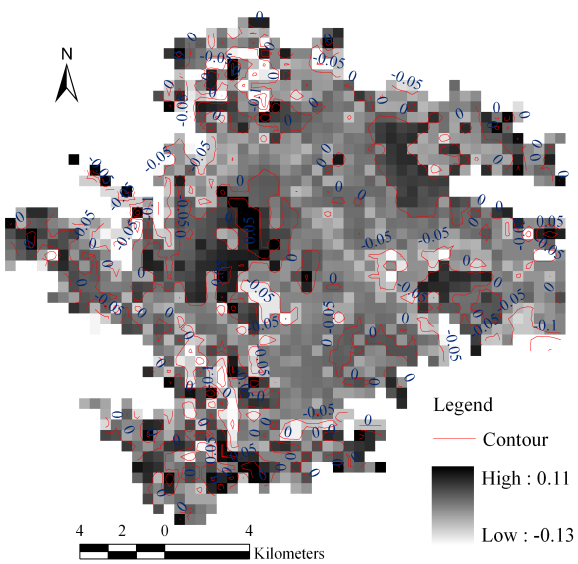

Figure 8. Differences between fuzzy and normalized DRAST index in study region.

Conclusion

The groundwater vulnerability map has developed to identify the aquifer's inherent capacity to become contaminated benefiting from fuzzy knowledge and some hydrogeological parameters that pertinent to groundwater contamination in the frameworks of GIS. A fuzzy rule based model has been proposed to incorporate the non linear mapping of intrinsic groundwater concept benefiting from some environmental and hydrogeological parameters used in DRASTIC method. A comparison between the output of fuzzy rule based model and the output from DRASTIC method was accomplished. The ability of fuzzy model to produce continuous vulnerability function in assessing groundwater vulnerability in the case of data scarcity of the study area may be considered as a pronounced advantage over index method like DRASTIC. It is recognized that the approach adopted to produce the vulnerability index was limited by the availability of data. However, in areas with limited data, this index provides important objective information that could be used for decision making. The developed fuzzy model has potential for facilitating groundwater vulnerability modeling at a regional scale and can be used for other regions, especially in the case of data scarcity, but, would require incorporation of appropriate input parameters and rule base suitable for the region.

Abstract:

This paper addresses the problem of accurate estimation of geospatial models from a set of groundwater recharge and discharge maps and from auxiliary remote sensing and terrestrial raster measurements. The motivation for our work is driven by the cost of field measurements, and by the limitations of currently available physics-based modeling techniques that do not include all relevant variables and allow accurate predictions only at coarse spatial scales. The goal is to improve our understanding of the underlying physical phenomena and increase the accuracy of geospatial models—with a combination of remote sensing, field measurements and physics-based modeling. Our approach is to process a set of recharge and discharge maps generated from interpolated sparse field measurements using existing physics-based models, and identify the recharge and discharge map that would be the most suitable for extracting a set of rules between the auxiliary variables of interest and the recharge and discharge map labels. We implemented this approach by ranking recharge and discharge maps using information entropy and mutual information criteria, and then by deriving a set of rules using a machine learning technique, such as the decision tree method. The novelty of our work is in developing a general framework for building geospatial models with the ultimate goal of minimizing cost and maximizing model accuracy. The framework is demonstrated for groundwater recharge and discharge rate models but could be applied to other similar studies, for instance, to understanding hypoxia based on physics-based models and remotely sensed variables. Furthermore, our key

contribution is in designing a ranking method for recharge and discharge maps that allows us to analyze multiple plausible recharge and discharge maps with a different number of zones. This JAVA based software package, Spatial Pattern To Learn (SP2Learn), is designed to be user-friendly and universal utilities for pattern learning to improve model predictions from sparse measurements by computer-assisted integration of spatially dense geospatial image data and machine learning of model dependencies. The reliability indices from SP2Learn will improve the traditionally subjective approach to initiating conceptual models by providing objectively quantifiable conceptual bases for further probabilistic and uncertainty analyses. This new approach has been tested using the dataset from Buena Vista Groundwater Basin, a thoroughly understood system in the Central Sand Plains of Wisconsin. This project was supported by the National Center for Supercomputing Applications - Faculty Fellows Program and the Illinois Water Supply Planning Project.

Extended Abstract:

There is a large class of problems where the complexity of the underlying phenomena is overwhelming and therefore physics-/chemistry-/biology-based modeling is limited in its accuracy of predictions. The accuracy is typically limited due to (1) the unavoidable uncertainty of direct and indirect measurements feeding complex models, (2) the high cost of measurements collected at sufficient sampling frequency in space, time and variable dimensions, (3) the insufficient computational resources to process all input measurements and execute complex models to make accurate predictions, (4) the lack of scalability of existing models coming from unsatisfied approximations/conditions of the models and/or implementations not utilizing computational resources, and (5) the simplifications in modeling, for instance, by using only a sub-set of variables relevant to predicting the underlying phenomena. This work is motivated by seeking approaches to overcome the accuracy limitations of modeling of complex phenomena.

The class of problems described above occurs in applications coming from the Earth Science domain, although, similar problems concerned with improving modeling accuracy might be

found in other domains. The applications from Earth Sciences would include prediction of precipitation, estimation of recharge/discharge rates from various indirect measurements, predictions of algal biomass in rivers or hypoxia along coasts, or simulations of optimal sewage networks. For instance, estimation of groundwater recharge and discharge (R/D) rates from a set of point geospatial measurements of hydraulic conductivity, bedrock elevation and water table elevation can be based on multiple existing physics-based models, such as MODFLOW , PEST and PRO-GRADE. These models might not generate predictions at fine geospatial scale because the model assumptions have not been met. In this case, exploring the data-driven rules between additional variables such as water proximity, topographic slope or soil type, could also lead to accuracy and model improvement.

Approaches to solving the above class of problems vary. In general, each specific application is decomposed according to multiple sources of accuracy limitations. Each cause of accuracy limitation is tackled separately and then all partial improvements are combined. It is apparent that predicting complex phenomena accurately becomes not only a modeling effort (decoupling and linking model components into a workflow) but also an optimization effort. Optimization is needed for finding the 'best' combination of theoretical models, model parameters, input products, and implementations of theoretical models, as well as for accessing computational resources for executing the models and obtaining predictions. Furthermore, all these modeling and optimization operations require human interactions with intermediate prediction results. Many times, the best predictions are decided based on considerations and tacit knowledge of a scientist or a group of scientists investigating complex phenomena.

The objective of our work is to design a computer-assisted optimization and exploratory framework enabling improvements of modeling accuracy. This work presents a framework for accurate geospatial modeling using image ranking and machine learning. The framework involves the support of optimizations and explorations, and aims at extracting tacit knowledge of domain experts. It could be also viewed as an informatics workflow with a hybrid modeling approach, where physics-based modeling and data-driven modeling approaches are combined. The novelty of our work is in designing a methodology for ranking and extracting relationships, as well as in developing a general framework for building accurate geospatial models. This

quantitative and systematic approach has bridged the gap between the traditional subjective approaches for initiating conceptual models and advanced stochastic and uncertainty analysis.

We will demonstrate how to improve our understanding of R/D pattern by incorporating auxiliary variables, ranking variables for relationship extraction and extracting variable relationships. We used the physics-based R/D rate model that takes field measurements of hydrologic conductivity, water table level and bedrock elevation. In our framework, we explored the accuracy improvements when several image de-noising techniques with a decision tree machine learning technique were employed, and several remote sensing and terrestrial raster measurements were used, for example, topographic slope, soil type and proximity to water bodies. For the specific application, the ranking approach in SP2Learn provides quantifiable reliability indices of R/D maps which enable hydrogeologists to recognize R/D patterns and compare R/D estimations with a more objective approach. In addition, the machine learning process also summarizes the rules and provides the capability of recommending a new optimal R/D pattern. The rules provide the insights of special parameter correlations of each individual study site which were not available to the expert and objective measures such as the confidence of each rule and the description length of the decision tree are given to help the experts make decision. The experts have now the capability to apply those correlations interactively in SP2Learn in order to improve the maps in more systematic and reliable approach.

Our work led to a prototype solution called Spatial Pattern To Learn which is available for free download at http://isda.ncsa.uiuc.edu/Sp2Learn/.

Implementation of the sustainable development concept in the field of groundwater management

C. Schöpfer[1]

ABSTRACT

Sustainable development is defined by the Brundtland Commission as a *"development that meets the needs of the present without compromising the ability of future generations to meet their own needs".*

Unfortunately, in the public discussion sustainability is often equated with ecology and an intact environment, which doesn't meet this definition. Examinations of sustainability have shown that it has to be put in a context of three partly competing goals: ecology, economy and social affairs. These goals can be described by the so-called sustainability triangle, in which those solutions that reach a balance among all three goals are sustainable.

The approach of sustainable development is being applied more and more often in groundwater management. Development and use of the decision system are presented for two large and intensively used groundwater systems with regards to the water supply. These are a multi-layered aquifer of unconsolidated rock and an aquifer of consolidated rock.

EU WATER FRAMEWORK DIRECTIVE AND THE TERM SUSTAINABILITY

At the beginning of the 1990s, the European Commission developed the idea of a standardized water protection guidelines intended to secure the quality and quantity of water. The **EU Water Framework Directive** (European Parliament and the Council of the European Union 2000) went into effect in December 2000, harmonizing European laws for the protection of all bodies of water. The guidelines contain three major, new elements:

- Detailed specifications were introduced to make the management of water bodies transparent.
- Furthermore, economic criteria, such as using efficient measures to ensure water prices are cost-effective and including environmental and resource-

related costs, play central roles in water management.
- Finally, early public involvement would be permitted in all decision making processes.

The specifications set out in the EU Water Framework Directive represented a fundamental shift for European water policies. The duty to protect water is integrated in all policy areas and the responsibility of society and private enterprises in terms of water protection was heightened. The EU Water Framework Directive, therefore, met the definition for the principle of sustainability (see Figure 1).

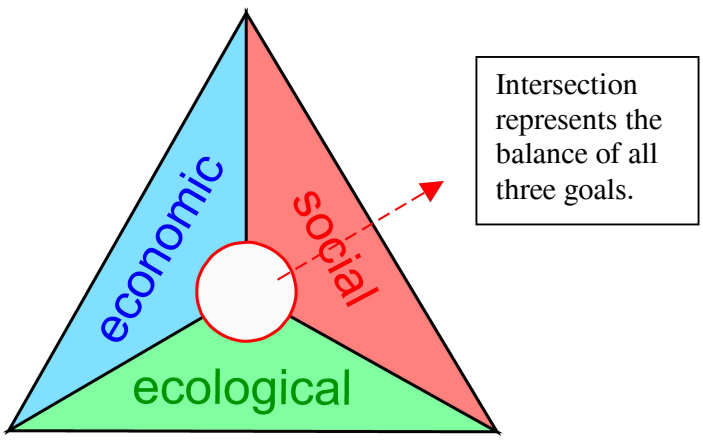

Figure 1. Sustainability triangle.

UNCONSOLIDATED ROCK CASE STUDY RHINE-NECKAR-REGION

The **Rhine-Neckar-Region** is one of the most densely populated areas in Germany (location see Figure 2) and spreads across an area of 1,400 km². Drinking and industrial water is taken from the Oberrheingraben's accumulation of unconsolidated material, which in places is several hundred meters thick, at an annual rate of 160 million m³. In particular, the drinking water supply is taken out of the deeper aquifers for quality reasons. The location of the water extraction, the hydrogeology (especially the composition and location of intermediate layers) and the interaction with surface water (especially the seepage from larger surface waters due to water extraction) influence the upper aquifer.

For the area of the Rhine-Neckar-Region that is located on the east bank of the Rhine, the state of Baden-Württemberg has developed criteria that help evaluate the sustainability of groundwater management (RP Karlsruhe 2003). The study was conducted because of the demands associated with a high degree of groundwater extraction due to the Rhine-Neckar-Region's intense water use among the local population and industry.

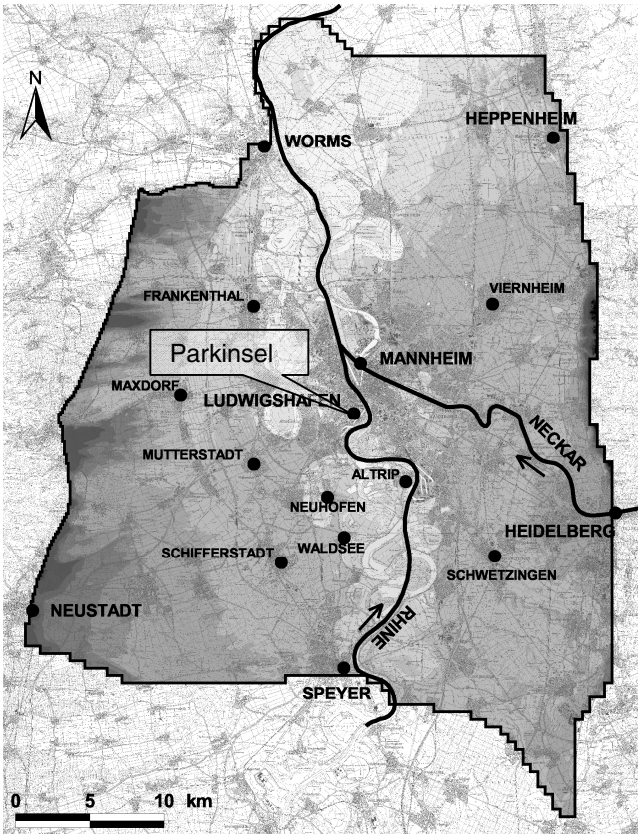

Figure 2. Model area Rhine-Neckar-Region and location of the water extraction point "Parkinsel".

The area of the Rhine-Neckar-Region located on the west bank of the Rhine belongs to the state Rhineland-Palatinate. The groundwater situation is characterized by high groundwater extraction, large-scale contamination in the upper aquifer (OGWL) and an increased risk of contaminant movement from the upper into the middle aquifer (MGWL). Here, the OGWL is not especially thick, making large-scale groundwater extraction impossible. Only in some areas parallel to the Rhine, can larger quantities of groundwater be extracted due to a thicker OGWL. For this reason, groundwater for drinking water supply and industry has for years been extracted in the deeper aquifers (MGWL and UGWL).

In Rhineland-Palatinate, a sustainable groundwater management system was required. The goal of the project's examinations was the **development of an evaluation method** that enables the comparison and evaluation of the requested solution with its alternatives in terms of sustainability in a water rights proposal. The base used for the project was a groundwater model setup to examine different management alternatives.

The developed evaluation method was derived from a cost-benefit analysis. The different effects of groundwater management were evaluated in a quantitative manner, in which single valuations were aggregated and were given different weights. A span of 50 years was defined as the period under observation. This period meets the lifespan of waterworks, and a prognosis of costs and demands is not possible for longer periods of time.

The **main goal is the sustainable management of groundwater**. In this case, the maximum number of points given is 90, which is the sum of the number of points of the three sub-goals. According to the sustainability triangle, the goal "sustainable groundwater management" is distinguished into the three sub-goals of ecology, economy and social affairs. All three sub-goals are given equal weight with a maximal number of points of 30. Figure 3 gives an overview over the different goals and sub-goals.

Target-level 1 to 4						
1	G	2	G	3	G	4	G
Sustainable Groundwater Management	90	1.Ecological	30	Groundwater quality	24	Contaminant movement to MGWL	8
						Contaminant movement to UGWL	8
						Amount of contaminants in deeper aquifers	8
				Interaction with groundwater-dependent ecosystems	6		
		2.Economic	30	Actual costs of drinking water	6		
				Actual costs of process water	6		
				Cost of a groundwater remediation / securing	6		
				Mobilization of contaminant potentials	6		
				Effort for groundwater regulation due to high groundwater levels	6		
		3.Social	30	Conflicts of interest with other types of land use	30	Conflicts of interest with agriculture	10
						Conflicts of interest with industry and trade	10
						Conflicts of interest with habitation and leisure	10

Figure 3. Overview of the goals, criteria and weights "G".

The sub-goal **ecology** includes the two sub-goals "groundwater quality" and "interaction with groundwater-dependent ecosystems". The sub-goal "groundwater quality" is weighted considerably higher with 24 points because of its high importance in groundwater management. Also, the natural protection areas make up only a small part to the total area studied.

The sub-goal **economy** is composed of 5 sub-goals, which represent the economic impact of changes in groundwater management. These are the actual costs of drinking water and process water, the cost of a possible groundwater remediation or securing, the mobilization of contaminant potentials as well as the effort for groundwater regulation due to high groundwater levels. Attention should be paid to the fact that within the sub-goal economy it's not distinguished between measures and costs. The five sub-goals are evaluated equally with 6 points.

The sub-goal **social affairs** covers the conflicts of interest that arise when the water extraction's catchment area is also used for other types of land use. This sub-goal is divided into three areas of importance: conflicts of interest with agriculture, industry and trade, and with habitation and leisure. All these types of land use can impact the groundwater if located in the catchment area.

To **distribute the points**, the following approach was chosen:
- A quantifiable factor was chosen for each criterion that had to be evaluated.
- The alternative with the worst factor is given 0 points.
- The alternative with the best factor is given the maximal number of points.
- In between, for each given factor the points are linearly interpolated.

The implementation of the developed evaluation method is shown on the basis of the **water extraction point "Parkinsel"** of the Technical Works Ludwigshafen AG (see Figure 2 for location). The extraction of groundwater is carried out mainly in the intermediate aquifer (MGWL). Close to the extraction point, a gallery of protection wells in the MGWL helps to keep away contaminants from a nearby contaminated site.

The following alternatives are examined using the evaluation method:
- Reference alternative: extraction of groundwater in the MGWL (7.5 Mio. m³ annually)
- Alternative 1: relocation of the extraction point into the UGWL to protect the extraction with an additional dilution and the aquitards functioning as a barrier
- Alternative 2: relocation of the extraction point into the OGWL to minimize the inflow of contaminated groundwater due to the high proportions of bank filtrate

In all the alternatives, protection wells continue to be operated to stop the contaminant spread from a nearby contaminated site.

The analysis and evaluation of the points according to the above method results in 54 points for the reference alternative, 58 points for alternative 1 and 55 points for alternative 2. The results are very close, even though the relocation in the UGWL is more sustainable than the reference alternative and the relocation in the OGWL. However, the three sub-goals show very different results.

In regards to the sub-goal ecology, the reference alternative is considerably more sustainable than both relocations into the OGWL or the UGWL. For example, a

relocation of extraction point in the OGWL would lead to damage of the population of old trees on the "Parkinsel" due to the lowering of the groundwater table. These trees are parts of a landscape conservation area, which give this alternative very few points for the ecology sub-goal.

For the economy sub-goal, the relocation of extraction point into the UGWL is considerably more sustainable than both the reference alternative and the relocation in the OGWL. For the last two, an adjustment of water treatment would be necessary.

For the social affairs sub-goal, the relocation of extraction point into the OGWL is considerably more sustainable than relocation into the UGWL or the reference alternative. This can be explained by the very small catchment area that results from an extraction in the OGWL (see Figure 4).

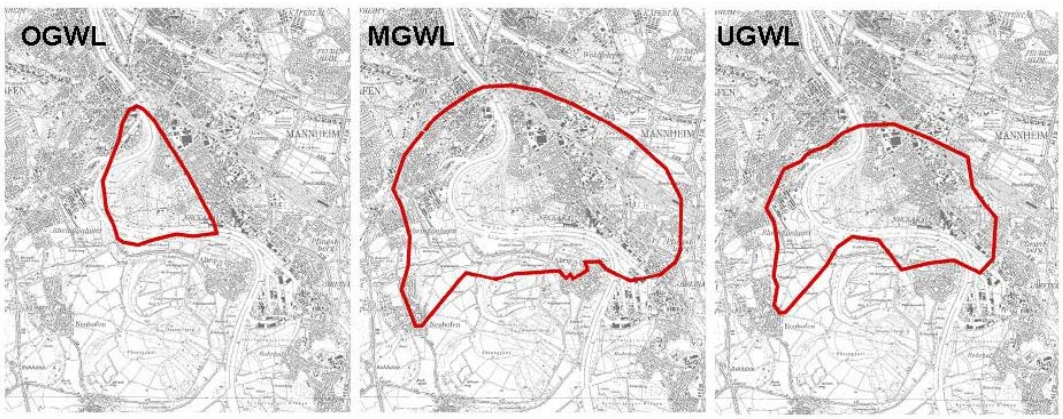

Figure 4. Borders of the catchment area of the water extraction point "Parkinsel" resulting at an extraction in the different aquifers.

CONSOLIDATED ROCK CASE STUDY IN LUXEMBOURG

Luxembourg's water supply demands are mainly met by springs and wells in the uncovered Luxembourg Sandstone. The springs, however, deliver only small amounts of water in times of little precipitation. There is also a potential hazard to water quality in areas where the aquifer of consolidated rock is not covered. For these reasons, new extraction wells are planned to be built in areas where the Luxembourg Sandstone is covered. The extractions are intended to improve the security of the water supply as water demand increases. Figure 5 shows wide fractures in the Luxembourg Sandstone.

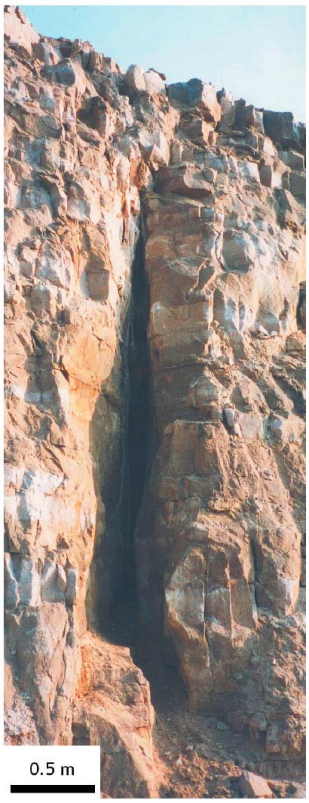

Figure 5. A wide fracture in the Luxembourg Sandstone.

The area under investigation spans the entire range of the Luxembourg Sandstone and extends 15 km west and 10 km south of the state of Luxembourg's borders and spreads across an area of 900 km² (Figure 6).

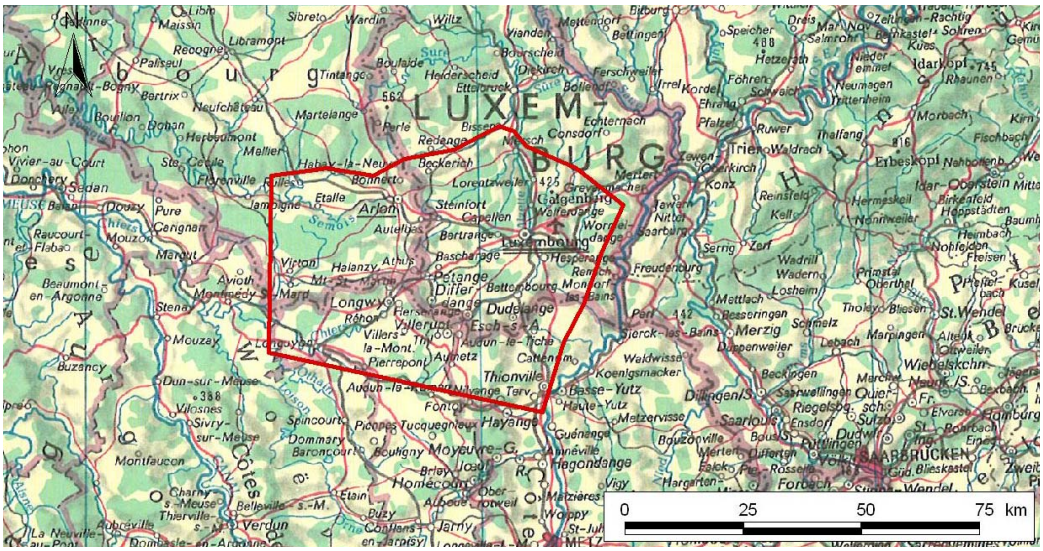

Figure 6. Area of investigation in Luxembourg case study.

The area under investigation lies within the range of the bay of Trier's sedimentation area. In geo-hydraulic terms, there are two aquifers, which, for the most part, are separated with intermediary aquitards. For this reason, the groundwater model was divided into three layers. The first model layer represents the Quaternary period, the second model layer the clays of the Lias geologic period. The third model layer represents the Luxembourg Sandstone, which forms an aquifer that is about 70 m to 80 m thick and can reach a maximum thickness of 100 m. Figure 7 shows how the geology was entered into the groundwater model.

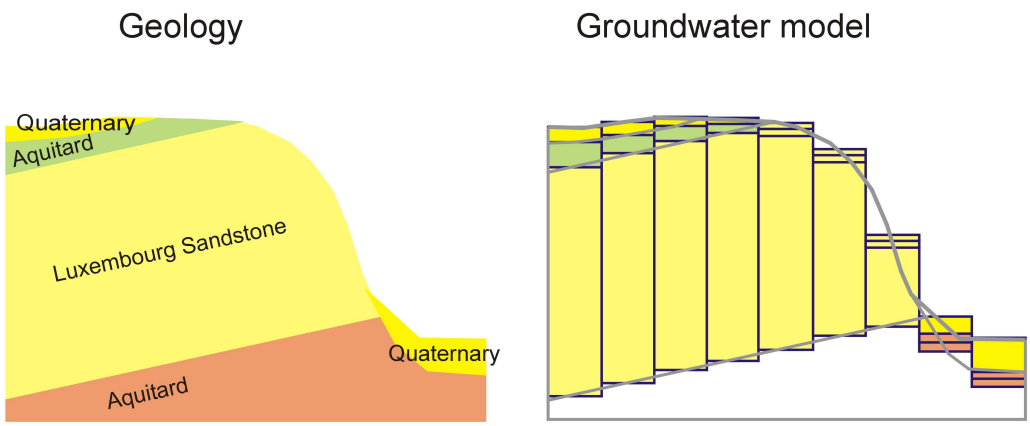

Figure 7. Implementation of the geology in the layers of the numerical groundwater model.

In the model area, approximately 4.5 million m³ of water are extracted annually from the Luxembourg Sandstone. However, the water rights are considerably higher. Furthermore, numerous springs are used for water supply. These springs extract about 9.6 million m³ of water per year.

The **groundwater situation** is substantially influenced by the water extractions. For example, the "Weyler" groundwater measurement point shows a drop in groundwater level of 2 m since 1990 (Figure 8). The overall trend of a falling groundwater level, without a substantial rise of the groundwater level in times of high precipitation, can be interpreted as an indication of the emptying of the Luxembourg Sandstone water storage in this area.

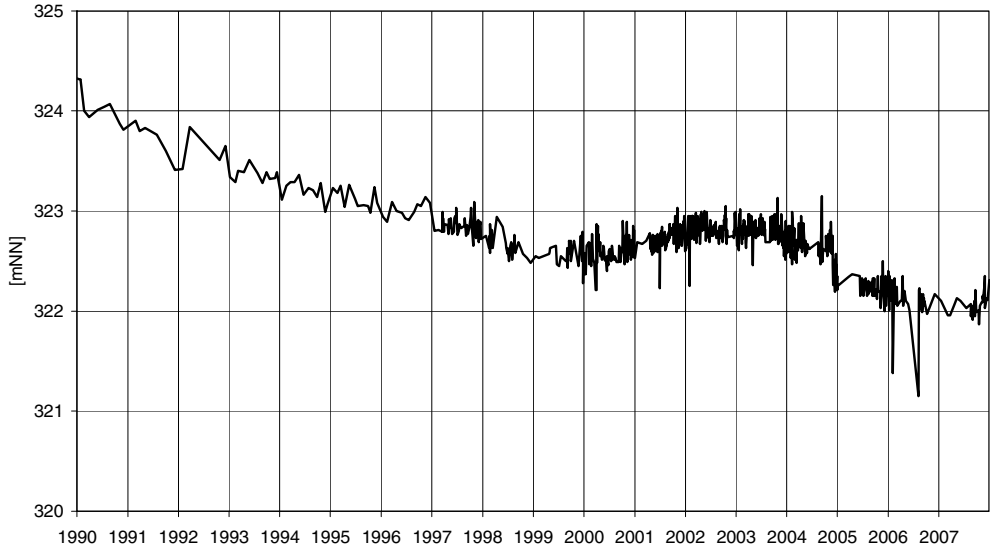

Figure 8. Groundwater hydrograph at the Weyler measurement point.

Another example of the obvious effects the extractions have on the groundwater situation is seen in the groundwater hydrograph at the well SH-15-4, which is located on the model's eastern edge. After very high amounts of groundwater were pumped in 1991, and despite little extraction, three years were required to reach the static level of 1990 (Figure 9).

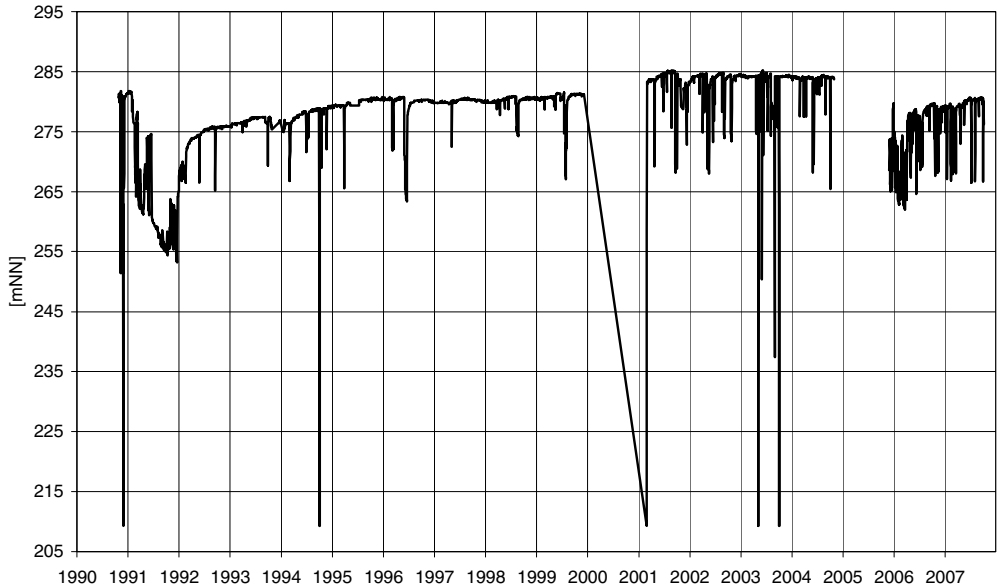

Figure 9. Groundwater hydrograph at well SH-15-4.

These measurements show that, in addition to quality problems, there are also problems regarding the amount of groundwater in aquifers of consolidated rock. The country of Luxembourg currently intends to secure the drinking water supply on its own. In addition to groundwater extractions, a water reservoir dam on the Sauer River provides Luxembourg with drinking water. In light of the rising number of inhabitants and the risks involved using surface water for drinking water, a management plan is designed for the Luxembourg Sandstone. The plan is intended to show, how much groundwater can be extracted with wells in the short and intermediate-term without harming the delivery of the springs. Short-term extractions imply periods ranging from a couple of weeks to as long as six months, and must provide enough water to make up for the complete loss of water from the reservoir for this amount of time. For these time intervals, ideal positions for the extraction wells are to be found, allowing for an operation that doesn't harm the delivery of water from the springs. The evaluation method described in the previous chapter is used and modified for the Luxembourg management plan.

CONCLUSIONS

The statements above show that a sustainable groundwater management system has to include the goals ecology, economy and social affairs. Since water demands and technical means of treating water can change quickly, the period of observation should be chosen according to the service life of the investments (chosen approach: 50 years). Under the given basic conditions, management alternatives can be found to be sustainable in the individual case, but differ from the superior goals of a sustainable water management system. The implementation of the developed evaluation method assumes that various alternatives with the same target achievement can be defined for the case under evaluation.

ABSTRACT

Water sustainability is becoming an issue throughout the United States where population and environmental concerns intensify the competition among municipal, agriculture, industrial, and power generation demands. The demand for groundwater has increased beyond its primary historical uses of agriculture and water supply. Viewed as a problem of sustainability, the long-term challenge for water supplies and regulatory agencies is to maintain steady growth and living standards without compromising the ability of future generations to meet their own needs. Water resource planners must now account for increased power generation needs for a new generation of nuclear power plants that will compete with other demands that typically comprise the existing water availability projections. Planners typically project future groundwater availability using elusive concepts of sustainable yield, safe yield, optimal yield, and consensus yield. These water use projections, resources availability, and allocations are becoming increasingly under scrutiny as demands stretch the available resources and as water consumption decisions are weighed in public policy debates. In this paper, case studies from proposed plant expansions are evaluated for their consideration of groundwater availability.

INTRODUCTION

As surface water allocation within the United States became increasingly expended, reliance upon groundwater to meet the increasing demands of new development (public supply and agricultural irrigation) surged from about 25 percent to about 40 percent since 1950 (Reilly and others, 2008). This has lead to aquifer depletion, groundwater quality deterioration, and land subsidence in many parts of the country, and has prompted states to regulate groundwater withdrawals in an effort to protect the resource and the environment from the effects of over allocation. Planners generally have adopted a conventional “safe yield” approach to manage and regulate the resource, yet depletions still occur. Most regulations and availability estimates are rarely based upon principles of capture described by Theis (1940) and expounded by so many other hydrologists. Two case studies are discussed to illustrate the concepts of safe yield and sustainability, and how management, regulations, and

availability estimates are established and the implication to the federal licensing application process to construct and operate new nuclear power generation facilities.

NUCLEAR ELECTRICAL POWER GENERATING PLANTS

The U.S. Nuclear Regulatory Commission (NRC) licensed and regulates 104 operating nuclear power reactors in the United States. These reactors supply about 20 percent of the nation's electricity (Figure 1) (US NRC, 2009). Nearly all have been operating for 10 years or more. About half have been operating in excess of 20 years while some have or are undergoing license renewal to extend their operating life by an additional 20 years. In addition to the operating power reactors, there are 16 power reactor sites being decommissioned (Taylor and Day, 2007).

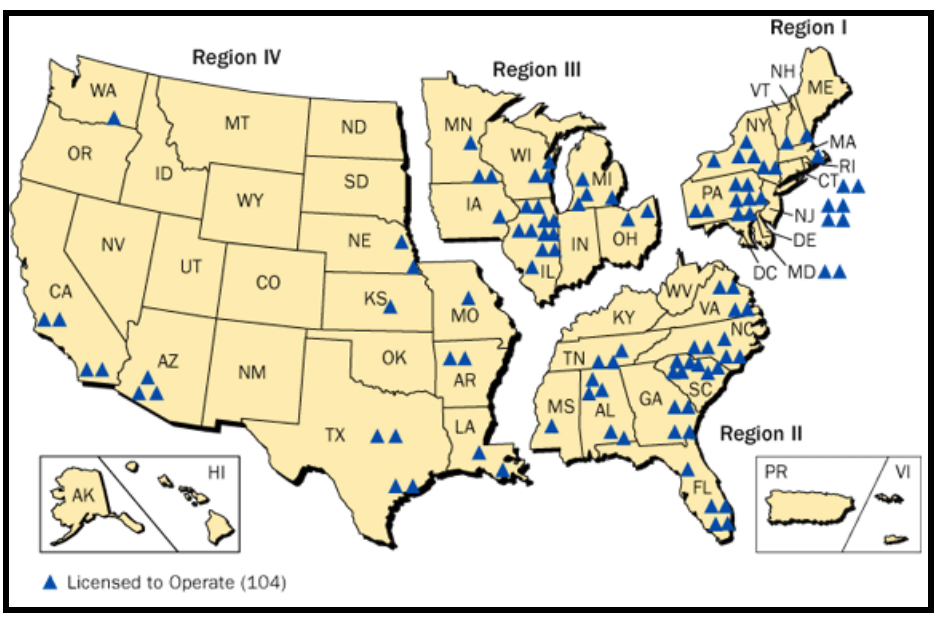

Figure 1. Location of commercial nuclear power reactors in the United States

There has been renewed interest on the part of the electrical utilities to license and construct new power reactors in the United States. This new interest is the result of the reliability and profitability of the current nuclear fleet, a streamlined licensing process that reduces the financial risk to applicants, anticipated growth in the demand for electricity, increased public acceptance of nuclear power, and recent changes to the United States energy policy that promote energy independence as well as reductions in greenhouse gas emissions (Taylor and Day, 2007). Currently, there are 21 new power reactor sites that have initiated or plan to initiate the licensing process (US NRC, 2009). The first of the new generation of power reactors is expected to begin operation in 2015.

This recent surge to submit Combined License (COL) applications to build and operate new nuclear electric power generating plants will require an evaluation of the water resources. Although most electric power generation plants obtain their cooling

water from surface water supplies, their potable, sanitary, fire suppression, and make-up water is typically withdrawn from groundwater. The NRC will question the availability and sustainability of both surface water and groundwater supplies to the plants, as well as the expected environmental impacts by proposed plant withdrawals not only during the construction phase but throughout the operating lifespan. Identifying the long term sustainability of these resources will include an evaluation of plant water demands, water resource availability, and projected future water use allocations. Ultimately, the NRC's concern lies in the possible loss of bonds and plant shut down if projected water availability is later found not to be obtainable throughout the plant's lifetime. Viewed as a problem of sustainability, the long-term challenge for water suppliers and regulatory agencies is to maintain steady growth and living standards without compromising the ability of future generations to meet their own needs (Barker, 2007).

CONCEPT OF GROUNDWATER AVAILABILITY, SAFE YIELD AND SUSTAINABILITY

During the COL application process and the subsequent NRC review, the applicant must evaluate not just the plant's impact to these water resources but future impact (use) projections to the resource, including drought cycles, environmental interactions, and the local or state regulatory controls to protect and provide the water resources. The applicant must determine if the groundwater resources are sustainable through the life of the project. Sustainability is evaluated through hydrogeologic investigations and interpretations, and most importantly, an understanding of the local or state regulatory agencies' water allocation policies and projections.

Planners who project future groundwater availability have used the now elusive concept of safe yield originally defined in 1915 as "the limit to the quantity of water which can be withdrawn regularly and permanently without dangerous depletions of the storage reserve" (Domenico and Schwartz, 1990). The definition has evolved over the years as the volume of water that can be withdrawn annually from an aquifer without exceeding average annual recharge, violating water rights, creating uneconomic conditions for water use, or creates undesirable side effects such as subsidence or saline water intrusion (Neuendorf and others, 2005). As Domenico and Schwartz (1990) state "in practice, safe yield has no unique or constant value, its value at any time depending of the spacing and location of the wells and their influence on the dynamic of interchange between ground water and other elements of the hydrologic cycle". Since the early 1950s researchers have suggested abandoning the term because of its indefiniteness. Sustainability gained popularity in the late 1980s but suffers from a similar lack of definability.

Use of safe yield as a de facto basis to establish availability contrasts with published opinions from hydrologists who argue that average annual recharge (natural recharge) is based on a steady-state, predevelopment condition and is not suitable for a dynamic system. Natural recharge-based safe yield provides only a single numerical value that does not consider transient conditions such as non-steady pumping, increased

withdrawals, seasonal trends, or droughts. Whereas the concept of sustainable groundwater availability can vary not only from one place to another, but also from one time to another as policy, socioeconomic, environmental and climatological conditions change. Groundwater resources can suffer under the misconception that groundwater allocation decisions based on the belief that safe yield projections are sustainable.

The interchangeability of the two terms, safe yield and sustainability, has been questioned by hydrologists. Safe yield is generally considered to be applicable to supply, economics, water quality, and legal rights, whereas sustainability is applied to a broader concept revolving around the complex interdependence of the resource, the environment, and society (Seward, 2006). Groundwater availability has been defined simply as "the amount of water available for use" whereas safe yield and sustainable yield concepts are methods to quantify availability (Mace and others, 2001 and 2006). To help clarify the concept of a safe and/or sustainable yield, other terms have been brought forth, but the nuances of these terms appear to be based on a researcher's philosophy of how to incorporate human needs, policy, law, and management. Eloquently stated; "sustainability, like safe yield, is a value-laden concept and one that in many respects is in the eye of the beholder" (Alley and Leake, 2004).

In defining sustainable safe yield, leading researchers refer to a publication (Theis, 1940) as a starting point, but differ on their interpretation of the role natural recharge has in regards to deriving a sustainable safe yield. One position claims that natural recharge is irrelevant (Bredehoeft, 1997 and 2002), whereas another position defends its use for modern numerical models used to quantify sustainable yields (Kalf and Woolley, 2005 and Sophocleous, 1998 and 2004). Additionally, some argue that emphasizing a scientific approach over a policy/managerial approach to deriving a sustainable safe yield is unrealistic (Mace and others, 2006 and Seward, 2006). From such arguments, two schools of thought in defining safe and sustainable yield have emerged; one takes a scientific approach whereas the other favors subjective, value-laden principles to determine sustainability (Seward, 2006). Despite the conflicting views researchers have formulating a definition and method for evaluating sustainable safe yield, most researchers and planners do agree that modern numerical groundwater models play a large role in defining and quantifying sustainable yield.

GROUNDWATER AVAILABILITY AND ALLOCATION PROJECTIONS

At a federal level, the Sole Source Aquifer (SSA) Program, which is authorized by the Safe Drinking Water Act, allows for protection when a community is dependent on a single source of drinking water. Once a SSA is designated, proposed federal financially-assisted projects that have the potential to contaminate the aquifer are subject to federal review. However, the SSA designation provides only limited federal protection of groundwater (US EPA, 2009).

At state and local levels, groundwater resources are appropriated according to laws and institutions that usually control water use through a permitting process.

Depending on the jurisdiction, and the requested allotment, the applicant may be required to provide a hydrogeologic impact evaluation. In some areas the rule of capture still exits, allowing landowners to capture the water beneath their property.

Case studies from two COL applications in different areas of the country are discussed to present how consideration of groundwater availability is evaluated during COL applications.

Case Study - Texas

An existing electric power generation facility in Texas has submitted a COL application to construct a new two-unit nuclear power generation plant. The existing units obtain cooling water from surface water, while groundwater is withdrawn from a deep aquifer that also supplies most of the potable water to the surrounding area. Operation of the new units would require a two-fold increase in the groundwater presently used by the existing units but would remain within the permitted groundwater allocations held by the utility at this plant.

The NRC's review of this COL application resulted in several follow-up questions that request a description of the sustainable groundwater resource concept (e.g., safe yield or available groundwater resource) and an analysis of current and future sustainable groundwater availability projections throughout the plant's life span. As part of the requested analysis, the utility was asked to quantify the expected impacts from the plant's increased groundwater withdrawal to the regional groundwater resource. The following is a description of the evaluation that followed.

In Texas, surface water belongs to the state, while in general, groundwater is governed by the rule of capture, which grants the landowners the right to capture available groundwater beneath their property regardless of the effects that pumping may have on neighboring wells (Lesikar and others, 2006). In many parts of the state, more groundwater is being used than is being replenished. As a result of these concerns, the Texas Legislature passed laws to encourage the establishments of Groundwater Conservation Districts (GCDs) to develop and implement comprehensive management plans that conserve and protect groundwater resources while protecting the rights of private landowners. The GCD is required to estimate the amount of groundwater available, the amount being used, the amount of recharge, and project water supply and demand. The GCD must address water supply needs in a way that will not conflict with the approved regional water plan that uses groundwater availability data acceptable to the Texas Water Development Board (TWDB). Some GCDs within a common Groundwater Management Area (GMA) may opt to plan jointly. The Texas Supreme Court reserves the right to change groundwater law if the existing laws do not adequately protect the groundwater resources (Lesikar and others, 2006).

Many methods have been used in the past to estimate groundwater availability in Texas. The TWDB has defined groundwater availability as "…the effective recharge

plus the amount of water that can be recovered annually from storage over a specified planning period without causing irreversible harm such as land-surface subsidence or water-quality deterioration" (Mace and others, 2001), and has estimated groundwater availability using average recharge, recharge with storage changes, both recharge approaches with limitations to prevent water-quality deterioration, land-subsidence, or other undesired effects, and systematic depletion (Muller and Price, 1979).

The Regional Water Planning Groups (RWPG) within Texas have also provided groundwater availability estimates using various recharge and systematic depletion approaches, a specific criterion approach – such as subsidence or recharge, or in some cases the TWDB or other outside agent (Mace and others, 2001). These estimates were used by GCD to permit pumping limits. Where there is no GCD, the rule of capture exists. However, the differing approaches and definitions of groundwater availability often produced conflicting results for the same aquifer, and generated uncertainty and mistrust among some RWPG's (Mace and others, 2001). The variety of water planning approaches in use and the conflicting results prompted the RWPG's to request the TWDB develop a standard for estimating groundwater availability (Mace and others, 2001).

In an effort to provide a standard, it has been recommended that the TWDB reject the concept of safe yield and optimal yield in favor of consensus yield (Mace and others, 2001) – an optimal yield that emphasizes policy and stakeholder input – based on the belief that groundwater scientists alone cannot estimate groundwater availability and numerical groundwater availability models are the best tools to use to help estimate groundwater availability. While such criteria are noteworthy, consensus yield may place too much emphasis on stakeholders' involvement over science. One researcher concludes that individuals or groups cannot selfishly allocate groundwater as if it was dam storage because the physics of groundwater flow through a porous media will not allow it (Kalf and Woolley, 2005).

Groundwater availability estimation methods and the planning authority roles in Texas changed following the passing of House Bill 1763 in 2005. This bill requires joint planning among GCD's within a GMA to determine "desired future conditions" of aquifers, including those where rule of capture still pervades (Mace and others, 2006). Each GCD is scheduled to submit to the TWDB in 2010 a "desired future conditions" plan detailing quantitative conditions (e.g., water levels, stream flows) for their respective aquifer in the future based on its planned use (Mace and others, 2006). As part of this process, the TWDB stresses the use of its Groundwater Availability Models (GAM) to estimate the quantitative "desired future conditions". Using the "desired future conditions", the TWDB calculates "managed available groundwater" volumes for use by RWPGs in their future regional water plans and by the GCD's in their groundwater management plans and permitted withdrawal amounts (Mace and others, 2006). In the areas where rule of capture still pervades, if a water user requires state funding to complete a project, they would have to accept an allocation amount given to them by the RWPG.

In the Texas case study, the site had a permit to obtain the groundwater required for plant operations but a detailed review of groundwater sustainability and water use projections was still required. We found that one GCD used values established by the RWPG, while simultaneously declaring the values should be used with caution because they are unscientific and further evaluations are needed. Because Texas groundwater law is continually changing (Jarvis and Campana, 2008) the ability to present an accurate availability scenario is difficult. Ultimately, the TWDB oversees all management plans and sets the "managed available groundwater" volumes to be implemented by the GCD and RWPG.

Case Study - Maryland

An existing electric power generation facility in Maryland has submitted an application to construct a new nuclear power generation plant. The existing units at this facility obtain cooling water from a nearby bay and groundwater use needs from aquifers that supply most of the potable water to the surrounding area. The proposed new unit would also obtain cooling water from the bay. However, options for potable water use by the proposed unit include: increase the plant's existing groundwater allocation, develop a source in a deeper aquifer, and/or desalinization. An evaluation was performed to determine groundwater availability and permit requirements during the COL application.

In Maryland, decades of unchecked pumping within the Atlantic Coastal Plain has led to a decline of groundwater levels, which, if left unchecked, could affect the long-term sustainability of the resource, affect the natural discharge to sensitive streams and estuaries, and increase salinization of the aquifer systems (Shedlock and others, 2007). Groundwater withdrawals are managed by the Maryland Department of Environment (MDE) through the Water Supply Program (WSP), a permitting process aimed to prevent the regional water levels from declining below 80 percent of the aquifer's available drawdown. However, the WSP currently does not have the adequate tools to make science-based groundwater management and permitting decisions (Shedlock and others, 2007).

The Maryland Geologic Survey (MGS) conducts modeling efforts that simulate water-level trends to 2030 in various Coastal Plain aquifers in order to better manage the resource. However, no comprehensive scientifically based method or tool has been devised to provide WSP with a better management system. In response to this, the Advisory Committee on the Management and Protection of the State's Water Resources recommended in a 2004 report that a comprehensive study of the sustainability of the Maryland Coast Plain aquifer system be undertaken. The MGS and the U.S. Geological Survey (USGS) developed a "science plan" that provides new scientific data, and data management and analysis tools for the WSP to use for future groundwater allocations. As part of this plan, a comprehensive review and update of the hydrostratigraphic framework of the Atlantic Coastal Plain of Maryland, Delaware, and several counties of Virginia will be performed primarily for a new modeling effort. The first part of this effort involves development of a regional

numerical groundwater flow model. The second part of the model involves an optimization model that is incorporated with the flow model. These models will be used to optimize conditions based on various management goals to produce optimal locations, pumping rates, and pumping periods of supply wells to better manage the aquifer system with respect to long-term sustainability of the resource (Shedlock and others, 2007). Results of model runs will be evaluated by scientists, resource managers, and decision-makers from both scientific and socioeconomic viewpoints (Shedlock and others, 2007). Implementation of this new tool is scheduled for 2013.

In the Maryland study, the review of existing state groundwater models, water demand projections, and the current water allocation process allowed the utility to rank and prioritize the plant's water supply options. This approach is still under development and will require approval from local, state, and federal agencies. The approach and water use allocation requests are expected to be finalized prior to the state's implementation of the optimization groundwater models.

CONCLUSION

In the case of COL applications, it can be difficult to provide groundwater availability and projections to the NRC that are independent from those set by state and local regulatory authorities and therefore, an understanding is required to determine the difference between "sustainable yield", "safe yield", and "groundwater availability" and how such terms relate to the actual availability evaluations conducted by state and local governments. The issues described in this paper are not unique to Texas and Maryland, but emphasize the stress placed on the nation's water resources and the pressure on water use planners to allocate the resources while addressing changing political, socioeconomic and environmental conditions.

For many researchers and planners, policy is considered to be paramount in determining how much and to whom the groundwater resource is allocated. As one researcher stated, "We cannot use a natural system without altering it" (Sophocleous, 1997). Texas is employing GAMs to allocate groundwater in sensitive areas, and Maryland plans to use a comprehensive modeling system to optimize its permitted withdrawal amounts and points. However, if the results of such modeling efforts are not adhered to because of social economics or politics; the effort of quantifying sustainable yield may remain biased.

Abstract

A two-dimensional mathematical model has been developed using Galerkin finite element method for simulation of transient saturated-unsaturated groundwater flow in multi-aquifer system with window based, menu-driven, user friendly interface to provide on screen input data interpretation, to guide user through steps of data processing , and to generate reports and graphs from output results. The model is able to handle combined and system-dependent boundary conditions that can be used in practical situation of groundwater flow in the complex hydrogeological conditions of a country like Bangladesh in general and particularly for Dhaka City. Due to less complexity in two-dimensional simulation and the availability of Graphical User Interface (GUI) the model is easier to use and time efficient.

1. Introduction

Groundwater modeling in Bangladesh needs special attention in addition to the usual obstacles such as irregular geometry, boundary conditions, temporal and spatial variation of aquifer characteristics and excitations. During monsoon aquifers are replenished directly from the precipitation-infiltration process due to the accumulated standing water over the submerged lands, the occurrence and distribution of which vary with time. Also the rivers fed the aquifers naturally, or in induced way when heavy pumping near the river occurs, particularly in densely populated urban areas like Dhaka city. In Dhaka the huge demand for drinking and sanitation purposes is exclusively (95% of total abstraction) fulfilled by the groundwater abstractions through approximately six hundred deep tube wells. The unprecedented growth rate of Dhaka City both caused the Dhaka Water Supply and Sewerage Authority (DWASA) to increase the production of drinking water supply by more than six times since the sixties but still the supply is far lagging behind the demand. As a result, beneath Dhaka City, water levels in the aquifers have fallen steadily over the last decades in response of ever increasing abstraction (MPO, 1987). Thus the groundwater resource evaluation, prediction and management bear much attention at this time in Bangladesh.

The present study is devoted to develop a two-dimensional groundwater model that can handle a situation like Dhaka City. Galerkin finite element method is used to develop a two-dimensional numerical algorithm for treating saturated and

unsaturated flows simultaneously. With a view to make the model more user friendly and efficient in operation a Graphical User Interface (GUI) is designed to handle the user input, reporting the output and graph generation.

2. Literature Review

Finite element techniques to two-dimensional saturated-unsaturated flow problems were applied by several researchers. Among them are *Neuman* (1973), *Neuman et. al.* (1974), *Reeves and Duguid* (1976), *Bruch* (1977), *Frind et. al.* (1977). In all of these studies nonlinearities were treated using standard Picard solution algorithm and the models were developed by Galerkin finite element method. To deal with wider range of field conditions, an improved Picard algorithm and a Newton-Raphson algorithm were used by *Huyakorn et. al*. (1984). *Cooley* (1983) used somewhat different sub-domain finite element method in combination with Newton-Raphson and strongly implicit procedure. *Allen and Murphy* (1986) introduced a finite element collocation technique for solving variably saturated flow in two space dimensions. The scheme used a mass-conservative formulation of Richards' equation as the basis for the finite difference time stepping method. *Panday et. al.* (1993) discussed recent advances in finite element modeling techniques for variably saturated flow problems. Although till now, a large number of numerical models in the finite element method have been developed, the number of models handling real problems is very few.

3. Status of Groundwater Modeling in Bangladesh

In Bangladesh several groundwater modeling exercises have been undertaken which can be classified as Single Cell models, Multiple Single Cell models and Multiple Cell Integrated Finite-difference models (MPO, 1987). The first groundwater model used in Bangladesh is in 1977 under BADC/IDA Tubewell Project. The BWDB/ UNDP (1984) water balance study also modeled the groundwater components. From 1983 to 1986, MPO designed a groundwater evaluation program within the National Water Plan (NWP) preparation schedule (MPO, 1987, 1991). RMP/ Montogomery in 1980 developed a finite-difference groundwater model, known as Parsons' model, for DWASA to assess the impact of additional groundwater abstraction from the aquifer systems in Dhaka city region (DWASA, 1991). In 1986 Solomon and Chidley used a United States Geographical Survey (USGS) model to assess the groundwater resources of Dhaka City (MPO, 1987, 1991). Lastly in 1991, the Dhaka region groundwater and subsidence model study, using integrated finite-difference method, was carried out for assessing the impact of proposed installation of 50 new and 10 replacement tubewells (DWASA, 1991). All of the mentioned studies used finite difference models and no finite element model was applied in the major groundwater studies of Bangladesh.

4. Methodology

Galerkin finite element method is used to develop a two-dimensional numerical algorithm for subsurface flow by solving the governing flow equation – the Richards equation (1931). A two-dimensional isothermal Darcian flow of water is considered, in a variably saturated rigid porous medium, assuming that the air phase plays an

insignificant role in the liquid flow process. A modified form of the van Genuchten's (1985) closed-form functions as proposed by Vogel and Cislerova (1988) is used to identify soil moisture characteristics in unsaturated zone.

The Richards' flow equation is obtained by combining Darcy's law with continuity equation, which gives

$$\frac{\partial}{\partial x_i}(K_{ij}\frac{\partial \phi}{\partial x_i}) = \frac{\partial \theta}{\partial t} + S \tag{1}$$

For a two-dimensional vertical soil profile, with the hydraulic conductivity decomposed, it reads:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x_i}\left[\mathrm{K}\left(\mathrm{K}_{ij}^{A}\frac{\partial h}{\partial x_j} + \mathrm{K}_{iz}^{A} \right)\right] - S \tag{2}$$

where θ (dimensionless) is the volumetric moisture content, h [L] is the pressure head, S[T^{-1}] is a sink term, x_i (i=1,2)[L] are the spatial coordinates, t [T] is the time, K^A_{ij} (dimensionless) are components of the anisotropy tensor K^A, and K [LT^{-1}] is a scalar unsaturated hydraulic conductivity function given by

$$K(h, x, z) = K_s(x, z)\, K_r(h, x, z) \tag{3}$$

where K_r (dimensionless) is the relative hydraulic conductivity and K_s is the saturated hydraulic conductivity. The anisotropy tensor K^A_{ij} in equation (2) is used to account for the direction-dependent hydraulic conductivity of the porous medium. The diagonal entries of K^A_{ij} equal one and the off-diagonal entries zero for an isotropic medium.

According to the Galerkin method, the approximate or trial solution in terms of pressure head $h(x, z)$ at any given time t can be expressed as a series summation of the products of the nodal pressure heads, h_n, and the associated nodal basis functions $U_e\xi_n^e(\mathrm{x}, \mathrm{z})$:

$$\begin{aligned}\hat{h}(x,z,t) &= \sum_{n=1}^{N} h_n(t) U_e \xi_n^e(x,z); \qquad n = 1,2,.....,N \\ &= \sum_{n=1}^{N} h_n(t)\phi_n(x_i)\end{aligned} \tag{4}$$

The values of h_n must be determined so as to satisfy the initial and boundary conditions of the problem together with the orthogonality requirement:

$$\sum_e \int_{\Omega^e} L(\hat{h})\xi_n^e d\Omega = 0; \qquad n = 1,2,.....,N \tag{5}$$

where Ω^e is the interior of e and L is differential operator of the governing flow equation.

The flow domain is sub-divided into a network of triangular elements with the corners of the triangles as nodes. The spatial discretization transforms the continuous partial differential equation into semidiscrete system of ordinary differential equations, which can be written in a matrix form as

$$[A_{nm}]\{h_m\} + F_{nm}\frac{d\{\theta_m\}}{dt} = \{Q_n\} - \{B_n\} - \{D_n\}; \qquad n, m = 1,2,.....,N \tag{6}$$

in which the elements of the matrices are

$$A_{nm} = \sum_e KK_{ij}^A \int_{\Omega^e} \frac{\partial \xi_n^e}{\partial x_i} \frac{\partial \xi_m^e}{\partial x_j} d\Omega \quad (7a)$$

$$F_{nm} = \delta_{nm} \sum_e \int_{\Omega^e} \xi_n^e d\Omega \quad (7b)$$

$$Q_n = -\sum_e \int_{\Gamma^e} \xi_n^e q d\Gamma \quad (7c)$$

$$B_n = \sum_e KK_{iz}^A \int_{\Omega^e} \frac{\partial \xi_n^e}{\partial x_i} d\Omega \quad (7d)$$

$$D_n = \sum_e \int_{\Omega^e} S \xi_n^e d\Omega \quad (7e)$$

A fully implicit finite difference scheme is used for time discretization and special treatment of the time derivative term is given to ensure mass conservation at each time step as proposed by Celia et al. (1990). An implicit (backward) finite difference scheme is used for both saturated and unsaturated conditions:

$$[F]\frac{\{\theta\}_{j+1} - \{\theta\}_j}{\Delta t_j} + [A]_{j+1}\{h\}_{j+1} = \{Q\}_{j+1} - \{B\}_{j+1} - \{D\}_{j+1} \quad (8)$$

where $(j+1)$ denotes the current time level at which the solution is being considered, j refers to the previous time level, and $\Delta t_j = t_{j+1} - t_j$. The above equation represents the final set of algebraic equations to be solved. Since the coefficients θ, A, B and D are functions of the dependent variable h, the set of equations is generally highly nonlinear. These equations are linearized by Picard iteration scheme and then solved by Gaussian elimination to find the unknown values.

Prior to solving the set of equations proper boundary conditions – system independent Dirichlet, Neuman and Mixed type boundary conditions and system dependent atmospheric and seepage face boundary conditions are incorporated in the model. The input data required to run the model are the material information, nodal information and the atmospheric information.

5. Application of the Model to a Dhaka City Aquifer

During the development and modifications of the different features of the model a number of familiar published problems (Simunek et. al.,1992) have been used to verify the algorithm. After satisfactory performance of all the cases, a real situation in the Dhaka City is simulated to analyze the model behavior.

The study area is located within the north central region of Bangladesh bounded by the rivers Jamuna, Ganges, Meghna and Old Brahmaputra. The study area is bounded by Tongi khal on the north, Buriganga on the west, Balu River on the east and by the District boundary on the south (Fig. 1). The model area covers approximately 320 km^2 and has been selected to cover DWASA's supply area and adjacent areas influenced by the groundwater abstraction. The ground elevation of Dhaka metropolitan area varies from 1m to 8m PWD (Public Works Department) sloping gradually from north to south with the average ground elevation of 4.5 m PWD.

Figure 1. Location of the Study Area

The average yearly rainfall in the study area is 2000 to 2200 mm based on the period April 1976 to March 1997. The long term mean for Dhaka city is 2040 mm per annum (MPO, 1987). Most of the annual rainfall, 80 to 90 percent, falls during the monsoon season from May to September (EPC, 1991). Temperature ranges from lows of about 10°C at night during December and January to daytime highs of over 35°C during April and May (EPC, 1991). Average monthly potential evapotranspiration of Dhaka City ranges from about 2.87 mm/day in January to about 6.25 mm/day in April with a yearly total of 1500 mm. During the monsoon season mean daily values are about 4.8 mm/day (EPC, 1991).

Lithological data of 66 discrete boreholes from Bangladesh Water Development Board (BWDB) have been used to describe the geology in the model. Thirty six of those are located in the Dhaka Metropolitan area. Borehole logs clearly show that the deposits underlying Dhaka are alluvial, heterogeneous and a certain degree of conceptualization is required to derive an operational model. Despite the occurrence of several interbedded layers it is possible to identify at least four major geological units: Upper aquitard (clay and silt), Upper aquifer (fine to medium sand), Lower aquitard (clay and silt), and Lower aquifer (medium to coarse sand).

DWASA have defined the saturated hydraulic conductivity of different zones of Dhaka region from a correlation between the results of pumping tests and lithological profiles. A distributed transmissivity map (Hossain, 1997) based on a number of aquifer tests carried out by DWASA shows transmissivity values in the range of 300-1200 m^2/day. Taking into account the saturated thickness of the layer, horizontal hydraulic conductivity and storage coefficient are calculated and subsequently interpolated to cover the entire model area. The vertical permeabilities are derived from the horizontal permeabilities by assigning (K_h/K_v) a value of anisotropy. Based on the mean anisotropic ratio evaluated by British Geological

Survey (BGS, 1998), ratio of 2.5 for the lower aquifer is adopted. For accurate characterization of the unsaturated soil behavior, a set of field data is required for moisture content, soil water suction and unsaturated hydraulic conductivity. But in the present study in absence of such field data a set of arbitrary fitting parameters is taken.

Observation well data indicates continually increasing abstraction caused the water levels in the Dhaka city aquifer to fall steadily over the last decades and have reached a maximum of over 20 to 25 meters in some areas. A total of 27 observation wells in and around the model area are available, out of which 11 are located within Dhaka City (Fig. 2). The groundwater level of Dhaka City exhibits a large fluctuation between monsoon and the dry season. The groundwater level is declining at a rate of approximately 1.2 m/yr. in Dhaka City. The declination rate is higher in Sabujbagh area (DHA019, DHA020) which is about 1.7 m/yr (DWASA, 1998). This may be due to the installation of deep tube wells (DTW) to keep pace with the rapid expansion of the residential areas. The lowest groundwater level was found in South Basabo (DHA020) which is about -26m PWD. The highest level was found in Maniknagar (DHA013) which is about -14m PWD. Both were found in the year 1996-97. The falling rate of water table is increasing gradually which indicates an alarming situation.

Figure 2. Location of Observation Wells

Based on the available input data the model area has been discretized into 500m grid squares in the horizontal plan. The total number of elements is 1263 and nodes are 1295. The west, east and north of the model area are bounded by the vertical planes passing through the axes of the Buriganga River, Balu river and Tongi khal respectively. As in the city side abstraction is enormously higher than the opposite side of the river obviously a high gradient towards the city from the opposite side of the river prevails. It is assumed that the river is hydraulically connected with the soil layers below its bed. Thus a time dependent Dirichlet boundary condition is imposed on west, east and north boundaries of the study area. No distinct natural condition exists along off-river boundary, i. e., the south boundary of the model area. An artificial time dependent Dirichlet boundary condition is imposed based on the observation well data and their interpolation values in the intermediate nodes. Except boundaries all other internal nodes are treated with atmospheric boundary condition.

Atmospheric data (mean daily precipitation and evaporation) (Fig. 3) and river water level data are collected from the central database of the Surface Water Modeling Center (SWMC) and BWDB. Daily rainfall data are collected for station R009 within the study area. Pan evaporation data for the period has been extracted from the E13 station. The piezometric and abstraction data for the area are collected from DWASA. There are 459 DTWs around the study area of which nearly 220 are located within the study area. A national DEM, based on 500m grid elevation data surveyed during 1960-64, is available covering most of Bangladesh. Dhaka metropolitan area as part of the FAP8A (1991) study, has been utilized.

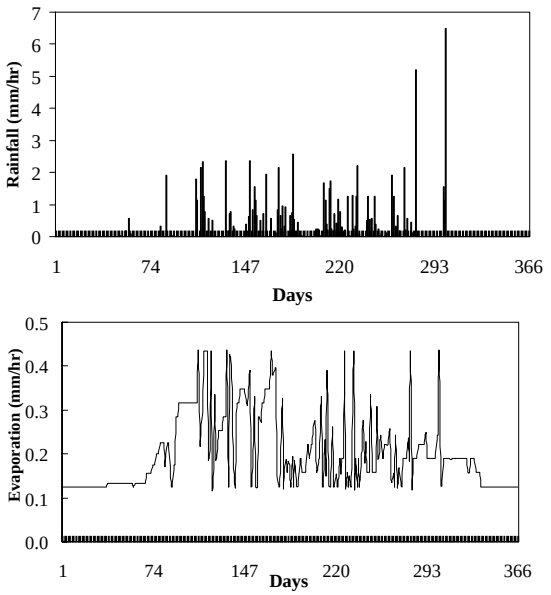

Figure 3. Hydrometeorological Input Data for the Study area for the year 1996

In Dhaka City the groundwater level in general is not affected by annual variations as the impermeable urbanized areas prevent any significant recharge by infiltration. Variations of up to 2m are, however, found for DHA009 at some points and for DHA010, DHA012 and DHA013 at one point each. The absence of annual variations is found both in observations and in simulations. The time series show a steady decrease as a response to increased abstraction in the area in general. The rate of decrease is in general captured very well by the model (DHA001, DHA005, DHA009, DHA011, DHA014, DHA019 and DHA020) while it is slightly underestimated in DHA010, DHA012, DHA013 and DHA021. A comparison between simulated and observed heads inside the study area is shown in Fig. 4.

Given the constraints in data the model calibration is satisfactory. The model is capable of simulating a correct average level and a correct rate of decline in groundwater levels. If more time is spent a closer fit between simulation and observation can be achieved, but more important an effort should be made to verify and complete the input data. After fulfilling the calibration requirement the water balance of the domain is shown in Table 1 for the time period January, 1996 to December, 1996.

Table 1 : Simulated Water Balance for the Model Area, 1996

Components	Volume (m^3)
Abstraction	2652.71×10^6
Atmospheric face (cumulative outward)	$^*1685.14 \times 10^6$
Rainfall	3597.52×10^6
Atmospheric face (cumulative inward)	255.92×10^6
Recharge	1610×10^6
Return flow from water supply	795.8×10^6

*Value indicates loss of water from the surface when no ponding of the surface exists, i. e., evaporation loss from the ponding water instantaneously after heavy precipitation is excluded.

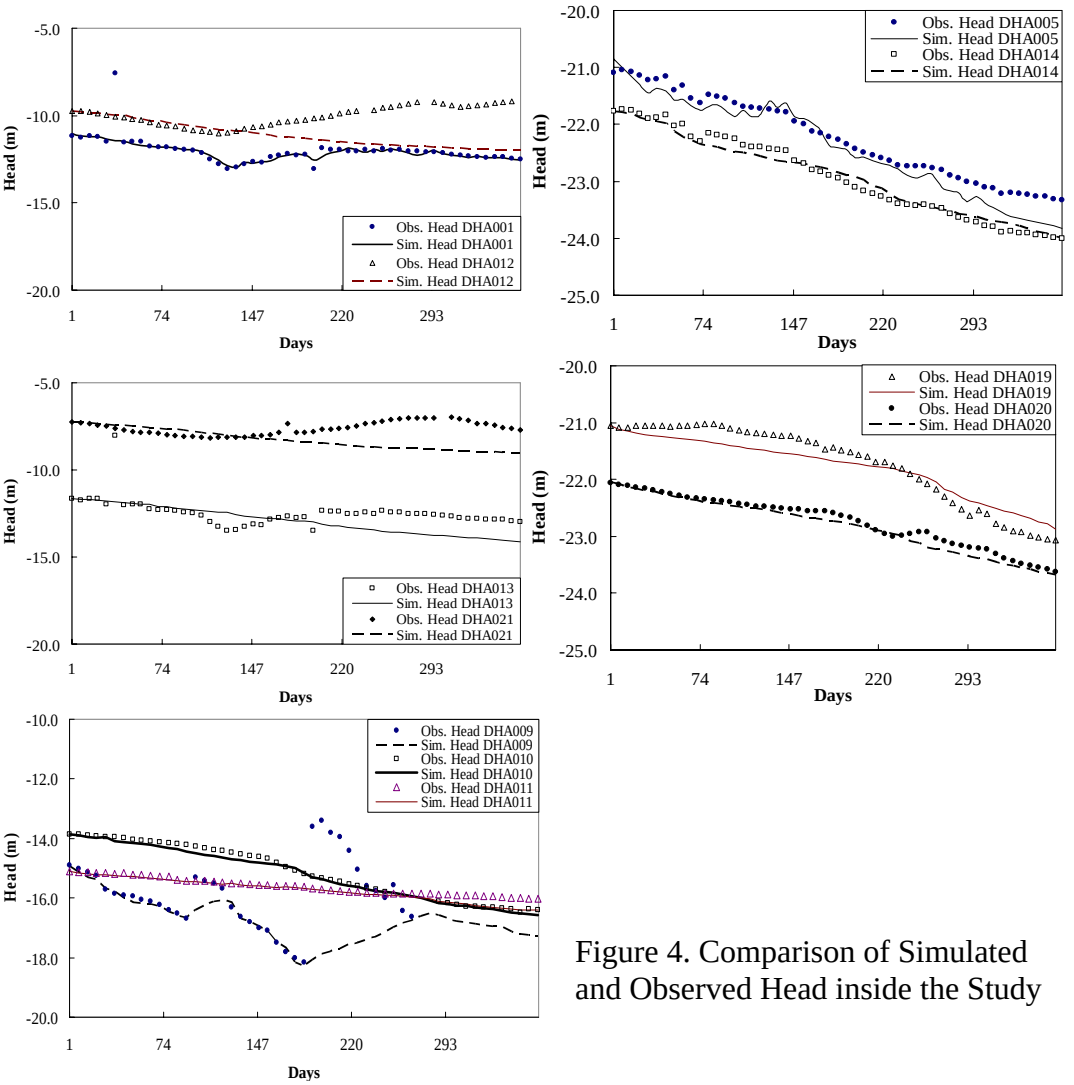

Figure 4. Comparison of Simulated and Observed Head inside the Study

The abstraction of water is mainly compensated in the domain by the boundary flow from the riverside, not only contributed from the river itself but from the high water table of the surrounding area. The volume of water entered to the soil domain from the direct precipitation is only 9.65 percent of the abstraction volume. Most part of the precipitation gets evaporated and lost by surface runoff due to the low hydraulic conductivity of the aquifer.

6. Graphical User Interface (GUI)

A GUI is designed and implemented using Object Oriented Programming language Visual Basic that makes the Fortran program operable in the 32-bit faster windows environment. Selected input and output windows are presented in Figures 5, 6 and 7.

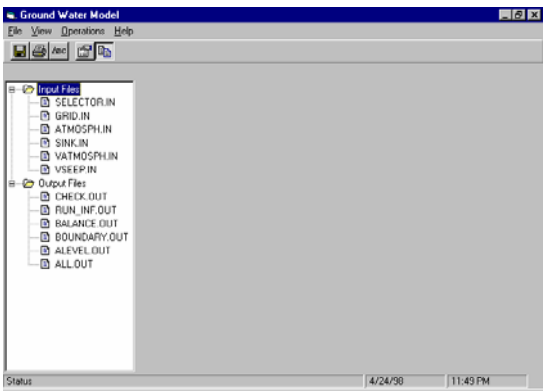

Figure 7. Interface Window that Triggers Different Function depending on User Event

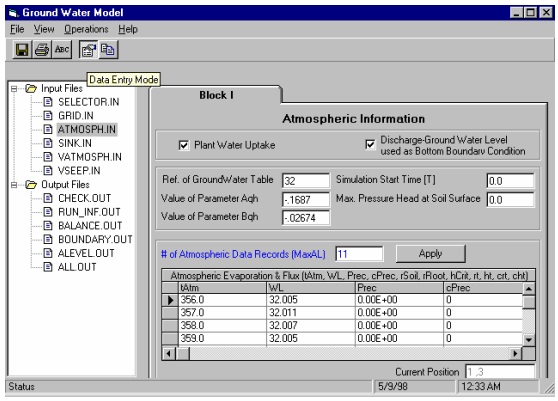

Figure 8. Input of Atmospheric Information in ATMOSPH.IN

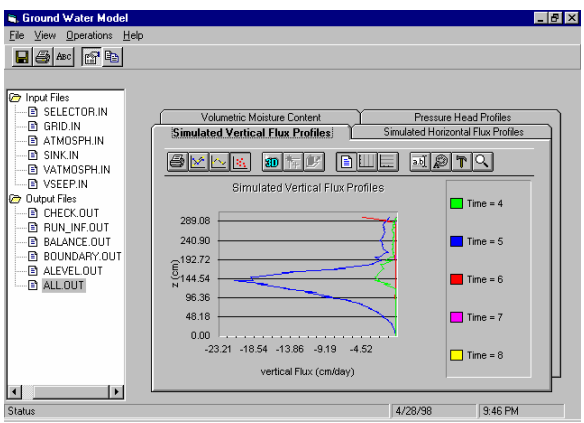

Figure 9. Simulated Vertical Flux Profiles for Selected Days

7. Conclusions

Different features incorporated in the model have been verified by simulating a number of published schematized problems. The model responses in simulating a complex real hydrogeological situation of a real city (Dhaka, Bangladesh) aquifer are reported. The boundary conditions of the domain are derived from the river water level and piezometric level data. Model calibration of the parameters has been performed under this study as well. Simulated water balance components identify the river effect as the most dominating recharge mechanism of the area, which contributes around sixty percent of the total volume of abstraction. Urban recharge (taken 30% of the total abstraction) also contributes to the abstraction volume of the area. The results of simulation show that the approach is fruitful and can be used for detailed study of the groundwater status of densely populated and growing cities like the Dhaka City in future.

The program is proved to work well but have a disadvantage of being associated with the time step of the atmospheric input data, which is usually one day. Shorter and/or automatically set time step for the atmospheric input data, as well as for the boundary-condition subroutines, is therefore recommended. A need has been also identified for yet more flexible treatment of combined and system-dependent boundary conditions (e.g. a combination of the variable atmospheric boundary condition with the variable seepage-face one) and for the coupling of the present model with a two-dimensional model of surface runoff in a flood plain.

A Methodology to Reconstruct Groundwater Contamination History with Limited Field Data[1]

Jiabao Guan[2], Morris L. Maslia[3], and Mustafa M. Aral[4]

Abstract

A health risk assessment of exposure to contaminants in drinking water frequently requires reconstructing the groundwater contamination history in aquifers. The development of groundwater flow and contaminant fate and transport models used in such an analysis is time-consuming and expensive. Therefore, new approaches need to be explored to reconstruct groundwater contamination history that may reduce the time and expense of the traditional numerical modeling approaches.

An ongoing health study at U.S. Marine Corps Base Camp Lejeune, North Carolina, will determine if an association exists between exposure to contaminated drinking water and birth defects and childhood cancers in children born to women who were pregnant while living at the base during the period 1968–1985. For this study, there are no field data on groundwater contamination at water-supply wells prior to 1985. Limited contaminant concentration data at several observation wells are available during and after 1992 when remedial investigations of the contaminated aquifers began. To assist the epidemiological study in determining historical exposure scenarios, groundwater contaminant history needs to be reconstructed at base housing areas. Interpreting the mathematical models that are used in the analysis of groundwater flow and contaminant fate and transport and using the field data available on contaminant levels, a linear control model is proposed for the purpose of reconstructing the historical exposure to contaminated groundwater. The control model includes two matrices: (i) the first matrix describes the system behavior of the contaminant movement in aquifers in a natural environment and, (ii) the second matrix reflects the effect of pumping operations on contaminant concentrations. In the control model, the system matrix is recognized by using the least-squares method and the effect of pumping operations is determined by using an optimization method and an improved genetic algorithm when solving for matrix coefficients. To test the proposed methodology and to demonstrate the effectiveness of the model and proposed algorithm, the Tarawa Terrace base housing area of Camp Lejeune, which has been modeled in detail, is chosen. Computational results show that the model proposed herein can be used as a screening method to recover

groundwater contamination history with reasonable accuracy considering the lack of data that may exist at many sites.

Key words: control model, least square method, genetic algorithm, groundwater contamination.

Introduction

An ongoing health study at U.S. Marine Corps Base Camp Lejeune, North Carolina (Figure 1), will determine if an association exists between exposure to contaminated drinking water and birth defects and childhood cancers in children born to women who were pregnant while living at the base during the period 1968–1985. In this situation there are no field data on groundwater contamination at water-supply wells prior to 1994. Limited contaminant concentration data at several observation wells are available after during and after 1992 when remedial investigations of the contaminated aquifers began. To assist the epidemiological study in determining historical exposure scenarios, groundwater contaminant history needs to be reconstructed at base housing areas. The traditional approach used to solve this problem is to develop groundwater flow and contaminant fate and transport models and then to apply them to a study area to obtain the contaminant concentration distribution in time and space. However, determining and calibrating model parameters, such as aquifer hydraulic conductivity distributions and boundary conditions, is time-consuming and expensive. Therefore, new approaches need to be explored to reconstruct groundwater contamination history. These new approaches should reduce the time and expense of the traditional numerical modeling approaches. In this paper, a linear control model is proposed to reconstruct the contamination history at the site. The control model consists of two linear parts: the first part describes the system behavior of contaminant movement in aquifers in a natural environment and the second part reflects the effect of pumping operations on contaminant concentrations. Both are expressed as matrices that are separately identified using optimization methods based on the available concentration records and pumping-schedule data. The Tarawa Terrace base housing area of Camp Lejeune which has been modeled in detail (*Maslia et al.* 2007), is used to demonstrate the effectiveness of the model and proposed algorithm described herein.

Control Model

Groundwater resources within the Hadnot Point base housing area at Camp Lejeune were contaminated by leaking landfills for more than 40 years. Contaminated water-supply wells ceased operations during 1994, but contaminant sources were not removed or remediated at the time. Pumping data for water-supply wells prior to 1994 are available, but there are no water-quality records. Some concentration data are available after 1994. For generality, it is assumed that the study period spans from the starting time t_0 to the terminal time T_f and t_a is the time at which the water-supply wells stopped operating. In the study domain there are n locations (water-supply and observation wells) where concentration distributions during the period $[t_a, T_f]$ are recorded, and m water-supply wells whose pumping rates are known within the period $[t_0, t_a]$. For consistency with control systems, the concentrations at observation wells are represented by the vector $X(t)$, denoted as $X(t) = [x_1(t), x_2(t), \ldots, x_n(t)]^T$, and the pumping rates at water-supply wells by $U(t)$, denoted as $U(t) = [u_1(t), u_2(t), \ldots, u_m(t)]^T$, where $x_i(t)$ is the concentration at location i in time t, $u_j(t)$ is the pumping rate at water-supply well j in time t. The concentration states at observation wells can be determined by the system behavior of the contaminant movement in aquifers in a natural environment and the effect of pumping operations. Therefore, the concentration states in the aquifer system can be approximately described by a discrete linear system state equation as

$$\begin{cases} X(k+1) = \mathbf{A}X(k) + \mathbf{B}U(k) \\ X(t_0) = X_0 \end{cases} \tag{1}$$

where $\boldsymbol{A}$ is the $n \times n$ matrix associated with aquifer parameters including contaminant source characteristics, $\boldsymbol{B}$ is the $n \times m$ matrix associated with pumping rates, X_0 is the initial concentration vector at observation wells —it is zero in general—and k is the time step or time stress period. In the model, the matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are unknown and require being identified using existing recorded data such as time series data of concentrations at observation wells and pumping rates at pumping wells. Once both matrices are identified, Equation (1) can be used to reconstruct the contaminant distribution in time and space.

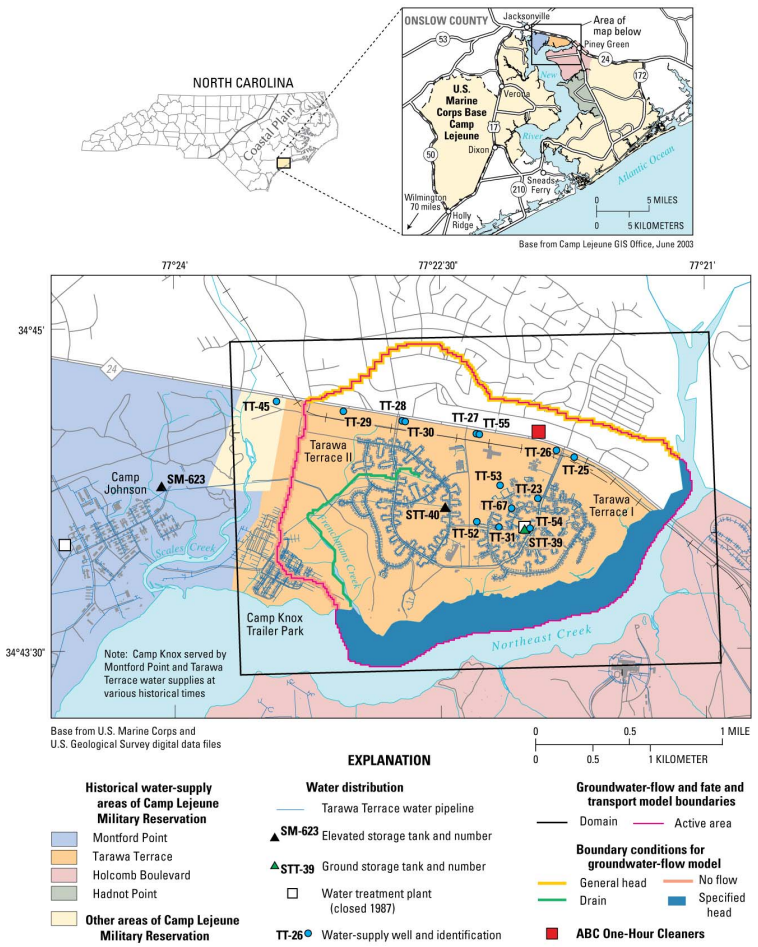

Figure 1. Water-supply areas, groundwater-flow modeling area, and water-supply facilities used for historical reconstruction analyses at Camp Lejeune.

Solution Algorithms

In order to reconstruct contamination history, the system equation described above needs to be recognized, i.e., matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ need to be identified. Based on available data, both matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ can be obtained using a two-step procedure.

Step 1: Since the pumping wells cease operation after t_a, the system states at observation sites depends on just the concentrations at previous time stress period. $\boldsymbol{A}$ can be identified by using the least-squares method based on the concentration data within $[t_a, T_f]$ (*Björck,* 1996).

Step 2: The concentration data are not available during $[t_0, t_a]$ and need to be reconstructed, the least square method cannot be used to estimate matrix $\boldsymbol{B}$. However, it is obvious that concentrations at t_a are both initial concentration distributions during $[t_a, T_f]$ and also a consequence of pumping operations during $[t_0, t_a]$. In some sites there are some additional internal concentration data points during $[t_0, t_a]$. Taking advantage of these concentration data together with the pumping rate data, the estimation of matrix $\boldsymbol{B}$ can be formulated as an optimization problem that finds the matrix $\boldsymbol{B}$ by minimizing the total error between the estimated and observed concentrations at t_a as well as internal data points. The optimization model is then solved by using a genetic algorithm (*Holland*, 1975, *Guan et al*., 2007).

Numerical Applications

In this paper, the Tarawa Terrace base housing area at Camp Lejeune is used as an example to demonstrate the effectiveness of the model and proposed algorithm. The Tarawa Terrace housing area at the Camp Lejeune was constructed during 1951. Drinking water, supplied to the family housing, was contaminated with volatile organic compounds (VOCs), mostly with tetrachloroethylene (PCE) and its degradation by-products. The contamination was linked to the release of PCE from the ABC One-Hour Cleaners (Figure 1) into the groundwater system (*Faye and Green*, 2007; *Jang and Aral*, 2007; *Maslia et al*., 2007). To assist the epidemiological study (*Jang and Aral*, 2007; *Maslia et al*., 2007), detailed groundwater-flow and contaminant fate and transport models in the area were developed by the Agency for Toxic Substances and Disease Registry (ATSDR) and the Georgia Institute of Technology, Multimedia Environmental Simulations Laboratory (*Maslia et al*., 2007; *Jang and Aral*, 2007). The groundwater system at Tarawa Terrace and vicinity was modeled as 12 aquifer layers (*Jang and Aral,* 2007). Fourteen water-supply wells supplied drinking water to the base housing area from the underlying aquifer system (Figure 1). Water-supply wells, TT-26, TT-53 and TT-67 significantly impacted contaminant spreading toward the base housing area. For verification purpose, the calibrated simulation models developed for the ATSDR study are used to calculate contaminant concentration distributions within the study domain. Aquifer parameters, boundary conditions, source characteristics used in the current study (this paper) are exactly same as those used in *Jang and Aral* (2007). The simulation period is from January 1951 through December 1994 and consists of 528 monthly stress periods. To demonstrate the effectiveness of the methodology proposed herein, three Tarawa Terrace water-supply wells—TT-26, TT-53, and TT-67—are selected to operate during 408 monthly stress periods (from January 1951 to December 1984) using pumping schedules described in *Jang and Aral* (2007). Also, it is assumed that pumping operations cease after stress period 408. Five nodes around the contaminant plume are used to test the model, which are nodes 102570, 103438, 103860 (TT-26), 104066 and 104892 in the 7^{th} layer and are closed to the contaminant source ABC Cleaners.

The resulting PCE concentration distributions at the aforementioned nodes are shown in Figure 2. The concentrations from stress period 408 to 528 (December 1984–December 1987) are used to identify system matrix ***A*** using the least-squares method. For identification of the coefficients of the matrix ***B***, two cases are presented. In case 1, only concentration data at stress period 408 (December 1984) are used and in case 2, 8 additional internal concentration data points from stress periods 1–408 are available and this concentration data along with the data at stress period 408 are used together. The PCE concentration distributions at five observation sites for cases 1 and 2, reconstructed using the identified system equation (1), are shown in Figures 3 and 4, respectively. In these figures, a solid line represents the reconstructed concentration distribution and a dashed line represents the measured concentration.

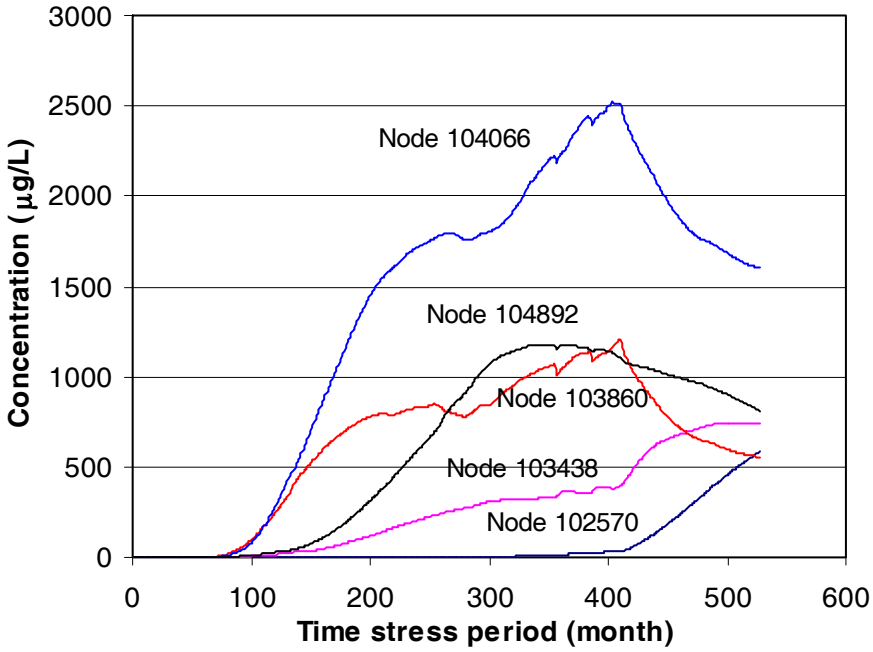

Figure 2. Resulting PCE concentration distributions in five nodes.

Results shown in Figure 3 (case 1, without additional internal data points), clearly show that the concentrations at stress period 408 are nearly identical to "measured" values. Overall, concentration distributions at observation nodes show good recovery, although some errors occur the estimation. Comparing each individual observation site, the concentrations at Node 104892 are best recovered. The maximum concentrations at Nodes 103860 and 104066 contain relatively large error compared to "measured" data. Considering the limited data availability, these results are encouraging and could be used with confidence for the epidemiological study.

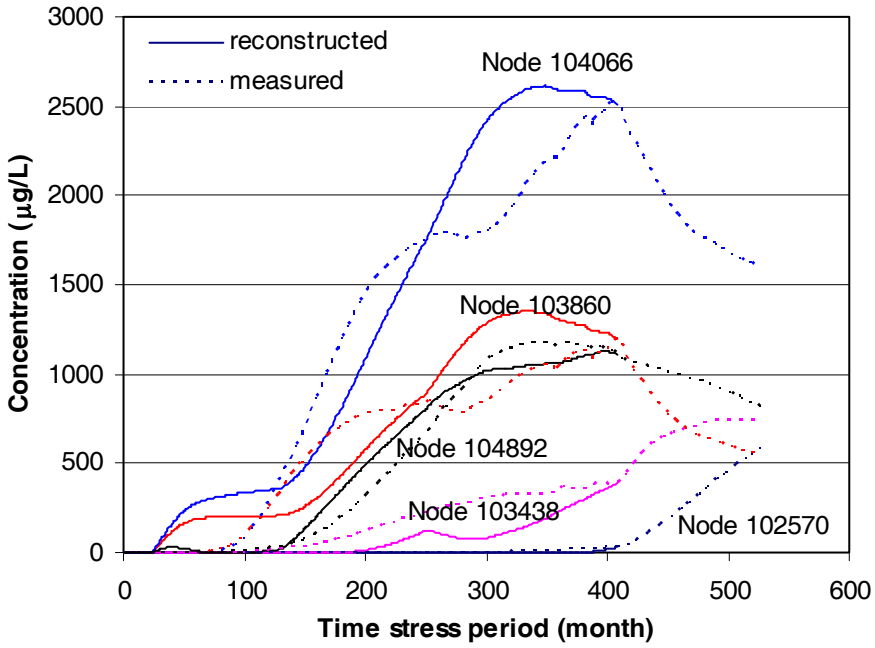

Figure 3. Concentration distributions recovered in case 1 (Without internal data points).

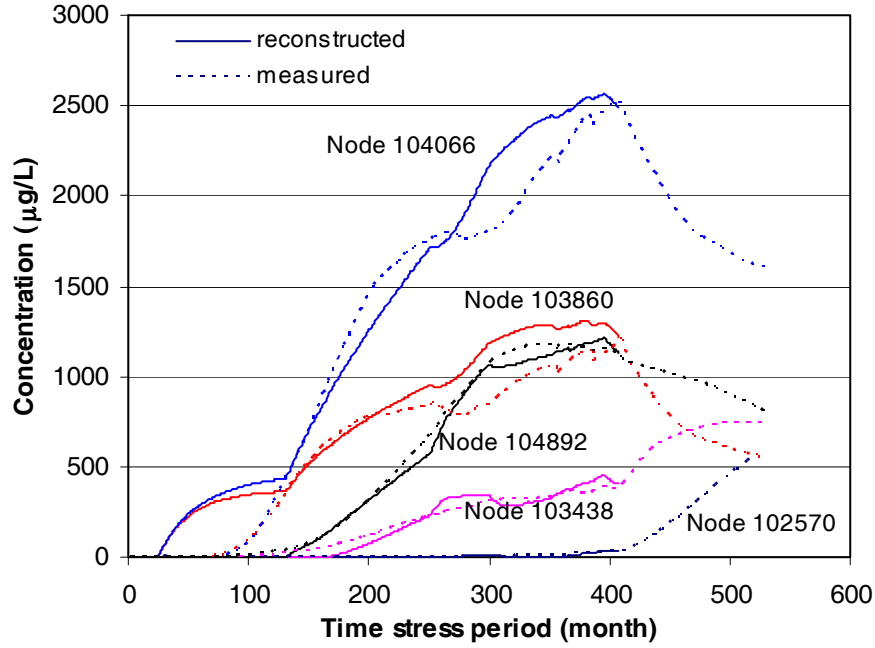

Figure 4. Concentration distributions recovered in Case 2 (With additional 8 internal data points).

If additional internal contaminant concentration data within stress periods 1–408 are available, the estimation accuracy may provide significant improvement. This is demonstrated in case 2 with the addition of 8 "measured" concentration data points within stress periods 1–408. For this scenario (case 2), calculation of the objective function value in optimization includes the additional internal concentrations in estimating coefficients of matrix $\boldsymbol{B}$. Comparing results shown in Figure 4 to those shown in Figure 3 indicates that concentrations distributions at all observation sites in Figure 4 (Case 2, 8 additional data points) are more closely reconstructed.

Conclusions

In this study a linear discrete system state equation is proposed to approximately describe the aquifer system in order to reconstruct the contamination history in the study domain. Compared to costly and time consuming groundwater-flow and contaminant fate and transport model development and calibration, the methodology proposed herein solely requires some measured concentration data at observation wells and water-supply well operation schedules to identify system and pumping effect matrices. The system and pumping effect matrices are determined by the least-squares method and a genetic algorithm, respectively. In this paper, the Tarawa Terrace base housing Camp Lejeune is used as an example to demonstrate the effectiveness of the proposed model and algorithm. The concentration distributions at the observation wells reconstructed from the control model provide a reasonable estimate of accuracy. This probably implies that the proposed model and algorithms provide an effective screening method for reconstructing groundwater contamination history when there are limited or missing historical contaminant concentration data.

TOPIC: 7th Symposium on Groundwater Hydrology, Quality, and Management
SUBTOPIC: Groundwater Quality and Human Health

Abstract

Rural public water supply systems represent the majority of systems in the U.S. Challenges facing the public water supply systems include documented water quality issues such as the presence of coliform bacteria and nitrate and urbanization resulting from development projects in the area. Strategies for dealing with these challenges can vary widely. This paper will present two case studies from a source water protection project being conducted in Central Texas. Both systems are privately owned, rural water system managed by a water supply corporation. Differences between the two systems arise in the populations they serve, with one being a community water system and the other being a non-community system serving a campground. The paper highlights the unique differences between the two systems in terms of implementation of protection measures as well as funding opportunities.

Introduction

Drinking water contamination in source water is a major issue across the nation, from lead contamination in Washington, D.C., Cryptosporidium contamination in Milwaukee to nitrate contamination in rural communities. While the implementation of the Safe Drinking Water Act has resulted in superior drinking water quality in many parts of our country, much room for improvement still exists.

One program US EPA has developed to prevent pollution of groundwater that serves as a source of drinking water for local communities is Source Water Assessment and Protection program. This program provides an opportunity to protect water sources by actively engaging in pollution prevention and engaging the local communities and water systems. Source water protection is a priority for the US EPA and for many states across the nation that have assumed primacy on implementing the program, including Texas (TCEQ, 1999).

This paper will present two case studies from a source water protection project being conducted in Central Texas: one rural system managed by a water supply corporation and the other a private owner/operator system for a campground. The paper will highlight the unique differences between the two systems in terms of potential sources of contamination (PSOCs) as well as implementation of protection measures and funding opportunities.

System #1 - Rural System Managed by a Water Supply Corporation

Water System Description

The first rural public water supply system serves a small city comprised of approximately 1,000 individuals located south of medium sized city in Caldwell County Texas. The system is a water supply corporation (WSC) and managed by a board of directors. Day to day operations are supervised by a WSC General Manager. The water supply serves a rural town with a population of 953 but also provides drinking water for some unincorporated portions of the county as well. Land uses in the community consist primarily of agricultural and residential lands. A small portion of the community consists of commercial land use.

Currently the system serves 860 active connections using two operational public supply wells to withdraw water from the San Marcos alluvium, an unconfined alluvial aquifer under the influence of surface water. The water is treated using a membrane process that injects the waste from the treatment process back into the aquifer via underground injection.

High levels of nitrates and atrazine have been detected in the source water in the past several years. These concentrations have been above the maximum contaminant limit and customers of the system are concerned about their water quality. Additionally, the system has also seen a number of source water samples test positive for total coliform.

Capture Zone Modeling

An early step in the project was to identify the land area that may pose a risk of contamination to a public water supply well. This land area is called a wellhead protection area (WHPA). Modeling to establish the WHPA was conducted using the Wellhead Analytic Element Model (WhAEM2000), a groundwater flow model distributed by the US EPA.

Modeling for this system took into account effects of hydrologic features such as rivers, recharge into the aquifer, aquifer properties, regional groundwater flow, and the effect of pumping of the city's public water supply wells on groundwater flow. The resulting WHPA covers approximately 2,000 acres across two counties, much of it

unincorporated. It is important to note that the WHPA for this system extends beyond its service area.

Potential Contaminant Source Inventory

After developing a WHPA, an inventory of potential sources of groundwater contamination was performed within the WHPA. A search of available environmental regulatory agency databases was conducted for the supply wells, adjoining properties and surrounding properties within a two-mile search radius. Following the database review, representatives from the study team performed a site visit to observe the condition of the existing system wells, identify potential sources of contamination (PSOCs).

The database searches and field inventory identified the potential sources of contamination shown in **Table 2** within the WHPA. Key PSOCs identified in the survey include septic tanks, abandoned water wells, two cemeteries, seven gravel mines, and two petroleum storage tanks. Field visits were limited to observations made using public right of ways; the field team did not enter private property. Therefore, not all PSOCs could be field verified.

Management Strategy

Potential sources of contamination should be managed to minimize the risks of ground water quality degradation within the WHPA. This can be accomplished by developing and implementing best management practices (BMPs) for the PSOCs.
BMPs were recommended for each of the potential sources of contamination described in **Table 1**above. In addition, non-PSOC specific management strategies were identified as well. A summary of the BMPs for this system are provided in **Table 2**.

Septic systems are considered a priority PSOC to address, because improperly maintained septic tanks may contribute to nitrate and coliform contamination of the water supply source water. The large number of septic systems in the WHPA may contribute to source water contamination for various reasons including improper location of the system, poor design, faulty construction, incorrect operation, and poor or no maintenance of the system. Another high priority BMP is investigating and establishing the extent of chemical usage at the two cemeteries in the WHPA. Herbicide and fertilizer use at cemeteries may contribute to source water contamination if improperly applied. Finally, education and outreach BMPs were also recommended for abandoned water wells and chemical using businesses.

PSOC	Quantity	Quantity Field Verified
Abandoned Landfills	2	2
Active/Abandoned Mines	7*	0
Abandoned Water Wells	2	2
Petroleum Storage Tank	2	2
Cemeteries	2	2
Chemical Storage	1	1
Class 5 Injection Well	1	1
Septic Tanks	200**	11
Cotton Gin	1	1
Grain Elevator	2	2
Auto Repair, Sales, Salvage and/or Towing	2	2
Wood Preserving	1	1
• Mines were located on private property and not accessible to the field team **Quantity estimated based on information provided by water supply system personnel		

Table 1
Summary of Potential Sources of Contamination for Rural Community Water System #1

PSOC	Recommended BMPs
Septic System	■ Develop a program to educate homeowners and businesses on septic system maintenance. ■ Provide information from this report to the city to encourage promulgation of a septic system maintenance ordinance. ■ Work with TCEQ and county staff to determine whether septic system inspections are current systems located within the WHPA and coordinate activities to undertake those inspections.
Cemeteries	■ Determine the status of cemetery maintenance. The system staff will contact the owners to determine if chemicals are used or stored on-site. ■ Discuss the SWAP program with cemetery owners and review maintenance activities with them to determine if herbicides and pesticides are being applied in correct amounts. Distribute educational material if applicable.
Abandoned Water Wells	■ Contact the owner, Texas Water Development Board and/or Texas Department of Licensing and Regulation to have wells capped or plugged.

Table 2
Best management practices for Rural Community Water System #1

Chemical using businesses	■ Determine the status of chemical usage. The system staff will contact the businesses to determine if chemicals are used or stored on-site as part of standard business practices. ■ Discuss the SWAP program with business owners. If chemicals are used or stored on-site, distribute applicable literature to the owner/operator.
Other Management Strategies	■ Identify a source water protection coordinator to be the main point of contact and act as a liaison and facilitate source water protection related communication with the city. ■ Form a local planning committee to work on source water protection activities, such as maintaining records of PSOCs and reviewing land use changes.

Table 2 continued
Best management practices for Rural Community Water System #1

Because implementing source water protection in Texas is voluntary and the water system has limited funding and no jurisdictional control over most issues as a water supply corporation, the BMPs listed in **Table 2** are focused on working with the local city and educating home owners. This makes implementing the program extremely challenging for the system. Community involvement and commitment to the Source Water Protection program is the key for success. Therefore, the study team also recommended establishing a local planning committee and source water protection coordinator to champion the program.

Funding opportunities

Adequate resources are needed for a water system to implement their Source Water Protection program. To support these efforts, the regulating agency, the Texas Commission on Environmental Quality (TCEQ) has provided assistance for one outreach event for each water supply system that has agreed to participate in a special Source Water Protection program. The outreach event requested by this system is to staff a booth at the community's Fourth of July celebration. The booth will have brochures and promotional items to educate and encourage residents to protect their source water.

Other funding sources, however, may also be available to a water system to support further implementation activities. The study team performed a search of applicable funding sources for source water protection activities. **Table 3** presents the funding assistance opportunities that were identified for the rural community's recommended BMPs. These funding sources are provided primarily by federal and state government programs focused on drinking water infrastructure. Some of these funding

BMP	BMP Implementation	Funding Availability	Funding Type
Septic Systems – Public Education	System staff	Y	Grants/Loans
Cap Abandoned Wells	Owner of Well	Y	Grants
Local Planning Committee	System staff	Y	Grant
Monitoring Plan	System staff	Y	Grants/Loans

Table 3
Funding Assistance Opportunities for Rural Community Water System #1

mechanisms would require the water system to work in cooperation with a nearby city to apply for funds. There is limited funding available from a nonprofit organization for developing a local planning committee, if the system cooperates with the City to apply for funding.

System #2 – Privately Managed Transient System at Campground

Water System Description

The second rural public water supply system serves a campground in Hays County, Texas. The campground supplies drinking water primarily to a transient (i.e., non-residential) population of recreational visitors, where peak times of use occur on weekends of the summer months. The campground contains 27 sites for recreational vehicles, 35 camping sites, an office, and public bathrooms and showers. In addition to the campground, the area also contains picnic areas, low-density rural residential housing, and undeveloped natural forest. The system is a privately managed system by a single owner who has a full-time operator on staff to handle day-to-day operations of the system.

The campground has one operational well and one emergency well and serves approximately 100 individuals at any given time. Both wells draw from the Trinity alluvial aquifer. The system has several documented problems with coliform bacteria.

Capture zone modeling was completed using the same approach as that for the rural community system. The resulting WHPA covers approximately 700 acres in a single county, all of it unincorporated.

Potential Contaminant Source Inventory

After developing a WHPA, an inventory of potential sources of groundwater contamination was performed within the WHPA. The database searches and field inventory identified the potential sources of contamination shown in **Table 4** within the

PSOC	Quantity	Quantity Field Verified
Septic Tanks	20**	4

Table 4
Summary of Potential Sources of Contamination for Rural System #2

WHPA. Few PSOCs were identified for this system but include septic tanks, chemical storage, and active water wells. Field visits were limited to observations made using public right of ways; the field team did not enter private property so not all PSOCs could be field verified.

Management Strategy

In conjunction with input from the water system, BMPs were recommended for each of the potential sources of contamination described in **Table 4** above along with general management strategies. A summary of the BMPs for this rural system is provided in **Table 5**.

PSOC	Recommended BMPs
Septic System	■ Continue to perform routine inspection and maintenance on the septic system located at the campground and maintain documentation of inspection and maintenance activities. ■ Educate homeowners in nearby subdivision on septic system maintenance. ■ Work with TCEQ and county staff to determine whether septic system inspections are current for systems located within the WHPA
Chemical Storage	■ Send a mail-out brochure or discuss with elevated storage tank owner the potential risks of petroleum storage tanks. Ask for regular inspections (quarterly or semi-annually) of tank and ground for signs of leaks. ■ Distribute an informational brochure on proper care of propane tanks to all campers when they register at the front office.

Table 5
Best management practices for Campground

Water Wells	■ Outreach to water well users in the subdivision near the campground should be performed and include education on regular well maintenance as well as proper procedures for capping wells that are no longer in use.
Other Management Strategies	■ Continue routine inspection and maintenance of public drinking water wells and maintain records of all inspection and maintenance activities; ■ Exercise care in disinfecting the source water to ensure that residual is maintained through distribution system; ■ Maintain and update records of potential sources of contamination within the WHPA on a routine basis. This includes a review of land use changes and potential sources of contamination.

Table 5 continued
Best management practices for Campground

The BMPs in **Table 5** describe management strategies to address the PSOCs in the WHPA. Septic systems are considered a priority PSOC to address, because improperly maintained septic tanks may contribute to coliform contamination of the water supply source waters. Septic systems, which are located at the campground itself and at neighboring homes, were considered to require BMPs most urgently because improperly maintained septic tanks may contribute to coliform contamination. Storage of chemicals for fuel, such as diesel, gasoline, or propane, either through elevated storage tanks or individual propane canisters, was another PSOC noted in the campground WHPA. The individual propane canisters are used by individual campers. BMPs for these PSOCs focus on education.

Management strategies within the WHPA are directed at all potential sources of contamination within the WHPA boundary. The WHPA is composed entirely of unincorporated areas and thus there is no city to provide jurisdictional support. In addition, septic system inspections are performed by the State in this area. Because this is a private water system supporting a transient population, there is limited opportunity for creating a source water protection planning committee. Therefore, the non-PSOC management strategies focus on drinking water supply well maintenance and record keeping tasks.

Funding opportunities

Funding for the implementation of source water protection activities at private water systems is minimal. The only readily available funding source for private systems is from the Texas Water Development Board through their Drinking Water State Revolving Fund. TCEQ, however, does provide an outreach activity at no cost to the system because of their involvement with the Source Water Protection program that

The outreach event requested by this system is to write and produce an educational brochure which will be handed out to all campers when they enter the campground. The brochure will discuss source water protection and recommend some simple BMPs that campers and RV owners can undertake while staying at the campground. These will focus on managing trash, chemicals, propane canisters, as well as gray water handling.

Discussion

Preliminary findings from investigations suggest that that the rural community water system (system #1) has a diverse set of potential contaminants of concern (PSOCs) while the campground PSOCs at system #2 are primarily related to septic systems, chemical storage and water wells. This difference in PSOCs is a result of the more diverse land uses found in the vicinity of small rural system.

Comparison of Best Management Practices

The BMPs for the system #1 included on a variety of PSOCs, including septic systems, cemeteries, businesses that use chemicals and abandoned water wells. This reflects the land use of the area with residential, agricultural, and commercial land. The campground system (#2), however, was located in a region that has low density residential housing and undeveloped natural forested areas and consequently had many fewer PSOCs, consisting only of septic systems, water wells, and different types of chemical storage.

The BMPs recommended for septic systems warrant an especially close look between the two systems. BMPs in both communities focus on education and outreach. The differences between the two, however, result from the jurisdictional authorities. In the rural community water system (system #1), the recommended BMPs include greater enforcement of existing regulations through inspection by regulatory agencies, and promulgation of septic system maintenance ordinances by the nearby city that has some jurisdictional authority over the WHPA for this system. The community system is afforded these options because of potential teaming with a neighboring town. The WHPA for system #2, on the other hand, is located in an entirely unincorporated area. Therefore, the BMP options are limited to increased maintenance of its own wastewater treatment system. It is important to note that neither water system has the direct ability to impose requirements to septic systems as the Texas Source Water Protection program is voluntary and does not have any enforcement ability.

Comparison of Funding Opportunities

The funding opportunities for the two water systems also exhibited differences. The community water system (system #1) has a greater breadth of opportunities available to

it as a result of potential partnerships with the local city and its status as a water supply corporation. The designation as a water supply corporation affords the system access to several Texas Water Development Fund financial assistance programs, such as the Rural Water Assistance Fund, Clean Water State Revolving Fund. Additionally, the opportunity to team with the city, a political subdivision, provides access to certain federal government programs, such as the Office of Rural Community affairs. The campground, on the other hand, is a private system and thus has very limited funding opportunities as a result of their private status and inability to team with other political subdivisions.

Giving priority to community systems may be intended to help a larger number of individuals, but this is not necessarily true in call cases. The campground serves several thousand customers over the course of a year, merely for a shorter period of time, but exposure to degraded water poses on equally serious health risk.

Conclusions

These findings suggest that community water systems face different challenges than privately owned transient systems. These disparities result from the differences in land uses patterns and associated contaminants that could reach the supply wells, and in funding availability. At the same time, some potential sources of contamination are consistent between the two, such as the presence of potentially failing septic systems. There are no simple solutions to the water quality issues facing either system due to limited funding. Both systems must undertake a dedicated public education and outreach effort to meet the challenges they face.

ABSTRACT

Arsenic contamination in groundwater in many countries, including India, has become an issue of global concern. After a relatively recent discovery of arsenic in the upper Brahmaputra floodplains, a Rapid Assessment Program for drinking water in Assam state of India covering all the districts was conducted. The study revealed presence of arsenic beyond permissible limit of 50 ppb in 72 blocks out of 192 blocks spread over 22 districts. A three phase analysis procedure adopted in this study yielded consistent results, showing good analytical performances for a large scale study. Of total 1726 samples spread across 18 districts, a major percentage of samples indicated concentration range of 60 to 150 ppb, emphasizing the need to take up intensive arsenic based research and to develop technologies and water management strategies to provide arsenic free drinking water in the region.

INTRODUCTION

Groundwater arsenic contamination and its impact is one of the most burning issues of global concern. Processes of arsenic mobilization from its source to groundwater are mainly either natural or anthropogenic. Among the anthropogenic causes, activities resulting in discharge of untreated industrial, effluents from metallurgical operations, ceramic, dye and pesticides manufacturing industries, petroleum refinery etc. into water sources are the prime causes of increased arsenic levels in surface and groundwater. However, as regards the geogenic causes, it is ubiquitous in the natural environment. In nature, there are 150 species of As bearing minerals, however, only 3 of them, i.e., As sulphide or Realgar (As_2S_2), as tri-sulphide or orpiment (As_2S_3) and Arsenopyrite or ferrous As sulphide ($FeAsS_2$) are considered as As ore because the amount of As is higher in these three compounds (Harvey, 2006). The main ores of arsenic are Arsenopyrite, Orpiment, Realgar and Arsenopalledenite and is present in nature as iron arsenate, iron sulphate, and in calcareous soils as calcareous arsenolite.
In general, the presence of arsenic depends on the hydro-chemical characteristics of groundwater aquifers, presence of oxidized/ reduced mineral phases and arsenic rich solid phases (Moore et al, 1988; Huang et al, 1994), and they occur principally in the form of inorganic or organic compounds, with arsenite (more toxic form) and

arsenates (less toxic form) constituting the inorganic compounds (WHO Guidelines for Drinking Water Quality,2004). Arsenic can occur in the environment in four different oxidation states (-3, 0, +3, +5) but in natural waters it is mostly found in the inorganic form as oxyanions of trivalent arsenite, As (+3) or pentavelent arsenate, As (+5). In the natural waters of pH ranging from 5 to 9, the predominant species of arsenic are $H_2AsO_4^-$ (lower pH) and $HAsO_4^{-2}$ (higher pH) in +5 (Arsenate state), which is more common in aerobic surface water and H_3AsO_3 in +3 (Arsenite) state, which can be found in anaerobic groundwater (Panthi et al, 2006).

Arsenic contamination in drinking water is a public health issue worldwide. The catastrophic health problems caused due to consumption of arsenic affected water in Bangladesh and West Bengal, India have been in the front page and mass media for more than a decade, the problem being described as the "greatest mass poisoning in history". A total of 9 districts in West Bengal, India with a population of 42.7 million and 42 districts in Bangladesh with a population of 79.9 million have arsenic levels in groundwater above the permissible limits of 50 g/L (Uttam K. et al, 2000). Elevated levels of Arsenic have also been reported in water supplies of communities in Argentina, Austria, Brazil, Canada, China, Ghana, Greece, Hungary, Iceland, India, Japan, Korea, Malaysia, Region Lagunera (Torreon, Mexico), Inner Mongolia, Nepal, Romania, Taiwan, Vitenam, Zimbabwe, and the U.S., with the worst sufferings of the people being reported Bangladesh, West Bengal in India, Inner Mongolia and Xin-Xiang Provinces of People's Republic of China and Taiwan in order of their magnitude. Numerous scientific papers (Ahmed et al., 2005, Ahmed et al., 2004, Horneman et al., 2004, Zheng et al., 2004, Nan Green et al., 2003 , Harvey et al., 2002, Fazal et al ., 2001a, Fazal et al., 2001b, Karimk, 2000, Kamal and Karim, 2000, Begum and Karim, 2000, Hossain et al., 2000, Adel, 2000, Bridge and Husain, 1999, Bridge and Husain, 2000a, Bridge and Husain , 2000b; Karim and Badruzzamann, 1999; Chowdhury et al., 1999, Kamal et al., 1999, Nickson et al., 1998, Nickson et al., 2000, Khalequzzaman, 1999, Ullah, 1998 and Karim et al., 1997) and many organizations have implemented different Arsenic programs and revealed the extent and severity of the problem.

The arsenic contamination in groundwater of northeastern region of India (Assam, Tripura, Manipur, Arunachal Pradesh and Nagaland), the largest storehouse of replenishing freshwater, has been reported by Singh (2004); with maximum arsenic concentration being observed in Johrat, Dhemaji, Golaghat and Lakhimpur districts in the state of Assam; West Tripura, Dhalai and North Tripura districts in the state of Tripura; Thuobal in Manipur; Dibang Valley in Arunachal Pradesh and Mokokchung and Mon districts in the state of Nagaland. Although there have been no clinical manifestations of Arsenicosis in the region (UNESCO, 2005) there could be a likelihood where such manifestation can occur due to the consumption of arsenic contaminated water; because natural springs and dug wells are the only cost effective and viable means of fulfilling the water needs for the people dwelling in this region. Arsenic interferes with a number of essential physiological activities, including the actions of enzymes, essential cations and transcriptional events in cells; including cancer of the skin, kidney, lung and bladder as well as other diseases of the skin,

neurological and cardiovascular system. It is in fact classified as a Class 1 human carcinogen by the USEPA.

Studies around the globe have well documented the impacts that arsenic enriched water has caused to the people in Bangladesh and West Bengal, India (Bhattacharya et al, 1997; Chowdhury, T. R., et al; Chowdhury, U.K. et al, 2000a, b; Chakraborti et al; 2002, 2003, 2004). Recent studies by Chakraborti et al (2004) and Mukherjee et al (2006) has shown that the As occurrence in this region is of geogenic origin and as the sedimentological history of the Brahmaputra valley in Assam is similar to that in Bangladesh, it is thought that the problem would be of similar nature in Assam. With the alarming threat to the people in these areas, it has become utmost important to carry out studies pertaining to the source, distribution, and the magnitude of the problem and thereby provide appropriate means and raise community awareness about the health problems related to chronic As exposure. The aim here is to report the first region-wide picture of arsenic concentrations in groundwater of Brahmaputra valley and to compile and evaluate these analytical results. This information can then be used for a number of purposes, from protection of human health to gaining a better understanding of arsenic geochemistry in regional groundwater.

STUDY AREA

Situated between latitude of 24° - 28° N and longitude of 90° - 96° E, Assam, the landmark state marks the gateway to the northeastern part of India, with three distinct physical units, the Brahmaputra valley in the north along with its vast floodplains, the Barak valley in the narrow protruding south and the hilly region separating the two valleys. With a total of 23 districts - Nalbari, Barpeta, Bongaigaon, Darrang, Dhemaji, Dhubri, Dibrugarh, Goalpara, Lakhimpur, Karbi Anglong, (in the northern bank of the Brahmaputra Floodplain) Nagaon, Sivsagar, Sonitpur, Tinsukia, Golaghat, Jorhat, Karimganj, Kokrajar, Morigaon, Kamrup (in the southern bank of the Brahmaputra Floodplain), Hailakandi, Karimganj, Cachar, North Cachar Hills (in the Barak Valley) and its 192 blocks, it forms an integral part of the Brahmaputra floodplain. With a total length of about 2,900 kms and a drainage basin covering an area of 1.6×10^6 sq. km, the Brahmaputra is the fifth largest river in terms of average discharge at mouth, and a flow of 19,830 m^3s^{-1} (Goswami 1985). The Brahmaputra Basin in Assam is confined by the eastern Himalayas in the north and east, the Patkai and Naga Hills on the northeast and Mikir Hills and Shillong Plateau in the south. The oldest (Precambrian) rocks are exposed in the Shillong Plateau and Mikir Hills and on the northern side the alluvial plains of Assam abuts against the Shiwalik ridge of the Himalayas, which are in turn overlain by highly tectonized Paleozoic sediments. Further on the southeastern part of the alluvial plain the Tertiary rock sequence occurs in Naga and Patkai hills which are overlain by the Quaternary sediments (Older Alluvium). The Recent sediments in the Brahmaputra Valley were deposited as alluvial fan and floodplain sediments of the Brahmaputra and its several tributaries (Evans, 1932 and Mathur and Evans, 1964). Figure 1 shows the study area under consideration including the districts of Assam state in India.

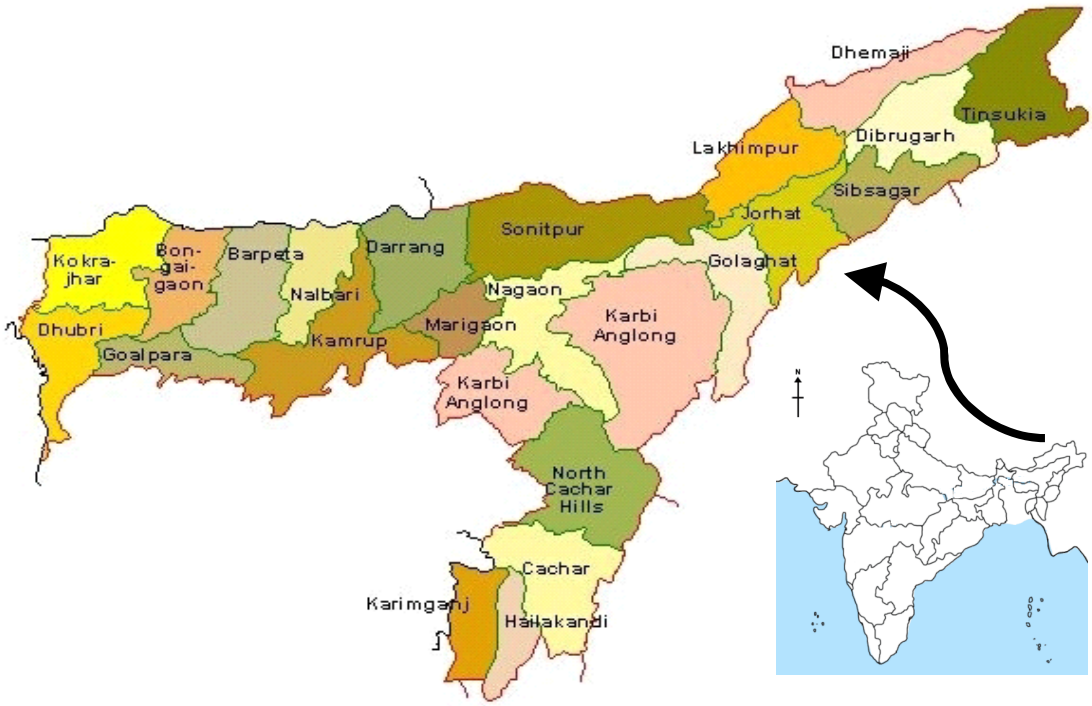

Figure 1. Map of the study area showing different districts of Assam, India

MATERIALS AND METHODS

The project is a joint effort by the United Nations Children's Fund (UNICEF) and Public Health Engineering Department (PHED) of Assam, in collaboration with Indian Institute of Technology (IIT), Guwahati, to study the arsenic problem in Assam, India. A total of around 5,729 samples, from 192 blocks spread across 22 districts were tested for the presence of arsenic. Concentration of arsenic in groundwater sources were determined by a three phase analysis - at the sampling site using an Arsenator, then analyzing 10% of the random samples and all samples showing concentrations of more than 40 ppb using the UV-1 Spectrophotometer (using wavelength of 550 nm and a band width of 2.0 mm) and finally 10% of the samples tested in UV-1 were tested using the Atomic Absorption Spectrophotometer (AAS) for confirmatory test. The Hydride generator method for arsenic analysis in the Atomic Absorption Spectrophotometer (HG-AAS) was used for this.

Water samples from PHED installed tube wells were collected at 200 ml sampling bottles with liner and screw caps and 1 ml dilute Nitric acid or Hydrochloric acid in the ratio 1:1 was added to maintain the pH below 2 and to prevent precipitation of iron and co-precipitation of arsenic. Prior to sample collection the tube wells were pumped for 10 minutes to remove any stagnant water from the water tanks to ensure that only fresh water samples were collected.

RESULTS AND DISCUSSION

A previous study conducted by the current authors including the Bongaigaon and Darrang districts of Assam, India indicated a high risk of groundwater arsenic contamination (Mahanta et al. 2008). During that study out of 50 sampled groundwater wells 15 wells indicated an arsenic concentration above the national drinking standard of 50 µg/l, and 33 had concentrations above the WHO guideline of 10 µg/l. However, no distinct depths/zones, sedimentological features or water chemistry were identified to produce arsenic enriched groundwater. After the initial, reports of excess arsenic in groundwater in Dhubri, Karimganj, and Dhemaji districts by the PHED, Assam a Rapid Assessment of water quality for arsenic and fluoride was conducted by PHED with support from UNICEF. Extensive sampling was done at different locations around the state to understand the source, spread and mobilization mechanism of As in groundwater of the region. The test results of district wise sampling for As and the affected blocks are shown in Table 1.

Table 1. Test results of district wise samples with Arsenic in groundwater and the affected blocks as found during the Rapid Assessment by PHED in 2005

District Name	Distribution of samples having presence of As at different levels (mg/l)			Number of affected blocks
	< 0.01	0.01-<0.05	> 0.05

Nagaon	258	55	01	01
Karbi Anglong	126	02	_	NIL
Total	4216	1151	362	72

A total of 5,729 samples, from 192 blocks spread across 22 districts were tested for the presence of arsenic. The test results indicated that 72 blocks out of the total 192 blocks were reported to have arsenic beyond the permissible limits of 50 ppb. This implies a grave risk to the public health of the region. With the excess use of groundwater for drinking and irrigation purposes, weathering would increase with the downward groundwater flow. So far no signs of arsenicosis have been documented in Assam. However, there is scope for research why this is so. Sand filters are extensively used in Assam and are used to reduce the wide spread high iron content from water. This seem to reduce the As content too through adsorption and co-precipitation. Arsenic rich water is also partly avoided since the drillers seek water low in iron, which often also has low arsenic content.

District wise categorization of samples for different concentration ranges for a total number of 1738 samples with the Atomic Absorption Spectrophotometer (AAS) shows major percentage of samples falling in the concentration range of (60-100) ppb and (100-150) ppb, while for three districts (Kamrup, Morigaon and Nagaon, located in the southern bank of the Brahmaputra floodplain) the percentage of samples in the concentration range of (0-40) ppb were found to be much higher. The district wise categorizations of the samples under the different concentration ranges are shown in figure 2 (a, b). Concentrations of more than 300 ppb are also observed in 9 districts although the percentage of samples occurring in this category is very low, with the highest percentage of 4% in Jorhat in the Southern bank and Cachar in the Barak Valley.

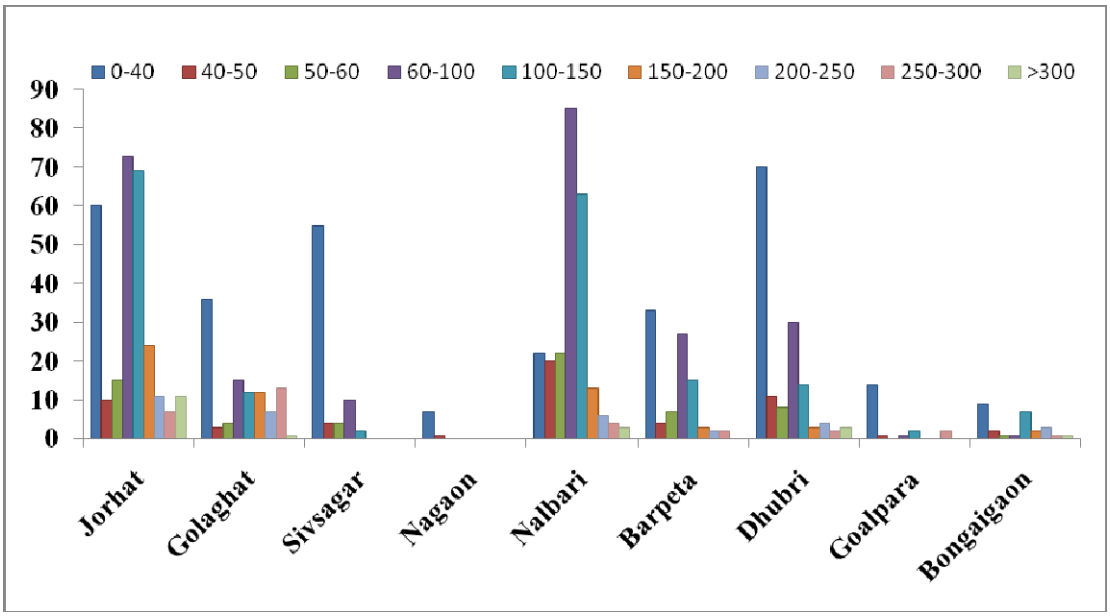

Figure (2a): District wise categorization of samples under particular range (in ppb) after analysis with AAS

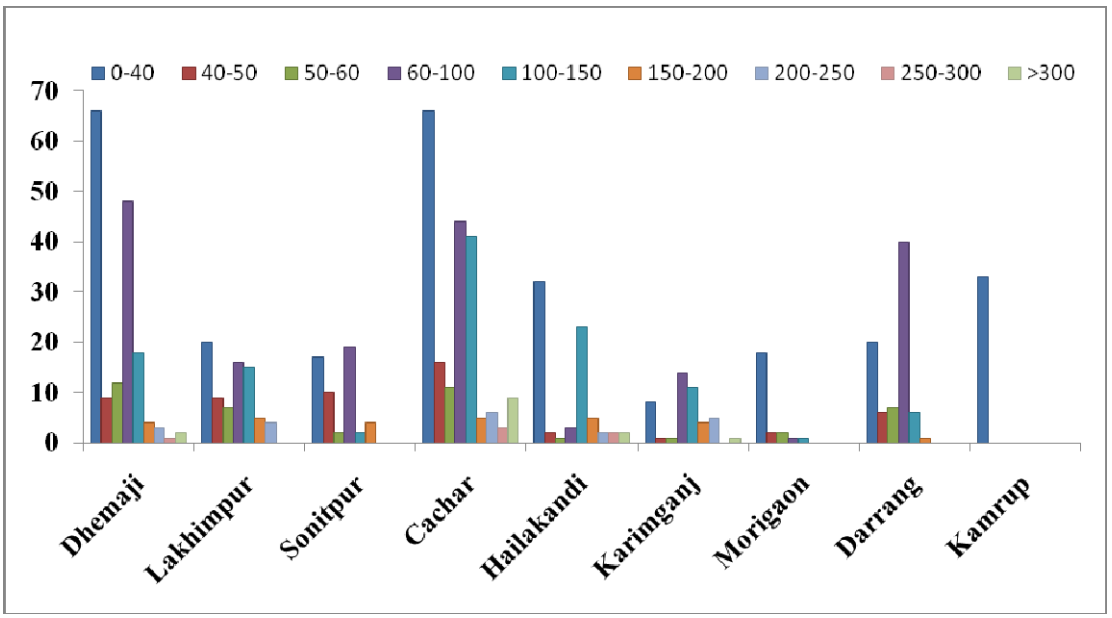

Figure (2b): District wise categorization of samples under particular range (in ppb) after analysis with AAS

The Brahmaputra floodplain bears a close similarity to the hydro- geologic set up of the floodplains in Bangladesh. Therefore, the occurrence of arsenic concentration above the permissible limit of 50 ppb is not unexpected. The locations in this study where the percentage of occurrence of arsenic concentration within the ranges of (60-100) ppb and (100-150) ppb are higher are on or very close to the floodplains. These areas are mainly composed of the recent alluvium, and studies (Smedley, 2005) have shown that most of the areas with arsenic contamination are of Quaternary age. Studies have indicated that the vast tract of Indo-Gangetic alluvium extending further to the west and the Brahmaputra alluvium, both have elevated concentrations of As in wells placed in the late Quaternary and Holocene aquifers. Arsenic released during the weathering of sulphide minerals is generally adsorbed onto the surface of iron oxyhydroxides that precipitated under oxidizing conditions generally prevailing during the deposition of the Holocene sediments. Recent research have also established that bed rock geology also plays an important role (Grosz et al, 2004) and the rapid erosion associated with active tectonics (e.g. the Himalayas) or glacial expedited Holocene weathering of Arsenic bearing minerals also contributes to the enrichment of arsenic in the groundwater (Saunders et al, 2005). A large local variations in As concentrations are probably due to the heterogeneity of the sediments and the resulting variations in redox conditions as well as possible remobilization due to periodic seismic events.

CONCLUSIONS

From the three phase study based on analysis with three instruments i.e. Arsenator, UV Spectrophotometer and AAS, the following can be concluded:

- The Arsenic enrichment in groundwater of some of the affected districts reflects concentration range much above the permissible limit of 50 ppb, suggesting the region to be seriously affected with arsenic contamination.
- The variation in concentration in different districts is probably due to heterogeneity of the sediments and their diverse location in the floodplain.
- Source is mainly considered to be geogenic, as the floodplain is composed of recent alluviums which are generally proved source of arsenic contamination and since there is limited arsenic contributing anthropogenic sources.
- Although no case of arsenicosis has been documented so far in the region, research based studies needs to be taken up to develop technological and remedial measures that best fit the region, to provide safe water to the people in the region.
- The success of the current three tier methodology suggests that this approach can be an effective tool for similar study to be taken up in other arsenic affected areas so far the agreement of the analytical instruments are concerned.

ABSTRACT

Using data from previous studies about nitrate contamination in Agua Dulce, CA and the numerical modeling program HYDRUS-1D, nitrate transport in the vadose zone associated with septic system discharges was evaluated. Thirty-six modeling scenarios were assessed and the results analyzed. With soil borings less than 6 m deep, steady state nitrate transport within the system is reached within 200 days, while steady state is not reached with the deeper boring within 500 days. The modeling results show that the nitrate concentration plume is less than the maximum contaminant level (MCL) of 10 mg/L within 1.3 m below the septic leachfield in all scenarios. The analysis of the fully-mixed tank scenario clearly shows that nitrate concentrations in groundwater are of greater concern during drought conditions. These findings help explain the pattern of nitrate concentrations observed in the aquifer system in this region.

I. Introduction

Septic systems service approximately 23 percent of homes in the United States [*EPA*, 2002], primarily in suburban and rural areas. In some areas entire communities are serviced by septic systems, forming areas with high septic system densities. Communities that have septic systems also often use private wells as their drinking water supply source rather than a public water supply. This leads to public concern regarding the drinking water quality, as septic system effluent recharges groundwater, and private wells can potentially extract contaminated water. Older or poorly designed septic systems can surcharge effluent to the ground surface or readily transport contaminants to the groundwater [*Bouma*, 1975], thus increasing the risks of adverse health effects due to elevated contaminant levels.

Nitrogen is one of the contaminants about which there is the most public concern as it can cause accelerated eutrophication in open water bodies [*Beal et al.*, 2005] and can negatively affect human health. Because of these concerns, the United States Environmental Protection Agency (EPA) established the regulatory limit for nitrate in drinking water, known as the maximum contaminant level (MCL), at 10 mg/L (measured as NO_3-N).

Although nitrate occurs naturally in many environments, anthropogenic activity also increases nitrate levels in groundwater. Point and diffuse sources such as agricultural areas, livestock manure, and septic systems are some of the most common anthropogenic sources of nitrate. Factors that influence the effect of septic systems on groundwater include the density of septic systems, lot size, soil type, depth to groundwater, location of drinking water wells, local groundwater recharge, and hydraulic conductivity [*Beal et al.*, 2005; *EPA*, 2002]. Numerical models can be used to evaluate how contaminants such as nitrogen travel through the vadose zone between the septic leachfield and groundwater. The model HYDRUS-1D (Simunek et al. 2005) has been used to model water movement through unsaturated soil [*Pang et al.*, 2006; *Hu et al.*, 2007; *Ndiaye et al.*, 2006; *Pachepsky et al*, 2006] and can be applied to simulate nitrate transport.

Increased levels of nitrate in the Sierra Pelona Groundwater Basin near Agua Dulce, located near Los Angeles, CA were detected in drinking water from private wells since the early 1980s. Through various research investigations into the source of the nitrate contamination, the private domestic septic systems in this rural area faced additional scrutiny. Could the septic systems be the cause of the increased nitrate levels? Additional investigations were undertaken in the mid-1990s, and the need for a public wastewater treatment plant was hotly debated at town meetings.

The proposal to build a wastewater treatment plant and associated sewer system was eventually defeated by the community in 1996 due to concerns over cost and questions about the source of the nitrate. This paper uses site-specific soil data from previous investigations and the HYDRUS-1D computer program to numerically model water and nitrate in the vadose zone, and assesses whether the reasoning behind the community's decision was sound.

II. Site Information

Agua Dulce is a relatively rural area despite its close proximity to Los Angeles. It covers approximately 44.5 km^2 and all homes are served by on-site private septic systems and private drinking water wells. Nitrate levels in groundwater have been a contentious and sensitive topic in Agua Dulce for many years.

Agua Dulce has an arid, Mediterranean climate [*Bailey*, 1966] in the foothills of the San Gabriel Mountains. This area, known as the Sierra Pelona Valley, is underlain by two groundwater source regions. The groundwater in the south-central part of the watershed comes from an alluvial aquifer which is greater than 50 m thick. This is the most densely populated section of the watershed and is shown on Figure 1 between the Mint Canyon fault and the Elkhorn fault. In the higher elevations, there is either no alluvium or the alluvium is above the groundwater table; in these areas groundwater develops in fractures in the underlying crystalline rock. Groundwater is recharged throughout the watershed primarily through rainfall percolation following rainstorms and irrigation [*Williams et al.*, 1998a].

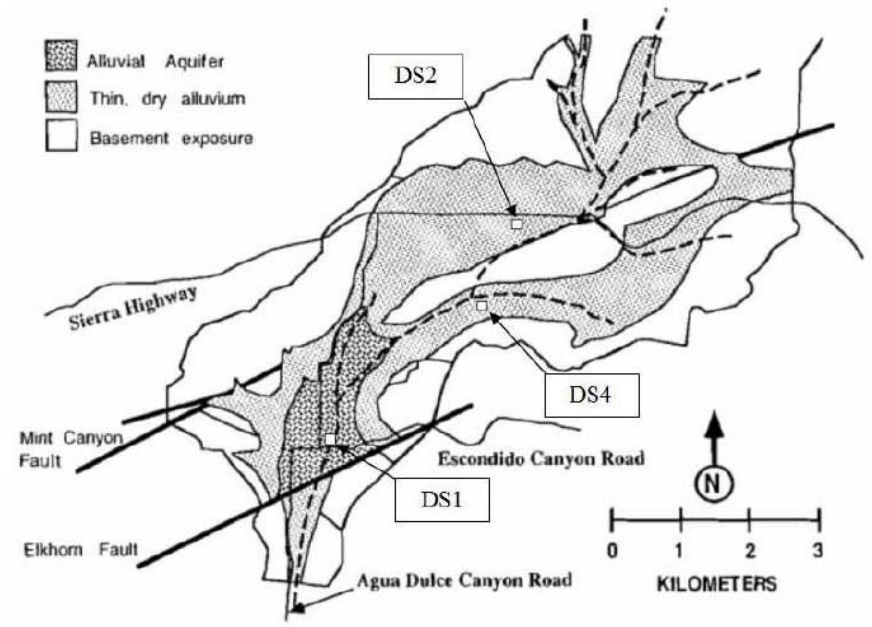

Figure 1: Hydrogeologic map of Agua Dulce with drill site locations

As part of the UCR study, soil borings were advanced at four sites in 1993 and 1994, representing the various land uses in the Sierra Pelona Valley. The groundwater table below Drill Site 1 (DS1) is shallow, and nitrate concentrations are known to be moderate to high, most likely due to anthropogenic influences since the area has been residential for many years. Groundwater at Drill Site 2 (DS2) has high nitrate concentrations. Groundwater beneath this site has been produced from fractured granitic bedrock beneath the thin alluvium of the Agua Dulce Canyon. This area is low density residential. Drill Site 4 (DS4) is located in an area with an alluviual aquifer and a thick vadose zone. The area was previously used for agricultural and animal pens and does not currently have any residential use. Locations of DS1, DS2, and DS4 are shown on Figure 1.

Soil profiles from DS1, DS2, and DS4 were evaluated as part of this research. Several soil borings were advanced at each drill site, and one boring from each drill site was investigated further. Using the soil boring designations from the UCR report, these three borings are labeled #1.4 (from DS1), #2.3 (from DS2), and #4.3 (from DS4).

a. Previous Work

Los Angeles County began evaluating the quantity of nitrates in groundwater in the 1980s. Investigations were done into the source and solution of the nitrate levels by James M. Montgomery Consulting Engineers (1982), the Agua Dulce Ad Hoc Committee (1983), and CH2M Hill (1989). Researchers at the University of California at Riverside (UCR) further investigated the area in the mid-90s [*UCR*, 1996; *Williams et al.*, 1998a; *Williams et al.*, 1998b]. The report by J.M. Montgomery assessed groundwater resources in the Agua Dulce and Mint Canyon drainage basin [*Montgomery*, 1982] and included sampling 17 wells for water quality parameters. The Agua Dulce Ad Hoc Committee [1983] followed up on the Montgomery report

and analyzed water samples from 32 wells. CH2M Hill [1989] investigated the groundwater conditions in the area and determined through its sampling of 84 wells that nitrate levels exceeded the drinking water standards in a significant number of wells, which they concluded to be due to the use of septic systems. Following the release of the CH2M Hill report, the results were questioned by residents as it was believed that the report did not evaluate all potential nitrate sources. Because of these doubts, UCR was asked to evaluate the situation further.

The researchers from UCR set out to evaluate the nitrate conditions and groundwater quality in Agua Dulce, identify and quantify the potential sources of nitrate to groundwater, and propose measures to reduce nitrate concentrations in groundwater. Wells were sampled in three separate events by UCR in 1992-93 for a total of 400 samples in addition to three sampling events conducted in the 1980's. Wells with high concentrations of nitrate were found to be randomly distributed throughout the watershed, but were primarily those which were pumping water from fractured bedrock. Table 1 summarizes sampling dates, number of wells sampled, nitrate concentrations, and percentage of wells above the MCL from the six sampling rounds conducted for this region.

Report	Sampling Date	Number of wells sampled	Range (mg/L)	Mean (mg/L)	% above MCL
Montgomery	1982	17	0.2-43	6.9	24%
Agua Dulce Ad Hoc Comm	1983	32	0.98-12.3	3.8	6%
CH2M Hill	1988	84		5.8	24%
UCR	1992	235	<0.1-37.4	5.6	33%
UCR	Spring 1993	92	<0.1-44.7	9.96	34%
UCR	Fall 1993	73	<0.1-33.0	8.2	26%

Table 1: Groundwater Sampling Results and Percentage of Samples above the Maximum Contaminant Level (MCL)

As part of the UCR study, Williams et al. [1998a] evaluated nitrogen isotopic compositions to determine the sources of nitrogen in the Sierra Pelona Valley groundwater samples. Following sampling and isotope analysis of groundwater, surface rocks, soils, and shallow soil profiles, they ascertained that anthropogenic sources such as human and animal waste contribute greater than half of the nitrate in the groundwater and were the primary source of nitrate in the approximately 40 percent of the drinking water wells that are routinely above regulatory limits.

Williams et al. [1998b] also delineated the spatial and temporal nitrate variations in order to determine contamination sources and patterns. Contamination was revealed to be in three major patterns: (i) high nitrate concentrations in isolated wells, affected by localized NO_3 sources, (ii) high nitrate concentrations in a cluster of wells, and (iii) moderate yet consistent nitrate concentrations documented in a large area of the groundwater region. Most of the isolated wells with the high nitrate concentrations were located in fractured basement-rock aquifer regions. Clusters of contaminated

wells occurred mostly in the north-central region of the watershed and contamination is most likely due to stormwater runoff flowing over natural soil and rock containing nitrate. The regional contamination occurred in the south-central section of the watershed in the vicinity of the alluvial aquifer region, as depicted on Figure 1. The majority of the nitrate concentrations in this region were between 5-10 mg/L, and no concentrations were below 2 mg/L. Williams et al. [1998b] determined through pattern analysis that septic waste was more likely to be the cause than animal wastes in this region. These results aligned with the results from Williams et al. [1998a] and presented a unified picture of the nitrate contamination in Agua Dulce.

Williams et al. [1998b] were able to see the effect of rainfall on nitrate concentrations. The large amounts of precipitation in the winter of 1992-93 caused the nitrate to quickly be transported to the groundwater and diluted. The sudden contaminant transport was speculated to have several causes: direct recharge through fractures in the bedrock, direct recharge through faulty septic systems and/or wells, and/or recharge to the aquifer which raises the groundwater level and dissolves nitrates in the capillary and vadose regions above the dry climate water table.

b. Objectives

Previous studies evaluating nitrate contamination in the Sierra Pelona Watershed have determined that domestic septic systems are one of the primary causes of the contamination and help explain its spatial variations. However, numerical modeling of the nitrates and groundwater in the vadose zone between the septic systems to the groundwater has not been completed so the previous conclusions could be considered somewhat inferential. Using site-specific soil data from the previous investigations and the HYDRUS-1D computer program to numerically model water and nitrates in the vadose zone, this research assesses whether or not nitrate-impacted leachate from septic systems reach groundwater and what the likely concentrations would be. This study focuses on the area of Agua Dulce where the vadose zone exists and will not address areas of Agua Dulce where there is fractured rock.

III. Methodology

Water flow and contaminant transport through porous media is a three-dimensional process. However, the modeling efforts for this study were limited to a 1-dimensional representation of transport vertically through the vadose zone given the limited data that was available, the access of computing capabilities, and the knowledge that horizontal flow in the vadose zone is generally less pronounced than vertical flow.

The HYDRUS-1D Software Package was used to simulate water and nitrate movement in one dimension through unsaturated soil given model parameters and boundary conditions [*Simunek et al.*, 2005]. HYDRUS-1D is based on the computer code for HYDRUS, which numerically solves Richards Equation for saturated-unsaturated water flow and numerically approximates the convection-dispersion equation for solute transport using standard Galerkin-type linear finite element schemes. A mass balance equation is also included where the mass of nitrogen going

in from the precipitation and septic system equals the mass of nitrogen exiting the system.

Model simulations were conducted for the three soil profiles described previously. Model inputs were estimated from previous reports and soil investigations as well as from values reported in the literature. The upper boundary conditions for Richards Equation were set as constant flux equal to the regional precipitation rate for a given scenario and estimates of average domestic septic flow rates. The lower boundary condition for water flow was set as a constant pressure head of zero, representative of fully saturated conditions, since the groundwater table was considered to be at the bottom of each soil profile. The upper boundary conditions for the solute concentration were set as constant flux.

Initial conditions for the pressure head were prescribed as linearly distributed along the soil profile. Two pressure head scenarios were run: one representing a dry surface and one representing hydrostatic equilibrium (set as the negative value of the depth of the soil boring). The initial solute concentration throughout the system was set to zero to represent nitrate-free groundwater and a soil system with no existing nitrate impacts.

Three different precipitation cases were considered to represent the range of possible leaching rates and dilution effects: the median precipitation, the driest year on record, and the wettest year on record [*UCR*, 1996]. To account for the fact that the simulations were run in only one dimension, additional simulations were run using a larger surface area for the septic system leachfield. A larger leachfield area was used to simulate that septic loading was uniformly distributed through the area it would reach to the groundwater depth. The smallest leachfield surface area is the most conservative (upper bound) estimate, and the surface areas ranged from 92 m^2 to 507 m^2. Simulations were run for 500 days in order to aim for a steady-state condition.

Analysis of a fully-mixed tank model was used to determine the cumulative effect of septic effluent on the groundwater in the alluvial aquifer region of Agua Dulce. This was done using a mass balance approach which accounts for the background nitrate concentration and the groundwater flow rate flowing into Agua Dulce aquifer, the concentration and flow rate of the precipitation, the septic effluent nitrate concentration and the septic flow rate, and the nitrate concentration and groundwater flow rate leaving Agua Dulce.

IV. Results and Discussion

a. Septic system nitrate transport modeling

Thirty-six different scenarios were modeled using HYDRUS-1D, twelve for each of three drill sites evaluated (at soil borings #1.4, #2.3, and #4.3). Parameter input values for each soil boring and soil layer are shown in Table 2. The UCR report provided the necessary soil parameters, including θ_s, the saturated water content, and K, the unsaturated hydraulic conductivity. Septic effluent flow was taken to be 1.136 m^3/day in all scenarios.

Drill Hole	Layer	Depth (m)	θ_s	K (m/d)
#1.4	Layer I	surface to 1.2 m	0.52	0.191
	Layer II	1.2 m to 3.2 m	0.36	0.263
	Layer III	3.2 m to 4.8 m	0.46	0.172
	groundwater at 4.8 m below grade			
#2.3	Layer I	surface to 0.6 m	0.36	2.263
	Layer II	0.6 m to 1.8 m	0.34	0.335
	Layer III	1.8 m to 3.9 m	0.34	2.494
	Layer IV	3.9 m to 5.4 m	0.31	0.36
	unsaturated region below 5.4 m: fractured crystalline basement			
#4.3	Layer I	surface to 1.5 m	0.34	0.429
	Layer II	1.5 m to 2.7 m	0.34	3.48
	Layer III	2.7 m to 17.2 m	0.3	0.065
	no groundwater reached to 17.2 m below grade			

Table 2: HYDRUS-1D parameter input values for each soil boring and soil layer

For each drill site, three precipitation scenarios were run: low, average, and high precipitation. For each precipitation scenario, two pressure head scenarios were run: one representing a dry surface and one representing hydrostatic equilibrium. In addition, for each pressure head scenario, two effective leachfield area scenarios were run: the actual leachfield area and an adjusted leachfield area.

The modeling results indicate that the simulated nitrate concentration plume would reach groundwater (defined as the nitrate concentration at the bottom of the soil profile greater than zero) within 100 days at soil borings #1.4 and #2.3 when groundwater is at 3.8 m below the leachfield and 4.4 m below the leachfield, respectively, primarily due to the shallow depth of the soil borings. Steady state was not reached within 500 days for soil boring #4.3, with a depth of 17.2 m.

Results showed that soil borings representative of a historically residential site in the alluvial aquifer (boring #1.4) and in an area with historically high natural nitrate underlain by thin, dry alluvium (boring #2.3) have higher nitrate concentration levels entering groundwater than simulations representative of primarily agricultural area also underlain by thin, dry alluvium (boring #4.3). Since nitrate concentration plumes were evaluated for only three soil borings, conclusions about the site usage versus nitrate concentration were unable to be drawn. It was clear that as precipitation amounts increase, the nitrate is diluted and concentrations at groundwater are lower. Larger leachfield areas were shown to yield lower nitrate concentrations since the initial nitrate concentration is dispersed over a larger area. Model runs showed that the effect of the pressure head on nitrate concentrations reaching groundwater was minimal.

Based on average values for nitrate concentration in septic effluent as given by the EPA (2002), along with our model results, we can deduce that the nitrate

concentration plume is below the MCL within 1.3 m below the leachfield. This is useful information for regulators looking to establish an offset distance between groundwater and the bottom of the leachfield.

b. Fully-Mixed Tank Model

The lowest bound on the sampling range from the UCR data sampling was used for the background nitrate concentration and the average number of septic systems located in the alluvial aquifer region of Agua Dulce was estimated. Using the EPA estimates for gallons discharged per day per septic system, and the average nitrate concentration for the effluent, a fully mixed-tank model was used to calculate the nitrate concentration leaving the populated area of Agua Dulce. Soil input parameters were based on UCR data, and the regional minimum, maximum, and average precipitation amounts were used. Based on these assumptions and methods, the nitrate concentrations leaving Agua Dulce range from 0.50 mg/L to 11.6 mg/L.

The worst case scenario with the highest concentrations under these conditions is given the very low value of hydraulic conductivity that occurs due to low soil moisture conditions in times of drought. This condition replicates nitrate concentrations around 5 mg/L, half of the MCL. Since the hydraulic conductivity values are based on soil borings in the vadose zone only, these results are estimates only until more testing is undertaken to determine more specific values throughout the depth of the entire alluvial aquifer. However, these results indicate that nitrate concentrations of water percolating into groundwater (and therefore drinking water) are of greater concern during drought conditions.

Despite the heavy rains in the winter of 1992, nitrate concentrations varied only slightly [*Williams et al.*, 1996b]. In order to investigate this finding an additional series of model simulations were undertaken. The hydraulic conductivity value from the bottom of soil boring #1.4 along with estimates of the hydraulic gradient and a range of precipitation values were used. The findings of these simulations suggest that when the annual precipitation is between 11 and 24 cm/yr (median rainfall is 21 cm/yr), the nitrate concentration leaving the region is between 5 and 10 mg/L. When there is less than 11 cm of annual precipitation, the nitrate concentration leaving the region is greater than 10 mg/L.

V. Conclusions

Using data from previous soil borings collected in Agua Dulce, CA and the numerical modeling program HYDRUS-1D, nitrate transport through the vadose zone was evaluated. Thirty-six modeling scenarios were assessed and the results analyzed. The following are the results of the modeling efforts:

- With shallower soil borings (less than 6 m below grade), steady state nitrate transport within the system is reached within 200 days, while steady state is not reached with the deeper boring (approximately 17 m below grade) within 500 days. However, the steady state for this boring is expected to be reached within approximately 1000 days. By examining steady state solutions, we can determine how the system will behave in the future.

- The modeling results show that the nitrate concentration plume is less than the maximum contaminant level (MCL) of 10 mg/L within 1.3 m below the septic leachfield in all scenarios.
- The analysis of the fully-mixed tank model shows that nitrate concentrations in groundwater are of greater concern during drought conditions. Care should be taken when the precipitation is less than 17 cm/yr. Under these circumstances, nitrate concentrations leaving the Agua Dulce region are high enough that residents should consider using bottled water as their drinking water source, although nitrate-rich water is acceptable for showering and laundry uses.

Based on these results, the decision to keep the town on septic systems and not build a wastewater treatment plant and associated sewer system seems to have been a sound decision. Although the septic systems in town are contributing to the groundwater contamination beneath Agua Dulce it is only under extreme drought conditions that the septic system leachate would cause the high concentrations observed in the groundwater sampling events in the early 1990s. This shows that natural nitrate sources also contribute quite a bit to the groundwater, which is likely what is putting the groundwater nitrate concentrations in this region over the MCL.

In order to limit the amount of nitrate transported to groundwater from septic systems, it is recommended that all septic systems in the Sierra Pelona Valley be inspected regularly (for example, when homes change owners), and replaced when they are no longer optimally performing. Particularly important in the Agua Dulce area is septic system density. By increasing the number of septic systems, the nitrogen loading of the groundwater will increase. No increase in settlement density should be allowed.

Exploring the potential of nonlinear and non-equilibrium alcohol partitioning for assessment of DNAPL source zone architecture

Rhiannon E. Ervin and C. Andrew Ramsburg

Department of Civil and Environmental Engineering, Tufts University, 200 College Ave., Room 113 Anderson Hall, Medford, MA 02155; PH (617) 627-3211; FAX (617) 627-3994; email: andrew.ramsburg@tufts.edu

Abstract

Recent research highlights the importance of quantifying the relationship between dense nonaqueous phase liquid (DNAPL) spatial distribution, source strength and source longevity. Since acquiring knowledge of the precise distribution of DNAPL saturations (also known as the DNAPL architecture) may be impracticable (technically or economically), attention is being placed on understanding the key features of the DNAPL architecture that control contaminant mass discharge. Examples of metrics describing DNAPL architecture include reactive travel times, spatial moments of the DNAPL mass, and ratios of DNAPL mass present in ganglia to that present in pools. While other metrics may yet be advanced, the utility of any source zone architecture metric as a site management tool requires that the metric be readily quantifiable. Partitioning tracers are one tool that may permit interrogation of DNAPL architecture. Traditional use of partitioning interwell tracer tests, however, provides an estimate of DNAPL saturation that is integrated over the flow path of the tracer. While helpful in estimating overall saturations or total mass of DNAPL, few interwell tracer tests are designed to provide the spatial resolution required to assess DNAPL architecture. Here we explore the use of partitioning tracers under the conditions of nonlinear and non-equilibrium transport, with the longer-term goal of estimating DNAPL architecture in localized portions of a source zone. Initial efforts were directed toward elucidating liquid-liquid equilibria of 2-octanol, a common partitioning alcohol, in a system comprising water and TCE-NAPL. Results illustrate the importance of assessing tracer partitioning over a wide range of concentrations. Column experiments were conducted in a sandy medium to explore limitations to tracer transport with both the aqueous phase and a uniformly entrapped nonaqueous phase. These preliminary results suggest nonlinear and non-equilibrium partitioning may be exploited to assess DNAPL source zone architecture.

Introduction

In 1993, the EPA concluded that approximately 60% of all National Priority List sites have high likelihood of dense nonaqueous phase liquid (DNAPL) contamination (U.S. EPA, 1993). In the intervening years, relatively few of these source zones, the region containing DNAPL as well as sorbed phase, have reached site closure (National Research Council, 2005). Low water solubilities give chlorinated solvents the potential to remain in the subsurface for decades, resulting in prolonged groundwater contamination. However, aqueous solubilities of chlorinated solvents are orders of magnitude higher than aqueous concentrations known to be harmful to human health (Pankow and Cherry, 1996). Consequently, the dissolved

phase plumes emanating from DNAPL source zones pose risks to human and environmental health.

Upon release, dense organic liquids migrate downward through the subsurface. During this process, DNAPL is entrapped by capillary forces in pores and pools in regions of permeability contrast (Pankow and Cherry, 1996). The term "architecture" is often used to describe the spatial distribution of DNAPL within a source zone. The technical and economic impracticability of determining the exact DNAPL architecture has focused efforts on developing metrics that link DNAPL architecture and contaminant discharge (Christ et al., 2006; Fure et al., 2006; Stroo et al., 2003). Examples of metrics describing DNAPL architecture include reactive travel times (e.g., Jawitz et al., 2005), spatial moments of the DNAPL mass (e.g., Moreno-Barbero and Illangasekare, 2005), and ganglia to pool (GTP) mass ratio (e.g., Christ et al., 2006). Recognition that no treatment can provide complete contaminant removal necessitates an ability to quantify the benefits of partial mass removal (Stroo et al., 2003; Abriola, 2005; Christ et al., 2006). A number studies indicate that reductions in source zone mass may lead to lower downgradient, dissolved-phase concentrations and shorter source longevity (Soga et al., 2004; Christ et al., 2005; Jawitz et al., 2005; Suchomel and Pennell, 2006; Brooks et al., 2008; Kaye et al., 2008). Yet for aggressive source zone treatments to be effective, some knowledge of the amount and distribution of the DNAPL in the source zone is necessary (Christ et al., 2005). Based upon these reports, model upscaling is now incorporating DNAPL architecture metrics (Falta et al., 2005; Moreno-Barbero and Illangasekare, 2005; Park and Parker, 2005; Christ et al., 2006) illustrating the need for these (or other forthcoming metrics) to be reliably quantified.

It is well established that partitioning tracers can be employed to characterize DNAPL source zones (Jin et al., 1995; Annable et al., 1998; Brooks et al., 2002; Meinardus et al., 2002). Use of these tracers involves passing a pulse of partitioning and non-partitioning tracers through a source zone. Analysis of the resulting breakthrough curves permits estimation of an overall DNAPL saturation – one that is averaged along the tracer flow path. Partitioning tracer tests can be conducted using any number of hydraulic designs (Brooks et al., 2002), though assessment of DNAPL architecture requires high resolution (temporal and spatial) sampling. An alternative approach is to obtain estimates of average DNAPL saturation though the use of push-pull tests (Istok et al., 2002). Push-pull tests involve pumping tracers into the subsurface during the "push" phase, and then reversing the flow ("pull" phase) to recover the tracers from the same well.

Objectives

Analysis of partitioning tracer tests commonly assumes linear, equilibrium partitioning. Many partitioning tracers, however, have been observed to exhibit nonlinear or non-equilibrium partitioning (e.g., Wise et al., 1999; Wilson et al., 2000; Moreno-Barbero and Illangasekare, 2006). It is hypothesized that push-pull tests may be designed to quantify local DNAPL architecture metrics such as GTP by exploiting non-idealities in tracer partitioning. Testing this hypothesis requires a thorough understanding of tracer partitioning under both equilibrium and non-equilibrium conditions. Therefore, the specific objective of this work is to evaluate the liquid-

liquid equilibrium (LLE) and non-equilibrium transport of 2-octanol (a representative partitioning tracer).

Materials and Methods

Materials. ACS grade tricholoethene (density-1.46 g/mL, aqueous solubility-1100 mg/L), obtained from Sigma Aldrich, was used as the representative NAPL throughout all experiments. When used in column experiments, the TCE was dyed with 10^{-4} M Oil-Red-O (Alfa Aesar) for visualization purposes. Previous work has shown that the addition of Oil-Red-O at this concentration does not significantly affect the relevant physical properties of the NAPL (Taylor et al., 2001). 2-octanol (density-0.82 g/mL, aqueous solubility-1120 mg/L) was obtained from Arcos Organics (97% purity) and used as the partitioning tracer. HPLC grade isopropanol was received from Sigma Aldrich and used for sample dilution. All aqueous phase solutions were made using water obtained from a Millipore A-10 filtration system (resistivity > 18.1 MΩ*cm). Columns were packed with a 45-50 fraction obtained by sieving Ottawa Federal Fine sand (US Silica). All non-partitioning tracer tests were conducted with 0.01 M solutions of ACS grade sodium bromide and sodium chloride (Fischer Chemical).

Batch Methods. Previous studies have employed one or two points to measure partition coefficients for tracers, but evidence suggests some tracers exhibit nonlinear partitioning (Wise et al., 1999). Thus, LLE batch experiments were conducted over a wide concentration range to more accurately quantify the partition coefficient of 2-octanol in the TCE-water-2-octanol ternary system. Various compositions of 2-octanol, water and TCE were added to 35 mL borosilicate glass centrifuge tubes. Each selected composition was created in tripilicate. Centrifuge tubes were then placed on oscillating shakers (LabQuake) located within a controlled temperature room (Harris Environmental), and allowed to mix for 72 hr at 22.0±0.1°C. Previous experiments suggest 72 hr is sufficient for these systems to reach equilibrium. After equilibration, the tubes were centrifuged at 1500 rpm and 22 °C for 10 min (Beckman Coulter Avanti J-25). After centrifugation, the aqueous and organic phases were carefully separated using disposable glass pipettes. Samples of each phase were subsequently prepared for compositional analysis and density measurements (see analytical methods).

Column Methods. Mass exchange kinetics for the 2-octanol tracer and residual TCE system were studied using 1-D column experiments. The 45-50 sieve fraction of Federal Fine Ottawa sand was dry packed in a Chromaflex glass column having a diameter of 4.8 cm. Upon saturation of the porous medium with the aqueous phase, a non-reactive tracer test was conducted using 0.01 M Br^-. Following the completion of the first tracer test, the aqueous phase was displaced by TCE-NAPL. After obtaining a maximum TCE-NAPL saturation (as evidenced by the absence of water in the column effluent), a residual entrapped saturation of TCE-NAPL was obtained by displacing the mobile NAPL with water. After establishing a residual NAPL saturation, 0.01 M Br^- was used to conduct a second tracer test. Following the preparation of the column, an aqueous solution containing the desired concentration

of 2-octanol was introduced to the column at a flow rate of 2.2 mL/min for approximately 10 pore volumes. The flow rate and packed length were selected to promote non-equilibrium conditions so that partitioning kinetics could be quantified. After the pulse of 2-octanol solution, the column influent was switched to Milli-Q water. Effluent samples were collected throughout the duration of the experiment using an automated fraction collector. Fractions were subsequently sampled and analyzed following the methods described below.

Analytical Methods. Aqueous phase samples collected for 2-octanol and TCE analysis were diluted (~20x) using Milli-Q water and isopropanol (IPA), respectively. NAPL samples collected for 2-octanol and TCE analyses were diluted (~10x) using IPA. NAPL samples collected for water content analysis were not diluted. Concentrations of 2-octanol and TCE in both the aqueous and NAPL phases were quantified using a Hewlet Packard 6890 Gas Chromatograph (GC) equipped with a DB-5 column and flame ionization detector. A five-point calibration curve was obtained on each day of use and checked using a calibration standard every 20 samples. Sample dilutions were prepared in triplicate, with each diluted sample quantified using duplicate injections. Effluent samples from the column experiment were also quantified using duplicate injections. The water content in each NAPL sample was quantified in triplicate using a Mettler Toledo DL38 Karl Fischer Titrator. Prior to each day of use the titrator was calibrated with an AquaStar 1% water standard. Calibration was checked with the water standard at least every ten samples. Density of the NAPL phase was measured in triplicate with a 2.5 mL glass pycnometer that was calibrated with water prior to each use. Effluent samples from the tracer tests were quantified for chloride and bromide concentration using a Dionex ICS-2000 Ion Chromatograph (IC) equipped with an AS-11 column. The instrument was calibrated with a six-point standard curve every fifteen samples.

Results & Discussion

While 2-octanol partitioning data are available from previous studies, most of these data lie within a narrow concentration range at the lower end of possible aqueous phase concentrations (Dwarakanath and Pope, 1998; Young et al., 1999; Brooks et al., 2002; Ramsburg et al., 2005; Thal et al., 2007). In many instances, 2-octanol partitioning data were used to generate partition coefficients at a particular aqueous phase concentration. The resulting partition coefficients are then often assumed to be constant over a wide range of aqueous phase concentrations. Many alcohols, however, exhibit nonlinear partitioning due to their ability to hydrogen bond in both phases (e.g., Wise et al., 1999). Analysis of batch data confirms that 2-octanol exhibits nonlinear partitioning in two-liquid system comprising water, TCE and 2-octanol. For aqueous phase concentrations below 300 mg/L, the partitioning of 2-octanol may be approximated as linear and thus described with a partition coefficient of 338 L_{aq}/L_{NAPL}. Note that this value is between the previously reported values (for the TCE, water, 2-octanol system) of 226 and 389 (Dwarakanath and Pope, 1998; Thal et al., 2007). Above an aqueous phase concentration of 300 mg/L the partition coefficient of 2-octanol increases six-fold, demonstrating the nonlinearity of the partitioning. This increase in 2-octanol affinity for the organic

phase above aqueous concentrations of 300 mg/L indicates that a single valued partition coefficient cannot be employed to accurately describe all possible aqueous phase concentrations of 2-octanol. To accurately describe the 2-octanol distribution in this ternary system, more sophisticated techniques (e.g., UNIQUAC modeling) are required.

LLE data were used to design two column experiments in which the kinetics of tracer mass transfer were examined. To explore the effect of the varying partitioning coefficient, experiments were conducted at two different 2-octanol concentrations. The influent concentrations of 2-octanol for Column 1 and Column 2 were 370 mg/L and 657 mg/L, respectively. Column parameters for each experiment are shown in Table 1.

Table 1. Column Parameters

Column	Influent 2-octanol Concentration (mg/L)	Pore Volume (mL)	Length (cm)	Porosity	TCE-NAPL Saturation
1	370	27	3.6	0.40	20.0%
2	657	28	3.7	0.41	18.5%

The two distinct BTCs resulting from these column experiments are shown in Figure 1. Both BTCs exhibit characteristics of nonequilibrium behavior - a rapid increase in concentration over the duration of the influent pulse, and a long tail thereafter. Visual assessment of the BTCs is made difficult by the competing influences of influent concentration and NAPL saturation. NAPL saturations are difficult to replicate due to the hysteretic nature of the capillary pressure-saturation relationships governing the entrapment process.

To explore the mass transfer kinetics in more detail, a dual diffusion model was employed. The model was based on that developed by Rasmuson and Neretnieks (1980), with minor modifications for use in NAPL-water systems (Adams et al., 2007). The dual diffusion model was coupled with an aqueous phase mass transfer coefficient estimated using data from Powers et al. (1992). Model predictions employing independently determined column parameters failed to capture the shape and maximum C/C_0 value of the BTCs (Figure 1). Consequently, the model was visually fit to the data by adjusting NAPL saturation. The best visual fit, as seen in Figure 1, required NAPL saturations of 2.0% and 1.4% for Columns 1 and 2, respectively. While these model fits capture the general shapes of the BTCs, the fitted saturations are not consistent with experimental observations of NAPL saturation. One possibility for this discrepancy in saturation may relate to of the presence of a surface resistance to 2-octanol partitioning, which was not present within the model. Current efforts are focused on exploring this possibility.

Results from equilibrium batch experiments demonstrate that the partitioning of 2-octanol between TCE and water may be approximated as linear at low aqueous concentrations (<300 mg/L), though the linear assumption fails to describe partitioning data over the larger range of aqueous concentrations. Observations of a linear range in the partitioning of 2-octanol indicate that traditional partitioning tracer tests can be designed to avoid influence of the nonlinearity in the partition coefficient.

In addition, the multistep nature of the equilibrium partitioning data offers potential for novel chemical perturbations that may enhance DNAPL source zone characterization. The long term objective of this research is to determine whether a partitioning tracer approach can be developed to distinguish high and low saturation regions through exploitation of nonlinear and non-equilibrium partitioning. Results from our initial column experiments demonstrate the effects of the nonlinear partitioning and suggest the need for revised descriptions of mass exchange in systems comprising TCE-NAPL for 2-octanol, and water. Current efforts are focused on resolving the 2-octanol partitioning kinetics, characterizing additional tracers, and exploring tracer response from non-uniform NAPL saturations.

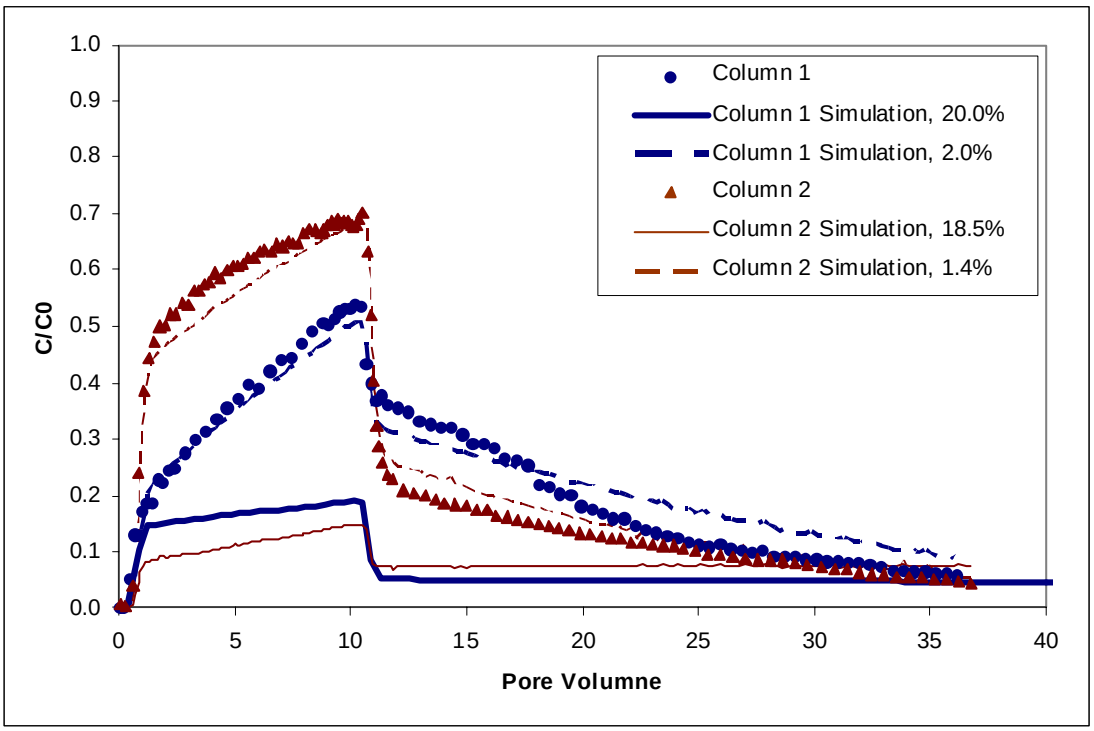

Figure 1. Breakthrough curves (symbols) and model predictions (solid lines) for the laboratory-determined saturations of 20.0% and 18.5% for Columns 1 and 2, respectively. Also shown are visual best fit simulations (dashed lines) at 2.0% saturation (Column 1) and 1.4% (Column 2).

Solute Flux Rate Uncertainty Evaluation at a Monitored Boundary

David E. Langseth, Sc.D., P.E., D. WRE

Gradient Corporation, 20 University Road, Cambridge, MA, 02138; PH (617) 395-5000; FAX (617) 395-5001; email: dlangseth@gradientcorp.com

Abstract

Limitations on data collection density, aggregated spatial and temporal modeling scales, and variations in time can lead to substantial uncertainty in estimated ground water and solute flux rates. Difficulties associated with quantitative characterization of uncertainty often lead to use of conservative assumptions in management decision-making processes, which can lead to non-optimal resource management. This poster describes a computational method for estimating solute flux rate uncertainty at a monitored boundary that can be programmed on an ordinary spreadsheet application and discusses parameter estimation approaches. This method produces results comparable to those produced by Monte Carlo simulation under a reasonable range of assumptions. Two alternative conceptual models at the monitored boundary can be used, one in which the entire area of interest is treated in an integrated manner and the other in which the area of interest is segmented into zones. This poster addresses only the segmented approach. Case study results not shown here indicate that the conceptual model choice has an impact on the analysis results. Use of uncertainty analysis to evaluate likelihood of exceeding target impacts on receiving waters is also illustrated.

Introduction

Estimation of the solute flux rate across a specified boundary is commonly needed. Example boundaries include property boundaries and natural boundaries such as a ground water/surface water interface. A series of monitoring wells is often installed along or near the boundary of interest. Under steady- or quasi steady-state conditions, measured parameters in the monitoring wells along the boundary of interest, combined with other site data, can be used in relatively simple equations to estimate the solute flux rate. The equation simplicity, however, belies the parameter uncertainty and variability. Available data are essentially always sparse with respect to the total area of interest, measured data such as hydraulic conductivity and solute concentration measurements are uncertain, and some conditions, such as the gradient, flow direction, and solute concentrations can change in time. The manner in and degree to which the uncertainty and variability are characterized can have a substantial impact on flux rate characterization and hence on decision-making. For example, in performing human health risk assessments, it is common to use the 95th percentile upper confidence limit on the estimated mean concentration to represent the reasonable maximum concentration at a location (USEPA December 1989). Higher variance in the estimated concentration can, therefore, lead to higher estimates of the reasonable maximum value.

This document presents a computationally simply method for estimating the solute flux rate uncertainty at a monitored boundary that can be easily programmed on a spreadsheet, hopefully helping to address the need for a greater selection of simple and user-friendly stochastic approaches available to hydrogeology practitioners that was noted by Freeze (2004) and Neuman (2004).

Method Description

The one dimensional flux rate in the direction of ground water flow may be approximated as: $F = -CKiA$, where F [MT^{-1}] is the flux rate over area A [L^2], C [ML^{-3}] is the dissolved solute concentration, K [LT^{-1}] is the hydraulic conductivity and i [-] is the hydraulic gradient. For independent variables, the expected value of F ($\overline{F}$) is the product of the expected values of each parameter equals $\overline{F} = -\overline{CAiK} = -\overline{C}\,\overline{A}\,\overline{i}\,\overline{K}$ (Benjamin and Cornell 1970). For independent variables, the coefficient of variation for F (CV_F) is given by:

$$CV_F^2 = CV_C^2 + CV_K^2 + CV_i^2 + CV_A^2 +$$
$$CV_C^2CV_K^2 + CV_C^2CV_i^2 + CV_C^2CV_A^2 + CV_K^2CV_i^2 + CV_K^2CV_A^2 + CV_i^2CV_A^2 +$$
$$CV_C^2CV_K^2CV_i^2 + CV_C^2CV_K^2CV_A^2 + CV_C^2CV_i^2CV_A^2 + CV_K^2CV_i^2CV_A^2 +$$
$$CV_C^2CV_K^2CV_i^2CV_A^2$$

Consider the situation of a property with known ground water contamination and a series of downgradient perimeter monitoring wells, as illustrated in Figure 1. Total solute flux rate across the property boundary may be estimated by either using representative parameters over the entire cross-sectional area of interest (integrated approach) or dividing the total flow cross sectional area into zones, each represented by one or more of the monitoring wells (segmented approach). In general, as the site conditions become more heterogeneous or as spatial trends become more prominent, it becomes more appropriate to divide the flux computation into zones, with each zone ideally representing relatively homogeneous conditions. The integrated and segmented approaches will not in general produce the same results. This poster describes only the segmented approach.

For the segmented approach the total flux is the sum of the flux in each zone, $F = \sum_{i=1}^{n} a_i F_i$, and the mean and variance of the total flux rate are given by Benjamin and Cornell (1970) as $\overline{F} = \sum_{i=1}^{n} a_i \overline{F}_i$ and $\sigma_F^2 = \sum_{i=1}^{n} a_i^2 \sigma_{F_i}^2 + 2\sum_{i=1}^{n}\sum_{j=i+1}^{n} a_i a_j Cov\left[F_i, F_j\right]$, where $\sigma_F^2\left[M^2T^{-2}\right]$ is the variance. The coefficients a_i would commonly all equal 1, but could take other values if, for example, they represented unit conversion factors from the individual zone computations to the total flux rate statement.

Care must be taken to distinguish between variances for point values and variances of a mean over an area or time. The appropriate variance term will often be the variance of the mean value for the area to be evaluated, not the variance of the point values (Jacobson et al. 2002), which is given by Benjamin and Cornell (1970) as

$$\sigma_{\bar{X}}^2 = \frac{\sigma_X^2}{n} + \frac{2}{n^2}\sum_{i=1}^{n}\sum_{j=i+1}^{n} Cov\left[X_i, X_j\right]$$

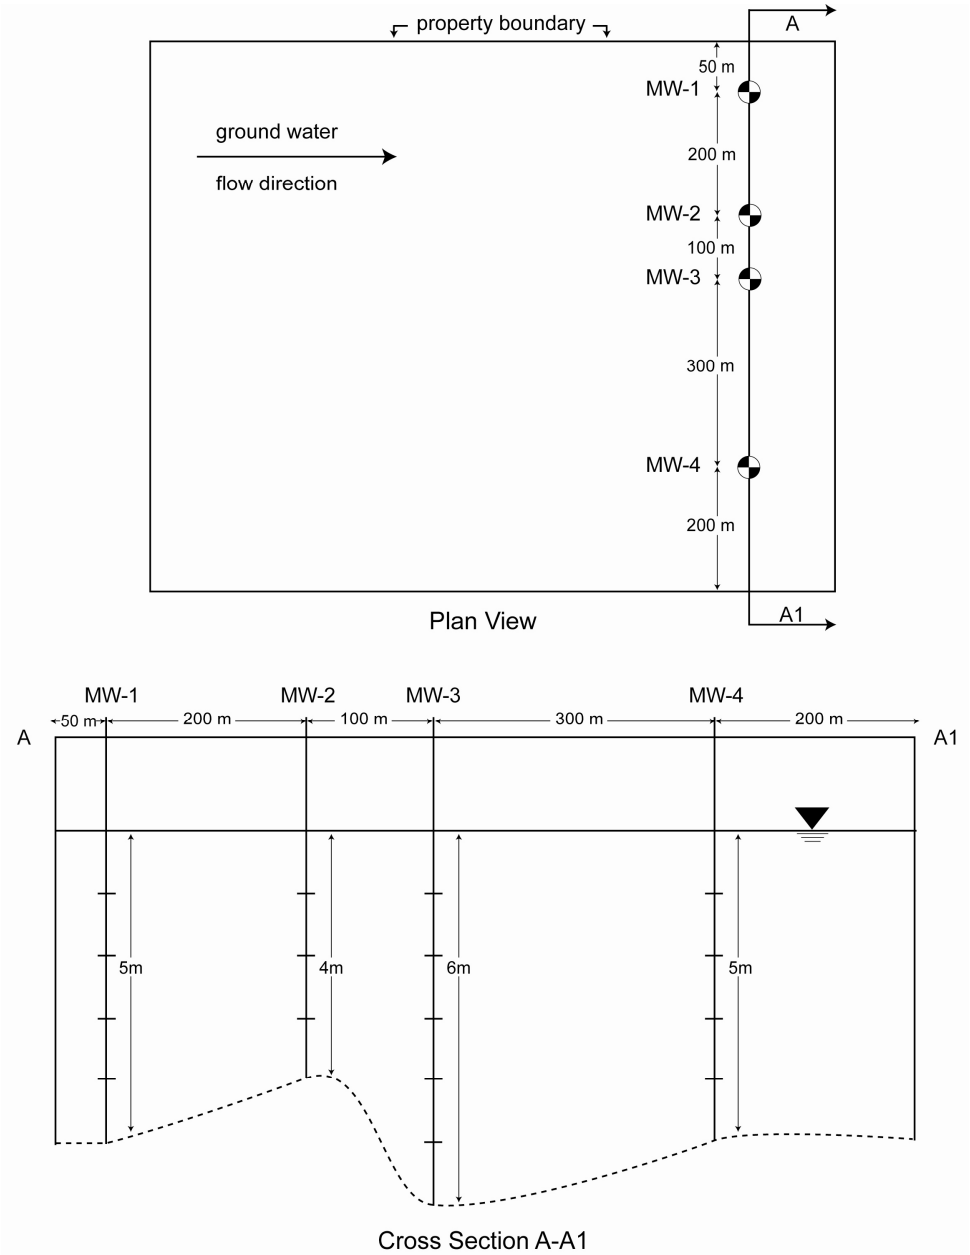

Figure 1: Boundary Monitoring Well Example Schematic

Example Calculation and Parameter Estimation

Table 1 provides hypothetical data of the type that would typically be developed for a monitored boundary as shown in Figure 1. These values represent point estimates at a given time.

Table 1 Example Measured Parameter Values

Well	C [ug/L]	K [cm/s]	Gradient [-]	Saturated Thickness [m]
MW-1	50	4.6E-04	-0.02	5
MW-2	80	2.3E-03	-0.04	4
MW-3	30	1.2E-03	-0.03	6
MW-4	100	1.2E-04	-0.05	5

Estimation of the uncertainty and variability for each of these parameters is discussed below.

Concentration (C): A specific solute, benzene, is specified in this example because measurement error in chemical analysis is compound specific. For benzene measurement error using method 624, Table 6 in 40 CFR 136, app. A, gives the equation for single analyst total variability as $\sigma_r^{'} = 0.26\overline{X} - 1.74$ and the equation for variability including different analysts and laboratories as $\sigma^{'} = 0.25\overline{X} - 1.33$, where $\overline{X}$ is the average recovery for the true concentration, C, all in µg/L. Recovery can be evaluated from site-specific data. Alternatively, recovery in the study used to develop the above equations was characterized as $\overline{X}' = 0.93C + 2.00$.

The measured concentrations were taken as the most likely values of the true concentrations for each zone and were not corrected for recovery in this example. Variance due to measurement error was represented as σ' calculated using $\overline{X}'$. For this sample calculation, the potential mean concentration variability over time in each zone was assumed to range from 0.5 to 1.5 times the measured value. The standard deviation was estimated by dividing this range by 6.

Hydraulic Conductivity (K): Hydraulic conductivity variability in space, after removal of impacts due to trends or correlation in space, has been demonstrated to often follow a lognormal probability distribution (Freeze 1975, de Marsily 1986, Sudicky 1986, Hess et al. 1992), though some data sets that follow a normal distribution have been reported (Vieira et al. 1981). For situations like this example in which the number of site-specific K measurement is small, a-priori information about the shape and magnitude of $\sigma^2_{\ln K}$ can be used to help estimate model parameters. Based on the studies cited above, the probability distribution of K

values was assumed to be lognormal. For the segmented approach, $\sigma^2_{\ln K}$ within each zone was assumed to equal 1, a common value based on data in the citations above, and the median value for each zone ($\breve{K}$) was assumed equal to the measured value in the zone. With only one measurement, the variance of the point values and zonal mean are the same. $\overline{K}$ in each zone was then computed using $\overline{K} = \breve{K} \exp\left(\frac{\sigma^2_{\ln K}}{2}\right)$ (Benjamin and Cornell 1970).

Gradient (i): Mean gradient values in each zone were assumed to range from 0.5 to 1.5 times the Table 1 values in each zone. The standard deviation was estimated by dividing this range by 6. Variance due to measurement error was assumed negligible.

Cross-Sectional Area (A): Variance of the cross-sectional flow area represented by each zone was evaluated by assuming that the horizontal distance represented by each well was known with little uncertainty, but the saturated depth of the aquifer was known with certainty only at the well location. The measured value at the well was taken as the most likely value for each zone and variability for the mean saturated depth in each zone was estimated by assuming that the variance of the point values within each zone was equal to the variance of the point values over the whole area of interest. With only one measurement in each zone, the variance of the mean value for the zone was then equal to the point value variance.

Monte Carlo Simulation

For the MCS, the probability distributions of concentration, gradient, and saturated thickness were represented in two ways: normal distributions with mean and variance as described above, truncated at 0, and uniform distributions ranging $\pm 3\sigma$ around the means. The probability distribution of hydraulic conductivity was represented as a lognormal distribution with mean and variance equal to the values described above. 10,000 realizations were used in each MCS. Figure 2 shows the MCS results using normal distributions for concentration, gradient, and saturated thickness.

Results and Discussion

In order to use the estimated statistics to quantify the flux rate probability distribution, the shape of the distribution must be known or assumed. Results from MCS with both normal and uniform distributions for C, i, and A indicate that the flux rate variation generally follows a distribution that is approximately lognormal. A lognormal distribution for F is consistent with flux being a product of several variables and the parameter with the highest coefficient of variation, K, being lognormally distributed.

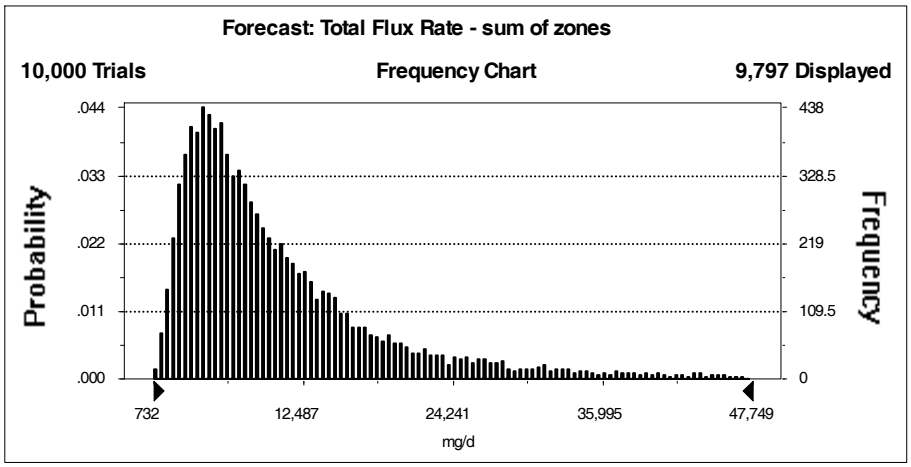

Figure 2: Monte Carlo Simulation Results for Flux Rate

Figure 3 shows flux rate probability distributions from the MCS simulation results using normal (N) and uniform (U) probability distributions for the parameters. As expected, the variance is higher when using uniform probability distributions. Based on the MCS results, the statistics of F computed using the direct calculation approach were applied to a lognormal distribution and are also shown on Figure 3.

Figure 3 shows that the direct computation results are nearly identical to the MCS results. In the absence of having performed the MCS simulation, we would not have known whether lognormality of the flux rate distribution was a reasonable assumption, but equipped with that information, and applying the calculated statistics to the lognormal probability distribution, the direct calculation approach produces a comparable result.

Example Application

Consider the case of contaminated ground water discharging to a stream. The stream has been determined to have a certain capacity to receive the contaminant load from the site, based on dilution or other factors such as volatilization or degradation, without exceeding relevant criteria. Capacity, however, is often a random variable, as it will generally depend at least on the flow rate in the river and perhaps on other variables. In the situation where the capacity depends primarily on the flow rate, and the relationship is linear, the capacity will often follow an approximately lognormal distribution.

The probability that the solute load from the ground water will exceed the river capacity is of interest. The difference between the capacity (C) and load (L) is commonly called a safety margin $SM = C - L$ (Freeze et al. 1990). The system is considered to fail when C is less than L, or when SM is less than zero. If the SM is normally distributed, regardless of the distributions for C and L, the failure

probability is given by Chow *et al*. (1988) as $\overline{R} = F_Z\left(\frac{-1}{CV_{SM}}\right)$, where $F_Z(z)$ is the standard normal cumulative distribution function of z.

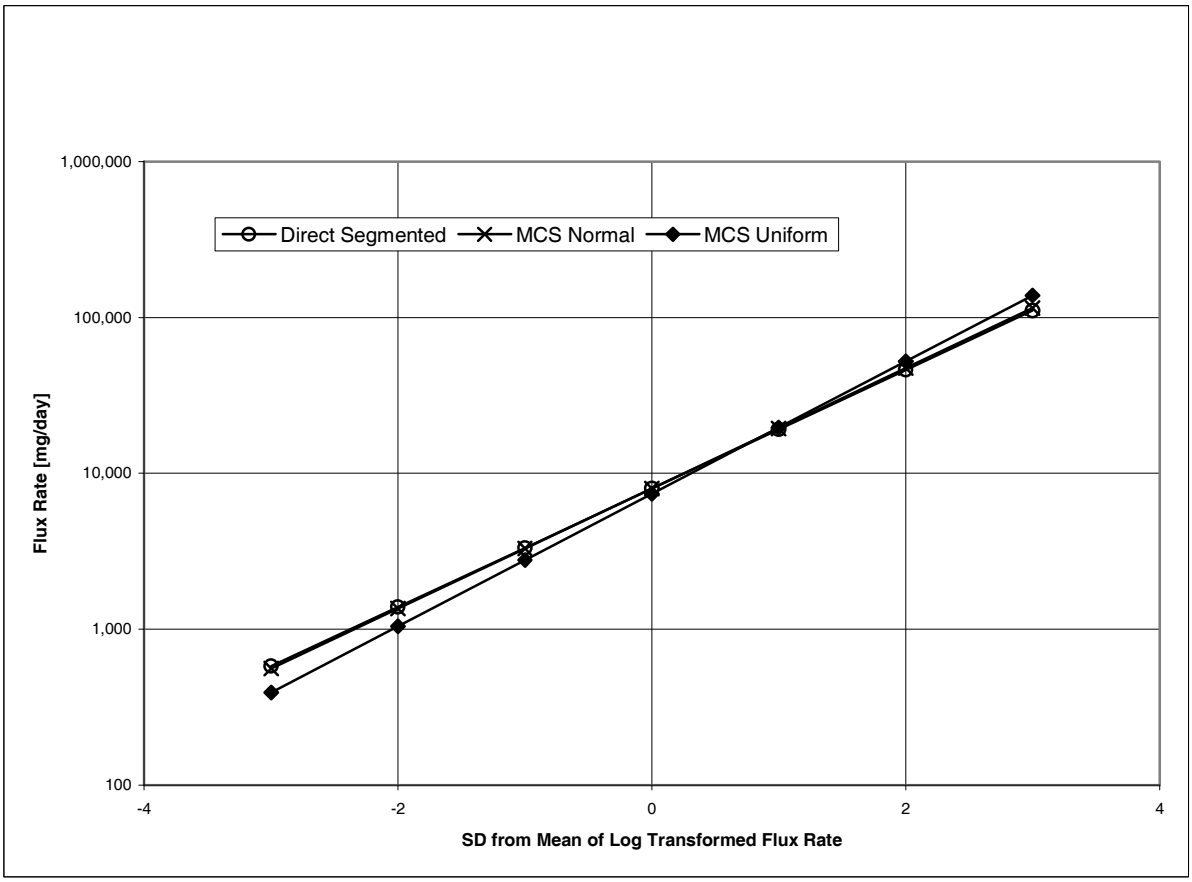

Figure 3: Direct Calculation and MCS Results

Alternatively, if C and L are lognormally distributed and independent, the failure probability in terms of the safety factor, SF = C/L, being less than 1 is given by Chow *et al*. (1988) as $\overline{R} = F_z\left(\frac{-\ln\left[\frac{\overline{C}}{\overline{L}}\left(\frac{1+CV_L^2}{1+CV_C^2}\right)^{0.5}\right]}{\left\{\ln\left[\left(1+CV_C^2\right)\left(1+CV_L^2\right)\right]\right\}^{0.5}}\right)$

Consider a situation in which the load has a mean of 10,000 mg/d with a standard deviation of 12,500 mg/d and the river capacity has been determined to have a mean of 25,000 mg/d with standard deviation also of 12,500 mg/d. Figure 4 shows the probability density functions for the load and capacity. MCS was used to evaluate the safety margin and safety factor assuming all parameters are independent and

characterizing load (flux rate) and capacity using lognormal distributions. Visual evaluation of MCS results for this situation (not shown here) indicates that the safety margin distribution is approximately normal, while the safety factor distribution is approximately lognormal.

The failure risk computed from MCS was 0.12 for both the SM and SF. The failure risk computed using the SM equation above was 0.20, higher than computed using MCS, and using the SF equation above was 0.12, the same as computed using MCS.

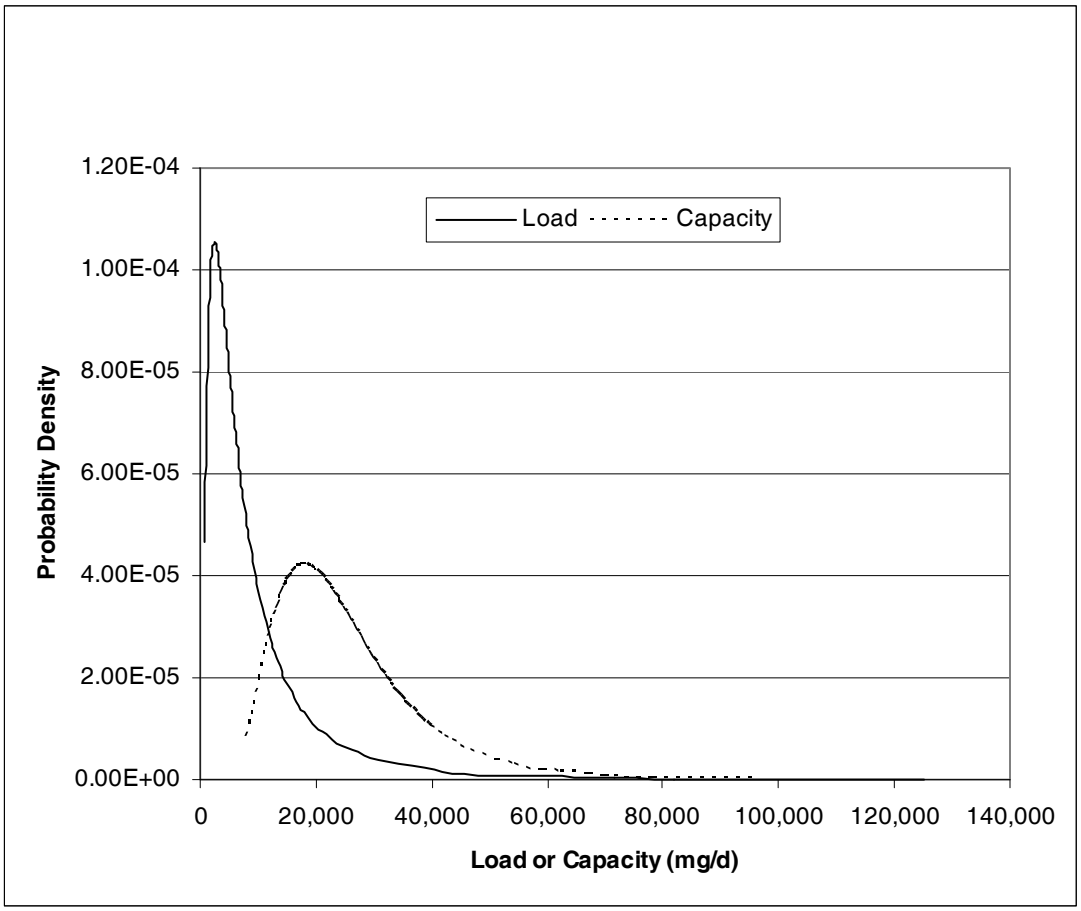

Figure 4: Example Load and Capacity Probability Density Functions

Summary and Conclusions

Application of simple relationships for the moments of linear functions of random variables to issues of ground water solute flux at a monitored cross-section, and associated parameter estimation, has been demonstrated. These relationships may be solved analytically on a spreadsheet. Through comparison with MCS, these simple methods have been shown to produce reasonably accurate results over a range of conditions, with the most comparable results being produced when all the parameters may be considered independent (the impacts of correlation have not been presented here). The principal limitations of the direct calculation method are

related to the inability of the direct method to define the shape of the resultant probability distribution or fully simulate the impact of correlations among the parameter values. Both theory and the MCS simulations, however, indicate that the flux rate has a lognormal distribution. Correlation can be addressed using MCS and partially addressed using expansions of the methods discussed here.

When considering uncertainty in the ground water solute flux rate and receiving water body capacity simultaneously, direct equations for failure risk produce results comparable to those produced by MCS in the absence of correlation between the load and capacity. Direct safety factor calculation in the Example Application produced results almost identical to those from MCS, while the failure risk computed directly from the safety margin approach in the Example Application was somewhat higher. For many situations where ground water discharges to rivers, capacity and load can be expected to be independent of each other and both lognormally distributed, matching the assumptions under which the safety factor equation was developed.

ABSTRACT

This paper presents an analytical model for evaluating a contaminant's in-situ retardation coefficient from concentration data obtained from an extraction well in a region of initially uniform contamination. Effective retardation estimates are required to effectively evaluate contaminant transport. This estimate often relies on literature values for the distribution coefficient, K_d, and site-specific estimates for effective porosity, bulk density, and chemical composition of the porous medium. When more accuracy is required, column or field studies may be performed to define a contaminant breakthrough curve which is used to determine retardation. These data can, in many instances, be difficult and expensive to obtain and interpret. In practice, in-situ retardation coefficients have been frequently evaluated using the results of injection well data and analytical solutions to the governing transport equation in radial coordinates or multi-dimensional numerical modeling of the transport equation using data from extraction wells.

This study presents a solution and method to use extraction well data and the in-situ contaminant, rather than injection well data and an introduced tracer. Since the solution is based on extraction well data, no tracers or chemicals need to be injected into an aquifer and data from potential remediation wells can be used to obtain these values. In addition to the solution, an integral solution to the instantaneous concentration at the extraction well is presented which allows retardation estimates to be made using only extraction well data and not requiring an observation well. The solution method presented is a numerical inversion of a Laplace transform solution using the Stehfest algorithm to provide non-dimensional results in real time and space.

INTRODUCTION

This paper presents an analytical model for evaluating a contaminant's in-situ retardation coefficient from concentration data obtained from observations wells or an extraction well in a region of initially uniform contamination. An in-situ retardation estimate is required to effectively evaluate contaminant transport. In practice, this estimate often relies on literature values for the distribution coefficient, K_d, and site-specific estimates for effective porosity, bulk density, and chemical composition of the porous medium to calculate retardation. When more accuracy is required, column or field studies are performed to define a contaminant breakthrough curve to determine the contaminant's retardation. These data can, in many instances, be difficult and expensive to obtain and interpret. In practice, in-situ retardation coefficients have been frequently evaluated using the results of injection well data and analytical solutions to the governing transport equation in radial coordinates (Hoopes and Harleman 1967; Tang and Babu 1979; Pickens et al. 1981; and Chen 1985, 1986), or multi-dimensional numerical modeling of the transport equation fitted to field data. This study presents a solution and method to use extraction well data and the in-situ contaminant, rather than injection well data and an introduced tracer to establish in-situ retardation values.

While undergoing transport through a porous medium, a dissolved contaminant often travels at a velocity less than that of the groundwater because of interactions between the contaminant and the solid matrix. The ratio of the relative velocities between the groundwater and dissolved contaminant can be described as the effective retardation; the larger the retardation, the smaller the velocity of the contaminant compared to the groundwater velocity (Freeze and Cheery 1979). That is,

$$V_c = \frac{V_{gw}}{R} \qquad (1)$$

where R is the retardation coefficient, V_c is the velocity of the center of mass of the contaminant plume, and V_{gw} is the average groundwater velocity.

The average groundwater velocity, V_{gw}, is obtained from the Darcy velocity, $V_d = K\nabla h$, by the following relationship:

$$V_{gw} = \frac{K\nabla h}{\phi} \quad or \quad V_{gw}\frac{V_d}{\phi} \qquad (2)$$

where K is the hydraulic conductivity of the porous medium, ϕ is the effective porosity of the porous medium, and ∇h is the hydraulic gradient of the fluid in the porous medium (Freeze and Cherry 1979).

Assuming fast, reversible reactions of the contaminant with the solid matrix, the retardation coefficient, R, in Equation 1 can be written:

$$R = 1 + \rho_b \frac{K_d}{\phi} \qquad (3)$$

where K_d is the distribution coefficient for the contaminant in contact with the solid matrix and ρ_b is the bulk density of the porous medium (Freeze and Cherry 1979). K_d depends on both the contaminant and the physical and chemical makeup of the porous media and is therefore site specific.

This paper presents an analytical solution to estimate *R*, from field extraction and observation wells or even a single extract well located in the plume. The solution relies on a unique boundary condition, a zero contaminant concentration at the edge of the well bore. While this boundary condition allows a useful mathematical solution, it may not accurately represent actual field conditions. This issue is discussed in this paper.

MATHEMATICAL MODEL

This section presents the mathematical description of the model including the governing equations, initial and boundary conditions, various assumptions, the resulting solution, and solution methods.

The equation describing time-dependent, radial flow with dispersion in a porous medium (Ogata 1970) can be written:

$$R\frac{\partial C}{\partial t} = \frac{1}{r}\frac{\partial\left(rD_r\frac{\partial C}{\partial r}\right)}{\partial r} - V_{gw}\frac{\partial C}{\partial r} \qquad (4)$$

Where *C* is the contaminant concentration, *D* is the dispersion coefficient, *r* is the radial coordinate, *R* is the retardation coefficient, and *t* is time.

The steady-state seepage velocity, V_{gw}, at any radius r in Equation 4 is obtained from the continuity equation:

$$V_{gw} = \frac{Q}{2\pi b r \phi} \qquad (5)$$

Where *b* is the thickness of the homogeneous, isotropic, infinite horizontal porous medium and *Q* is the constant rate of groundwater extraction.

For this paper we set $A = \frac{Q}{2\pi b\phi}$ so that $V = \frac{A}{r}$ is the seepage velocity or V_{gw}. From this point in the paper we will drop the subscript for conciseness.

Dispersion in the aquifer is assumed to follow the functional form presented by Bear (1972):

$$D = \alpha V \qquad (6)$$

Where α is the dispersivity. Because mass transfer by diffusion is small relative to advection, it is assumed to be included in the dispersion term (Freeze and Cheery 1979). The dispersivity in Equation

6 is taken to be scale-dependent (Lallemand-Barres and Peaudecerf 1978), i.e., $\alpha = 0.1L$ where *L* is the separation distance from the extraction well to some point of interest in the aquifer.

In terms of the previously defined symbols, the velocity-dependent dispersion coefficient can be written:

$$D = \alpha V \quad or \quad D = \frac{\alpha A}{r} \qquad (7)$$

To solve Equation 4, initial and boundary conditions are required. For this model, the initial contaminant concentration in the aquifer is assumed to be equal to C_0, $\{C(r,0) = C_0\}$ as the radius *r* approaches infinity, the concentration is assumed to be finite and equal to C_0, $\{C(\infty,t) = C_0\}$, and at the radius of the effective well bore, r_w, the concentration is assumed to go to zero instantaneously and stay at that value for all future time $\{C(r_w,t) = 0\}$ (Luckner and Schestakow 1991). These boundary and initial conditions allow a solution, but may not be exactly honored at actual sites.

By substituting Equations 5 and 6 into Equation 4, and making the following substitutions; $c = \frac{C}{C_0}$, $a = \frac{r_w}{\alpha}$, $\tau = \frac{\alpha A t}{R r_w^3}$, and $\bar{r} = \frac{r}{r_w}$, equation 4 can be rewritten in dimensionless form as:

$$\frac{\partial c}{\partial \tau} = \frac{1}{\bar{r}} \frac{\partial^2 c}{\partial \bar{r}^2} - \frac{a}{\bar{r}} \frac{\partial c}{\partial \bar{r}} \qquad (8)$$

Transforming Equation 13 to Laplace space (Hildebrand 1976) and using the initial boundary condition gives the following non-homogeneous, ordinary differential equation:

$$S\bar{c} - 1 = \frac{1}{\bar{r}} \frac{d^2\bar{c}}{d\bar{r}^2} - \frac{a}{\bar{r}} \frac{d\bar{c}}{d\bar{r}} \qquad (9)$$

where S is the Laplace variable and $\bar{c}$ is the dimensionless contaminant concentration in Laplace space.

The solution to Equation 9 can be found by using the method of undetermined coefficients (Kreyszig 1967). With this method, the general solution to the equation is the sum of the solution to the homogeneous portion of the equation and a particular solution that incorporates the non-homogeneity.

The homogeneous part of Equation 9:

$$S\bar{c} = \frac{1}{\bar{r}} \frac{d^2\bar{c}}{d\bar{r}^2} - \frac{a}{\bar{r}} \frac{d\bar{c}}{d\bar{r}} \qquad (10)$$

was solved using the computer package Mathematica version 3 (Wolfram 1996) which yields:

$$\bar{c} = c_1 e^{\frac{a}{2}(\bar{r}-1)} Ai\left[\left(\bar{r} + \frac{a^2}{4S}\right)S^{1/3}\right] + c_2 e^{\frac{a}{2}(\bar{r}-1)} Bi\left[\left(\bar{r} + \frac{a^2}{4S}\right)S^{1/3}\right] \qquad (11)$$

The simplest solution to the particular portion of Equation 9 is:

$$\bar{c} = \frac{1}{S} \qquad (12)$$

Using Equations 11 and 12, the general solution to Equation 9 can be written as:

$$\bar{c} = \frac{1}{S} + c_1 e^{\frac{a}{2}(\bar{r}-1)} Ai\left[\left(\bar{r} + \frac{a^2}{4S}\right)S^{1/3}\right] + c_2 e^{\frac{a}{2}(\bar{r}-1)} Bi\left[\left(\bar{r} + \frac{a^2}{4S}\right)S^{1/3}\right] \qquad (13)$$

Where *Ai* and *Bi* are Airy functions (modified Bessel functions of order 1/3) where *Ai(z)* tends to zero for large *z* while *Bi(z)* increases without bound, and c_1 and c_2 are constants.

To proceed we invoke the two boundary conditions. For the first boundary condition, the concentration is assumed to stay finite as $\bar{r}$ approaches infinity. For this case, since *Bi(z)* increases without bound, the constant c_2 in Equation 18 must equal zero, eliminating the second term.

$$c_2 = 0 \qquad (14)$$

The second boundary condition requires that the concentration be equal to zero for $\bar{r}$ equal to 1.0. To satisfy this condition, the constant c_1 in Equation 18 must have the value:

$$c_1 = \frac{-1}{S} \frac{1}{Ai\left[\left(1 + \frac{a^2}{4S}\right)S^{1/3}\right]} \qquad (15)$$

Using Equations 13, 14, and 15, the solution to Equation 9 can be written as:

$$\bar{c}(S) = \frac{1}{S} - \frac{\left(e^{\frac{a}{2}(r-1)}\right) Ai\left[\left(\bar{r} + \frac{a^2}{4S}\right)S^{1/3}\right]}{S\, Ai\left[\left(1 + \frac{a^2}{4S}\right)S^{1/3}\right]} \qquad (16)$$

Although a closed-form solution to the inversion of Equation 15 to real space is possible, the resulting integrals are difficult to evaluate, as indicated in the solution for an injection well presented by Tang and Babu (1979). To simplify the procedure for converting the concentrations in Laplace space to real space, we use the Stehfest algorithm (Stehfest 1970a and 1970b). The Stehfest algorithm replaces the *S* in Equation 21 with:

$$S = \frac{i\ln(2)}{\tau} \qquad (17)$$

and an approximate solution to the contaminant concentration in real dimensionless time and space is found using a numerical inverse Laplace transform with the expression:

$$C(\tau) = \frac{\ln(2)}{\tau}\sum_{i=1}^{N} V_i \bar{c}\left(\frac{i\ln(2)}{\tau}\right) \qquad (18)$$

where N determines the accuracy of the approximation (an even machine-dependent value, typically between 10 and 18), and the values for V_i are constants that depend on N in the following manner:

$$V_i = (-1)^{\frac{N}{2}+i} \sum_{k=\frac{i+1}{2}}^{\min\left(\frac{N}{2},i\right)} \frac{k^{\frac{N}{2}}(2k)!}{\left(N/2-k\right)!\,k!\,(k-1)!(i-k)!(2k-i)!} \qquad (19)$$

In carrying out the inversion of Equation 16, values of the Airy function were obtained from Amos (1983, 1985, and 1986) as implemented in Matlab (Mathworks 2008).

Estimating Retardation

Contaminant concentrations in the porous medium can be computed as a function of K_d, time, and radial distance from an extraction well by the numerical inversion of Equation 16 and used to determine the in-situ retardation coefficient by matching field measured values to computed values with K_d as the independent variable. This assumes that the initial and boundary conditions in the field are approximated by the assumptions used in this solution. In general, the initial condition of a uniform concentration and the assumption of a constant concentration at infinity are applicable for the scale of most field tests, where the concentration is limited in extent, but the effects from the boundaries are not evident near the well for typical testing time periods.

The second boundary condition is more problematic and may not be approximated at field sites.

Summary

This paper presented the development of a model for estimating the instantaneous concentration of a contaminant in an extraction well located in an initially uniform contaminant distribution. The radial transport equation with velocity-dependent dispersion solution was computed with the Stehfest algorithm to invert the Laplace space function to a dimensionless concentration in real space.

ABSTRACT

Licensing of commercial nuclear power reactors requires an assessment of a postulated accidental release of radioactive liquid effluent in ground and surface waters to demonstrate that the dose to an individual member of the public does not exceed regulatory limits. The radioactive liquid effluent with the highest potential exposure consequences to offsite water users is associated with the liquid waste management system and is comprised of a mixture of fission and activation products with a wide range of half-lives. The liquid effluent containing tanks postulated to fail are located below ground such that a liquid release would enter the groundwater and then be subject to groundwater transport offsite with radionuclide concentrations being attenuated by the processes of radioactive decay, adsorption, and dispersion. Evaluations of these postulated releases have been completed and included in the license applications for 17 new nuclear power reactor sites. Results of these analyses indicate that groundwater travel times vary widely from site to site and that groundwater to surface water pathways are present for many of the sites. Comparisons of predicted radionuclide concentrations at offsite receptor locations to regulatory limits indicate compliance with the dose limits for an individual member of the public, with tritium having the potential for the greatest dose contribution.

INTRODUCTION

Recently, there has been renewed interest on the part of the electrical utilities in licensing new nuclear power reactor in the United States. This interest has been stimulated by a streamlined licensing process that reduces the financial risk to applicants, anticipated growth in the demand for electricity, increased public acceptance of nuclear power, and recent changes to United States energy policy that promote energy independence as well as reductions in greenhouse gas emissions. Currently, there are 21 new power reactor sites planned, with 17 having submitted license applications to the U.S. Nuclear Regulatory Commission (NRC), which regulates the construction and operation of commercial nuclear power plants in the United States. The 17 sites are located primarily in the Central and Eastern United

States; 15 are adjacent to existing reactors and 2 are greenfield sites. Current license application are based on one of five reactor technologies, which include Areva's EPR™, General Electric's Advanced Boiling Water Reactor (ABWR) and Economic Simplified Boiling Water Reactor (ESBWR), Mitsubishi's U.S. Advanced Pressurized Water Reactor (US-APWR), and Westinghouse's AP1000™. These reactors are standardized Generation III designs, as classified by the U.S. Department of Energy, that are in various stages of design certification by the NRC. Table 1 summarizes the sites, locations, and technologies for which licenses applications have been submitted.

Table 1. Current License Applications for New Nuclear Power Reactors.

Site	Location	Technology

Vogtle Units 3 & 4	Burke County, GA	AP1000

Nuclear power plants, like any other complex industrial facility, utilize substances that, if released to the environment, could result in adverse impacts to human health. In the case of a nuclear power plant, the primary substances of concern include radioactive isotopes generated as fission or activation products. Outside of safety-related containment facilities, the highest liquid phase inventories of these radioactive isotopes generally occur in the Liquid Waste Management System (LWMS) of a nuclear power plant. A typical LWMS includes tanks, piping, pumps, valves, filters, demineralizers, and any additional equipment necessary to process and treat liquid wastes and route them to the point of discharge from the system. As part of the nuclear power plant licensing process, applicants are required to demonstrate that an accidental release of radioactive liquid effluent from a LWMS to the groundwater would not result in a radiation dose to a member of the public in excess of the Federal limit. Assessing a hypothetical, accidental liquid release for a particular site involves data collection efforts needed to characterize the site geology, establish site-specific hydrogeologic properties, and develop conceptual transport models. The radioactive source term, which may include a large number of radionuclides, must also be defined. Transport modeling is then used to estimate radionuclide concentrations in the groundwater, or surface water receiving groundwater discharge, that a member of the public could potentially ingest. Predicted concentrations are then compared against Federal limits, considering dose contributions from multiple radionuclides and radioactive progeny, to determine regulatory compliance.

This paper describes the process of assessing postulated accidental releases of radioactive liquid effluents from nuclear power plants. Regulatory requirements and associated guidance documents are summarized. Radioactive source terms from the different reactor types are described in terms of location, inventory, and radionuclide properties. An overview of the hydrogeologic site characterization activities required to support an accidental liquid release assessment is provided. Reactive transport modeling approaches used to support an accidental release analysis are described. Finally, accidental release analysis results included in current license applications are presented and discussed.

REGULATORY REQUIREMENTS

Radiation dose limits for members of the public from the operation of a nuclear power plant are established in 10 CFR Part 20. In particular, 10 CFR 20.1302 indicates that compliance with the dose limit for liquid releases may be established by demonstrating that (i) the annual average concentrations of radioactive material released in liquid effluents at the boundary of the unrestricted area do not exceed the values specified in Table 2, Column 2 of Appendix B to 10 CFR Part 20; and (ii) the annual dose from external sources to an individual continuously present in an unrestricted area does not exceed 50 mrem. Note that the concentration values given in Table 2, Column 2 of Appendix B are equivalent to the radionuclide concentrations which, if ingested over the course of a year, would produce an annual dose of 50 mrem assuming that an individual ingests water at a rate of 2 L/d.

To assist applicants in preparing license applications for nuclear power plants, the NRC has issued Regulatory Guide 1.206 (NRC, 2007a). Section C.I.2.4.13 of this guidance document is relevant to accidental releases of radioactive liquid effluents and indicates that the applicant should describe the ability of the ground and surface water environment to delay, disperse, dilute, or concentrate liquid effluents, as related to existing or potential future water users. Regulatory Guide 1.206 also indicates that the bases used to determine dilution factors, dispersion coefficients, flow velocities, travel times, adsorption, and pathways of liquid contaminants should be discussed and references to the locations and water users as well as release points be provided.

To provide NRC staff guidance in reviewing license applications for nuclear power plants, the NRC has published NUREG-0800 (NRC, 2007b). In particular, Section 2.4.13, Accidental Releases of Radioactive Liquid Effluents in Ground and Surface Waters, directs NRC staff to: (a) use best current practices to analyze groundwater transport of radioactive liquid effluents; (b) consider sufficient alternate conceptual models to bound the hydrogeologic conditions that define the transport of radioactive liquid effluents; (c) identify the bounding set of plausible pathways that may result in the worst-case contamination; and (d) establish radionuclide transport characteristics from on-site measurements. Also of interest is Branch Technical Position (BTP) 11-6, Postulated Radioactive Releases Due to Liquid-containing Tank Failures. This document provides guidance on developing the radioactive source term to ensure that the highest potential radioactive material inventory is selected among the expected types of liquid waste streams processed by the LWMS. Specifically, this document requires that the radionuclides selected for the radioactive source term and

total inventory should include those that have the highest potential exposure consequences to users of water resources, including long-lived fission and activation products and environmentally mobile radionuclides. BTP 11-6 further prescribes that the radionuclide inventory for the LWMS tank assumed to fail is based on 80% of volume capacity of the tank. BTP 11-6 also indicates that the evaluation of a LWMS tank failure consider the impact on the nearest potable water supply, and the use of water for direct human consumption or indirectly through animals (livestock watering), crops (agricultural irrigation), and food processing (water as an ingredient).

RADIOACTIVE SOURCE TERM

The radioactive source term needed to evaluate the potential dose consequences to individual members of the public from a postulated LWMS tank failure is dependent on the reactor technology adopted for a given site. Radioactive source terms, to be used for assessing a LWMS tank failure, have been identified by the reactor manufacturers based on the criteria provided in BTP 11-6. Table 2 summarizes the characteristics of these source terms for the AP1000, EPR and ESBWR, including physical data on the tank that would have the highest potential exposure consequences, if it were to fail, and the radiological characteristics of the tank's contents.

Table 2. Radioactive Source Terms for Current Reactor Technologies.

Characteristic	AP1000	EPR	ESBWR
Controlling tank	Effluent holdup tank	Reactor coolant storage tank	Equipment drain collection tank
Location	Auxiliary building	Auxiliary building	Radwaste building
Capacity (m^3)	140	115	106
Floor elevation (m bgs)	10.2	9.6	14.0
Radionuclides in mixture	56	60	60
Initial activity (Ci)	476	785	39.8
Activity after 2-y decay (Ci)	111	144	9.17
Radionuclides exceeding individual ECLs after 2-y decay (in descending order of ECL exceedance)	Cs-137, Cs-134, H-3, Co-60, Sr-90, Mn-54, Ag-110m, Ce-144, Fe-55	Cs-134, Cs-137, H-3, Co-60, Sr-90, Zn-65, Mn-54, Ru-106, Fe-55, Ce-144	Cs-137, Co-60, Zn-65, Sr-90, Cs-134, Fe-55, Ru-106, Mn-54, Ce-144, H-3, Ag-110m

A review of the information in Table 2 indicates that the controlling tanks for the source terms are of similar capacity as well as in location relative to site grade. Each tank is located well below grade at depths ranging from 9.6 to 14.0 m below ground surface (bgs) such that a postulated accidental release from a tank failure would occur in the subsurface. At these depths, the source term for each of the designs could be below the water table at many sites in the Central and Eastern United States where new nuclear power plants are being considered.

The radiological data included in Table 2 indicate that each source term represents a mixture of a relatively large number of isotopes, with up to 60 isotopes present. Each isotope has a unique half-live for radioactive decay, while isotopes of a common element have unique transport characteristics in terms of adsorption. In addition, some isotopes may produce progeny that can have significant dose consequences themselves and must be considered in the accidental release analysis.

The total initial activities of the source term, based on 80% of the controlling tank capacity, vary significantly across the reactor technologies, with the ESBWR having the least activity and the EPR having the greatest activity. The half-lives of the isotopes in the source terms are highly variable and range from 30 seconds for Rh-106 to 15.7 million years for I-129. Because the time scales for groundwater transport are relatively large, the short-lived radionuclides in the source term will decay to levels such that they have no impact on demonstrating regulatory compliance. As a measure of the short-lived radionuclide content, each radionuclide was decayed for a two-year period, a representative groundwater travel time, and the total activity determined for each source term. Results summarized in Table 2 indicate that when compared to the total initial activity, only about 20% of the initial source term activity is expected to participate in the assessment of 10 CFR 20.1302 compliance. Comparing the resulting individual radionuclide concentrations against the Effluent Concentration Limits (ECLs) specified in Table 2, Column 2 of Appendix B to 10 CFR Part 20, the radionuclides expected to be important in an accidental release analysis can be identified. The results provided in Table 2 indicate that these radionuclides are similar across the three source terms with the common radionuclides including, in order of decreasing half-life, the following: Cs-137, Sr-90, H-3, Co-60, Fe-55, Cs-134, Mn-54, and Ce-144.

SITE CHARACTERIZATION

In order to assess the dose consequences of a postulated LWMS tank failure on an individual member of the public, a thorough understanding of the geologic and hydrogeologic site characteristics is required, both conceptually and quantitatively. In fact, 10 CFR 100.20(c)(3) requires that factors important to hydrological radionuclide transport be obtained from on-site measurements. Site characterization efforts must be sufficient to: (a) identify the most likely conceptual model for the site along with alternative conceptual models; (b) establish bounding subsurface pathways from the point of release to the nearest potable water supply in an unrestricted area; and (c) define the radionuclide transport characteristics of the groundwater environment. While a complete description of the required site characterization activities is beyond the scope of this paper, the following overview is provided.

Site characterization efforts involve drilling and sampling geotechnical boreholes, and field and laboratory testing for the purpose of defining the stratigraphy as well as determining the geotechnical and transport properties of the subsurface materials. Typically about 100 boreholes per reactor are required to sufficiently define the subsurface conditions for the systems, structures, and components that comprise a nuclear power plant. Observation wells are installed in a subset of the boreholes and completed in the hydrogeologic units of interest. Ideally, observation wells are located such that synoptic measurements yield reliable distributions of piezometric head from which groundwater flow directions and pathways may be inferred. Following installation, slug tests are performed in observation wells to provide estimates of hydraulic conductivity. Pump tests are also typically conducted to define the hydraulic characteristics of the hydrogeologic units of interest. These field and laboratory testing efforts provide on-site measurements of hydraulic

conductivity, total and effective porosity, bulk density, and radionuclide distribution coefficients. Observation wells are then monitored to determine the seasonal variation in piezometric head elevations. These piezometric head data are used to develop piezometric surfaces from which hydraulic gradients can be estimated and groundwater flow paths can be identified.

Groundwater flow models are often used to integrate the large amounts of field and laboratory data described above. Groundwater models provide additional value in that once they are developed and calibrated for pre-construction conditions, they can be used predict post-construction groundwater conditions. This is particularly important for a nuclear power plant because the large foundations may extend below the water table and locally alter the hydrogeologic characteristics. Also, the groundwater recharge characteristics may be altered over relatively large areas with changes in land cover and grading of the site. With these post-construction changes represented and site-specific hydrogeological characteristics represented, the groundwater model can then be used to identify the groundwater pathways for an accidental release of radioactive liquid and associated receptors, and provide a best estimate of the groundwater travel time.

ACCIDENTAL RELEASE ANALYSIS

With the source term, groundwater pathways, and transport characteristics defined, the accidental release analysis becomes a simple matter of performing reactive transport modeling to predict the radionuclide concentrations in the nearest potable water supply in an unrestricted area. Figure 1a depicts a simple conceptual model in which liquid effluent is released from a failed LWMS tank to a water table aquifer with subsequent saturated zone transport to the site boundary. Although each of the current reactor designs incorporate engineered features to mitigate a release (e.g., level alarms, collection sumps, steel and concrete barriers), usually no credit is taken for these features in preventing a release the groundwater environment. At the site boundary, outside of which is considered an unrestricted area, it is hypothesized that an individual member of the public installs a well and ingests water supplied from the well. Figure 1b illustrates the case in which liquid effluent released to the groundwater discharges to surface water within the restricted area, which then discharges offsite to the unrestricted area. In this case, it is assumed that an individual member of the public installs an intake and ingests water supplied from the intake.

A variety of reactive transport modeling approaches can be used to predict radionuclide concentrations at the site boundary, ranging from simple analytical models that consider radioactive decay alone to multi-dimensional numerical models that mechanistically represent all key transport processes. As a rule of thumb, it is desirable to use the simplest model with the fewest parameters in conjunction with conservative assumptions to demonstrate compliance. Because several radionuclides in the source terms produce radioactive progeny that must accounted for, the reactive transport model should normally represent these decay chain sequences. The simplest model that represents these sequences, but ignores hydrodynamic dispersion and retardation, is given by Kennedy and Strenge (1992). Use of this model accounts for advection only, but has the advantage of requiring only one transport parameter, the

groundwater travel time, which can be estimated from on-site measurements of hydraulic conductivity, hydraulic gradient, effective porosity, and groundwater travel distance. A groundwater flow model, used as part of the site characterization effort, can also be used to estimate the groundwater travel time.

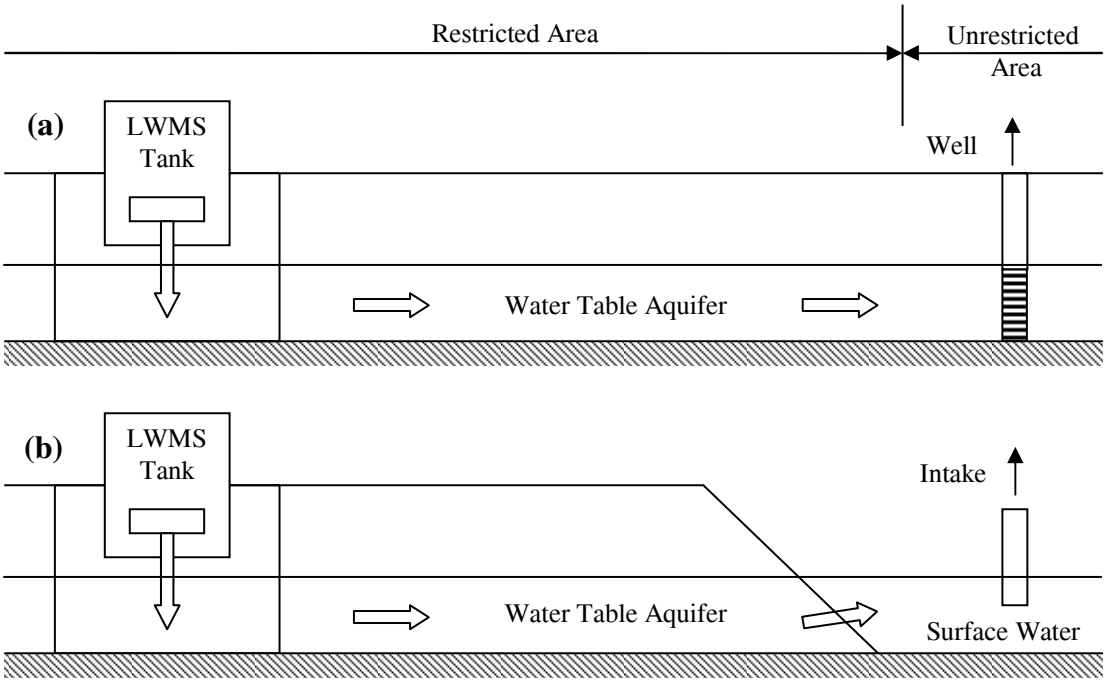

Figure 1. Conceptual Models for an Accidental Release of Liquid Effluent.

If accounting of retardation and hydrodynamic dispersion is needed to further attenuate radionuclide concentrations to demonstrate compliance, a more complex model would be required along with additional parameters needed to represent these processes. Javandel et al. (1984) provide one-dimensional analytical solutions for advective-dispersive-reactive solute transport that can be applied. Use of these solutions requires definition of the groundwater velocity, coefficient of longitudinal hydrodynamic dispersion, and retardation factor. These solutions do not consider decay chain sequences and are applicable only for radionuclides that undergo simple decay. Fortunately, this is the case for most, but not all radionuclides that have the greatest impact on regulatory compliance (i.e., H-3, Mn-54, Fe-55, Co-60, Cs-134, Cs-137, and Ce-144). Note that Sr-90, common to all radioactive sources, produces progeny that may require modeling. Note also that Np-239, present in the source term for the ESBWR, rapidly decays to Pu-239 and can impact compliance. In these cases, Srinivasan and Clement (2008) provide one-dimensional analytical solutions that can be used to model the decay chain sequences.

A complex hydrogeological setting may necessitate the use of a numerical flow and transport model to represent the relevant flow and transport phenomena. Commonly used codes that consider multi-species reactive transport and are capable of modeling radioactive decay chain sequences include RT3D (Clement, 1997) and MT3DMS (Zheng and Wang, 1999). The obvious advantage of numerical models is

their ability to more accurately represent complex hydrogeologic systems. The primary disadvantage is that the data needed to fully define the spatial variability in formation properties and boundary conditions are usually not available, which can introduce uncertainty into the model predictions.

In some cases groundwater contaminated with radioactive liquid effluent may discharge to the surface and mix with uncontaminated surface water before reaching the unrestricted area. In such cases estimating the radionuclide concentrations at the point of compliance should account for dilution of the groundwater discharge in the surface water.

Once radionuclide concentrations are determined for the unrestricted area, they can be compared against the ECLs given in Table 2, Column 2 of Appendix B to 10 CFR Part 20 to assess regulatory compliance. Because the source term consists of a radionuclide mixture and because the individual ECLs correspond to annual dose of 50 mrem, it is necessary to apply the unity rule to ensure that the dose contributions from all radionuclides present, when summed, do not exceed the 50 mrem limit. The unity rule may be expressed as

$$\sum_{i=1}^{n} \frac{C_i}{ECL_i} \leq 1$$

where: C_i is the concentration of the i^{th} radionuclide at the point of compliance; ECL_i is the effluent concentration limit for the i^{th} radionuclide; and n is the number of radionuclides in the mixture. Provided that the unity rule is satisfied, compliance with the requirements of 10 CFR 20.1302 is demonstrated. Note that the left hand side of the unity rule equation is time dependent because the radionuclides in the mixture are retarded by varying degrees and would arrive at the point of compliance at different points in time.

RESULTS AND DISCUSSION OF CURRENT ASSESSMENTS

The analyses described above have been completed for 17 reactor sites and included in license applications submitted to the NRC. The complete applications are available online at http://www.nrc.gov/reactors/new-reactors/col.html. The accidental release assessments are included in Part 2, Final Safety Analysis Report, Section 2.4.13. Table 3 summarizes the groundwater travel times, surface water dilution factors (as applicable), sums of fractions (left-hand-side of unity rule), radionuclides having the greatest dose contributions, and methodologies used for reactive transport analysis. Groundwater travel time was selected as a representative site characteristic because: (a) travel time effectively integrates many of the important hydrogeologic properties (i.e., hydraulic conductivity, hydraulic gradient, effective porosity, groundwater travel distance) into a single parameter; and (b) travel time determines the amount of radionuclide attenuation due to radioactive decay. The surface water dilution factor was included because groundwater to surface water pathways are present at many of the sites, and dilution in surface water plays an important role in reducing radionuclide concentrations.

Table 3. Results of Accidental Release Assessments.

Site	Travel Time (y)	Dilution Factor	Sum of Fractions	Primary Radionuclides	Reactive Transport Methodology
Bell Bend	0.56	4.75E-06	4.70E-03	H-3	Kennedy and Strenge (1992)
Bellefonte	2.33	-	4.92E-02	H-3	Yu et al. (2007)
Callaway	3020	-	2.48E-01	I-129	Kennedy and Strenge (1992)
Calvert Cliffs	4.02	5.09E-04	4.29E-01	H-3	Kennedy and Strenge (1992)
Comanche Peak	-	-	2.20E-01	Cs-134, Cs-137	Assumed diluted in 1.7E+8 m^3 of water and 1-y decay
Grand Gulf	NA	-	7.93E-02	Zn-65	Yu et al. (2007)
Levy Co.	68	-	6.41E-03	H-3	Codell and Duguid (1983)

North Anna	5.03	1.02E-03	2.26E-01	Sr-90	Kennedy and Strenge (1992)
River Bend	2.63	-	1.69E-02	Ru-106, Mn-54, Ce-144, Sr-90, Y-90, H-3	Yu et al. (2007)
Harris	2.3	NA	1.40E-01	H-3	Codell and Duguid (1983)
South Texas	123	-	1.00E-02	H-3	Kennedy and Strenge (1992)
Victoria Co.	25.7	-	6.28E-01	H-3	Javandel et al. (1984)
Summer	17.4	1.34E-06	5.32E-04	H-3	Kennedy and Strenge (1992)
Vogtle	6.7	8.30E-05	5.80E-02	H-3	Kennedy and Strenge (1992)
Lee	NA	NA	2.44E-02	H-3	Yu et al. (2007)

Results in Table 3 indicate that the groundwater travel times vary widely, ranging from 0.56 to 3020 years and having a median value of 6.7 years. Groundwater to surface water pathways are present at 8 of 15 sites, with dilution factors ranging in magnitude from 10^{-3} to 10^{-6}. The sum of fractions for all sites is less than unity, suggesting that all sites meet 10 CFR 20.1302 requirements. Based on the magnitude of the dilution factors, it should be noted that compliance may not have been achieved without relying on surface water dilution. Results in Table 3 further indicate that H-3 has the greatest contribution to the sum of fractions at 11 of 16 sites, and is generally the primary radionuclide of interest. This occurs because: (a) initial H-3 concentrations are large relative to its ECL for the AP1000 and EPR technologies; (b) the 12.35-year half-live for H-3 is long relative to many of the site groundwater travel times; and (c) H-3, when integrated into a water molecule, does not undergo adsorption or retardation. In terms of methods used for reactive transport modeling, solutions derived from Kennedy and Strenge (1992) were applied at 8 of the sites, RESRAD-OFFSITE (Yu et al., 2007) was used at 4 of the sites, the solution given by Codell and Duguid (1983) was applied at 2 sites, and the one-dimensional solution given by Javandel et al. (1984) was used at one site.

For the Comanche Peak site, no site-specific accidental release assessment was performed. Instead, the applicant cited the generic assessment included in the US-APWR's Design Control Document, which assumes dilution of the released liquid in 1.7×10^8 m^3 of water prior to reaching the location of the potable water supply and one year of radioactive decay. Therefore, no site-specific travel time or dilution factor is reported for this site. In the Fermi license application, the applicant assumed that ESBWR design features would preclude an accidental release, citing

guidance provided in BTP 11-6 (NRC, 2007b). No assessment was therefore completed for this site.

SUMMARY AND CONCLUSIONS

The licensing of nuclear power reactors requires an assessment of a postulated accidental release of radioactive liquid effluent in ground and surface waters to demonstrate that the dose to an individual member of the public does not exceed regulatory limits. The assessment process requires definition of a radioactive source term, characterization of hydrological transport properties, and reactive transport modeling to predict radionuclide concentrations in water supplies accessible by the public. Seventeen assessments have been completed to date. The liquid effluent containing tanks postulated to fail are located below ground such that the liquid release would enter the groundwater and then be subject to groundwater transport offsite with concentrations being attenuated by the processes of radioactive decay, adsorption, and dispersion. Groundwater travel times vary widely from site to site and groundwater to surface water pathways are present for many of the sites. Comparing predicted concentrations to Federal limits indicates regulatory compliance at all sites.

MODELING OF CHLORINATED VOCs TRANSPORT UNDER DUAL BIOREACTIONS

Wonyong Jang and Mustafa M. Aral
Multimedia Environmental Simulation Laboratory, School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, GA, USA

ABSTRACT

Once chlorinated volatile organic compounds (CVOCs) are released into the subsurface they are spread out through the porous soil matrix by complicated processes such as advection, dispersion, and sorption. CVOCs can be also biodegraded by indigenous microorganism via aerobic and anaerobic bioreactions, which generate distinct benign or harmful by-products. Heterogeneous subsurface characteristics and non-uniform distribution and consumption of oxygen in the subsurface may allow the dual bioreactions to coexist within a representative subsurface volume (RSV). The portion of each bioreaction within a RSV will depend on multiple factors such as oxygen, contaminant, and microorganism levels. Oxygen can be supplied into the contaminated zone through the dispersive and advective transport of oxygen in gas phase as well as the flow of the groundwater containing dissolved oxygen. As the dual bioreactions are coupled with multiple fluid flows (groundwater and gas) and multispecies transport, the analysis of the bioreactions is very complicated. However, the enhanced understanding of the dual bioreactions of CVOCs is required in accurately predicting the fate and transport of CVOCs at the contaminated sites.

This study numerically investigates: the effects of dual bioreactions on the fate and transport of CVOCs in the variably saturated zone; and, the temporal and spatial evolution of bioreaction zones in the domain. Trichloroethylene is selected as a primary contaminant, and its sequential aerobic/anaerobic bioreactions are considered.

INTRODUCTION

Soil and groundwater contamination is often initiated by an accidental spill or leakage of chlorinated volatile organic compounds (CVOCs), such as trichloroethylene (TCE) and dichloroethylenes (DCEs), in the form of a non-aqueous phase liquid (NAPL). Leaked NAPL CVOCs volatilize into soil gas, dissolve into water, and absorb onto soil in multi-phase subsurface environments. They often become a long-lasting contaminant source, contributing to subsurface pollution, which may cause ecological and/or human health risks. The transport of the contaminants in the subsurface is a combined outcome of complicated processes such as advection, dispersion, sorption, and chemical and biological transformations. Among those multiple processes, biological transformation of CVOCs can play an important role in converting the toxic contaminant into daughter toxic contaminants or into benign chemicals within the aerobic-anaerobic subsurface environment.

Biological degradation of CVOCs depends on many physicochemical and biological parameters such as oxygen, carbon-sources, and indigenous microorganisms. And the bioprocesses of CVOCs are typically divided into three

main groups: dehalogenation, cometabolism, and oxidation for growth under anaerobic or aerobic conditions (Figure 1). Under anaerobic conditions, TCE can be biologically transformed by sequential reductive dechlorination: TCE ⇒ dichloroethylenes (DCEs) ⇒ vinyl chloride (VC)⇒ Ethene (Figure 1). Under aerobic conditions, however, CVOCs can be biologically degraded via cometabolic processes, which usually don't generate harmful byproducts.

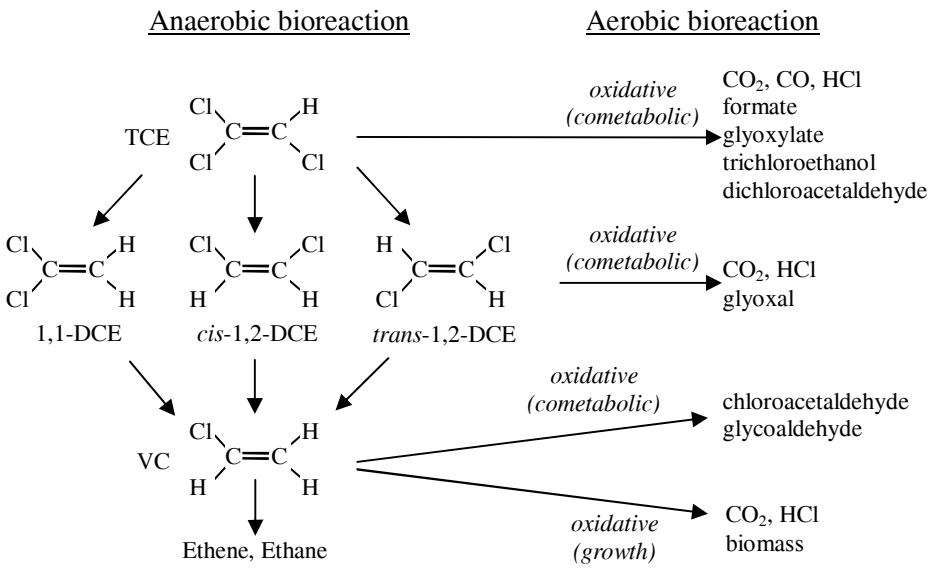

Figure 1. Anaerobic/aerobic degradation of CVOCs.

The aerobic and anaerobic biotransformation of CVOCs has been reported at contaminated sites (Hinchee et al. 1995; Lenczewski et al. 2003). At TCE-contaminated sites, DCEs and VC were also detected within both water and gas phases in the unsaturated zone as well as within the water in the saturated zone (Maslia et al. 2007). These occurrences are due to anaerobic biotransformation and partitioning processes of the contaminants (Lorah and Olsen 1999; Wiedemeier 1998). In addition to anaerobic bioreactions of CVOCs, aerobic bioreactions of DCEs and VC have been also documented at contaminated sites, especially at the aerobic fringe of contaminant plumes (Clement et al. 2000; Lenczewski et al. 2003). It is important to note that the anaerobic and aerobic bioreactions of CVOCs, coexisting at contaminated sites, generate totally different byproducts (Figure 1), resulting in distinct environmental effects. Thus, a well-defined classification of target sites into co-existent aerobic or anaerobic regions is very important in accurately predicting the fate and transport of parent and daughter contaminants.

The subsurface is highly heterogeneous in terms of hydro-geological, physical, chemical, and biological conditions. Considering the heterogeneities, such as rate-limited dispersion of oxygen through porous media and locally distinct utilization of oxygen, we could expect three-types of bioreaction blocks: pure aerobic block, pure anaerobic block, and aerobic-anaerobic-mixed block. The last block refers to a representative subsurface element, in which both aerobic and anaerobic bioreactions occur simultaneously. The concentration and distribution of oxygen in

the subsurface system result from complicated interrelationships between oxygen supply and consumption. Oxygen can be transported into the ground via air circulation between the atmosphere and the subsurface mostly in the unsaturated zone or induced oxygen supply in air sparging (Jang and Aral 2007a; 2009). Aerobic biological processes consume oxygen as an electron acceptor, resulting in the reduction of oxygen concentration.

The purpose of this study is to investigate the aerobic-anaerobic biological transformation of CVOCs and their fate and transport in the subsurface. We focus on the evolution of aerobic and anaerobic bioreaction zones and the development of contaminant plumes under the dual biodegradation of the contaminants. Among CVOCs, TCE is selected as a primary NAPL contaminant. Sequential dehalogenation and cometabolism of contaminants are considered as biological processes in anaerobic and aerobic subsurface environments.

MATHEMATICAL FORMULATION AND NUMERICAL METHOD

The groundwater system considered here consists of groundwater, soil gas, solid soil, and nonaqueous phase liquid (NAPL) TCE. The NAPL TCE is only present in a TCE source area and is assumed to be immobile. The groundwater and soil gas are mobile here, leading to two-phase flow (multiphase flow) in the subsurface system. Contaminant migration occurs along with the flows of groundwater and soil gas.

Flow Equation of Groundwater and Gas: The governing equation for multiphase flow can be written as (Jang and Aral 2007b)

$$\frac{\partial\left(\phi s_f \rho_f\right)}{\partial t} = \nabla \cdot \left[\frac{\rho_f k_m k_{rf}}{\mu_f} \left(\nabla P_f + \rho_f g \nabla z \right) \right] + I_f + Q_f; \quad f = g, w \tag{1}$$

where the subscript f represents the mobile fluids (g: gas and w: water), ϕ is the porosity, s is fluid saturation, ρ is fluid density (ML^{-3}), μ is the dynamic viscosity ($ML^{-1}T^{-1}$), k_r is relative permeability, k_m is the intrinsic permeability tensor for the soil media (L^2), P is the fluid pressure ($ML^{-1}T^{-2}$), g is the gravitational constant (LT^{-2}), z is elevation (L), I_f indicates a sink/source term for the gas phase due to the partitioning processes of contaminants between phases ($ML^{-3}T^{-1}$), and Q is a sink/source ($ML^{-3}T^{-1}$).

Contaminant Fate and Transport Equation: The transport equation of multiple contaminants in the water and gas phases can be written as

$$\frac{\partial\left(\phi s_f C_f^i\right)}{\partial t} = \nabla\left(\phi s_f D_f^i \nabla C_f^i\right) - \nabla\left(q_f C_f^i\right) + I_{f,MT}^i + I_{f,BT}^i \tag{2}$$

where the superscript i and the subscript f represent indexes for chemical species and fluid phases, respectively; C is a concentration of contaminants in each phase (ML^{-3}); D and q are the dispersion tensor (L^2T^{-1}) and Darcy flux (LT^{-1}), respectively; and, I_{MT} and I_{BT} indicate inter-phase mass transfer of contaminants and biotransformation ($ML^{-3}T^{-1}$), respectively. Applying first-order relationships in describing the

dissolution, volatilization, and water-gas partitioning processes for contaminants, the mass transfer terms for the water and the gas phases can be written as,

$$I^i_{w,MT} = \phi s_w \lambda^i_D \left(C^i_{we} - C^i_w\right) + \phi s_g \lambda^i_H \left(C^i_g - H^i C^i_w\right) \quad (3)$$

$$I^i_{g,MT} = \phi s_g \lambda^i_V \left(C^i_{ge} - C^i_g\right) - \phi s_g \lambda^i_H \left(C^i_g - H^i C^i_w\right) \quad (4)$$

where λ_D, λ_V and λ_H are the first-order mass transfer coefficients (T^{-1}) for NAPL/water, NAPL/gas and water/gas phases, respectively; C_{we} and C_{ge} are the maximum contaminant concentrations in water and gas phases, respectively; and, H is a dimensionless Henry's law coefficient. Biological transformations under anaerobic and aerobic conditions, as shown in Figure 1, yield different byproducts. The biological processes of TCE considered herein are listed in Table 1. Among the three isomers of DCEs, cDCE is chosen as the representative of the isomers.

Table 1. Simplified anaerobic and aerobic biotransformation of TCE.

Reaction	Kinetics
• Anaerobic dehalogenation without inhibition or with sequential inhibition. TCE → cDCE → VC	• First-order • Michaelis-Menten
• Aerobic biodegradation. TCE, cDCE, VC → (Oxygen and microbes) → CO_2, H_2O, HCl	• First-order • Michaelis-Menten
• No bioreaction due to lack of carbon sources and/or microorganisms.	None

The bioreaction kinetics of contaminants is very important in designing a bioremediation system, and is also required as components of fate and transport models (Alvarez-Cohen and Speitel 2001). Due to the complexities of biological processes of contaminants, however, it is almost impossible to entirely understand and express all biological reaction mechanism and kinetics. In numerical applications, Michaelis-Menten (or Monod) and first-order kinetics are often used to express reductive dechlorination and cometabolic biodegradation reactions of chlorinated hydrocarbons (Alvarez-Cohen and Speitel 2001; Clement et al. 2000; Haston and McCarty 1999; Schmidt et al. 1985; Wiedemeier 1998). The two kinetics are used herein to delineate co-existing aerobic-anaerobic bioreactions of CVOCs (Table 1). Michaelis-Menten model are (Pavlostathis and Prytula 2000):

$$r_b = -\frac{k' C}{K_S + C} \quad (5)$$

where r_b is the rate of bioreactions ($ML^{-3}T^{-1}$); $k' = kX$ is the maximum bioreaction rate (MT^{-1}); k is the maximum specific rate of substrate degradation ($M_{substrate}\ M^{-1}_{cell}\ T^{-1}$); C is the chemical concentration (ML^{-3}); X is the active microbial concentration (ML^{-3}); K_S is the half-saturation constant for the substrate (ML^{-3}). A first-order model can be written as:

$$r_b = -k_1 C \tag{6}$$

where k_1 is the first-order reaction coefficient (T^{-1}). The biological processes can be expressed:

$$I^i_{w,BT,Anaerobic} = \phi s_w \varepsilon r^{i-1}_{b,Anaerobic} - \phi s_w \varepsilon r^i_{B,Anaerobic} \quad \text{for anaerobic bioreaction} \tag{7}$$

$$I^i_{w,BT,Aerobic} = -\phi s_w (1-\varepsilon) r^i_{B,Aerobic} \quad \text{for aerobic bioreaction} \tag{8}$$

where ε is a ratio of an anaerobic bioreaction to all bio-reaction within a soil matrix.

A three-dimensional Galerkin-finite-element-based numerical model, TechFlowMP (Jang and Aral 2005) is used to solve the multiphase flow and contaminant transport equations. Globally-continuous Darcy velocity estimation process, which was proposed by Yeh (1981), is applied here to improve the accuracy and also to overcome the discontinuity problems in calculating flow velocities.

MODEL APPLICATION

A two-dimensional unconfined aquifer with dimensions of (200 m × 16 m) in (x, y) directions, shown in Figure 2, is used to investigate the plume evolution of TCE, cDCE, and VC under aerobic and anaerobic biotransformation and density-driven advection of the gas phase. TCE in NAPL as a primary contaminant is introduced to the unsaturated zone and resides in the pore spaces as an immobilized contaminant source. The TCE residual is set to NAPL saturation of 0.1 at the source zone.

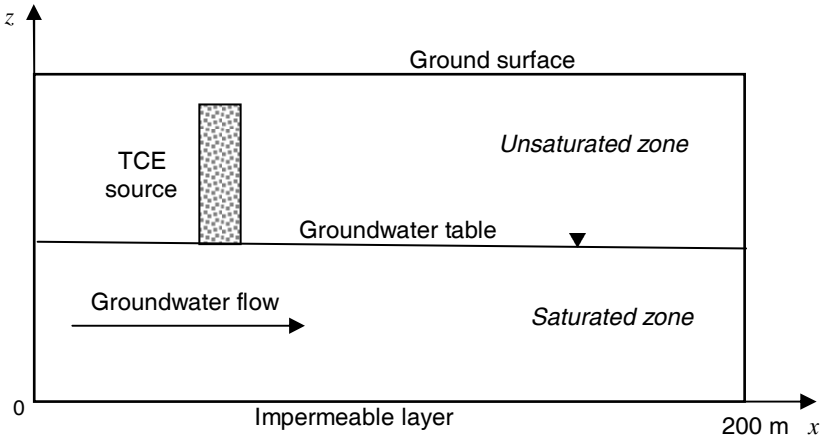

Figure 2. A modeling domain for dual biotransformation of CVOCs.

Initial concentrations of TCE, cDCE, and VC in gas, water, and solid soil phases are set to zero within the domain. As boundary conditions at the ground surface, infiltration for water phase, and constant atmospheric pressure for gas phase are applied. For contaminant transport in gas phase, the ground surface is set to a stagnant boundary layer of 0.3 m thickness. The parameters of a soil medium used here are: k_m=1.0×10^{-10} m^2 and Porosity ϕ=0.35. First-order rate coefficients for dissolution, water-gas partitioning, and volatilization are 1.0 d^{-1}.

Three scenarios are considered here to examine the effect of dual biological reactions on contaminant transport in the subsurface system:

- Case I: Single anaerobic biotransformation can occur in the whole modeling domain. No aerobic bioprocess is assumed.
- Case II: Dual bioreactions. Both anaerobic and aerobic bioreactions coexist in the domain.
- Case II: No bioreaction

EXPECTED RESULTS

The co-existence concept of aerobic and anaerobic bioreactions is implemented in analyzing the transport of multiple CVOCs within the flow of gas and groundwater in the subsurface. In this study, we expect to present the following outcomes:

- the effects of dual bioreactions on the fate and transport of CVOCs in the variably saturated zone;
- the temporal and spatial evolution of bioreaction zones in the domain; and
- the variation in the concentrations of oxygen and other nutrients in the subsurface domain.

The bioreactivity for both aerobic and anaerobic processes can be evaluated according to the distribution and availability of carbon sources for microorganisms. Under the consideration of no, single, and/or simulataneous-multiple bioreactions of CVOCs, more accurate fate and transport of both parent and daughter contaminants could be predicted, which will enhance our understanding of natural attenuation processes at contaminated sites. The temporal and spatial concentration distributions of the contaminants could be used in identifying highest-contamination regions and in assessing potential human health risk due to the toxicity effects.

Abstract

The argument of what is the rate of an equilibrium reaction in a transport system is very controversial. It has been argued that the rate of an equilibrium reaction "can be mathematically abstracted as infinity" for the convenience of decoupling equilibrium reactions from kinetic reactions. It has also been argued that the rate of an equilibrium reaction is indefinite. This controversy should not have been aroused at all since, by definition, an equilibrium reaction should not have been associated with a rate per se. We can associate a rate to an equilibrium reaction only if we treat it as an extremely fast kinetic reaction. Then it is legitimate to ask what its rate is. For an extremely fast reaction, its forward and backward rates are asymptotically tending to infinity. The question is then what is its net rate? To answer this question, it is necessary to understand the interplay between transport and reactions. Transport processes and kinetic reactions try to alter the concentrations at each time and at each point of the computational domain. The rates of equilibrium reactions are those rates which are "necessary" to assure that the thermodynamic equations remain fulfilled, i.e., the solution of the concentration field remains on the manifold defined by thermodynamic equations. With this definition of the rates of equilibrium reactions, we can calculate the posteriori equilibrium rates using a subset of decomposed transport equations after all species concentrations are solved. Thus the rate of a fast equilibrium reaction is finite and definite. On the other hand, rates of kinetic reactions require either proposition of reaction pathways or empirical rate equations. Two example problems are used to demonstrate how consistent sets of governing equations are employed to simulate rates of asymptotic kinetic reactions or fast/equilibrium reactions.

1. Introduction

Groundwater has always played an important role in human's history and groundwater contamination has been attracting intensive investigations since the mid 1980's. Contaminants in the water environment undergo changes in concentration resulting from physical, chemical, and/or biological processes, and a capability to understand and model these processes is at the core of water-quality management

(Chin, 2000). Accurate tools for reliable prediction of contaminant migration and transformation are necessary to support the task. Consideration of equilibrium chemistry, kinetic chemistry, and hydrologic transport and the interaction between fluid flow and reactive transport is necessary to be able to reflect the complexity of many real systems. For example, solid phase reactions including precipitation and dissolution can potentially plug pores or open fractures reducing matrix diffusion and promoting rapid flow through fractures.

The development of mechanistically-based reactive chemical transport models has exploded in the last two decades (Yeh and Tripathi, 1989, 1990; Nienhuis et al., 1991; Engesgaard and Kipp, 1992; Šimunnek and Squares, 1994; Chilakapati, A. 1995; Steefel and Yabusaki, 1996; Lichtner and Seith, 1996; Steefel and Van Cappellen, 1998; Tebes-Stevens et al., 1998; Nitao, 1998; Parkhurst and Appelo, 1999; Mann, 2000; Bacon et al., 2000; Steefel, 2001; Yeh et al., 2001; Xu et al., 2003; Yeh et al., 2004a, 2004b; Yang et al., 2008). These numerical reactive transport models have had varied scopes. Many models have coupled simulation of transport with equilibrium geochemistry (e.g. Miller and Benson, 1983; Cederberg et al., 1985; Hostetler and Erikson, 1989; Narasimhan et al., 1986; Liu and Narasimhan, 1989; Griffioen, 1993; Yeh and Tripathi, 1991; Cheng, 1995; Parkhurst, 1995). Some models couple transport with kinetic geochemistry for certain geochemical processes like precipitation-dissolution (e.g. Lichtner, 1996; Steefel and Yabusaki, 1996; Suarez and Šimunnek, 1996) or adsorption (e.g. Theis et al., 1982, Lensing et al., 1994). General reactive transport models capable of handling a complete suite of geochemical reaction processes (aqueous complexation, adsorption, precipitation-dissolution, acid-base, and reduction-oxidation phenomena) and allow any individual reaction for any of these geochemical processes to be handled as either equilibrium or kinetic as appropriate for the system being considered have emerged since the late 1990's and early 2000's (e.g., Yeh et al., 1996; Bacon et al., 2000; Steefel, 2001; Steefel, CRUNCH; Yeh et al., 2001; Xu et al.,2003). A number of models combine the ability to simulate transport with microbial growth and biodegradation reactions but do not encompass inorganic geochemistry (e.g. Widdowson et al., 1988; Kindred and Celia, 1989; Taylor and Jaffee, 1990; Wood et al., 1994; Dykaar and Kitandidis, 1996). Work in reactive transport modeling has been done to couple microbially mediated and at least some purely geochemical processes with transport. Marzel et al. (1994) includes microbial reactions and equilibrium aqueous geochemical speciation. Rittman and Van Briessen (1996) couple equilibrium aqueous complexation and kinetic adsorption with microbiological degradation. Hunter et al. (1998) couple one-dimensional transport with microbial and geochemical reactions for a suite of reactions involving major redox and acid-base pair species. Smith and Jaffee (1998) couple one-dimensional transport with equilibrium speciation and kinetic biogeochemical reactions affecting trace metal transport. Coupled specific microbiological and generic geochemical processes have also been developed (Salvage and Yeh, 1998; Yeh et al. 1998). Chilakapathi (1995) provides significant flexibility in handling any type of kinetic biogeochemical reaction coupled with transport, representing equilibrium processes as fast reversible kinetic reactions, but requires problem specific modifications to the code for new simulations to be run. Recently, these types of reaction-based paradigms capable of simulating any number

of reactions incarnating both geochemical and biological processes have gained popularities and implemented in a number of codes (e.g., Yeh et al. 2004a, 2004b; Kräutle and Knabner, 2005, 2006; Zhang et al. 2007).

This paper describes the development and application of the latest versions of HYDROGEOCHEM (Yeh et al. 2008a, 2008b), a mechanistically-based numerical model for simulation of coupled fluid flow, thermal transport, and reactive chemical transport in variably saturated porous and fractured media. These latest versions are a slight modification of the previous versions. A concept of defining reaction rates of fast reactions is proposed, which makes the modeling of mixed fast/equilibrium and slow/kinetic reactions consistent. The argument of what is the rate for an equilibrium reaction is very controversial. It has been argued that the rate of an equilibrium reaction "can be mathematically abstracted as infinity" for the convenience of decoupling equilibrium reactions from kinetic reactions (Fang et al., 2003). It has also been argued that the rate of an equilibrium reaction is indefinite (Lichtner, 1996). This controversy should not have been aroused at all since, by definition, an equilibrium reaction should not have been associated with a rate per se. We can associate a rate to an equilibrium reaction only if we treat it as a fast kinetic reaction. When we treat an equilibrium reaction as a fast kinetic reaction, then "the rate of an equilibrium reaction is the rate which is 'necessary' to assure that the corresponding thermodynamic equation remains fulfilled." With this definition of equilibrium reactions, we can make posteriori calculation of the rates of equilibrium reactions after all species concentrations are solved. Furthermore, with this definition, all equilibrium reactions must be linearly independent so the system of governing equations is exactly determined. Two example problems are used to demonstrate how consistent sets of governing equations are employed to simulate rates of asymptotic kinetic reactions or fast/equilibrium reactions. For kinetic reactions, both reaction-pathway and empirical approaches to calculate their rates are discussed.

2. Governing Equations of Reactive Transport

The reactive transport equation of any species can be derived based on the conservation law of material mass stating that the rate of mass change is due to biogeochemical reactions (Yeh, 2000)

$$\sum_{i\in\{M\}} \mu_{ik}\hat{C}_i \quad \Leftrightarrow \quad \sum_{i\in\{M\}} \nu_{ik}\hat{C}_i, \;\; k\in\{N\} \tag{1}$$

and advective-dispersive transport as

$$\frac{\partial(\theta C_i)}{\partial t} = \iota_i L(C_i) + \theta \sum_{k\in\{N\}} (\nu_{ik} - \mu_{ik}) R_k, \;\; i\in\{M\} \tag{2}$$

in which

$$L(C_i) = -\nabla\cdot(\mathbf{V}C_i) + \nabla\cdot[\theta\mathbf{D}\cdot\nabla C_i] \tag{3}$$

where μ_{ik} is the reaction stoichiometry of the i-th species in the k-th reaction associated with the reactants; $\hat{C}_i$ is the chemical formula of the i-th species; ν_{ik} is the

reaction stoichiometry of the *i*-th species in the k-th reaction associated with the products; $\{N\}=\{1,2,...,N\}$ in which N is the number of reactions; θ is the effective moisture content (L^3/L^3); C_i is the concentration of the *i*-th species in unit of chemical mass per water volume [M/L^3]; t is the time (T); ι_i is an indicator, $\iota_i=1$ if C_i is a mobile species, $\iota_i=0$ if C_i is an immobile species; L is the advection-dispersion transport operator; R_k is the rate of the *k*-th reaction in chemical mass per water volume per unit time [$M/L^3/T$]; $\{M\}=\{1,2,...,M\}$ in which M is the number of species; **V** is the Darcy's velocity of groundwater (L/T); and **D** is the dispersion coefficient tensor [L^2/T]. In the summation on the right-hand-side of Equation (1), $\nu_{ik}=0$ if $\hat{C}_i$ is not a product of the *k*-th reaction and $\mu_{ik}=0$ if $\hat{C}_i$ is not a reactant of the *k*-th reaction.

Initial conditions for every immobile species must be prescribed. No boundary condition is needed for any immobile species. On the other hand, for every mobile species, in addition to initial conditions, boundary conditions must be specified. Four types of boundary conditions are taken into account, including Dirichlet, variable (inflow-outflow), Cauchy, and Neumann (Yeh et al., 2004a, 2004b).

There are $M+N$ unknowns (M $C_i's$ and N $R_k's$) but only M equations in Equation (1). The system needs to be closed. Let us assume that there are N_E fast/equilibrium reactions (which must be all linearly independent) and N_K slow/kinetic reactions, i.e., $N=N_E+N_K$, where N_E and N_K are the number of equilibrium/fast reactions and kinetic/slow reactions, respectively. For N_K reactions, a rate equation can be formulated for each reaction as

$$R_k=f_k,\ k\in\{N_K\} \tag{4}$$

where $f_k=f_k\left(C_i:i\in\{M\}\right)$ is an explicit function of M $C_i's$ that represents the rate equation of the *k -th* reaction and $\{N_K\}\subset\{N\}$ is the set index of kinetic reactions having N_K members. Substitution of Eq. (4) into Eq. (1) yields

$$\frac{\partial(\theta C_i)}{\partial t}=\iota_i L(C_i)+\theta\sum_{k\in\{N_K\}}(\nu_{ik}-\mu_{ik})f_k+\theta\sum_{k\in\{N_E\}}(\nu_{ik}-\mu_{ik})R_k,\ i\in\{M\} \tag{5}$$

where $\{N_E\}\subset\{N\}$ is the set index of equilibrium/fast reactions having N_E members.

Equation (5) still involves more unknowns (M $C_i's$ and N_E $R_k's$) than the number of equations (M). To close the system, for every equilibrium reaction, thermodynamic approaches are used where a consistent algebraic equation, for example a mass action equation, can be used to describe the corresponding fast/equilibrium reaction as

$$F_k\left(C_i : i \in \{M\}\right) = 0,\ e.g.\ \beta_k^E - \prod_{i \in M} \left(C_i\right)^{\nu_{ik}} / \prod_{i \in M} \left(C_i\right)^{\mu_{ik}} = 0,\ \ k \in \{N_E\} \qquad (6)$$

where $F_k\left(C_i : i \in \{M\}\right) = 0$ is a nonlinear algebraic equation and β_k^E is the modified equilibrium constant of the *k -th* equilibrium reaction (Yeh and Tripathi, 1989). Equations (5) and (6) constitute a system of M nonlinear transport equations and N_E nonlinear algebraic equations for M $C_i's$ and N_E $R_k's$ of unknowns. Simultaneous solutions of this system of M reactive transport equations and N_E nonlinear algebraic equations over the entire domain of interest would demand excessive computational time and computer storage (Yeh and Tripathi, 1989) even with today's computer capacities.

3. Decomposition of Reactive Transport Equations

Decoupling of the N_E $R_k's$ unknowns from the M $C_i's$ unknowns can be made via the Gauss-Jordan reduction of reaction networks (Chilakapati, et al., 1998; Fang, 2003; Kräutle and Knabner, 2007). Performing matrix decomposition of the reaction matrix in Eq. (5), we can reduce it into two subsets of equations as described below.

1) $M - N_E$ transport-equations for $M - N_E$ reaction extents

$$\frac{\partial \theta E_i}{\partial t} = L\left(E_i^m\right) + \theta \sum_{j \in \{N_K\}} D_{ij} f_j,\ i \in \{M - N_E\} \text{ in which } E_i = \sum_{j \in \{M\}} a_{ij} C_j \qquad (7)$$

where E_i is the *i-th* reaction extent [M/L^3]; E_i^m is the portion of E_i , which contains the linear combination of only mobile species; D_{ij} is an element of decomposed reaction matrix; $\{M - N_E\} \subset \{M\}$ having $(M - N_E)$ members is a subset of $\{M\}$; and a_{ij} is the element of a $M \times M$ matrix resulted from the matrix decomposition of a unit matrix and it represents the coefficient of the linear combination of θC_j in E_i.

2) N_E rate-equations for N_E fast/equilibrium reactions

$$\theta D_{ik} R_k = \frac{\partial \theta E_i}{\partial t} - L\left(E_i^m\right) - \theta \sum_{j \in \{N_k\}} D_{ij} f_j,\ k \in \{N_E\},\ i \in \{M_E\} \qquad (8)$$

where D_{ik} is an element of decomposed reaction matrix corresponding to a linearly independent equilibrium reaction; E_i , the *i-th* reaction extent, shall be called an equilibrium variable since it corresponds to a linearly independent equilibrium reaction; and $\{M_E\}$, having M_E $(= M - N_E)$ members, is a subset of $\{M\}$

Before proceed further, several comments are in order here. Firstly, instead of solving M nonlinear reactive transport equations in Equation (5) and N_E nonlinear

algebraic equations in Equation (6) simultaneously, one solves $(M - N_E)$ nonlinear reactive transport equations in Equation (7) one by one for $(M - N_E)$ reaction extents, $E_i's$. Having obtained these variables, $(M - N_E)$ $E_i's$ over the domain, one then solves $(M - N_E)$ linear algebraic equations of Equation (9) and N_E nonlinear algebraic equations for M species concentrations, $C_i's$, at the discretized domain of interest point by point

$$\sum_{\ell \in \{M\}} a_{i\ell} C_\ell = E_i, \quad i \in \{M - N_E\}; \quad F_k\left(C_\ell : \ell \in \{M\}\right) = 0, \quad k \in \{N_E\} \tag{9}$$

Secondly, the argument of what is the rate for an equilibrium reaction is very controversial. It has been argued that the rate of an equilibrium reaction "can be mathematically abstracted as infinity" for the convenience of decoupling equilibrium reactions from kinetic reactions (Fang et al., 2003). It has also been argued that the rate of an equilibrium reaction is indefinite (Lichtner, 1996). This controversy should not have been aroused at all since, by definition, an equilibrium reaction should not have been associated with a rate per se. We can associate a rate to an equilibrium reaction only if we treat it as a fast kinetic reaction. When we treat an equilibrium reaction as a fast kinetic reaction, then "the rate of an equilibrium reaction is that rate which is 'necessary' to assure that the corresponding thermodynamic equation remains fulfilled." With this definition of equilibrium reactions, we can posteriori calculate the N_E rates of N_E equilibrium reactions with Equation (8) after all species concentrations are solved.

4. Numerical Methods

Ideally, one would like to use a numerical approach that is accurate, efficient, and robust. Depending on the specific problem at hand, different numerical approaches may be more or less suitable. For research applications, accuracy is the primary requirement, because one does not want to distort physics due to numerical errors. On the other hand, for large field-scale problems, efficiency and robustness are primary concerns as long as accuracy remains within the bounds of uncertainty associated with model parameters. Thus, to provide accuracy for research applications and efficiency and robustness for practical applications, three coupling strategies (Yeh et al., 2006 and Hammond et al., 2005) were investigated to deal with reactive chemistry. They are: (1) a fully-implicit scheme, (2) a mixed predictor-corrector/operator-splitting method, and (3) an operator-splitting method. For each time-step, we first solve the advective-dispersive transport equations with or without reaction terms. We then solve the reactive chemical system node-by-node to yield concentrations of all species. Details of these coupling strategies can be found elsewhere (Yeh et al., 1996).

Five numerical methods are investigated for solution of the advective-dispersive transport equations (Yeh et al., 2006). Method 1, the finite element methods (FEM) is applied to the conservative form of the transport equations. Method 2, the FEM is

applied to the advective form of the transport equations. Method 3, the modified Lagrangian-Eulerian (LE) approach is applied to the Lagrangian form of the transport equations. Method 4, the LE approach is applied to all interior and downstream boundary nodes while the FEM is applied to the conservative form of the transport equations for the upstream flux boundaries. Method 5, the LE approach is applied to all interior and downstream boundary nodes while the FEM is applied to the advective form of the transport equations for upstream flux boundaries.

In the Lagrangian-Eulerian approaches, there are two computational steps. The first step is to compute the Lagrangian concentration with particle tracking methods dealing with the advection term, and the second step is to compute the final concentration with finite element method dealing with all other terms in the transport equation (Yeh, 1990).

5. Demonstration Examples

Example 1: This example is used to demonstrate the need of species switching in dealing with stiff reactive system under transport and to illustrate the computation of fast/equilibrium rates. It involves the transient simulation of advection-dispersion and equilibrium complexation/precipitation reactions in a domain having a size of 10 dm x 5,000 dm. The domain consists of three heterogeneous zones and is discretized with 200 equal size elements, a moisture content of 0.3, a constant flow field of 155.5 dm/day, and a longitudinal dispersivity of 150 dm (Figure 1). The chemical reactions are shown in Table 1. The network consists of 24 reactions (20 aqueous complexation and four precipitation-dissolution reactions) involving 30 species excluding the species H_2O(aq).

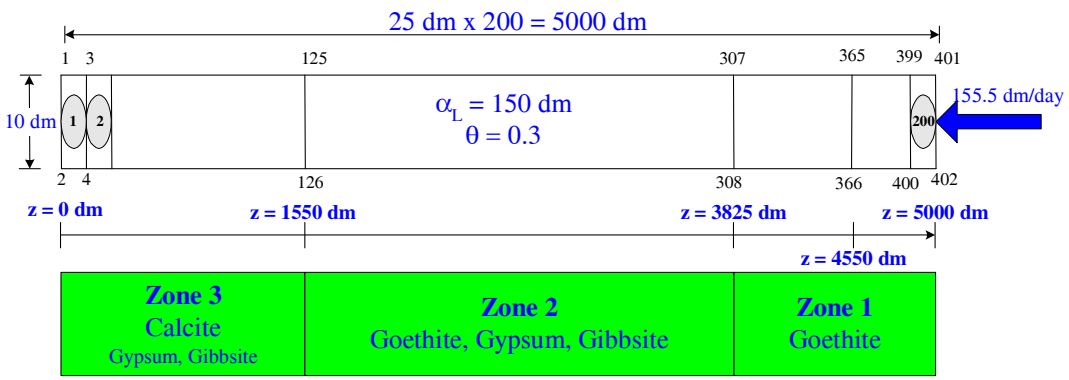

Figure 1 Problem domain and discretization Example 1

Table 1 Reaction Network for Example 1

Reaction	Number	Parameter
Aqueous Complex Reaction		
$H_2O(aq) \leftrightarrow H^+ + OH^-$	(R1)	$LogK_e$= -14.00
$Fe^{3+} + H_2O \leftrightarrow H^+ + FeOH^{2+}$	(R2)	$LogK_e$ = -2.19
$Fe^{3+} + 2H_2O \leftrightarrow 2H^+ + Fe(OH)_2^+$	(R3)	$LogK_e$ = -5.67
$Fe^{3+} + 3H_2O \leftrightarrow 3H^+ + Fe(OH)_3$ (aq)	(R4)	$LogK_e$ = -12.56
$Fe^{3+} + 4H_2O \leftrightarrow 4H^+ + Fe(OH)_4^-$	(R5)	$LogK_e$ = -21.60
$Al^{3+} + H_2O \leftrightarrow H^+ + AlOH^{2+}$	(R6)	$LogK_e$ = -5.00
$Al^{3+} + 2H_2O \leftrightarrow 2H^+ + Al(OH)_2^+$	(R7)	$LogK_e$ = -10.20
$Al^{3+} + 4H_2O \leftrightarrow 4H^+ + Al(OH)_4^-$	(R8)	$LogK_e$ = -23.00
$Al^{3+} + 3H_2O \leftrightarrow 3H^+ + Al(OH)_3$ (aq)	(R9)	$LogK_e$ = -17.20
$H^+ + CO_3^{2-} \leftrightarrow HCO_3^-$	(R10)	$LogK_e$ = 10.33
$2H^+ + CO_3^{2-} \leftrightarrow H_2CO_3$	(R11)	$LogK_e$ = 16.68
$Ca^{2+} + CO_3^{2-} \leftrightarrow CaCO_3$ (aq)	(R12)	$LogK_e$ = 3.22
$Ca^{2+} + H^+ + CO_3^{2-} \leftrightarrow CaHCO_3^+$	(R13)	$LogK_e$ = 11.44
$H^+ + SO_4^{2-} \leftrightarrow HSO_4^-$	(R14)	$LogK_e$ = 1.99
$Ca^{2+} + SO_4^{2-} \leftrightarrow CaSO_4$ (aq)	(R15)	$LogK_e$ = 2.30
$Al^{3+} + SO_4^{2-} \leftrightarrow AlSO_4^+$	(R16)	$LogK_e$ = 3.50
$Al^{3+} + 2SO_4^{2-} \leftrightarrow Al(SO_4)_2^-$	(R17)	$LogK_e$ = 5.00
$Fe^{3+} + SO_4^{2-} \leftrightarrow FeSO_4^+$	(R18)	$LogK_e$ = 4.04
$Fe^{3+} + 2SO_4^{2-} \leftrightarrow Fe(SO_4)_2^-$	(R19)	$LogK_e$ = 5.42
$Na^+ + SO_4^{2-} \leftrightarrow NaSO_4^-$	(R20)	$LogK_e$ = 0.07
Precipitation/Dissolution Reactions		
$Ca^{2+} + CO_3^{2-} \leftrightarrow CaCO_3$ (s)	(R21)	$LogK_e$ = 8.48
$Al^{3+} + 3H_2O \leftrightarrow 3H^+ + Al(OH)_3$ (s)	(R22)	$LogK_e$ = -9.11
$Fe^{3+} + 3H_2O \leftrightarrow 3H^+ + Fe(OH)_3$ (s)	(R23)	$LogK_e$ = -4.89
$Ca^{2+} + SO_4^{2-} \leftrightarrow CaSO_4$ (s)	(R24)	$LogK_e$ = 4.58

Table 2 shows the distributions of the initial total concentrations of each component in the domain. Variable boundary conditions with the incoming dissolved concentrations as listed in Table 3 are assigned on the right (nodes 401 and 402) and left (nodes 1 and 2) sides (Figure 1). On the top and bottom sides, zero flux is imposed. A constant time step size of 0.025 day is used for 400 time steps resulting in a total simulation time of 10 days.

To start the simulation, the preprocessor in HYDROGEOCHEM (Yeh et al., 2008a) automatically choose Ca^{2+}, CO_3^{2-}, Al^{3+}, SO_4^{2-}, H^+, Fe^{3+}, and Na^+ as 7 components. Without using the species switching, the simulation will stop at node 299 while checking the mass balance of the Al^{3+} component during the first precipitation cycle at the first nonlinear iteration (between solving solute transport and chemical reaction) of the first time step. To resolve this mass non-balance error, the species switching was applied to re-run this example. From the output file, the species switching was performed for nodes 299 and 300 during the first precipitation cycle at the first and second nonlinear iterations of the first time step, and for nodes

301 and 302 during the first precipitation cycle at the first through seventh nonlinear iterations of the first time step. The aqueous complexed species $Al(OH)_4^-$ was selected by the pre-processor in HYDROGEOCHEM (Yeh et al., 2008a) to replace Al^{3+} as the new component for all these switches. With the species switching to overcome this mass non-balance error, all 400 time steps of the simulation were successfully achieved.

The spatial-temporal distributions of total analytical, total precipitated concentrations of all seven components were reported elsewhere (Yeh et al., 2004a). The concentration evolutions of four precipitated species were also discussed. The interactions between transport and reactions governing the reactive transport processes were well addressed (Yeh et al., 2004a). Here only new results on the rates of all 24 fast reactions are presented. Figures 2 through 6 depict rates of 20 complexation reactions. Reaction (R10) has the highest rate while Reaction (R4) has the lowest rate. Figure 7 depicts the rate of four precipitation-dissolution reactions. It is seen that Reactions (R21) and (R24) have the highest precipitation-dissolution rates and Reaction 23 has the slowest rate. It is clear that all 24 reaction rates are finite and definite and both are time and space dependent under the transport system.

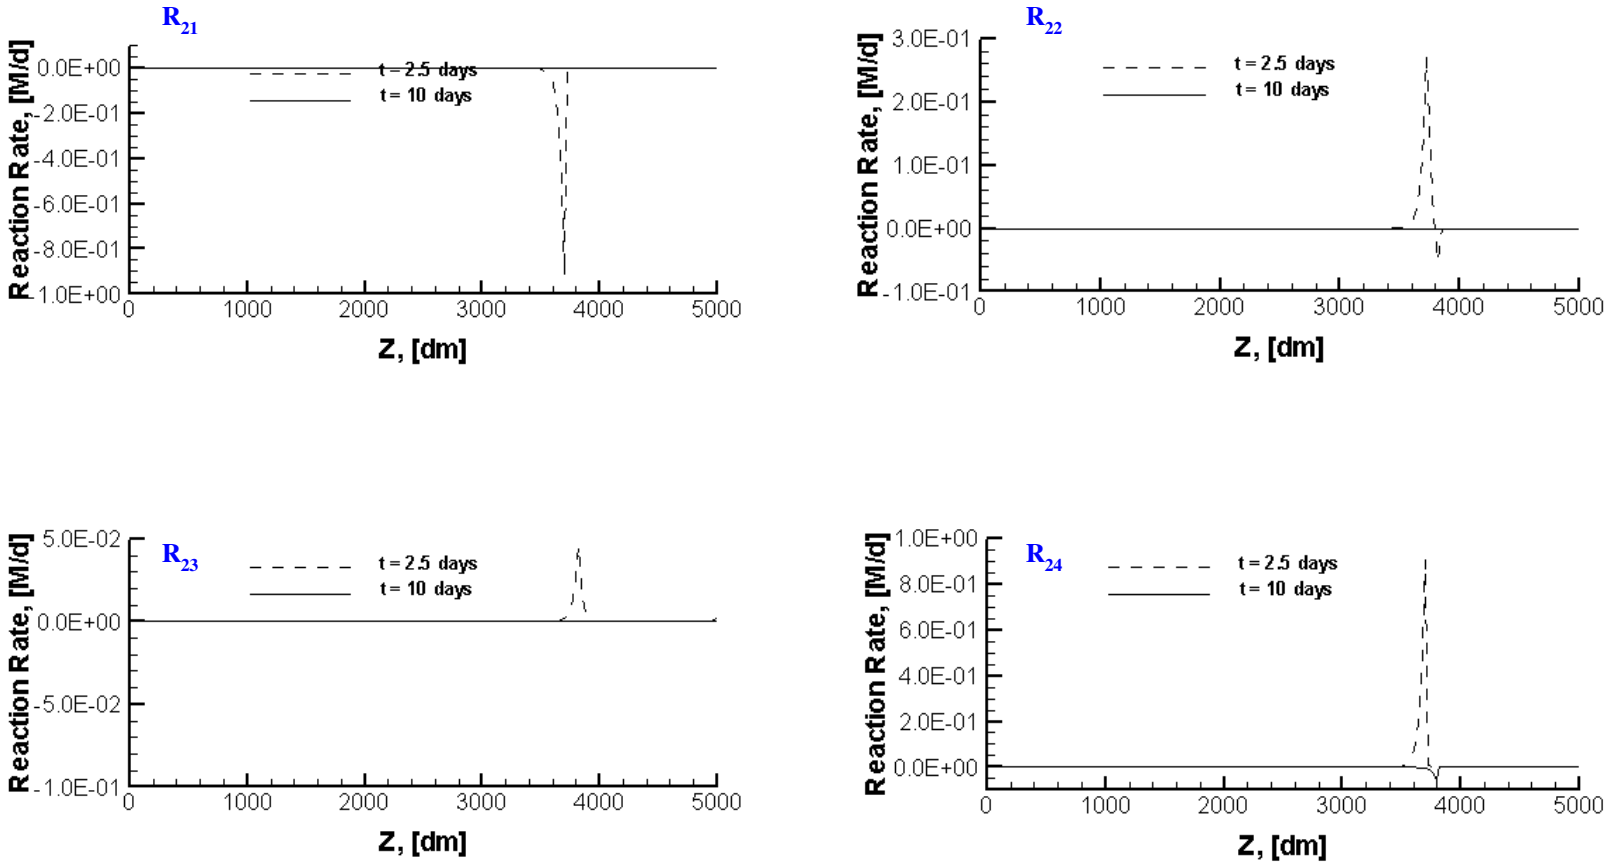

Figure 7 Reaction Rates of Reactions (R21) through (R24) for Example 1

Example 2: This example involves steady flow and transient reactive transport within a regular region with size 200 dm × 200 dm × 100 dm. The simulation region is discretized into 20 × 20 × 10 = 4,000 elements connected at 21 × 21 × 11 = 4,851 nodes. Each element has the same size of 10 × 10 × 10 = 1,000 dm^3.

The flow boundary conditions are given as: no flux is imposed on the left (x = 0), on the back (y = 200 dm), and at the bottom (z = 0) sides of the region; pressure head is assumed to vary from zero at z = 30 dm to 30 dm at the bottom (z = 0) on the right (x = 200 dm) and front (y = 0) sides; variable boundary conditions are applied elsewhere (Figure 8). Ponding depth is assumed zero for all variable boundary surfaces. The incoming fluxes of variable boundary are assumed to be 1 dm/day for the top surface and zero for the front and right sides above the water surface. The steady-state solution is to be sought. A pre-initial condition is set as h = 30 - z, which means the pre-initial water table is located at z = 30 dm.

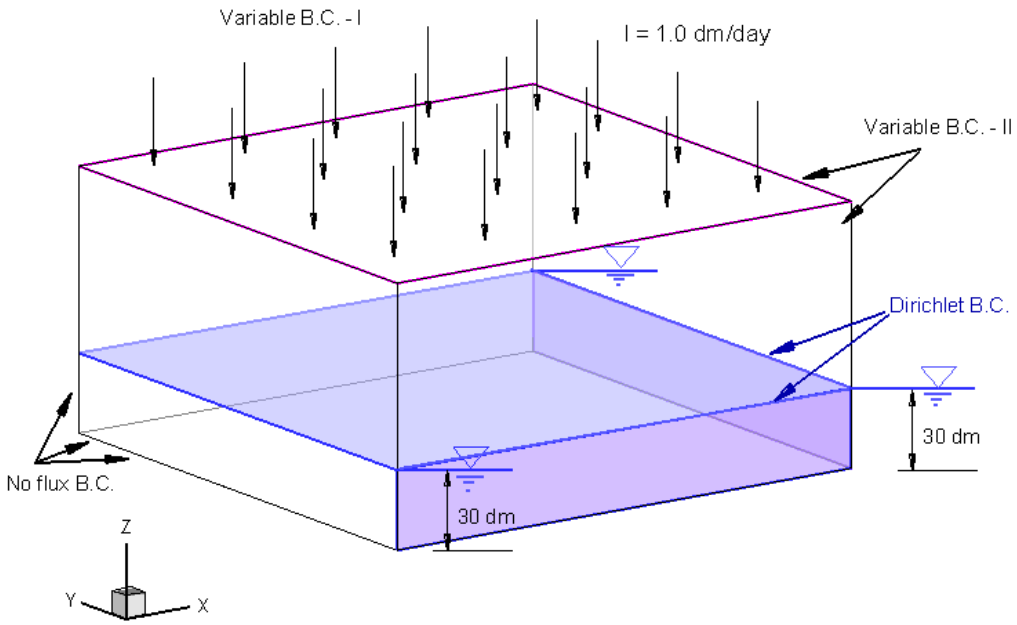

Figure 8 Problem domain and boundary conditions for Example 2 (unit: dm)

The problem domain contains one type of material. The material has the saturated hydraulic conductivities of $K_{xx} = K_{yy} = K_{zz} = 1$ dm/day and $K_{xy} = K_{xz} = K_{yz} = 0$ dm/day. The unsaturated characteristic hydraulic properties of the material are given as

$$\theta = \theta_r + (\theta_s - \theta_r)\frac{A}{A + |h - h_a|^B} \quad \text{and} \quad K_r = \left(\frac{\theta - \theta_r}{\theta_s - \theta_r}\right)^n \tag{9}$$

where $h_a = 0$ m, A = 1,000 m^2, B = 2, $\theta_s = 0.25$, and $\theta_r = 0.05$ are the parameters used to compute the water content and n = 2 is the parameter to compute the relative hydraulic conductivity.

The steady-state pressure head contours and the velocity fields are plotted in Figure 9 along a 2-D cross-section (x=0) of the domain.

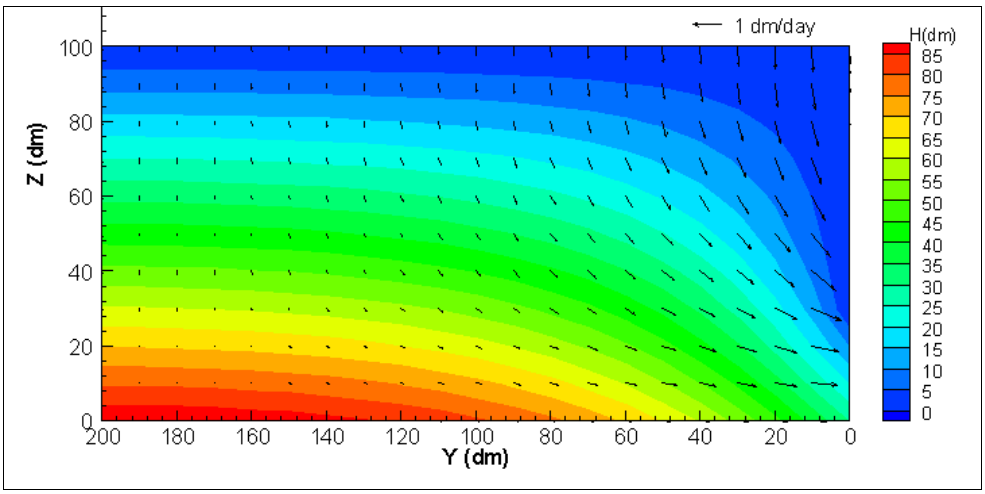

Figure 9 Steady-state velocity and pressure distribution along cross-section x = 0

Given the flow fields, transient reactive transport is simulated. The types of boundary condition are described in Figure 10. No flux is imposed on the left (x = 0), on the back (y = 200 dm), and on the bottom (z = 0) sides of the region. Dirichlet boundary is located on the top surface of the domain within 0 dm < x < 90 dm and 130 dm < y < 150 dm. Variable B.C-I is imposed on the top surface excluding the domain of Dirichlet boundary. Variable B.C-II is specified on the right side (x = 200 dm) and front side (y = 0).

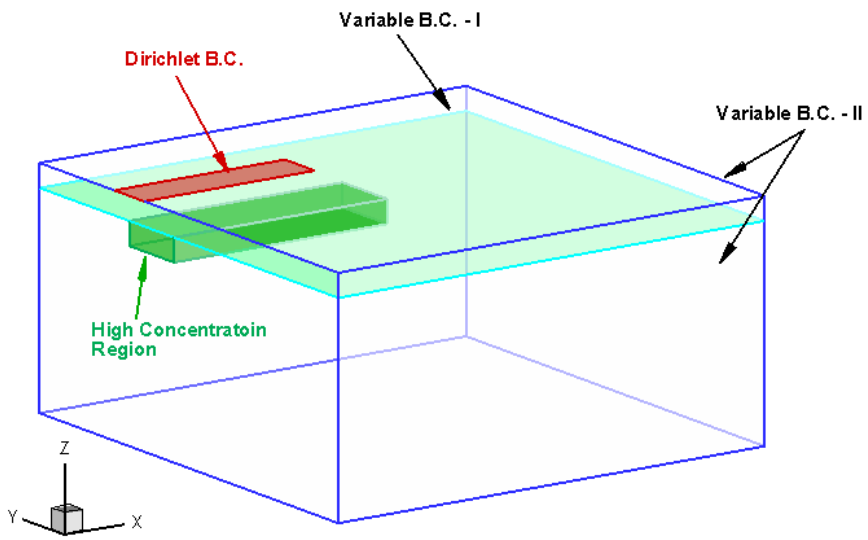

Figure 10 Boundary conditions and a high initial concentration region

For reactive transport simulations, the system of adsorption-dissolution reactions affecting the distribution and stability of Co(II)-EDTA in Fe-oxide coated sand (Szecsödy et al., 1994) is adopted here. To make the model more general, two ion-

exchange reactions (one fast reaction and one slow reaction) are appended. As a result, the reaction network consists of a total of 33 reactions involving 42 species (30 aqueous complexes, 8 adsorbed species, 3 ion-exchanged species, and one mineral) as shown in Table 4 (Yeh et al., 2004b).

Table 4 Reaction Network for Example 2

Reaction	**No**	**parameter**
Mineral Dissolution and Surface Site Formation Reactions

$Ca^{2+} + 2\ \overline{Na^+} \leftrightarrow \overline{Ca^{2+}} + 2Na^+$	(R33)	$Log\ k_{33}^e = 0.6$

* $\frac{S_A N_s}{N_A} M_{mineral}[M] = [S_1] + [S_2] + [S_3] + [S_4] + [S_5] + [S_6] + [S_7] + [S_8]$ This users' specified equation is modified from Stumm and Morgan, 1996, in which S_A is the unit surface area ($m^2\ g^{-1}$) of mineral, N_S is the surface site density (mol sites m^{-2}), N_A is Avogadro's number (mol sites per mol), $M_{mineral}$ is the molecular weight of mineral

&The species H_2O can be decoupled from the system if its activity is assumed 1.0.

The reaction network in Table 4 is complex involving both kinetic and equilibrium reactions in every type of reactions (aqueous complexation, adsorption-desorption, and ion-exchange). Initially, the metal-hydroxide mineral $Fe(OH)_3(s)$ becomes solubilized and produces two aqueous species Fe^{3+} and H^+ through an irreversible reaction [Reaction (R1) in Table 4]. In addition, adsorbing sites, FeOH, are formed on the surface of the mineral $Fe(OH)_3(s)$ [Reaction (R2)]. The surface site commonly undergoes ionization reactions upon contact with water [Reactions (R25) and (R26)]. Species $CoEDTA^{2-}$ dissolves into Co^{2+} and $EDTA^{4-}$ [Reaction (R3)]. Then Co^{2+}, $EDTA^{4-}$, Ca^{2+}, and Fe^{3+} react to form various complexed species [Reactions (R4) through (R23)]. In turn, some of these complexed species are adsorbed on the surface of mineral $Fe(OH)_3(s)$ [Reactions (R27) through (R31)]. In addition, three ions (Ca^{2+}, Mg^{2+} and Na^+) are involved in ion exchange reactions to form three ion-exchanged species ($\overline{Ca^{2+}}$, $\overline{Mg^{2+}}$, and $\overline{Na^+}$)in the reaction system [Reactions (R32) and (R33)].

The reacting system involves a total of 41 species, excluding the species H_2O whose activity is set as 1.0, 25 equilibrium reactions ($N_E = 25$) and 8 kinetic reactions ($N_K = 8$). The preprocessor in HYDROGEOCHEM performs a formal matrix decomposition of the reaction network (Fang et al., 2003) and automatically set up 25 nonlinear algebraic equations and 16 nonlinear transport equations for reaction extents (Yeh et al., 2004b). Out of these 16 reaction extents, five involved only immobile species; thus, instead of solving 29 nonlinear transport equations for 29 aqueous species, one has to solve only 11 nonlinear transport equations for 11 reaction extents each of which involved both mobile and immobile species.

For numerical simulations, the initial conditions are listed in Table 5 for the species whose concentration is not zero. Low initial concentrations are given in the entire domain, except for a small region $[0 \le x \le 100, 110 \le y \le 140, 80 \le z \le 90]$which has high initial concentrations (Figure 10). The species concentrations with non-zero values on the boundaries are listed in Table 6.

Table 5 Initial conditions for reactive chemical transport for Example 2

Species	High Concentration Region	Low Concentration Region
Ca^{2+}	1.0e-5	1.0e-5
Fe^{3+}	1.0e-7	1.0e-7
Co^{2+}	1.0e-5	1.0e-5
H^{+}	3.0e-5	1.0e-5
$EDTA^{4-}$	1.0e-5	1.0e-5
$FeEDTA^{-}$	1.0e-5	1.0e-5
$Fe(OH)_3(s)$	2.0e-5	1.0e-7
$CoEDTA^{2-}$	1.0e-6	1.0e-7
Mg^{2+}	1.0e-5	1.0e-5
Na^{+}	1.0e-4	1.0e-5
$\overline{Mg^{2+}}$	1.4e-4	1.0e-5
$\overline{Na^{+}}$	7.0e-4	1.0e-5
$\overline{Ca^{2+}}$	1.5e-4	1.0e-5

Note: The unit for species concentration is mole/dm^3.

Table 6 Boundary conditions for reactive chemical transport for Example 2

Species	Dirichlet B.C	Variable B.C-I	Variable B.C-II
Ca^{2+}	1.0e-3	1.0e-5	0
Fe^{3+}	1.0e-7	1.0e-7	0
Co^{2+}	1.0e-5	1.0e-5	0
H^{+}	1.0e-5	1.0e-5	0
$EDTA^{4-}$	1.0e-3	1.0e-5	0
$FeEDTA^{-}$	1.0e-5	1.0e-5	0
$CoEDTA^{2-}$	1.0e-3	1.0e-7	0
Mg^{2+}	1.0e-5	1.0e-5	0
Na^{+}	1.0e-4	1.0e-5	0

Note: The unit for species concentration is mole/dm^3.

For transient simulations, a time step size of 2 days is used and a total 100 time-step transient simulation is performed in this example. The concentration evolutions of all 41 species were obtained elsewhere (Yeh et al., 2004b). Here only new results on selective equilibrium and kinetic rates are given (Figure 11). The transport and reaction processes governing the spatial-temporal distributions of the mineral [$Fe(OH)_{3(s)}$], surface site [Fe(OH)], and three aqueous species [Fe^{3+}, $EDTA^{4-}$, and $FeEDTA^{-}$] were addressed. The slope of $Fe(OH)_{3(s)}$-versus-time curve was shown almost constant (Yeh et al., 2004b). Under a batch system, this slope should be the sum of rates of Reactions (R1) and (R2) [Eq R1 + k R1 in Figure 11]. It is seen that the rate, R_1 or Eq R1, plus the rate, R_2 or k R1, are clearly not constant due to complicated interactions between transport and reactions. Furthermore, it is seen that the kinetic rates are not necessarily smaller than the equilibrium rates.

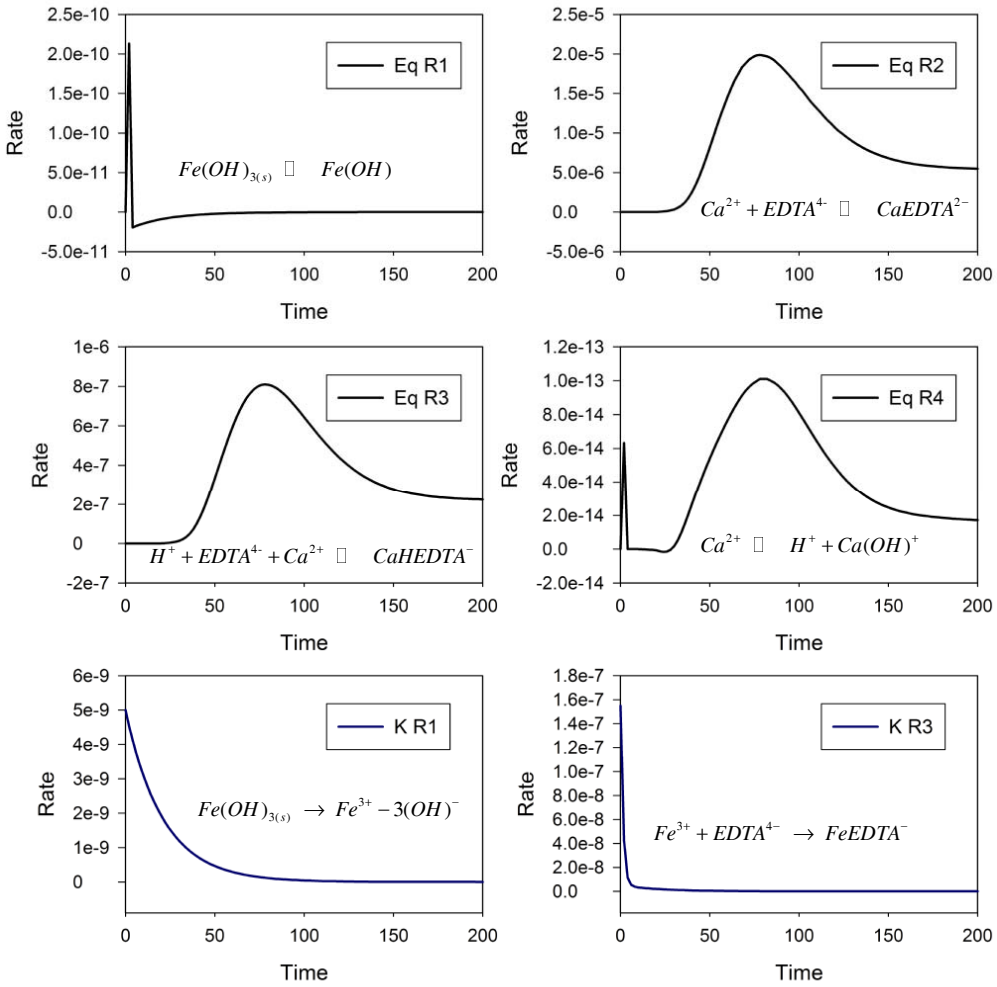

Figure 11 Rates of Selective Reactions at x = 30, y = 120, z = 30

Summary and Conclusion

This paper communicates the development of a mechanistically-based coupled fluid flow and reactive chemical transport model including both fast and slow reactions in variably saturated media. A new concept to define rates of fast/equilibrium reactions is proposed. The rates of equilibrium reactions are those rates which are "necessary" to assure that the thermodynamic equations remain fulfilled, i.e., the solution of the concentration field remains on the manifold defined by thermodynamic equations. With this definition of the rates of equilibrium reactions are finite and definite. They depend on not just the chemical reaction itself, but also on transport processes. The theoretical bases and numerical techniques of the model were summarized and two example problems were presented. The first example focused on a complicated but realistic advective-dispersive-reactive transport problem. It exemplified the need of species switching scheme to solve stiff geochemical equilibrium problems. It also highlighted that consistent, finite, and definite rates of all fast/equilibrium reactions can be obtained. The second example was a reactive transport problem of a comprehensive reaction network in three dimensions. It demonstrated the design capability of the model to simulate the interplay of transport and reactions in the adsorption-dissolution Co(II)-EDTA in Fe-oxide coated sand. It also showed that rates of slow/kinetic reactions are not necessarily smaller than those of fast/equilibrium reactions.

Comparative Study of Two Standard Septic Tank Drain fields Using Different Sand with Recirculation for Nutrient Removal

Ni-Bin Chang, Marty Wanielista, Fahim Hossian, Zhemin Xuan,
and Ammarin Daranpob

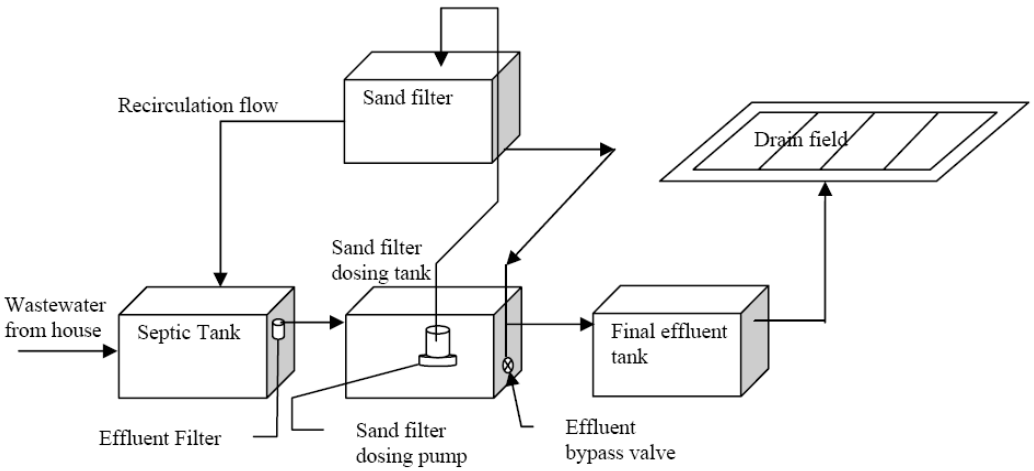
Department of Civil, Environmental, and Construction Engineering,
University of Central Florida, Orlando, Florida, USA

ABSTRACT

On-site Wastewater Treatment System (OWTS) using a septic tank followed by a recirculating sand filter (RSF) with effluent discharged to an unlined standard drain field is a typical performance-based treatment facility for nutrient removal. The type of effluent distribution in the standard drain field systems include gravity systems, low pressure dosed systems, drip irrigation systems, etc. The standard drain field that is constructed by a series of parallel, underground, perforated pipes allows the septic tank effluent to percolate into the surrounding soil in the vadose (unsaturated) zone where most of the residual nutrients may be assimilated. The inclusion of RSF may improve the nitrification to some extent so as to promote denitrification in the drain field. With such design, most residual nutrients in wastewater are expected to be consumed as the wastewater passes through the soil. This author's aim of this paper is to present the effectivenss of RSF and a comparative study with these two different drain field sands for nutrient removal in vadose zone. They include astatula sand (i.e., citrus grove sand) and washed building sand, popular in Central Florida for drain field use. The use of a gene identification method is novel in supporting the biological removal. Research findings show that the performance of washed building sand and the astatula sand in terms of ultimate nutrient removal is about the same. Because astatula sand is less costly it can possibly be considered for replacement of the more expensive washed building sand.

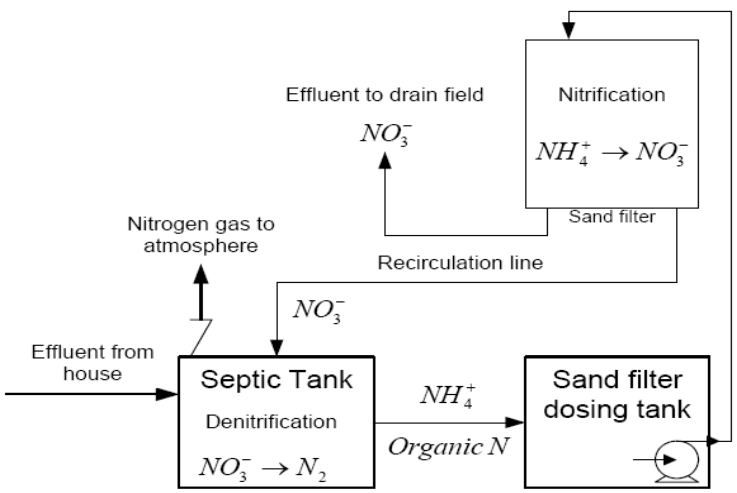
INTRODUCTION

When urban regions gradually expand due to regional development, centralized sewage collection, treatment, and disposal is often unavailable for both geographic and economic reasons. Thus, decentralized or on-site wastewater treatment systems (OWTS) may be necessary to protect public health. Septic tank system was developed in 1860 in France by John Mouras (Crites and Tchobanoglous, 1998). After that it has changed in many aspects of design strategy to give the present shape. Septic tank makes its way in the USA and some part of Africa by British navy around 1883 (Crites and Tchobanoglous, 1998). Later on, septic tank system becomes very common in both developed and developing countries. More than 25 million homes, or 25 percent of the U.S. population, use onsite wastewater treatment systems to meet their wastewater treatment and disposal needs (USEPA, 2002). According to USEPA, about 33% of new septic systems are constructed each year (USEPA, 2003).



On average, medium strength (i.e. 460.00 L/capita*day) untreated domestic wastewater has 40.00 mg/L of total nitrogen (TN), 25.00 mg/L of ammonia (NH_3-N), 720.00 mg/L of total solids (TS), 190.00 mg/L of biochemical oxygen demand (BOD_5), 7.00 mg/L of total phosphorus (TP) and 90.00 mg/L of oil and grease (Metcalf and Eddy, 2003; WEF and ASCE, 2005). As a consequence, nationwide, wastewater effluent from OWTS can represent a large fraction of nutrient loads to groundwater aquifers causing negative impact on drinking water quality and ecosystem integrity. This is due to the presence of phosphorus and nitrogen compounds that are the most frequent measurements to indicate nutrient loadings in natural and build environments. Hence, on-site wastewater effluent disposal has contributed significant adverse impacts to the dynamics of the natural environment. Traditional septic tank system is still not efficient to remove nutrient from wastewater to meet the Clean Water Act (CWA) goals (USEPA, 2003). The aim of this paper is to present a passive OWTS technology that is designed to promote both nitrification and denitrification on one hand and exhibit how the use of different types of sand popular in Florida in standard drain field ends up differing performance of denitrification on the other hand. Supplementary to the routine monitoring and measurement of the nutrient parameters, real-time polymerase chain reaction**,** also called quantitative real time polymerase chain reaction (Q-PCR/qPCR), was used to evaluate the nitrogen removal effect of media by quantifying the ammonia-oxidizing bacteria (AOB), nitrite-oxidizing bacteria (NOB) and denitrifying bacteria in the drain fields.

MATERIALS AND METHODS



System Configuration

The OWTS test center at University of Central Florida (UCF) is sponsored by Florida Department of Environmental Protection (FDEP) with guidance from the state Department of Health (DOH) and is designed for systematic evaluation of nutrients removal, which includes four treatment trains. The system presented in this paper consists of a septic tank followed by a recirculating sand filter (RSF), with effluent discharged to two unlined conventional gravity drain fields in parallel equally, called standard drain fields hereafter, filled with washed building sand and citrus grove (i.e., astatula sand) sand, respectively. The wastewater source for the test center is the 15-person BPW Scholarship House (a female dormitory at UCF campus), which contains a kitchen and living quarters. The wastewater is pumped to a 5.10 m^3 (1,350 gallon) septic tank from where the effluents are divided into different final disposal alternatives.

Figure 1(a) shows the schematic of such a treatment process that elucidates a typical septic tank system with enhanced nitrification and denitrification by using a RSF (EPA, 1999). The influent of wastewater contains some dissolved oxygen so it can trigger the nitrification in the septic tank at first and in the RSF later on because of the full exposure of the effluent to the air. On the other hand, the area between sludge and scum can be completely anaerobic with time so it is possible to support denitrification process in the septic tank (Bounds, 1997). Figure 1(b) illustrates the rationale via the use of RSF to promote the nitrification. A schematic diagram of system layout is shown in Figure 2.

(a) A typical septic system configuration

(b) Nitrification and denitrification in a septic tank system

Figure 1: A layout of an effluent filter and a gravel filled drain field (Chang et al., 2007; Venhuizen, 1998)

The tank with a capacity of 5,110.30 liters (i.e. 1,350 gallons) receives the sewage from 15-person BPW scholarship house. A Hydraulic Retention Time (HRT) of 24 hours is assumed in the septic tank. The tank then discharges the sewage to a dosing tank. The dosing tank sends the flow into two directions: one part is going to the distribution tank as feed-forward flow and the other three parts are going to the recirculation sand filter (RSF) as recycled flow. So the recycling ratio is about 3:1. RSF has a depth of about 1.22 meter (i.e. 4 ft) and it is filled with filter media up to 1.067 meter (i.e. 3.5 ft). RSF has three layers: top layer is a gravel layer, middle layer is a sand layer with a depth of 0.61 meter (i.e. 2 ft) and the bottom layer is a gravel layer with depth 0.3048 meter (i.e. 1 ft). The capacity of the sand filter tank is about 3,974.68 liters (i.e. 1,050 gallons). RSF has received frequent dosing at a rate of every 1 hour from the dosing tank. It is found in literature that multiple dosing is very effective to increase the removal efficiency

(USEPA, 1980). The recycled flow from RSF goes to the septic tank and mixes with the fresh sewage flow that promotes further denitrification.

From distribution tank, the wastewater goes to the two drain fields in equal volume. So each drain field may receive about 50% of the total flow from dosing tank. The size of each drain field is about 6.096 m x 4.57 m x 1.22 m (i.e. 20 ft x 15 ft x 4 ft). One of the drain fields is filled with astatula sand and the other drain field is filled with washed building sand. Each drain field is filled with native soil on the top with 0.61 meter in depth and the remaining 0.61 meter is filled by astatula sand or washed building sand, respectively. Astatula sand is used without any pretreatment and the washed buildingsand is washed to make it free from all impurities. These two types of sands are generally available in Florida. Astatula sand has a permeability of 25 cm/min and washed building sand has a permeability of 40 cm/min. Washed building sand is frequently used by contractors in drain field though. Astatula sand is selected as our laboratory experiment shows that this type of sand has the potential capability to remove nutrient.

To sample the infiltrate and proceed with water quality monitoring in vadose zone, three lysimeters (i.e., Soil Moisture Equipment Corporation) are installed in each of the two standard drain fields. The lysimeter is equipment that can collect water from unsaturated or vadose zone by a porcelain cup. The water from a lysimeter is collected by using a vacuum pump. The lycimeters are placed over three different depths: one is at a depth of 20.32 cm (i.e. 8 inches), another one is at a depth of 40.64 cm (i.e. 16 inches) and the other one is at a depth of 60.96 cm (i.e. 24 inches).

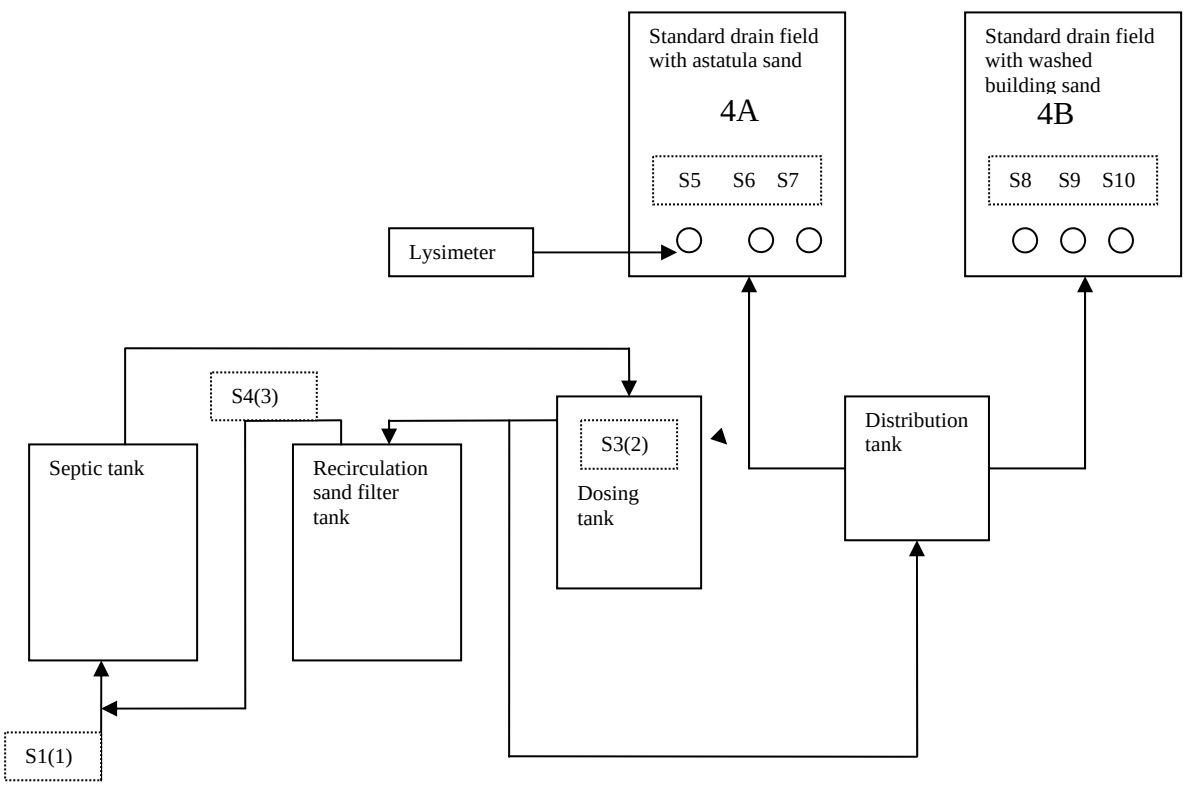


Figure 2. System layout of the OWTS that consists of a septic tank, a dosing tank, a sand-filtered circulation tank, a distributing tank, and two parallel drain fields

There are about 9 sampling points shown in Figure 2 denoted from S1 to S10. Points from S5 to S10 provide samples that were collected from lysimeter directly. S5, S6 and S7 sampling points are located at drain field filled with astatula sand. S8, S9 and S10 sampling points are drain field filled with at washed building sand. Composite sampling method is applied for sample collection (i.e., Composite sample is a mixture of samples collected at different time period and made one representative sample for chemical analysis and can save significant amount of analysis cost as only one sample is analyzed rather than samples collected in different time period.) Samples are collected biweekly in the morning (i.e. from 6:00 to 8:00 AM), in the afternoon (i.e. from 11:00 AM to 1:00 PM) and in the evening (i.e. from 5:00 to 7:00 PM). Major nutrients of concern include ammonia, NO_X-N (i.e. the sum of nitrate and nitrite), NO_2^--N, TN, soluble reactive phosphorus (SRP), TP, fecal coliform and E. coli. All the samples were analyzed by a certified laboratory - Environmental Research & Design Inc. (ERD) in Orlando, Florida. The groundwater nutrient concentrations were also observed in this project. For this purpose, 17 monitoring wells are constructed around the study site as shown in Figure 3. The monitoring wells are divided into two groups: 1) monitoring wells used to observe the effect of drain field and 2) monitoring wells used to observe the effect of whole system including wetlands and B&G drain field system. M1 to M8 are monitoring wells for the first group and MW1 to MW8 are wells for the second groups. All the wells are about 3.048 meter (i.e. 10 feet) deep. The groundwater depth of each well was monitored once in every week and nutrient concentration is analyzed bi-weekly.

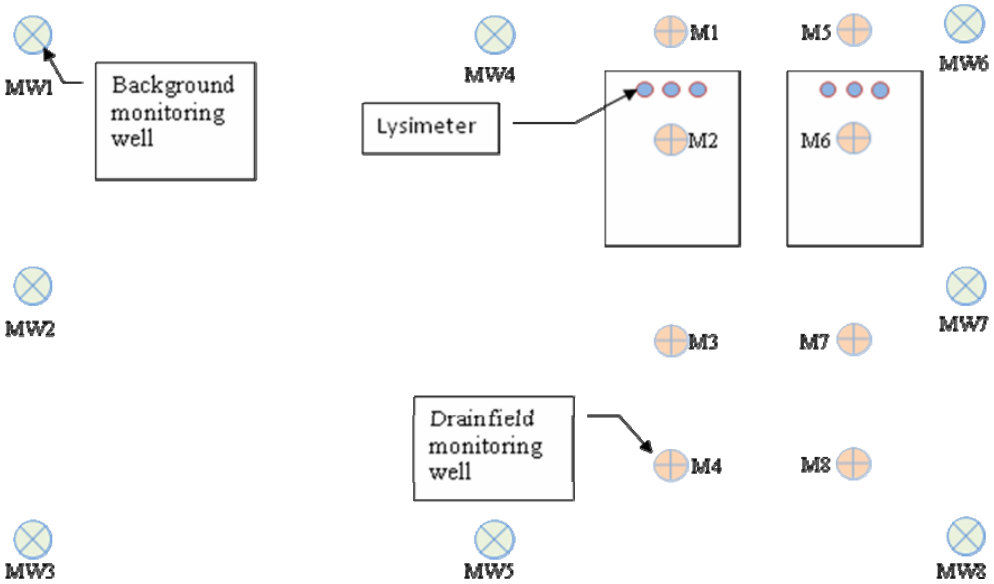

Figure 3: Figure shows the approximate location of groundwater monitoring well

Sampling and Chemical Analysis

A list of methods used to determine the concentrations of these chemicals is shown in Table 1 for reference. Quality assurance and quality control was conducted for each constitute in a sample set. To measure precision, duplicate samples are analyzed to produce a relative percent difference (RPD) between the two measurements. The

accuracy of the measurements is determined by spiking a sample with a known concentration of the parameter and calculating the percent recovery.

Table1: Column study water quality parameters and methods

Parameter	Method	Range*
Nitrates + Nitrites	Hach method 8192	0.01-0.50 mg/L NO_3^-N
Nitrites	Hach method 8507	0.002-0.30 mg/L NO_2^-N
Ammonia	Hach method 8155	0.01-0.50 mg/L NH_3-N
Total Nitrogen	Hach Method 10071	0.5-25.0 mg/L N
Reactive/Orthophosphate	Hach method 8048	0.02-2.50 mg/L PO_4^{3-}
Total phosphorus	Hach method 8190	0.06 to 3.50 mg/L PO_4^{3-}

*Note: In some cases samples were diluted with DI water to fall within this range.

Microbiological Assessment

As mentioned above that the middle layer of the RSF has a depth of 0.61 meter (i.e. 2 ft), sand samples were collected from the top (i.e. 0 ft, Sample No., R1), midpoint (i.e. 1 ft, Sample No., R2) and bottom (i.e. 2 ft, Sample No., R3) of the middle layer of RSF respectively for quantifying the ammonia-oxidizing bacteria (AOB) and nitrite-oxidizing bacteria (NOB) to simulate a profile of microbial activity in regard to the nitrification effect. As part of the total nitrogen removal in this whole wastewater treatment system, the dinitrification effect of soil profile along the flow path was also measured by quantifying the dinitrifier in both drain fields. Three samples were collected from each drain fields at different depth with the same principle. The first was collected at the depth of the bottom of shallowest lysimeter installed (i.e. 20.32 cm (8 inches) deep in sand layer, denoted as Sample No., W1 or A1. The deepest, denoted as Sample No., W3 or A3, was close to the groundwater table. The other one was collected in between: about 1.8 m (6ft) deep from the surface of the ground, denoted as Sample No., W2 or A2. All 9 samples were collected into 1.5mL microcentrifuge tubes, transported at 4 °C and kept at -20 °C until use.

DNA from the sample was extracted in duplicate by using a SoilMaster® DNA Extraction Kit (EPICENTRE) and following the accessory direction. 50 mg of the sample instead of 100 mg was weighed out into the 1.5mL microcentrifuge tube to decrease the effects of enzymatic inhibitors. The extracted DNA was finally resuspended in 300 μL TE Buffer. Real-time PCR quantification was performed on the Stepone® (Applied Biosystems) to amplify the *amoA* gene from the AOB, *NSR* gene from NOB and *nirK* gene from dinitrifier respectively. The target genes are in direct proportion of the number of bacteria. The PCR mixture was prepared in a total volume of 25 μL using 12.5 μL of the SYBR Green PCR Master Mix kit (combines SYBR Green 1 Dye, AmpliTaq Gold® DNA Polymerase, dNTPs with dUTP, Passive Reference 1, and optimized buffer components, Applied Biosystems), 10uM of each primer, standard DNA or extracted DNA from samples and DEPC water to complete the 25 μL volume (Table 2).

Table 3 shows the sequence of the used primes. For generating the standard curves for real-time PCR, Plasmid carrying the target DNA was extracted with a PureLink™ Quick Plasmid Miniprep Kit (Invitrogen), and the plasmid DNA concentration (ng/μL) was measured with spectrophotometer (NanoDrop™ 1000). Since

the sequences of the vector and PCR insert are known, we calculated the copy numbers of *amoA,* NSR and nirK directly from the concentration of extracted plasmid DNA. The standard DNA from plasmid DNA was prepared for tenfold serial dilution, and each of them was quantified in triplicate. Standard curves were obtained by plotting Ct (threshold cycle) as a function of log of the copy number of target DNA. The copy number can be obtained by the known mass concentration of standard DNA and molecular mass of the target gene.

Table 2: The composition of PCR mixture for different genes to be amplified (unit: μL)

	amoA	NSR	nirK
SYBR Green	12.5	12.5	12.5
Primer	1.5	1.5	1
Standard DNA or template DNA	2	2	1
DEPC water	9	9	10.5
Total	25	25	25

Table 3: The oligonucleotide sequences of the primers.

Ammonium monooxygenase (*amoA*)	amoA-1F GGGGTTTCTACTGGTGGT	Rotthauwe et al. (1997)
	amoA-2R CCCCTCKGSAAAGCCTTCTTC	
16S rRNA Nitrospira sp. (*NSR*)	NSR 1113F CCTGCTTTCAGTTGCTACCG	Dionisi, et al (2004)
	NSR 1264R GTTTGCAGCGCTTTGTACCG	
Nitrite reductase (*nirK*)	nirK 876 ATYGGCGGVAYGGCGA	Braker, et al (1998)
	nirK 1040 GCCTCGATCAGRTTRTGGTT	

The PCR protocol for *amoA* quantification was as follows: 2 min at 50°C, 10 min at 95°C, and then 40 cycles consisting of 30 s at 95°C, 45 min at 55°C, and 30 s at 72°C (Okano et al. 2004). PCR amplification for *NSR* consisted of 2 min at 50 °C, 10 min at 95 °C, 35 cycles at 95°C for 15 s, 63 °C for 30 s (Harms et al. 2003). The conditions for *nirK* real-time PCR were 120 s at 50 °C, 900 s at 95 °C afterwards six touchdown cycles were performed: 15 s at 95 °C for denaturation, 30 s at 63 °C for annealing, 30 s at 72°C for extension and 30 s at 80 °C for a final data acquisition step. The annealing temperature was progressively decreased by 1 °C down to 58 °C. Finally, a last cycle with an annealing temperature of 58 °C was repeated 40 times (Henry, et al. 2004).

RESULTS AND DISCUSSION

Standard Drain field Performance for Nutrient Removal

Nutrient concentration is very high in influent wastewater. In microbiological process, ammonia and nitrite can be converted to nitrate through nitrification process and nitrate can be converted to nitrogen gas through denitrification process. Concentration at different point is shown in Table 4. It is found that both ammonia and NO_x-N concentrations decreased in sand filter and drain fields showing that both nitrification and denitrification were present in the drain fields. The RSF can achieve about 99.53% ammonia removal. But at the same time, RSF filter was also removing about 84.31% of

NO_x-N. So it can be concluded that RSF can support both nitrification and denitrification process. In fact, the top layer of RSF may support the nitrification process and the bottom layer the denitrification process. To prove this, we need to use the RT-PCR analysis.

Ammonia and NO_X-N removal can be further removed in drain field with washed building sand. The average concentration of ammonia in astatula drain field and washed building sand drain field is about 0.071 mg/L (i.e. average of S5, S6 and S7) and 0.027 mg/L (i.e. average of S8, S9 and S10), respectively. So the removal efficiency is about 99.83% and 99.93%, respectively. NO_x-N removal in astatula sand and washed building sand drain field is about 82.35% and 93.13%, respectively. Effluent TN concentration is lower than the influent TN concentration. TN removal in astatual sand drain field is about 84.57% and 84.54% in washed building drain field. Denitrifiers may use oxygen rather than nitrate if no anaerobic condition is created. Denitrification may be started in a slow pace or no anaerobic condition is created in the sand filter and continues in both drain fields. It is possible that anaerobic condition may be available in ground at higher depth. In our project the depth of drain field is only 1.219 meter. Sand cannot remove nitrate and nitrite by adsorption. Nitrate, nitrite and sand all are negatively charged and when they come close to each other, they repel due to same charge (Kim et al., 2000).

For phosphorus removal, washed building sand drain field performed well. Average removal efficiency of SRP in the astatula sand drain field and washed building sand drain field is about 47.84% and 56.63%, respectively. TP removal is about 70.83% in astatula sand drain field and 71.20% washed building sand drain field. RSF has played an important role for removing phosphorus species too. About 44.60% of SRP and 70.50% TP is removed by RSF. After the operation of RSF, the phosphorus concentration increased or remained unchanged. It might be due to the feed-forward flow from dosing tank to the drain field as dosing tank has higher phosphorus concentration. So RSF performance for phosphorus removal is almost valueless in this feed-forward flow pathway. Phosphorus can be removed by chemical reaction with minerals present in the sand drain fields or adsorption by clay particles present in the sand. Figure 4 summarizes the variations of pathway in terms of nutrient removal. Table 5 summarizes the nutrient removal efficiencies over all constituents of interest.

Table 4: The nutrient concentrations at different sampling points

Sample description	NH_3-N in mg/L	NO_X-N in mg/L	TN in mg/L	SRP in mg/L	TP in mg/L
S1	42.140	0.102	46.110	4.918	9.891
S3	6.398	0.005	8.318	3.122	3.802
S4	0.199	0.016	7.329	2.725	2.918
S5	0.056	0.005	4.737	2.815	2.989
S6	0.048	0.005	6.674	2.591	2.771
S7	0.110	0.044	9.931	2.289	2.897
S8	0.006	0.011	4.128	2.273	2.430
S9	0.032	0.005	11.579	2.054	2.214
S10	0.044	0.005	5.667	2.072	3.907

Microorganism concentration in influent is very high. Fecal coliform concentration is about $412*10^3$ cfu/100 mL and E. coli concentration is about $214*10^3$ cfu/100 mL (i.e., CFU means colony forming unit.) The concentration is much lower in the drain fields and washed building sand drain field performs better for microorganism removal. Both the drain fields have achieved about 99.99% removal efficiency though. Average E. Coli concentration in astatula sand drain field and washed building sand drain field is about <1 cfu/100 mL and <1 cfu/100 mL, respectively. Average fecal coliform concentration in the astatula sand drain field and washed building sand drain field is about <1 cfu/100 mL and <1 cfu/100 mL, respectively.

Table 5: Summary of nutrient removal efficiency from influent to drain field

Description	NH_3-N (%)	NO_X-N (%)	TN (%)	SRP (%)	TP (%)
astatula sand	99.83	82.35	84.57	47.84	70.82
washed buildingsand	99.93	93.13	84.54	56.62	71.18

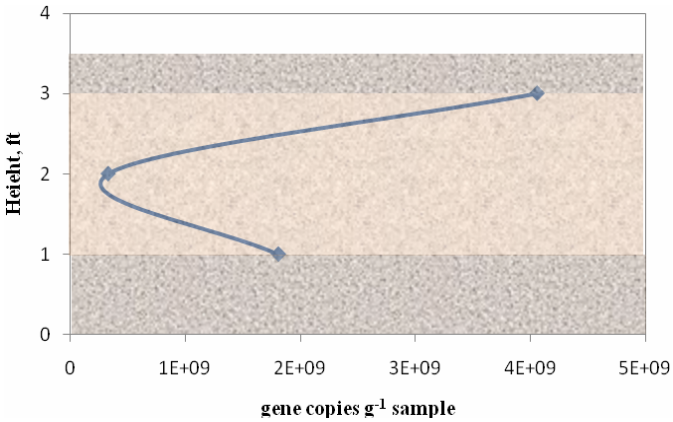
Microbiological Assessment

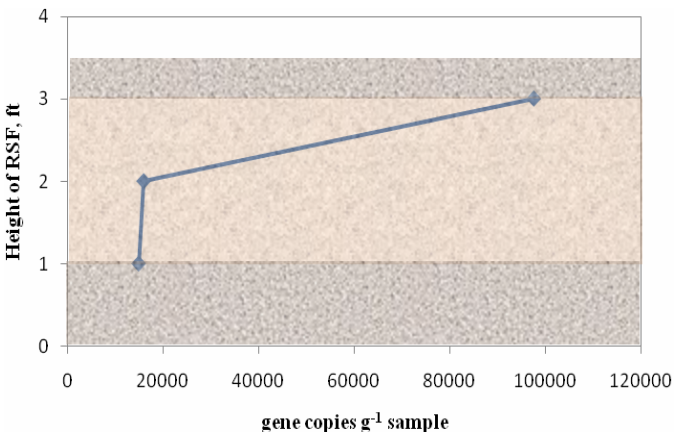
The standard DNA from plasmid DNA was prepared for tenfold serial dilution (from 10^1 gene copies/uL to 10^5 gene copies/uL), and each of them was quantified in triplicate. Stepone^{TM} V1.0 software (Applied Biosystems) was used to process and ananysis the data. Standard curves were obtained by plotting Ct (threshold cycle) as a function of log of the copy number of target DNA (Table 6).

Table 6: The quantity of different target gene in samples and standard curves used.



Target gene	Sample NO.	gene copy number g^{-1} sample	Standard Curves			
			Slope	Y-Intercept	R^2	Dilution range, gene copies/uL
amoA	R1	4.1×10^{9}	-3.452	49.153	0.989	$10^{5} – 10^{9}$
	R2	3.3×10^{8}				
	R3	1.8×10^{9}				
NSR	R1	9.8×10^{4}	-3.249	32.652	0.995	$10^{1} – 10^{5}$
	R2	1.6×10^{4}				
	R3	1.5×10^{4}				
nirK	W1	1.4×10^{4}	-3.489	36.369	0.984	$10^{1} – 10^{5}$
	A1	UD				
	W2	9.5×10^{4}				
	A2	1.6×10^{5}				
	W3	UD				
	A3	UD				

UD: Under detection limit (which is about 6000 gene copy number g^{-1} sample)



Ammonium oxidation is the first stage of nitrification. The function of autotrophic AOB is to convert ammonium to nitrite within aerobic condition. As the Figure 5(a) shown below, the top sample has highest quantity of AOB with the most oxygen exposure. The amoA gene copy number per gram sample supposed to decrease with the depth. The reason why the bottom sample has more AOB than the midpoint sample may be that there is still some oxygen remaining between the coarse particles in gravel layer. Thus, the midpoint sample has the least amount of AOB rather than bottom sample.

Nitrite oxidation is the other stage of nitrification process. Autotrophic nitrite-oxidizing bacteria convert nitrite to nitrate within aerobic condition. Figure 5(b) below shows that the top sample has highest quantity of NOB in similar principle. From the Table 4, about 40% of NH_3-N had not been removed and flowed out of the outlet of the RSF. The limited concentration of nitrite produced by AOB made the number of NOB keep almost the same at middlepoint and bottom of RSF.

Seen from the Figure 6 above, the *nirK* gene copy numbers per gram sample showed a trend for higher values with the increase of depth. And the *nirK* gene copy numbers per gram of the sample close to the water table reduced to zero approximately. Oxygen content in soil decreased with depth, which is the main reason why *nirK* gene copy number per gram sample increased with depth. The dissolved oxygen in groundwater and reduction of organic matter may cause the reduction of denitrifying bacteria number in sample close to groundwater table abruptly. In addition, the number of denitrifier in washed buliding sand is more than that in astatula sand. However, NO_X-N removal in astatula sand drain field is as good as that in washed building sand drain field. As discussed in previous subsection, the anaerobic condition probably has not been created thoroughly during the initial test run of the treatment system. The nitrification may be started in the drain fields but denitrification had not fully started yet. This implies that the number of denitrifiers has not represented the process of denitrification yet.

Groundwater Monitoring

Groundwater elevation data is shown in Figure 7. The groundwater was flowing towards south-west direction indicated by an arrow sign. Nutrient concentration in groundwater was analyzed and found that the concentration was varying widely. Ammonia concentration varied from maximum 7.870 mg/L at M7 to minimum 0.153 mg/L at MW2. The distance between these two wells is about 45.87 meter. NO_X-N concentration was maximum 2.233 mg/L at MW2 to minimum 0.005 mg/L at M4 at a distance of 37.340 mg/L. Both NO_X-N and NO_2-N concentration in groundwater was within the USEPA given guidelines. Note that USEPA recommended maximum NO_3^--N concentration is 10.00 mg/L and NO_2^--N concentration is 1.000 mg/L (USEPA, 1988). It indicated that denitrification rate may increase with increasing depth. It is logical because less oxygen was present at larger depth and more nitrate was available for denitrifiers. Maximum TN concentration was 9.610 mg/L at M7 and minimum TN was 1.300 mg/L at MW8 within a distance of 37.83 meter. Maximum SRP concentration in groundwater was about 0.900 mg/L at MW6 and TP concentration was about 1.76 mg/L at MW7. This phosphorus concentration may not be harmful for groundwater as it is for surface water. Yet, drinking water should contain some phosphorus for teeth and bone formation in human body. National Academy of Science (NAS) recommended about 700 mg of phosphorus per day. Number of E. coli was about <1 cfu/100 mL in all the wells. Maximum fecal coliform concentration was 57 cfu/100 mL at well M8. These microorganisms concentration had also decreased with higher depth. So it can be said that soil in this area was very effective to remove nutrient and harmful microorganisms.

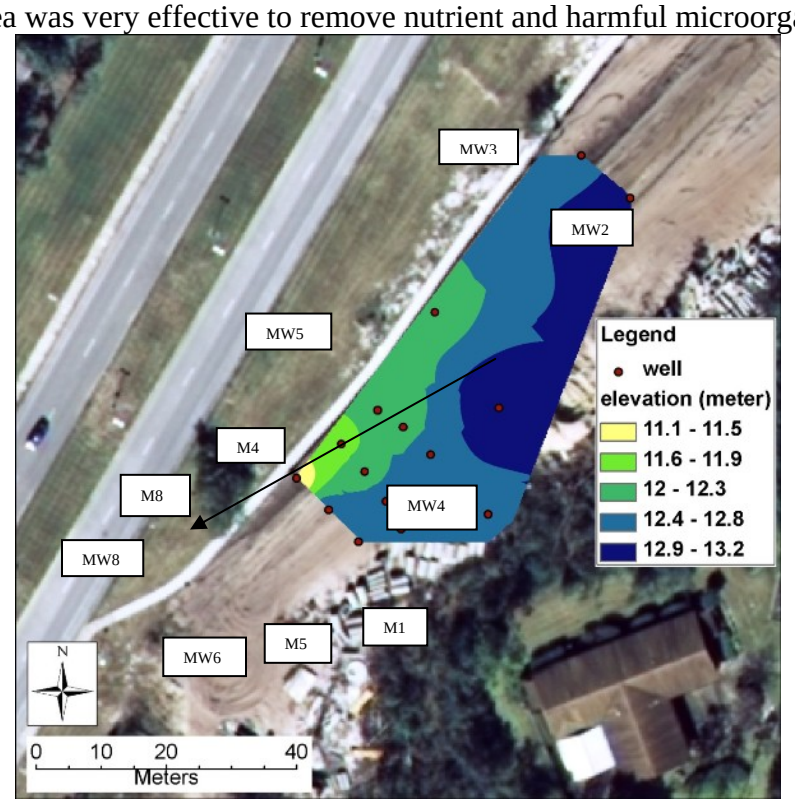

Figure 7: The groundwater table at different groundwater monitoring well at the test site. The arrow sign shows the direction of groundwater flow

CONCLUSIONS

Removal of nutrient by RSF and drain field is basically a combination of physicochemical and microbiological processes. NO_X-N removal efficiency in washed building sand drain field is slightly better than that in astatula sand drain field. In all cases, the ammonia and NOx-N concentration meet the USEPA regulation. While the above said system was removing significant amount of ammonia, it was not removing substantial amount nitrate. In any circumstance, groundwater sample analysis supports that NO_X-N and NO_2-N concentrations are within safe limit according to the USEPA requirement. Phosphorus removal is not high enough in the system. But it would most likely not have a negative affect on groundwater quality. Research findings suggested that phosphorus removal can be enhanced possibly by adsorption, chemical reaction or ion exchange if the sand has more clay and mineral particles. Sorption using a tire crumb mix being investigated at the University OWTS test center is proved effective phosphorus removal too. Due to the cost effectiveness concern, astatula sand may be used to replace the costly washed building sand in the future.

Abstract

Global climate change and its related impacts on water supply are universally recognized. In the past few years, drought impacts affecting big metropolitan water supplies alone have plagued Maryland and the Chesapeake Bay in 2001 through 2002, Lake Mead in Las Vegas in 2000 through 2004, the Peace River and Lake Okeechobee in South Florida in 2006, and Lake Lanier in Atlanta in 2007 that especially affected the water resources distribution in three states - Alabama, Florida, and Georgia. One group of unnatural sites, namely crushed stone quarries, holds promise for expanding the reservoir capacity in water supply systems. Inspired by the past and future trend of global change and the need to generate adaptive water resources management strategies, this study develops the conceptual and numerical framework of a spatial decision support system for evaluating the feasibility of water supply development using abandoned and active stone quarries. Whether or not a particular abandoned or active quarry can be used as a water supply reservoir depends on many different factors. Some important factors are the size of a quarry and the volume of water that can be stored, the location of a quarry and its distance to the city or community that needs water supply, the source of water that can be diverted into a quarry, surface runoff input from watershed to quarry, evaporative loss of water in quarry, and groundwater input to quarry. Water storage and recharge in the aquifers must be achieved with caution since water quality may be changed by biogeochemical reactions with aquifer materials. We demonstrate in two cases that mixing of recharge water and groundwater of different hydrochemistry may dissolve certain minerals while allow others to precipitate in the aquifers. A quarry reservoir can become thermal stratification during summer if it is deep enough, and the stratification can lead to oxygen depletion in the bottom waters, and then it may require hypolimnetic oxygenation (aeration) to improve water quality. A lake water quality model is used to examine water quality dynamics in different types of stone quarry reservoirs under different climate and watershed input scenarios.

Introduction

Global climate change and air temperature increase due to rising atmospheric concentrations of carbon dioxide and other green house gases can lead to an increase of water loss by evaporation (Stefan et al. 1998). One model (Burke et al. 2006) suggests that "if global warming–related precipitation changes continue apace, the percentage of the Earth's surface in severe drought could rise from the current 3% to 30% by 2100". "We can project that there is going to be competition for water in the future. We want to take a look over the horizon and see what kind of procedures and innovative approaches we need to make sure we don't end up in water wars" (Manuel 2008). Provision of an adequate quantity of water has been a matter of concern since the beginning of civilization. The average daily per capita water consumption in American cities varies from 130 to 2000 liters (35 to 530 gallons) (McGhee and Steel 1991). The National Academy of Engineering in USA has developed 14 grand challenges for engineering, and one of them is to provide access of clean water: "The world's water supplies are facing new threats; affordable, advanced technologies could make a difference for millions of people around the world." The first common practice for solving the shortage of water is to develop and implement various polices and efforts to conserving water. These conservation practices can be very effective for short periods. Yet the development of sources and/or storage of water supply that can carry a community through extended periods of low streamflow are needed for a long-term solution to the threat of droughts, climate change, and population growth. The source for water supply includes groundwater and surface water supplies. The surface water supplies require the construction of impoundments (storage reservoirs) to meet demand during periods of low river flow. Inspired by the past and future trend of global change and the need to generate adaptive water resources management strategies, the final objective of this study is to develop a spatial decision support system (Chang and Chang 2002) - a robust, efficient, mechanistically-based, integrated decision support tool – for evaluating the feasibility of water supply development using abandoned and active stone quarries. In this writing, we develop a conceptual and numerical framework for understanding, quantifying, and modeling key attributes and criteria that affect development of stone quarries as water-supply reservoirs.

In the recent years the Southeast of United States suddenly finds itself the most rain-starved region of the country. The U.S. Drought Monitor on May 13, 2008 (Figure 1) shows that about 18% of the Southeast remains either in severe or extreme drought even after most of the region had 10 to 12 inches of rain in the previous three months. Although there currently is no immediate public health threat posed by the southeastern drought, it does pose significant challenge and struggle to policy makers and utility companies or authorities to maintain an adequate supply of potable water. At a time when there is a need for more water-supply reservoirs, one may find that the supply of natural sites is quite limited. Most economically attractive and environmentally acceptable natural sites for storage reservoir development in USA have already been developed. "One group of unnatural sites, namely crushed stone quarries holds some promise for expanding reservoir capacity" (Moreau 2007).

Aggregates are natural materials mined either from gravel pits or from quarries. Generally, "pits" produce sands and gravels and "quarries" produce crushed hard rocks. Crushed-stone mining includes four possible important components: stripping, excavation, processing, and trucking. Major rock types processed by the crushed stone industry include limestone, granite, dolomite, sandstone, and quartzite. Most of quarry mines were dug below the local groundwater table, sometimes exceeding 1,000 feet beneath the ground surface. A quarry

lake forms and develops over time when groundwater, surface water and other post-mining drainage accumulates inside an inactive (abandoned) open quarry after dewatering stops. One example of quarry lakes is shown in Figure 1. Recently, some of quarry lakes are created for water storage sites and filled by diverting water from nearby rivers, streams, and reservoirs when contributions from groundwater and surface runoff are limited (Moreau 2007). Whether or not surface runoff or groundwater flow from surrounding watersheds can provide adequate source water during wet seasons for the quarry reservoir is one of the limiting factors for the inclusion of a quarry for integrative water supply development. Another consideration is that diverting water from a nearby stream to a quarry must satisfy aquatic habitat and in-stream flow requirements to maintain a healthy ecosystem downstream of the diverting point.

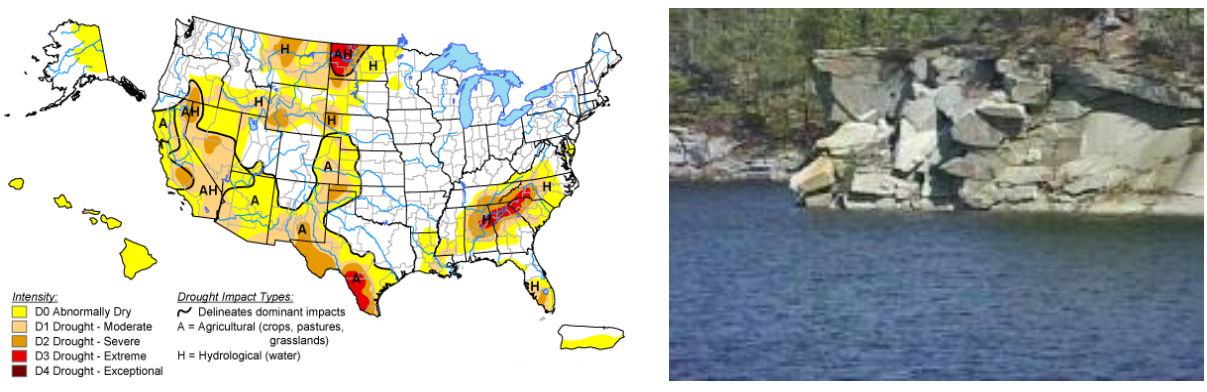

Figure 1. U.S. Drought Monitor for May 13, 2008 (from National Drought Mitigation Center, University of Nebraska – Lincoln) (left panel) and an abandoned quarry in Wake County, North Carolina (right panel).

Feasibility of Using Stone Quarries as Water Supply Reservoirs

Most of drinking water in the Southeast is stored in man-made reservoirs, such as Falls Lake and Lake Jordan for the city of Durham in North Carolina. Water supply systems are "sociotechnical" systems with strong links to society (Grigg 1996). For instance, the Southeast drought has already had not only serious economic consequences (losses of more than $1.3 billion in 2007), but also political consequences, pitting downstream and upstream users (i.e., three states) against one another. Potential climate change and cyclical droughts pose threats to water supplies for many cities in the United States. In addition to water conservation practices, it is important and necessary to examine feasibility and possibility to develop new sources and/or storage of water supply, and this could be an essential alternative in the long-run to solve the problem of shortage in water supply. The USGS Mineral Industry Surveys show that there are 3,358 active quarries for crushed stone production and there are numerous abandoned or inactive quarries in the United States. "What is the feasibility of using active and abandoned quarries for water supply development and solving current and future water supply crisis?" is a question that has yet to be studied holistically. "Abandoned quarries have been largely overlooked as storage sites until recently" as stated by Dr. David H. Moreau, Director of the Water Resources Research Institute of The University of North Carolina. It is worth to mention that some abandoned quarries work better than others for storing water. Any site, according to Dr. Moreau, would need to be examined for contamination that could threaten public health. Another factor to consider is the cost of moving water from the quarry to treatment plants and distribution pipes.

Whether or not a particular abandoned or active quarry can be used as a water supply reservoir depends on many different factors involving water resources, geological, public health, socioeconomic and environmental impacts. Some important factors are the size (volume) of a quarry (affecting how much water can be stored), the location of a quarry and its distance to the city or community that needs water supply, the source of water that can be diverted into a quarry, surface runoff input from surrounding watersheds to quarry, groundwater input to quarry, evaporative loss of water in quarry, etc. To face the future challenge, water supply planning requires us not only to identify abandoned quarries that can be possibly developed as storage reservoirs in the near future but also to consider and identify active quarries for long-term future development, especially in kart regions (covering nearly 25% area of the contiguous USA) where the hydrogeological environment is challenging. In the Southeast the karst geology might strongly affect the decision making process of using stone quarries as alternative water storage.

Impacts of Surface Water and Groundwater on Stone Quarry

In considering the planning, design, and expansion of a water supply system, many competing issues must be addressed and the competing demands must be balanced within the legal and administrative framework (Maidment 1993). Modifications to the water supply system also depend on the extent to which the alternative stone quarries are integrated into the community's existing water resources systems. Regional precipitation variation and extreme drought events are important to water supply development for the fast growing urban regions. Surface runoff input to a quarry lake depends on watershed size surrounding the lake, geological conditions, and regional precipitation variation. Using the lake as outlet, contributing watershed can be delineated from contour maps, field surveys, aerial photographs, and the digital elevation models. If the contributing watershed area to the lake is limited, then surface runoff to fill the lake will be limited. Rainfall is the driven force and the key controlling parameter on surface water input to a quarry lake. Figure 2 shows variations of mean annual precipitin over the contiguous U.S. from 1971 to 2000, and annual precipitation is on the order of 120 cm or more in the Southeast United Sates, but annual evaporation loss from shallow lakes and reservoirs in the area is also high on the order to 100 cm (from Figure 6.1, Viessman and Lewis 2002). The map allows us to examine regional precipitation variations at any site with stone quarry for potential water supply development. Projection of future climate scenarios such as the third generation coupled global climate model from the Canadian Climate Centre for Climate Modeling Analysis (CCCma) and from the Hadley Centre Coupled Model in the United Kingdom can provide us potential change on future precipitation for the study.

Investigation groundwater hydrology of quarry lakes

For potential quarry lake sites in karst regions, it is important to identify land-use risks using geophysical imaging and hydrological field studies. Imaging the subsurface structure of quarry sites and related geologic features such as fractures, solution-generated conduits, and evolving sinkholes is of both practical and academic interest. These geologic features serve to increase the hydraulic conductivity, either as sources of stored water or as preferential pathways for groundwater flow. The use of geophysical methods for imaging void features has demonstrated success; previous research projects have used such methods as electrical resistivity and ground-penetrating radar for this purpose (Carpenter et al. 1998; Kruse et al. 2006). Multielectrode systems allow for true 3-D inversion of the acquired electrical data; however, it is essential that the survey and measurement design be targeted to the scale of the features expected at each

potential quarry lake site. Geophysical imaging methods provide an effective means to locate and characterize important shallow geologic features that may control hydrological transport. For example, the presence of low-permeability layers below the quarry can restrict the leakage of water. The presence of impervious aquitard layers stratigraphically above and surrounding the quarry, however, may retard the artificial recharge process. In cases where such confining layers are absent, water can percolate down-dip in the direction of hydraulic gradient and recharge the underlying aquifers or deep-seated fractured zone. Knowledge of water-table depths not only provide constraints for geophysical data interpretation and hydrological modeling, but also mark the presence of areas with high hydrologic conductivity as characterized by troughs and low hydraulic gradients below the water table. Superimposing these data on a discharge hydrograph provides insight into the internal structure and transportation characteristics of the aquifer (Ryan and Meiman 1996). Multiple-well aquifer pumping tests (Tiedeman and Hsieh 2001) can also be conducted near the quarry sites. For example, a pressure transducer can be used to record the head changes during a pumping test over time. This aquifer test can reveal the degree of hydraulic connection between boreholes and yield valuable insights into the hydrological characteristics of rocks surrounding the quarry. The relation of measured drawdown to distance from the pumped well can be compared to that theoretically observed during radial flow in an aquifer, as predicted by the Theis solution (Viessman and Lewis 2002). The hydraulic conductivity calculated for both the highly conductive and less-conductive parts of the rock represent high-conduit clusters and low-conduit matrix, respectively. These field experiments allow the assessment of water-level change in response to quarry water replenishment; such data are important for recharge operation and water resources management. Both the hydrological and geophysical measurements are geared toward understanding how the geologic features of each candidate site might affect its suitability as a water-supply reservoir.

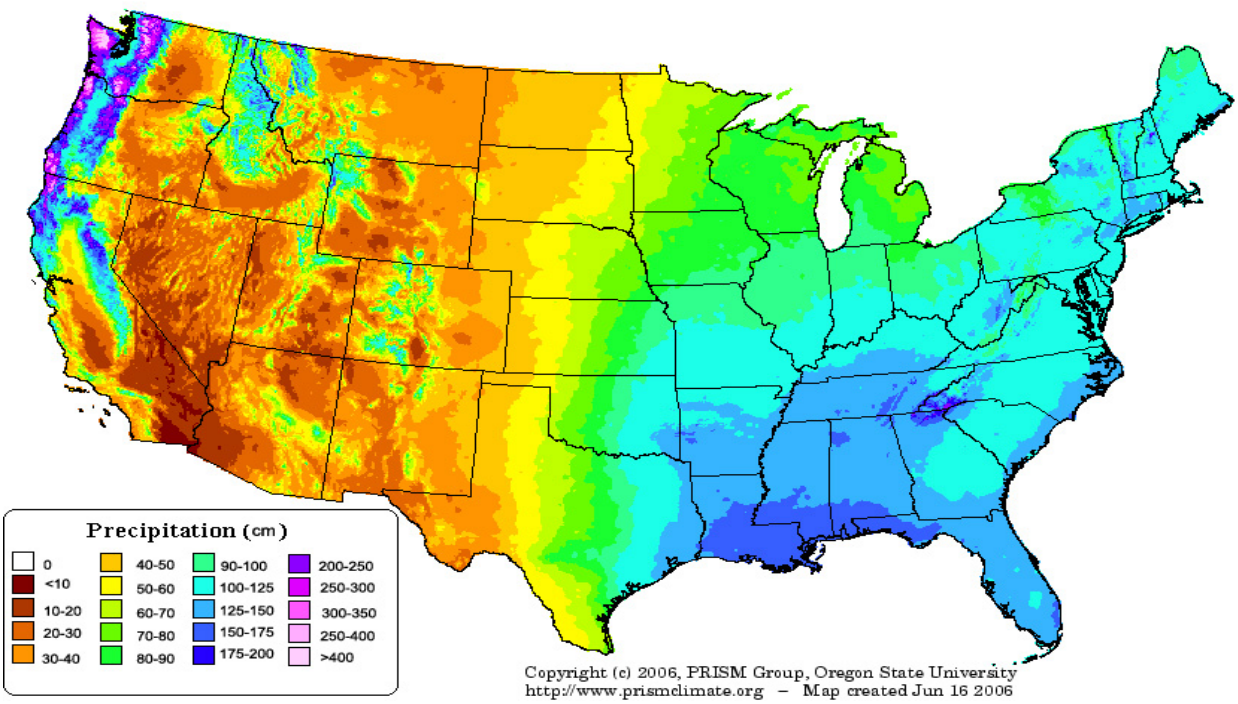

Figure 2. Mean annual precipitation in millimeters by climate divisions, 1971-2000 (Courtesy from Oregon State University).

Investigation of environmental impacts for quarry lakes

In order to evaluate stone quarries development as water supply reservoirs, models for surface-water, unsaturated zone, groundwater, and watershed should be integrated to quantify water budgets and geochemical evolution and consequences for quarry reservoirs under different environmental scenarios. The following discussion show possibility to integrate a watershed model (TOPMODEL), geo-environmental model (FRACFLOW), and lake-water-quality model (MINLAKE96) to assess and characterize stone quarry and its watershed for sustainable water supply development.

Watershed Modeling Analysis: A quarry under feasibility study for water supply serves as outlets or pour points of the surrounding watersheds that can be simulated by TOPMODEL, directing it to connect the simulation domain for a lake water quality model - MINLAKE96 (Fang and Stefan 1996). TOPMODEL is a distributed hydrological model and can use a GIS interface (e.g., ArcMap) for the analysis and manipulation of spatial data (i.e., digital elevation topography, spatial distributions of soil characteristics such as hydraulic conductivity, depth to bedrock, depth of AB soil horizon, and field capacity). Although the model was first developed by Beven and Kirkby (1979), the latest version reflects the current understanding of how precipitation moves over and through watersheds to become streamflow (Wolock 1993). The model is designed to simulate hydrological fluxes of water (infiltration-excess overland flow, saturation overland flow, infiltration, exfiltration, subsurface flow, evapotranspiration, and channel routing) through a watershed and simulates the variable-source-area concept for streamflow generation. The algorithm may assess explicit groundwater/surface-water interactions by predicting the movement of the water table, which determines whether saturated land-surface areas may have the potential to produce saturation overland flow. It uses time series of precipitation and air temperature as part of model input, making it a suitable platform to examine climatic and drought scenarios on water budget for quarry development. Consequently, TOPMODEL has been used in a variety of water resources engineering studies, such as topographic effects on streamflow (Kirkby 1986) and water quality (Wolock et al. 1990), and effects of climate change on hydrological processes (Wolock and Hornberger 1991). Since it is a module-based modeling system with publicly available FORTRAN source code, it can be coupled with other modeling components and systems, such as the lake/reservoir water quality model MINLAKE96 (Fang and Stefan 1996). The hydrographs generated by TOPMODEL at daily time steps are therefore compatible for model integration with a daily-time water quality model of lakes (MINLAKE96, coded in FORTRAN) and assess water balances for a targeted watershed for water quarry development.

Lake Modeling Analysis: A verified, process-oriented, unsteady and one-dimensional (vertical) year-round lake water quality model (MINLAKE96) was used to study impact of global climate change on water temperature, dissolved oxygen (DO), and fish habitat for small lakes in the contiguous U.S. (Stefan et al. 1998). This model is a good candidate to simulate the continuous change of lake stratification and water quality in response to weather (precipitation), inflow, outflow, and exchange processes at the sediment interface, and inlake processes. The water quality parameters that can be modeled after model enhancements include temperature, up to three forms of algae (expressed as chlorophyll-a), available phosphorus, ammonia, nitrate-nitrite, detritus as biochemical oxygen demand, zooplankton, inorganic suspended sediment, and dissolved oxygen. The depth profile of water temperature is computed from a balance between incoming heat from solar and long-wave radiation and the outflow of heat through convection, evaporation, and back radiation. Water loss through evaporation and input from precipitation are

included in the model. MINLAKE96 can simulate daily lake water temperature and DO profiles in a continuous mode for multiple years. Thermal stratification in a quarry reservoir is modeled first before it models transport and fate of contaminants in the quarry. The model requires dividing a lake (quarry reservoir) into a series of well-mixed horizontal water layers and including a sediment layer below (Fang and Stefan 1996).

Stratification characteristics of water temperature and dissolved oxygen in a hypothetic stone quarry lake are simulated using MINLAKE96. The lake simulated has a surface area of 1.7 km^2 (420.1 acre), maximum depth of 24 m (78.7 ft), and lake volume of 1.25 x 10^7 m^3 (3,302.3 MG). Based on the lake volume, this hypothetic lake has similar size as the second stone quarry that the Orange Water and Sewer Authority in North Carolina purchased for future water supply (Moreau 2007). Water temperature and dissolved oxygen concentrations from 1961 to 1995 (more recent weather data can be obtained from NOAA) were simulated using weather data at Raleigh, NC. The numerical simulation model for daily DO profiles in a lake solves the one-dimensional, unsteady transport equation. The vertical DO profiles in the lake are computed from a balance between oxygen sources (surface reaeration and photosynthesis) and oxygen sinks (sedimentary oxygen demand, biochemical oxygen demand, and plant respiration). Oxygen production is related to chlorophyll-a concentration and limitation of available light determined by Haldane kinetics. In the model chlorophyll-a is specified by a mean annual value and a function that calculates typical seasonal chlorophyll cycles based on observation data from 56 lakes or reservoirs in Europe and North American (Marshall and Peter 1989). In the model, the oxygen transfers through the water surface (reaeration) during the open water season is used as an oxygen source or sink term in the topmost water (surface) layer of the lake, and surface oxygen transfer coefficient is calculated as a function of wind speed.

Figure 3 shows simulated time series of dissolved oxygen concentration at five different depths from the water surface under 1979 weather conditions, and simulated results for other years are similar to patterns given in Fig. 3. The lake geometry ratio $A_s^{0.25}/H_{max}$ (where A_s is the surface area in m^2, and H_{max} is the maximum lake depth in m) is equal to 1.5 for this quarry, and this indicates that the lake is strongly stratification during summer (Stefan et al., 1998). Figure 3 does clearly show strong stratification in dissolved oxygen concentration from early spring to later fall, and more or less well mixed for winter months (November to February). It does have weak inverse stratification on dissolved oxygen (due to biochemical and sediment oxygen demand) during winter months. The lake was assumed to be an eutrophic lake with mean annual chlorophyll-a concentration of 15 µg/l and Secchi depth of 1.2 m, and this condition could be resulted from rich nutrient inputs draining from surrounding watersheds. Simulated results for eutrophic lake are shown in the top panel of Figure 3. Starting from early May, dissolved oxygen concentrations at the lake bottom become zero; and anoxic condition last for six months. Even the lake becomes anoxic from 6.5 m depth to the lake bottom in June up to the middle August. Anoxic condition in the large portion of the lake volume will have profound impacts on lake ecosystem and dynamics of many other water quality parameters in the lake. It may require hypolimnetic aeration to improve water quality before it can be used as the source of water supply. The presence of high levels of nitrate in drinking water appears to be the cause of methemoglobinemia or “blue babies”, and this disease primarily affects infants less than 6 months old. Under anaerobic condition the nitrate can be reduced to nitrite and the nitrite converted to free nitrogen by the process of denitrification, and therefore, with some parts of lake volume with anoxic condition could avoid public health problem with nitrate toxicity. If the lake is assumed to be an oligotrophic lake (poor nutrient inputs) with less biochemical oxygen

demand and lower chlorophyll-a concentration (2 µg/l), the lake will not have any volume with anoxic condition as shown in bottom panel of Figure 3 for comparison.

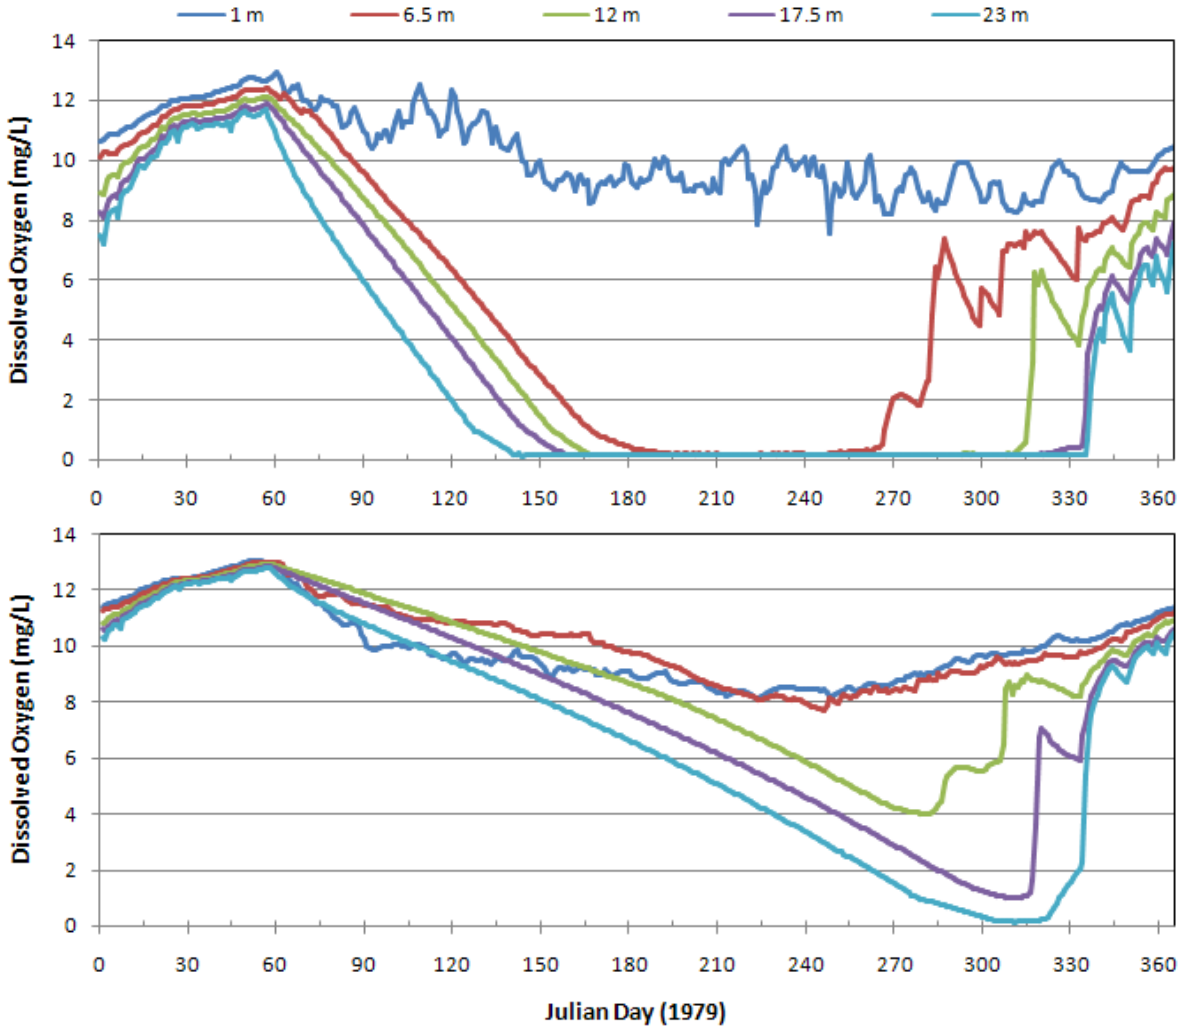

Figure 3. Simulated time series of dissolved oxygen concentration at five depths for a 24-m deep **eutrophic** (top panel) and **oligotrophic** (bottom panel) hypothetic lakes in Raleigh, NC.

Geo-environmental Modeling Analysis: Water storage and recharge in the aquifers must be achieved with caution since water quality may be changed by biogeochemical reactions with aquifer materials. Recharge water may be warmer or cooler than native groundwater and it may dissolve certain minerals while allow others to precipitate. This is because of the temperature-dependent retrograde and prograde solubility of carbonates and sulfates versus silicates mineral groups, respectively. A successful operation of artificial recharge in a quarry requires a more comprehensive understanding of the changes in groundwater flow, storage, and chemical conditions. When surface water is diverted for artificial recharge in quarries, it may or may not be in thermal, redox, or chemical equilibrium with minerals in quarry rocks. In this study we demonstrate the use of a geochemical model, Geochemist's Workbench (Bethke 2008) as a part of the SDSS to investigate the chemical states of surface water and groundwater and quantify how injected water may cause dissolution or precipitation minerals in the quarries. Moreover,

typical fractured rocks consist of confining units and water bearing units that permit the rapid transport of water through connected fractures and conduits (National Research Council 2001; White 2006). We have developed a computer software, FRACFLOW (Lee and Wolf 1998), to simulate such flow characteristics and hydraulic head distribution in fractured/karst rocks bounded by constant-head streams or lakes. This model can be integrated with the watershed and lake models to account for the impact of karst geology on the quarry reuse.

The numerical tools described above can be integrated to address science questions related to (1) chemical interactions among surface water, groundwater, and quarry or aquifer materials; (2) pathogen fate and transport from possible sources in nearby watersheds if the quarry is included; and (3) hydrological loading and storage capacity of the quarry under different geologic conditions. These considerations can be synthesized to generate index values reflecting the feasibility of the sustainable development of water supply with each candidate site for final decision making. One case study is given below to demonstrate geo-environmental analysis. Artificial recharge, storage, and recovery can augment water supply during peak summer seasons or periods of extended drought. One option is to bring river water into the quarries or aquifers during the high-flow and low-demand seasons, the water stored in recharged aquifers can be withdrawn to meet demands during drought. The injected surface water, however, may not be chemically or thermally compatible with the native groundwater and hosting aquifer minerals during recharge conditions. This case study uses Geochemist's Workbench to simulate the geochemical consequences of mixing of surface water and groundwater in the limestone aquifers of Florida and Nevada. Water mixing in limestone aquifers may cause calcite ($CaCO_3$) precipitation that would affect artificial recharge and storage operations or reduce permeability of near-by pumping wells. In the Florida Panhandle area, excess groundwater withdrawals near the coastal areas have forced many municipal supply wells to be abandoned due to saltwater intrusion (McCartha et al. 2003). In the Las Vegas Valley, water demands due to rapid population growth have exceeded the city water system's producing capability from the Paleozoic carbonate aquifers and valley-filled sediments (Katzer and Brothers 1988). Both areas are using artificial recharge and recovery as an option to augment water supply.

In the model, a packet containing 1 kg of Ca-Mg-HCO_3 type Floridian groundwater maintains equilibrium with calcite and dolomite in the aquifer. We used the chemical analyses of PCB1 well in the Panama City Beach area to set the fluid's initial compositions (Table 1). A second type of surface water recharges and mixes into the first fluid packet in a mass ratio of 10:1. The calculation used the surface water chemical data collected from the Appalachicola-Chattahoochee-Flint (ACF) River basin (station ID 023358694, Table 1). As the fluids mix over the course of reaction path modeling, any minerals that become supersatured precipitate. The modeling results indicate that calcite remains undersaturated during mixing and its precipitation does not occur (Figure 4). By contrast, the recharge of Colorado River water into Paleozoic carbonate aquifers in the Las Vegas Valley can lead to significant calcite supersaturation and precipitation (Figure 4). Chemical analyses for well 11A and the injected Colorado River water are shown in Table 1. These waters are more concentrated and have higher calcium and bicarbonate concentrations than those in the Florida Panhandle study area. The geochemical modeling can determine whether mixing of surface water with groundwater may cause significant calcite precipitation under different physio-chemical conditions. The water manager can use the model as a tool to find a site with minimum potential of calcite precipitation that would reduce aquifer permeability.

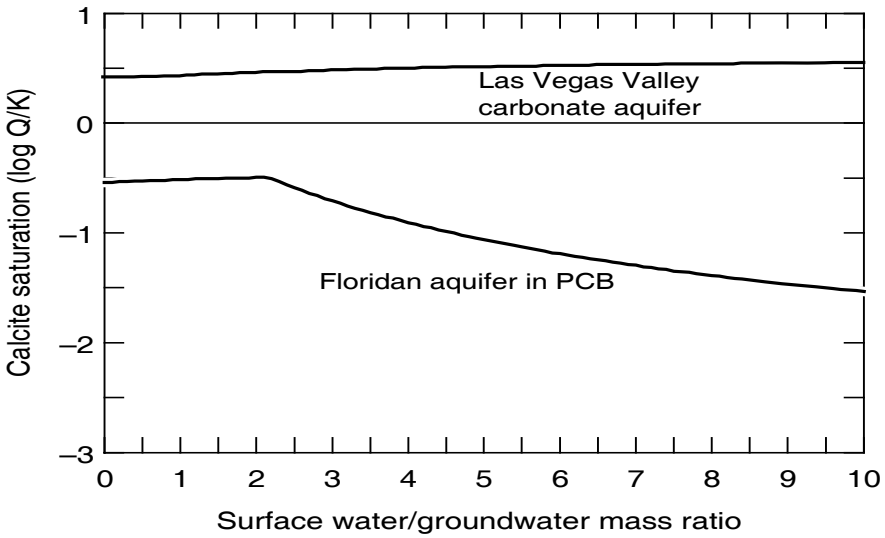

Figure 4. Results of mixing surface water with carbonate groundwater in the Panama City Beach (PCB) and Las Vegas Valley areas. The diagram shows how the saturation index (log Q/K) of calcite varies with mixing ratio of surface water versus groundwater.

Table 1. Major ion compositions (in mg/kg) of surface water and groundwater used in computer simulations of mineral oxidation and fluid mixing reactions

Sample	ACF River[1]	PCB 1[2]	Colorado River[3]	Las Vegas 11A[4]
Alkalinity (HCO_3^-)	15	190	140	224
Ca	4.7	62	86	53.5
Mg	1.2	49	22	26.8
Cl	2.9	196	104	4.8
K	2.5	4.3	3.9	3.8
Na	5.3	104	109	7.1
SO4	5.7	13	311	68
pH	6.6	7.6	8.2	7.8

Future Development of Spatial Decision Support System

Our long-term plan is to combine data collection, model integration, field investigation, and decision support tool development from five subject areas relating to the environmental, water resources, geological, public health, and socioeconomic factors that influence the way in which water utility move in the decision making process. The study is to pursue a systematic approach (Change et al., 2008) in order to see interrelationships rather than a misleading cause-effect chain and to use a wealth of modeling and sensing outputs and measurements to examine the process of change rather than simply analyzing snapshots of data for evaluating the feasibility of using stone quarries for sustainable water supply development.

Conclusions

This study has identified potential problems of global climate change and cyclical droughts to water supply in growing urban regions. Inspired by the past and future trend of global change and the need to generate adaptive water resources management strategies, this study has developed the conceptual and numerical framework for future development of a spatial decision support system in order to evaluate the feasibility of water supply development using abandoned and active stone quarries. We used Geochemist's Workbench to demonstrate biogeochemical reactions in two different aquifers, and the necessity to carefully examine chemical equilibrium and mineral precipitation and dissolution reactions in artificial recharge and storage operations for potential stone quarries as water supply development. The field study such as pumping tests and geophysical images can be important in determining key groundwater hydraulic parameters and locating and characterizing shallow geologic features that are important to stone quarry development in karst regions. A deep quarry reservoir can become thermally stratified during summer, and the stratification can lead to oxygen depletion in the bottom waters, thus requiring hypolimnetic oxygenation (aeration) to improve water quality. The water quality model MINLAKE96 was used to examine a hypothetical deep lake in Raleigh, North Carolina, under eutrophic and oligotrophic conditions. Eutrophic lake with rich nutrient input from surrounding watersheds results in long-period of anoxic conditions in hypolimnion during summer. In this study, the conceptual and numerical framework is developed for understanding, quantifying, and modeling key attributes and criteria that affect developing stone quarry as water-supply reservoirs. These consider geological, environmental, public health, water resources, and socioeconomic impacts.

ABSTRACT

The geochemical patterns of nitrate and selenium exhibit spatial variability within the shallow aquifer of San Diego Creek Watershed, Orange County California. The surface streams in the watershed are fed primarily by groundwater baseflow from the shallow aquifer. A new area was investigated in the watershed in 2004 and 2005 near "Santa Ana Delhi Channel." A covariate relationship is shown in the groundwater data collected near Santa Ana Delhi Channel for selenium, nitrate, and salinity. Despite wide scatter of data, there is a clear positive correlation shown between selenium and nitrate concentrations, and a negative correlation between nitrate/specific conductance and selenium/specific conductance.

A possible set of hypotheses for the correlative relationships between selenium, nitrate, and salinity are as follows: (1) Geologic history plays an important role in controlling selenium content in the shallow aquifer, and selenium may originate from upland marine shales of Miocene age. (2) A historic marsh in low lying swampy areas of the watershed acted as a sink for selenium in runoff waters. (3) Draining the marsh in the late 1800s changed prevailing hydrologic and geochemical structure of the land, essentially converting this selenium sink to a selenium source whereby infiltrating precipitation and shallow groundwater leaches selenium from the historic marsh deposits. Selenium-rich groundwater contributes substantial flow to surface streams via groundwater seepage and springs. (4) Oxidation of selenium by nitrate produces a positive correlation between high nitrate and high selenium. (5) Groundwaters with highest salinity in the local areas near Santa Ana Delhi Channel are sourced from lower permeability alkali soils that were never planted to crops, and nitrogen fertilizer was not used on these soils. These fine textured soils were not leached as effectively historically, and retained more salt

during leaching, so crops were not planted there. As a result, low selenium, high salinity, low nitrate correlations are observed in areas with saline soils; and high selenium, low salinity, high nitrate correlations are observed in the lower salinity areas where agriculture was practiced.

INTRODUCTION

Study Area and Problem Statement. The San Diego Creek Watershed covers approximately 112 square miles in Orange County, California. Regional streams drain headwaters from the Santa Ana Mountains in the north and northeast and the San Joaquin Hills in the southeast. These waters drain ultimately into Upper Newport Bay, one of the last remaining coastal estuaries of southern California (Hibbs and Lee, 2000).

Before 1890, waters draining from the highlands collected in the central low-lying part of the watershed creating a wetland environment known as the "Swamp of the Frogs" Marsh (Trimble, 2003). Wetlands existed where the water table was at ground surface, creating an area where water-logged soils prevented land development. In the late part of the nineteenth century, part of this swamp was drained to make way for the expansion of ranching and agriculture (Trimble, 2003). By dredging channels to drain the marsh, the water table was effectively lowered by several feet so that today a shallow groundwater system exists above deeper regional aquifers.

Previous research found high levels of selenium in the shallow groundwaters flowing within the boundary of the historic Swamp of the Frogs Marsh (Hibbs and Lee, 2000). Geologic history plays an important role in controlling selenium content in the now shallow aquifer. Selenium may originate from upland marine shales of Miocene age (Tracy, 1990). Hibbs and Lee (2000) proposed that the historic marsh acted as a sink for selenium derived from weathering and erosion of upland marine shales. Draining the marsh changed prevailing hydrologic and geochemical structure of the land, essentially converting this selenium sink to a selenium source whereby infiltrating precipitation and shallow groundwaters leach selenium from the historic marsh deposits. Selenium in reduced forms are usually low solubility species, while selenium in oxidized form is highly soluble and moves freely in oxidizing groundwater. Once selenium is oxidized, the selenium-bearing aquifer contributes substantial flow and selenium loading to surface streams in the watershed via groundwater baseflow (Hibbs and Lee, 2000; Meixner and others, 2004).

High levels of selenium in surface water have been linked to birth defects and increased mortality of fish and waterfowl (Frankenberger, 1998). Aquatic life forms depend on regional streams and on the principle drainage feature of the catchment, Upper Newport Bay. Habitats in San Diego Creek Watershed and in Upper Newport Bay could potentially suffer adverse impacts from this naturally occurring source of selenium.

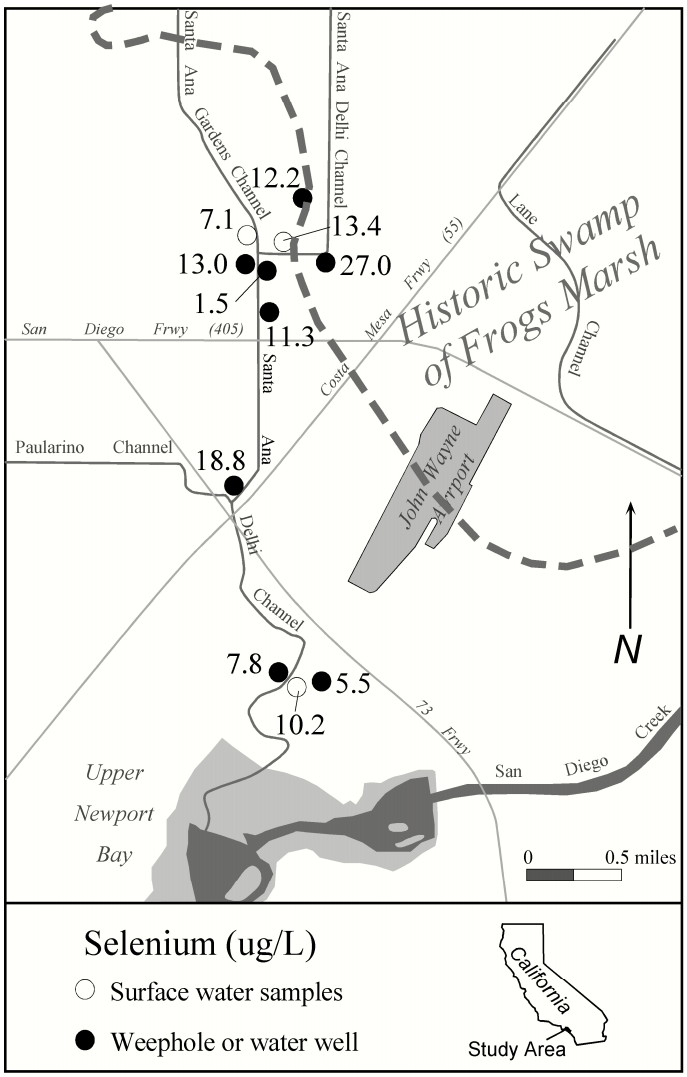

Figure 1. Location of study area in the vicinity of Santa Ana Gardens Channel and Santa Ana Delhi Channel. Results of sampling in Santa Ana Delhi and Santa Ana Gardens Channel showing selenium concentrations in springs, shallow water wells, and surface flows, January 2004.

Land Use History of the Study Area. Three factors placed constraints on specific types of historic agricultural development of the land that was previously occupied by the Swamp of the Frogs Marsh: 1) poor drainage of heavy, fine textured soils; 2) high salinity and high alkali content of soils; and, 3) shallow depth to the water table. The soils of the watershed formed due to historic drainage features of the catchment, where coarser grained materials formed along the flood plains of the ancestral San Diego Creek and other washes, and finer-grained material formed in the central, low-lying part of the watershed.

Considerable effort was made in the early 1900s to improve the poorly drained, alkali lands and increase their productiveness. Additional lowering of the water table did much toward reducing salt concentration, while irrigation water, natural rainfall, and in some instances overflow waters assisted in leaching away some of the alkali (Eckmann, 1919). As a result, crops were eventually put into production in areas close to and even within the area once occupied by the historic marsh. Both synthetic fertilizer and animal manures were subsequently added to regions above and near the outer margins of the Swamp of the Frogs Marsh.

Purpose of Study. The purpose of this sub-study is to determine if groundwater baseflow conditions dominate near Santa Ana Delhi Channel, and to determine the extent to which loading of selenium, nitrate, and other constituents occurs as a result of groundwater seepage. Previous investigations by Hibbs and Lee (2000) and Meixner and others (2004) did not include detailed investigations of Santa Ana Delhi Channel, and vicinity (Figure 1). It is important to determine the relationship between surface water and groundwater in this part of the watershed to determine concentrations of selenium and other hydrochemical parameters. Therefore, we investigated Santa Ana Delhi Channel in January 2004 and March 2005. The work supplements our knowledge of selenium and nitrate in shallow groundwater in San Diego Creek Watershed. This information is expected to help policy-makers to mitigate the effects of these chemical species in the surface waters and groundwater of the watershed.

METHODS

Surface and groundwater samples collected from the Santa Ana Delhi Channel area were analyzed for index parameters, general minerals, selenium, other select trace elements, and nitrate. Field parameters were measured by two field instruments; a Yellow Springs Instrument-63 (YSI-63) gave readings for pH, temperature, temperature-compensated electrical conductivity (EC), and salinity while a YSI-550A gave readings for dissolved oxygen (DO). In addition to field parameters, a number of water samples were collected at each site depending on the types of chemical analyses required. All groundwater samples were collected in triple-rinsed HDPE or LDPE bottles. Aliquots were separated and preserved within twenty-four hours of collection for various chemical analyses. Filtration was performed using 0.45 μm polycarbonate filter paper.

Samples collected for anion analysis were filtered and kept refrigerated below a temperature of 4˚C. Samples to be analyzed for dissolved selenium and cations were filtered and acidified to less than pH 2 with nitric acid (HNO_3) then kept refrigerated (< 4˚C). Anion analysis was conducted by ion chromatography in the Hydrogeology Laboratory at California State University-Los Angeles. Cation analysis was performed by the Soil Water and Plant Laboratory at the University of Arizona. Analysis of total dissolved selenium was conducted by hydride generation atomic absorption (HG-AA) following the

method described by Zhang and others (1999) at the University of California-Riverside.

RESULTS

Our investigation discovered a number of groundwater flows (springs and adjacent shallow wells) along several portions of Santa Ana Delhi Channel (Figures 1 and 2). Electrical conductivity measurements and analysis of general minerals indicates that surface flows were definitively composed of groundwater baseflow. Groundwater contains moderate to small amounts of selenium relative to concentrations observed in other parts of the watershed (Figure 1). With respect to surface flows, selenium is highest in Santa Ana Delhi Channel above the confluence with Santa Ana Gardens Channel (13.4 ug/L Se) and is lowest in Santa Ana Gardens Channel (7.1 ug/L Se) (Figure 1).

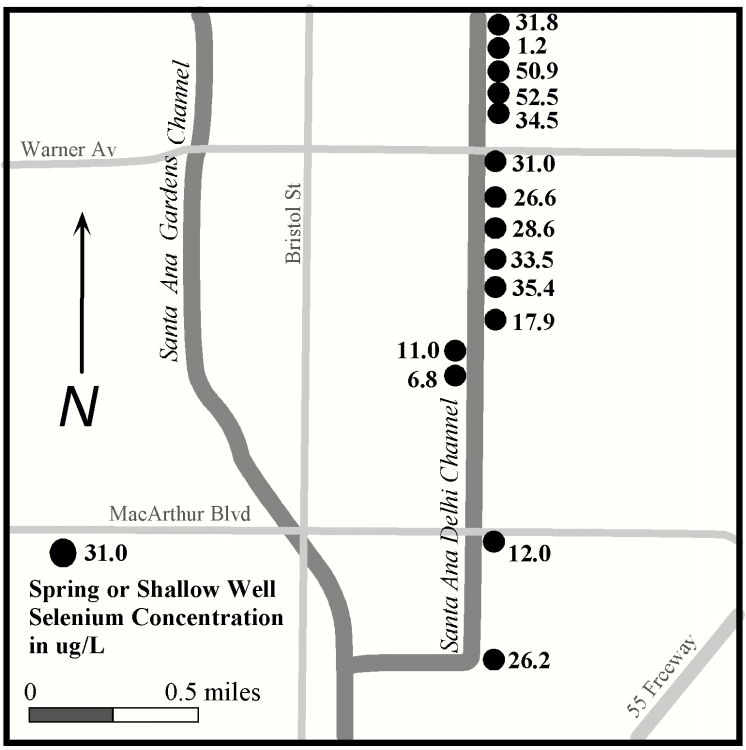

Figure 2. Shallow groundwater data near Santa Ana Delhi Channel showing sampling points at water wells and springs with selenium data, March 2005. All 15 sampling points lie within the historic Swamp of the Frogs Marsh area (see Figure 1).

The portion of Santa Ana Delhi Channel upstream of the groundwater data point "27 ug/L" flows entirely within the boundaries of the historic Swamp of the Frogs Marsh (Figure 1). Therefore, the research team investigated the upstream parts of this channel more intensively in March 2005. This was done

to test apriori predictions of high selenium concentrations in the upper part of Santa Ana Delhi Channel (Figure 1). Data collected from Santa Ana Delhi Channel included 15 new samples, all collected within the historic marsh boundaries. Most samples show moderate to moderately high concentrations of selenium in groundwater (25 to 55 ug/L Se; Figure 2). A few samples are well below 25 ug/L Se however. Selenium is generally lowest in samples collected closest to MacArthur Blvd (Figure 2). One groundwater sample contained only 1.2 ug/L Se. This sample also contained a non-detect concentration of nitrate (<0.5 mg/L NO3-N) and a very high salinity value (9260 uS/cm) (Figures 3, 4 and 5). Previous analysis showed that highly saline ground waters (>10,000 uS/cm) seldom contain high concentrations of selenium (<15 ug/L Se), even within the historic Swamp of the Frogs Marsh region (Meixner and others, 2004). The data suggests that nitrate may be correlated to elevated selenium in groundwater.

DISCUSSION

A covariate relationship is shown for selenium, nitrate, and salinity in groundwaters from Santa Ana Delhi Channel (Figures 3, 4 and 5). Despite wide scatter, there is a clear positive correlation between selenium and nitrate concentrations, and a negative correlation between nitrate/specific conductance and selenium/specific conductance. A possible set of hypotheses for the correlative relationships between selenium, nitrate, and salinity (specific conductance) is as follows:

- Oxidation of selenium by nitrate produces a positive correlation between high nitrate and high selenium. The higher the nitrate concentration, the higher the selenium concentration. Though nitrate is consumed in the oxidation/reduction process, nitrate does not diminish substantially in Santa Ana Delhi Channel due to the stoichiometric relationships between ppb (ug/L) concentrations of selenium, and ppm (mg/L) concentrations of nitrate. This results in a positive correlation between selenium and nitrate (Figure 3).

- Groundwater with highest salinity in the local areas near Santa Ana Delhi Channel near MacArthur Blvd are sourced from lower permeability alkali soils (clays, clayey silts). Fine textured soils were not leached as effectively historically, and retained more salt during leaching. Leaching of salts was important when the alkali soils of the Swamp of the Frogs Marsh region were developed for eventual crop agriculture (1890 to 1960). Leaching was first accomplished simply by draining the water table to allow livestock grazing. Leaching occurred naturally by rainfall infiltration and by percolation of overland flows. Later, as soils started to be leached of salts naturally, alkali resistant crops were planted and irrigated, which increased the rate of leaching. The finer textured, poorly drained soils that were never completely

leached of salts (and were never planted substantially to agriculture) contain organics that consume nitrate (reducing conditions), retain ammonium, and respond to leaching sluggishly. This set of conditions may create an inverse correlation between salinity and nitrate in the data set (Figure 4).

• A low selenium, high salinity, low nitrate correlation is consequently observed in the data set (Figures 3, 4, and 5). The soils with high salinity may contain selenium. However, without the presence of abundant nitrate to oxidize selenium from soils, the selenium concentration remains low in shallow groundwater beneath the soils that are leached by rain or by applied water. High selenium, low salinity, high nitrate correlations are observed in the more permeable, salinity poor areas where agriculture was practiced (Figures 3, 4, and 5). Thus, nitrate availability sourced from agriculture may be a likely factor in selenium mobility.

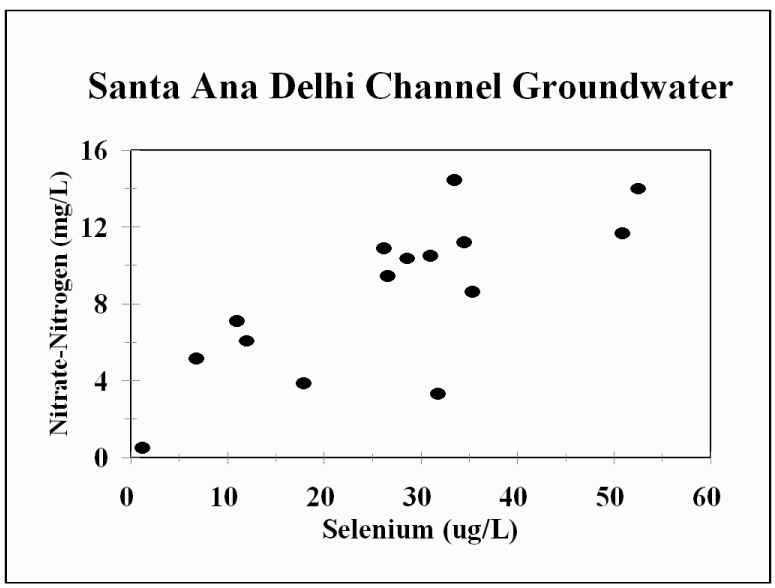

Figure 3. Santa Ana Delhi Channel area shallow groundwater data, showing a positive correlation between selenium and nitrate.

Wright (1999) found that selenium can be oxidized by nitrate from irrigation on Cretaceous marine shale. Dissolved selenium concentrations are positively correlated with dissolved nitrate concentrations in both surface water and ground water samples from irrigated areas in Wright's study area. Theoretical calculations done by Wright (1990) for the oxidation of selenium show favorable Gibbs free energies for the oxidation of selenium by nitrate, indicating nitrate can act as an electron acceptor for the oxidation of selenium. Laboratory batch experiments with selenium-bearing shale and zero-dissolved-oxygen water containing nitrate showed increased selenium concentrations over time with increased nitrate concentrations (Wright, 1990). Wright concluded

that careful management of nitrogen-fertilizer applications in Cretaceous shale settings might help to control the oxidation and mobilization of selenium into surface water and groundwater. If nitrate oxidizes bound forms of selenium in the soils of San Diego Creek Watershed as we postulate, the same type of nitrogen management practices might prove fruitful in the watershed.

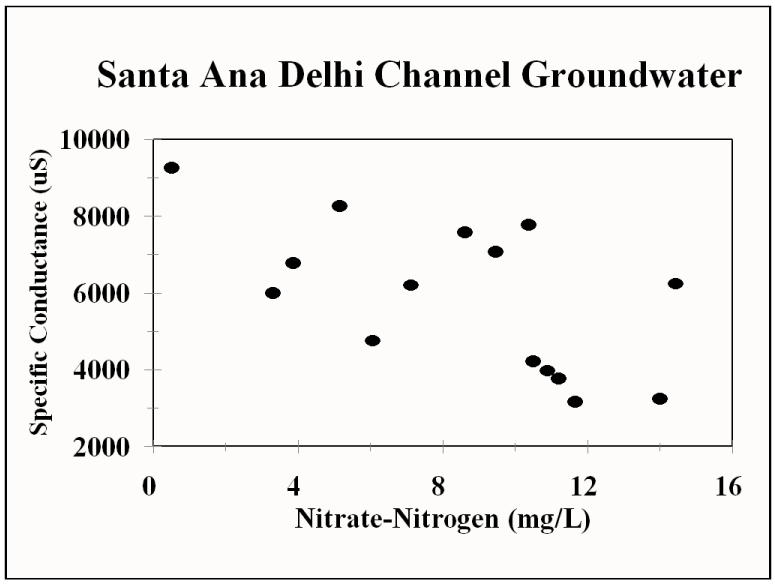

Figure 4. Santa Ana Delhi Channel area shallow groundwater data, showing a negative correlation between nitrate and specific conductance.

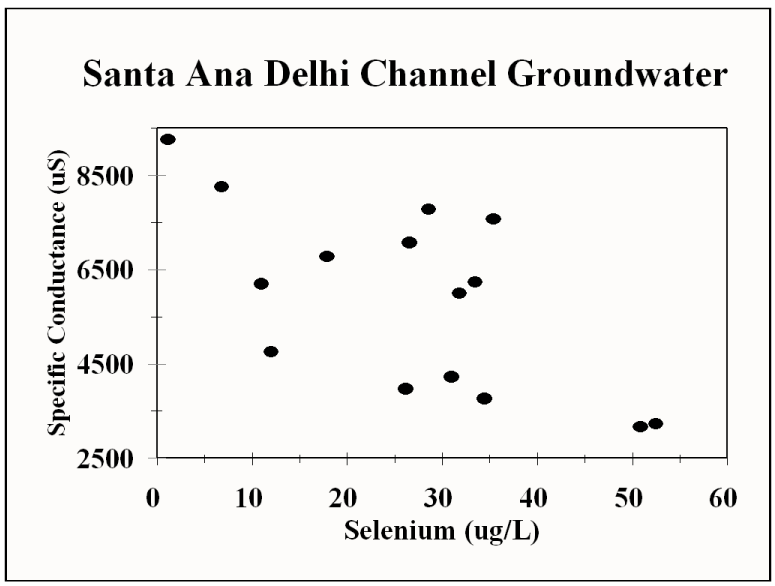

Figure 5. Santa Ana Delhi Channel shallow groundwater data, showing a negative correlation between specific conductance and selenium.

CONCLUSION

We do not exclude oxidation of reduced forms of selenium by dissolved oxygen as a process to explain high selenium in shallow groundwater. This common process was first suggested as the dominant factor by Hibbs and Lee (2000). However, we feel that nitrate is probably as important as dissolved oxygen as an oxidant of reduced forms of selenium. This is because dissolved oxygen is often depleted to suboxic concentrations (<0.3 mg/L) during aquifer recharge through organic rich topsoils and aquifer matrix. We believe dissolved oxygen and nitrate act together to raise oxidation potential in shallow groundwater and both help to oxidize reduced forms of selenium. When dissolved oxygen is near depletion, nitrate continues to keep oxidation potential high. If our hypotheses are correct, and if nitrate continues to be added to the shallow aquifer via application of nitrogen to urban landscapes (by household application, treated wastewater, etc.); or if substantial amount of nitrate is left over in soils from the historical period of agriculture in the region, the selenium in soils could be mobilized by nitrate in greater concentrations than would naturally occur.

Further work is needed in several areas. Selenium speciation work, application of nitrogen and selenium isotopes, and collection and analysis of soil samples are all needed to test these hypotheses. Soil sequential extraction work and geochemical modeling are also recommended.

Investigating the Temperature Effects on Nutrient Removal in Green Soprtion Media

Ni-Bin Chang, Marty Wanielista, Devan Henderson, and Ammarin Daranpob

Department of Civil and Environmental Engineering, University of Central Florida, Orlando, Florida, USA

ABSTRACT

High nitrogen and phosphorus concentrations in stormwater runoff, contaminated groundwater, landfill leachate, and domestic and industrial wastewater effluents have negatively impacted the drinking water quality in many regions. The use of filter media, such as tire crumb, sawdust, sand, clay, zeolite, sulfur, limestone, etc., to get better removal efficiencies of nutrients has been the focus in the planning and design of green infrastructure. These material mixes mainly promote the adsorption/absorption and precipitation of orthophosphate in physicochemical process and the transformation of ammonia, nitrite, and nitrate via oxidation and reduction reactions in the microbiological process. However, temperature changes affect nutrient removal efficiencies in both natural and engineered systems. This paper aims to explore the filtration kinetics of selected filter media for nutrient removal at various temperatures to improve their application potential in all weather conditions. Constitutes of concern include ammonia, nitrite, nitrate, total nitrogen, and orthophosphate. Such a kinetics study leads to investigate the capabilities of comparing a natural soil with soil augmentations in regard to removing nutrients under a range of initial concentrations at three different temperatures (i.e., 28°C, 23°C, and 10° C). Significant differences of removal efficiencies associated with these prespecified temperatures were statistically confirmed by ANOVA analyses.

INTRODUCTION

Before 1995, much work was devoted to research for the removal of nutrients primarily with the sand filter method. For this reason, different types of sand filter methods had been developed like: 1) the Washington D.C. sand filter method, 2) the Delaware sand filter design and 3) the Austin sand filter (USEPA, 1999). The removal efficiency of the Delaware sand filter is Total Suspended Solids (TSS) 70.20%, Total Phosphorus (TP) 71.10%, ammonia nitrogen (NH_3-N) 67.00% and Total Kjeldahl nitrogen (TKN) 59.90% (Bell et al., 1995). Recent development shows that removal of ammonia, nitrite, nitrate, and phosphorus can be enhanced by mixing different sorption media, such as sawdust, tire crumb, sand, clay, zeolite, sulfur, and/or limestone, etc., with natural soil (Kim et al., 2000; Clark et al., 2001; Jokela et al., 2002; Hsieh and Davis, 2005). Appropriate media mix in this research is deemed as a kind of multifunctional material or functionalized sorption media that may be used in both natural and built environments to improve the existing physicochemical and microbiological processes for

nutrient removal (Chang et al, 2008). Such media mix has the "green" implications because of the inclusion of some recycled materials, such as tire crumb and sawdust, as part of the recipe to promote the treatment efficiency and effectiveness (Chang et al, 2008). From engineering standpoint, with the aid of such green sorption media, nutrients in the water bodies can be reduced or even mostly removed by enhanced absorption/adsorption, nitrification/denitrification and other chemical reactions, such as precipitation and ion exchange (Hossain et al., 2008).

The adsorption, absorption, ion exchange, and precipitation reactions are actually intertwined with physicochemical and microbiological processes in porous media intermittently. Pollutants removed by the adsorption process in the "green sorption media" may subsequently desorb. Two important biochemical transformation processes are the nitrification and denitrification that occur at the same time as the adsorption, absorption, ion exchange, and precipitation reactions move on. They result in the transformation of ammonia, nitrite, and nitrate via oxidation and reduction reactions in the microbiological process. In short, nitrification is a microbiologically mediated process that occurs under aerobic conditions, resulting in the formation of nitrate whereas denitrification is a microbiologically mediated process but occurs under anoxic or anaerobic conditions, resulting in the formation of gaseous forms of nitrogen. In reduction-oxidation chemistry, however, nitrification is a process in which ammonium is oxidized via nitrifiers and denitrification is a process in which nitrate is reduced to nitrogen gas via denitrifiers. However, nitrifiers can grow best in a temperature range of 35^0C to 42^0C (Rittmann, 2000; USEPA, 1993) and denitrifiers can work well in a range of 10^0C to 25^0C.

The integrated impact of temperature changes on both physicochemical and microbiological processes remains unknown when removing nutrient in these soprtion media mixes. This paper aims to explore how the filtration kinetics of selected filter media for nutrient removal is affected by various temperatures leading to improve the application potential of green sorption media in all weather conditions. It starts with a through literature review followed by the material characterization of a selected sorption media, and a laboratory column study that was conducted to simulate a wastewater/stormwater treatment unit with saturated media conditions. Such a filtration kinetics study may lead to a comparison to investigate the capabilities of comparing a natural soil with soil augmentations in regard to remove nitrogen and phosphorus associated with a range of initial nutrient concentrations at three different temperatures (i.e., 28°C, 23°C, and 10° C).

MATERIALS AND METHODS

Column Design and Setup

The columns were designed to simulate field environments with saturated conditions. By using three columns, it is possible to test the performance of two mixes as compared with a control. The control column is filled with natural soil from the Hunters Trace Pond in Ocala, Florida. The soil was sun dried and sieved with a #10 sieve to remove vegetation, rocks, and large particles. The selected two media recipes are Media Mix 1 consisting of 50% fine sand, 30% tire crumb, 20% sawdust by weight and Media

Mix 2 consisting of 50% fine sand, 25% sawdust, 15% tire crumb, 10% limestone by weight based on a multicriteria decision making (MCDM) analysis (Henderson, 2008)..

The clear Plexiglas columns have an inside diameter of 14.7 cm (5.8 inches) and are 91.4 cm (3.0 feet) in length. The bottom of each column contains a filter with three inches of fish tank rocks to prevent the media and soil mixes from exiting the columns and clogging the tubes. These columns were secured onto a constructed wooded frame with straps. Two ports were installed in each column to take core samples at different heights and hydraulic retention times (HRT). In addition to the ports, the water was sampled from the bottom of each column. The gaps surrounding the ports were sealed with Rectorsell 5 and Plumbing Amazing Goop. One peristaltic pump with peristaltic tubing was used to pump water from three, five gallon reservoirs into each of the columns. A fourth reservoir was used to maintain saturated conditions by connecting the column outlet tubing at a height equal to the desired water level inside the columns. Figure 1 shows the schematic of the column setup.

The HRT for the columns was calculated by using the following equations into a MathCAD file so that any changes in parameters can be quickly adjusted. The contributing parameters include porosity (n), column inside diameter (d_{column}), and the height above sampling port (h). First, the volume ($V_{media(h)}$) was calculated using the following equation.

$$V_{media}(h) := \left[\frac{\pi \cdot \left(d_{column}\right)^2}{4} \cdot h \right] \cdot n \tag{1}$$

Then using this volume and the desired HRT at the bottom of the column, the flow rate (Q) for the pump was calculated.

$$Q := \frac{V_{media3}}{\theta_3} = \cdot \frac{mL}{min} \tag{2}$$

Lastly, by using this flow rate the HRT for each port (θ) can be calculated.

$$\theta_1 := \frac{V_{media1}}{Q} = \cdot min \tag{3}$$

The columns were placed in a room capable of setting a constant temperature for two of the temperatures and a refrigerator for the lowest temperature. This design would allow for the testing of the media mixes at various constant temperatures to determine the temperature impacts on filtration kinetics.

Column Analysis

The pond water wais first augmented with KNO_3 and HK_2PO_4 to pre-selected ranges and then pumped from each of the reservoirs through the columns. The concentration ranges were employed to validate the kinetics. Water samples were taken from three locations of each column; port 1, port 2 and port 3 (i.e., the bottom of

column). These samples were then tested for variations of nitrogen and phosphorus. A summary of these methods is listed Table 1.

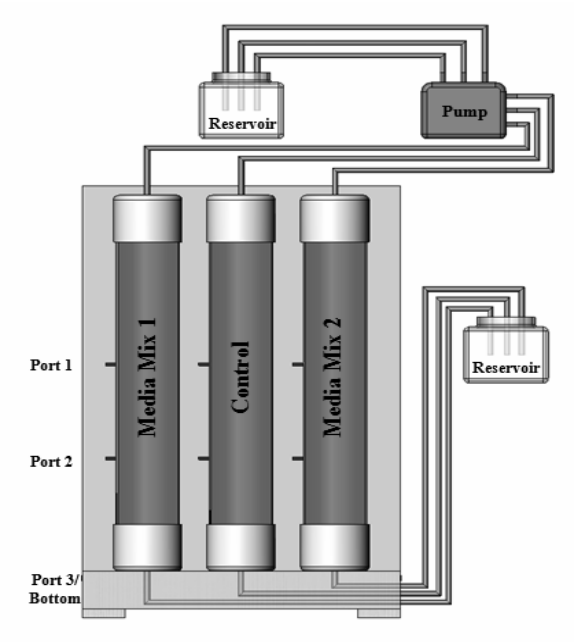

Figure 1: The schematic of Column Design

When the rate of the equation is unknown, as in this experiment, other methods for determining the rate constant can be employed. This type of analysis is often referred to as determining the rate constant from the integrated rate law. The integrated rate law involves integrating the rate law and arranging the equation in terms of the linear equation of a line (Equations 4-6). The definitions of the variables are [C] is the final concentration of the reactant, $[C_0]$ is the initial concentration of the reactant, k is the rate constant, and t stands for time.

Table 1: Column Study Water Quality Parameters and Methods

Parameter	**Method**	**Range***
pH	Fisher Scientific Accumet portable AP61 pH meter	pH units
Dissolved Oxygen	YSI Model 58 DO Meter	
Nitrates + Nitrites	Hach method 8192	0.01-0.50 mg/L NO_3^-N
Nitrites	Hach method 8507	0.002-0.30 mg/L NO_2^-N
Ammonia	Hach method 8155	0.01-0.50 mg/L NH_3-N
Total Nitrogen	Hach Method 10071	0.5-25.0 mg/L N
Reactive/Orthophosphate	Hach method 8048	0.02-2.50 mg/L PO_4^{3-}

*Note: In some cases samples were diluted with DI water to fall within this range.

$$\text{Zero Order: } [C] = -kt \quad (4)$$

$$1^{st} \text{ Order: } Ln[C] = -kt + ln[C_o] \quad (5)$$

$$2^{nd} \text{ Order: } 1/[C] = kt + 1/[C_o] \quad (6)$$

This type of analysis was applied to the columns in an attempt to describe the removal in terms of zero, first, or second order kinetics. The concentrations, inverse concentrations, and natural log of concentrations are plotted versus the retention time to show the removals as low order kinetic functions. A linear regression was performed to each condition and the mean squared error was calculated to justify the best fit. To investigate the actual values for the reaction rate, the differential rate law equations was used.

Temperature Correction Factor Model was applied to biological processes that have small temperature variations. The variables in the Temperature Correction Factor Model are defined as rate constant at temperature T (k_T), the rate constant at 20°C (k_{20}), the temperature correction factor (θ), and temperature in °C (T). A temperature range of around 20°C was used as the reference temperature. Three different temperatures (i.e., 28°C, 23°C, and 10° C) were considered for temperature effects.

$$k_T = k_{20}\theta^{(T-T_{20})} \quad (7)$$

RESULTS AND DISCUSSION

Column Analysis

A comparison of the nitrate removal for the columns at a specific temperature was constructed utilizing an average of the removals at the bottom of the columns for all doses Table 2. From this table it is easy to distinguish how the media mixtures reacted to the change in temperature in terms of nitrate removal. All of the columns achieve their highest removal at 28°C. The nitrate performance increased with temperature. Media Mix 1 and 2 had similar increases; with approximately 10% increase from 10°C to 23°C and then a 15% increase from 23°C to 28°C. The Control column experienced a 12% increase for the first temperature gap and 25% increase between the higher temperatures. Media Mix 1 has the best removals of all three columns for 23°C, 25°C and 28°C with 69.7%, 79.7%, and 95.3% respectively. Media Mix 1 has the highest nitrate removal for all of the experiments with 95.3% nitrate removal. Overall, Media Mix 2 is the best on average.

Table 2: Nitrate Removal Comparison between Temperature and Column (Final Port Comparison)

NO_3^--N	Temp. 1 10° C	Temp. 2 23° C	Temp. 3 28° C
Control Case	8.0%	20.9%	45.8%
Media Mix 1	69.7%	79.7%	95.3%
Media Mix 2	63.2%	77.9%	93.6%

A comparison of the orthophosphate removal for the columns at a specific temperature was also constructed utilizing an average of the removals at the bottom of the columns for all doses Table 3. From this table it is easy to distinguish how the media mixtures reacted to the change in temperature in terms of orthophosphate removal. The

columns all achieved the highest orthophosphate removal at different temperatures; the Control, Media Mix 1, and Media Mix 2 at 10° C, 23° C, and 28° C, respectively. However, the difference between the highest and second highest removals for the Control was only 1%. The highest overall orthophosphate removal was achieved by Media Mix 2 at 28° C. The Control column outperformed the Media Mixes for 10° C and 23° C and came in at a fairly close second for 28°C. Overall, Media Mix 2 and Control are the best equivalently.

Table 3: Orthophosphate Removal Comparison between Temperature and Column (Final Port Comparison)

OP (PO_4^{3-}-P)	Temp 1 10° C	Temp 2 23° C	Temp 3 28° C
Control Case	84.8%	80.0%	72.1%
Media Mix 1	38.5%	63.3%	59.9%
Media Mix 2	58.8%	67.4%	85.5%

ANOVA Analysis

In order to determine the effect of temperature, dose, and media mixture have on the removal efficiency which is statistically valid, the two-way ANOVA analysis was conducted for each dose and nutrient. The removal efficiencies from the bottom of each column were used to standardize the data for comparison. These efficiencies were inserted into SAS® software and a two-way ANOVA was executed. Removal efficiency and media were designated as the main effects in the ANOVA model. The assumed alpha value for all of the computations was 0.1, providing 90% confidence. The assumptions associated with performance of an ANOVA test; independence, normal distributions, and equal variance were considered and the following results were obtained from this analysis. The samples were assumed to be independent since the columns are contained environments and the water travels through each one individually with no interaction. The normal assumption was assumed since only three data points for each combination were taken and thus a reliable normality test can not be performed. Lastly, statistical analysis has shown that the requirement of equal variance does not have a significant effect on the outcome of an ANOVA analysis, due to the robustness of the F distribution under unequal variance conditions when the sample sizes are the same (Neter, 1974 and Rogan, 1977).

From the ANOVA analysis, the change from low to high concentrations seemed to have an effect on the nitrate and orhtophosphorus removals. In terms of nitrate, the ANOVA for low concentration and high concentration had the same results in terms of columns, but there were differences between the low and high concentrations in terms of temperature. This might show that the lower concentration range was near the equilibrium for the microbes. The difference in efficiency for the columns between the temperatures is interesting. Since there is seemingly no difference between 10°C and 23 C°C for the columns, it is assumed that this is the lower range for the microbial activity

and removals were dictated by sorption. The difference between 23°C and 28°C would indicate that there was biological activity along with sorption. The differences between the media mixes could be due to the sorption capacity, ability to provide carbon source for denitrification, and ability to provide an ideal environment for the microbes to attach and thrive.

Filtration Kinetics Analysis

Table 4 shows an example of one of the best runs for material mix 2 column, species, and temperature. An average of all of the R^2 values at each temperature were compared; the highest R^2 values across all three temperatures was taken to be the best model for the overall reaction order (Table 5). Once the reaction order was determined, the rate constants could be calculated. The rate constant for each temperature is equal to the slope of the linear regression of the removals for the selected order. The averages of all rate constants were then computed for each temperature (Tables 6-7).

Table 4: Example Linear Regression Equations for the Media Mix 2 Column

Temp.	Species	Initial Concentration (mg/L)	Zero Order		1st Order		2nd Order	
			Equation	R^2	Equation	R^2	Equation	R^2
10	Nitrate	8	0.06x + 8.3	0.96	-0.03x + 3.1	0.88	0.08x + -0.8	0.65
		25	-0.071x + 24	0.97	-0.004x + 3.2	0.99	0.0002x + 0.04	0.99
	Orthophosphate	3.7	-0.008x + 3.7	0.94	-0.0023x + 1.3	0.91	0.001x + 0.26	0.87
		6.4	0.03x + 6.4	0.98	-0.012x + 2	0.85	0.006x + 0.02	0.84
23	Nitrate	7.2	-0.03x + 5.8	0.75	-0.008x + 1.8	0.91	0.003x + 0.16	0.99
		31.2	-0.18x + 0.33	0.97	0.0098x + 3.6	0.95	0.0006x + 0.02	0.89
	Orthophosphate	2.3	-0.008x + 1.9	0.73	-0.007x + 0.62	0.57	0.008x + 0.66	0.34
		3	-0.014x + 0.14	0.89	-0.008x + 1.1	0.94	0.005x + 0.3	0.91
28	Nitrate	13	-0.09x + 12	0.96	-0.033x + 3.1	0.88	0.06x -1.8	0.65
		25	-0.07 + 24	0.97	-0.004x + 3.2	0.99	0.0002x +0.04	0.99
	Orthophosphate	3.7	-0.0083x + 3.7	0.94	-0.0029x +1.34	0.91	-.001x + 0.256	0.87
		6.2	-0.034x + 6.4	0.98	-.012x + 2.0	0.95	0.006x + .02	0.84

Table 5: Average R^2 Values for Each Temperature for Media Mix 2

Media Mix 2	Nitrate			Orthophosphate		
	10°C	23°C	28°C	10°C	23°C	28°C
Zero	0.69	***0.84***	***0.62***	***0.81***	0.69	0.73
1st	***0.69***	0.82	0.60	0.78	***0.70***	***0.79***
2nd	0.56	0.73	0.59	0.72	0.60	0.77

Table 6: Average Nitrate Kinetic Rate Constants

k	10°C	23°C	28°C
Control (Zero Order)	0.014	0.007	0.03
Media Mix 1 (1st Order)	0.012	0.017	0.05
Media Mix 2 (Zero Order)	0.047	0.076	0.07

Table 7: Average Orthophosphate Kinetic Rate Constants

k	10°C	23°C	28°C
Control (Zero Order)	0.04	0.02	0.02
Media Mix 1 (2nd Order)	0.001	0.02	0.004
Media Mix 2 (1st Order)	0.08	0.01	0.01

Finally, the specific temperature conversion factors (θ) for the Media Mixes can be calculated by plugging in the values for the rate constants and their corresponding temperatures). The temperature conversion factor value was solved for with all three possible permutations and then an average of these produces the modeled value for θ (Tables 8-9). The permutations in the table below are found by taking the kinetic constants found in Tables 38 and 39 above. The values of 1, 2, and 3 stand for the temperatures 10°C, 23°C, and 28°C, respectively, along with the kinetic values associated with those temperatures. For example, θ_{12} was found using the k values for 10°C and 23°C and plugging in 10°C and 23°C for the temperature. Average temperature correction factors were calculated due to smaller variations in magnitude when compared with the Arrhenius Model.

Table 38: Temperature Conversion Constants (θ)

NO_3^--N	Control	Media Mix 1	Media Mix 2
θ_{12}	0.95	1.02	1.04
θ_{13}	1.04	1.07	1.02
θ_{23}	1.30	1.22	0.98
θ_{avg}	***1.10***	***1.11***	***1.01***

Table 39: Temperature Conversion Constant (θ)

OP (PO_4^{3-}-P)	Control	Media Mix 1	Media Mix 2
θ_{12}	0.93	1.28	0.84
θ_{13}	0.97	1.08	0.91
θ_{23}	1.07	0.69	1.11
θ_{avg}	***0.99***	***1.02***	***0.95***

CONCLUSIONS

The selected two media recipes were Media Mix 1 consisting of 50% fine sand, 30% tire crumb, 20% sawdust by weight and Media Mix 2 consisting of 50% fine sand, 25% sawdust, 15% tire crumb, 10% limestone by weight. The control for this study was taken from Hunter's Trace Pond in Ocala, Florida. The best media mixes to select were complicated by the unexpected nutrient addition by some of the media. After taking all aspects into account, the best media for both nitrate and orthophosphate removal was

Media Mix 2 in this study. Yet the best column for nitrate removal for all temperatures is Media Mix 1. Selection of the best media in terms of orthophosphate was less straightforward. The Control Column had the best average removals at 10°C and 23°C. However, in terms of the media performance, Media Mix 1 outperforms Mix 2 for two of the temperatures; although Media Mix 2 does have the highest individual occurrence of orthophosphate removal of all the mixes for all of the temperatures.

The kinetic rates would be helpful in determining the retention time required for the Media Mixes to achieve the best removals. Using this information, along with the media characterization information and desired removals, the depth of media that would be recommended for pilot studies in a retention pond or other high nutrient concentration application could be calculated. The results of this research are limited to the specific media and specific composition of the media mixes eventually selected. The three temperatures selected for this study were accommodated to span the Floridian climate. Data were collected during controlled laboratory experimentation; natural conditions could potentially cause some deviations. Future applications may support use in bioswales, bioinfiltration ponds, pervious pavement, and green roof in the context of Low Impact Development (LID).

Nutrient and Pathogen Removal with an Innovative Passive Underground Drainfield for On-site Wastewater Treatment

Ni-Bin Chang, Marty Wanielista, Ammarin Daranpob, Fahim Hossian, and Zhemin Xuan

Department of Civil, Environmental, and Construction Engineering, University of Central Florida, Orlando, Florida, USA

ABSTRACT

When urban regions gradually expand due to regional development, centralized sewage collection, treatment, and disposal is often unavailable for both geographic and economic reasons. As a consequence, about a quarter of the residences in the United States relied on decentralized treatment of wastewater. Household wastewater contains high concentration of nutrients (mainly nitrogen and phosphorus), disease-causing organisms and viruses, and some toxic chemicals. Nation wide, wastewater effluent from on-site wastewater treatment (OWTS) can represent a large fraction of nutrient loads to groundwater aquifers. Phosphorus and nitrogen compounds are the most frequent measurements to indicate nutrient loadings. Some aquifers may discharge into springs or other surface waters adversely affecting public health. Hence, on-site wastewater effluent disposal has contributed significant adverse impacts to the dynamics of the natural environment. Nowadays, due to widespread septic tank failure, scientists, engineers, and manufacturers in the wastewater treatment industry have developed a wide range of alternative passive technologies designed to address increasing hydraulic loads, energy saving requirement, and water contamination by nutrients and pathogens in OWTS. This paper aims to present an innovative design of the underground drainfield with soil amendments (sorption media) in a pilot septic tank system. The new system located at the OWTS test center, University of Central Florida (UCF) was tested and proved cost-effective in the initial test run in fall 2008.

INTRODUCTION

Onsite sewage contains organic matter (biochemical oxygen demand), suspended solids, nutrients, and some pathogens, which can cause a number of diseases through ingestion or physical contact. Those water-related diseases include shigellosis, salmonellosis, typhoid fever, and infectious hepatitis (Katzenelson et al., 1976). More than 25 million homes, or 25 percent of the U.S. population, use onsite wastewater treatment systems to meet their wastewater treatment and disposal needs (USEPA, 2002). The most common type of onsite wastewater treatment plant ("mini treatment plant") is the septic system. When properly constructed and maintained, the septic systems can provide years of safe, reliable, cost-effective service.

A septic system consists of four main components. The first component is a home's indoor plumbing, which is a system of drains and pipes located inside a home in

charge of transporting wastewater outside to the next major component, the septic tank. The septic tank is normally an underground, watertight container, made of concrete, fiberglass, or other durable material, which provides primary wastewater treatment. In the septic tank, solids settle to the bottom of the tank and partially decompose by naturally occurring bacteria resulting in a layer of soaps, greases and scum float on top of the liquid wastewater. There is a need to periodically remove the floating scum and submerged solids accumulated in the tank. The liquid wastewater between the floating and settled solids has to be discharged from the septic tank to the next major component of a septic system, the drainfield. The standard drainfield that is constructed by a series of parallel, underground, perforated pipes allows the septic tank effluent to percolate into the surrounding soil in the vadose (unsaturated) zone where most of the residual nutrients may be assimilated. Through various physical, chemical, and biological processes, most bacteria, viruses and nutrients in wastewater are expected to be consumed as the wastewater passes through the soil. The type of effluent distribution in the standard drainfield systems include gravity systems, low pressure dosed systems, drip irrigation systems, etc. and some of them require having an additional pump.

Nutrients such as ammonia, nitrite, nitrate, and phosphorus are common contaminants in the water bodies all over the world, as well the emerging contaminants that affect aquatic ecosystems. All these nutrients have direct and indirect acute and chronic harmful outcome for human beings and ecosystems. Ammonia is an important compound in freshwater ecosystems. It can stimulate phytoplankton growth, exhibit toxicity to aquatic biota, and exert an oxygen demand in surface waters (Beutel, 2006). Hence, primarily due to the limited nitrogen-removal treatment capabilities of conventional septic systems, their density of use in a watershed can produce adverse and undesired aquatic resource impact through accelerated eutrophication. Besides, unionized ammonia is very toxic for salmonid and non-salmonid fish species (Tarazona et al., 2008). Fish mortality, health and reproduction can be hampered by the presence of minute amount of ammonia-N (Servizi and Gordon 2005). Nitrate is more toxic than nitrite and can cause human health problems such as liver damage and even cancers (Gabel et al, 1982; Huang et al., 1998). Nitrate can also bind with hemoglobin and create a situation of oxygen deficiency in an infant's body called methemoglobinemia (Kim-Shapiro et al., 2005). Nitrite, however, can react with amines chemically or enzymatically to form nitrosamines that are very strong carcinogens (Sawyer et al., 2003).

In addition, wastewater also carries different kinds of microorganisms such as bacteria like Escherichia coli and Salmonella typhi, protozoa like Cryptosporidium parvum and Giardia lamblia, helminthes and viruses like hepatitis A virus. Concentration of total coliform is about 10^{7}-10^{9} no./100 mL, fecal coliform is about 10^{4}-10^{6} no./100 mL, Cryptosporidium parvum oocysts is about 10^{-1}-10^{1} no./100 mL and Giardia lamblia cysts is about 10^{-1}-10^{2} no./100 mL in a medium strength wastewater (Metcalf and Eddy, 2003; WEF and ASCE, 2005). Oocysts and cysts are spore phase that will help to survive for a long time for certain microorganisms. These entire microorganisms are responsible for different kinds of diseases like diarrhea, jaundice, food poisoning, dysentery and nausea (Metcalf and Eddy, 2003; WEF and ASCE, 2005). If these diseases are not controlled properly, they may cause harmful effect on health even death due to domestic sewerage pollution.

As a consequence, nutrient and pathogen removal is very important for the sustainability of the aquatic ecosystem and environment. There are many ways for homeowners with septic systems to minimize the potential nutrient impacts that on-site wastewater treatment (OWTS) may have on the environment. Yet early codes did not consider the complex interrelationships among nutrient impacts, soil conditions, wastewater characteristics, biological mechanisms and climate, or geoclimatic differences that might be big in vastly different regions. At present, there is a need for promoting enhanced nitrogen removal in septic systems, as well as a better understanding of nitrogen removal behavior of the septic system effluent plume as it passes through soil to a receiving water body. In general, passive technologies might be advantageous due to their cost effectiveness, system reliability, and low maintenance requirement. This triggers an acute need to perform a thorough technology comparison, screening, and prioritization.

To reduce organic and nitrogen impacts, an aerobic treatment unit (ATU) may be used to treat wastewater prior to ground discharge, typically by adding aeration to promote decomposition of organic matter, reduce pathogens, and transform nutrients. Basic ATU designs include suspended growth systems, fixed-film systems, and integrated fixed film and suspended growth systems (USEPA, 2005). All three types usually have a septic tank ahead of them that removes the large solids and provides some protection to the ATU. Yet passive treatment and disposal systems, which do not use aerator pumps and include no more than one effluent dosing pump, are relatively new (Chang et al., 2007). Passive OWTS is defined by the Florida Department of Health (FDOH) as a type of onsite sewage treatment and disposal system that excludes the use of aerator pumps and includes no more than one effluent dosing pump with mechanical and moving parts and uses a reactive media to assist in nitrogen removal. Reactive media are materials that effluent from a septic tank or pretreatment device passes through prior to reaching the groundwater. This may include but are not limited to soil, saw dust, zeolites, tire crumbs, vegetative removal, sulfur, spodosols, or other media. Hence, a new generation of performance-based, passive (as opposed to conventional) OWTS to effectively remove septic tank effluent nutrients and protect public health and the environment in a cost-effective manner will need to be devised and implemented with innovation. For example, some technologies use a reactive media to assist in nitrogen removal. Saw dust and other wood products, zeolites, tire crumbs, vegetation, sulfur, spodosols, etc. have been suggested or used as such possible treatment media (Chang et al., 2008a). These systems with new materials and methods will require increased focus on system performance, pollutant transport and fate, resulting environmental impacts, and an integration of the planning, design, siting, installation, maintenance, and management functions. Cost effectiveness, system reliability, and proper management become the major concerns in applications. The author's aim of this paper is to present an innovative design of the underground Drainfield with soil amendments (sorption media) in a pilot septic tank system. In the initial test runs, the new system located at the OWTS test center at UCF has been tested and proved cost-effective..

MATERIALS AND METHODS

The development of performance-based passive on-site wastewater treatment systems (i.e., septic tank) for nutrient removal becomes an engineering challenge in the context of sustainability concern. Initial candidates listed for "Passive Nitrogen Removal Technologies" may include but are not limited to: 1) nitrification process: single pass media filters and recirculating media filters; 2) denitrification process: autotrophic versus heterotrophic condition with singles pass or two-stage process; 3) Drainfield modification: autotrophic versus heterotrophic condition; and 4) groundwater treatment (permeable reactive barrier): autotrophic versus heterotrophic condition. During operation, they require no energy and minimal maintenance, thus the use of the word passive. New generation of material mixes with pollution prevention and control potential used for the selective removal of dissolved nutrient species in wastewaters have received a renewed interest recently. This impact led to this invention that had been directed towards developing a new generation of functionalized sorption media with a unique hydraulic pattern for improving the nutrient and pathogen removal in the B&G drainfield which is one of the three treatment trains at the UCF OWTS test center.

System Configuration

With such understanding, the UCF OWTS test center, sponsored by Florida Department of Environmental Protection (FDEP) with technical support of Florida Department of Health (FDOH) and designed for evaluation of nutrients removal on campus, includes (see Figure 1): 1) a septic tank followed by a recirculating sand filter (RSF), with effluent discharged to an unlined conventional gravity drainfield, called standard drainfield hereafter, filled with washed builder's sand; 2) a septic tank followed by a recirculating sand filter (RSF), with effluent discharged to a unlined standard drainfield filled with citrus grove (i.e., astatula sand) sand; 3) a septic tank followed by a subsurface flow (SSF) wetland system; and 4) a septic tank with effluent discharged to a lined underground drainfield (Black & Gold™ (B&G) nugget drainfield), called B&G drainfield hereafter, to allow for soil substitution. Different sorption media for pollution control may be configured into the vegetative unit in the SSF system and the underground drainfield.

The wastewater source for the test center is the 15-person BPW Scholarship House (a female dormitory at UCF campus), which contains a kitchen and living quarters. The wastewater is pumped to 3.78 m^3 (1,000 gallon) and 5.10 m^3 (1,350 gallon) septic tanks from where the effluents are divided into different final disposal alternatives. While the former one handle both B&G drainfield (Figure 2a) and wetland system (Figure 2b), the latter one handles both standard drainfields (Figure 2c). A dosing tank is connected to one septic tank for handling the collected effluent from treatment processes 3) and 4). The pump and pipe arrangement delivers an average of 0.75 m^3/day (200 gpd) to each of the four drainfield systems.

Environmental Monitoring Network

There are two sets of monitoring wells at UCF Test Center, eight drainfield monitoring wells and eight background monitoring wells (Figure1). The eight drainfield monitoring wells are located near the two standard drainfields to monitor the water quality of the groundwater up-gradient, immediate, and down gradient of each standard

drainfield. The eight background wells are located along the perimeter of the test site to monitor the flow regime and the water quality underground. The background monitoring wells (MW1-MW8) were sampled once in a month. The drainfield monitoring wells were sampled on a biweekly basis for monitoring their water quality.

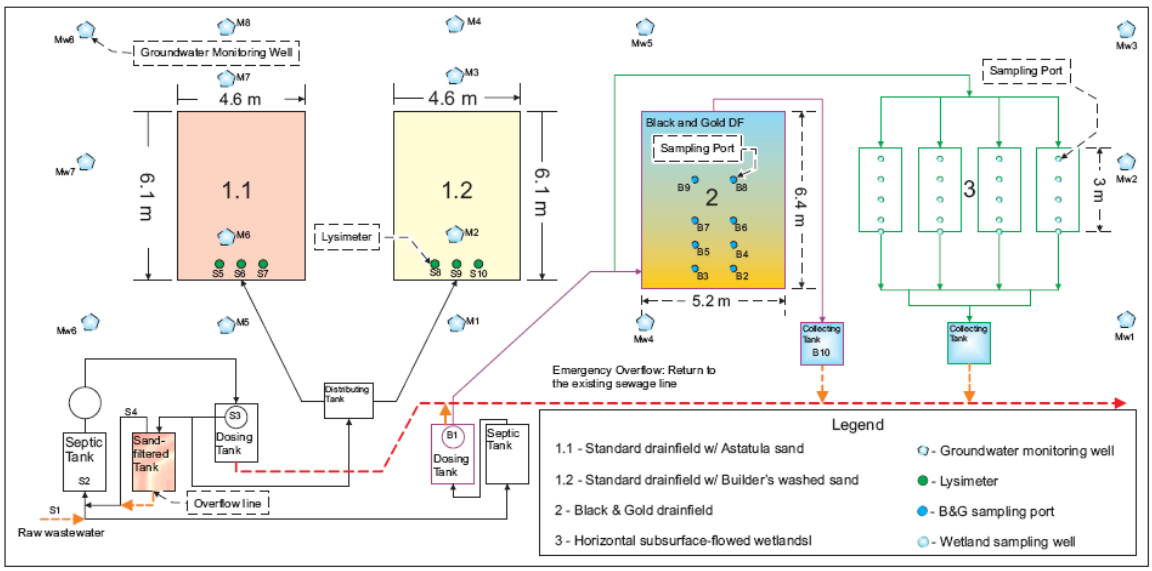

Figure 1. System layout of the UCF Test Center. The first OWTS train consists of a septic tank, a dosing tank, a sand-filtered circulation tank, a distributing tank, and two parallel drainfields. The two drainfields have different infiltration sands, Astatula and Wash Builder's Sand. Three lysimeters are installed at three levels at the header of each drainfield. The three levels of lysimeters are 8", 16", and 24" below the infiltrate surface.

Figure 2: Photographs of conventional and passive drainfields at UCF Test Center

B&G Drainfield

In fact, engineered, functionalized, and natural sorption media can be used to treat stormwater runoff, wastewater effluents, groundwater flows, landfill leachates and sources of drinking water for nutrient removal via physicochemical and microbiological processes (Chang et al., 2008b). They include but are not limited to sawdust, peat, compost, zeolite, wheat straw, newspaper, sand, limestone, expanded clay, wood chips, wood fibers, mulch, glass, ash, pumice, bentonite, tire crumbs, expanded shale, oyster shell, and soy meal hull (Chang et al., 2008b). This approach has "green" implications because of the inclusion of recycled material as part of the material mixture promoting treatment efficiency and cost-effectiveness (Chang et al., 2008b). The choice of material

mixes depend on the desired length of service, residence time during an operating cycle, and pollutants in the wastewater. The projected uses of the media are for soil amendments in the B&G drainfield in this paper for on-site wastewater systems filled with the proposed media in a manner that may foster an anaerobic or anoxic environment saturated. The appropriate arrangement of piping system for correct dosing along with the optimal sizing of the anoxic environment with adequate partition eventually sustain the functionality of these functionalized sorption media in the passive drainfields (Wanielista et al., 2008). However, comparative studies are required to prove the advantageous features of passive treatment technologies within all treatment trains at the test center.

With the aid of green sorption media, the objective of this paper is to present the basic functionality of the B&G drainfield filled with a unique recipe of green sorption media to remove both nutrients and pathogens. It leads to develop an innovative passive underground drainfield that is highly sustainable to fit in any landscape and built environment on one hand, and highly applicable in dealing with any type of septic tank systems on the other hand (Wanielista et al., 2008). Figure 3 shows the schematic of the B&G drainfield.

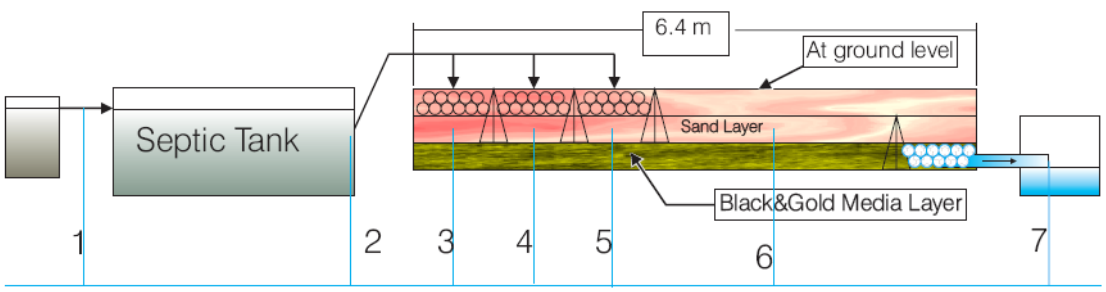

Figure 3. Schematic of the B&G Drainfield (Wanielista et al., 2008).

Reaction Mechanism

The adsorption, absorption, ion exchange, and precipitation processes are actually intertwined with the overall physicochemical process. Some nutrients, such as phosphorus, removed by inorganic media are likely a sorption/precipitation complex. The distinction between adsorption and precipitation is the nature of the chemical bond forming between the pollutant and sorption media. Yet the attraction of sorption surface between the pollutant and the sorption media causes the pollutants to leave the aqueous solution and simply adhere to the sorption media. In the context of using various green sorption media for nutrient removal, it might appear that sorption is followed by precipitation or occurs at the same time in the same physicochemical process. Within the microbiological process, if there are organic sources in the wastewater streams, hydrolysis converts particulate organic nitrogen (N) to soluble organic N, and ammonification in turn releases ammonia into the water bodies. In addition to ammonification, important biochemical transformation processes include nitrification and denitrification. They result in the transformation of nitrogen between ammonia, nitrite, and nitrate forms via oxidation and reduction reactions in microbiological processes. In the presence of ammonia-oxidizing bacteria (AOB) and oxygen in the aerobic environment, ammonium is converted to nitrite (NO_2^-) and nitrite-oxidizing bacteria (NOB) convert nitrite to nitrate (NO_3^-) continuously. Collectively these two reactions are

called nitrification. Conversely, denitrification is an anaerobic respiration process using nitrate as a final electron acceptor with the presence of appropriate electron donors, resulting in the stepwise reduction of NO_3^- to NO_2^-, nitric oxide (NO), nitrous oxide (N_2O), and nitrogen gas (N_2). Denitrification also requires the presence of an electron donor, which may commonly include organic carbon, iron, manganese, or sulfur, to make the reduction happen. As long as the hydraulic retention time (HRT) is long enough, microbe-mineral or sorption media interface can be initiated for either or both nitrification and denitrification process. In our case, sawdust is used as electron donors. The two steps of ammonia oxidation can be summarized as below in equations 1 and 2 (Metcalf and Eddy, 2003),

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 4H^+ + 2H_2O \quad (1)$$

$$2NO_2^- + O_2 \rightarrow 2NO_3^- \quad (2)$$

And the denitrification of wastewater is shown in equation 3 (Metcalf and Eddy, 2003),

$$C_{10}H_{19}O_3N + 10NO_3^- \rightarrow 5N_2 + 10CO_2 + 3H_2O + NH_3 + 10OH^- \quad (3)$$

Sampling and Analysis

Seven process steps and sampling points within the B&G drainfield system can be identified by Figure 3. Steps 3, 4, and 5 have two media layers; the sand and the B&G layers. B&G thickness is 30.48 cm (12 inches) which contain 68% sand, 7% sawdust, and 25% tire crumb by volume. The sand layer is astatula sand with thickness of 60.96 cm (24 inches) from the ground surface. The PTI pipe is installed for equal distribution of influent. The B&G drainfield was monitored continuously for eight weeks in late 2008. Three sampling campaigns were completed during early Oct., early Nov., and mid Nov. Samples were analyzed by the Environmental Research and Design (ERD), a certified laboratory in Orlando, Florida, for the water quality analysis. Only two datasets addressing the water quality conditions on Oct. 14th and Nov. 5th 2008, were presented in this paper. The initial concentrations of the sewerage can be seen in Table 1 below.

Table 1(a) Initial concentrations of basic parameters

	ALK	Turb	TSS	VSS	BOD_5	$CBOD_5$
Unit	mg/l	NTU	mg/l	mg/l	mg/l	mg/l
Influent (S1)	293.0	123.0	175.0	154.0	31.3	31.2

Table 1(b) Initial concentrations of nitrogen parameters (unit: μg/l)

	NH_3	NO_x-N*	Nitrite	Particulate N		Dissolved Organic N	Total N
Influent (S1)	32,864.0	11.0	8.0	3,760.0		9,635.0	46,270.0

* NO_x-N = NO_2^--N+ NO_3^--N

Table 1(c) Initial concentrations of phosphorus constitutes (unit: μg/l)

	SRP	Dissolved P	Particulate P	Dissolved Organic P	Total P
Influent (S1)	4,928.0	32.0	2,240.0	4,960.0	7,200.0

RESULTS AND DISCUSSION

Nutrient Removal

Figure 4 presents the water quality analysis of the October 14th, 2008 samples. To examine the comparative advantage, the blue bars show the total removal efficiencies of the combination of septic tank and the B&G drainfield whereas the red bars present the removal efficiencies of the B&G drainfield only. If a blue bar is higher than a red bar, removals occurred in both the septic tank and the B&G drainfield. If a red bar is higher than a blue bar, an increase occurred in the septic tank and a removal occurred in the B&G drainfield. For example, by comparing the nitrite removal efficiencies of the total (blue bar) and the B&G drainfield (red bar), the overall removal (blue bar) is less (shorter) than the red bar, and thus the nitrite concentration increases in the septic tank, and nitrite is removed in the B&G drainfield. Overall, this set of data revealed that the B&G drainfield performed very well (see Figure 4) in terms of nutrient and pathogen removal across all relevant species. Nitrate and Nitrite measured at the effluent were less than 2 ppb and 5 ppb (parts per billion), respectively, which are far lower than the USEPA Maximum Contaminant Levels (MCLs) published in the National Primary Drinking Water Regulations (NPDWR or primary standards) at 10,000 ppb and 1,000 ppb, respectively. More than 96 percents of Total Phosphorus was removed. The removal efficiency of $CBOD_5$ and Ammonia was above 90 percents. Turbidity was 30 percent higher than the USEPA MCL standard; however, the primary cause of high turbidity is suspected to be the sawdust mixed in the media. Preliminary tests in the UCF laboratory suggested that the negative effect of sawdust will slowly decrease over time.

The second dataset collected on November 5th, 2008 showed that the performance of the B&G drainfield had improved over time (see Figure 5). Total Nitrogen removal efficiency increased from 58% (October 14th, 2008) to 85% (November 5th, 2008). Total Phosphorus removal stayed above 98%. Fecal Coli and E. Coli removal efficiencies are above 99.9% (below 1 cfu in the effluent samples). The second dataset also confirmed that a smooth nitrification-denitrification process occurred in the B&G drainfield system. Most ammonia conversion occurred mainly in the sand layer of the B&G drainfield, and the nitrate and nitrite conversions occurred in the B&G layer of the B&G drainfield where denitrification plays an important role.

In Figure 6, it also shows that most ammonia was removed in the process steps 3, 4, and 5 at the sand layer (shallow layer); while the nitrate and nitrite were added in the B&G layer (bottom layer) of the same process steps. Figure 6 also revealed the conversion from ammonia to nitrate and nitrite in the B&G drainfield has been successful. Figures 7 and 8 proved that the B&G drainfield not only removes the nutrient but also filters the pathogens especially in the B&G layer of the B&G drainfield.

CONCLUSIONS

This paper presents our initial effort of test run of the B&G drainfield, aiming to demonstrate a new generation performance-based cost-effective passive OWTS technology with sustainability implications. Sampling campaign was conducted in the fall 2008 to support our observations that such a new passive OWTS technology can remove both nutrient and E-coli several more orders of magnitude stringent than required by the

current regulation (MCLs). Overall, more than 85% and 96% of Total Nitrogen and Phosphorus were removed, respectively. The removal efficiency of $CBOD_5$ and Ammonia was also above 90 percents.

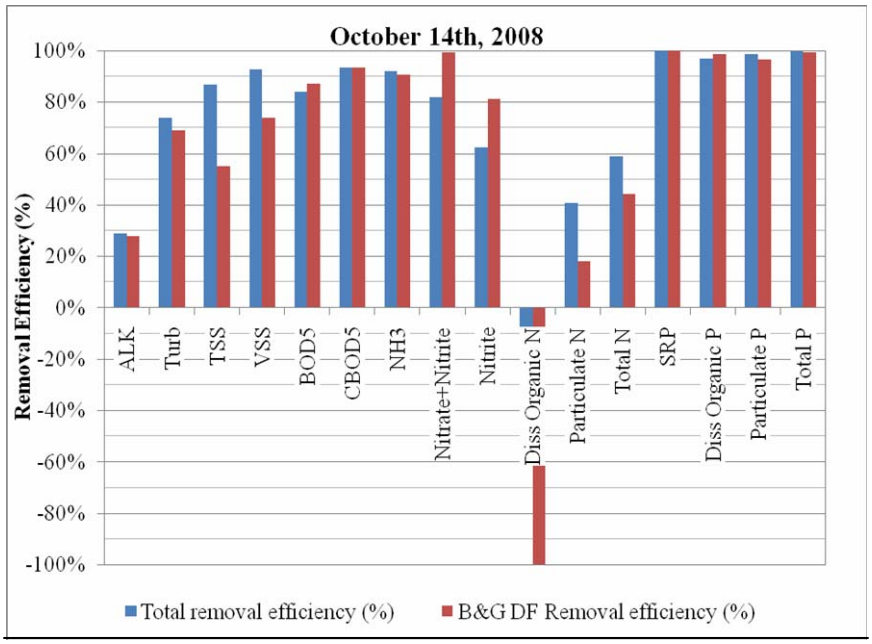

Figure 4. Total removal efficiencies of the Septic Tank and B&G Drainfield (blue bars) compared to the Black and Gold Drainfield only removal efficiencies (red bars). If the blue bar is less in a positive direction than the red bar, it means that the septic tank effluent increases in concentration relative to the input.

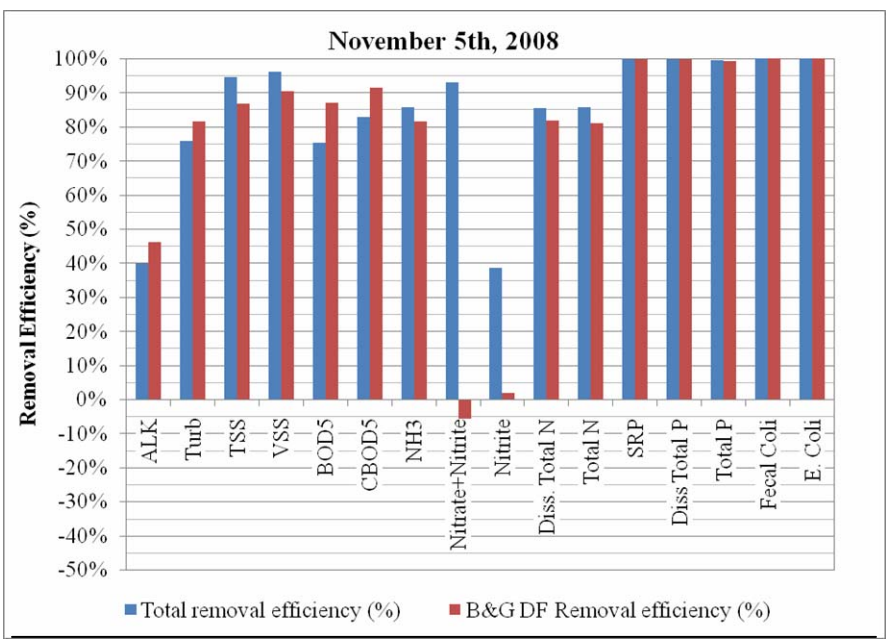

Figure 5. Removal efficiencies of the November 5th, 2008 dataset are presented an improved overall performance of the B&G Drainfield.

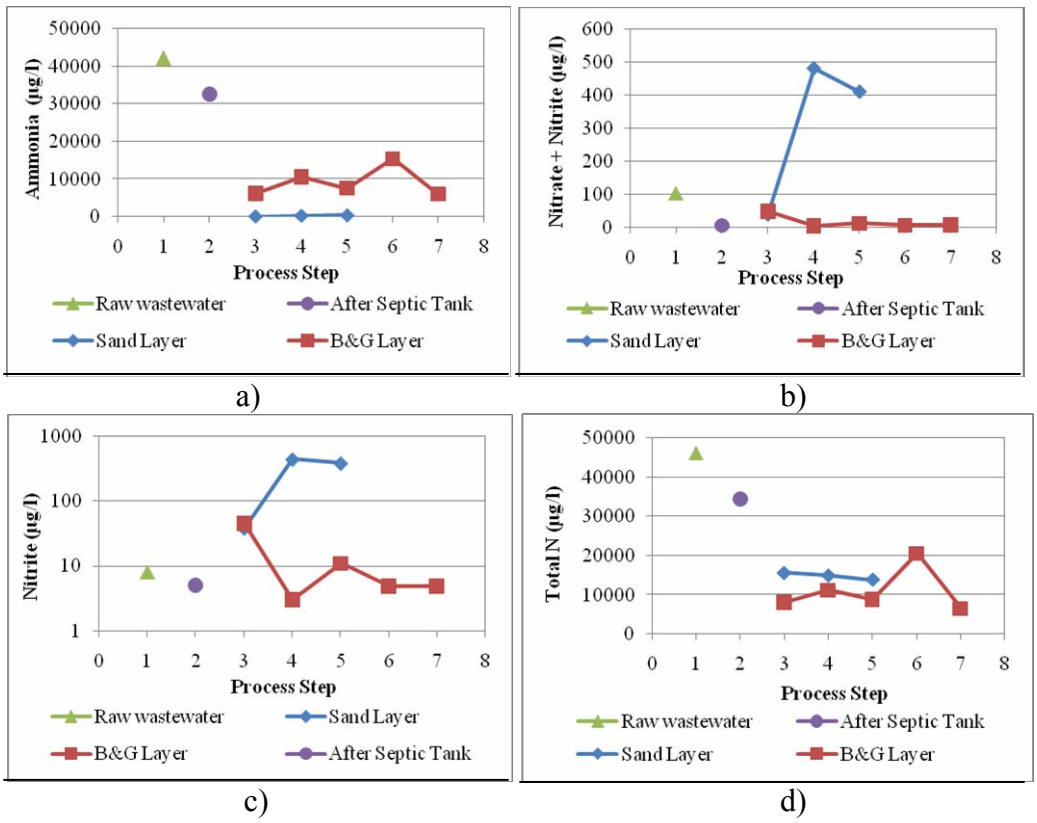

Figure 6. Concentrations of Ammonia, Nitrate, Nitrite, and Total Nitrogen in B&G System.

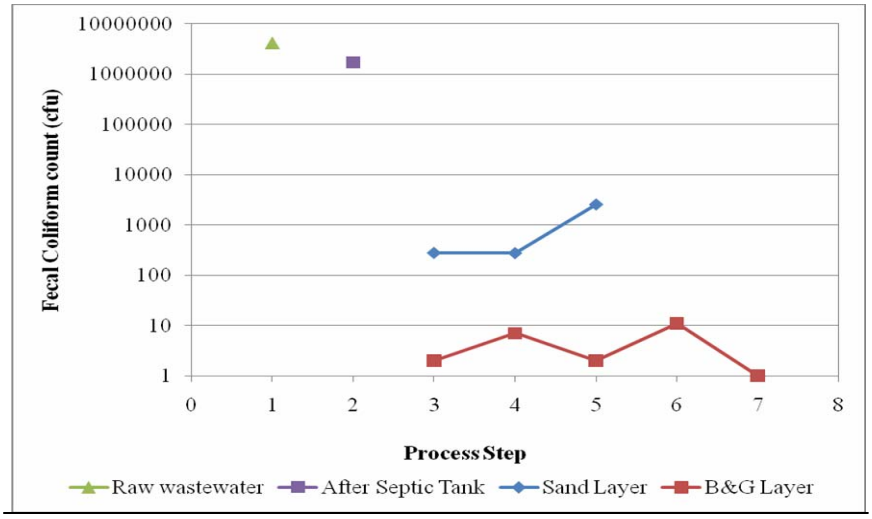

Figure 7. Fecal Coliform Counts after the wastewater has passed through the B&G Drainfield. The average count at the effluent was less than 1 cfu for the two datasets.

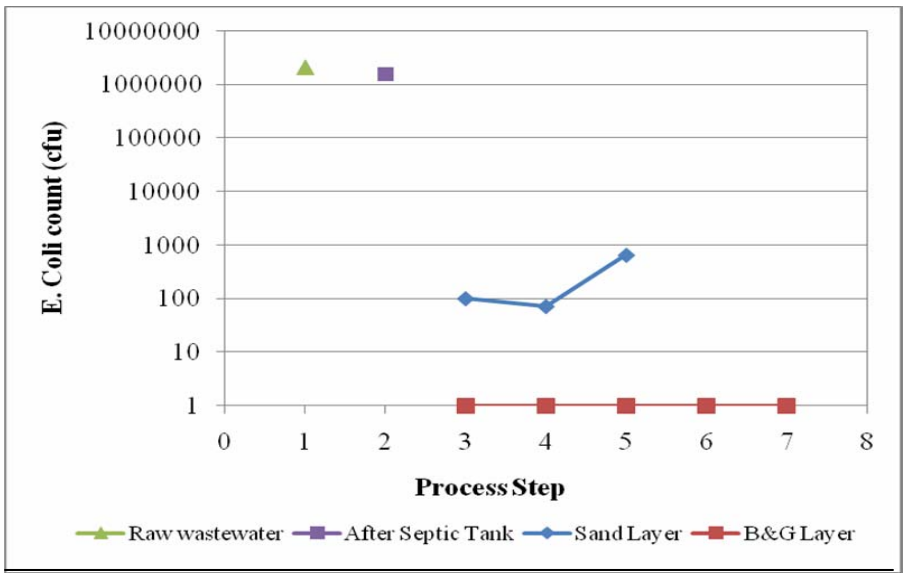

Figure 8. E. Coli Counts in the B&G Drainfield System

Such advancement, however, would be ultimately justified by environmental economics, including direct and indirect costs and benefits, which have been viewed as important information for decision making (Etnier et al., 2000). Besides, the estimation of direct and indirect costs should also be associated with various risk-reduction strategies and methods of risk assessment for decision making. For the design of sustainable neighborhoods, more advanced and adaptive materials, biomaterials, and enabling or multifunctional engineering materials with co-treatment capacities are needed to remove more pollutants, such as heavy metal, pesticides etc., simultaneously. With risk management options at the individual home or community level that are practical, acceptable, and cost effective, the passive OWTS and source separation alternatives may be further integrated based on their comparative advantages.

Abstract

Implementing best management practices (BMPs) is one of the key outcomes of a successful Source Water Protection program. BMPs are activities that can be implemented to reduce the risk of adverse future impacts to a public water supply. They can include structural activities such as building additional containment around storage vessels and nonstructural activities such as implementing land use restrictions.

The objective of this paper is to discuss a new and innovative approach to evaluate, select and prioritize BMPs for multiple public water supply systems in Texas. For this project, a database prioritization and selection tool was developed and used to assist in screening BMPs for multiple public water systems in Texas. The BMP selection process included a three-tiered screening process that is described in detail. This tool differs from previous US EPA approaches in that it is streamlined and can be applied efficiently for multiple systems.

Introduction

Best management practices (BMPs) are activities that can reduce the risk of adverse future impacts to a public water supply. These can include structural activities such as building additional containment around storage vessels and nonstructural activities such as implementing land use restrictions. Implementing BMPs is one of the key outcomes of a successful Source Water Protection (SWP) program. [it would be appropriate to briefly describe here what the SWP program is, who administers it, who it applies to, etc] Source Water Protection functions as a component of the Texas Source Water Assessment and Protection (SWAP) Program which functions to implement management strategies to mitigate or eliminate risks associated with potential sources of contamination (PSOCs). Public drinking water supply systems are the focus of the program and the responsibility for implementation lies with the systems and any local coordinators they may designate.

BMPs were selected to help protect the source water supply. Typically multiple BMPs are employed to mitigate the risk from a particular potential source of contamination (PSOC). BMP effectiveness may vary according to site-specific conditions. In addition, a single BMP can control several sources of contamination. A cost effective BMP

strategy may involve a combination of BMPs strategically selected and located to balance the risk of a contaminant's impact and the cost of BMP implementation.

The US EPA (1991) developed an approach to identifying best management practices for groundwater systems that relies on ranking threats to groundwater supplies by potential sources of contamination (PSOC). This approach, however, is quite cumbersome because of the high level of detail required for the assessment and the treatment of each PSOC threat individually.

For this project, a database prioritization and selection tool was developed and used to assist in screening BMPs for multiple public water systems in Texas. The BMP selection process included a three-tiered screening process . This tool differs from previous US EPA approaches in that it is streamlined and can be applied efficiently for multiple systems. Compared to the EPA (1991) approach which requires numerous worksheets and focuses on prioritizing PSOCs, this tool requires just two forms for each PSOC and focuses on prioritizing their associated BMPs rather than PSOCs. A brief summary of the process is presented below.

First, for each water system, a list of PSOCs is developed from office and field investigations within a defined wellhead protection area and entered into the database. The water system PSOCs are screened against a comprehensive listing of BMPs, which is based in part on the Texas Commission on Environmental Quality's "Draft BMP Guidance Manual" (PBS&J, 2006). The initial screening database query creates a table of appropriate BMPS that are applicable to the system PSOCs.

Next, a ranking system within the database was developed to help users further screen BMPs and assess the relative risks associated each PSOC. The approach included evaluating and ranking each BMP giving consideration to the following criteria:

- effectiveness in eliminating contamination;
- addresses known water quality concerns;
- entity who will be implementing the BMP (the system, the owner of the PSOC);
- ease of implementation;
- operations impact;
- funding availability; and
- cost.

Users assess each BMP identified for each PSOC and assign rankings, generally high, medium or low. After ranking all BMPs, the database can be queried to compile a report of rankings and generate a draft list of prioritized recommended BMPs for each public water system.

Finally, BMP selection is coordinated with the local planning team and stakeholders for each public water system because of the direct economic consequences associated with BMP implementation. Additional considerations discussed with the local planning team and stakeholders included public acceptance, impacts and effects on other programs, availability of funding assistance and compatibility with overall goals. A proposed timeline for BMP implementation was developed for each public water system.

Database Development

To evaluate and prioritize selection of BMPs for multiple public water systems, a database was envisioned to easily document and streamline the process. The purpose of the database is to:

- Store a comprehensive listing of potential sources of contamination and the BMPs associated with them.
- Allow entry of water system specific information, including information on each PSOC in the wellhead protection area.
- Allow evaluation and prioritization of BMPs for each system, based on established criteria and site specific PSOCs.

The comprehensive list of PSOC's and associated BMP's was based in part on the Texas Commission on Environmental Quality's "Draft BMP Guidance Manual" (PBS&J, 2006). Additional BMP's were added based on previous project experience. Forms were developed to allow entry of data related to each water system, and it's PSOC's. Finally, a tiered evaluation process was developed to quickly and consistently evaluate each BMP available for use with each PSOC. A detailed description of the evaluation process follows.

BMP Evaluation and Prioritization

Following completion of the initial data gathering, wellhead protection area delineation, site specific research and field data collection activities, a better understanding of potential sources of contamination (PSOCs) to the groundwater supply will emerge. This information is used to undertake the preliminary BMP evaluation and selection.

Upon opening the database, users are given a menu of options to choose from as reflected in Figure 1. To begin BMP evaluation the Tier 1 BMP evaluation is selected.

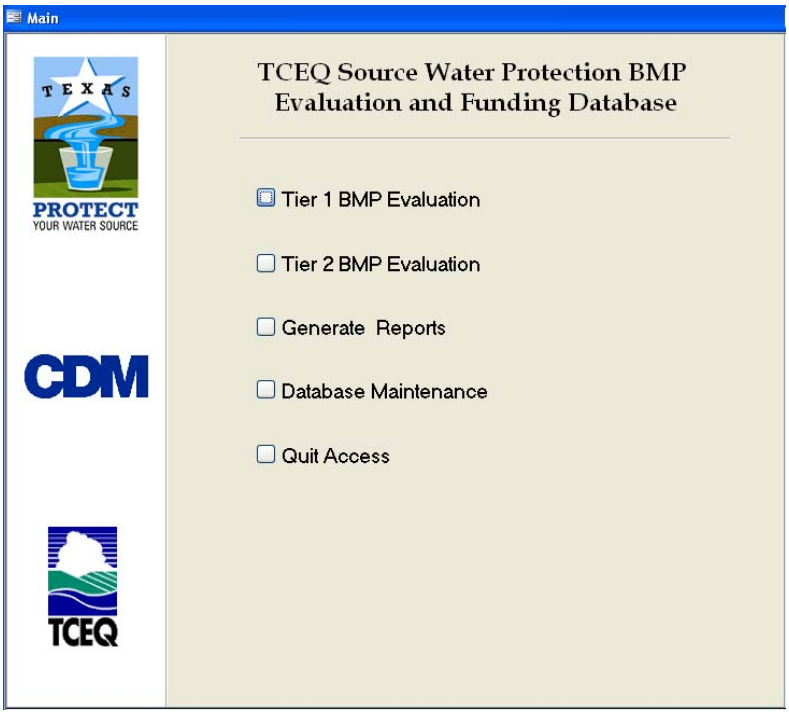

Figure 1. SWAP Database Menu

Tier 1 BMP Evaluation

The initial Tier 1 evaluation consists of reviewing each BMP available for each PSOC identified in the wellhead protection area. The initial review is to determine the applicability of the BMP for the specific PSOC identified. **Figure 2** presents a graphic of the form used in the database to perform this evaluation. As shown in the figure, page 1 of the form includes the public water supply (PWS) Identification Number, and description of the PSOC being evaluated, and the list of BMPs which may be applicable. Page 2 of the form (**Figure 3**) includes additional information or clarifying remarks made by the field team during the site investigation. Page 3 of the form (**Figure 4**) includes information on the types of contaminants associated with the PSOC. Only those BMP's deemed applicable move forward to the Tier 2 Evaluation process.

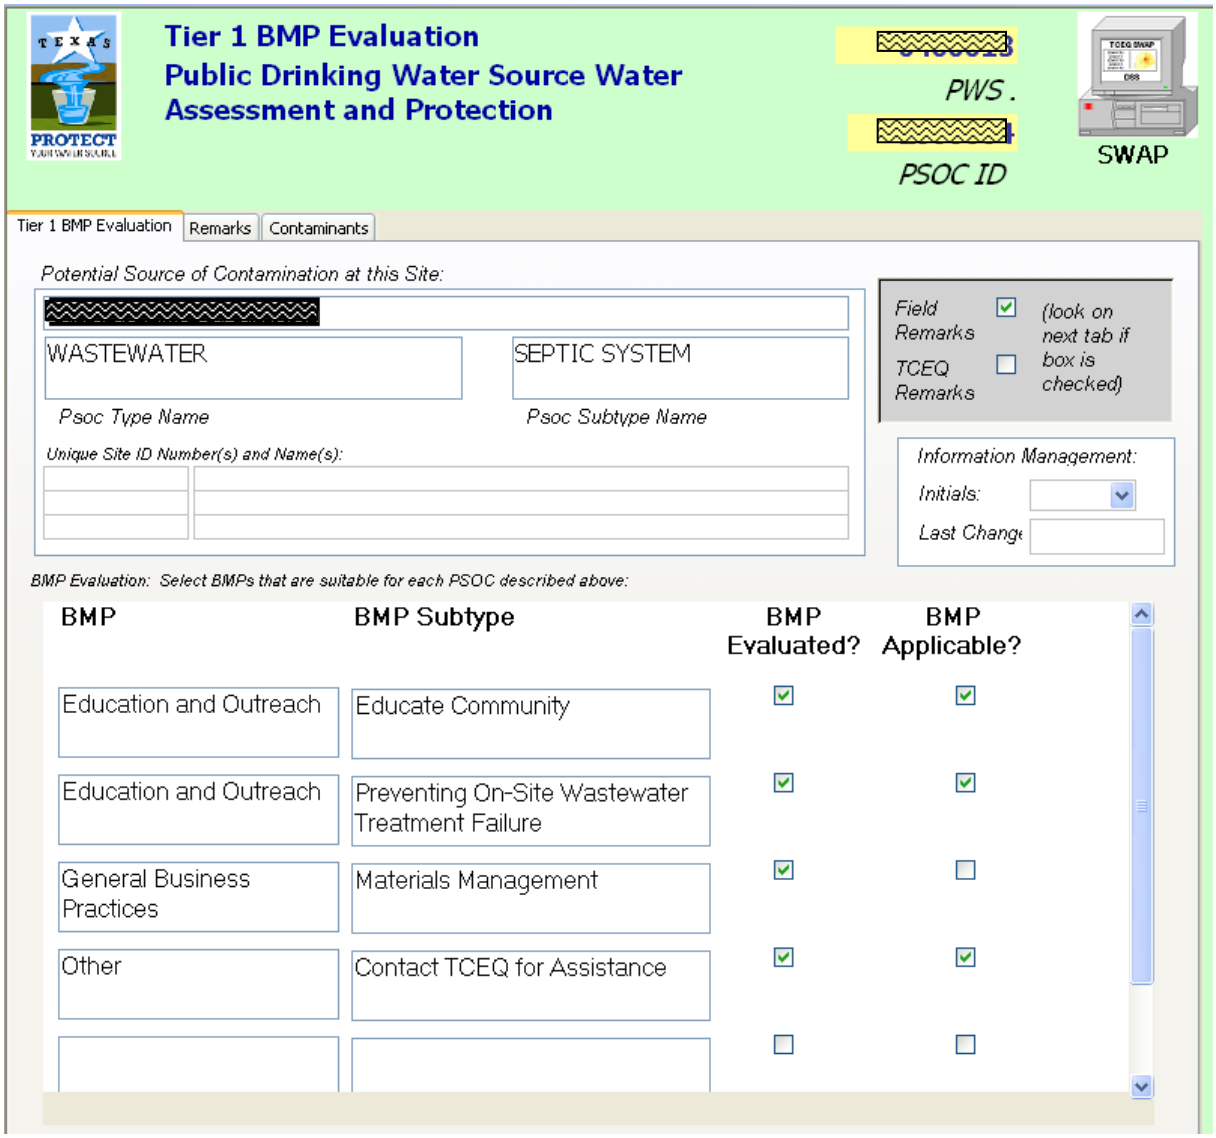

Figure 2. Page 1 of Tier 1 BMP Evaluation

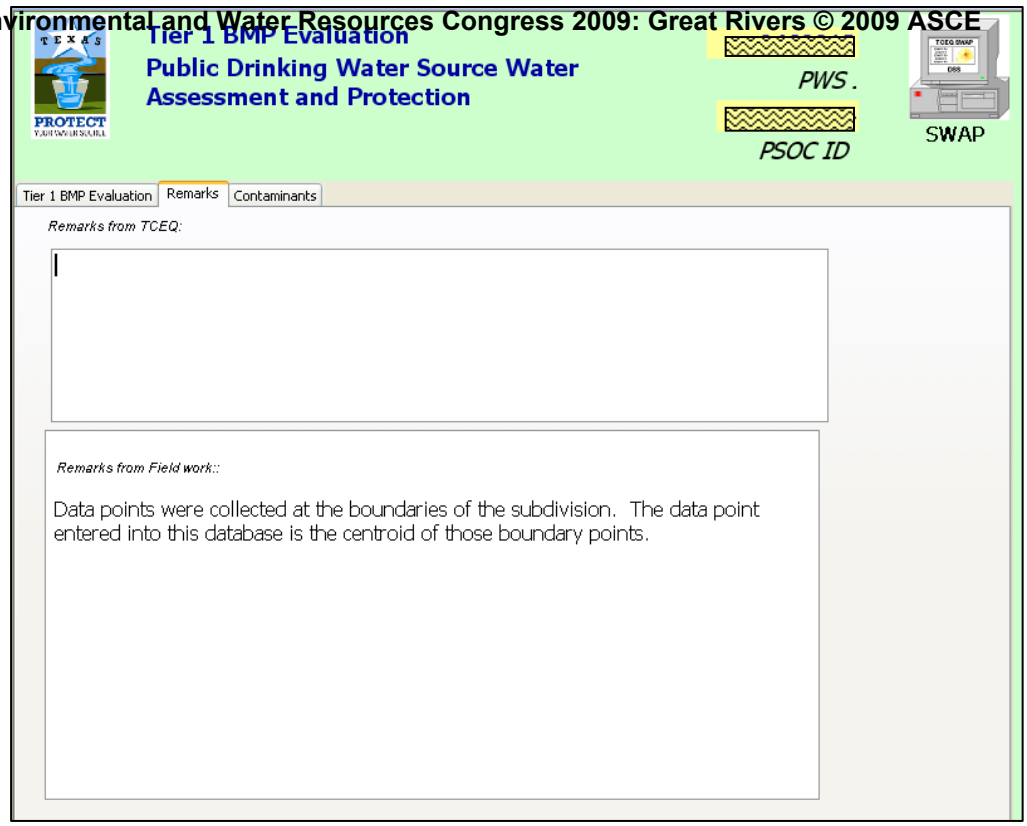

Figure 3. Page 2 of Tier 1 BMP Evaluation

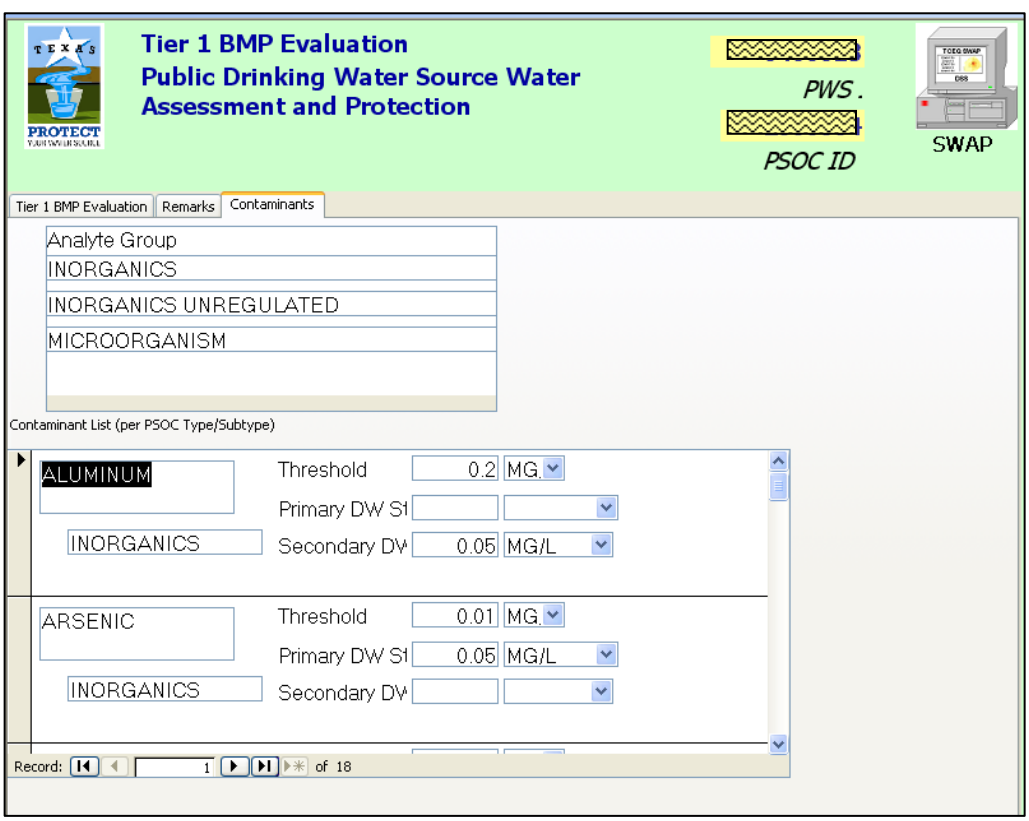

Figure 4. Page 3 of Tier 1 BMP Evaluation

Tier 2 BMP Evaluation

The Tier 2 Evaluation portion of the database is designed to help users further screen BMPs. The approach included evaluating and ranking each BMP giving consideration answering the following questions:

- Does this BMP address an existing water quality concern?
- Will this BMP be effective in elimination or reducing the risk of contamination?
- Who is required to implement this BMP?
- How easy is this BMP to implement?
- What impact on PWS operations will implementing this BMP have?
- What is the relative cost of this BMP?
- Is funding available to assist with implementation of this BMP?

Users assess each BMP identified for each PSOC and assign rankings, generally high, medium or low. The database also links to photos of each PSOC taken during the site investigation portion of the project. After ranking all BMPs, the database is queried to compile a report of rankings and generate a draft list of prioritized recommended BMPs for each public water system. The recommended BMPs then are compiled and presented in the SWP report for the PWS. Figure 5 presents the Tier 2 Evaluation form.

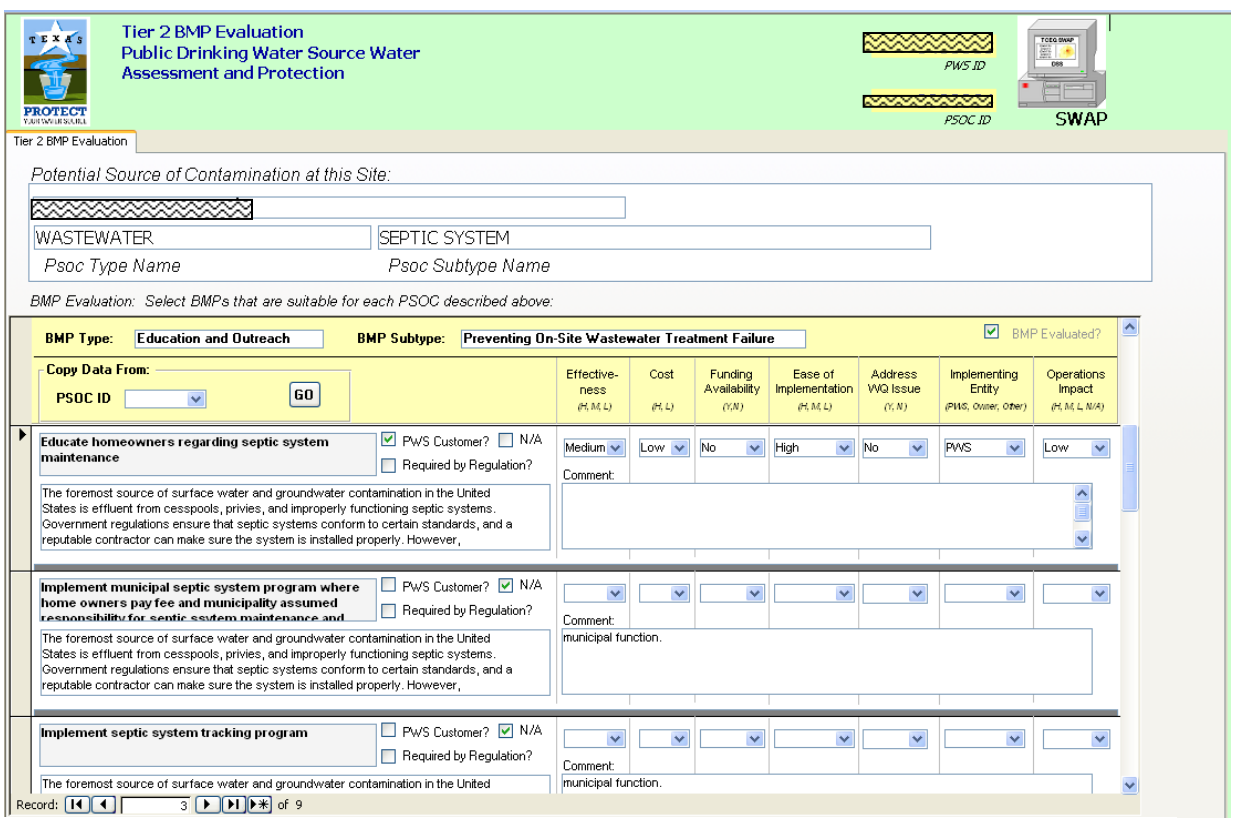

Figure 5. Tier 2 BMP Evaluation Form

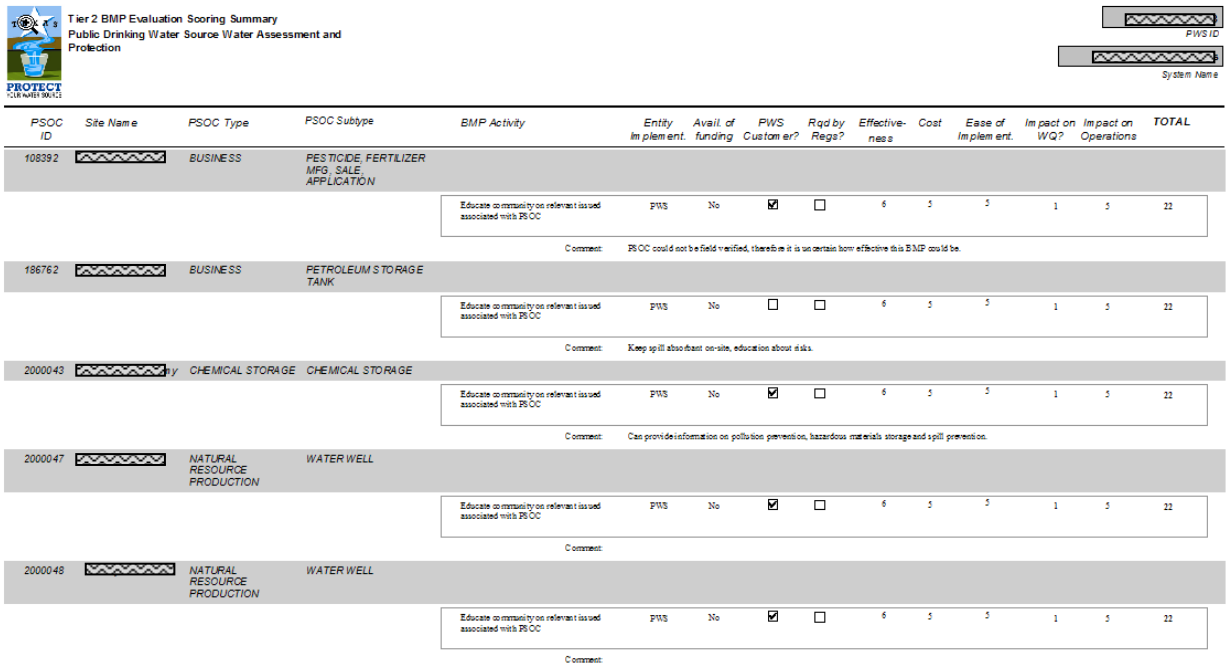
Tier 3 BMP Evaluation

The Tier 3 Evaluation is the Project Follow-Up Meeting that is conducted with the public water system and interested local stakeholders. The purpose of the meeting is to keep the system informed of progress to date and obtaining consensus on the recommended BMPs. Meeting objectives include:



- Conveying the groundwater modeling results and the defined wellhead protection area.
- Discussing any known water quality problems or contamination incidents.
- Reviewing the PSOCs located in the wellhead protection area.
- Discussing BMPs recommended to address the PSOCs in the wellhead protection area.

This meeting is essential to obtain system and stakeholder buy-in on the recommended BMPs. Because the local stakeholders will be relied on to implement many of the BMPs and due to the direct economic impacts associated with BMP implementation, stakeholder input and anticipated level of engagement in the process is factored into the BMP selection and evaluation.

Results

The result of this project is a new and innovative approach to evaluate, select and prioritize BMPs for multiple public water supply systems in Texas. This user-friendly, menu-driven database is designed to allow users to efficiently compile, manage and evaluate large amounts of data associated with multiple PSOCs and multiple public water systems. The prioritization report is shown in **Figure 6**. The report provides a total score to each BMP which is used to rank the potential BMPs.

The ranking system places highest priority on those BMPs that can have a direct impact on PSOCs affecting drinking water quality and consequently human health. That focus is consistent with the priority setting approach used by EPA (1991). Use of the Tier 1 and Tier 2 evaluations, however, avoids the need to complete numerous source, wellhead, contaminant, and transport worksheets to yield a final risk score.

Conclusions

The goal of any source water protection is to take action by implementing BMPs to protect drinking water supply. The database and BMP selection process developed for public water supply systems in Texas focuses on key information that will impact BMP implementation, such as existing water quality issues, funding availability, and who will ultimately implement the BMPs. Consideration of these factors will ultimately allow systems to move to implementation more quickly than previous US EPA approaches, and consequently, will result in a higher level of implementation.

Controlling Salt-Water Intrusion to Environmental Sensitive Areas due to the Construction of the Rio Anton Ruiz Flood Control Project

By

David Weston and Rafael Velez
Jacksonville District – US Army Corps of Engineers

A. ABSTRACT

The Rio Anton Ruiz Flood Control Project was authorized to reduce flood damages to the coastal communities of Punta Santiago, Verde Mar and Villa Palmira, near Humacao, Puerto Rico. Flood damages used to impact those communities throughout the year until the authorized flood control project was built. Historically, flooding occurred when runoff from the mountains within the watershed would flow into a large upland lagoon and then flooded those communities before reaching the Caribbean Sea. The authorized flood control project protected those communities from flooding by the lagoon with a large levee system and a series of canals to the sea. Since the completion of the authorized flood control project in 2001 there have been major impacts to the lagoon and a surrounding environment due to salt water intrusion. Some of the primary impacts have affected Humacao Wildlife Refuge, which has the last major remnant Pterocarpus Forest on the Island of Puerto Rico. That species of tree is endangered and has a low saltwater tolerance, thus requires mainly freshwater to survive. The lagoon has some fish and other plant species such as mangroves that rely on both fresh and saltwater. Therefore, a series of saltwater intrusion measures were developed and constructed to limit the amounts of saltwater that impact the lagoon and the Pterocarpus Forest as a result of the some of the constructed features from the authorized flood control project. This paper will show how the flood control project was developed, illustrate the some of the project oversights and project dynamics that caused the saltwater intrusion problem, and then explain how saltwater intrusion measures were developed with unique construction measures that were required for installation in environmentally sensitive areas.

B. INTRODUCTION

The Rio Anton Ruiz Flood Control Project is located on the southeast coast of Puerto Rico. The Rio Anton Ruiz Project was developed and authorized as a flood control project to reduce flood damages to the coastal communities of Punta Santiago, Verde Mar and Villa Palmira, near Humacao, Puerto Rico. Flood damages used to impact those communities. Historical flooding occurred when runoff from the mountains within the watershed would flow into a large upland freshwater lagoon (Mandri Lagoon) and forested swamp, then flooded those communities before reaching the Caribbean Sea. The authorized flood control project protects those communities from flooding with a large levee system and a series of canals to the ocean.

Since the completion of the authorized flood control project in 2001 there have been major impacts to the freshwater lagoon and a surrounding environment due to salt water intrusion. Some of the primary impacts have affected Humacao Wildlife Refuge, which has the last major remnant Pterocarpus Forest on the Island of Puerto Rico. That species of tree is endangered and has a low saltwater tolerance, thus requires mainly freshwater to survive and since the completion of the project a vast amount of trees have died due to the saltwater intrusion. Additionally, the biodiversity within the lagoon has changed to a point where some other species of plant, such as mangroves that rely on both fresh and saltwater and fish have evolved since the completion of the flood control project in 2001. Therefore, in order to preserve the approximately 650 acre site of Pterocarpus Forest and preserve some of the biodiversity both the freshwater and saltwater fauna and flora, a series of saltwater intrusion measures were developed and constructed to limit the amounts of saltwater that impact the lagoon and the Pterocarpus Forest.

C. WATERSHED DESCRIPTION

The Rio Anton Ruiz watershed is located on the eastern coast of Puerto Rico with the headwaters originating in the steep mountains near the El Yunque Rainforest. The drainage area map is shown on Figure 1.

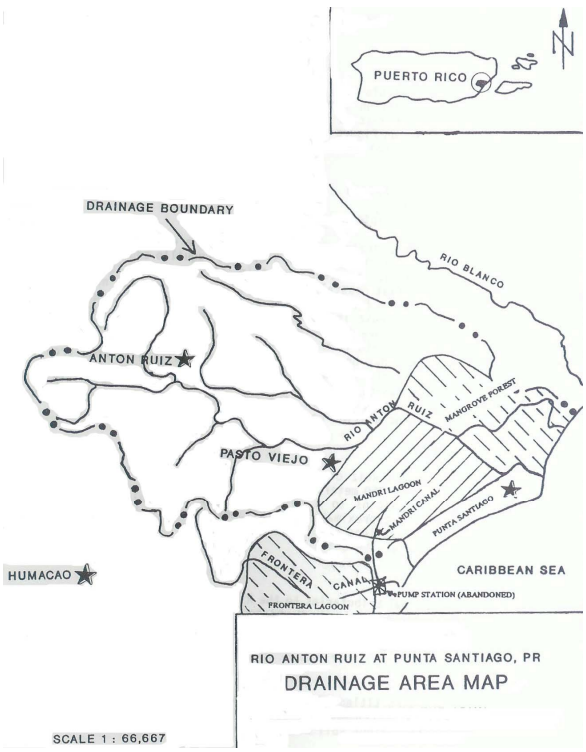

Figure 1

Rainfall will collect into steep mountain streams, then flow in a southeasterly direction across a flat coastal plain before flowing into the Mandri Lagoon. There is a large forest that is thick with primarily freshwater flora such as the Pterocarpus and certain types of Mangroves located within the coastal plain adjacent to the Mandri Lagoon. The Rio Anton Ruiz and Boca Prieta channels are the only outlets for the Rio Anton Ruiz drainage basin. The Mandri Lagoon and low coastal flood plain serve as detention areas during floods and the communities (e.g. Punta Santiago, etc.) at the coast are the main populated areas within in the watershed.

D. HYDROLOGY AND HYDRAULICS

Historically the coastal areas have experienced frequent flooding, which can happen at anytime during the year. The most serious flooding occurs when the runoff from the mountains exceeds the detention capacity of the lagoon and floods the low coastal areas in and around Punta Santiago.

1. Hydrology

The hydrology for the project area was developed with a limited amount of data. Using the US Geological Survey (USGS) quadrangle topographic maps with a scale of 1 to 20,000, the drainage basin was delineated and subdivided into five subbasins as shown on Figure 2.

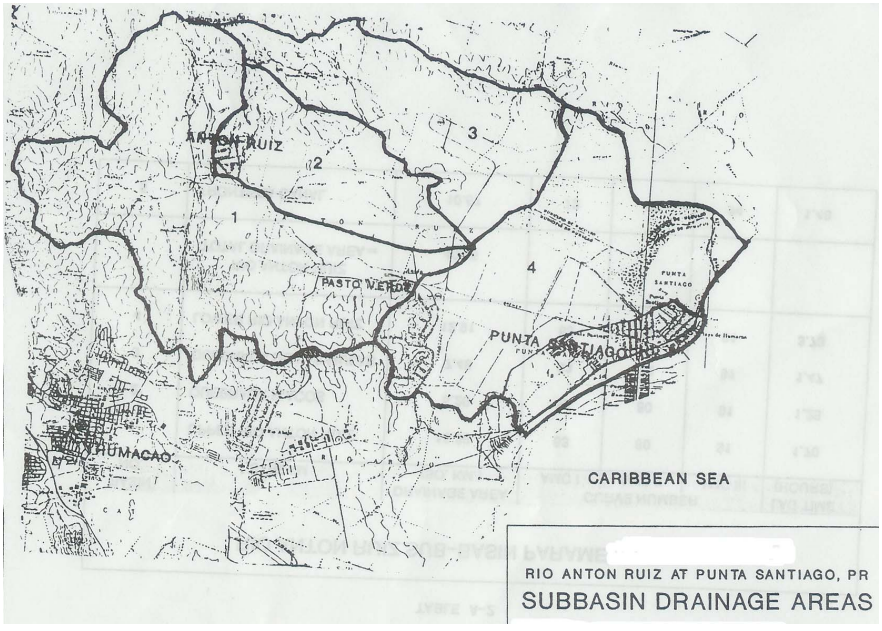

Figure 2

The USGS operates several rain gages near the basin and the National Weather Service (NWS) Technical Paper No. 42 (TP-42) shows generalized estimates of rainfall depth-

frequency data for the area. Contained in the report are the isopluvial maps of precipitation contours for selected frequencies. Table 1 shows the average point rainfalls that were developed for the study area after the adjustments for aerial distribution were applied.

TABLE 1
RAINFALL FOR RIO ANTON RUIZ BASIN
FOR VARIOUS FREQUENCIES AND DURATIONS

Percent Chance Storm	Rainfall in mm						
	Duration in Hours						
	0.25	1	2	3	6	12	24
50	39	70	85	94	110	133	155
20	52	90	114	126	152	185	217
10	61	103	132	148	180	221	260
4	72	119	157	177	217	269	316
2	81	132	176	199	246	306	361
1	89	144	195	221	276	345	408
SPF	89	144	229	290	406	470	540

The Standard Project Storm (SPS) is defined as the most severe flood-producing rainfall depth-area-duration relationship and isohyetal pattern of any storm that is considered reasonably characteristic of the region. The Probable Maximum Precipitation (PMP) is defined as the greatest depth of precipitation for a given duration that is physically possible over a given size storm area at a particular geographical location at a certain time of the year. The SPS was assumed to be 50 percent of the PMP to determine the Standard Project Flood (SPF) for this project study.

The US Army Corps of Engineers (USACE) Hydrologic Engineering Center (HEC) "HEC-1 Flood Hydrograph Package" computer program was used to calculate the runoff volumes and peak discharges for several frequencies. HEC-1 estimates surface runoff resulting from synthetic or observed storm events. The rainfall-runoff relationship for this study was computed by the Soil Conservation Service (SCS) curve number methodology. The SCS method calculates losses from curve numbers which are related to soil types, land uses, and antecedent moisture conditions. Table 2 shows the subbasin parameters that were developed for each of the subbasins.

TABLE 2 - RIO ANTON RUIZ SUBBASIN PARAMETERS

Subbasin No.	Drainage Area (km^2)	Curve Number			Lag Time (Hr)
		AMC I	AMC II	AMC III	
1	15.36	63	80	91	1.70
2	5.20	63	80	91	1.28
3	7.48	63	80	91	1.47
4	12.91	63	80	91	3.73
5	10.57	72	86	94	1.48

Note: Lag times were computed for each basin using the following Kirpich Formula:

$$Lag = 0.0013L^{1.155} / H^{0.385}$$

Where:

Lag = Lag time in hours

L = Length of basin in feet

H = Fall elevation of basin in feet

2. Hydraulics

The original project hydraulic models were developed and compared to Hurricane Donna which according to USGS data was close to 37 year storm event. During that event the rainfall exceeded 371 millimeters for 24 hours and caused major flooding within the project area.

USACE models were developed in the hydraulic analyses of the project. The following USACE numerical models were used: "DWOPER - Dynamic Wave Routing Model", "HEC-2 Water Surface Profiles" model, "HEC-6 Scour and Depositions in Rivers and Reservoirs", "HEC-River Analysis System" (HEC-RAS), and "ACES – Automated Coastal Engineering System" model. These models were used to design the levee protection system, which accounted for wind wave forces generated in the lagoon, as well as the interior and exterior channels. "HEC-6 Scour and Depositions in Rivers and Reservoirs" model was used to analyze the channel scour performance at the coastal outlets.

The levee was designed for an SPF event with stone revetment at the toe. Additional toe protection was provided by vegetation located near the toe of the levee to break up any waves generated on the lagoon side of the levee.

The interior drainage system was designed for a 10 year event and would drain the interior flooded area through two outlets, one at the coast through the existing Boca Prieta outlet and the other outlet would drain into the diversion channel through a culvert structure and into the existing Rio Anton Ruiz outlet. The original design of the proposed diversion channel was to have an invert elevation of -1.5 meters, NGVD, a bottom with of 6 meters, and a 1 vertical to 5 horizontal side slope, which was designed to be close to the conveyance capacity of of the existing Boca Prieta outlet It was anticipated the Rio Anton Ruiz and Boca Prieta outlets at the Caribbean Sea would periodically close and under frequent storm events (5 year or less) these outlets would open due to rainfall runoff.

E. FLOOD CONTROL PROJECT

The project levee is approximately 11,870 feet long and protects those communities along the coastline from SPF flooding from the upland lagoon. The culvert that drains

into the diversion channel consists of 3 – 1.83 m corrugated metal pipes with flap gates. This structure provides an additional outlet for the interior drainage system in the event that the existing Boca Prieta outlet is closed. The diversion channel conveys flows from the lagoon to the sea through the existing Rio Anton Ruiz outlet. The flood control project was completed in June 2001 and is shown on Figure 3.

Figure 3

1. Project Performance

Since the projects completion there has been no flooding from the Mandri Lagoon. All of the runoff from the uplands goes through the Rio Anton Ruiz outlet, however, the outlet does not close as originally anticipated. There has been no damage to the levees due to wave action but there has been a significant amount of Red Mangrove growth along the toe of the levee. Boca Prieta has not opened since the completion of the project and the interior drainage is more dependant on the performance of the culvert structure to drain the interior flooded areas.

F. SALT WATER INTRUSION

Approximately four years after the completion of the flood control project it was noted that there were significant impacts to the Mandri Lagoon and the adjacent forest. Salinity data was gathered by the Department of Natural and Environmental Resources (DNER) in Puerto Rico and are shown on Figures 4, 5 and 6. That data indicates that the salinity levels have more than quadrupled within the Mandri Lagoon since the completion of the flood control project.

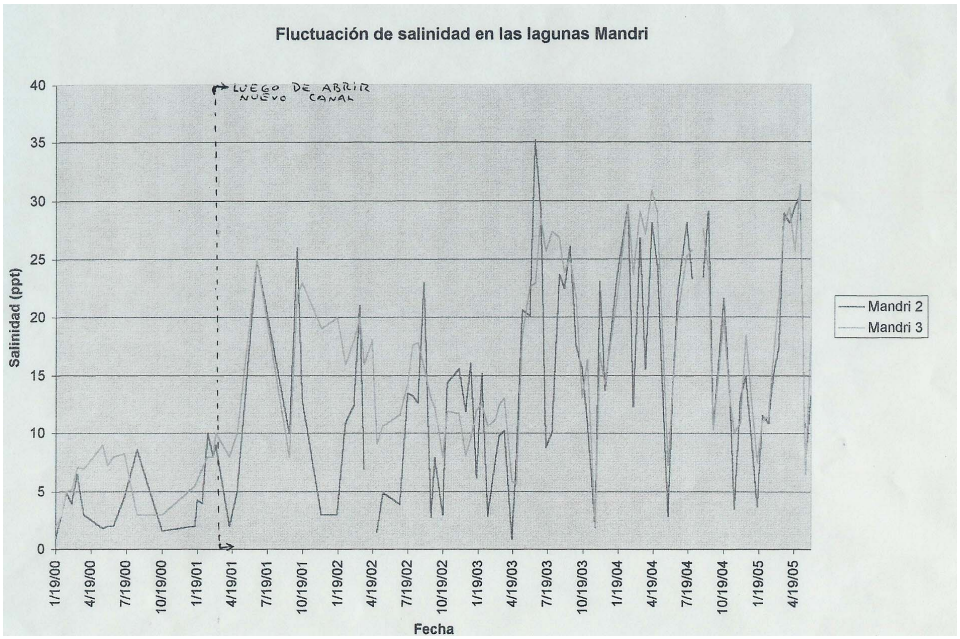

Figure 4

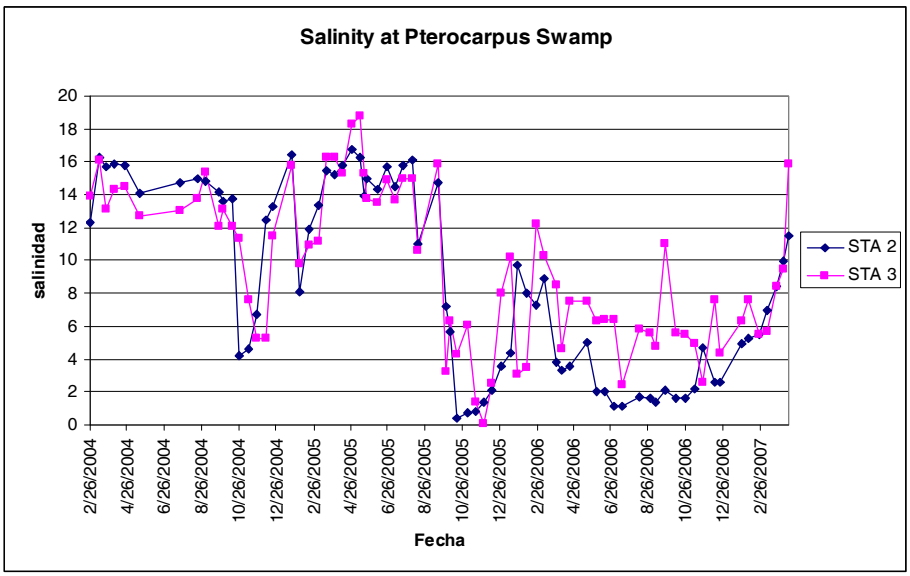

Figure 5

1. Environmental Impacts

The Mandri Lagoon is about 2 meter deep and has a surface area of about 1,237 acres. Historically, the lagoon had low salinity levels, which promoted the growth of Black and White Mangroves, However, due to the much higher salinity levels there has been a significant amount of Red Mangroves that have grown along the edges of the lagoon. The increase of this type of mangrove is consistent with the data shown and as a result there has been a decrease in the white and black mangroves.

It was determined that the cause of the increase in salinity levels in the lagoon were due to the increased capacity of the diversion channel, which were built much larger than originally anticipated. Due to the fill requirement for the levee construction the bottom width of the diversion channel was increased to approximately 24.4 meters, which is approximately four times larger than the originally proposed channel. Additionally, the channel dredged 1 to 2 meters deeper than the invert elevations at the Mandri Lagoon and Rio Anton outlet. Therefore, it was determined that the increased capacity of the diversion channel would allow significantly more water to flow through Rio Anton Ruiz outlet and into Mandri Lagoon. The channel velocities were such that sedimentation would only occur during a limited amount of time throughout the tidal cycle and according to the on-site DNER staff, the Rio Anton Ruiz outlet at the sea had not closed since before the project in 2001.

Additionally, the saltwater intrusion had an adverse effect on a 1400 acre forest, which has about 650 acres of Pterocarpus trees along the Rio Anton Ruiz channel. It was apparent that since the Rio Anton Ruiz outlet had been open for extended periods of time the saltwater had flowed 1,000 to 1,500 meters inland, which was well within the limits of the freshwater forested swamp. Additionally prior to the constructed flood control project, it was personally noted that in 1998 shortly after Hurricane Georges, the Rio Anton Ruiz outlet had not opened but the Boca Prieta outlet was opened due to the storm water runoff from Mandri Lagoon draining to the Caribbean Sea through the Boca Prieta outlet.

2. Salt Water Intrusion Measures (SWIM)

Comparing the data with the areas affected by saltwater it was determined that two SWIM plugs would be better than one for several reasons. The main reason for installing two plugs was the Mandri Lagoon did not have many Pterocarpus trees but did have a vast amount of mangroves. The Rio Anton Ruiz River had a significant amount of Pterocarpus trees that were affected by the saltwater intrusion. These SWIM plugs were temporary measures and additional salinity monitoring would be required to determine the best permanent measure by installing two plugs both system would be independent of each other. Figure 6 shows the locations of the SWIM plugs and the two primary salinity monitoring sites (Mandri 2 and Mandri 3).

Figure 5

The elevations of the plugs were based on closest NOAA tide gage, which was located at Roosevelt Roads approximately 6 km from the site. The elevations of the plugs were set to Mean Low Water (MLW) for several reasons. Based on the historic data there was no desire to completely eliminate the saltwater, only to limit saltwater intrusion to a level of near 5 parts per thousand (ppt). Also DNER staff needed to navigate to the salinity gages, thus the would have to push their small boats over the plug sites.

3. Performance of the Salt Water Intrusion Measures (SWIM) Plugs

The temporary SWIM plugs were installed at the end of March 2007. They were constructed of high-density polyethylene bags that were armored with riprap on upstream and downstream sides to resist damage during storm discharges. The bags have a high tensile strength and could be used for bridging, which facilitated the construction process and as a result the work was completed within a two week time period. These plugs are also durable and UV resistant.

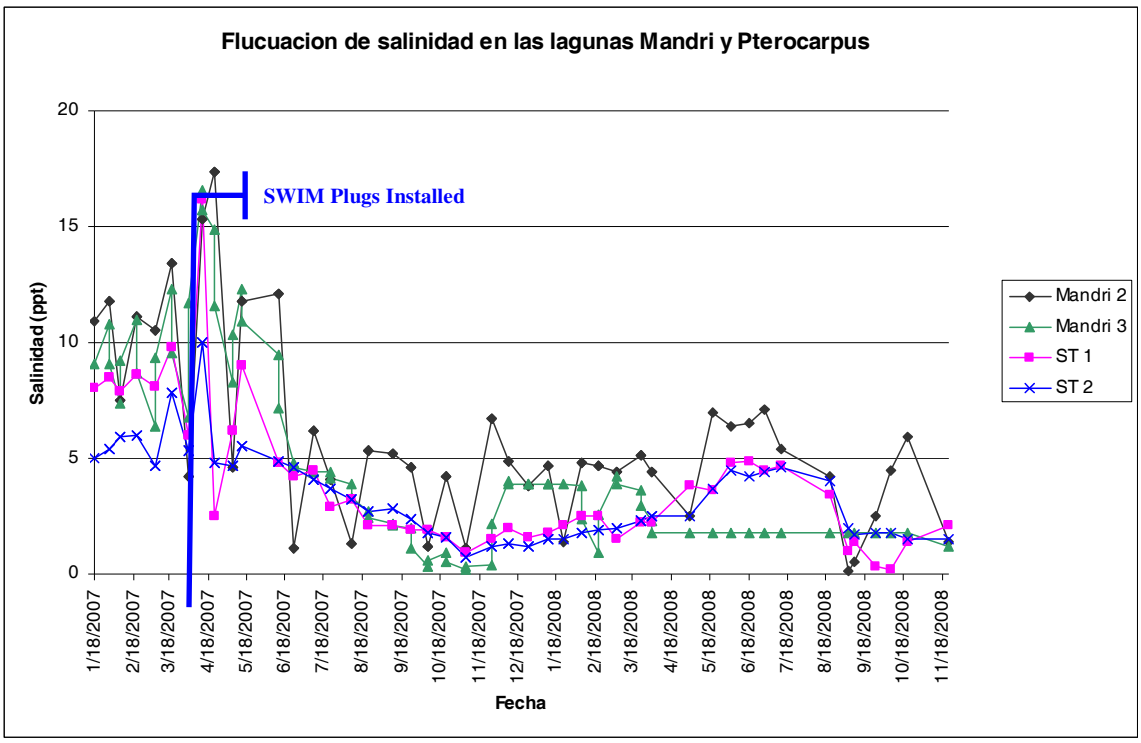

Figure 6

Figure 6 shows the data from the salinity gages in the lagoon and the Rio Anton Ruiz River. The data shows that the salinity levels are much lower now and that could be attributed to the plugs and rainfall. However, it is uncertain as to how well the Pterocarpus trees will respond to the decrease in saltwater.

G. CONCLUSION

It is envisioned that if the SWIM plugs can maintain salinity levels well below 5 ppt then the temporary SWIM plugs may soon developed into a permanent measure. However, if the salinity is such that the levels are reduced enough to promote a reforestation of the Pterocarpus trees, then the height of the SWIM plugs may need to be raised to a point where no saltwater will be permitted at the boundaries of the Pterocarpus forest.

There is a level of uncertainty associated with the data gathered to date because it does not describe the conditions of the Rio Anton Ruiz outlet at the Caribbean Sea. Some of the data has shown that the outlet may have closed since the construction of the plug but it is not noted within the data. It was anticipated that all of the information will be compared to local rain gages that are near the project in order to help develop a better correlation and understanding the physical conditions that affect the Rio Anton Ruiz outlet. However, if there is little to no data on conditions of this outlet, then it will only increase the securitization of the correlations derived from available data.

As a lesson learned from this project, the tools to analyze the potential effects over excavating the diversion channel were developed but not readily available. Additionally, we do not always see some potential project flaws due to the need to help others in an immediate manner and as a result it could cause irrevocable damage to the environment in which we live. In this case, we hope that we have sufficiently stopped the saltwater intrusion into the Pterocarpus forest but it may take a long time until the Pterocarpus trees grows back to the level that existed before the flood control project.

H. ACKNOWLEDGEMENT

We would like to acknowledge Nelson Colon for providing biological expertise. Also Jimmy Matthews P.E. for providing technical assistance the design and installation of the SWIM measures and V. Danuskodi P.E., Ph. D. for hydrological analysis to develop the proposed project. Finally, the Project Manager, Cynthia Perez and DNER for making this project happen in an expedited manner.

Abstract

In this paper, four analytical models describing hydraulic interaction of stream-aquifer systems were applied to St Lucie Estuary (SLE) River Estuaries. These are analytical solutions for: (1) flow from a finite aquifer to a canal, (2) flow from an infinite aquifer to a canal, (3) the linearized Laplace system in a seepage surface, and (4) potential flow through stratified unconfined aquifers. Input data for analytical solutions were obtained from monitoring wells and river stages at seepage-meter sites. Four transects in the study area are available: Club Med, Harbour Ridge, Lutz/MacMillan, and Pendarvis Cove located in the St. Lucie River. The analytical models were first calibrated with seepage meter measurements and then used to estimate of groundwater discharges into St. Lucie River. From this process, analytical relationships between the seepage rate and river stages and/or groundwater tables were established to predict the seasonal and monthly variation in groundwater seepage into SLE. It was found the seepage rate estimations by analytical models agreed well with measured data for some cases but only fair for some other cases. This is not unexpected because analytical solutions have some inherently simplified assumptions, which may be more valid for some cases than the others. From analytical calculations, it is possible to predict approximate seepage rates in the study domain when the assumptions underlying these analytical models are valid. The finite and infinite aquifer models and the linearized Laplace method are good for sites Pendarvis Cove and Lutz/MacMillian, but fair for the other two sites. The stratified unconfined aquifer model gave similarly good agreements with measurements at three sites but poorly at the Club Med site. None of the analytical models presented here can fit the data at this site. To give better estimates at all sites numerical modeling that couple river hydraulics and groundwater flow involving less simplifications of and assumptions for the system may have to be adapted.

1 Introduction

In order to manage the freshwater inflows to the St. Lucie estuary (SLE) more effectively for the benefit of the ecosystem, it is necessary to quantify the influence of freshwater inflow on salinity and other conditions. Past studies indicated groundwater seepage into the SLE is a significant part of freshwater inflow into the system. The quantity of groundwater seepage needs to be put into consideration for water management and ecosystem protection.

During dry seasons or a drought, groundwater input to the estuary is a more significant part of the total freshwater inflow in terms of percentage. Therefore it is a critical parameter for system operation and water reservation during dry seasons or a drought. An accurate quantification of the groundwater input to the system will also lead to more cost effective planning and project design as well as system operation.

The amount of groundwater seepage to the estuary has been the focus of several studies. Seepage meters were deployed to take measurements of groundwater seepage rate. A salinity model was used to "back calculate" the amount of groundwater seepage into the system during a dry period (Morris, 1987). The results of these studies vary and some were not sufficiently documented.

In recent years, South Florida Water Management District (SFWMD) staff has conducted field measurements at several locations in the St. Lucie Estuary and the Indian River Lagoon (IRL). The preliminary analysis has generated valuable information about the process and an estimate of the average seepage rate into the system. It is necessary to continue the analysis of the dataset obtained and use the information to predict the seasonal changes in groundwater seepage into the system.

In this paper, groundwater seepage into the St Lucie Estuary (SLE) was estimated with four analytical models using data obtained by SFWMD. Input data for analytical solutions were obtained from monitoring wells and stream stages at seepage-meter sites. Four transect sites in the study area are available: Club Med, Harbour Ridge, Lutz/MacMillan, and Pendarvis Cove located in the St. Lucie River. Analytical models were first calibrated with seepage meter measurements and then used to estimate of groundwater discharges into the St. Lucie River. Input data included aquifer properties, groundwater levels, and river stages in the study area. From this process, analytical relationships between the seepage rate and groundwater table or stream stage as time series data were established to predict the seasonal and monthly variation in groundwater seepage into the SLE.

2 Description of Four Analytical Models

Analytical solutions to the groundwater flow equation were used to derive hydraulic relationship of stream-aquifer systems with assumptions and simplifications. These solutions analyze subsurface drainage process based on aquifer properties and predict responses of aquifers to various stream stages. In this paper, four analytical solutions describing hydraulic interaction of stream-aquifer systems were applied to SLE system. The analytical solutions presented here are: Model No. 1 - flow from a finite aquifer to a river, Model No. 2 - flow from an infinite aquifer to a river, Model No 3 - 2D linearized solution for a seepage surface, Model No 4 - Potential flow

through stratified unconfined aquifers, and Model No 5 - flow through stratified confined aquifers.

Model No 1 - Transient Flow to Canal from Finite Unconfined Aquifers. Figure 1 depicts unsteady flows to a constant level river from finite unconfined horizontal aquifers. The approximating governing equation for the one-dimensional unconfined aquifers is

$$\frac{S_y}{K\hbar}\frac{\partial h^2}{\partial t} = \frac{\partial^2 h^2}{\partial x^2} \tag{1}$$

where S_y is the specific yield of the aquifer, K is the hydraulic conductivity of the aquifer [L/T], $\hbar$ could be h_o for small time t and could be $(h_r + h_o)/2$ for large time t [L], t is the time [T], h is the water table [L], and x is the distance from the river [L].

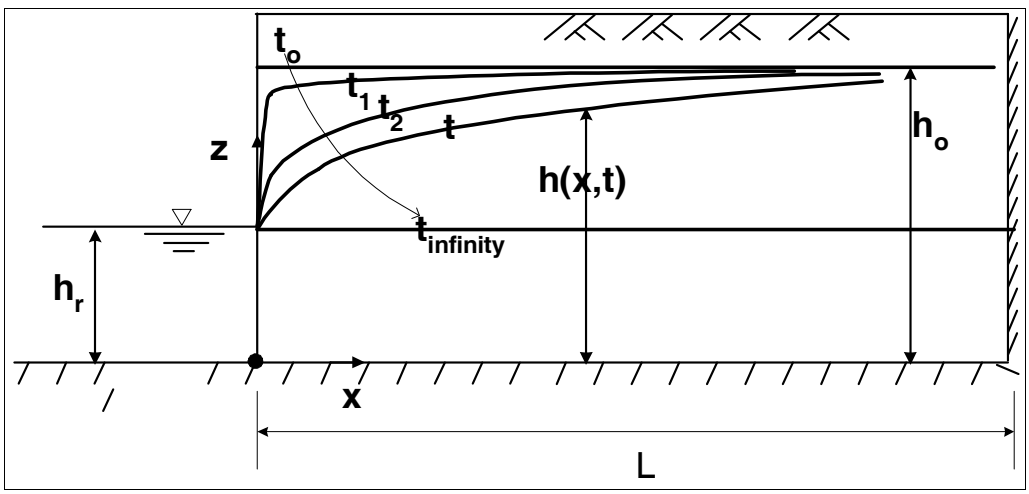

Figure 1 Finite Unconfined Horizontal Aquifer Problems

The initial and boundary conditions for the problem are specified as follows

$$h(x,0) = h_o;\ \ h(0,t) = h_r;\ \ -Kh(L,t)\frac{\partial h(L,t)}{\partial x} = 0 \tag{2}$$

where h_o is the initial water table [L], h_r is the river elevation [L], and L is the width of the aquifer [L]. Steady state condition in the aquifer after infinite time is $h(x,\infty) = h_r$.

The solution for the head h and the aquifer discharge U are:

$$h^2 = h_r^{\,2} + \frac{4(h_o^{\,2} - h_r^2)}{\pi}\sum_{n=1,3,5,\ldots}\frac{1}{n}\sin(\frac{n\pi x}{2L})e^{-\frac{n^2\pi^2\alpha^2}{4L^2}t} \tag{3}$$

and

$$U = -\frac{2(h_o^2 - h_r^2)}{L} K \sum_{n=1,3,5,\ldots} e^{-\frac{n^2\pi^2\alpha^2}{4L^2}t} \tag{4}$$

where $\alpha^2 = \hbar K / S_y$ in which S_y is the specified yield. Equation (4) is valid only when h_r are constant. The well head can be taken as the initial head, $h_o = h_{well}$ if the well is located far away from the river and its head is not affected by the river head.

Model No 2 - Transient Flow to River from Infinite Unconfined Aquifers. The governing equation and initial and boundary conditions are the same as for Model No 1, except for that the boundary condition at $x = L$ should be replaced by

$$h(\infty, t) = h_o \tag{5}$$

The solution for the head h and the aquifer discharge U for this problem are

$$h^2 = h_r^2 + \left(h_o^2 - h_r^2\right) erf\left(\frac{x}{2\alpha\sqrt{t}}\right) \tag{6}$$

and

$$U = -K\left(h_o^2 - h_r^2\right)\frac{1}{\alpha\sqrt{\pi t}} \tag{7}$$

where $\alpha^2 = \hbar K / S_y$ which S_y is the specified yield. As in Model No 1, the initial head can be taken as the well head, i.e., $h_o = h_{well}$, when the well is located far away from the river such that its head is not affected by the river head.

Model No 3 – Two-Dimensional Linearized Model for Seepage Surface. Transient drainage of an aquifer underlying a horizontal impervious layer can be described by the Laplace equation in saturated flow theory (Szilagyi, 2003). Figure 2 depicts the flow system in a two-dimensional domain. The governing equation for this two-dimensional flow in a saturated porous medium was described by the Laplace equation (Van de Giesen et al., 1994)

$$\frac{\partial^2 H(x,z,t)}{\partial x^2} + \frac{\partial^2 H(x,z,t)}{\partial z^2} = 0 \tag{8}$$

where H is the total hydraulic head, x and z are the horizontal and vertical coordinates, and t is time. The above equation is subjected to the following initial and boundary conditions:

$$H(x,z,0) = h_o;\ \ H(0,z,t) = h_r,\ \text{t} > 0;\ \ \frac{\partial H(x,0,t)}{\partial z} = 0;\ \ \frac{\partial H(L,z,t)}{\partial x} = 0 \tag{9}$$

$H(x,z,t) = z = h(x,t)$ at the free furace

where L is the aquifer width, h_o is the initial flat equilibrium water level in the river and in the aquifer, h_r is the value to which the initial water level in the river falls instantaneously (Fig. 2), and h is the phreatic surface, a function of distance from the river and of time as described by the following equation:

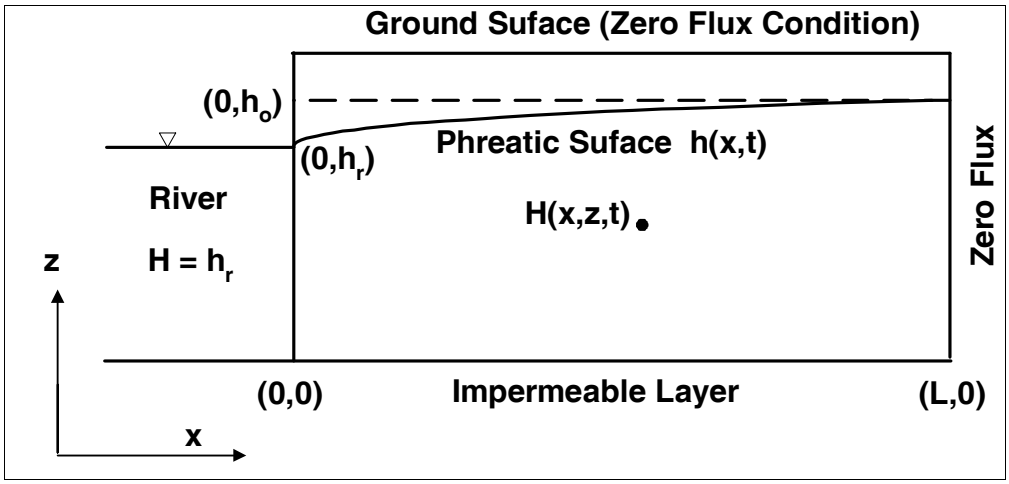

Figure 2 The River-Aquifer System with Full Penetration

$$f\frac{\partial h}{\partial t} = K_s\left(\frac{\partial H}{\partial x}\frac{\partial h}{\partial x} - \frac{\partial H}{\partial z}\right)\Bigg|_{z=h(x,t)} \tag{10}$$

where f is the drainable porosity or specific yield of the aquifer and K_s is the saturated hydraulic conductivity, both assumed to be constant in time. The Laplace equation, Eq. (8), can be solved analytically (Van de Giesen et al., 1994) if Equation (10) is linearized, which implies that the changes in the phreatic surface elevation are small compared to the characteristic depth(h_r), of the saturated zone, then the boundary condition on the phreatic surface is given by the following linear partial differential equation

$$f\frac{\partial h}{\partial t} = -K_s\frac{\partial h}{\partial z} \tag{11}$$

The aquifer discharge, U, to the river ($x = 0$) in the problem is defined by the following equation,

$$U(t) = -\frac{4(h_o - h_r)k_{sat}}{\pi}\sum_{n=1,3,5,\ldots}^{\infty}\frac{1}{n}\tanh\left(\frac{n\pi h_r}{L}\right)\cdot\exp\left(-\frac{K_s}{f}\tanh\left(\frac{n\pi h_r}{L}\right)\frac{n\pi}{L}t\right) \tag{12}$$

which contains parameters: K_s, f, L, h_r ,and h_o, where h_o is initial head that can be taken as the well head, i.e., $h_o = h_{well}$, if the well is located far way from the river

and its head is not affected by the river head. Equation (12) describes aquifer drainage for a fully penetrating river when both h_o and h_r are constant.

Model No 4 - Potential Flow through Stratified Unconfined Aquifers. Analytical models are available for conditions where hydraulic parameters change in the vertical direction, but remain uniform along the horizontal plane. These models provide an alternative that is sometimes useful compared to the general reliance on numerical simulation models such as MODFLOW (McDonald and Harbough, 1988), FEMWATER (Yeh, 1999) and FEWA (Yeh, 1999), WASH123D (Yeh et al., 2006), etc. Figure 3 shows the cross-section forflow in a stratified unconfined aquifer.

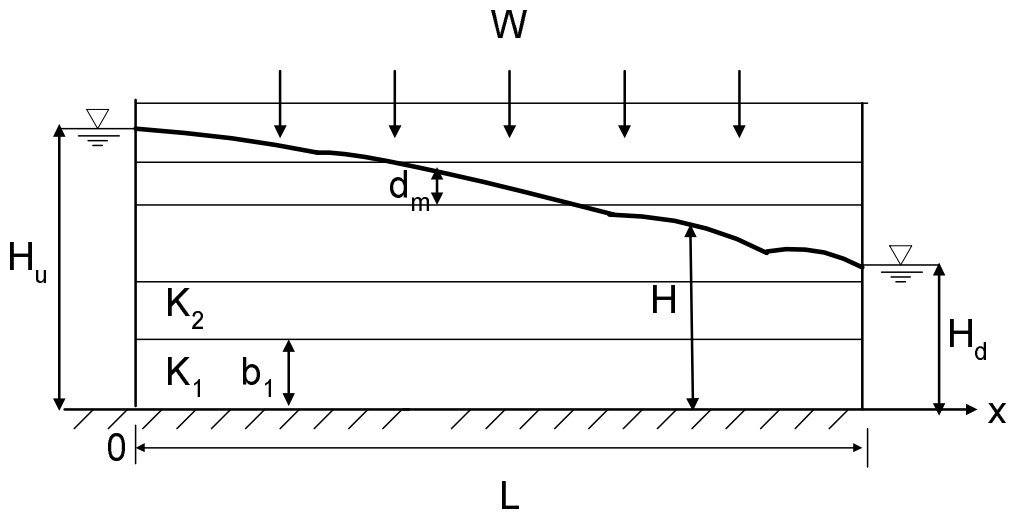

Figure 3 Steady State Flow in Stratified Unconfined Aquifers

Girinskii (1946) has shown that so long as the flow is essentially horizontal, then a potential function can be defined for stratified aquifers which generalize the saturated thickness used for homogeneous unconfined aquifers (also see Bear, 1972). The primary assumption is that the energy losses associated with vertical flow are negligible, which implies that the Dupuit-Forchheimer assumptions apply. For our present purposes, a potential function is one whose gradient gives the aquifer flux. This potential function was defined by Girinskii (1946) and thus is called Girinskii potential function Φ

$$\Phi = \int_0^H (H - z) K(z) dz \tag{13}$$

The continuity equation for flow in stratified unconfined aquifers subject to rainfall rate W is given in terms of the Girinskii potential function as

$$\frac{d^2\Phi}{dx^2} + W = 0 \tag{14}$$

The boundary conditions for the given system are specified as follows

$$\Phi = \Phi_u \text{ at } x = 0 \text{ and } \Phi = \Phi_d \text{ at } x = L \tag{15}$$

in which Φ_u and Φ_d are related to H_u and H_d, respectively, through Equation (13).

The analytical solution of the system described by Equations (14) and (15), is given as follows

$$\Phi(x) = \Phi_u + \left(\Phi_u - \Phi_d\right)\frac{x}{L} + \frac{Wx}{2}\left(L - x\right) \tag{16}$$

The aquifer flux is given by

$$U(x) = -\frac{d\Phi}{dx} = \frac{\left(\Phi_u - \Phi_d\right)}{L} - \frac{WL}{2} + Wx \tag{17}$$

so that

$$U_u = \frac{\left(\Phi_u - \Phi_d\right)}{L} - \frac{WL}{2} \quad \text{and} \quad U_d = \frac{\left(\Phi_u - \Phi_d\right)}{L} + \frac{WL}{2} \tag{18}$$

Equation (18) provides a working equation to calculate seepage rates given the aquifer information (K_1, b_1, K_2, b_2, .., K_n, b_n), upstream and downstream boundary conditions H_d and H_u, and the rainfall rate, W. Given a H, Equation (13) is integrated to yield the following working equation for calculating Φ

$$\begin{aligned}\Phi = H\left(\sum_{i=1}^{m-1} K_i b_i + K_m d_m\right) - \frac{b_1^2}{2}\left(K_1 - K_2\right) - \frac{\left(b_1 + b_2\right)^2}{2}\left(K_2 - K_3\right) - \ldots \\ - \frac{\left(b_1 + b_2 + \ldots + b_{m-1}\right)^2}{2}\left(K_{m-1} - K_m\right) - \frac{K_m H^2}{2}\end{aligned} \tag{19}$$

3 Estimation of Seepage Rate into SLE

The hydrologic data for seepage measurement site was prepared to calculate groundwater seepage by analytical solutions mentioned in Section 1. Four sites of seepage measurement in the St. Lucie River were located as shown in Figure 4 (SLLT: Lutz/MacMillian, SLPD: Pendarvis Cove, SLHR: Harbour Ridge, SLCM: Club Med). The required hydrologic data include monitoring river stage and well stage data. Available 2002-2004 time series data were used to match seepage measurements for the 2002-2003 period for the calibration at monitoring sites. In addition, hydraulic conductivity data for study area were prepared to input analytical solution. To simplify, hydraulic conductivity data was normalized by Box-Cox transformation method over St. Lucie and Martin County.

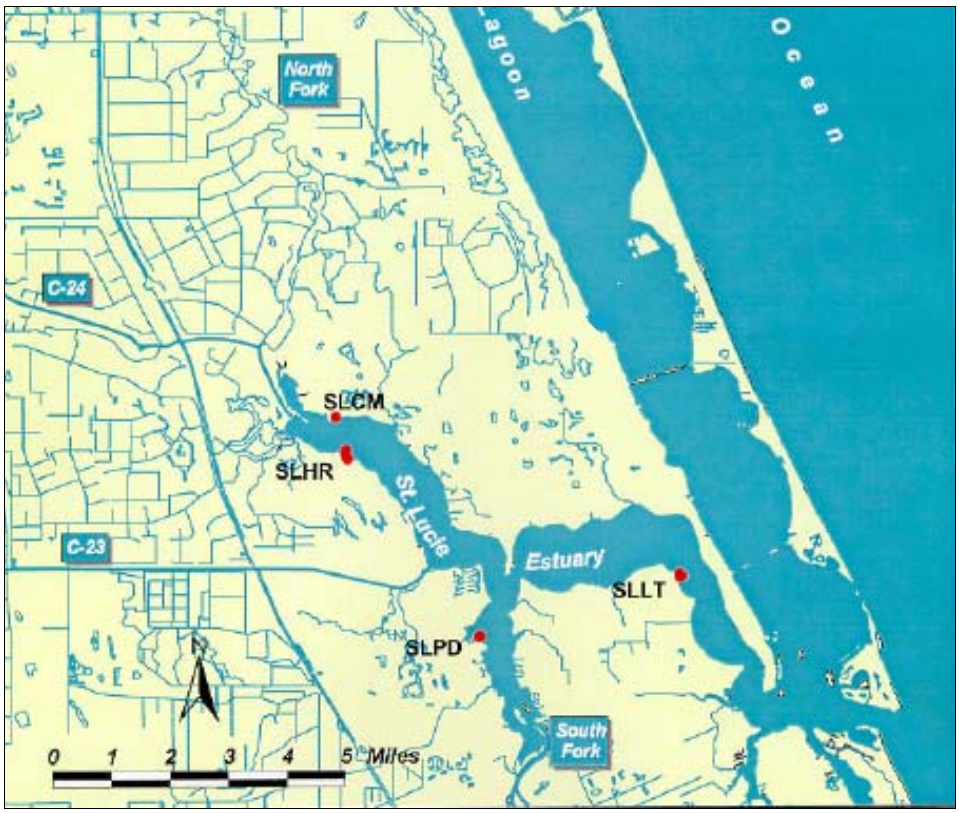

Figure 4 Location of the Seepage Measurement

On every monitoring site, seepage rates (cm/sec) were estimated based on river stage, water table, and/or recharge rate using four analytical models. The daily seepage rate into the SLE were calculated and compared with mean transect seepage for monitoring sites (Belanger et. al. 1998) having several stations of seepage meter. The gaging daily data of corresponding sites have missing or incorrect data. Therefore we selected data period that has available river stage and well stage data in the study domain (DBHYDRO, SFWMD). The stream stage and groundwater table data during 08/01/2002 – 09/25/2004 were used as input to analytical models.

Four analytical models are applied to St. Lucie River watershed to estimate seepage rates using hydrologic and aquifer data from the database (Morris, 1987). Calibrated aquifer parameters of the study area, used in four analytical models, are shown in Table 1.

For the finite aquifer (Model No 1) and the 2D linearized solution model (Model No. 3), the daily water level from the monitoring well is used as an initial condition, h_o . The boundary condition was specified by the river stage, h_r .. The other boundary condition is flux equal to zero at a distance L far away from the river. This distance can be estimated using $L = 1.5\sqrt{\frac{0.5K(h_r + h_{well})t_d}{S_y}}$, where K is the hydraulic conductivity, S_y is the specific yield, and t_d is the duration time of simulations.

Table 1 Calibrated parameters used in analytical models

Parameters	Monitoring sites and available values			
	SLPD	SLLT	SLCM	SLHR
Hydraulic conductivity (K_h : ft/day)	0.3 – 1200.0	0.08 - 520.0	0.001 – 6.0	0.002 – 16.0
Storativity (s)	0.0009	0.0009	0.0001-0.0003	0.0001-0.0003
Specific yield (s_y)	0.20	0.10	0.10	0.20
Thickness of Aquifer (b : ft)	11.0	16.0	11.0	11.0
Width of Finite Aquifer (L : ft)	71 – 85	50 – 80	8 - 13	1 – 2
Width of Stratified Aquifer (L' : ft)	10	267	229	772
Amplitude (η) for the wave propagation model (ft)	2.0	2.0	1.5	1.5
Leakage Rate (W : ft/day)	0.00778	0.00639	0.0	0.0

In the semi-infinite aquifer (Model No 3), water level at the monitoring well is adopted as the initial conditions, h_o. Water level at the gage station in the river, h_r, was specified as boundary condition.

For the stratified unconfined aquifer model (Model No. 4), the measurement head at the monitoring well was used as upstream boundary condition, H_u. The water stage at the gage station in the river was used as downstream boundary condition, H_d. The aquifer with, L, is the distance between the gage station in the river and monitoring well in the aquifer. From MODFLOW input data, the river channel depth is very shallow compared to total aquifer thickness. Therefore, the aquifer information such as hydraulic conductivity has uniform distribution along the vertical direction. The leakage rate data was obtained from recharge data in the MODFLOW input data set.

The estimated seepage rates by four analytical solutions were presented for four sites in Figures 5 through 20. In all figures, the positive values denote seepage from aquifers to the river while the negative values denote discharge from the river to aquifers.

For the Pendarvis Cove site, the seepage rates computed by the finite aquifer model ranged from -1.853×10^{-4} cm/sec to 3.202×10^{-4} cm/day (Figure 5). The seepage for semi-infinite aquifer was obtained from -2.345×10^{-4} cm/sec to 4.053×10^{-4} cm/sec (Figures 9). The seepage rates computed by 2D linearization ranged from -1.637×10^{-4} cm/sec to 3.809×10^{-4} cm/sec (Figure 13). The result of stratified unconfined and confined aquifer ranged from -2.507×10^{-4} cm/sec to 3.564×10^{-4} cm/sec and from -3.618×10^{-4} cm/sec to 5.829×10^{-4} cm/sec (Figure 17) Each of the four analytical model results was compared with the measurement data from seepage meter sites. These figures show that all analytic models have a good agreement with seepage measurement data during the study period.

At the Lutz/Mac Millian site, the finite and infinite aquifer models calculated the seepage rates ranging from -2.067×10^{-5} to 5.494×10^{-4} cm/sec and from -2.616×10^{-5} cm/sec to 6.954×10^{-5} cm/sec, respectively (Figures 6 and 10, respectively). The 2D linearization results ranged from -3.894×10^{-5} cm/sec to 2.214×10^{-4} cm/sec (Figure 14). The seepage rates for stratified unconfined problem give result of -8.580×10^{-6} to 8.866×10^{-5} cm/sec (Figure 18). All four models yielded reasonably good agreements with observation seepage flux measured.

For the Club Med site, the finite and infinite aquifer models generated seepage ranges of -1.840×10^{-8} to 1.103×10^{-5} cm/sec and -2.388×10^{-7} cm/sec to 1.509×10^{-5}, respectively (Figures 7 and 11, respectively). In addition, The 2D linearization method rendered seepage rates of -1.238×10^{-7} to 7.211×10^{-6} cm/sec (Figure 15). The seepage rate for stratified unconfined aquifer was obtained -1.582×10^{-7} to 1.063×10^{-5} cm/sec (Figure 19). None of the models can reproduce the measurement data to within a reasonably accuracy.

In the Harbour Ridge site, the finite aquifer model, semi-infinite aquifer model, 2D linearization method, and stratified unconfined models computed seepage rates in the range of 5.355×10^{-6} to 1.806×10^{-5} cm/sec, 4.792×10^{-6} to 1.617×10^{-5}, 4.809×10^{-6} to 1.523×10^{-5} cm/sec, and 2.282×10^{-6} to 8.924×10^{-6} cm/sec, respectively (Figures 8, 12, 16, and 20, respectively). The stratified model gave good agreements with the measurements at this site except for one data point. All other models performed poorly. It is also noted that all models predict only seepages (i.e. without recharge) in this most upstream site

4 Evaluations of Analytical Modeling of Seepages

From Section 3, it was found the seepage rates estimation by analytical models agreed well with measured data for some cases but only fair for some other cases. This is not unexpected because analytical solutions have some inherently simplified assumptions, which may be more valid for some cases than the others. From Figures 5 through 20, it is seen that the finite and infinite aquifer models and the 2D Linearization method are good for sites Pendarvis Cove and Lutz/MacMillian, but fair for the other two sites. The stratified unconfined model gave good agreements with measurements at three sites but poorly at the Harbour Ridge site. None of the analytical models presented here can fit the data at this site. It is possible to predict approximate seepage rates or seepage amount in the study domain using the analytical models when the assumptions underlying these models are valid.

ABSTRACT

To have a better understanding of seepage from the canal beds, authors developed a new infiltration method to analyze seepage beneath canal beds during ponding tests. This is distinct from Green-Ampt method for infiltration on a uniform unsaturated zone and with a constant head in a ponding area. An analytical-numerical equation was derived to represent the seepage flow based on Darcy's law and Romos' method. Five ponding tests conducted on the selected sections of Franklin Canal in El Paso, Texas were analyzed using the proposed methods. The comparison between analytical solution and other ponding test observation indicated that analytical-numerical solution gives a good approximation of seepage losses. The annual canal seepage losses vary spatially depending on hydraulic conditions in the canal, ranging from 86,245~299,467 m^3/km for low flow in the canal, to 177,184~564,875 m^3/km for high flow, which provide a great potential for water conservation.

INTRODUCTION

Ponding test is one of field methods to identify canal seepage loss (Rohwer and Stout, 1948; Warnick, 1951; Worstell, 1976; Kuo, 1982; Sheng et al., 2003; Alam and Bhutta, 2004; Kahlown and Kemper, 2004; Leigh and Fipps, 2004a, 2004b). Vedernikov (1934) derived a first closed-form solution to the problem of seepage form canals of various shapes with water table at infinite depth. Muskat (1946), Polubarinova-Kochina (1962), and Harr (1962) studied seepage losses by using mathematical analysis for triangular and trapezoidal canals. Bouwer (1978) presented solution for canal seepage for various depths and shapes of the canals and of positions of groundwater table in three types of soil conditions: high hydraulic conductivity; low hydraulic conductivity; and the hydraulic conductivity in which the thin layer of sediment below the canal is much lower than the underlying soil. Jeppson (1968) presented a solution for seepage from channels through layered porous mediums by using the method of finite differences. He considered the layers with different permeability and each layer is to be anisotropic condition with different ratios of horizontal to vertical permeability, but the interface between the two layers restricted to being horizontal. For transient seepage of canal, Collis-George and Smiles (1963) got a solution for a rectangular channel and Bouwer (1969) got a plot in terms of dimensionless factors A_w / W_s^2 and Kt / fW_s. The terms A_s, W_s, K, t, and f represent the wetted soil area, the width of the surface water, soil hydraulic conductivity, time and the fillable pore-space fraction of the soil, respectively.

The assumptions for each theoretical study above are: 1. soil behavior is homogeneous and isotropic; 2. ground water is infinitely deep; 3. flow is laminar, thus obey Darcy's law; 4. capillary fringes are negligible; 5. groundwater table is 100% saturated and above the table is 0% saturated; and 6. canal water depth is constant. It should be pointed out, however, that canal water head is usually free falling for ponding test (Sheng, 2003; Leigh and Fipps, 2004a, 2004b). Few theoretical solutions have been found for canal ponding tests with free falling head in literature. Even Green-Ampt (1911) equation also ignores the depth of surface water for infiltration. In this study, the authors presented a new method to assess seepage losses for a trapezoidal shaped canal based on Darcy's law and Romos' method. Five ponding tests conducted at four sites along the Franklin Canal in El Paso, Texas (Sheng et al., 2003) were used to demonstrate applications of the new method.

METHODOLODY

The trapezoidal shaped canal is shown in Figure 1. The canal bed soil with lower hydraulic conductivity K_1 is assumed to be saturated and the seepage flow through the saturated bed soil is assumed to be vertical during ponding test after the canal bed and side banks are wetted for over 48 hours (Sheng, et al, 2003). The wetting front is assumed to be fixed on the interface of the fine bed soil and its underlying sand layer. Let h_c represent the capillary pressure head on the wetting front; h_0 and $h(t)$ represent the initial and any time water depths, respectively, of the canal for the ponding test; b represents the width of the canal bed; d represents the thickness of the canal bed top soil with the lower hydraulic conductivity K_1. Water table is assumed to be deep enough without hydraulic connection with the canal. At the time t, the water volume change rate for a unit length of canal can be written as $(b + 2h/\tan(\alpha))dh/dt$; and the seepage rate through the canal bed and bank soil can be written as $-K_1(h + d - h_c)b/(b + 2h/\tan(\alpha))[1/d + 2\ln((h + d)/d)/\tan(\alpha)]$ based on Darcy's law. The above volume water change rate of the canal is equal to the seepage rate based on water mass balance, so we can have the free falling head rate of the canal as following

$$f \equiv \frac{dh}{dt} = -\frac{K_1(h + d - h_c)b}{b + 2h/\tan(\alpha)}\left[\frac{1}{d} + \frac{2\ln(1 + h/d)}{\tan(\alpha)}\right] \quad (1)$$

with $h(0) = h_0$. Equation (1) is one kind of initial value problem with an autonomous function of h. Ramos (2007) developed a non-standard explicit integration scheme for the initial-value problem. A numerical solution for equation (1) can be written as following based on Ramos (2007)

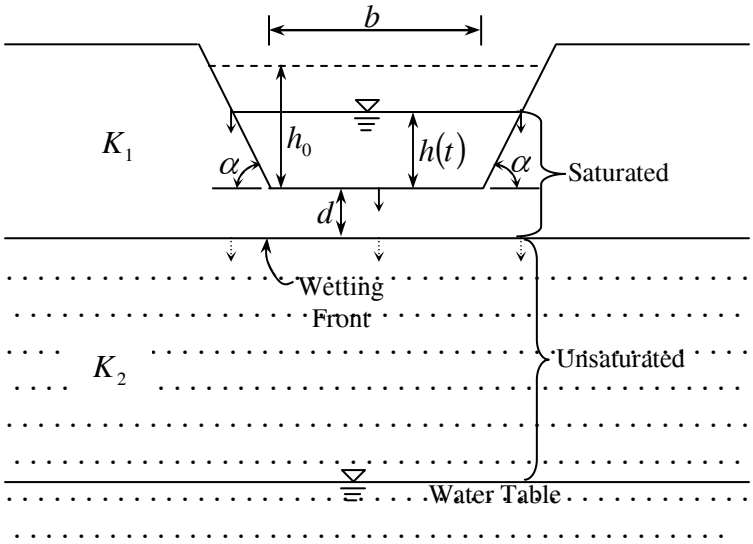

Figure 1. Geometry and symbols for trapezoidal cannels in soil underlain by permeable material: a. The top soil with lower hydraulic conductivity (K_1) below the cannel is homogeneous and underlain by material of much higher hydraulic conductivity (K_2); b. The water table is below the top of this permeable layer which acts as a drainage layer for seepage water.

$$h_{n+1} = h_n + \frac{2 f_n \Delta t}{2 - j_n \Delta t} \tag{2}$$

where h_n represents an approximation of $h(t_n)$ with $t_n = n\Delta t$, Δt is the time step size, and $j_n \equiv \partial f / \partial h(h_n)$. j can be obtained through the derivative of equation (1) with respect to h as following

$$j \equiv \frac{\partial f}{\partial h} = -K_1 \frac{(c_1 h + c_2)\ln(d+h) - 4bdh^2 + c_3 h + c_4}{4\tan(\alpha)h^3 + 4(d^2 + bd\tan\alpha)h^2 + c_5 h + b^2 d^2 \tan^2\alpha} \tag{3}$$

where $c_1 = 4bd^2 - (4bh_c + 2b^2\tan\alpha)d$;

$c_2 = 4bd^3 - (4bh_c + 2b^2\tan\alpha)d^2$;

$c_3 = [(2b^3\tan\alpha + 4bh_c)d - 4bd^2]\ln d - 4bd^2 + (4bh_c - 2b^2\tan\alpha + 2b\tan\alpha)d - 2bh_c\tan\alpha - b^2\tan^2\alpha$;

$c_4 = [(2b^2\tan\alpha + 4bh_c)d^2 - 4bd^3]\ln d + 2(1-b)bd^2\tan\alpha + [2(1-b)bh_c\tan\alpha - b^2\tan^2\alpha]d$; and

$c_5 = \tan\alpha(4d + b\tan\alpha)bd$.

When α is $\pi/2$, the canal shape becomes rectangular. For a rectangular canal, an analytic solution for equation (1) were obtained as following

$$h = (h_0 + d - h_c)e^{-\frac{K_1}{d}t} - d + h_c \tag{4}$$

Figure 2 shows the numerical free falling water depth solution in equation (2) with ponding time for a trapezoidal canal and the analytical solution in equation (4) for a rectangular canal. The good match between equations (4) and numerical results in Figure 3 for $\alpha = 90^\circ$ demonstrated that Ramos' numerical solution works very well.

From equation (1), the seepage rate per unit canal length, $F(h)$, for trapezoidal canals can be calculated using following equation (5):

$$F(h) = (b + 2h/\tan\alpha)\frac{dh}{dt} = -K_1(h + d - h_c)b\left[\frac{1}{d} + \frac{2\ln(1 + h/d)}{\tan(\alpha)}\right] \tag{5}$$

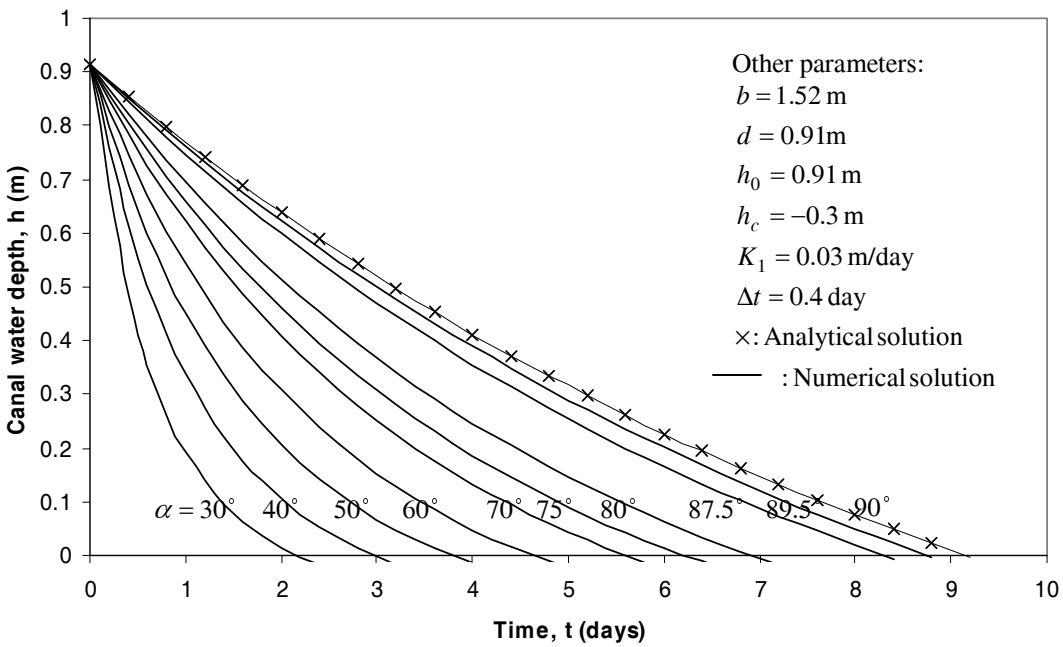

Figure 2. Free falling water depth with ponding time for a trapezoidal canal with different side bank slopes

PARAMETER ANAYSIS OF PONDING TESTS

Five ponding tests were conducted to determine seepage losses from Franklin Canal in the El Paso Country Water Improvement District No. 1, Texas (Sheng et al.,

2003). The top soil in El Paso farm land usually consists of clay or loam with a varying depth of 0.3 to 1 m. This fine top soil mantles the upper unconfined Rio Grande alluvium aquifer with a depth of up to 600 m consisting of fine- to medium-grained sand with interbedded lenses of clay, silt, gravel and caliche (Sheng and Devere, 2005). The canal bed and bank consist of the top soil with lower hydraulic conductivity. Groundwater table in our ponding test area is 15 to 37 m below land surface. The sand between the bottom of the canal bed soil and the water table can be considered to be unsaturated while the bed soil is saturated by seepage. The wetting front with a capillary pressure is assumed to be fixed on the interface of the fine bed soil and its underlying sand layer. This lower permeable canal bed soil controls the canal seepage.

In order to determine parameters that affect seepage losses the equation (2) is employed to inversely analyze ponding test data using parameter estimation software PEST (Doherty, 2002). The values of parameters, d, K_1, and h_c for five ponding tests along Franklin Canal were estimated. The canal bed soil thickness was found to be almost 0.3 m for Sites 1, 2, and 3, and almost 0.9 m for Site 4 (Table 1), respectively.

Table 1. Canal ponding parameter estimation results

Ponding location	Slope $(\tan\alpha)$	Bed width, b (m)	Initial water depth, h_0 (m)	PEST estimation			
				Bed soil thickness, d (m)	Hydraulic conductivity of the bed soil, K_1 (m/day)	Wetting front capillary pressure head, h_c (m)	Average matching error, %
Site 1	0.523	6.68	0.28	0.31	0.0122	-0.09	1.9
Site 2	0.450	3.96	0.36	0.31	0.0147	-0.10	10.4
Site 3 (1^{st})	0.662	9.72	0.64	0.30	0.00384	-0.08	0.1
Site 3 (2^{nd})			0.77	0.31	0.00451	-0.09	0.4
Site 4	0.710	10.12	0.39	0.88	0.020	-0.39	5.3

The average error (see Table 1) of the simulated canal water depth to its observed (see Figure 3) is 1.9 to 10.4%. The hydraulic conductivity of the canal bed soil was found to be 0.012, 0.015, 0.004, and 0.02 m/day for Sites 1, 2, 3, and 4, respectively. According to hydraulic conductivity value ranges from Green-Ampt infiltration for different kinds of soil (Rawls et al., 1983; Rawls et al., 1993), the canal bed soil may be categorized as silty clay at Sites 1 and 2, clay at Site 3, and sandy clay at Site 4, respectively. The lab value of the hydraulic conductivity for the underlying material-sandy loam or fine sand is in range of 2.3 to 9.4 m/day. The hydraulic conductivity value of the canal bed soil is 2 to 3 orders of magnitude less than its underlying sandy loam or fine sand material. The wetting front capillary pressure on the bottom of the thin canal bed soil was found to be almost -0.1 m for Sites 1, 2, and 3, and -0.4 m for Site 4, respectively. It means that there exists a vadose zone below the bottom of the saturated canal bed soil during ponding test.

This further proves that the canal bed fine soil layer controls the seepage of the canal water to its underlying phreatic aquifer when the canal is hydraulically disconnected with water table or ground water.

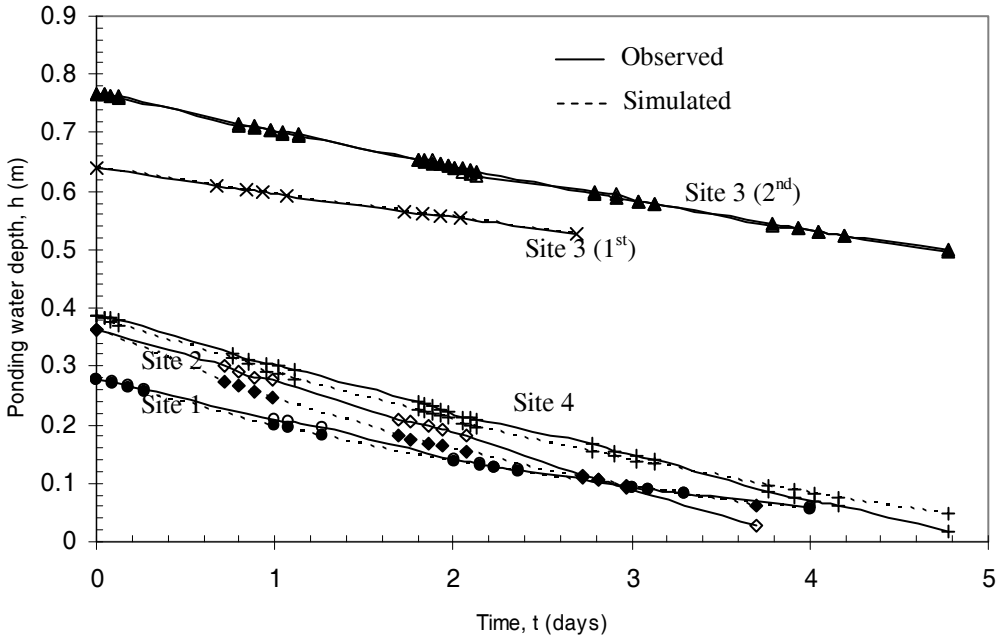

Figure 3. Observed ponding water depth compared to its simulated results along the Franklin Canal in El Paso, TX

POTENTIAL FOR WATER CONSERVATION

Once parameters are determined, one can use equation (5) to estimate seepage losses under different conditions. The Franklin Canal water seepage loss rate with canal water depth were estimated and shown in Figure 4. The seepage loss of the canal at Site 4 is the largest among the four sites because high hydraulic conductivity of its bed and its large bed width, while the seepage loss of the canal at Site 3 is the lowest because its low hydraulic conductivity. Lining canal to decrease canal bed material hydraulic conductivity is the first choice for improvement of water delivery efficiency (water savings or reduction in water diversions for a given level of surface water diversion, Sheng et al., 2003). The annual canal seepage losses vary spatially depending on hydraulic conditions in the canal, ranging from 86,245~299,467 m^3/km for 0.62-meter water depth in the canal, to 177,184~564,875 m^3/km for 1.23-meter water depth (Table 2). If we assume 80% of seepage losses as shown in Table 2 can be saved, then it is anticipated that approximately 451,900 m^3/km can be saved during the irrigation season if the canal is operated at a high capacity at site 4. On the other hand, if the canal is operated at a low water capacity, less water conservation potential of approximately 239,574 m^3/km is anticipated at site 4. At site 3, much lower water conservation potential is anticipated, ranging from 141,747 m^3/km for high flow and 68,996 m^3/km for low flow. Canal beds and hydrological condition in the canal control potential for water conservation.

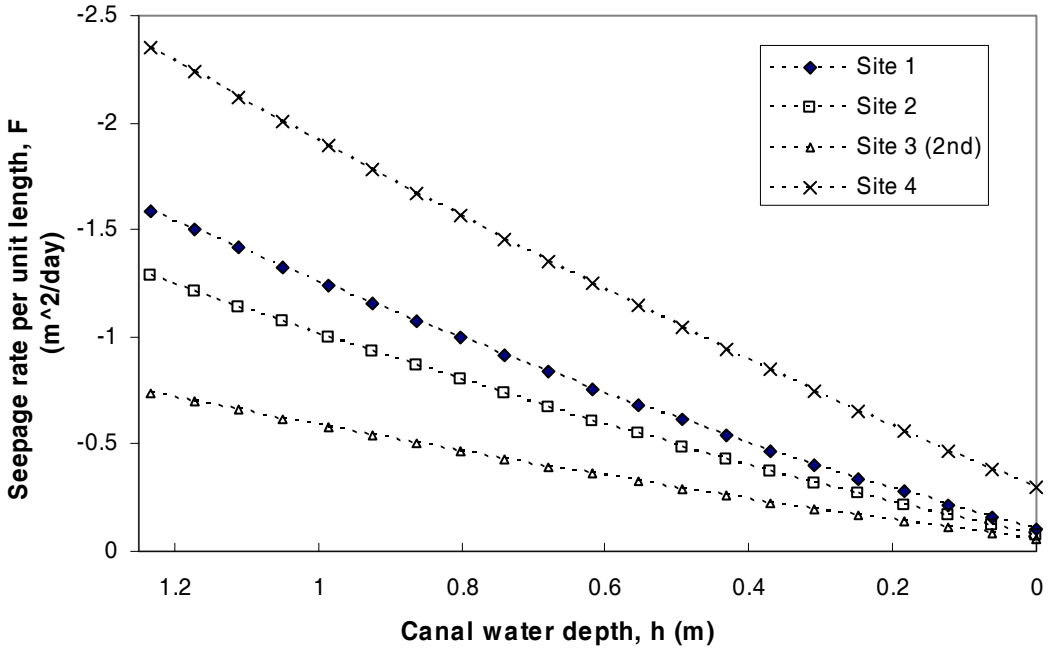

Figure 4. Canal seepage loss rate with canal water depth

Table 2. Canal seepage loss rate

Canal location	Canal water seepage loss rate			
	Canal water depth (m)			
	1.23		0.62	
	m^3/m/day	m^3/km /irrigation season	m^3/m/day	m^3/km /irrigation season
Site 1	1.6	381,333	0.8	182,388
Site 2	1.3	308,145	0.6	146,129
Site 3 (2^{nd})	0.7	177,184	0.4	86,245
Site 4	2.3	564,875	1.2	299,467

CONCLUSION

A conceptual model for trapezoidal canals in low permeable soil underlain by high permeable material is proposed. Water table is assumed to be deep enough without hydraulic connection with the canal. It is assumed in this model that seepage flow is vertical and laminar after the canal soil is wetted and saturated for over 48 hours.

A numerical solution presented in this paper can be used to determine values of canal bed soil parameters such as hydraulic conductivity, thickness and capillary pressure head on the wetting front from the ponding test. After the parameter values are obtained from ponding tests, an analytical solution is employed to calculate canal seepage loss with variable water depth in canal.

Five ponding tests at four sites along the Franklin Canal were analyzed by coupling the numerical solution for free falling water depth in canal with inverse

model PEST (Parameter Estimation). The hydraulic conductivity of the canal bed soil was found to be 0.012, 0.015, 0.004, and 0.02 m/day for Sites 1, 2, 3, and 4, respectively. The thickness of the bed soil was found to be almost 0.3 m for Sites 1, 2, and 3, and 0.9 m for Site 4. The wetting front capillary pressure head was found to be almost -0.1 m for Sites 1, 2, and 3, and -0.4 m for Site 4.

Franklin Canal seepage loss was evaluated for the four sites using obtained parameter values from the ponding tests. The annual canal seepage losses vary spatially depending on hydraulic conditions in the canal, ranging from 86,245~299,467 m^3/km for 0.62-meter water depth in the canal, to 177,184~564,875 m^3/km for 1.23-meter water depth. There is a great potential to conserve water by lining canals, ranging from 68,996 m^3/km at a low flow condition of site 3, to 451,900 m^3/km at a high flow condition at site 4 for one irrigation season.

ACKNOWLEDGEMENT

ABSTRACT

Water District No. 1 of Johnson County, Kansas (WaterOne) is constructing their Phase V-A Expansion. The expansion program began with an evaluation of the best source of supply to meet their growing needs.

The water supply evaluation included the investigation of horizontal collector wells, which would provide a reliable, high quality supply. A large number of test borings and pumping tests were conducted in the alluvial valleys of the Kansas and Missouri Rivers west of the Kansas City metropolitan area. The results of the testing were used to develop alternative wellfield scenarios. Life-cycle costs were developed, and this information was used to select the most favorable alternative for WaterOne.

PURPOSE OF PROJECT

Water District No. 1 of Johnson County, Kansas (WaterOne) provides drinking water to a population of approximately 400,000 in the Kansas City metropolitan area. The population of the service area has grown significantly and is projected to continue growing. To meet the demands from the expanding service area population, WaterOne identified the need to construct a new water treatment plant and source of supply with a projected long-term capacity of 150 mgd. The expansion program began with an evaluation of the best source of supply.

WaterOne has chosen to implement horizontal collector wells for the first 60 mgd of their expansion. Several factors drove that decision including the following:

- Water pumped from a collector well has relatively consistent water quality and temperature compared to surface water, and it is easier to treat than surface water.
- The water level in the Missouri River has declined over the years due to riverbed degradation.

- Expansion of a collector well supply can be phased more easily than a surface water supply allowing WaterOne to defer costs.

INIITIAL EXPLORATION

Exploration to determine potential locations for horizontal collector wells began with a series of test holes drilled into the alluvium of the Missouri River north of WaterOne's service area. A series of seven borings were drilled and short-term low capacity pumping tests were conducted along a one- mile stretch of the river alluvium.

The borings encountered bedrock approximately 90 to 99 feet below grade. Generally, the top 15 to 20 feet of the formation is sandy silt. From a depth of 20 feet to approximately 55 feet, the aquifer consists of coarse sands. Below 55 feet, the aquifer is very coarse consisting of gravels and sands. Based on the short term pumping tests, estimates of transmissivity were made. Transmissivity is an indication of the ease with which water moves through an aquifer. The estimated range of transmissivity was 300,000 gpd/ft to 650,000 gpd//ft, indicating a highly productive aquifer. Based on the initial results a more detailed aquifer test was conducted.

AQUIFER TESTING

In June of 2005, a detailed aquifer test was performed for Water One north of Wolcott, Kansas, on newly acquired property adjacent to the Missouri River just upstream of River Mile 385. The purpose of the test was to determine the quantity and quality of water that can be obtained at the site by a new horizontal collector well and to help estimate the amount of water that can be obtained by additional future collector wells across the site.

Using the results of the borings and initial testing conducted in 2003, it was determined that the site conditions were favorable for large capacity horizontal collector wells and worthy of additional, more detailed aquifer testing. In 2005, Water One purchased approximately 182 acres. The acquired property set the limits for the detailed aquifer test performed in June 2005. It was decided to perform the aquifer test in the northwest corner of the acquired property, near the location of a test boring from 2003 which indicated some of the best aquifer conditions across the site.

The aquifer test consisted of installing four new observation wells surrounding a new test production well. The test production well was pumped at a constant rate of approximately 1400 gpm for 48 hours, and groundwater level readings were taken from the surrounding observation wells. The Missouri River level was also monitored during the test. The results of the aquifer test indicate that a horizontal collector well at this location should be able to produce up to 17 mgd in the winter and up to 26 mgd in the summer. The aquifer was shown to have a good hydraulic connection with the Missouri River at this location. Upon construction and testing of the first horizontal collector well, coarser aquifer material with higher

transmissivity was encountered than at the location of the nearby aquifer test. Initial yields of as much as 30 mgd are expected from this collector well, which will allow the construction of the second collector well to be deferred by two years.

The results of the aquifer test also provide an initial indication of potential capacities of additional horizontal collector wells in the area, assuming aquifer conditions and the connection of the aquifer with the river are similar in other locations across the site. It is estimated that four collector wells spaced at least 1000 feet apart across the site should be able to maintain the targeted 60 mgd of groundwater supply over a 50-year design life, factoring in loss in well production due to future riverbed degradation and routine lateral maintenance to control the normal loss in well capacity due to natural plugging of the lateral screens.

Over time, wells typically lose capacity due to clogging of the lateral screens and adjacent aquifer. This clogging is primarily the result of migration of fines, chemical precipitation, and bacterial growth. The rate of screen plugging and subsequent loss of efficiency within a horizontal collector well is generally much lower than a typical vertical well as the design entrance and approach velocities are much lower.

In this setting, well capacity will also likely diminish over time because the bed of the Missouri River is degrading. Over the last 70 years, the level of the Missouri River at Kansas City has declined by an average of about 8 feet under low to average flows. The reduction in water level also causes a reduction in saturated thickness of the aquifer and corresponding loss in available drawdown in the well. Over the course of 50 years, it is estimated that the yield of a collector well may be reduced by about 15% if the rate of decline in water levels in the Missouri River continues.

The above resulted in the following assumptions for estimating collector well and wellfield capacity over the 50-year planning period.

- Loss of well capacity, including river degradation is 6% after 3 years and 3% per year thereafter.
- Well redevelopment is performed at the frequency necessary to maintain the desired total system yield of 60 mgd.
- 90% of the previous well capacity is regained each time a well is redeveloped.
- 95 % of the previous well capacity is regained when new laterals are installed.

Based on these assumptions, each well will have its laterals replaced once and will require 10 well redevelopments. This indicates that four collector wells with average capacity of 15 mgd are adequate to reliably produce 60 mgd over the 50-year planning period.

RAW WATER QUALITY

Groundwater quality testing was also performed in 2005 to determine both the water quality at the location of the aquifer test and the water quality between the newly acquired property and the industrial area located to the west. A comprehensive groundwater sample was collected at the end of the detailed aquifer test. This sample was analyzed for the following parameters:

- General chemistry (including such parameters as pH, hardness, alkalinity, etc.).
- Metals.
- Microbiology.
- Radionuclides.
- Disinfection byproducts.
- Volatile and semi-volatile organic chemicals.
- Viruses.
- Asbestos, dioxin, foaming agents.
- Dissolved gases.

No man-made organic chemicals were detected in this groundwater sample. The parameters of interest from a treatment standpoint for this groundwater sample are provided in Table 1.

This groundwater sample was collected after only 48 hours of pumping at approximately 1400 gpm. A future collector well at this site will be pumped nearly 10 times this rate for much longer periods of time and will induce a much larger percentage of surface water. Therefore, the raw water quality being pumped by the collector well is expected to change somewhat over time. Table 2 shows how the raw collector well water quality has changed over time for another nearby well.

Table 1. Selected Laboratory Results for Groundwater Sample

Parameter	Result	Units	Regulatory Maximum Contaminant Limit (MCL)
Iron	8.7	mg/L	0.3 (Secondary MCL)
Manganese	1200	ug/L	50 (Secondary MCL)
pH	6.99	pH units	6.5 to 8.5
Dissolved solids	600	mg/L	500 (Secondary MCL)
Turbidity	84	NTU	-
Total alkalinity	510	mg/L as CaCO3	-
Total hardness	500	mg/L as CaCO3	-

Based on the above characteristics, a softening process has been chosen to reduce mineral concentrations to a level WaterOne's customers are accustomed to.

The concentration of iron in the nearby raw collector well water has decreased significantly over the past five years. The concentrations of dissolved solids, total hardness, and total alkalinity have slowly decreased roughly 10 to 15 percent since startup of their collector well. The concentrations of these parameters tend to go up slightly in the cold winter months when the collector well pumps a higher percentage of groundwater because of the higher river water viscosity and lower Missouri River stages. The concentration of barium has decreased by about 40 percent over time for the nearby well. The concentration of manganese, however, has remained above 400 ug/L since startup. Similar long-term changes to raw water quality may occur at the WaterOne collector well site.

Table 2. Comparison to Nearby Collector Well Water Quality

Parameter	Units	Water One Test Result[1] (6/23/2005)	Nearby Startup[2]	Nearby Long-term[2] (4 years after startup)	Regulatory Maximum Contaminant Limit (MCL)
Iron	mg/L	8.7	4.4	0.4	0.3*
Manganese	ug/L	1200	480	580	50*
pH	pH units	6.99	7.33	7.36	6.5 to 8.5
Dissolved solids	mg/L	600	525	437	500*
Turbidity	NTU	84	13	NA	-
Total alkalinity	mg/L as CaCO3	510	212	198	-
Total hardness	mg/L as CaCO3	500	301	262	-

[1] Groundwater sample collected at test well
[2] Sample taken from plant influent
*Secondary maximum contaminant limit (SMCL)

Total dissolved gases in the groundwater were measured in the field at the same time the comprehensive sample was collected. The total dissolved gas pressure in the groundwater was slightly higher than that of barometric pressure, with a measured saturation of 106.5 percent. Such minimal over-saturation is not expected to significantly affect any treatment process. The measured dissolved oxygen concentration was low (approximately 0.33 mg/L) compared to the saturation concentration of 10 mg/L for fresh water at this temperature. The free carbon dioxide concentration was approximately 155 mg/L as measured by the total dissolved gases monitor and 110 mg/L as calculated from the pH and alkalinity data.

Historic pH and alkalinity data taken from the nearby collector well, indicate that the carbon dioxide concentration in the raw water pumped by their collector well is super-saturated. The concentration appears to peak approximately December of each year. This may be the result of a greater percentage of groundwater and reduced influence of surface water. There has however been an overall trend of reduced free

carbon dioxide concentration over time from approximately 40 mg/L to 10 mg/L over five years.

Based on the data from the nearby well, the carbon dioxide concentration at the WaterOne site is expected to decline over time. Two treatment alternatives are available for the removal of the excess free carbon dioxide: 1) air stripping and 2) reaction with caustic chemicals. Carbon dioxide can be removed from water through air stripping reasonably well and new designs eliminate the concerns over the potential for water to form scale in the aerator and potential biological fouling caused by the high iron concentration.

Without air stripping, additional lime would be required to remove the excess carbon dioxide. The lime added for this purpose would not accomplish any softening. Nearly 200 mg/L of lime would be required to remove 155 mg/L of free carbon dioxide and bring the solution to an equilibrium carbon dioxide concentration of 5 mg/L. This will result in nearly doubling the required lime dosage to treat the water. Additionally, 2.3 mg/L of additional calcium carbonate solids are generated for each part of free carbon dioxide removed, resulting in a substantial increase in solids.

Based on the free carbon dioxide levels, induced draft aeration was implemented at the new water treatment plant Aeration will help to offset the cost of additional lime and solids. For lime softening plants, when raw water free carbon dioxide concentrations exceed 20-25 mg/L, aeration is a cost effective solution.

INDUSTRIAL ACTIVITY

There is an existing industrial area consisting of grain elevators and above-ground tanks located approximately one half mile to the west of the newly acquired property. Products such as liquid calcium chloride, liquid asphalt, sulfuric acid, diesel fuel, liquid propane gas, molasses, coconut oil, gasoline, and methyl ester have historically been stored or handled at the site. It was decided to collect several screening groundwater samples to the west of the collector well site to determine if there is any contamination in the area from the industrial area. A small drilling rig called a “Geoprobe” was mobilized to the site, and two small diameter test wells were drilled. The first test well was drilled through the sands and gravels to a depth of 90 feet where bedrock was encountered. A groundwater sample was collected from the bottom of this test well and submitted to the laboratory for analysis of volatile organic chemicals. Adjacent this test well, another test well was drilled to a depth of 20 feet, which was just below the groundwater table. A groundwater sample was collected from this test well and submitted to the laboratory for analysis of volatile organic chemicals, semi-volatile organic chemicals, and metals.

The results of the laboratory analysis showed no detection of organic chemicals from either sample. Various metals were detected in the shallow sample at rather high concentrations. It was believed that the detection of some of the metals

was caused by soil particles in the unfiltered groundwater sample collected from the Geoprobe.

Later in 2005 during the Environmental Site Assessment activities at the site, it was revealed that there was a barge unloading facility operated to the west of the proposed collector well site for several years in the 1970s reportedly for storage and transport of oil products. Because of this finding and the interference of the first metals analysis by the soil particles, another set of geoprobe samples were collected. A shallow groundwater sample was collected at the western end of the site and both a shallow and deep groundwater sample were collected at the eastern end of the site.

The shallow samples were tested for metals, pesticides and industrial chemicals, PCBs, and other volatile and semivolatile organics. The deep sample was tested for pesticides and industrial chemicals, PCBs, and other volatile and semivolatile organics. The raw groundwater was filtered in the field prior to collection to reduce the amount of sediment in the samples. None of the metals concentrations were above the primary drinking water MCLs. Only iron and manganese were above the secondary MCLs.

The only organic chemical that was detected was in the deep geoprobe sample collected at the eastern site. Di(2-ethylhexyl)phthalate was detected at a concentration of 0.7 ug/L, which is just above the minimum detection limit of 0.6 ug/L for the laboratory apparatus and is below the primary drinking water MCL of 6 ug/L. The laboratory indicated that this detection of di(2-ethylhexyl)phthalate is suspect because their quality control procedures indicated that the laboratory equipment may have been reading high during the analysis. This compound is also found in plastic products and may have been introduced in the laboratory by such items as bottles or gloves at such a low concentration.

CONCLUSION

WaterOne has successfully implemented the first horizontal collector well with a yield greater than originally projected. The water treatment plant is under construction and expected to be on-line in 2009. These are the first steps in ensuring a long-term reliable water supply for its customers for the next 50 years.

A Heuristic Algorithm for Optimal Alignment and Matching of Borehole Stratigraphy

Gustavious P Williams, Norman Jones, and Jeffrey Handy

ABSTRACT

This paper presents an heuristic algorithm, Auto-Align Boreholes (AAB), that computes near-optimal stratigraphy sequences from borehole horizons to define subsurface geology in a computationally efficient manner. Matching horizons across boreholes is not trivial and problem complexity grows exponentially with the number of horizons and boreholes. Our algorithm is based on the Smith and Watermen algorithm used in gene sequencing with modifications.

Our algorithm computes a near optimal alignment between the horizons, subject to constraints. Matching horizons to develop subsurface models has traditionally been done manually, but for large sets of boreholes, manually selecting the horizons becomes difficult. Other methods exist to compute optimal sequences but they become computationally infeasible for even moderate numbers of boreholes.

The optimal alignment problem can be solved exactly by a multiple sequence alignment distance matrix (an exhaustive search method) but is computationally infeasible for even moderate-sized borehole sets. The literature presents other approaches such as dendrographic algorithms and genetic algorithms. Dendrographic method computational requirements vary with the number of borehole pairs squared (or cubed) and the results depend on the order in which sequences are paired. Genetic algorithms must be run many times to ensure that the solution found is not a local minimum (of which there many) and requires a long runtime if the number of boreholes is relatively large.

The AAB algorithm was implemented in the Groundwater Modeling System (GMS), a subsurface pre- and post processing system developed by the United States Army Corps of Engineers. The GMS system can compute and present the borehole horizon information to generate subsurface stratigraphic models.

1. Introduction

This paper presents a new heuristic algorithm, Auto-Align Boreholes (AAB), that computes near-optimal stratigraphy sequence alignments among borehole horizons to define subsurface geology layers and structures. A horizon is a geologic layer boundary and defines the top of the layer. Matching a horizon across numerous boreholes is not a trivial problem since there are many potential matches and the problem complexity grows rapidly with the number of horizons and boreholes (Robinson 1975).

The algorithm presented in this paper computes a near optimal alignment between the horizons, subject to constraints and can be used to develop fence diagrams or more complete subsurface volume models (Lemon and Jones 2003; Fugal 2005). Matching horizons to develop these subsurface models has traditionally been done manually (Lemon and Jones, 2003), but for large sets of boreholes, manually selecting the horizons becomes difficult (Fugal, 2005). Methods exist to compute an optimal sequence, based on the imposed constraints, but this approach quickly becomes computationally infeasible (Smith and Waterman 1980, Waterman and Raymond 1987, Fugal 2005). The AAB algorithm provides an automated means to assign horizons to borehole material interfaces in a computationally efficient, realistic manner.

The AAB algorithm for computing horizon alignments among boreholes presented in this paper was implemented in the Groundwater Modeling System (GMS), a subsurface pre- and post processing system developed by the United States Army Corps of Engineers (USACE) (Jones *et al*., 2002). The GMS system is an integrated pre- and post-processing system for groundwater flow and contaminant transport models and can present the borehole horizon information to users who can use it to generate subsurface stratigraphic models (Jones *et al*., 2002; Lemon and Jones 2003).

1.1 Historic Work

Sequencing of stratigraphic logs and matching layers among boreholes has traditionally relied on a geologist or practitioner to visually connect the material interfaces (horizons) in the boreholes to each other to define a material horizon (Robinson 1975). To support this manual approach early computational work, such as Robinson's (1975), focused on methods to transform borehole and well log data to better present sequences to the practitioners for manual matching.

There was significant work on computational methods for automatically sequencing proteins that mainly occurred in the biological sciences where there was a need for sequencing the genome and other data. These sequences were developed from overlapping or correlated strands of proteins that are analogous to soil layers in a borehole. Smith and Watermen (1980) extended this biological work to the geology problem and presented a dynamic programming technique (SW) to use the data from several boreholes to develop a single optimal stratigraphy for use in geochronology. Waterman and Raymond (1987) extended the SW technique to deal with the problem of gaps and added differing weighting methods to the earlier approach. The AAB algorithm presented in this paper is based on the SW technique.

Tipper (1988) provides a detailed history of this field in a review and annotated bibliography on quantitative geologic stratigraphic correlation that includes over 400 citations detailing the quantitative work done in the field up to that point

1.2 AAB Algorithm Overview

The AAB algorithm computes a set of connections between the horizons at each borehole to define the boundaries of the geologic units in the subsurface. This is done by matching stratigraphy horizons found on multiple boreholes to each other, subject to constraints that maximizes the number of common horizons connected between boreholes and minimizes the slope between the horizon locations on adjacent boreholes. The optimization problem is solved heuristically, which does not guarantee optimality.

The optimal alignment for a borehole alignment problem can be solved exactly by tracing a two dimensional multiple sequence alignment (MSA) distance matrix (Smith and Waterman 1980) which is an exhaustive search that determines the optimal solution based on the given constraints. However, the MSA approach using distance matrices cannot be used for even moderate-sized sets of boreholes due to the large number of traces required to create the distance matrix. For example, if one hundred boreholes with a geometric average length of eight segments (or horizons) were used, it would require 8^{100} or $2.04*10^{90}$ traces within the distance matrix to determine the optimal alignment, with each trace requiring several computer operations (Fugal 2005). This number of calculations is intractable with the computational resources available today.

The literature presents several approaches to the computational issues associated with MSA problem such as dendrographic algorithms (Do *et al.*, 2005) and genetic algorithms (Yokoyama et al. 2001). Dendrographic algorithms align only two or three sequences at a time; then align two or three pairs of sequences together; then two or three groups of sequences until the entire borehole set is aligned. With this method the computational requirements vary proportionally to the number of pairs squared (or cubed) rather than exponentially as with the exhaustive method (Do *et al*., 2005). The primary difficulty with this method is the optimality of the results depend greatly on the order in which sequences are paired. Various methods have been derived for optimizing the order in which sequences are paired within these algorithms—many of which appear to be very promising (Do et al., 2005).

Genetic algorithms have also explored (Yokoyama et al., 2001). However, a genetic algorithm must be run many times to ensure that the solution found is not a local minimum within the solution space which requires a long runtime if the number of boreholes is relatively large (Yokoyama *et al.*, 2001).

The AAB algorithm we developed provides a method to compute a near optimal alignment between boreholes in a computationally efficient manner. Our algorithm is based on the Smith and Watermen algorithm MSA approach (1980) with modifications and additions to address various issues.

The AAB algorithm differs from the globally optimal MSA method by performing the alignment in stages based on the calculation of only a portion of the distance matrix. This results in near-optimal solution that may not be globally optimal. The AAB algorithm follows a stepwise path through the matrix until an entire alignment is computed. Because only one path—or a few—is considered, this method seems to have the same weakness as the dendrographic and genetic algorithm methods. However, the AAB algorithm does not rely on predictive pairing of sequences, as with the dendrographic method, and it is always progressive, and therefore can be more time efficient than the genetic algorithm approach.

2. Algorithm Development

The AAB algorithm solves two main issues found with the SW approach, the computational complexity and the fact that using gap minimization as the only constraint often results in alignments that are not geologically practical (Fugal 2006).

To develop the heuristic AAB algorithm, we modified the distance matrix approach (Smith and Waterman, 1980; Needleman and Wunsh, 1970) with the addition of a slope constraint to address the geological issues and used heuristic search methods to address the computational issues. This section presents the traditional MSA approach and the AAB modifications.

2.1 Traditional MSA distance matrix

The simplest MSA distance matrix formulation finds the longest common subsequence of two sequences. The algorithm written for matrix of two dimensions is (Smith and Waterman, 1980):

$$d_{ij} = \begin{cases} m_i = m_j & \min(d_{i-1,j-1}, \quad d_{i,j-1}+1, \quad d_{i-1,j}+1) \\ m_i \neq m_j & \min(d_{i,j-1}+1, \quad d_{i-1,j}+1) \end{cases} \qquad \textbf{Eq 1}$$

Where: d is the distance (optimization value for $cell_{i,j}$)
m_i and m_j are sequence segments on sequences 1 and 2 respectively

Equation 1 generates a complete distance matrix that defines every possible set of alignments between two boreholes. In this matrix, the calculated cell value, d_{ij}, is the minimum number of gaps that could exist in an alignment between the two boreholes starting at the origin (upper left corner) and continuing to the point represented by the cell.

After computing the distance matrix, the optimal alignment is found by starting at the corner of the matrix where *i* and *j* are at their maximum and performing a recursion to define the alignment. The recursion moves from the current chosen cell to the next by examining the values used to calculate the current cell and selects the cell from this set with the minimum value. The trace is selected from the cells used to define each cell value which is calculated using the cells above or to the left of itself (Equation 1). By picking the minimum of these cell values, we select the trace which defines the optimal alignment by minimizing the number of gaps in this formulation. In the Figure 1 pseudo

code representation, the *trace* vector, is a list of cells which define the optimal alignment. If the values in two or more cells are equal, the solution is ambiguous. Either selection with result in a trace-back that is equally valid. For convenience, the algorithm simply chooses one.

Start
    l = 0
    select trace(l) = cell($d_{m,n}$)
    l = 1
    Do until cell is $d_{0,0}$
        select trace(l) = min { cell($d_{m-1,n}$), cell($d_{m,n-1}$), cell($d_{m-1,n-1}$)
        Cell($d_{m,n}$) = cell(trace(l)
        l = l +1
    EndDo
End

Figure 1 Pseudo code to compute the optimal trace from a distance matrix.

2.2 Slope Constraint

The traditional DMA approach described above gives results which are not always geologically likely. To better match the physical geologic constraints, we modified the traditional DMA approach by adding stratigraphy slope as a second constraint which better mathematically represents the physical constraints on the problem. The slope is defined as the elevation difference between the two connected horizons divided by the distance between the boreholes.

Equation 2 is the modified distance matrix equation with the addition of this constraint.

$$d_{ij} = h \cdot S_{ij} + \begin{cases} m_i = m_j & \min(d_{i-1,j} + g,\ d_{i,j-1} + g,\ d_{i-1,j-1}) \\ m_i \neq m_j & \min(d_{i-1,j} + g,\ d_{i,j-1} + g) \end{cases} \qquad \textbf{Eq 2}$$

Where:

d = distance (optimization) value for $cell_{ij}$
m_i and m_j = $material_i$ on borehole 1 and $material_j$ on borehole 2, respectively
S_{ij} = slope between material segments m_i and m_j
g = gap weight
h = slope weight

The two weighting factors are used to adjust the relative impact of slope and gap constraint violation in the alignment optimization. The addition of this additional constraint significantly improves the geologic representation of the resulting alignment (Fugal 2006).

2.3 Optimality function

The function be minimized by the *Auto-align boreholes* algorithm includes the number of gaps in the alignment and the slope of the connecting horizons is calculated according to Equation 3.

$$Error = w_G \sum_{i=0}^{n} \left(N - H_i\right) + w_S S \qquad \textbf{Eq 3}$$

Where :

S = slope error given in Equation 4,
N = number of horizons in the borehole set
H_i = number of horizons on borehole$_i$
w_G and w_S = weights given to the gap error and slope error, respectively.

In order to obtain the total slope error, borehole adjacency is determined by performing an adjusted Delaunay triangulation where a normal Delaunay triangulation is performed and then adjusted so that all existing cross sections in the model are honored and thin exterior triangles are deleted. Boreholes are then paired with each adjacent borehole as determined by the triangulation. The slope error for each of these borehole pairs is then calculated and summed to give the total slope error according to Equation 4.

$$S = \sum_{i=0}^{N} \left[abs\left(\frac{\left(a_0 - a_i\right) - \left(b_0 - b_i\right)}{d \cdot N \cdot S_0} \right) \right] \qquad \textbf{Eq 4}$$

Where:

S = Weighted slope error
a_0 and b_0 = base elevation for boreholes a and b respectively
a_i and b_i = elevation of horizon pair i in boreholes a and b respectively
d = distance between boreholes a and b
N = number of horizon pairs
S_0 = average horizon slope.

The variables a_0 and b_0 depend on whether the user wishes to compare slope to a level surface ($a_0 = b_0 = 0$) or the ground surface elevation. The average horizon slope is a user defined parameter that normalizes the slope error to an expected horizon slope.

3. Conclusions

The primary result of the creation of this algorithms is that reasonable stratigraphy models can now be created in a matter of minutes rather than in hours or days. For most finite element analysis projects, multiple models must be tested in order to obtain a stable model and informative results. The process of creating such models will likely be greatly facilitated by the implementation of this project.

This AAB algorithm has been shown to be very successful in almost every borehole case tested. Whereas the time requirements for this algorithm increase exponentially when

increasing the number of horizons considered per lift, using the default value for this parameter allows the algorithm to be completed in a relatively small amount of time.

The primary benefit of this new method of creating three dimensional stratigraphy models is not that it returns better results than could be obtained any other way, but that it gives good results faster than any other method.

ABSTRACT

A constant-head test, keeping the buildup or drawdown constant in the test well, is aimed at determining the aquifer parameters. A skin zone around the wellbore due to well drilling or completion has diverse property to the aquifer. Five parameters including the transmissivities and storage coefficients for each of the skin and aquifer zones and the outer radius of the skin zone are determined via the simulated annealing approach to describe the flow system with a finite-thickness skin. Estimated results indicate that analyzing the single-well responses, i.e., test-well flow rate and observation-well drawdown data separately, is insufficient for obtaining accurate estimates for skin and aquifer parameters. Analysis of specific drawdown in an observation well gives biased results in the negative-skin case. The skin and aquifer parameters appear to be accurately determined when the flow-rate and drawdown data are analyzed sequentially or simultaneously.

INTRODUCTION

In a constant-head test (CHT), the buildup or drawdown in the test well is kept constant throughout the test. The transient flow rate at the test well or dispensable buildup/ (drawdown) in an observation well is measured for site characterization. Jacob and Lohman (1952) derived the flow-rate solution for a CHT conducted on a fully penetrating well in a confined aquifer. They showed that the aquifer transmissivity and storage coefficient can be estimated by analyzing the large-time specific drawdown data (i.e., drawdown divided by flow rate) measured in the test well. Mishra and Guyonnet (1992) analyzed the specific drawdown in the

observation well to determine the aquifer parameters. Hiller and Levy (1994) showed that only the hydraulic diffusivity can be determined if drawdown data from an observation well is adopted in the analysis. A skin zone around the wellbore with diverse properties to the aquifer may exist after well drilling or completion. The skin can be classified into two categories: a positive skin having a smaller value of transmissivity than the aquifer zone while a negative skin having a larger one. Figure 1 represents a CHT operated in a confined aquifer with a skin zone around the test well. The analytical solutions for flow rate at the test well and drawdown in an observation well considering the skin effect were developed by Yang and Yeh (2002) and Yang and Yeh (2006), respectively.

This paper aims to show the most reliable ways in the parameter estimation from the analyses of various CHT data sets. The analyses are classified into two categories based on the well number. First, the single-well CHT responses being analyzed include the wellbore flow rate at the test well and drawdown in an observation well. Next, the multi-well responses are analyzed in three ways: interpreting the specific drawdown data in an observation well, examining the flow-rate and drawdown data in two stages, and analyzing the flow-rate and drawdown data simultaneously. The CHT is assumed to be conducted on a fully penetrating well in a confined aquifer with a finite thickness skin. The parameter estimation is achieved using the simulated annealing (SA) approach. The results of this work could provide instructive information in the analysis of the skin-affected CHT data.

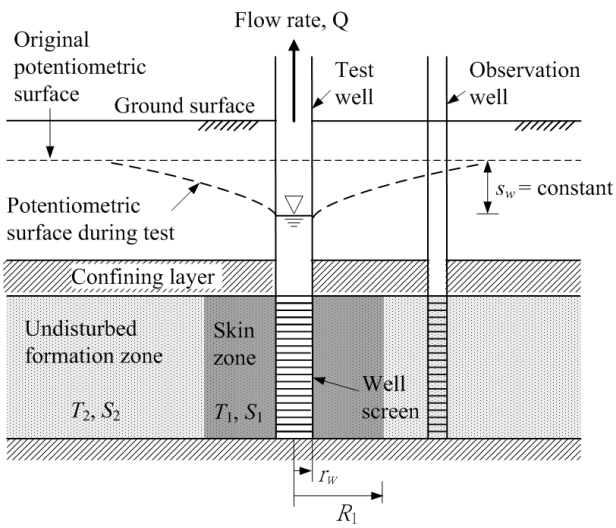

Figure 1. Schematic representation of skin-affected CHT in a confined aquifer.

METHODOLOGY

CHT solution. Yang and Yeh (2002) gave the flow-rate solution in the Laplace domain when the CHT conducted on a fully penetrating well in a confined aquifer with a finite thickness skin as

$$\overline{Q}(p) = \frac{2\pi r_w T_1 s_w q_1 [\Phi_1 I_1(q_1 r_w) + \Phi_2 K_1(q_1 r_w)]}{p[\Phi_2 K_0(q_1 r_w) - \Phi_1 I_0(q_1 r_w)]} \tag{1}$$

and the drawdown solutions as

$$\overline{s}_1(r, p) = \frac{s_w [\Phi_1 I_0(q_1 r) - \Phi_2 K_0(q_1 r)]}{p[\Phi_1 I_0(q_1 r_w) - \Phi_2 K_0(q_1 r_w)]} \tag{2}$$

and

$$\overline{s}_2(r, p) = \frac{s_w [\Phi_1 I_0(q_1 R_1) - \Phi_2 K_0(q_1 R_1)] K_0(q_2 r)}{p[\Phi_1 I_0(q_1 r_w) K_0(q_2 R_1) - \Phi_2 K_0(q_1 r_w) K_0(q_2 R_1)]} \tag{3}$$

with notations Φ_1 and Φ_2 respectively defined as

$$\Phi_1 = \sqrt{\frac{S_2 T_2}{S_1 T_1}} K_0(q_1 R_1) K_1(q_2 R_1) - K_1(q_1 R_1) K_0(q_2 R_1) \tag{4}$$

and

$$\Phi_2 = \sqrt{\frac{S_2 T_2}{S_1 T_1}} I_0(q_1 R_1) K_1(q_2 R_1) + I_1(q_1 R_1) K_0(q_2 R_1) \tag{5}$$

where $\overline{Q}$ is the flow rate across the wellbore in the Laplace domain; $\overline{s}_1$ and $\overline{s}_2$ describe the drawdown responses in the skin and aquifer zones, respectively; p is the Laplace variable; r denotes the location of the observation well; r_w is the radius of well; s_w is the constant drawdown maintained at the well during the test; T and S are the transmissivity and storage coefficient with the subscripts 1 and 2 representing the skin and aquifer zone, respectively; R_1 is the radial distance from centerline of well to outer boundary of skin zone; $q_1 = \sqrt{pS_1 / T_1}$; $q_2 = \sqrt{pS_2 / T_2}$; I_0 and K_0 are the zero-order modified Bessel functions of the first and second kinds, respectively; and I_1 and K_1 are the first-order modified Bessel functions of the first and second kinds, respectively.

Parameter estimation method. Analysis of a specific CHT data set, e.g., flow-rate data or drawdown data, was formulated as a single-objective problem with the objective function defined as the minimum sum of squared residuals. If both

flow-rate and drawdown data are fitted simultaneously to their solutions during the parameter estimation, a simple extension on objective function that combined the weighted sums of squares for both responses will be applied. The weight implemented on the flow-rate component of sum of squares has the unit in day^2/m^4. SA algorithm, which was chosen to find the least value of the sum of squares, was similar to that described in Yeh and Chen (2007).

ANALYSES AND DISCUSSION

Assume a CHT was conducted in a silty confined aquifer. The fully penetrating well with 0.2-m diameter was maintained with a constant drawdown of 3 m during the test. The observation well was located at 1.2 m away from the test well. The hypothetical aquifers have parameters T_1 = 0.05 m^2/d and T_2 = 1.0 m^2/d for positive-skin cases, T_1 = 1.0 m^2/d and T_2 = 0.05 m^2/d for negative-skin cases, $S_1 = S_2 = 10^{-4}$, and R_1 = 0.8 m. The analyzed data of flow rate in the test well and drawdown at the observation well were respectively generated using Eqs. (1) and (3). The estimated results of skin and aquifer parameters using various data sets for positive-skin and negative-skin cases were listed in Table 1.

Analyses of single-well response. The analyses of single-well CHT responses include the wellbore flow rate at the test well and drawdown in an observation well being analyzed separately. Table 1 reveals that analysis of wellbore flow-rate data for the positive-skin case results in fairly good estimates for T_1, S_1 and R_1 but biased estimates for T_2 and S_2. As for the negative-skin case, all the estimated parameter values are close to the target values. However, since we may not know the skin type *a priori*, the estimates for the aquifer parameters are unconvinced via examining wellbore flow-rate data. For both positive- and negative-skin cases, analyses of drawdown data show accurate estimates for R_1 yet significant deviations for T_1, T_2, S_1 and S_2. In short, the analyses of drawdown data are incapable of accurately estimating the skin and aquifer parameters.

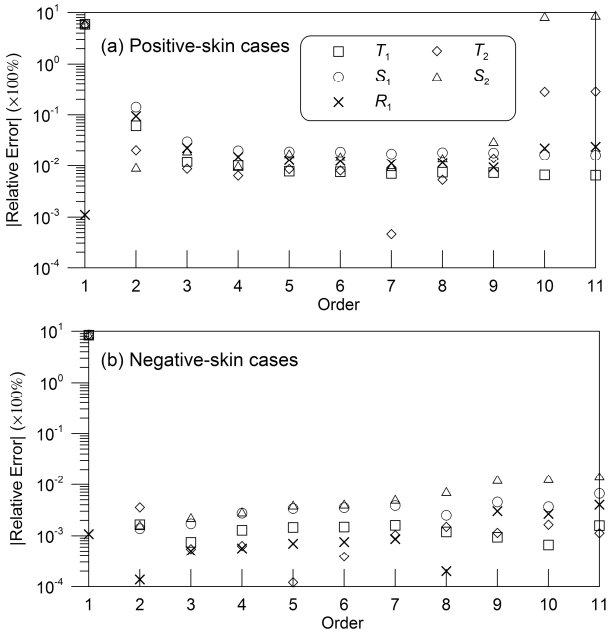
Analyses of multi-well responses. Three ways concerning the analyses of multi-well responses were considered. The first one analyzed the specific drawdown data in an observation well. Next, we fixed the skin parameters at the values obtained from the previous flow-rate data analysis and then determined the aquifer parameters only via the analysis of drawdown data. Finally, the flow-rate

and drawdown data were simultaneously fitted to their solutions using a weighted multi-objective optimization.

Table 1. Estimated skin and aquifer parameters using different sets of data.

Data sets being analyzed	Skin parameters			Aquifer parameters	
	T_1 (m^2/d)	S_1	R_1 (m)	T_2 (m^2/d)	S_2
Positive-skin cases					
Target value	**0.05**	**1.00×10^{-4}**	**0.8**	**1.0**	**1.00×10^{-4}**
Flow rate only	0.050	1.02×10^{-4}	0.819	0.718	9.91×10^{-4}
Drawdown only	0.345	6.88×10^{-4}	0.799	6.840	7.11×10^{-4}
Specific drawdown	0.048	1.09×10^{-4}	0.742	0.987	1.03×10^{-4}
Flow rate and drawdown[1]	0.050	1.02×10^{-4}	0.819	0.999	9.22×10^{-5}
Flow rate and drawdown[2]	0.050	1.02×10^{-4}	0.788	0.994	1.01×10^{-4}
Negative-skin cases					
Target value	**1.0**	**1.00×10^{-4}**	**0.8**	**0.05**	**1.00×10^{-4}**
Flow rate only	1.002	9.93×10^{-5}	0.803	0.050	9.85×10^{-5}
Drawdown only	9.389	9.50×10^{-4}	0.801	0.478	9.52×10^{-4}
Specific drawdown	7.525	7.09×10^{-4}	0.454	0.055	7.05×10^{-5}
Flow rate and drawdown[1]	1.002	9.93×10^{-5}	0.803	0.051	1.03×10^{-4}
Flow rate and drawdown[2]	0.999	1.00×10^{-4}	0.800	0.050	9.97×10^{-5}

[1] Flow-rate data is first used to determine the skin parameters (T_1, S_1, and R_1); drawdown data is then applied to determine the aquifer parameters (T_2 and S_2).



[2] Flow-rate and drawdown data are fitted to their solutions simultaneously; the weight applied on the flow-rate component of the objective function is 0.01 day^2/m^4.

The drawdown in the test well keeps constant during a CHT. Therefore, the estimated results for the five parameters from the analysis of specific drawdown response in the test well should be the same as those of flow-rate data. The specific drawdown data in an observation well were produced by the data generated using Eq. (1) divided by those generated using Eq. (3). The estimated parameter values for the positive-skin case, as indicated in Table 1, are fairly close to their target ones. However, for the negative-skin case, significant deviations are found in the estimations of skin parameters T_1, S_1 and R_1.

A two-stage analysis was applied to improve the accuracy of skin and aquifer parameter estimates. In the first stage, the three skin parameters were obtained from the single-well analysis of wellbore flow-rate data, since they reveal acceptable

estimates in both positive- and negative-skin cases based on the results of previous analysis. The values of skin parameters were fixed in the succeeding analysis. In the second stage, the drawdown data were applied to estimate the remaining aquifer parameters. Table 1 shows that the two-stage analyses significantly improve the estimated results for aquifer parameters. However, this method should be taken carefully because it serves only if the skin parameters had been correctly estimated.

The last analysis was achieved by fitting the flow-rate and drawdown data simultaneously to their solutions. The parameter estimation criterion was carried out by the weighted multi-objective function. Figure 2 demonstrates the estimated results for the cases using different magnitudes of weights on the flow-rate (w_1) and drawdown (w_2) components. The case of $w_1 = 0$ and $w_2 = 1$ represents the analysis of drawdown data only, which gives poor estimates on T_1, T_2, S_1 and S_2 for both positive- and negative-skin cases. For the cases of w_2 keeps one, Figures 2a and 2b reveal that even a small value of w_1 (e.g., $w_1 = 10^{-4}$ day^2/m^4) could significantly improve the estimated results for the positive- and negative-skin cases, respectively. On the other hand, the case of $w_1 = 1$ day^2/m^4 and $w_2 = 0$ represents the analysis of flow-rate data only, which obtains biased estimates on T_2 and S_2 but accurate estimates on the five parameters for the positive- and negative-skin cases, respectively. For the cases of w_1 keeps unique, the utilization of $w_2 = 10^{-4}$ during the composite analysis seems slightly improve the estimated results. However, it is suggested that, for positive-skin case, the value of w_2 is equal to or larger than 10^{-3} being used for further improving the estimated results. In fact, the flow-rate and drawdown data have the accuracy on the order of 10^{-2} m^3/day and 10^{-3} m, respectively. If the predicted flow-rate and drawdown data generated from the five estimated parameters are well fitted to their observed ones, the square sums for the flow-rate and drawdown components should be on the order of 10^{-4} m^3/day and 10^{-6} m, respectively. Therefore, in Table 1, the weight applied on the flow-rate component in the multi-objective function was chosen to be 0.01 day^2/m^4, so that the two objectives, i.e., the total sums of squared residuals, were balanced with the same unit and order. Table 1 reveals the estimated results for skin and aquifer parameters are in good agreements with their target values for both positive- and negative-skin cases. In short, composite analysis of flow-rate and drawdown data is highly recommended for obtaining accurate estimates of skin and aquifer parameters as long as the weights are carefully chosen.

Order	1	2	3	4	5	6	7	8	9	10	11
w_1 (day^2/m^4)	0	10^{-4}	10^{-3}	10^{-2}	0.1	1	1	1	1	1	1
w_2	1	1	1	1	1	1	0.1	10^{-2}	10^{-3}	10^{-4}	0

Figure 2. Absolute relative error plots for the five parameters with respect to various weights applied on the flow-rate (w_1) and drawdown (w_2) data in the composite analyses for (a) positive-skin and (b) negative-skin cases.

CONCLUSION

Two types of CHT analyses were considered, which were classified according to the analyses of well responses being conducted in a single or multiple wells. The analyzed results lead to the following conclusions. In the analyses of single-well responses, the use of flow-rate data yielded accurate estimates for skin parameters but might produce less reliable estimates for aquifer parameters. Next, the analyses of drawdown data were hard to obtain precise estimates for skin and aquifer parameters. In the analyses of multi-well responses, it seemed possible to obtain accurate aquifer parameters using the specific drawdown data when the CHT had the skin effect. In addition, the skin and aquifer parameters appeared to be determined accurately when both the flow-rate and drawdown data were employed in the two-stage analysis. Finally, simultaneous analyzing the flow-rate and drawdown data can obtain the most accurate estimates for all the five parameters if the weights in the objective function were carefully chosen. Therefore, it is highly

recommended to analyze the flow-rate and drawdown data simultaneously.

ABSTRACT

Heterogeneity of aquifer permeability has a significant influence on the transport of solutes; therefore accurate characterization of aquifer heterogeneity is needed to reliably predict the behavior of solutes. A critical characteristic of heterogeneity is the characteristic length scale that is a measure of the distance over which property values are correlated. We use two-dimensional continuous wavelet analysis to identify characteristic length scales of permeability in stationary and non-stationary porous media. We show that the global and local wavelet energy spectra are the appropriate measures to characterize length scales in stationary and non-stationary permeability fields, respectively. We demonstrate its effectiveness in identifying the characteristic length scales of two-dimensional synthetic permeability data.

INTRODUCTION

Flow and transport through porous media are affected by the heterogeneity of aquifer properties such as permeability. Permeability heterogeneity causes local velocity variations that enhance the dispersion of solutes migrating through the aquifer. Laboratory and field data have shown that both heterogeneity and dispersivity are scale-dependent (Gelhar, 1986; Silliman and Simpson, 1987; Tidwell and Wilson, 1999, 2000). In this paper, we use wavelet analysis to characterize dominant scales of permeability heterogeneity.

Wavelet analysis has recently been used to characterize spatial variability in geophysical systems. Spedding et al. (1992) used two-dimensional wavelets to obtain a scale-space decomposition of surface waves generated by unsteady winds. Kumar and Foufoula-Georgiou (1993) used wavelet transforms to decompose spatial rainfall fields into large-scale (mean behavior) and small-scale (fluctuations) features, and segregated components having characteristic features at different scales. Li and Loehle (1995) used wavelet analysis to identify scales of dominant structures in permeability of alluvial fan deposits in Nevada. Sahimi (2001) and Sahimi and

Hashemi (2001) used wavelet analysis of synthetic and real porosity data to identify the spatial distribution of rock fractures. Frantziskonis (2002) presented a wavelet analysis approach for characterizing scales of one-dimensional transects of porous material properties. Qi and Neupauer (2008) used a related method for identifying dominant scales in one-dimensional, stationary random fields.

Wavelet analysis has also been used to characterize dominant orientations in some geophysical systems. Kumar and Foufoula-Georgiou (1993) used wavelet transforms to isolate directional information to show the anisotropic behavior of rainfall intensity fluctuations. Kumar (1995) used a wavelet transform technique to analyze scale space anisotropy of spatial rainfall fields. Gaillot et al. (1997, 1999) used wavelet analysis to identify size, shape, and orientation in rock fabrics by identifying orientations of distinct boundaries between the mineral and the rock matrix. In a porous medium, permeability can vary gradually, without any distinct boundaries between regions. Neupauer et al. (2006) and Watkins et al. (2009) used a fully-anisotropic Morlet wavelet to demonstrate that wavelet analysis can be used to identify characteristic length scales and orientations in periodic statistically-heterogeneous permeability field.

In this paper, we present wavelet analysis as a method to identify characteristic length scales of permeability in stationary and non-stationary porous media. In the next section, we introduce wavelet analysis. In subsequent sections, we present a wavelet approach for analyzing characteristic length scales in stationary and non-stationary porous media.

BACKGROUND

Wavelet analysis involves the integral transform of a random space function (e.g., a permeability field), with a wavelet as the kernel. A wavelet is a zero-mean function that is non-zero over a finite region. In this work, we use the two-dimensional Mexican hat wavelet given by

$$\psi(\mathbf{x}) = \frac{1}{\sqrt{2\pi}}\left(2 - \mathbf{x}\cdot\mathbf{x}\right)\mathrm{e}^{-\mathbf{x}\cdot\mathbf{x}/2} \quad , \tag{1}$$

where $\mathbf{x} = (x,y)$ is a vector of spatial coordinates. Figure 1a shows a plot of the Mexican hat wavelet. The wavelet transform of a two-dimensional, zero-mean anisotropic function, $f(\mathbf{x})$, is given by

$$W_f(a,\mathbf{b},\theta,\Lambda) = \frac{\sqrt{\Lambda}}{a}\int_{-\infty}^{\infty} f(\mathbf{x})\psi^*\left(\frac{1}{a}\left[\mathbf{ACx}-\mathbf{b}\right]\right)d\mathbf{x} \quad , \tag{2}$$

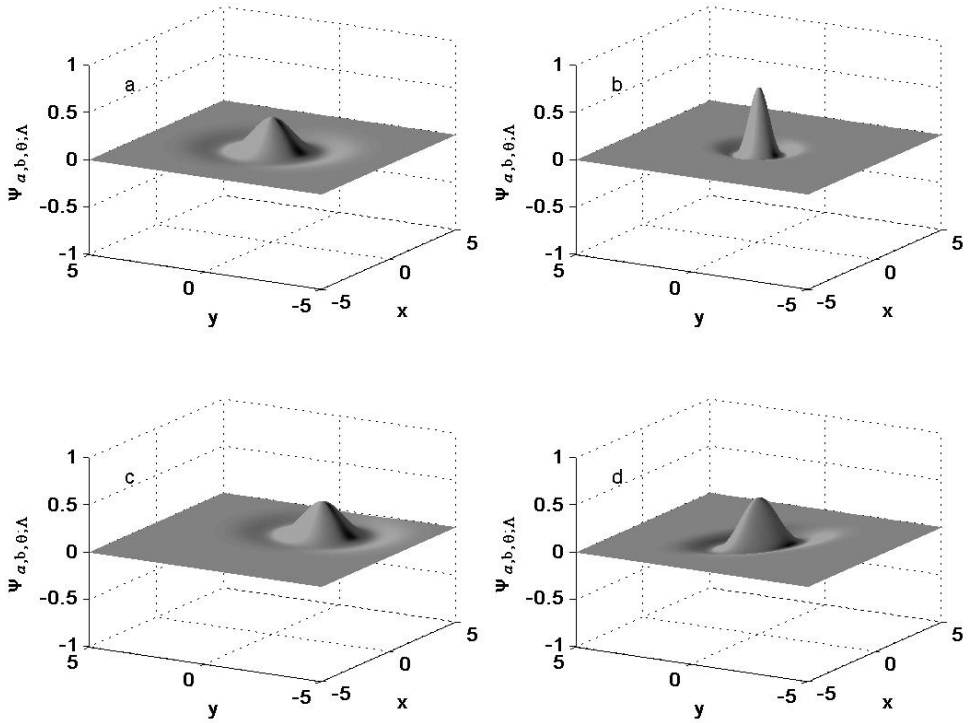

Figure 1. Mexican hat wavelet. (a) Standard wavelet. (b) Scaled wavelet with a = 0.5. (c) Shifted wavelet with (b_x,b_y) = (2,-1). (d) Anisotropic rotated wavelet with θ = -30° and Λ = 2.

where $W_f(a,\mathbf{b},\theta,\Lambda)$ is the wavelet coefficient, a is a scale parameter, $\mathbf{b} = (b_x,b_y)$ is a shift parameter, the asterisk denotes complex conjugate, **C** and **A** are rotation and anisotropy matrices, respectively, given by

$$\mathbf{C} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \qquad \mathbf{A} = \begin{bmatrix} 1 & 0 \\ 0 & \Lambda \end{bmatrix} \tag{3}$$

where θ is the orientation of the wavelet (defined as positive in the counterclockwise direction with θ = 0° in the +x direction), and Λ is the anisotropy ratio defined as the ratio of the length of the wavelet in the θ direction to the length of the wavelet in the direction perpendicular to θ. Figure 1b-d shows plots of scaled, shifted, and rotated wavelets, respectively.

To analyze a function using wavelet analysis, the wavelet transform in (2) is performed for a range of scales a, shifts **b**, orientations θ, and anisotropy ratios Λ, producing a five-dimensional wavelet coefficient (one scale dimension, two shift dimensions, one orientation dimension, and one anisotropy dimension). The wavelet

coefficients can be used to identify dominant features of the function $f(\mathbf{x})$, including the characteristic length scale. The characteristic length scale of $f(\mathbf{x})$ is related to the wavelet scale a at which a measure of the wavelet coefficient attains its maximum. The appropriate measure to use to determine the characteristic length scale depends on the character of the function.

WAVELET ANALYSIS OF STATIONARY RANDOM FIELDS

For periodic functions, the wavelet spectrum $|W_f(a,\mathbf{b},\theta,\Lambda)\ W_f{}^*(a,\mathbf{b},\theta,\Lambda)|$ can be used to identify the characteristic length scale at each position (e.g., Neupauer et al., 2006; Watkins et al., 2009). For each position $\mathbf{x} = \mathbf{b}$, the magnitude of the wavelet spectrum is relatively large at the wavelet scale a that is dominant at that position.

For random fields, the function $f(\mathbf{x})$ contains randomness; therefore the wavelet coefficients from (2) and the wavelet spectrum also contain randomness. For stationary random fields, the statistical properties of the random field do not vary in space; therefore the characteristic length scale is uniform throughout the random field. In the context of wavelet analysis, stationarity implies that the wavelet spectrum is independent of position $\mathbf{b}$. In other words, a single wavelet scale should be dominant throughout the entire $\mathbf{b}$ domain. In actuality, because of the randomness in $f(\mathbf{x})$, the wavelet spectrum does vary in the $\mathbf{b}$ domain.

Instead of using the wavelet spectrum to identify the characteristic length scales of stationary random fields, we use a measure related to the expected value of the wavelet spectrum. Qi and Neupauer (2008) and Qi (2008) showed that the global wavelet energy spectrum (GWES) is the appropriate measure for identifying characteristic length scales of stationary random fields. For a two-dimensional anisotropic random field $f(\mathbf{x})$, the GWES is defined as (Qi and Neupauer, 2009)

$$E(a,\theta,\Lambda) = \frac{\Lambda}{a^2}\left\langle \left| W_f(a,\mathbf{b},\theta,\Lambda)\right|^2 \right\rangle \tag{4}$$

where $E(a,\ \theta,\ \Lambda)$ is the global wavelet energy spectrum, the angle brackets denote expected value, and $|\ |^2$ denotes the L_2 norm. For a stationary random field, the spatial average of the wavelet spectrum (averaged over the $\mathbf{b}$ domain) is identical to the average wavelet spectrum based on many realizations of the random field; thus the GWES can be evaluated as

$$E(a,\theta,\Lambda) = \frac{\Lambda}{a^2}\left\langle \left| W_f(a,\mathbf{b},\theta,\Lambda)\right|^2 \right\rangle = \frac{\Lambda}{a^2 A}\int_{\mathbf{b}} \left| W_f(a,\mathbf{b},\theta,\Lambda)\right|^2 \, d\mathbf{b} \tag{5}$$

where A is the area of the spatial domain. The GWES is a three-dimensional function, with dimensions of scale, orientation, and anisotropy. If the principal directions of anisotropy are known, the wavelet transform can be performed for just

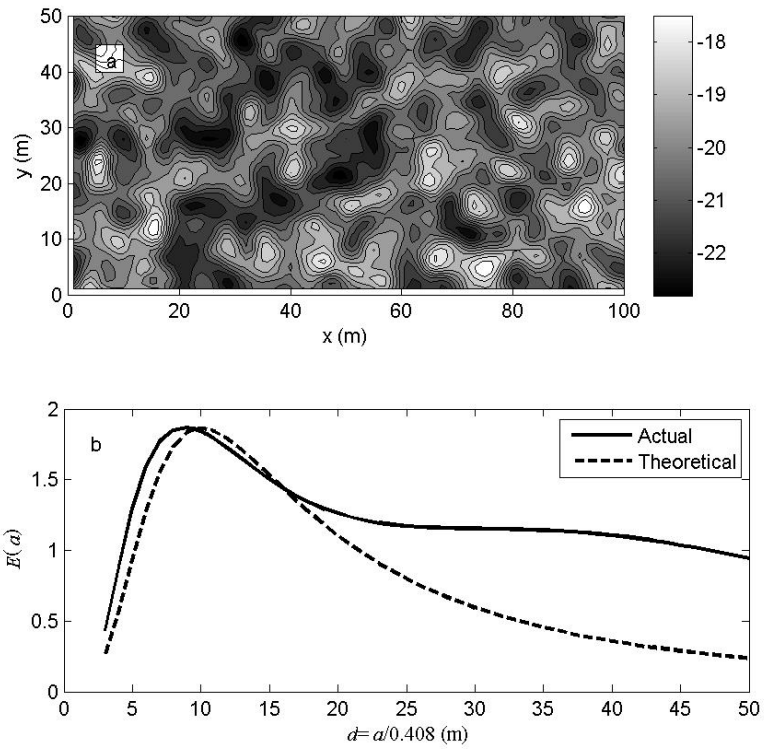

Figure 2. (a) Random field with Gaussian covariance with correlation length of 10 m. (b) GWES of random field.

the principal directions, and the GWES is essentially a two-dimensional function. For an isotropic random field, the statistical properties do not depend on orientation, so the wavelet transform must only be performed for a range of scales, with $\theta = 0^o$ and $\Lambda = 1$; thus the GWES is reduced to a function only of wavelet scale a. Let a_{max} be the wavelet scale at which the GWES attains its maximum. Qi (2008) has shown that the relationship between the characteristic length scale d of the random field and a_{max} depends on the dimensionality of the random field, the wavelet used in the analysis, and on the covariance structure of the random field. For a two-dimensional random field with Gaussian covariance, $a_{max}/d = 0.408$ when wavelet analysis is performed using the Mexican hat wavelet (Qi, 2008).

As an example, consider the two dimensional random permeability field shown in Figure 2a. This random field was generated using sequential Gaussian simulation from the GSLIB software package (Deutsch and Journel, 1992). It has an isotropic Gaussian covariance with a correlation length of 10 m and a spatial discretization of 1m. We performed wavelet analysis using (2) using $\theta = 0^o$ and $\Lambda = 1$ for this isotropic random field, and we used the resulting wavelet coefficients in (5) to calculate the GWES, which is shown in Figure 2b (solid line), where the horizontal axis is the length scale $d = a/0.408$, accounting for the relationship between wavelet scale and length scale. The GWES has a single peak that occurs at $d = 9$ m,

indicating that the characteristic length scale of the random field is approximately 9 m. Recall that this random field was generated with a correlation length of 10 m. Due to randomness, however, the correlation length is not exactly 10 m. Here, through wavelet analysis, we show that the correlation length is slightly smaller. For comparison, Figure 2b also shows the theoretical GWES (dotted line) for a random field with Gaussian covariance with correlation length of 10 m (see Qi (2008) for derivation). The GWES for this random field (solid line) is shifted slightly to the left relative to the theoretical GWES, indicating that the actual correlation length of the random field is slightly smaller than the theoretical correlation length.

WAVELET ANALYSIS OF NON-STATIONARY RANDOM FIELDS

For non-stationary random fields, the characteristic length scales may vary with position **b**; therefore the spatial average of the wavelet spectrum over the **b** domain is not identical to the expected value of the wavelet spectrum. In this situation, the second equality in (5) does not hold.

For non-stationary random fields, a more appropriate wavelet measure is the local wavelet energy spectrum, $E^*(a,\mathbf{b},\theta,\Lambda)$ (LWES), defined as (Farge, 1992)

$$E^*(a,\mathbf{b},\theta,\Lambda) = \frac{\Lambda}{a^2}\left|W_f(a,\mathbf{b},\theta,\Lambda)\right|^2 \tag{6}$$

for a two-dimensional function $f(\mathbf{x})$. Comparison of (5) and (6) shows that the GWES is the spatial average of the LWES.

We used sequential Gaussian simulation (Deutsch and Journel, 1992) to create a zonally-stationary random field with exponential covariance with correlation length of 100 m for $x < 1000$ m, and correlation length of 10 m for $x > 1000$ m (labeled Zone A and Zone B, respectively, in Figure 3a). The LWES of this random field is shown in Figure 3b, where the vertical axis is the length scale $d = a/0.42$. The denominator 0.42 is the ratio of wavelet scale to characteristic length scale for a one-dimensional random field with exponential covariance analyzed with a Mexican hat wavelet (Qi and Neupauer, 2008). The LWES has several isolated subregions with high magnitudes which represent subregions where the random field has strong spatial correlation. The characteristic length scale in those subregions is the scale d at which the LWES attains a local maximum. In Zone A, the characteristic length scales are around 100 m; while in Zone B, the characteristic length scales are around 10 m. Because of randomness in the random field, the LWES is not uniform within each zone. The average LWES for 1000 realizations of the random field (Figure 3c) shows a more uniform result, with the peak value of the LWES occurring at $d = 100$ m throughout most of Zone A, except at the edges; and the peak value of the LWES occurring at $d = 10$ m throughout Zone B except at the boundaries.

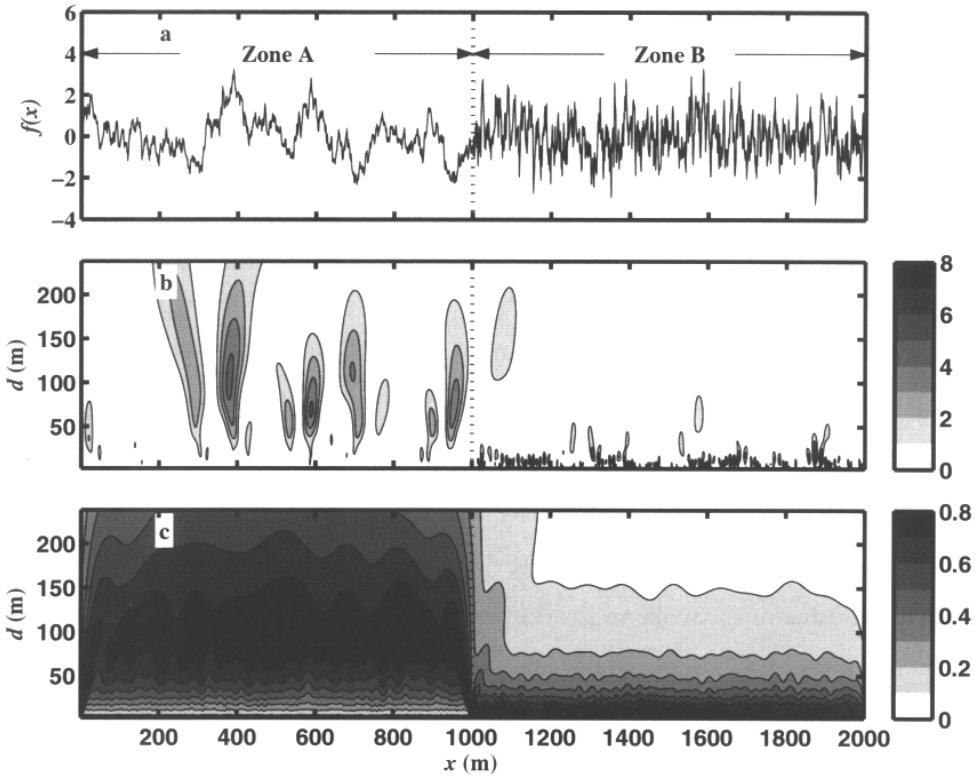

Figure 3. (a) Zonally-stationary random field. (b) LWES of random field. (c) average LWES over 100 realizations of random field. (from Qi, 2008).

CONCLUSIONS

Wavelet analysis can be used to identify characteristic length scales of permeability in statistically stationary and non-stationary porous media. For stationary random fields, the global wavelet energy spectrum has a single peak at a wavelet scale that corresponds to the characteristic length scale of the random field. For non-stationary random fields, the local wavelet energy spectrum must be used. It has local maxima at wavelets scales that correspond to characteristic lengths scales within a subregion of the random field that exhibits strong spatial correlation.

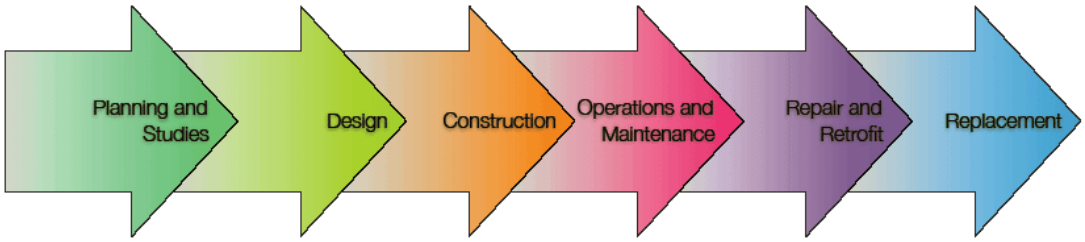
ABSTRACT

The environmental engineering core class at the University of Missouri-Kansas City has introduced a broader definition of "design" to the undergraduate students, and framed the open-ended work they produce in a design life-cycle, which is represented graphically.

STRUCTURE OF CLASS

The basic environmental engineering class at the University of Missouri-Kansas City focuses on water plant and wastewater treatment plant processes. In an effort to include more open-ended design project in the curriculum several years, the following format was established.

1. The class was divided into groups of three or four students.
2. Several different client town/cities were distributed to the groups. Variables include: town size/flow, soft or hard drinking water source, high or low dilution into receiving water (freshwater).
3. Four different designs are produced for the client town.
    a. Laboratory design
    b. Water plant design
    c. Wasteload allocation
    d. Wastewater treatment plant design



The variety of client types help educate students on plant designs different from those they visit on field trips in the class.

AMBIGUITY OF "DESIGN"

Discussions with an advisory board member revealed that when the faculty talks about "design" in engineering classes, we might imply very different steps in the overall design cycle. A graphic was created to differentiate various stages within a project to communicate

it to the students (see Figure 1).

Figure 1: Design process with environmental class indicated.

Water/Wastewater

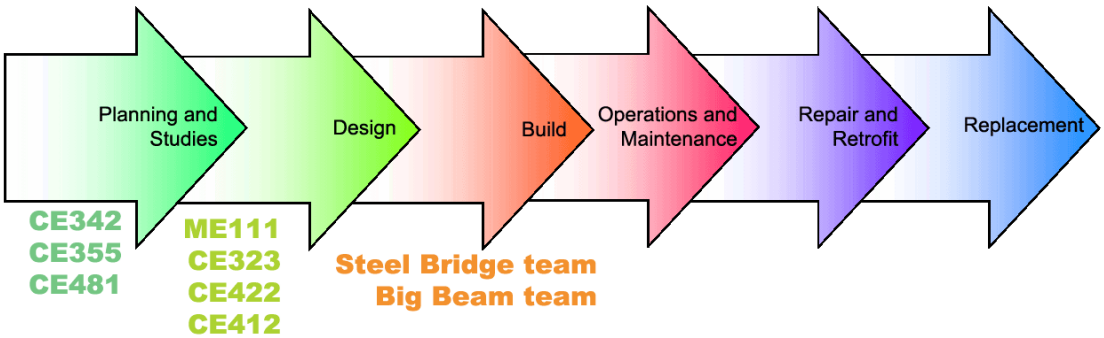
The graphic was printed in large format and posted several prominent places around the department.A modification of the student designs in the environmental engineering class now include a debriefing by professionals who can explain what comes next in the design sequence. The environmental engineering class produces brief planning reports, but are not specifying equipment or dealing with site topography. The professionals who now participate in the conceptual design review are

- architect, who share architectural plans for similar projects,
- water plant designer, who shares the blueprint set for a water plant,
- water quality modeler, who shares actual wasteload allocation efforts, and
- wastewater treatment plant designer, who shares portions of a blueprint set for a wastewater treatment plant.

HOW THE CURRICULA WORKS WITH THE DESIGN GRAPHIC

The required courses were evaluated by the faculty to show where they fit in the design sequence. The civil engineering courses are shown in Figure 2, and the mechanical engineering courses are shown in Figure 3.

Figure 2: CE Required Courses (CE342=Env. Eng; CE355=Water Resources; CE481=Traffic; ME111=freshman design; CE323=Concrete Design; CE422=Steel Design; CE412=senior design)



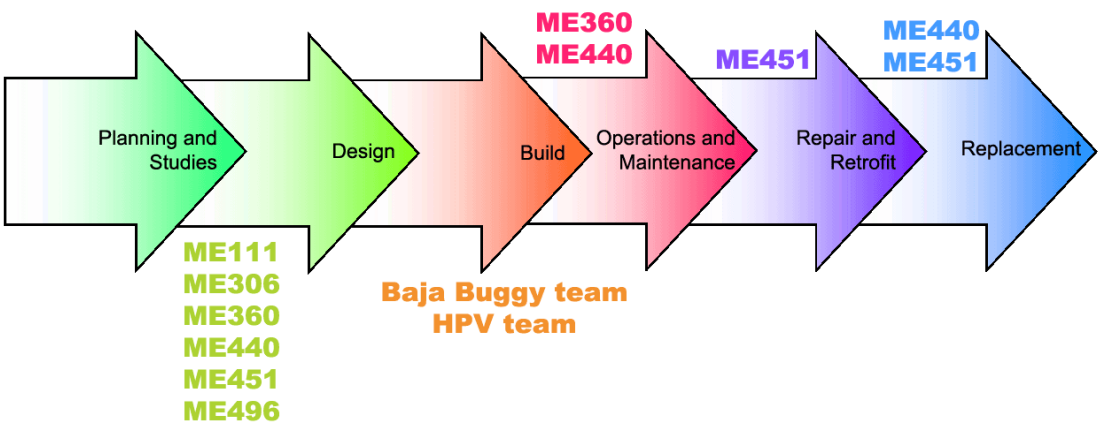


Figure 3: ME Required Classes (ME111=freshman design; ME306=; ME360=thermal systems design; ME440=heating&air conditioning; ME451 =power plant design; ME496=senior design)

CONCLUSION

The mechanical engineering curriculum presently does a better job of introducing students to the concepts of operations and maintenance, repair and replacement than the current civil engineering curriculum. The recent addition of construction engineering faculty will add the components of O&M and replacement into the civil engineering curriculum.

Integrating Design Heuristics in an Environmental Engineering Course

Kathleen M. Leonard

ASCE Fellow, Professor, Department of Civil and Environmental Engineering,
University of Alabama in Huntsville, Huntsville, AL 35899-0001;
PH (256) 824-6423; FAX (256) 824-6724; email: leonard@eng.uah.edu

ABSTRACT

Although design courses are mandatory requirements for all accredited engineering schools in the United States, in many cases these courses have become a technical exercise with little integration of management and innovation. As a result, current engineering educational strategies produce technicians lacking the advanced critical thinking and management skills required in the 21st century business environment. This paper presents a first approach to integrating modules on design heuristics into a mid-level environmental engineering design course. The goal is to facilitate students' skills in both understanding the mechanics of design and gain practice in research oriented design.

INTRODUCTION

Like most engineering schools, the University of Alabama in Huntsville (UA Huntsville), has several upper-level design courses that draw on technical knowledge accumulated during the students' academic career (while also fulfilling ABET requirements). At this point in their academic careers students are usually competent in integrating the technical tools, but have limitations associated with managerial skills and follow-through in design. In the past several years UA Huntsville has been aided in addressing these limitations by local civil engineering practitioners coming into the classroom as lecturers on topics such as "budgeting a project" and "resume writing skills."

Recently there has been discussion about the limitations of engineering education [Beder, Bordogna]. For example, the National Research Council (NRC) recommends that the engineering education system needs to become more flexible and adaptable to the changing needs of society [NRC]. We, as educators, are adept at traditional lecturing and assigning closed-ended problems. However, recent findings note that

students need to learn by doing, and that creative design skills can be sharpened if exercised. Unfortunately, towards the end of their academic careers students are usually competent in basic science, math and engineering knowledge, but have limitations in integrating these skills with solving a practical problem. One of the issues is novel idea generation. There are many different reasons for this problem. One explanation could simply be that civil engineering students do not have sufficient practice in open-ended problem solving. It may also be that engineering students get the subconscious message that there is only one way to solve problems from their early technical courses.

APPROACH

The environmental engineering curriculum at UA Huntsville includes an environmental engineering design class required of all majors. The design problems are "real-world" projects posed by local civil engineering companies and government agencies. The problem-solving heuristic used in this course is taken from Fogler and LeBLanc composed of five steps: define the problem, generate solutions, decide on a course of action, implement the solution and evaluate the solution. Several interactive classroom exercises were used to introduce problem-solving techniques such as brainstorming and Osborne's checklist. Next, they were introduced to decision analysis tools to assess solutions based on a list of performance objectives and design constraints. The students have to integrate ethics and cost analysis into the final design report and present their findings to the class with monthly research reports.

The project assigned to the students motivates students to use all levels of Bloom's Taxonomy for cognitive domain: integrating (1) knowledge to (2) comprehension through (3) application, (4) analysis: (5) synthesis, and (6) evaluation. A primary objective is to provide the Civil Engineering student with hands-on application of the principles of design and an opportunity for creativity.

The strategy of the course is to produce students who know "how to find out" and "how to examine and evaluate evidence." The following criteria were used in selecting the design problems:

- The design problems are "real" problems proposed by local clients, engineers and researchers.
- Each problem must have an experimental component that could be completed in the semester
- The students were introduced to performing research of refereed literature and technical data.
- The team must compile an experimental plan prior to any lab work
- The team must submit and verify weekly time sheets.

The approach in this study was to use the entire class to brainstorm ideas to solve each design problem. Then each individual two person team must research at least

three different alternatives and use a decision analysis technique to decide on the optimum solution. Each team is required to research, develop and then perform a bench-scale laboratory experiment to prove feasibility. Similarly, the concept of cooperative learning, an instructional method that involves people working in teams to achieve a common goal, was demonstrated by team teaching as documented by NRC.

Each team gives a final oral presentation to local professionals for twenty-five percent of their grade. It must incorporate the team objectives, approach to solving the design problem, all alternatives considered, their decision matrix, and laboratory results. This gives them practice with both oral and communication e benefits of this lecture extend throughout their college coursework for the presentations they will be required to make in most of their subsequent civil engineering classes.

RESULTS

The course has been offered for ten years since its inception in 1998. The students rate the class using a standard "instructor evaluation form" at the end of each semester. This course has consistently received high marks (over 95% agreement) for teaching methods and quality of instruction. Students are surveyed at graduation and mention that this course helped them become aware of that innovation is an important component of design. The course fits into the novel approach in the Civil Engineering department to incorporate design into all levels of the undergraduate curriculum.

CONCLUSIONS

Because engineers will be challenged to fulfill professional expectations within the twenty-first century, the educational system will have to adjust to meet these demands. As proposed in this paper, the utility of learning the art of design alongside hands on implementation can develop a more innovative engineer. The cooperation between the engineering professor and professionals also serves as a role model for teamwork and mutual appreciation.

ACKNOWLEDGEMENTS

The author would like to thank the professionals who suggested and supported this course. The study would not have been possible without the CE 458/558 design students who gave their energy and innovation to their projects.

Abstract
Goal 7 of the Millennium Development Goals addresses the need for safe water, sanitation, and hygiene by aiming to halve the proportion of people without access to safe water and adequate sanitation from 1990 benchmarks by 2015. One key for successfully integrating university research with global development is to develop strategic partnerships with non-traditional academic partners that have a strong community presence. Here we use several case studies to demonstrate how these partnerships are integrated with graduate education and research to develop sustainable solutions for global problems.

The Master's International Program in Civil & Environmental Engineering at the University of South Florida (USF) provides students with an opportunity to combine their graduate education with service in the U.S. Peace Corps as water/sanitation engineers and an overseas research component. Key features are a 6-credit research thesis and a 9-credit, three course sequence in: 1) global public health assessment, 2) applied anthropology, and 3) sustainable engineering technology. Students may also incorporate with their degree a new graduate certificate in Water, Health, and Sustainability.

An interdisciplinary graduate course allows students to investigate concepts of sustainability and research methods using a case study focus that focuses on mercury in the Tampa Bay area and a contrasting field based experience in Guyana. Students identify and integrate research approaches across disciplines, implement population surveying methods, and apply simple systems modeling. An NSF research project situated in Bolivia allows undergraduate and doctoral graduate students to work with a non-government organization and rural community water committees to research issues of water supply, water scarcity, sanitation, and watershed management. The Kiran C. Patel Center for Global solutions at USF also supports activities in this like the facilitation of graduate exchange training exercises with UNESCO-IHE students.

Introduction

The National Science Board views international Science and Engineering (S&E) partnerships for research and education as essential for maintaining U.S. competitiveness in the 21st century given the impact of September 11th on intellectual

exchanges across U.S. borders, the shift in leadership due to globalization, and the global nature of challenges like climate change and the spread of HIV (National Science Board, 2008). Successful international S&E partnerships contribute to economic development, capacity building of civil society, elevation of women and underrepresented groups, and productive, socially responsible solutions to global S&E problems (National Science Board, 2008). The United Nations Millennium Development Goals (MDGs) present examples of real challenges that today's graduate must be prepared to solve around the world and provide motivation for integrating international experiences with engineering education (United Nations, 2000; UN Millennium Project, 2005). For example, Goal 7 of the MDGs addresses the need for safe water, sanitation, and hygiene by aiming to halve the proportion of people without access to safe water and adequate sanitation from 1990 benchmarks by 2015. These targets present technological and socio-political challenges (Zimmerman et al., 2008) and to meet them, more non-traditional partnerships and funding mechanisms are emerging that include non-governmental and civic organizations (Hokanson et al., 2006; Mihelcic, et al., 2005, 2006). One key for successfully integrating university research with global development is to develop strategic partnerships with non-traditional academic partners that have a strong community presence.

This paper presents four case studies (Table 1) to demonstrate how these non-traditional partnerships are currently integrated with university level education (undergraduate and graduate) and research to develop sustainable solutions for global problems.

Case 1: Master's International Program (MIP)

The Master's International Program (MIP) in Civil & Environmental Engineering at the University of South Florida (USF) provides students with an opportunity to

combine their graduate education with service in the U.S. Peace Corps as water/sanitation engineers in a developing country. Through the program students learn: 1) to interact with the disciplines of public health, applied anthropology and sustainability, 2) to integrate a health and human dimension into engineering, 3) to apply appropriate and sustainable technology and correctly balance the dynamic between society, economy, and the environment, 4) to protect the environment while serving neighbors and humankind, and 5) the critical role engineering can play in the eradication of global poverty and hunger; improving global health; promoting gender equality; facilitating sustainable development, appropriate technology, and beneficial infrastructure; and promoting change that is environmentally and socially just (see http://cee.eng.usf.edu/peacecorps).

There are two program options at USF: a 30-credit M.S. Degree in Civil Engineering and Environmental Engineering which requires a first degree in engineering that is ABET accredited and a 30-credit Master of Science in Engineering Science – Environmental Engineering which is open to any student and does not require make up course work if the first degree is in math or science. For both degrees, 24 credits are taken on campus (4 classes per semester) and 6 are thesis research associated with a project identified and executed while a student serves in the Peace Corps. Eighteen of the 24 credits taken on campus must be in the Civil and Environmental engineering school and students must complete a 9-credit, three course sequence in: 1) global public health assessment, 2) applied anthropology, and 3) sustainable engineering technology. The curriculum includes 15 credits of electives to be suited to the student's area of interest (i.e., environmental, green engineering/sustainability, water resources and quality, transportation planning, structural, materials, geotechnical).

The program is also open to students without an engineering undergraduate degree who would earn a master's in Environmental Engineering Science and to students wishing to pursue a doctoral degree. Students may also incorporate with their degree a new 16-credit graduate certificate in Water, Health, and Sustainability that is intended for public health professionals, humanitarian aid providers, engineers and other planners, or anyone with an interest in addressing critical shortages and health problems associated with inadequate and unsanitary water throughout the world.

MIP students work on a wide variety of projects while serving as engineers with the Peace Corps which are detailed elsewhere (Mihelcic, 2004). Assignments range from the village to larger regional scale and typically consist of assisting communities on issues related to water supply and treatment, wastewater collection and treatment, water resources management, solid waste management, and public health education. Students get involved in all aspects of a engineering project, including surveying, financing, design, material selection, scheduling, construction, billing, worker supervision, and issues of operation and maintenance. Students work closely with public health professionals, assist in the creation and training of community water boards, and work on broader sustainability issues that impact residents of their host country. Under the supervision of a faculty advisor at USF students design their

research thesis which is presented at the end of their field placement. Table 2 lists examples of research derived from the MIP.

Table 2: Examples of research directly derived from, or that involved Master's International Students.

The USF MIP program started in fall 2008 and builds on a previous program initiated in 1997 by Dr. Mihelcic. Major differences in the new program are: requirements for students to take global public health and applied anthropology coursework, a thesis requirement, and the ability to accommodate students without an ABET-accredited first degree who do not wish to perform the entire make up course requirements.

To date 38 students have graduated from the program, of which, 42% of graduates have been female and 11% have been under-represented minorities. 11% of graduates have worked overseas for a non-governmental organization and 17% of graduates have begun doctoral studies. Another 25% of the graduates have worked after graduate for large municipality or the federal government. 32% have become fluent in Spanish, 24% in French, and the remaining students have learned languages such as Bambara, Bislama, Timorese, Palaun, and Patois. To date every student who has left for their Peace Corps assignment (after at least one year on campus) has completed their M.S. degree. Peace Corps graduates have preferential hiring by the U.S. government; therefore this program might be a good fit for engineers who want to work for the Environmental Protection Agency, Interior Department, Forest Service, Army Corps, or Indian Health Services.

Case 2: Interdisciplinary Graduate Course with International Field Experience
In 2006 the USF graduate school awarded interdisciplinary grants for graduate education and research that promoted Sustainable Healthy Communities. A focal area was water and faculty from across the university were invited to a "speed meeting" session where they interacted with each other for 2 minutes at a time to identify potential projects and partners for the grant competition. One of the funded projects, "Understanding and promoting sustainability related to mercury exposures through integrated research, graduate education, and community involvement" introduced two new 3-credit graduate level courses at USF through the departments of Civil and Environmental Engineering, Geography and the College of Public Health. These interdisciplinary courses allow students to investigate concepts of sustainability and research methods using a case study focus on mercury in the Tampa Bay area and a contrasting field based experience in Guyana. Students identify and integrate research approaches across disciplines, implement population surveying methods, conduct environmental sampling and analyses and apply simple systems modeling. The course is team taught and the first part was offered in the spring of 2008 to five students, three of whom are also funded for graduate research on the project. The second course is also being team taught in spring 2009 to ten students including the three research supported graduate students who took the first course.

The second course, Sustainability Concepts and Methods: Mercury in Guyana, includes a field experience in Guyana, South America for one week over the spring break period. By the end of the course students should be able to: 1) discuss and evaluate definitions of sustainability, 2) discuss developing country perspectives on

sustainability, 3) discuss aspects of the developing country context that affect and shape projects with sustainability goals, 4) identify and integrate sustainability research approaches (and/or experts) across disciplines, 5) apply Hg environmental sampling, population surveying, and systems modeling methods, and 6) discuss the value (and limitations) of the above methods from both scientific and social perspectives.

The field site was chosen based on existing partnerships between one of the PIs and entities in Guyana involved in small scale gold mines and mercury use that include Non Governmental Organizations (NGO) and the University of Guyana. Mercury is a global pollutant and the second largest user of mercury is small scale gold mining, especially prevalent in developing countries like Guyana. WWF-Guianas is leading efforts in Guyana, Suriname and French Guiana (the Guianas) to reduce the use of mercury in small scale gold mining through research, education and training programs and one of the PIs (Dr. Trotz) has already worked with them on projects that also involve faculty from the Environmental Studies Unit at the University of Guyana. Since 2005, three doctoral students have been recruited to USF's engineering school from the University of Guyana and two are currently taking this course. These students lead discussions on local culture and customs and share relevant experiences on the class topics to prepare the class for the field trip.

In addition to working in an active mining area, the students will also visit a biodiversity conservation reserve, Iwokrama (www.iwokrama.org), where illegal mining impacts livelihood of indigenous populations along the area's periphery. In developing countries like Guyana where democracy and governance remain focal points for agencies like USAID, partnerships with NGOs and civic organizations are crucial and seen as essential for local development (Trotz, 2008). USF's International Study Abroad program will provide administrative support in organizing this field experience and opportunities exist for converting it into a study abroad program that is self funded in the future through student fees.

Case 3: Bolivia Research Experience and International Capstone Design Course

An NSF research project situated in Bolivia allows undergraduate and doctoral graduate students to work with a non-government organization and rural community water committees to research issues of water supply, water scarcity, sanitation, and watershed management. The project objectives are:

1) Pairing undergraduate and experienced graduate students who have a demonstrated interest in issues of sustainable development.
2) Integrating the research experience into education initiatives that are focused on sustainable development.
3) Ensuring the research experience focuses on appropriate technology (defined here as the use of materials and technology that are culturally, economically, and socially suitable to the area in which they are implemented).
4) Using an operational model for sustainable development that is a global partnership, so students understand how to integrate and transfer the best and

most appropriate knowledge, methodologies, techniques, and practices between the developed and developing worlds.
5) Partnering with both a Bolivian University and nongovernmental organization to ensure students learn the importance of making research socially relevant.
6) Engaging women and underrepresented minorities in science and technology research that has a focus on sustainability.

This NSF research program pairs 3 U.S. undergraduate and 3 graduate students enrolled at either USF or MTU who have a demonstrated interest in issues of sustainable development with 6 ecological engineering students and faculty from the Universidad Tecnològica Boliviana (La Paz), and staff from a non-governmental organization. Students must be majoring in engineering, applied anthropology, or public health. M.S. students with a complimentary skill set are considered, however, doctoral students are preferred. Since 2007 students have conducted research in the small rural Bolivian communities of Palos Blancos, Sapecho, and San Antonio (located NE of La Paz near the Rio Beni River where the Andes begin to meet the Amazon) on topics related to: water supply and treatment, how communities select improvements in sanitation technology, the impact that land use has on water supply, and issues of willingness to pay and public health. Research ublications to date from Bolivia research project are: Fuchs et al. (2008), Fry et al. (2008), and Muga et al. (2009).

Understanding of written and spoken Spanish is required of all students. One modification to the program in Year 2 was that students completed a 1 to 2 week language and culture immersion in Bolivia prior to the start of their one month assignment. Students are housed with student families of the Bolivian student participants. In the first two years, there were 14 U.S. student participants, 12 were female. The third year will have participation from students in engineering, health, and applied anthropology. Graduate students will also be drawn from USF programs that allow students to obtain a dual graduate degree in environmental engineering, global public health, and applied anthropology.

The International Capstone Design (ICD) class allows students to obtain university capstone credit for working on engineering projects in the developing world (Phillips et al., 2004, 2007). The goal of International Capstone Design (ICD) is to provide students a service-learning design experience situated in the developing world so they can explore the technical, economical and social implications of engineering design and construction. Integration of the U.S. Accreditation Board for Engineering and Technology (ABET) accreditation criterion throughout the design experience is crucial to this activity. Practitioner involvement and affiliation with international partners has been a key to the success of the classes to gaining experience similar to that gained during the initial year on the job (Knox et al., 1998; Boschetto-Sandoval et al., 2007).

ICD is a 6-credit major design experience that may be used as a technical elective. The ICD course is structured to emulate the business of a design/build firm in

industry, since the student will likely find themselves in this work environment, within 6-12 months after the class experience. Students form a "design team," of 3-4 students; each team working on a different design project, just as in industry. Student work abroad requires 40 hours of volunteer construction work to learn local tools, materials and techniques. The remainder of time is spent gathering data from the local "clients," conduction topographical surveys, water and soil testing, and gathering other design data. Students return to campus to complete their actual project designs. The most important aspect of the course is that students experience the evolution of a project from conception through preparation of an engineering report which analyzes feasibility of various design options and then completion of final design drawings and specifications. Typical projects include water distribution, wastewater treatment, storm water management, solid waste, as well as roadway or structural design. Relationships built over the last 10 years allow students to work with local governments and NGO's for "real" design projects, benefiting "real" people. Once complete, student designs are transmitted to the international "clients or benefactors."

Due to the number and variety of design projects, industry mentorship is included both abroad and on campus, coaching the students on project delivery and procedures as well as the technical concepts. The mentors are either seasoned professional engineers or recent graduates working towards professional registration who have participated in the program. US professionals as well as local engineering and business professionals serve as in-country mentors.

The USF ICD program is beginning in Spring 2009, and is a relocation of the International Senior Design program formerly of Michigan Technological University. That program was created by Linda Phillips in 2000 and is co-directed by Dennis Magolan. To date 167 students have taken the "international senior design experience" in 15 offerings in either the Dominican Republic or Bolivia. Ownership of the student design projects is so great that 20% of the students have returned to act as in-country mentors, paying their way as the students do. Of the 20%, 40% have returned to mentor more than once.

Case 4: UNESCO-IHE partnership

The University of South Florida launched the Dr. Kiran C. Patel Center for Global Solutions on May 20, 2005. Potable Water and Sanitation, Sustainable Activities, and Urbanization and Migration are the three areas of specialization of the center which has played a crucial role in forging international partnerships for USF faculty to build research and education programs. Two examples of support that are discussed below include observation of the meetings of the UN Secretary General's Advisory Board on Water and Sanitation and facilitation of graduate exchange training exercises with UNESCO-IHE students.

The UNESCO-IHE Institute for Water Education (http://www.unesco-ihe.org/) in Delft, Netherlands formally signed a Memorandum of Understanding with USF in 2007 to develop collaborative educational and research programs. IHE carries out

research, education and capacity building activities in the fields of water, environment and infrastructure, and is the largest water education facility in the world. IHE offers graduate programs (MSc and PhD) related to water science, engineering and management and its students are recruited from around the world with high percentages from Asia and Africa. The USF-IHE partnership (only one of its kind in the US) stemmed from interactions between IHE and USF faculty who work closely with the Patel Center as faculty advisory board members and research fellows, and has led to faculty visits at both institutions, IHE student visits to USF and proposal submittals. While visiting IHE, USF faculty have participated in symposia, site visits and a course on Dutch water management.

For the past two years, the Patel Center, in collaboration with Florida Earth Foundation, hosted a group of IHE MSc students during their 3rd and 4th annual visit to south Florida. Their two day visit of the Tampa Bay area was hosted by Dr. Thomas Crisman from Biology (theme of water resources and wetland ecology) in 2007 and Dr. Daniel Yeh from Civil & Environmental Engineering (theme of Tampa Bay water infrastructure) in 2008. Several USF students from Dr. Yeh's class on Millennium Development Goals also accompanied the IHE students on the two-day visit. A NSF proposal was recently submitted for USF students to conduct summer research at IHE.

Conclusion

The programs discussed above are a part of a larger portfolio of efforts being undertaken at the College level to make more sustainable, international experiences for faculty and students (Thomas et al., 2008). In addition, these case studies align strategically with national goals that have documented the rapid social, political, economic, and environmental changes occurring in the world and associated implications for engineering education, research, practice, and importantly, the economic competitiveness of our Nation (see for example, the National Academy of Engineering in Educating the Engineer of 2020, and the American Society of Civil Engineers in 2025 Vision for Civil Engineering).

A decision support system for beneficial use of national dam water resources in Swaziland

J.I. Matondo[1] and K. M. Msibi[2]

ABSTRACT

The Government of Swaziland has undertaken the development of water storage and distribution facilities as a process towards overcoming the unevenly distribution of the water resource. However, the current water storage facilities with a total capacity of 720.9×10^6 m^3 can not meet the water demand which stands at 1795×10^6 m^3 annually. The overall objective of this project was to develop an optimum and sustainable decision support tool for water allocation and rationing options for national water reservoirs.

A Decision Support System (DSS) is defined as a user-oriented computer system which supports decision-makers in addressing unstructured problems. The rationing mode in the developed DSS was used to distribute the available stored water at the beginning of April in order to arrive at a priori predetermined reservoir storage level at the end of October. The DSS has three major components and that is the model input, modeling options and outputs screens. The model input component comprises of technical data (inflow, reservoir level, intended % volume at end of October and allowed lowest rationing %), and policy data (uniform rationing or differential rationing). The modeling options comprise of commands to determine optimum rationing %, provide % rationing and observed dam response and imposed rationing %. The output of the DSS comprises of the optimal rationing (%), monthly reservoir volume from April to end of October as well as a graphical representation of the reservoir response and the final recommendation.

The results of the DSS with a starting reservoir level at 15m at the beginning of April and a 10% reservoir level at the end of October, is that there is no need for rationing (that is the water demand for all uses are met) and the reservoir level stands at around 29% at the end of October. The results of the DSS with a starting reservoir at 6m at the beginning of April is that the rationing is 46% for all uses in order to arrive at a 10% reservoir storage level at the end of October is not recommended. This is because, with 54% deficit, there is a danger of crops to wilt beyond recovery. The final DSS recommendation starting with a reservoir level at 6m at the beginning of April is irrigation rationing at 60% (i.e. 40% water deficit) combined with a reduction of 14% of the hectares of irrigated fields. The Nyetane dam was used as a pilot reservoir in the development of the DSS. The developed DSS with all the relevant input data can be used to allocate water efficiently in other reservoirs in the country.

Keywords: Beneficial, Decision support system, Optimum, Rationing, Sustainable use

BACKGROUND

The Kingdom of Swaziland, is situated in South Eastern Africa between latitude 25^{o} and 28^{o} South and between longitudes 31^{o} and 32^{o} East. It lies some 48 to 225 kilometers inland of the Indian Ocean littoral and hence physically land locked. The country has a total surface area of 17,360 km^2 and therefore, is the smallest country in the southern hemisphere.

There are four distinct physiographic regions within the country namely: highveld, middleveld, lowveld and lubombo, which are clearly distinguished by elevation and relief (Murdoch, 1970). The highveld and upper middleveld are characterized by a Cwb climate. The lower middleveld and lubombo range have a Cwa climate whilst the western and eastern lowveld have a Bsh climate (Murdoch, 1970). Mean annual rainfall ranges from about 1500 millimetres in the highveld to less than 500 millimetres in the southern lowveld.

The water sources in Swaziland are mainly surface waters (rivers, reservoirs), ground water and atmospheric moisture. Figure 1 shows the major drainage basins of Swaziland namely: Komati, Usutu, Mbuluzi, Ngwavuma, Lomati, Pongola and Lubombo. The Komati and Usutu rivers both originate in South Africa while the rest of the basins originate within Swaziland. It should also be noted that all the rivers in Swaziland are international rivers and therefore, the development and management of the surface water resources must be undertaken in collaboration with the other riparian states namely: South Africa and Mozambique.

There are ten big dams in Swaziland which are greater than 5 million cubic metres (MCM). The existing infrastructure is not sufficient to carter for the whole country and currently the lowveld region continues to suffer from drought related problems. The challenge to the government remains that of constructing water storage and distribution facilities and transfers it to areas of acute water shortage. Water resources management is posing a complex challenge due to the increasing competing and conflicting water uses amongst different sectors and also due to population increase which puts pressure on the natural resources.

The overall objective of this project is to develop an optimum and sustainable utilization decision support tool for water allocation and rationing options for national water reservoirs. The specific objectives of this project were. (i) To develop different scenarios for optimal utilization to meet conflicting and competing dam water needs. (ii) To develop a decision support tool for competing dam water requirements, to help in the prioritization of allocations and rationing in times of scarcity i.e. during droughty years.

LITERATURE REVIEW

It has been established by scholars that water resources management problems are more complex world wide (Simonovic, 2000; Wurbs, 1998; Singh, 1995). Population growth, climate variability, regulatory requirements, temporal and spatial scales, socio- economic and environmental considerations, competing and conflicting water uses and transboundary considerations all of these contribute to the complexity of water resources management problems.

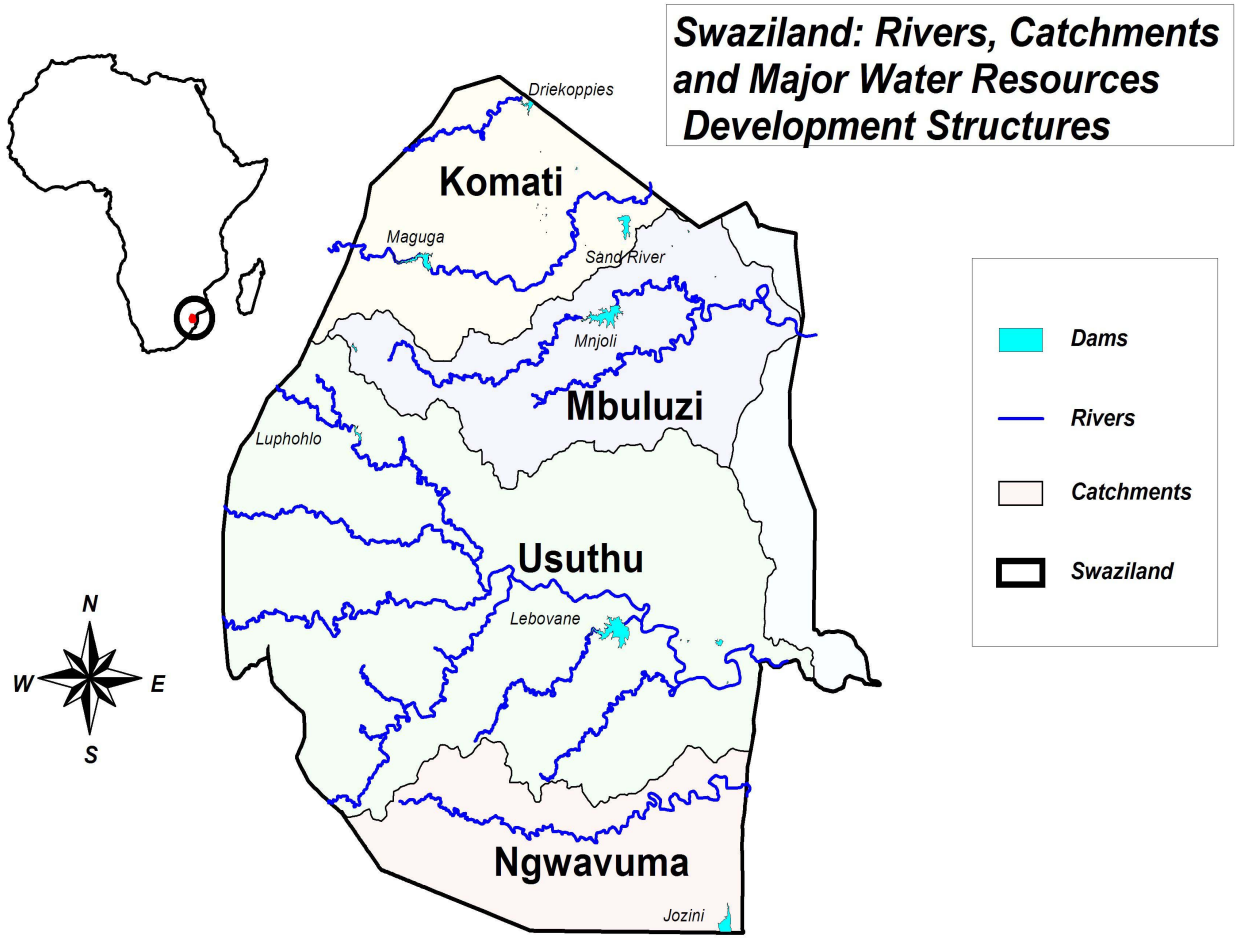

Figure 1. Map of Swaziland showing the major drainage basins and location of existing water storage facilities

The literature on water resources management is rich with Integrated Water Resources Management models that have tended to focus either on understanding how water flows through a watershed in response to hydrologic events or on allocating the water that becomes available among competing and conflicting water uses. Examples of such models are: The US department of Agriculture's Soil Water Assessment Tool (SWART , Arnold and Allen, 1993); RiverWare™ DSS (Zagona et al., 2001); The USA Geological Survey's Modular Modelling System (Leavesley et al., 1996); The US Army Corp of Engineers, HEC-ResSim (USACE, 2003) etc. The SWAT model includes sophisticated physical hydrologic watershed modules that describe, rainfall-runoff processes, irrigated agriculture process, and point and non-point watershed dynamics but with a relatively simple reservoir operation module. The RiverWare™ DSS is a hydrologic and hydraulics operations model, which can be used to develop multi-objectives simulations and optimizations of river and reservoir systems. The HEC-ResSim is a reservoir simulation model that can describe operating rules such as release requirements and constraints, hydropower requirements, multiple reservoir operations etc. All the above water management models require prescribed flows from other models.

Decision Support Systems (DSS) are a specific class of computerized information system that supports business and organizational decision-making activities. A properly designed DSS is an interactive software-based system intended to help decision makers compile useful information from raw data, documents, personal knowledge, and/or business models to identify and solve problems and make decisions. A Decision support system was used in California USA to handle conflict between two groups who have on-demand water management for irrigation, drinking water and hydropower generation (Rajasekaram and Nandalal (2005). Gu and Tang (2000) developed a Water Resources Management Decision Support System to unify the objective world, organization and human factors during intervention. Karamouz *et. al*, (2005) developed a multi-criterion decision making (MCDM) that utilized an analytical hierarchy process which enabled decision makers to incorporate the priority of different objectives in obtaining optimal reservoir operating policies. Both economic and MCDM utility functions are implemented and coupled with deterministic and stochastic optimization models. The DSS was applied to the largest surface water resources system in Iran (the Dez and Karoon river-reservoir system).

METHODOLOGY

Data collection

The information that was required for carrying out this project is: Dam characteristics, hydro meteorological data, water use data, irrigation water requirement, area under irrigation for each crop, and net financial income.

Dam characteristics:

The information that characterize, a dam is the reservoir water level, the corresponding surface area and volume. This information is available from the dam designs and was obtained from the Ministry of Agriculture and Cooperatives which constructed the Nyetane dam. This information was used to compute the evaporation and seepage water losses from the reservoir which are both a function of the reservoir water level. The reservoir level at the beginning of April was used in the Dam height surface area and volume relationship by interpolation to get the corresponding reservoir surface area and volume. The reservoir levels and corresponding surface area and volume were input to the DSS where all the computations are carried out. The dam level was also used to calculate the water seepage losses from the reservoir. The reservoir volume and the volume of seepage losses are used in the water balance equation.

Hydro meteorological data

The hydro-meteorological data needed in this project are: reservoir inflows, temperature, and evaporation values. There is no hydrometric station along Nyetane river and therefore, rainfall runoff modelling was used to establish the monthly inflows into the Nyetane dam. Air temperature and evaporation data was obtained from the department of meteorology. The air temperature and pan evaporation data was required for the computation of water losses from the reservoir through evaporation. The following relationship was used in the computation of evaporation loss from the reservoir:

$$E_t = e_t . A\left(\frac{V_t + V_{t+1}}{2}\right)$$

Where E_t is the total reservoir evaporation for month t, e_t is the evaporation index for month t (which is obtained from the pan evaporation values), A is the reservoir surface area which is a function of the reservoir volume in month t and t+1 (this is usually the reservoir volume at the begining of month t and the reservoir volume at the beginning of month t+1, which is equal to the reservoir volume at the end of month t).

Water use data

The water use data for domestic was obtained from the Rural Water Supply Board while the water use for livestock and irrigation was obtained from the Ministry of Agriculture and Cooperatives. Water use for industry was obtained from the Swaziland Water and Sewage Corporation while water use for hydropower was obtained from the Ministry of Natural Resources and Energy. It should be noted here that water use for hydro power generation is non-consumptive use. That is water can be used to generate hydro power and for other uses down stream. This information was input to the water balance computations in the DSS.

Irrigation water requirement per hectare.

The irrigation water requirement for sugar cane, maize, cotton, vegetables and fruits was obtained from the literature review material. The expression to estimate the crop water consumptive use is as follows:

$$ETc = ETr * Kc \quad \text{(mm/day)}$$

Where ETc is the crop water consumptive use, ETr is the potential evapotranspiration for a reference crop and Kc is the crop coefficient. Crop coefficient values have been established experimentally for different crops and in this study the crop was assumed to be at full canopy cover. Therefore, the crop water requirement as a volume per hectare was obtained when the ETc was multiplied by the area and in this case the hectare. This information was input to the DSS for computing the water demand abstraction.

Area under irrigation.

The area under irrigation for the different crops was obtained from the stakeholders who are irrigating using the water from the Nyetane reservoir. This information is necessary in quantifying the water demand and therefore, the required water abstraction from the reservoir in each month. This information was input to the DSS.

Net financial income

The gross income, input costs and net income per hectare for each crop was obtained from SWADE. This information was required in the DSS for the determination of the returns (net benefits) for the acreage under irrigation for the corresponding optimum water rationing (%).

All the information required for running the Decision Support System (DSS) is presented in Appendix A. All the other calculations are carried out within the DSS (the rationing component).

Development of Scenarios for reservoir operation

The major objective of reservoir operation (post contract problem) is the maximization of net benefits due to water releases for the different uses. This problem is set as follows:

$$Maximize \quad b_w.Q_t + b_p.P \tag{1}$$

$$Subject \quad to$$

$$V_{i+1} = V_i + I_i + R_i - Q_i - E_i \frac{V_i + V_{i+1}}{2} \tag{2}$$

The water release Q_t is the sum of all the water demand for all the activities during month t. The above relationship was used in the DSS in the water rationing process which is carried out from month t = 1,…, 7 (which is from April to October). This is because the water rationing procedure is carried out during the winter months to ensure that the reservoir is used efficiently. Secondly the rain season has been observed to have shifted to the beginning of November that is there is a delay in the onset of the rain season instead of starting at the beginning of October it has currently been observed to start in early November.

The scenarios that were considered are those based on the occurrence of drought recurrance interval such as one in five years, one in ten years etc. The average and wet year conditions are also scenarios for consideration when operating the reservoir. However, it should be noted that the wet year scenario is not of a problem because the water demand is expected to be met and should give the maximum net benefits.

Reservoir starting and ending levels were considered as scenarios in the management of the dam waters and they are linked to the frequency of droughts. This is because if the reservoir is full at the beginning of the season and operated to meet the water demand for the whole season and end up with a low reservoir level (depending on the inflows during the season) then the reservoir is not well operated. Thus, starting the next season with such a low reservoir level gives a high risk for the farmers, and that they might get severe losses. Therefore, the DSS was used to find optimal starting and ending reservoir levels for the different drought scenarios explained above.

Conceptualization of the DSS

Important characteristics of a Decision Support System (DSS) for sustainable water resources management include flexibility for tackling various 'what-if?' scenarios, the facilitation of problem identification and solving by analytical tools enabling the end-user to manage, analyse and present information, and interaction and ease of use to involve the stakeholders into the management process themselves [Simonovic and Bender 1996]. Integrated water resources management comprises numerous complex and unstructured management problems including a geographical component. Resolving ill-structured problems, however, can be achieved by disaggregating them into a series of structured components, each of which tackled with its unique set of tools [Reitsma 1996], and integrated into a comprehensive framework system.

According to Wurbs (1998), the concept of Decision Support Systems became popular during the 1980s in the water manahgement community, as well as in business, engineering and other profeesional fields (Wurbs, 1998). Wurbs, 1998 defines decision support system as a user-oriented computer system which supports decision-makers in addressing unstructured problems. Decision support systems include a collection of software packages and hardware. The decision support system might include data management software, watershed runoff, stream hydraulics, and reservoir system operation models, a computer platform with peripheral hardware devices and an automated real time stream flow and rainfall data collection system.

There are basically two distinct elements of the DSS, namely; *Rationing and Allocation* decision support tools. Ming-Yen Tu *et. al*, (2003) developed a mixed integer linear programming (MILP) model that considers simultaneously both the traditional reservoir rule curves and the hedging rules to manage and operate a multireservoir system. During normal periods of operation when inflows are plentiful, this optimization model efficiently distributes the available stored water from different reservoirs to meet the planned demands imposed by the competing users. However, during periods of drought, and/or when anticipating a drought the planned demand can not be fully met and a water shortage occurs. To minimize the impact of drought, the hedging rule was used to effectively reduce the ongoing water supply to balance with the target storage requirement.

As explained earlier Swaziland receives rainfall during the summer months with very little rain during the winter months. In fact the Lowveld region where the Nyentane reservoir is located does not receive any rainfall during the winter months and has been experiencing drought related problems since 2001 to date. Therefore, the approach by Ming-Yen Tu et. al (2003) was used in the developed DSS. The rationing mode in the DSS was used to distribute the available stored water at the beginning of April in order to arrive at reservoir target levels at the end of October which were determined a priori.

The water resources from the Nyetane dam is used for agricultural activities (sugar cane, citrus fruits, vegetables, and livestock) and domestic. All crops get the required water demand when there is enough water. Rationing is done to all crops and other uses during years with water scarcity.

The current situation in the country under irrigated agriculture is that the growing of sugarcane is a continuous process. That is come the rain season a farmer will have sugarcane fields at different growth stages. Therefore, the problem of water allocation among different crops can not be carried out in the usual way using optimization techniques. Therefore, the approach in this study was to rank the crops according to their net income per hectare. All other crops except dry maize have a high net income per hectare than sugarcane. Therefore, under water scarcity situations the hectrage under sugarcane will be reduced in order to make the available resource enough for part of the sugarcane field and other crops.

Since only a single reservoir site was used to pilot the DSS, a good framework was developed that could be expanded to cover other reservoirs and other scenarios. Figure 2. below illustrates the developed Decision Support System.

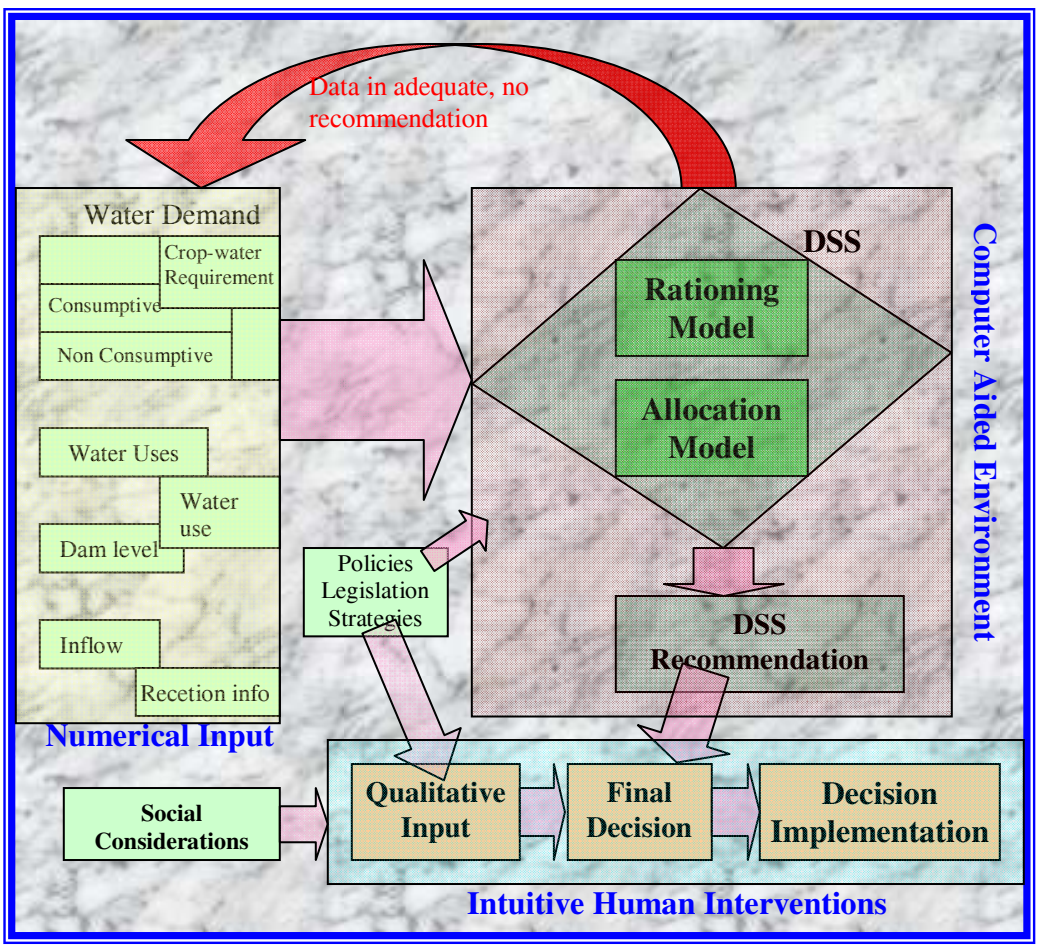

Figure 2: A diagram showing the DSS layout and components

Computational procedure in the DSS

The water balance equation was used in the computational processes in the DSS and is presented below:

$$Q_{t+1} = V_t + I_t - Q_t - Q_l - e\left(\frac{V_t + V_{t+1}}{2}\right) \quad (3)$$

The reservoir level at the beginning of April was used to determine the corresponding reservoir volume using the Dam level, surface area and volume relationship through an interpolation procedure. The inflow for the months from April to October is computed using the following equation:

$$I_{t+1} = I_t \rho^{k(t+1)} \quad (4)$$

Where I_{t+1} is the inflow at time t+1 and k is the groundwater recession constant and ρ is the natural log.

This is because the inflow into the reservoir during the winter months is due to ground water contribution and is recession flow. Q_l is the water loss in the reservoir through seepage and percolation which is computed as a function of the Dam level. Q_t is the total water abstraction for month t (irrigation, domestic, livestock, industrial etc.). The water abstraction is obtained from the water use tables. The water abstraction for each month is subjected to a water rationing iteration process in the DSS using the water balance equation from the beginning of April to the end of October.

Given the reservoir level at the beginning of April, the target reservoir level at the end of October, uniform rationing or differential rationing and the lowest allowed rationing (%), the DSS performs an iteration procedure from April to October to determine the optimal rationing (%). The rationing in this study is the % of the total water demand for that month. That is if the optimal rationing is 90% it means that a 10% water deficit is incurred for all the crops during that month.

RESULTS AND DISCUSSION

The developed DSS has three major components and that is the model input, modeling options and outputs. The model input component comprises of technical data (inflow, reservoir level, intended % volume at end of October and allowed lowest rationing %), and policy data (uniform rationing or differential rationing). The modeling options comprise of commands to determine optimum rationing %, provide % rationing and observed dam response and imposed rationing %. The output of the DSS comprises of the optimal rationing (%), monthly reservoir volume from April to end of October as well as a graphical representation of the reservoir response and the final recommendation.

The DSS is started by inputting the reservoir level at the beginning of April, the intended end of October reservoir volume (%) and the allowed lowest rationing (%). The policy data input is either uniform rationing or differential rationing. When differential rationing is selected two boxes become active at the bottom requesting to input the % of irrigation rationing and the % of rationing the other water uses and then click finish, modeling option and the compute buttons to activate the iterations in the DSS.

The starting reservoir level at the beginning of April is a function of climate and the previous history in the catchment (i.e the rainfall distribution during the previous rain season (October to march). That is during wet years, the reservoir level at the beginning of April is expected to be at maximum supply level and during dry years, the reservoir level at the beginning of April is expected to lie between minimum and maximum supply levels.

A sample output results for the developed DSS are presented in Figures 3 to 4. It can be seen from Figure 3 that with a starting reservoir level at 15m at the beginning of April, there is no need for rationing and the reservoir level stands at around 29% at the end of October. Figure 4 shows the DSS results with a starting reservoir level at 8m at the beginning of April and with uniform rationing the DSS recommends a 63% rationing for all water uses (that is a 37% deficit is incurred by all uses) in order to end up with a reservoir level at 10% at the end of October. Figure 5 shows the results of the DSS with reservoir level in April at 8m but with uniform imposed rationing of 80%. The DSS recommendation is that the imposed rationing of 80% is not recommended (because the reservoir storage is 0 at the end of October) and that a more stringent rationing should be used or to choose the optimization option. Figure 6 presents the results of the DSS with a reservoir at 6m at the beginning of April with uniform rationing. The DSS recommendation is that of rationing at 46% for all uses in order to end up with 10% reservoir storage at the end of October is not recommended. This is because, with 54% deficit, there is a danger of crops to wilt beyond recovery. The final DSS recommendation is irrigation rationing at 60% combined with a reduction of 14% of the hectares of irrigated fields.

CONCLUSIONS AND RECOMMEMNDATIONS

A Decision Support System (DSS) tool has been developed with the use of input information from Nyetane Dam as a pilot reservoir. The Developed DSS can be used to give optimal rationing given the starting reservoir level at the beginning of April and a priori reservoir level at the end of October. The corresponding hectares for the different crops that were irrigated in the season and net benefits can also be obtained. Input data from any other reservoir can be used in the developed DSS for optimal rationing of water resources for that dam.

It is recommended that the developed DSS be implemented in the rationing of the water resources of the Nyetane dam in order to establish the output results of the model in real time operation. This information can then be used to evaluate the sensitivity of the DSS and effects of the water deficits in relation to crop yield can also be analysed.

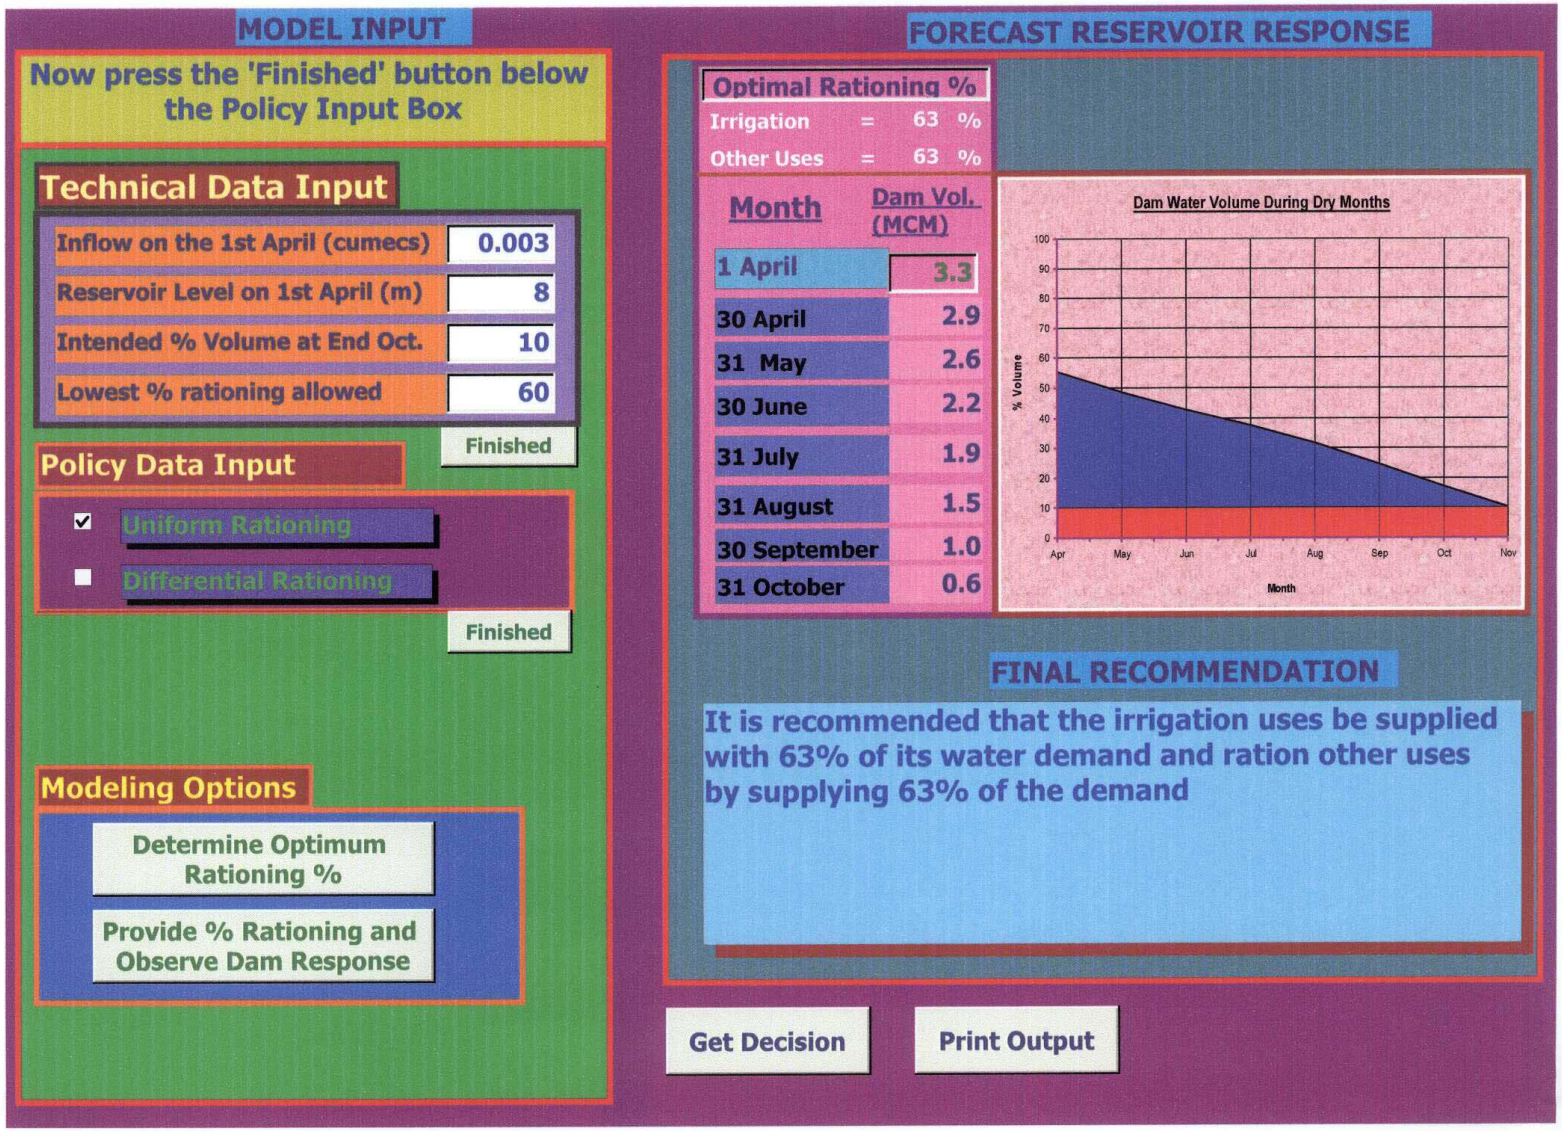

Figure 3: DSS results with starting reservoir level in April at 8m and 10% reservoir level at the end of October

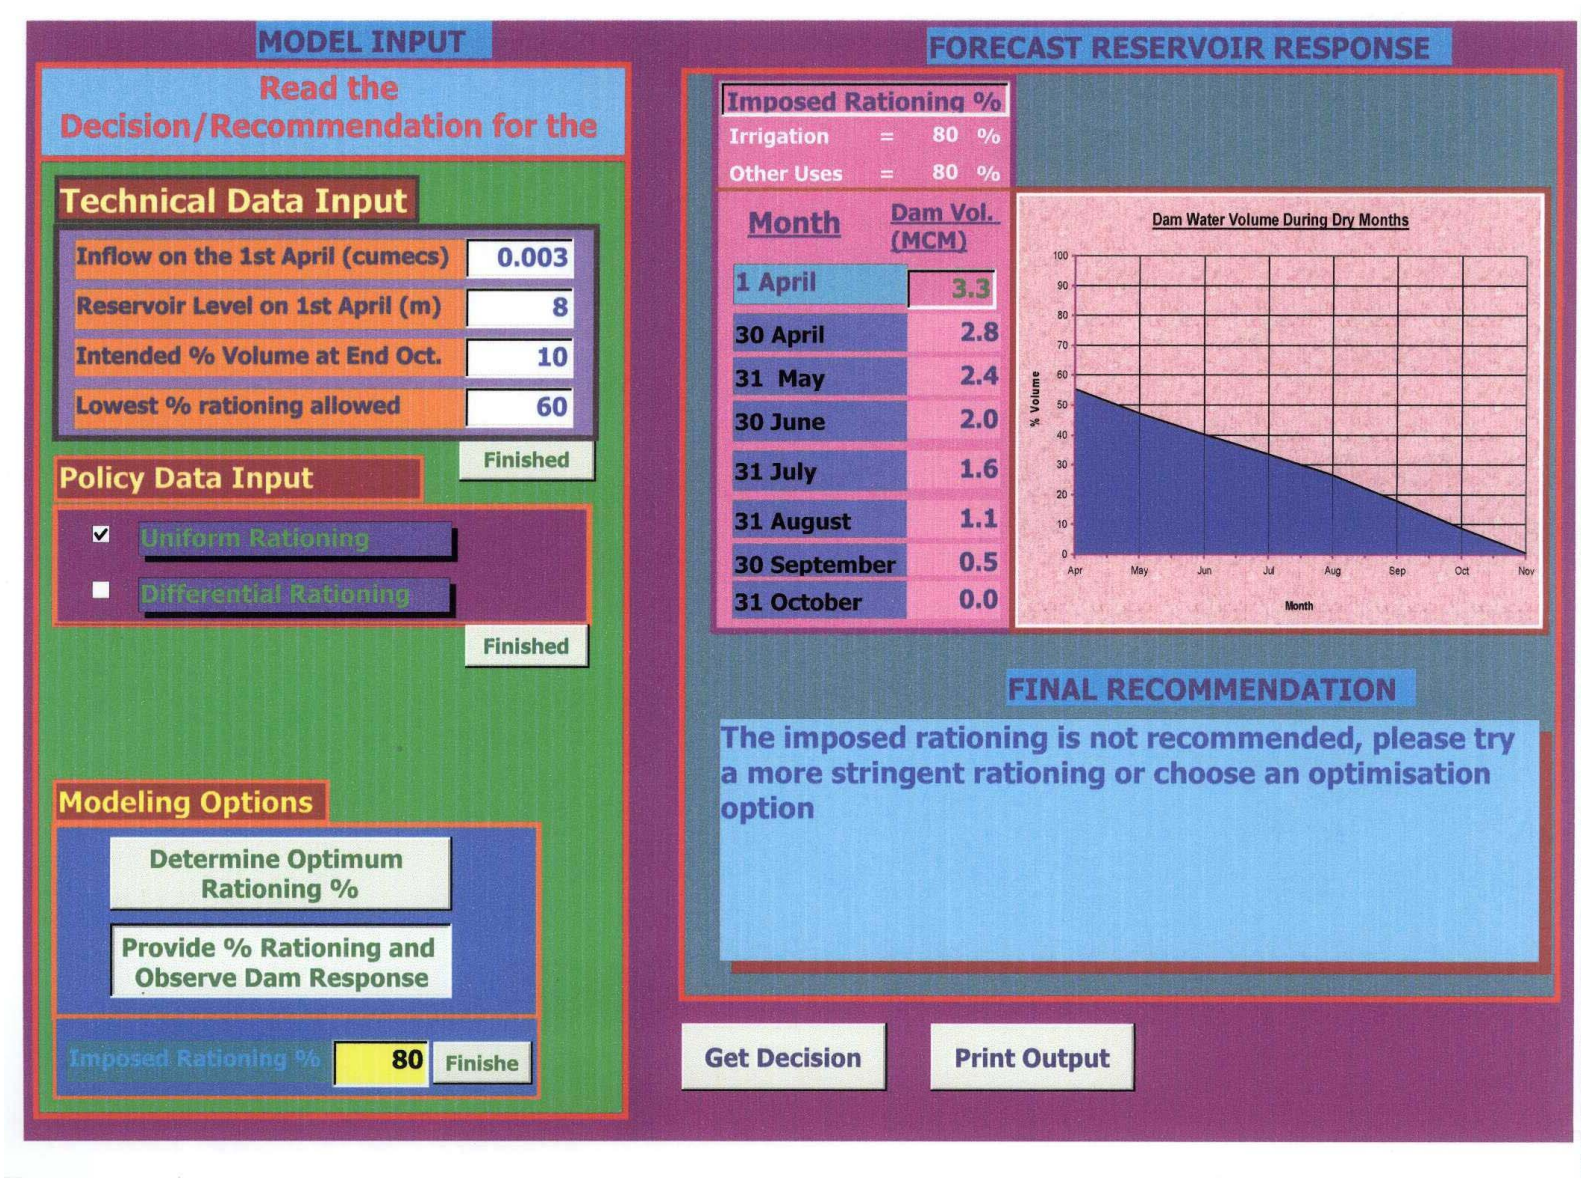

Figure 4: DSS results with starting reservoir level in April at 8m and 10% reservoir level at the end of October

Abstract: At present, the use of inert materials such as concrete and steel had always been relied as for slope stabilization and soil erosion. The widespread of these materials as stone riprap and concrete are now abridged due to its high cost. It is therefore encourage that the use of alternatives such as planting of grass or vegetation along the slopes is the most sensible form of soil erosion control. However, the use of these methods was not much taken into practice which does not account its efficacy for soil stabilization.

In this study, the researchers' premise is to congregate information that may be significant to evaluate the performance of Hydroseeding with Coconet in controlling soil erosion and ensuring its suitability and applicability in the protection of the slopes. A representative slope had been constructed and tested at 65º taking an account from the 71.56º of the maximum slope with a 10% factor of safety for both hydroseeding and coconet. A rainfall simulation study was conducted in order to assess the effectiveness of combined Hydroseeding with Coconet against surface run-off to control soil erosion. Performance of Hydroseeding with Coconet were assessed which gave progress to where the soil erosion was to be reduced or controlled. Results from the experiment were expected to give the desired data and outputs to the researchers which should show that combined Hydroseeding and Coconet representative slope yields to control soil erosion and protect the slope.

1.0 INTRODUCTION

Soil erosion, which is caused by water, wind and gravity, is a worldwide problem that threatens an important and non-renewable resource the farmland that is suitable for cultivation. To be able to take actions to this problem, an effective and economical method must be taken as a solution. One method that can be considered is Hydroseeding with combined Coconet. The use of combination of hydroseeding and coconet is cheap and time saving because it requires low-cost-maintenance and less effort. These advantages prove that it can be an effective and economical solution to soil erosion. Hydroseeding is another method of ground re-vegetation to stabilize bare surface to prevent soil erosion. The method calls for the use of cellulose mulch material mix with a tackifier acting as a binder. The cellulose fiber mulch, together with the grass seeds, fertilizer and water are mixed inside the tank of a hydroseeding machine to form into consistent and homogeneous slurry and then hydraulically sprayed to the ground. When sprayed the cellulose fiber mulch together with the fertilizer and the grass seed will act as an absorbent mat, holding enough moisture to allow proper germination of the grass seeds and at the same time performing a tenacious blanket cover to the soil surface even before the grass seeds germination to prevent soil erosion. The cementitious geobinder forms a permeable is non toxic cementitious binder that safely holds the grass seeds uniformly in place, prevents surface erosion and water evaporation in the soil. The cellulose fiber mulch which is biodegradable and will in time revert back to organic matter and assist in the vigorous establishment of the grass ground cover. The hydroseeding slope protection was constructed in the Subic-Clark-Tarlac Expressway Project to showcase the effectiveness of this method in protecting the slope after passing all the required and necessary tests based from the unpublished study of Bases Development Conversion Development Authority Report on the Result of Vegetation Cover Growth for Clay Slope Protection Works of Package 2 SCTEX, 2006, Clark, Angeles City, Pampanga, Philippines.

1.1 Statement of the Problem

The study would like to address the effectiveness of the combined Hydroseeding and Coconet to slope protection on how it will withstand the slope surface, either Hydroseeding or Coconet alone.

Hydroseeding is an innovative method designed for slope protection which is introduced in the Philippines in Subic-Clark-Tarlac Expressway Project. Since it is new in the engineering industry, there was only limited information about the said method. Tests to assess this method were barely made by private construction companies making the data exclusive for the company use.

1.2 Objectives of the Study

The objective of the study is to assess the performance of combined Hydroseeding and Coconet against soil erosion through means of determining the erosion rate from the laboratory test. From the 21-day period, assessment of the vegetative cover during its development growth period shall be done. Results from this experiment shall promulgate the method of combined Hydroseeding and Coconet as an alternative slope protection.

1.3 Significance of the Study

This study gives a comprehensible understanding on hydroseeding with Coconet significant to control soil erosion. Assessment of the properties and its physical behavior of hydroseeding were also determined. Through the test made, the researchers were able to seek new knowledge and announce the effectiveness of Hydroseeding with Coconet as an alternative slope protection.

1.4 Scope and Limitation

The study covers the assessment of the effectiveness of the combined Hydroseeding and Coconet against soil erosion. The study is an outdoor experiment which considers the natural factor such as wind and sunlight. The study of the factors from the outdoor was neglected due to this study which merely focused on the ability to control soil erosion. Transportation of the specimens to the laboratory was by means of a forklift neglecting the level of disturbance. To minimize the disturbance of soil, the test specimens were transported carefully. A fine grained material soil which is silt and clay with a 65º of slope and rainfall intensity rate of 120 mm / hr was used for consistency of the study. An intensity rate of 120mm/hr was used which is the maximum rate of rain happens in the Philippines over 100 yrs. This is based from the records of Flood and Control and Sabo Engineering Center, Department of Public Works and Highways, Technical Standards And Guidelines for Planning and Design, Vol. IV: Natural Slope Failure Countermeasure, 2002, FCSEC DPWH, Philippines.
Other condition prior to the study such as landslide was not included in the study.

2.5 Rainfall Simulation

This test method establishes the guidelines, requirements and procedures for evaluating the combination of Hydroseeding and Coconet to protect soils from rainsplash-induced erosion. This test method utilizes small-scale testing procedures, rather than full-scale simulation, and may not be indicative of conditions typically found on sites

Rainfall Apparatus

2.0 METHODOLOGY

The assessment of the effectiveness of the combination of Hydroseeding and Coconet to control soil erosion were done by comparing its performance to the performance of the bare soil in terms of surface runoff. Soil cores consisting of containers with bare soil and 21 day old soil with hydroseeding and coconet reinforcement were exposed in rainfall simulation. Each specimen had three representations soil core to gather accurate data. The rainfall intensity used in study is 120 mm/hr. The amount of soil and water splashed out by runoff from the containers were collected and weighed. The collections of runoff were done for every 10 minutes for 5 trials, which is equivalent to 50 minutes. Soil sediments were filtered and air dried for 24 hours then weighed using weighing balance sensitive to 0.001 gram. The weight soil sediment per trial was recorded for computation.

In order to assess the effectiveness of the combination of Hydroseeding with Coconet as reinforcement to control soil erosion, the researchers used the performance indicator as suggested by Sutherland, R. and Ziegler, A. in his study in Effectiveness of Coir-Based Rolled Erosion Control System in Reducing Sediment Transport from Hillslope. The following indicators were used:

Sediment Concentration which states the mass of sediments collected over the volume of water collected.

$$Sediment\ Concentration\ \left(\frac{g}{L}\right) \equiv \frac{Mass\ \text{of Sediments Collected (g)}}{Volume\ \text{of Water Collected (L)}}$$

Sediment Yield which states the mass of the sediments collected over the area of the plot and duration of Runoff Collection.

$$\text{Sediment Yield}\ \left(\frac{g}{m^2 h}\right) = \frac{\text{Mass of Sediment Collected (g)}}{\text{Area of the Plot } (m^2) \text{ x Duration of Runoff Collection (h)}}$$

Effectiveness Against Soil Erosion which states the difference between the sediment yield of bare soil and Hydroseeding and Coconet reinforcement over the sediment yield of bare soil.

$$\text{Effectiveness Against Soil Erosion (\%)} = \frac{\text{Bare Sediment Yield}\ \left(\frac{g}{m^2 h}\right) - \text{Sediment of Hydroseeding and Coconet Reinforcement}\ \left(\frac{g}{m^2 h}\right)}{\text{Bare Sediment Yield}\ \left(\frac{g}{m^2 h}\right)} \text{ x } 100$$

4.0 RESULTS and ANALYSIS

Table 1: Total Sediment Concentration and Sediment Yield

Experiment	*Sediment Concentration (g/L)*	*Sediment Yield (g/m^2h)*
Bare Soil	21.49 ± 28.26	563.95 ± 2457.47
Hydroseeding with Coconet	1.56 ± 11.57	5.72 ± 143.77

Table 1 compares the sediment concentration and sediment yield of bare soil and hydroseeding with coconet reinforcement. From the numerical value indicated above, it shows that the Hydroseeding with Coconet reinforcement lessen the mass of the soil eroded.

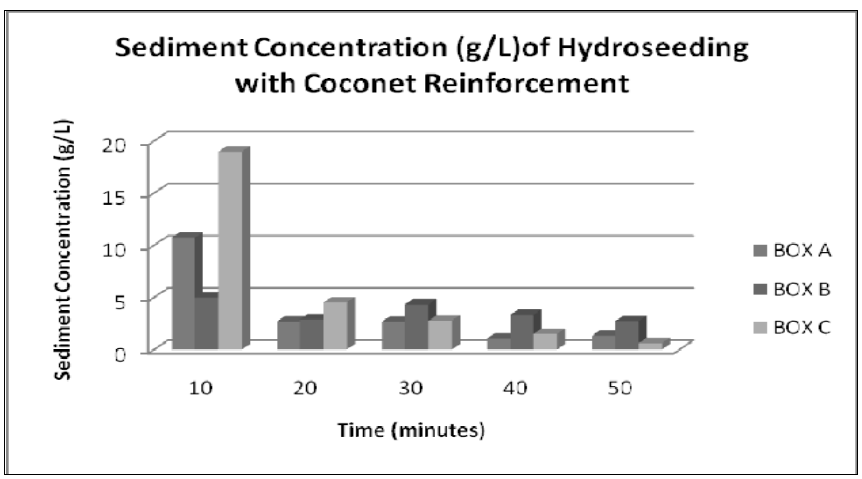

Figure 1: Sediment Concentration (g/L) for Hydroseeding with Coconet Reinforcement

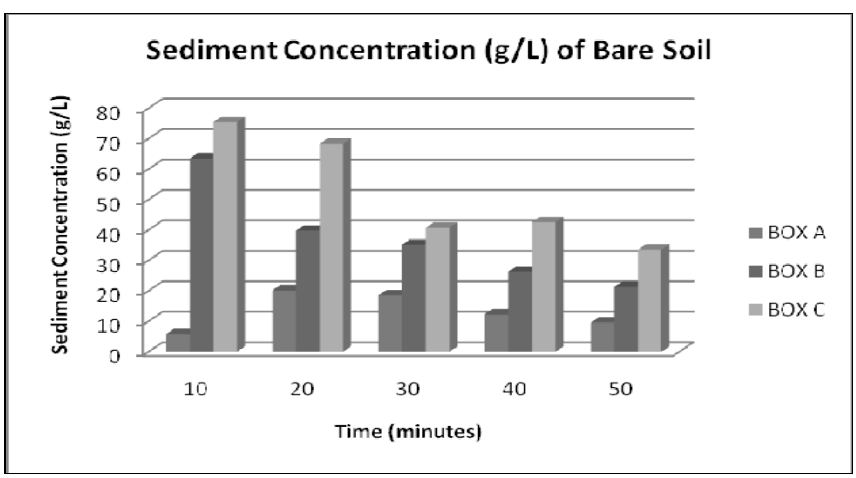

Figure 2: Sediment Concentration (g/L) for Bare Soil

Table 2: Effectiveness of Hydroseeding and Coconet Reinforcement versus Bare Soil against Soil Erosion

Time(mins)	Bare Soil versus Hydroseeding with Coconet (%)
0	0
10	94.15
20	97.95
30	98.4
40	99.01
50	98.99
Average	**97.7**

Table 2 determines the effectiveness of the applied hydroseeding with coconet reinforcement to control against soil erosion. According to the Effectiveness against Soil Erosion Formula, the greater the percentage computed the effective the Hydroseeding with Coconet reinforcement. From the Table 2, it shows that ninety-seven point seven percent (97.7%) of soil erosion was prevented by using hydroseeding with coconet reinforcement. Thus, the hydroseeding and coconet reinforcement is an effective soil erosion control instrument.

5.0 CONCLUSION and RECOMMENDATION

5.1 Conclusion

Results of actual laboratory experiments that were conducted with the use of the Department of Public Works and Highways Artificial Rainfall Simulation Apparatus showed that the use of the combination of Hydroseeding and Coconet reinforcement is effective in controlling soil erosion. From the results of the experiment, it shows that ninety-seven point seven percent (97.7%) of the soil was controlled from erosion given that the used slope is 65 degrees. It overcomes the threshold value of effectiveness of 80% defined from Sutherland, R. and Ziegler, A. in his study in Effectiveness of Coir-Based Rolled Erosion Control System in Reducing Sediment Transport from Hillslope. The researchers concluded that some of the discrepancies occur in the data results were from the calibration of rainfall apparatus.

5.2 Recommendation

The researchers suggests that if similar research(es) will be made in the future, adjustments on the proportions or mixtures of materials shall be given much attention and due consideration on other natural factors such as wind and sunlight. It has been noted by the researchers during the experiment that the slope may collapse easily when the saturation happens. Moreover, the researchers also suggest to use a lesser steep slope in the process, which is actually lower than 65 degrees.

The researchers have recommended taking note of the following basic steps in the application of hydroseeding with coconet:

1. Develop Hydroseeding product formulations and application procedures that will be compatible with current equipment and application methods at a given condition.
2. Take note of the right proportions of the required materials
3. Consider carefully the substitute or alternatives in case of non-availability of natural factors such as sunlight, etc., during the laboratory tests or experiments.
4. Evaluate and field test the various formulations using industry standard application equipment.
5. Conduct laboratory tests on the Hydroseeding and conventional hydroseed products for erosion control capabilities.
6. Conduct laboratory tests for water holding capacity, geobinder and other necessary organic materials, maturity of the materials after planting, water or moisture content, and the chemical and physical characteristics of the materials for Hydroseeding.
7. Develop cost analysis and cost comparisons between this method and other slope protection methods.

Designing Effective Rainfall Harvesting Systems in Developing Areas of Sub-Saharan Africa

Emmanuel U. Nzewi, PhD, PE, M. ASCE
emmanuel@engr.subr.edu

Department of Civil & Environmental Engineering

Southern University and A&M College
Baton Rouge, LA 70813

Abstract

This paper examines the design of rainfall-harvesting schemes that could be implemented to improve the availability of water in certain developing regions of sub-Saharan Africa. The focus of the paper is on the evaluation of rainfall distribution patterns in parts of Sub-Saharan Africa. Rainfall harvesting is a sustainable water supply alternative in the developing, as well as in the developed countries of the world. In the developed regions domestic rainfall harvesting is primarily a means for supplementing other sources of water (usually for non-potable water uses). This paper also highlights the activities of non-governmental organizations in the development and implementation of in-country (location specific) appropriate technologies for water supply. These groups fund and implement small projects which solve basic water and environmental engineering problems in small communities in developing areas. Usually the goal is to use in-country appropriate technologies to formulate innovative solutions to problems. In a recent study, the National Research Council, identified integrated water management as a high priority development requirement in its list of emerging technologies that would benefit farmers in Sub-Saharan Africa and South Asia. The study also stressed the need to address water shortage and access to water resources in Sub-Saharan Africa. Furthermore, the World Health Organization (WHO) estimates that the number of people without access to water services will increase from 300 million (in 2003) to 400 million by the year 2020. This paper will also provide an overview of the water resources inventory and distribution in Sub-Saharan Africa to emphasize the need for small-scale, community based water supply alternatives for developing areas in this region. The paper focuses on implementable solutions particularly tailored for the region. These solutions are termed "location-appropriate" and therefore employ locally available resources, whenever possible, to achieve solutions that are cost-effective, sustainable and efficient. It addresses the need to analyze the temporal and spatial variation of precipitation in the design of viable rainfall harvesting systems.

Introduction

Rainwater or rainfall harvesting is the collection and storage of rainfall from roofs or surface catchments for later use. A rainwater harvesting system may include a means for water treatment when the water is used for drinking or cooking. Rainwater harvesting includes processes whereby runoff can be collected and stored for usually non-potable water requirements and/or for irrigation. If potable water requirements are to be met, then some measure of water treatment is necessary.

This study is part of an effort to identify and outline effective solutions to basic water problems faced by peoples and communities in developing areas of the world. The localized solutions identified provide strategies and remedies with the potential of achieving sustained reliable water supply. With respect to domestic rainfall harvesting, any solutions must consider the prevailing climatic factors, cost, locally available materials, scale and any similar factors that might enhance or impede successful implementation of a solution. Domestic rainfall harvesting may be differentiated from communal systems where several families are served from a common water source.

According Nzewi and Luster-Teasley (2008), Nnadi (2004) and Nzewi (2004) several acute water problems have been identified in developing regions. They are: water scarcity, poor drinking water quality (and water borne diseases), roadway drainage and runoff management, surface water pollution, improper dumping of untreated wastewater and solid waste into streams and the flood plain, depletion of groundwater sources, and mismanagement of reservoir systems. This paper highlights one of these problems – water resource availability.

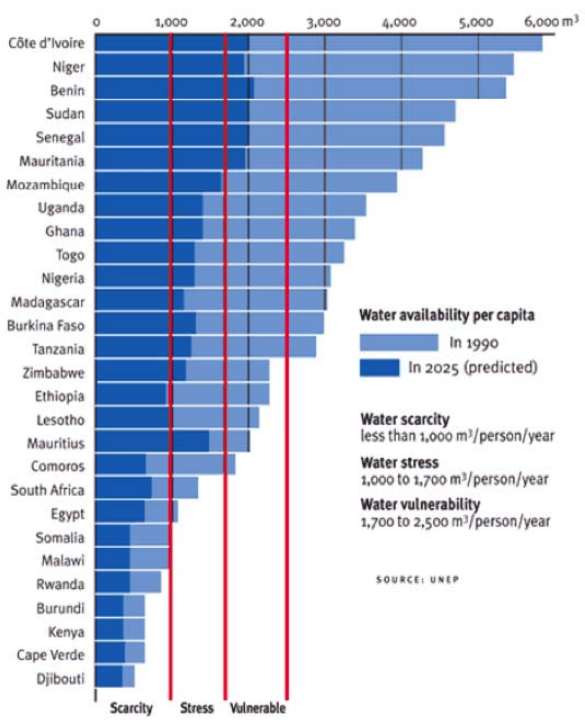

Figure 1 Water availability (m^3/person/year) in Africa in 1990 with 2025 projections.

Furthermore, based on the 1998 United Nations Medium Population Projections, 2.8 billion people in 48 countries will face water stress or scarcity conditions by 2025 (See Figure 1). Some of the countries in this list are in West Asia, Sub-Saharan Africa (Northern and Southern) and in the Middle East. It has been estimated that by 2050 (projected population 9.4 billion), as many as 54 countries with a combined population of about 4 billion may face water stress or scarcity.

Except for Asia, Africa has the highest average population growth in the world, approaching 13 percent of overall world population. This growth could increase percentage of Africa's population relative to the world to about 20

(Source: http://www.sahims.net)

percent ($1/5^{th}$) by 2050, according to the Population Reference Bureau. Significant population growth means more demand for water, which exacerbates the water situation since the continent is already suffering from water scarcity. Africa is the second largest inhabited continent but has only the fifth highest volume of water reserves available. There is therefore a need to increase available water, manage and conserve water resources in Africa.

Sub-Saharan Africa

Figure 2 and Figure 3, below, provide the annual rainfall distribution and list the major rivers in the African continent, respectively. It can be seen that the northernmost (corresponding to the regions around the Sahara desert) and southernmost (western portion) areas are arid. Sub-Saharan African encompasses the Sahel -- a series of countries across the northern part of the continent that are immediately south of the desert – to the southern tip of the continent. The climate is quite diverse ranging from topical humid (around the mid-section of the continent) to arid. A large portion of Sub-Saharan Africa (S-SA) is influenced by the monsoon season. As shown in Figure 3, 12 major rivers drain the area including the Nile river. In the humid (wetter) regions, there is an interconnection between the surface and groundwaters. This is not the case in the arid regions where the groundwater and surface waters are not connected and therefore the recharge of groundwater depends on rainfall. Additionally, base flow is relatively low in rivers in arid regions while evaporation is significantly higher (NAS, 2008). With respect to the distribution of water resources in S-SA, in the Sahel, water resources are limited and spatially unevenly available. As Figure 3 shows, the Nile River drains through basins in the eastern part of the Sahel. West S-SA is served by many rivers including the Niger, Senegal, Volta, Lake Chad and Benue (not listed in Figure 3). The Gulf of Guinea in the west includes the Niger (which drains in the Gulf) where there is a tropical climate highly influence by the monsoon. One fourth of the region's water resources may be found in this region. In comparison, east of the Gulf, is the humid tropical climate of central Africa. Central S-SA is served by the Congo and Ooguue Rivers – and includes almost 50% of the region's water resources. The climate ranges from semi-arid to tropical humid in eastern S-SA and as stated previously the major river here in the Nile. However, the region also boasts of the largest lake in the continent – the Lake Victoria. Finally, the southern region of S-SA has a diverse climate ranging from arid (south southwest) to sub-tropical humid. The Rivers: Zambezi, Limpopo, Orange; and inland lakes: Malawi and Tanganyika, serve the region. Comparatively, available water resources are less abundant in this region. Interestingly, therefore,

eastern and southern S-SA make up only about 25% of the continent's water resources.

Africa (and essentially S-SA) is populated by about 13% (about 905 million) of the world's inhabitants, and the total renewable water resource is approximately 5000 m^3/year/capita. Since S-SA is comparatively sparely populated (on the average), there is adequate (average) renewable water resource per capita even in countries in the Sahel. This is not true in densely populated countries like Nigeria. On the other hand, however the water is not always readily accessible to the population. Herein lies the problem in the region.

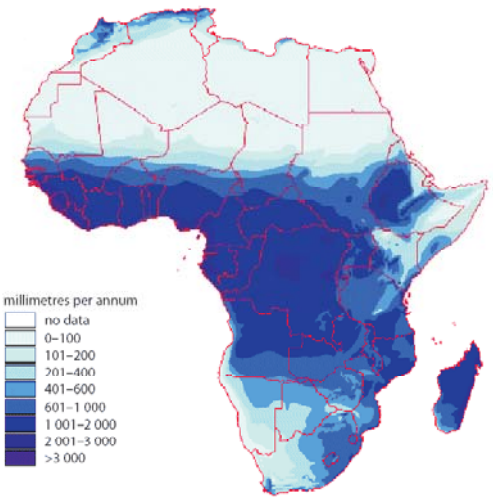

Figure 2 Annual Rainfall Distribution in Africa (Source: FAO/Agrymet)

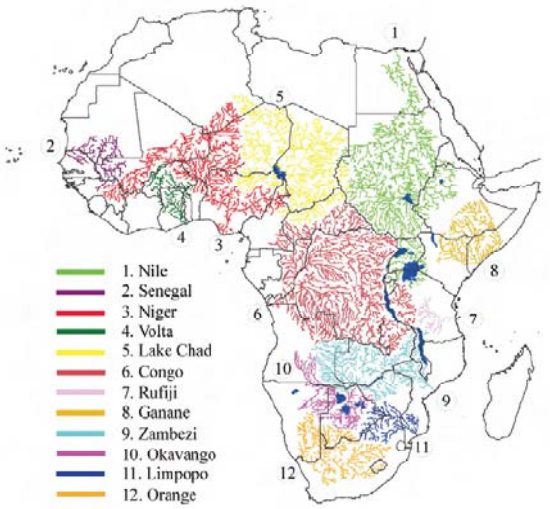

Figure 3 Major Rivers of Africa (Source: NAS, 2008)

Poverty and access to water seem to go hand-in-hand in many African countries, especially in rural areas as shown the relationship between rainfall and GDP for Ethiopia in Figure 4. Those without access to water must travel to find water sources, and the time spent doing this prevents them from improving their own standards of living. Often the quality of life of a rural area can be improved with the simple addition of a well or other source of water that provides clean water. Studies have been able to directly link access to water and poverty.

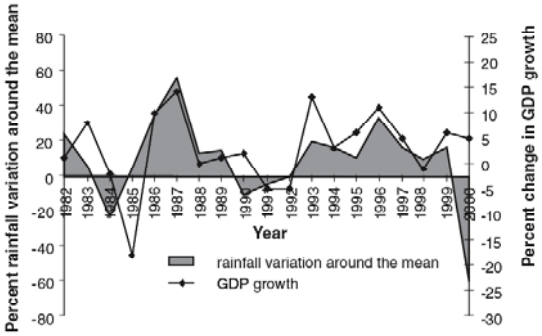

Figure 4 Rainfall Variation Around Mean and Gross Domestic Product in Ethiopia 1982-2000 (Source: NAS, 2008)

Impact of Non-Governmental and Private Groups

In the past, private and non-governmental have embarked on projects designed to alleviate the suffering, disease and poverty in developing regions of the world. Many of these projects have been successful while some have sometimes made the problem worse because the solutions did not adequately consider important factors such as sustainability and the unique cultural tendencies of the peoples involved. The failure of some of these systems resulted in the re-evaluation of solution strategies and provided a knowledge base for what does not work as well. More recently, perhaps in the last 10 years, there has been an increasing crescendo of more effective projects because the approach has shifted to become more location-specific, sustainable methods that employ "green technologies" instead. The term "green technologies" refers to the application of design strategies that minimize the degradation of the environment while making use of renewable resources in their design and implementation. Several organizations have championed this approach but there are two notable ones that are making significant impacts around the globe, but particularly in Sub-Saharan Africa: Engineers Without Borders (particularly United States of America) and WaterAid (United Kingdom)

Engineers Without Borders-USA (EWB-USA) describes itself as follows: "A non-profit humanitarian organization established to partner with developing communities worldwide in order to improve their quality of life. This partnership involves the implementation of sustainable engineering projects while involving and training internationally responsible engineers and engineering students." It has both professional and student-led chapters all over the United States of America. It has established itself in the business of implementing "green" solutions mainly through volunteers in the solution of a wide range of problems that go beyond water supply and sanitation. In fact, many universities have established chapters that sometimes work on a wide array of projects --- year round. Documented projects include: bore-hole (groundwater well) and water distribution system for a small community and local elementary school in Ghana, West Africa; A small hydropower plant and distribution system to benefit villages in India; a reactor that produces biodiesel fuel from oils containing large quantities of fatty acids; a sustainable water development program for a rural community in Nigeria, West Africa; a handheld bleach generator that can disinfect drinking water --- to list a few. EWB-USA has been so impactful that the news about the organization and its activities have been featured several times the American Society of Civil Engineers news in the past year. This is extremely important because the technologies that are being developed and implemented are highly successful and these programs can be easily extended to solve problems, perhaps with minor adaptations, in many communities in Sub-Saharan Africa (S-SA). The goal of this research is to device a means for collecting and disseminating information about "green" water development technologies that can be implemented in S-SA. First, the projects that fall under rainfall harvesting (and water treatment) will be addressed. The goal is not to re-invent the wheel, as the saying goes, but to determine what solutions already exist, catalog them and provide

a resources clearinghouse for disseminating and facilitating location-specific solutions.

Figure 5 Engineers Without Borders Project in Ghana: Water Distribution System

WaterAid (United Kingdom) – describes itself as **"**an international charity whose mission is to overcome poverty by enabling the world's poorest people to gain access to safe water, sanitation and hygiene education." "WaterAid enables the world's poorest people to gain access to safe water, sanitation and hygiene education. These basic human rights underpin health, education and livelihoods and form the first, essential step in overcoming poverty." WaterAid has projects along these lines in 17 countries located in Africa, Asia and the Pacific Region. WaterAid works with local partners so that local issues and conditions are brought to the fore, to provide skills, training and support, in the development of sustainable projects that meet community needs. In S-SA, WaterAid has current projects (sometimes multiple) in: Burkina Faso, Ethiopia, Ghana, Malawi, Mali, Mozambique, Nigeria, Tanzania, Uganda and Zambia.

The importance of the foregoing discussion is to identify established organizations that are at work in Sub-Saharan Africa. The need is great in the region because of population shifts toward urban areas and population growth. In addition, there may be complexities related to shifting rainfall patterns due to changing (whether short or long term) climate shifts. One of the objectives of this paper is to propose strategies that could help in addressing the problem of water availability and access in rural communities in S-SA.

Rainfall Harvesting

Rainfall harvesting can be an attractive water supply alternative because it can be easily integrated into existing water supply systems. Furthermore, it is an environmentally superior to other methods of water supply and an effective means for readily increasing available water resources. The cost of the infrastructure for domestic rainfall harvesting is comparatively lower than for other methods. Rainwater harvesting has the following environmental benefits: (a) reduced storm water volume and peak discharge rate; (b) reduction in urban flooding; (c) reduction in the amount of sewerage diverted to sewage water treatment systems; (d) increased groundwater recharge; and (e) minimal use of energy for pumping.

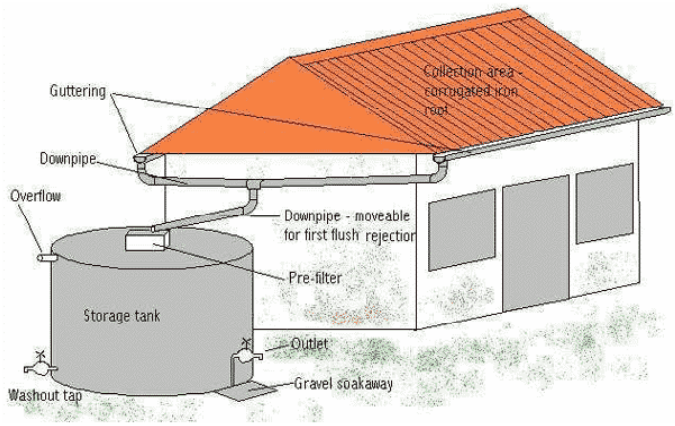

Figure 6 Rooftop Catchment For Rainwater Harvesting
[Courtesy of DTU -- www.eng.warwick.ac.uk/dtu/index.htm]

Several countries in both the developed and under-developed countries that already practice some form of rainwater harvesting; however, it is mostly used for non-potable water. These include, but are not limited to: South Africa, Kenya, Zimbabwe, Ethiopia, China and United States. In the under-developed world, rainwater harvesting can be divided into micro-catchments and macro-catchments. Micro-catchments are specially contoured areas with slopes and berms designed to increase the runoff from rain and concentrate it in a planting basin where it infiltrates and is effectively "stored" in the soil profile. The water is available to plants but protected from evaporation. There are three basic types of microcatchment systems: contour bench terraces, runoff strips and micro-watersheds. Runoff strips and contour bench terraces are best suited for agriculture as they require extensive mechanical re-shaping of the surrounding terrain and create regular patterns which are inconsistent with a natural landscape. Micro-watershed systems are more appropriate for revegetation. These include mound, strip and basin collectors.

Another method of rainfall harvesting is from rooftop catchments. This method is practiced in the developed world but not widely used in the developing world due to the lack of design and implementation knowledge; however it can be implemented in under-developed regions to help ease tension on their water resources. The system consists of three basic elements; a collection area, a conveyance system and a storage area. The collection area would be the roof; the conveyance system would consist of gutters and pipes to transport the collected water to the storage system which is basically a storage tank. In order to maintain the cleanliness of the system, gutters and pipes have to be cleaned periodically. Figure 1 below shows a diagram of a rooftop catchment water harvesting system.

Drinking water is an important requirement for human life, although, it only accounts for a small fraction of total human comsumptive use. Domestic water consumption is highly influenced by the "ease" with which it can be obtained.

Usually, a family that has ready access to water, tends to use more water than a family that has travel far to fetch water (Thomas, 1998).

Rainfall harvesting has been practiced in areas where conditions have been favorable or conditions for other means of water supply have been less desirable. The most expensive component of the RH system is because the storage tank of a system must be large enough to smooth-out both short-term and long-term fluctuations in available rainfall. The tank tends to be large and it is usually impractical to use one that is not well constructed. Most buildings already have a roof thus very little cost if any is incurred in retooling the roof for rainfall harvesting. In areas where rainwater harvesting is currently practiced on a significant scale, it is done out of necessity rather than due to a commitment to autonomy like in China, Rural East Africa and Singapore (Thomas, 1998).

The sizing of the storage tank is a very important design element in development of an effective water harvesting system. There are several web-accessible computer programs for accomplishing this task. Furthermore, for a given location, there is a limit to the amount of water that can be collected via rainfall harvesting. In sizing a storage tank the following information is normally required: household size, water use requirements, water availabilty (rainfall records – including distribution) (DTU 2001).

Rainwater Harvesting in Sub-Sahara Africa

Rainfall varies temporarily and spatially. The rainfall records for several countries in Sub-Saharan Africa were obtained and analyzed. Table 1 shows the monthly average rainfall for two countries: Nigeria and Angola. These sets were chosen to highlight differences in tropical humid and semi-arid climates and temporal variation over the months of the year. The data represents the average monthly rainfall between 1931 and 1960as reported by the National Climatic Data Center in the USA. Full dataset cannot be presented here due to space constraints. The data were obtained for Senegal, Ghana, Gambia, Nigeria, Togo, Mali, Burkina Faso, Cameroon, Republic of Congo and Angola. The sample for the 2 selected countries is provided in Table 1.

In Table 2, the average annual rainfall for all the reporting cities (for each country) have been provided. Table 2 shows a wide range of average annual rainfall values. The average of the annual rainfall values in Table 2 is of 40.7 inches, with a range of 40.1 inches and a standard deviation of 14.1 inches. For rainfall harvesting applications, while the average annual rainfall rate for a country may be used as a regional planning guide, the rainfall values for a city (or a geographic location) should be used in the design of any rainfall harvesting system.

Table 1 Monthly Rainfall [inches] in Selected Cities by Country

NIGERIA

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Total
Enugu	0.7	1.1	2.6	5.9	10.4	11.4	7.6	6.7	12.8	9.8	2.1	0.5	71.6
Kaduna	0.0	0.1	0.5	2.5	5.9	7.1	8.5	11.9	10.6	2.9	0.1	0.0	50.1
Lagos	1.1	1.8	4.0	5.9	10.6	18.1	11.0	2.5	5.5	8.1	2.7	1.0	72.3
Maiduguri	0.0	0.0	0.0	0.3	1.6	2.7	7.1	8.7	4.2	0.7	0.0	0.0	25.3

ANGOLA

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Total
Cangamba	8.9	7.4	6.8	1.8	0.1	0.0	0.0	0.2	0.2	1.6	5.1	8.5	40.6
Huambo	8.7	7.8	9.8	5.7	0.4	0.0	0.0	0.0	0.6	5.5	9.6	8.9	57.0
Luanda	1.0	1.4	3.0	4.6	0.5	0.0	0.0	0.0	0.1	0.2	1.1	0.8	12.7
Namibe	0.3	0.4	0.7	0.5	0.0	0.0	0.0	0.0	0.0	0.0	0.1	0.1	2.1

In addition, the temporal variation of rainfall is also important because it can be an factor in the determination of the size of the storage tank. For a system to be effective, the storage must be enough to handle both the short-term and long-term variability in rainfall. Furthermore, for enough water to be collected, the roof area must be adequate to concentrate a large enough volume of water.

Table 2 Average Annual Rainfall by Country (1930 – 1961)

Country	Average Rainfall [in]
Angola	28.1
Burkina Faso	40.8
Cameroon	59.2
Congo	54.9
Gambia	51.0
Ghana	41.8
Mali	19.1
Nigeria	54.8
Senegal	25.8
Togo	31.0

Figure 7, below presents the spatial distribution of rainfall in a country. The purpose is to highlight the in-country variation of rainfall of rainfall. It shows that it is vitally important to determine the rainfall patterns at a particular location rather than using average values determined for the country as whole. A case in point is Nigeria where there's a marked difference between Lagos and Maidugri. In the design of a rainfall harvesting system, it is therefore crucial to study the local rainfall patterns closely so that an effective design can be provided. In addition, since many areas in Sub-Saharan Africa are affected by the monsoon, it is equally important to consider the seasonality of precipitation in the areas.

As a follow up to this study, the rainfall patterns for the entire region will be analyzed and categorized to identify areas that have common/functionally similar patterns. This will help to identify areas that should follow "regionally" developed design guidelines. The purpose is to minimize the effort required to design the systems by "reusing" design "patterns" so as to reduce the effort in providing effective systems. Hopefully simple charts (the goal) will be provided whereby a chart-driven approach that locals can easily use to design an build there systems. The goal of this approach is to empower the local communities –as much as possible so that they play a very active role in providing the solutions themselves. Furthermore, as the activities of Engineers Without Borders and WaterAid expand, best practices will emerge and the methods can be cataloged and disseminated to aid local governments or local communities in generating their own solutions.

Spatial and Temporal Variation of Rainfall In Selected Countries

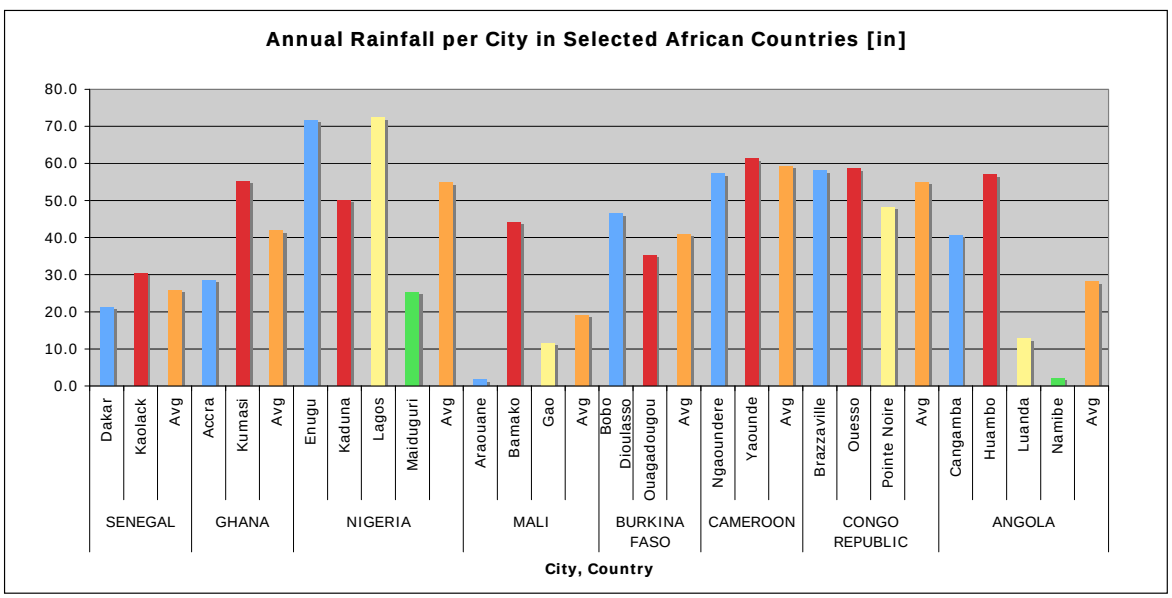

Figure 7 - Spatial Variation of Rainfall within Selected Countries Studied

To design a rainwater harvesting to meet the average demand of 50 liter/day/capita (according to Cowden et al, 2006) the per capita roof area available (**A** [m^2]), the roof runoff coefficient (**C** – a generally accepted value is 0.8, according to Cowden, et al, 2006) must be taken account as well as the expected rainfall amount over a period a time. Average per capita roof sizes (2 – 20 m^2) vary widely and for that reason, a relationship between $\mathbf{S_d}$ and **A** has been developed to aid in determining the viability of a system. The amount of water (liter/day/capita) that can be provided by the rainwater harvesting system is given by:

$$S_d = CAR_k$$

where, R_k is a rainfall coefficient = annual rainfall (mm) divided by 365.

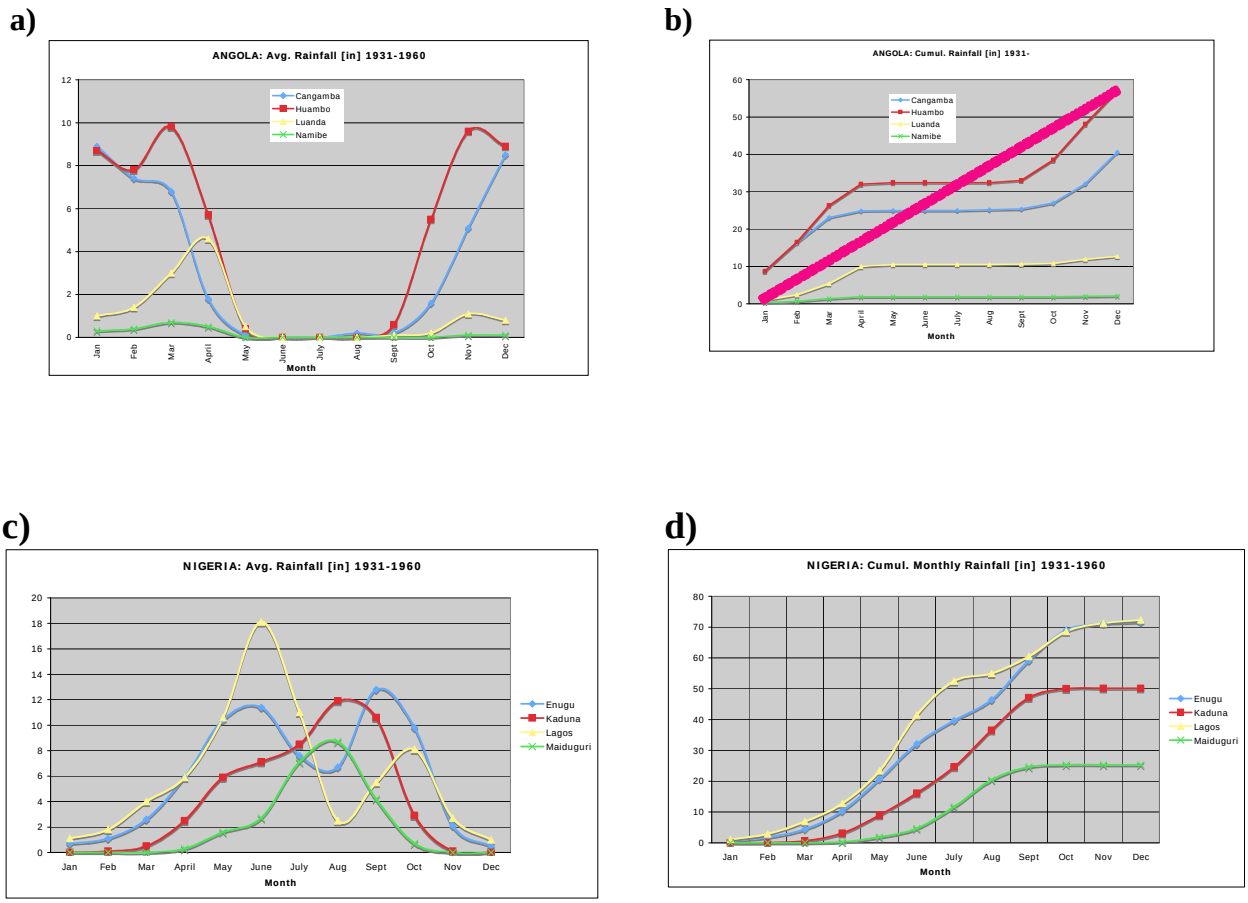

Figure 8 – Monthly Average Rainfall [in] (a, c) and Cumulative Rainfall [in] (b,d) for Selected Cities: Nigeria and Angola

It should be emphasized that in regions where most of the rainfall is concentrated during a few months of the year, much of the rainwater collection (and storage) must occur during those wet months and therefore storage and managed release for future use is necessary. The following presents the water demand/supply scenario for one country (Nigeria).

In Figure 8, the variation of rainfall is captured by evaluation the distribution during the year. It can be seen from Figure 8 (a,c) the difference between the rainfall patterns for Nigeria and Angola. While the cumulative values are not very different the periods over which a large percentage of the rainfall can be captured differs in length and in timing. Thus the design of storage components must be adjusted to reflect these differences.

Innovative Design at Lake Lenexa

Scott R. Brand, P.E.[1] and Tom A. Jacobs, P.E.[2]

[1]Geotechnical Engineer; Black & Veatch Corporation; 8400 Ward Parkway, Kansas City, Missouri 64114; brandsr@bv.com
[2] Stormwater Engineer; City of Lenexa, Kansas; 12350 West 87th St. Parkway, Lenexa, Kansas 66215-2882; tomajacobs@ci.lenexa.ks.us

ABSTRACT

As new dams get built closer to the public in existing neighborhoods and towns, the Public, through public participation workshops and events are asking for more amenities in the form of parks, recreational facilities, and education seminars be implemented to increase voter satisfaction. The public is also asking for more aesthetic designs if they can be proven cost-effective at providing an appealing element to new dams. Lake Lenexa was designed and built around the idea of providing for basic dam functions such as flood control, enhanced water quality, recreation but also to provide an inviting community focal point for the residents to visit and enjoy; truly interact with the dam. The residential setting became the impetus for a bigger vision emphasizing bold architecture and aesthetics. Innovative design techniques were implemented to capture the architectural elements of the dam.

Extensive architectural elements were incorporated into the dam design including MSE retaining walls, Use of CKD (Cement Kiln Dust), cantilevered spillway bridge, trellis, and a wide variety of landscape architecture.

Water quality enhancements were achieved through the use of wetland treatment cells on the upstream tributaries of the reservoir. In addition, several stream restoration projects were completed for the area.

The overall project includes the development of three wetlands; trails; recreational and park amenities; and a future amphitheater. Three miles of trails connect the lake to surrounding neighborhoods. The architecturally unique dam and "one of a kind" spillway were designed to symbolize the water cycle as water moves from nature into the urban environment and the back to nature. A pedestrian bridge that spans the spillway offers visitors a good view of cascading pools and a fountain.

INTRODUCTION

Lake Lenexa is under construction upstream of the existing Whispering Hills housing development in Lenexa, Kansas, a suburb of Kansas City, with a population of approximately 45,000 residents.

Lake Lenexa is on the western side of Lenexa. The primary roads bordering the site include State Highway 10 to the south, State Highway 7 to the west, 83rd Street to the north, and Woodland Avenue to the east (Figure 1).

Figure 1. Lake Lenexa Location

As an integral part of the city's Rain to Recreation program, Lake Lenexa was designed to reduce flooding for downstream developments, improve water quality, provide recreational opportunities, and preserve critical habitat.

Initial Studies

The purpose of the Coon Creek Watershed Study was to develop a plan for stormwater management tailored specifically for the watershed. The major items studied in the watershed were recent flooding and projected flooding potential after the watershed was developed, hydrologic and hydraulic modeling, water quality concerns, stream stability evaluations, and recreational opportunities.

Initial studies included the following to support permitting activities: determination of jurisdictional wetlands, endangered species, cultural resources, and preparation of mitigation plans for affected areas.

The proposed project included the following: retention lake, four upstream wetland treatment cells for water quality enhancement, and stream restoration projects along the upper reaches of Coon Creek. The project involved a unique solution to the problems within the watershed, while adhering to the Rain to Recreation requirements.

Community Involvement

With the proximity to existing neighborhoods, community involvement was a key requirement of the project. The city of Lenexa solicited community involvement and comments at all stages of the project through public events, workshops and meetings, planning "Input and Review Sessions," newsletters, Web sites and interactive email.

Through these events, the city and Black & Veatch determined how to increase the benefit to the local community by developing stream restoration projects along the upstream reaches of Coon Creek, fish and wildlife habitat, wetland areas in the upper reaches of the reservoir, hiking trails, and park and recreational facilities. Figure 2 details the recreational facilities planned for the park surrounding the reservoir.

Preliminary Design and Aesthetics

Initial design concepts for the dam included the use of roller compacted concrete (RCC) for the main dam and spillway components. However, geotechnical investigations showed potential sources of silts, clays, and weathered shale in the reservoir area that could be used for an embankment dam.

Geotechnical studies were performed to determine the soil and rock zones along the proposed dam alignment, the leakage in the rock zones, available borrow sources and properties, foundation materials, and abutment rock conditions. Additional studies included geological mapping of the abutments and reservoir areas. These studies indicated that the upper portions of the dam abutments consisted of limestone and shale units; the lower stratigraphy consisted of a thick shale layer underlying the reservoir area. Limestone outcrops were visible along the reservoir fringe, generally above the normal water level, except for the Frisbie Limestone (Figure 3).

The geotechnical investigations included soil and rock coring, water pressure testing of rock, installation of piezometers to monitor water levels, seismic refraction testing along the dam alignment, test pits to determine potential borrow sources, and laboratory testing of soil and rock samples to support the design activities.

Initial dam design included an analysis for a central core embankment with an internal chimney drain and blanket drains to control seepage through the embankment. Initial design also included slope stability analyses, seepage analyses, settlement analyses, and drilled pier design for the spillway bridge supports. Figure 4 shows a typical section through the embankment.

The spillway design included the Kansas requirement to pass the 0.4 Probable Maximum Flood (PMF) flows through the spillway with a minimum 3 feet of freeboard. The middle portion of the ogee spillway was designed to pass the 100 year storm event, and the entire spillway was designed to pass flows up to the 0.4 PMF (Figure 5).

Because of the urban location of the project, aesthetics played an integral role in the architectural design of the dam and its components. Elements in the design included a curved dam alignment, ogee spillway, unusual architectural spillway features, spillway bridge (cantilevered section with a separate viewing canopy), spillway steps, curvilinear spillway walls, spout structure, landscaping plans, recreational trails, and the stilling basin design. Figure 6 shows a plan of the dam alignment. Figure 7 shows a close-up of the lower spillway step details. Figure 8 shows details of the upper basin and the low flow channel.

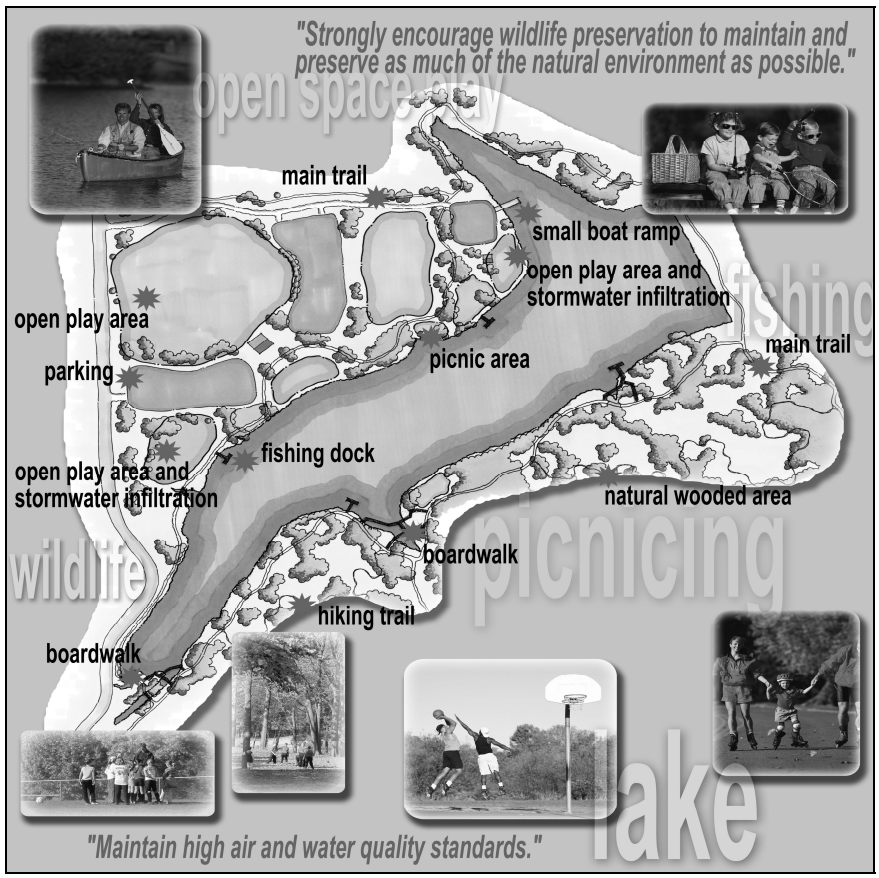

Figure 2. Recreation Components

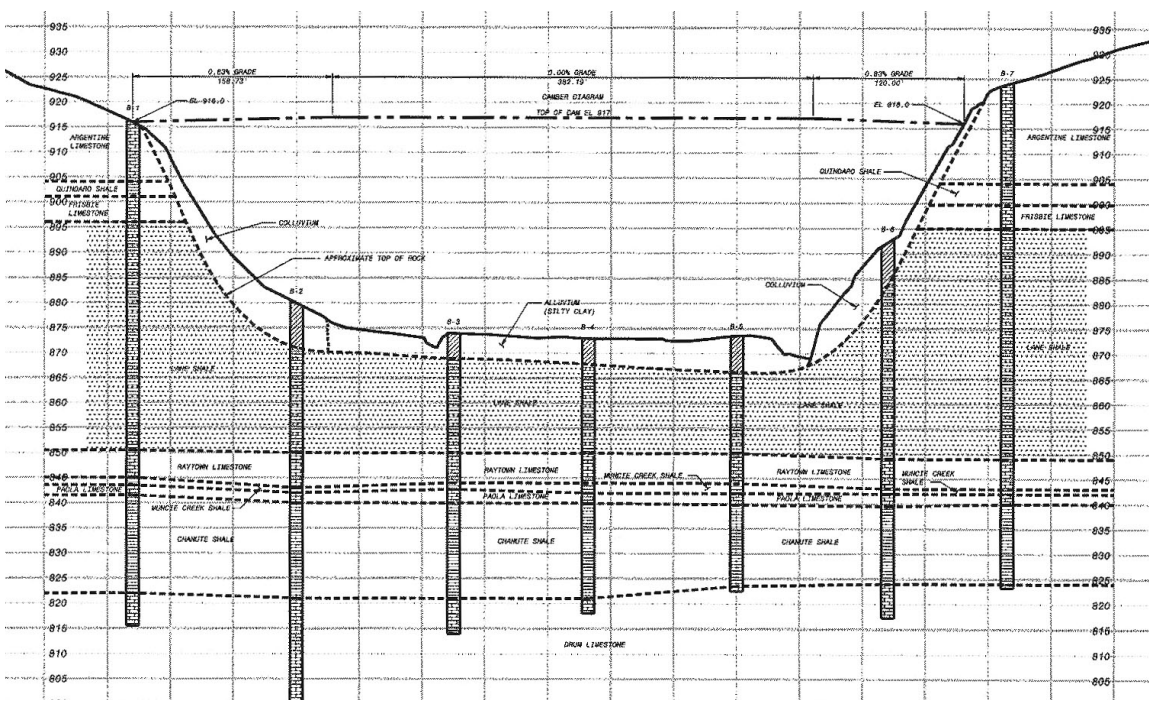

Figure 3. Geologic Cross Section at Dam

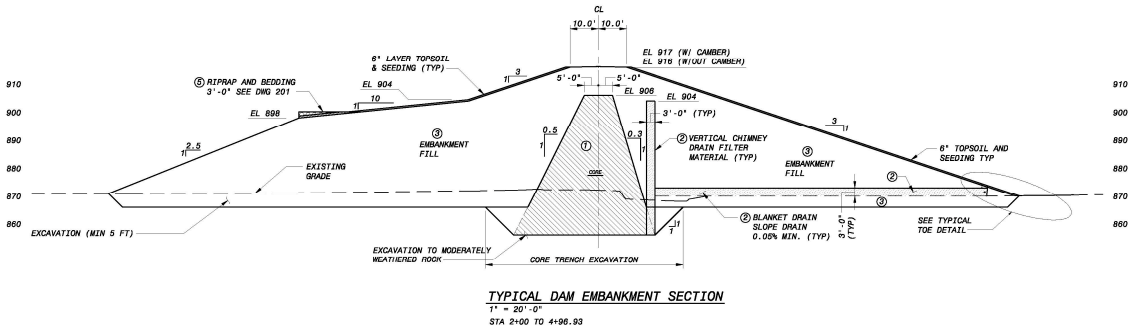

Figure 4. Typical Embankment Section

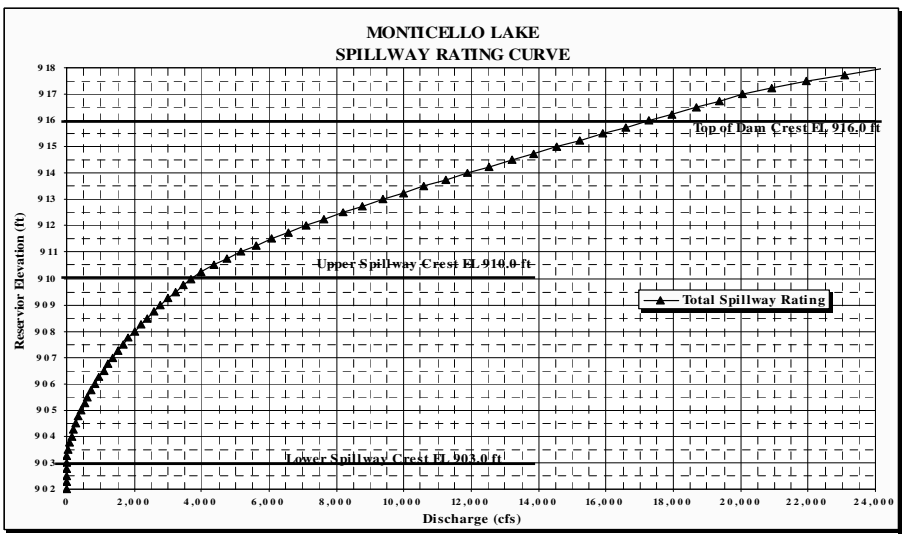

Figure 5. Spillway Rating Curve

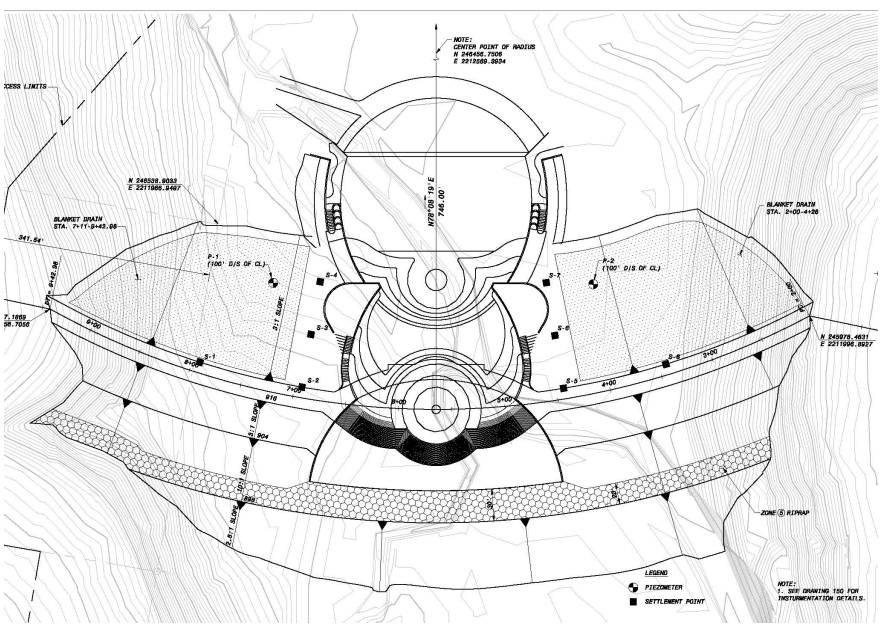

Figure 6. Dam Plan

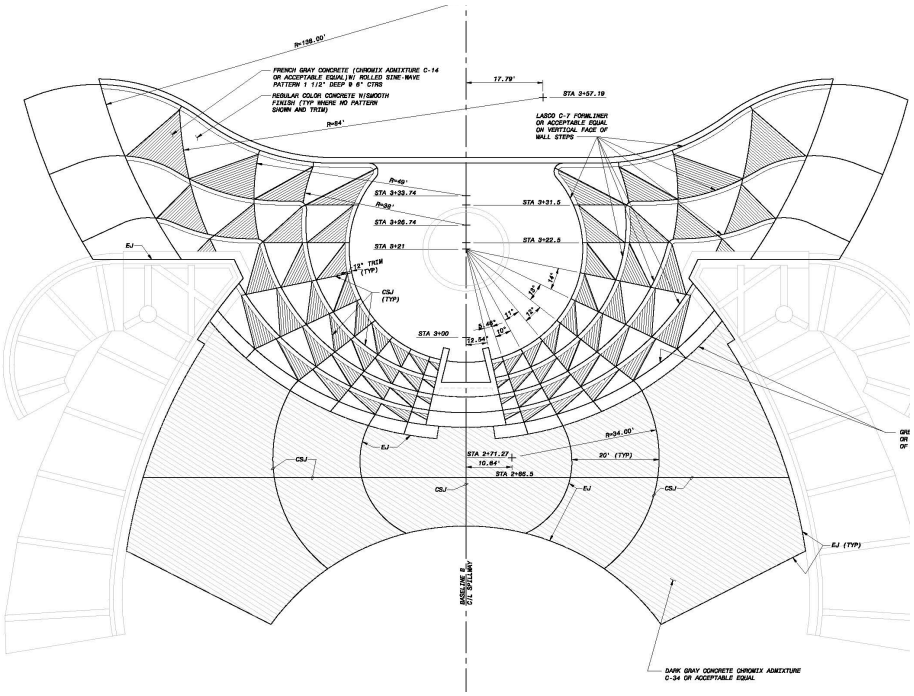

Figure 7. Lower Spillway Step Details and Middle Basin

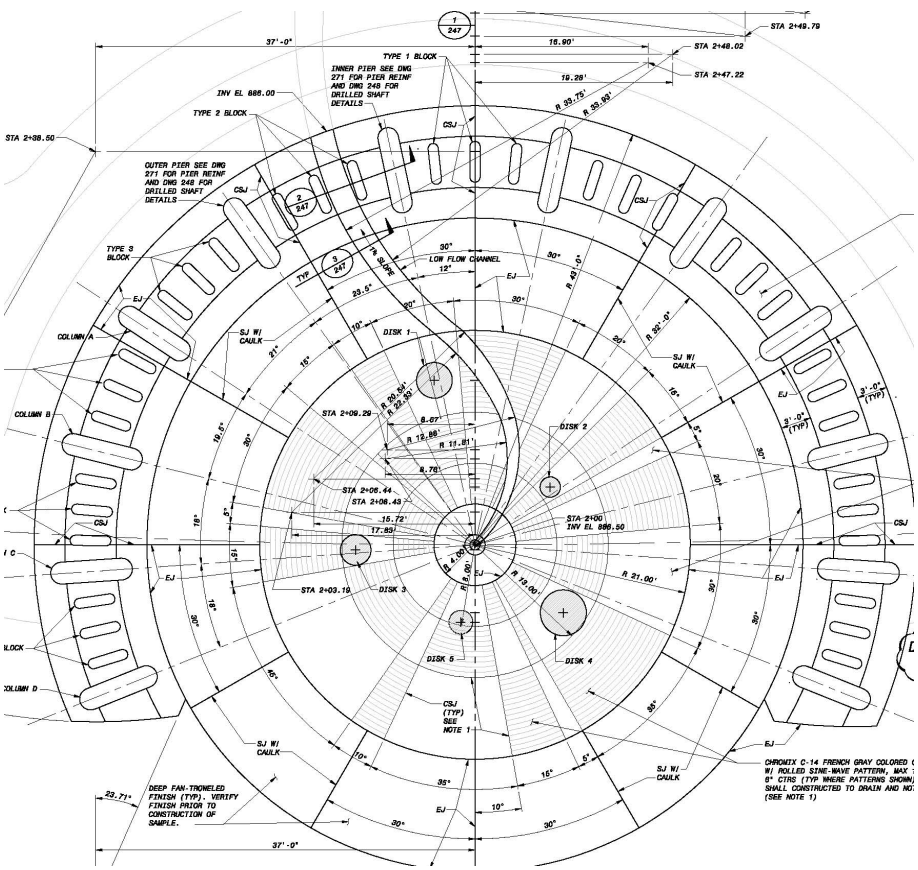

Figure 8. Upper Basin Details

Park facilities surrounding the dam and reservoir include a pavilion for community events, boat ramps and fishing docks, viewing areas, boardwalk and elevated bridges, wetlands, playgrounds, recreational trails, and outdoor classroom areas on the downstream side of the dam (refer to Figure 2).

Final Design/VE Workshop

The original spillway design included high retaining walls that formed the spillway training walls. These retaining walls were counterfort walls designed to withstand high bearing pressures and were a relatively rigid system. Adequate bearing capacity and differential settlement of the walls were design issues.

A VE workshop that included the Owner, Consultant, and Contractor explored cost-effective means to implement the architectural elements of the spillway. The workshop examined several options: various retaining wall systems in lieu of the counterfort walls, alternate materials for stable foundations for the spillway structures and structural slabs, options for providing a positive seepage cutoff under the spillway, options for spillway bridge systems, and changes to the landscaping requirements.

The VE workshop decided to use MSE retaining wall systems to form the high spillway walls and CKD to mix with the onsite borrow silts and clays to provide support for the spillway structures and slabs. Both items are innovative for use on a dam and reservoir project.

Typically, MSE walls are used for road and bridge projects. The decision to use MSE walls provided some valuable benefits: lower installed cost, a flexible wall system that could undergo some settlement, lower bearing pressures at the toe of the wall, ability to accommodate multiple curves in spillway design, and ability to provide a "Fractured Fin" pattern similar to the panels originally envisioned for the spillway walls. The project architect expressed concerns about the overall visual appearance of the walls because of the horizontal and vertical wall joints in the precast panels. However, the benefits outweighed this minor consideration.

CKD material produced by the cement industry is analogous to fly ash from the coal power industry. A mix design testing program demonstrated that the CKD material, mixed with silts and clays, was capable of reaching design strengths of 300 psi. CKD provided a high strength material to support all the spillway structures, including the spillway walls, spillway slabs, and ogee spillway. The onsite borrow clays mixed with the CKD provided a low permeability material that reduced the potential for seepage under the thin spillway slabs and potential uplift on the slabs.

Dam and Spillway Construction

Construction began in the summer of 2004 with general clearing and grubbing of the reservoir and dam areas. Subsequent work included excavation of the dam foundation and core trench areas and field testing of the CKD materials. The core trench

for the dam foundation was excavated into the hard and competent Lane Shale. Water pressure testing showed this material to be tight with no leakage, which provided a good seepage cutoff into the foundation below the dam.

Onsite mix testing of the CKD materials was performed using various proportions of the kiln dust to provide an optimum mixture to meet the strength requirements. Mixing methods, proportions of the materials, and placement procedures were determined during the field testing program. During the actual placement of the CKD materials, samples of mixed CKD materials from behind the mixing equipment were taken to the laboratory and cured under various temperature and curing durations to determine the compressive strength gain of the mixtures with time. Figure 9 shows some of the strength relationships observed from the testing.

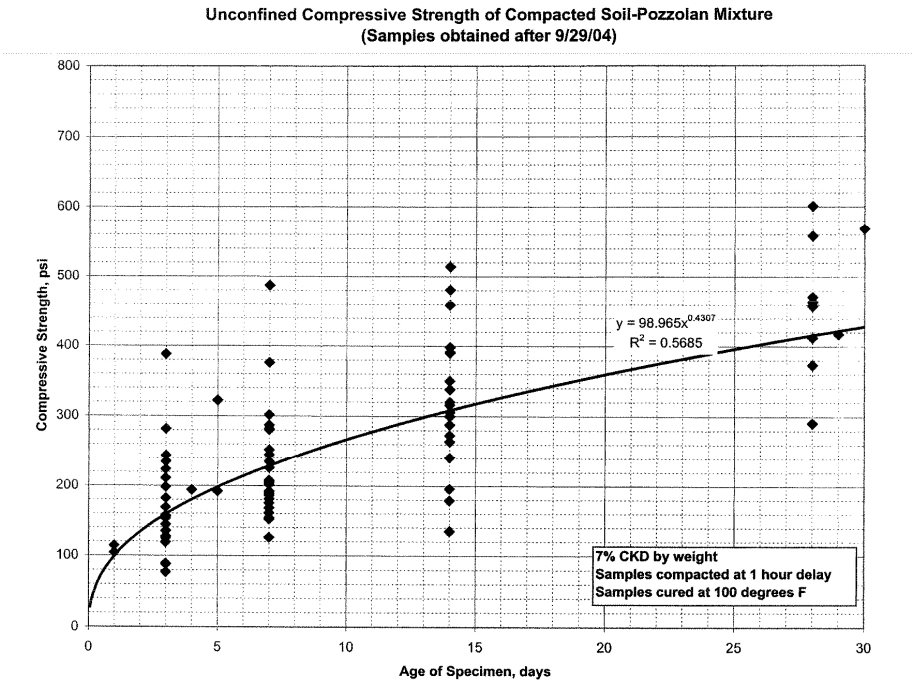

Figure 9. CKD Strength Test Results from Field Samples

Once the weathered materials had been excavated from the spillway area, the CKD materials were placed by mixing the borrow silts and clays with 7 percent kiln dust. The materials were mixed in place with a pulverizer and a water truck operating in tandem. Samples of the mixture were taken to the laboratory daily to create samples for the strength testing (Figure 10).

The MSE walls that formed the spillway training walls and the stilling basin walls were delivered to the site as precast interlocking units. A concrete footing was laid at the base of each wall section to provide a level surface to begin wall placement. As the walls were erected, stainless steel strips were placed to anchor the precast units. Geogrid materials were placed along the joints in the panels to prevent potential movement of fines from the aggregate backfill (Figure 11).

Figure 10. Mixing of CKD with Borrow Materials

Figure 11. MSE Wall Construction

All spillway slabs and walls within the spillway area were underlain and backfilled with the CKD materials. Once a section of the slab was poured and forms stripped, the walls were backfilled with CKD up to the next spillway step elevation.

The spillway bridge is one of the most interesting architectural elements of the project. It consists of a curved concrete section spanning the spillway just downstream of the ogee spillway and upper basin areas. The bridge has cantilevered supports that rely on drilled piers socketed into the underlying bedrock (Figure 12). Figures 13 to 15 show construction photos of the various components of the main spillway.

Grouting of the dam abutments was used on the upper portions of the abutments, primarily within the upper limestone units. A two pattern of grout holes was used on the north and south abutments to seal up the limestone units within the abutments.

Figure 12. Spillway Bridge Supports

Construction Schedule

The project is in the final phase of construction; the dam and spillway are scheduled to be completed in the spring of 2006. Structures will be substantially complete by the end of 2005. Only final grading and landscaping work on the dam remain to be completed. Work on the accompanying park facilities is scheduled to be completed in 2006.

SUMMARY

Through an innovative use of MSE walls and CKD materials, Lake Lenexa was built to combine the contrasting requirements of architecture and engineering to provide a valuable new addition to the city of Lenexa's park system.

ABSTRACT

Small community systems that use surface water as a source of drinking water are frequently faced with elevated levels of naturally-occurring organic matter (NOM) that are not removed by conventional filtration methods. These residual levels of NOM may combine with chlorine used for disinfection and create disinfection byproducts (DBPs) potentially in excess of the regulatory limit for various DBPs. Frequently, additional treatment for removal of these DBPs is necessary to avoid non-compliance with the requirements of the Safe Drinking Water Act (SDWA). The formation of DBPs can be prevented by removing NOM, which acts as a precursor to DBP formation. This paper presents the results of field tests conducted on lake water using a nanofilter membrane, incorporating a method for cleaning the membrane using a foam ball. The system uses a tubular membrane with the ends connected to effectively form a single, long, membrane. The lake water is fed into the inside of the membrane tube and the filtrate is forced out, through the membrane into the membrane housing outlet. Using a timer, a foam ball is periodically passed through the inside of the membrane by reversing the flow direction. This foam ball serves to remove accumulated organic matter capable of fouling the membrane surface. This organic matter is flushed to drain as the foam ball passes through the inside of the tube. The system can be operated with the membrane reject water recycled to the system inlet or in a dead-end mode where no membrane reject water is produced until the system is foam ball cleaned. Tests were conducted in both modes of operation. The system requires no pretreatment of the feed water other than a coarse (3mm) screen to prevent large solids from entering the system. The effectiveness of the system in producing drinking water was gauged by measuring the turbidity, color, and particle counts of the system inlet and outlet. Tests were also performed using the aerobic spore *Bacillus subtilis* (*B. subtilis*) as a surrogate for bacteria removal.

INTRODUCTION

The Water Supply and Water Resources Division (WSWRD) of the U. S. Environmental Protection Agency's (EPA's) National Risk Management Research Laboratory (NRMRL) has been conducting tests on small drinking water treatment systems since 1997 in response to the 1996 Reauthorization of the Safe Drinking Water Act (SDWA). The SDWA established standards for drinking water systems and required EPA to assess treatment technologies for small systems serving fewer than 10,000 people. Initial tests were focused on packaged bag and cartridge filtration systems. Subsequently, the program has been expanded to test a variety of filtration systems for the removal of turbidity, chemical contaminants, and microbial contaminants.

Small community systems that use surface water, such as lakes, as a source of drinking water are frequently faced with elevated levels of color and naturally-occurring organic matter (NOM) that are not removed by conventional filtration methods. The organic matter can also serve as a precursor to the formation of disinfection byproducts (DBPs). This paper presents the results of field tests conducted in August 2008 on the Fyne Technology system, which is a membrane-based filtration unit that incorporates hollow fiber nanofiltration membranes for the removal of turbidity, bacteria, color and organic matter from lake water. The membranes are periodically cleaned by a foam ball that removes accumulated organic matter from the membrane surface. The system tested is manufactured by ITT Corporation (Zelienople, PA). The tests were conducted at a field site in Ely, Minnesota, in collaboration with the Minnesota Department of Health (MDH). The results of the tests were compared to the standards for bag filters presented in the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) which requires a >3.0 log reduction of *Cryptosporidium* and a turbidity of <0.3 Nephelometric Turbidity Unit (NTU).

SYSTEM DESCRIPTION

The Fyne Process refers to a family of treatment systems offered by ITT Corporation that were originally developed in the United Kingdom to treat waters with high concentrations of organic materials. The Fyne Process can remove both microbial contaminants and reduce the organic content, thus reducing the potential to form DBPs and is well suited for small water systems with a typical capacity to produce 10 to 15 gallons per minute (gpm) of treated water per day. Its small footprint and modular construction makes the Fyne Process ideal for many small communities that must treat water containing high concentrations of organic compounds.

One unique aspect of the Fyne Process is the use of an automated foam ball cleaning process to remove accumulated filter cake and organic and inorganic foulants. In this process, a small foam ball is forced through the tubular filtration elements via water pressure flowing in the opposite direction of normal flow. The foam ball scours the tubular membrane surface, removing the accumulated foulants. "Filter-catchers" (small, perforated plates installed in the module inlet and outlet lines) retain the foam

balls in the system. The cleaning frequency is adjustable and the entire process is fully automated.

Figure 1 shows a process flow diagram for the Fyne Process pilot skid that was tested at the Ely, MN field site. This unit was fitted with two modules constructed of ABS plastic. One module contained the PCI Membrane type ES404 while the other module contained the PCI Membrane type CA2PF. The ES404 has a molecular weight cutoff (MWCO) of approximately 4,000 daltons and is referred to as "Membrane 1" in this paper. The CA2PF has a MWCO of approximately 2,000 daltons and is referred to as "Membrane 2" in this paper. Each module was 3 feet long and contained thirty-six individual, ½-inch diameter, membrane tubes. The 36 membrane tubes were fed in series through the module with U-Bends linking one tube with the next. The maximum operating pressure of the module was 175 pounds per square inch (psi) at 70°F. Figures 2, 3, and 4 show various features of the system.

TEST PROCEDURES AND SAMPLING TECHNIQUES

The Fyne Technology system was evaluated for the ability to remove color and turbidity. The American Public Health Association (APHA) Platinum-Cobalt (Pt-Co) standard method for apparent color was used to measure color removal. Turbidity was measured in NTU. Each membrane module of the Fyne Technology system was sampled and evaluated separately. The color and turbidity of the influent lake water was tested as received and there were no attempts made to modify the influent turbidity levels.

For evaluating specific bacteria removal performance, both systems were challenged with the soil-based aerobic spore *Bacillus Subtilis* (*B. subtilis*). *B. subtilis* was also used as a potential surrogate for *Cryptosporidium*. All samples collected were grab samples. For these challenges, a suspension of the *B. subtilis* spores was prepared by adding 1 mL of *B. subtilis* stock to 500 mL of 0.01% Tween-20 in a 1-L glass beaker. The 500 mL suspension and an additional 500 mL rinseate were added to the influent stream of each system tested, using a peristaltic pump. The total injection time ranged from 15 minutes to about 60 minutes depending on the test conducted. Samples were collected in 100 ml polypropylene containers that were pre-sterilized and contained sodium thiosulfate preservative in tablet form (Fisher Cat No. 09-730-91). The sample bottles were refrigerated to 4±2°C immediately after collection and shipped on ice. The samples were shipped to the EPA Test & Evaluation (T&E) Facility in Cincinnati, OH. All samples were kept in the refrigerator at the T&E Facility until analysis. The *B. subtilis* analysis was performed in accordance with the T&E SOP 021.00.R0, which is based on Method 9215D in Standard Methods for the Examination of Water and Wastewater.

TEST RESULTS

The following test runs were conducted on the Fyne Technology system to evaluate the removal of *B. subtilis*:

Test 1 – Fyne Technology System in Recycle Mode
Test 2 – Fyne Technology System in Recycle Mode (Replicate of Test 1)
Test 3 – Fyne Technology System in Dead End Mode
Test 4 – Fyne Technology System in Dead End Mode (Replicate of Test 3)

The sequencing of the test runs above was designed to allow the systems to undergo a cleaning cycling and flush to remove any residual *B. subtilis*.

Test 1 – Fyne Technology System in Recycle Mode

Table 1 presents the *B. subtilis* analytical results for Test 1 on the Fyne Technology system. For this test, the *B. Subtilis* was injected into the system approximately 10 minutes prior to the T0 sample (which was collected when permeate was observed to discharge from the system). Injection was completed just before the T5 samples were taken (followed by a chaser solution of Tween-20 for another 15 minutes). The system accidentally went into the foam ball cleaning mode immediately after the T30 samples had been collected. T60 samples were collected after the system was restarted. The average log removal for Membrane 1 was 6.34 and that for Membrane 2 was 5.88.

Table 1. *B. subtilis* Analytical Results for Test 1 - Fyne Technology System in Recycle Mode

Sampling Time (min)	No. Cells/100 ml			Log Removal

Test 3 – Fyne Technology System in Deadend Mode

Table 3 presents the *B. subtilis* analytical results for Test 3 on the Fyne Technology system. The *B. subtilis* injection for this test was started approximately 10 minutes prior to collecting the T0 sample and completed 5 minutes before the T30 sample (over 40 minutes). The chaser solution was injected for another 25 minutes. The average log removal during this test for Membrane 1 was 4.94 and that for Membrane 2 was 5.25.

Table 3. *B. subtilis* Analytical Results for Test 3 - Fyne Technology System in Deadend Mode

Sampling Time (min)	No. Cells/100 ml			Log Removal	
	IN	Out 1	Out 2	Membrane 1	Membrane 2

Test 4 – Fyne Technology System in Deadend Mode

Table 4 presents the *B. subtilis* analytical results for Test 4 on the Fyne Technology system. The *B. subtilis* injection for this test was started approximately 10 minutes prior to collecting the T0 sample and completed at the time of collection of the T30 sample (over 40 minutes). The chaser solution was started 7 minutes prior to collection of the final sample. The average log removal during this test was 5.66 for both Membrane 1 and Membrane 2.

Table 4. *B. subtilis* Analytical Results for Test 4 - Fyne Technology System in Deadend Mode

Sampling Time (min)	No. Cells/100 ml			Log Removal	
	IN	Out 1	Out 2	Membrane 1	Membrane 2
T0	3.6×10^5	0	0	5.56	5.56

T30	3.0×10^5	0	0	5.48	5.48
T60	4.0×10^4	0	0	4.60	4.60

Raw Water Sample

To confirm that there were negligible *B. subtilis* spores in the lake water (influent), a sample of the raw lake water was analyzed. The results of analysis on two lake water samples (Sample 1 – 0 cells/mL; Sample 2 – 0.2 cells/mL) confirmed that there was negligible *B. subtilis* in the lake water.

Particle Count Removal Data

While the *B. subtilis* challenge tests were used to demonstrate removal by the system, particle counts were measured as an indirect indicator of system performance. Data was collected for the two Fyne Technology system membranes on the removal of particles in the 2 micron (µm) and the 3 µm range, the same size range as that of *B. subtilis* and *Cryptosporidium*. The influent water had an average particle count of about 3,500 over both size ranges. Membrane 1 of the Fyne Technology system produced effluent with an average particle count of 14, representing a 99.6% removal. Membrane 2 of the Fyne Technology system produced an effluent with an average particle count of 17, representing a 99.5% removal. The particle count data was measured using a portable counter which generally gives a higher count than an on-line counter.

Turbidity and Color Removal Data

Specific field tests were not conducted to evaluate the removal of turbidity and color by the two systems tested. However, MDH collected this information on an ongoing basis for the two membranes comprising the Fyne Technology system. The average influent turbidity was 2.18 NTU and the average effluent turbidity for the Fyne Technology system Membrane 1 was 0.17 NTU and that for Membrane 2 was 0.18 NTU. Color was spectrophotometrically measured in terms of the APHA color index. The color index of the influent water was 85.5 while the color index of the effluent from the Fyne Technology system Membrane 1 was 1.28 and from Membrane 2 was 11.5 (for reference, the APHA color index for distilled water is 0). The conductivity of the influent water was 57 milliSiemens per cm (mS/cm) while that for the effluent from the Fyne Technology system Membrane 1 and Membrane 2 was 44.68 mS/cm and 47.32 mS/cm, respectively.

CONCLUSIONS

The performance of the Fyne Technology System confirmed the ability of membrane-based systems in removing bacteria from source water. The effluent from the Fyne Technology System showed nearly 6 to 7 log removal of *B. subtilis* in the recycle mode for both the membrane modules tested in the recycle mode. Membrane 1 (ES404 membrane with a MWCO of approximately 4,000 daltons) showed slightly better overall removal than Membrane 2 (CA2PF membrane with a MWCO of approximately 2,000 daltons). Both membranes showed nearly identical performance for *B. subtilis* removal when tested in the dead-end mode. As suggested in the literature, removal of *B. subtilis* in filtration systems is a conservative indicator of *Cryptosporidium* (Muhammad, et al, 2008). Thus, this removal performance satisfies the LT2ESWTR requirement of >3.0 log reduction for *Cryptosporidium* (U.S. EPA, 2006). The system also performed favorably when compared to the reduction

requirements of 6 log removal for bacteria presented in the "Guide Standard and Protocol for Microbiological Water Purifiers" (EPA, 1987).

Both membranes also showed nearly identical performance in turbidity removal producing water with an average effluent turbidity of 0.17 NTU when treating lake water with an average influent turbidity of 2.18 NTU (representing 92% removal of turbidity). This satisfies the LT2ESWTR requirement of <0.3 NTU effluent turbidity.

However, Membrane 1 showed significantly better performance in color removal by producing water with an average effluent color of 1.28 units PtCo color compared to Membrane 2 which produced water with an average effluent color of 11.5 APHA. Finally, both membranes showed approximately 99.5% removal efficiency for particles in the 2 µm and 3 µm size ranges (the size range for *B. subtilis* and *Cryptosporidium*).

Of significant note is that the system requires no pretreatment of the feed water other than a coarse (3mm) screen to prevent large solids from entering the system. The system is self-cleaning and the concentrated water can be discharged back to the lake water source.

Abstract

Due to recent concerns over the environmental impact of stormwater runoff and increased water demands, interest in rainwater harvesting systems as an innovative stormwater treatment practice has developed in humid, well developed regions, such as the southeastern United States. Rainwater harvesting systems are designed to capture runoff from rooftops. The captured water can be used as an alternative to municipal or well water for non-potable applications. The water can be used for irrigation, vehicle washing, toilet flushing, and other non-potable uses. Harvested water can potentially be used for potable uses with proper treatment. Water harvesting systems can reduce peak flows and pollutant loads as well as conserve valuable resources. In order to better understand the anticipated usage and reliability of rainwater harvesting systems in the southeastern United States, a monitoring study was conducted at 5 rainwater harvesting systems in North Carolina, measuring cistern water levels and rainfall. Harvested water was used for a variety of applications including vehicle washing, irrigation, and toilet flushing. In order for water harvesting to be a viable solution for stormwater management the harvested water must be used between storm events. The system must be drained as much as possible to provide storage and peak flow mitigation for the next storm event. Results of the monitoring study showed that the rainwater harvesting systems were typically underutilized. Water usage was most consistent at the location where harvested rainwater was used to flush a toilet; however, the water level within the cistern only dropped below 80% of capacity on one occasion during the 30 month monitoring period. Research showed that the harvested water may require a dedicated use for water harvesting to be an effective stormwater management tool.

Introduction

Throughout history, countless innovative techniques have been developed to collect water for consumption, irrigation, and many other purposes. One of these techniques, rainwater harvesting, is the practice of capturing stormwater runoff, typically from a rooftop, and storing it in a cistern for later use. Historical evidence suggests that sophisticated rainwater collection systems were built before 3,000 BC in Jordan (AbdelKhaleq and Alhaj Ahmed, 2007). Although historically used in areas where water supply was limited by climate or infrastructure, the practice of rainwater harvesting has recently been used in humid and well developed regions in response to

increased water demands and public awareness of the environmental impacts of stormwater runoff.

While water supply is often the primary concern in arid regions or locations where water supply infrastructure is lacking, implementation of rainwater systems in humid, well developed regions offers a unique set of benefits and challenges. There are a number of water uses around a household or business that do not require potable water, such as irrigation, vehicle washing, and toilet flushing. Despite the fact that treatment is not necessary, potable water is typically used to meet these demands because it is often readily available. When potable water is used to meet these demands, chemicals, energy, and money are effectively wasted in treating and distributing the water. This treatment can result in increased infrastructure demands as well as increased costs for the water user. Because there is an economic and environmental benefit of using harvested rainwater for non-potable uses, maintaining an adequate water supply is important, although not as critical in the southeastern United States as other areas since municipal water supplies are generally prevalent. Another advantage of harvested rainwater use in the southeastern United States is that harvested rainwater can often be used to meet water demands when restrictions are placed on potable water use, which is a common practice during times of drought. Due to water restrictions, residents have sought alternative sources of water such as rainwater harvesting systems. This increased interest was exemplified when a rainwater harvesting website hosted by the authors received over 2,000 unique visitors over the span of three days when a local news channel in Raleigh, NC, broadcast information on rainwater harvesting systems. Due to the availability of 55-gallon (208 liter) barrels used to transport and store a variety of industrial products, many homeowners have modified these barrels to capture rooftop runoff in what are commonly referred to as rain barrels.

In some configurations, rainwater harvesting systems can capture a substantial portion of the runoff volume leaving a rooftop during a storm event. When this water is subsequently used for irrigation and infiltrates into the ground, rainwater harvesting can serve as a low impact development (LID) practice. Rainwater cisterns can be particularly effective at capturing the most polluted runoff near the beginning of a storm, commonly referred to as the first flush. During the beginning of a storm event, pollutant concentrations are highest as contaminants are washed from the impervious surface (Zobrist et al., 2000). First flush depths vary based upon a variety of factors, but are often associated with the first 2.5 cm of rainfall in North Carolina. Although rainwater harvesting systems may capture the first flush runoff, the pollutant removal mechanisms employed by a rainwater harvesting system differ substantially from other stormwater best management practices (BMPs). In a conventional stormwater BMP, sedimentation, filtration, vegetative uptake, and microbial processes remove pollutants from runoff flows. In a rainwater harvesting system, pollutant removal within the cistern is minimal, with small amounts of sedimentation and microbial activity. Pollutant removal in a rainwater harvesting system is associated with the use of the harvested rainwater. For example, when rainwater is used to flush toilets, pollutants would be removed by a wastewater treatment plant or septic system. When used for irrigation, pollutants would be removed by plant uptake, filtration, and microbial processes within the soil. As interest in rainwater harvesting increases

within humid regions containing well developed water supply infrastructures, it is important to understand the function of these systems in this relatively recent application.

Methods

A monitoring study was conducted at five rainwater harvesting systems located within North Carolina. The rainwater harvesting systems were located in Craven County, the city of Raleigh, the city of Kinston, Holden Beach, and the city of Fayetteville. At each site, rainfall depths were monitored by tipping bucket rain gauges with a resolution of 0.25 mm and located within 100 m of each cistern installation. Pressure water level data loggers, manufactured by Infinities USA, were used to record water levels on a one hour interval at the Kinston and Craven County locations. A pulley-float stage monitor recorded water levels on a 15 minute interval at the Raleigh location. A pressure water level data logger on a half hour interval, manufactured by Global Water, was used to record water levels in Fayetteville.

In Raleigh, NC, (35°48'37.45"N, 78°42'54.21"W) a 5,300 liter cistern collected water from a 204 m² rooftop and the water was used to flush a toilet at a nature education center. The cistern constituted the primary water supply to the toilet and municipal water was only supplied when the cistern was depleted of rainwater, which did not occur during the study period. During the study period, there were no fixtures installed to supply water from the cistern for any uses other than flushing the toilet. The Raleigh rainwater harvesting system was monitored from June of 2005 through January of 2008.

In Craven County, NC, (35° 8'34.94"N, 77° 9'31.87"W) a 167 m² section of rooftop contributed water to an 11,350 liter cistern and was used to irrigate gardens around the facility. A formal irrigation schedule was not established and water was used when deemed necessary by the building's occupants. Water could be withdrawn from the Craven County cistern using either a gravity fed faucet located at the base of the cistern or a pump supplied faucet located adjacent to the cistern. Faucets connected to the municipal water supply were available at several locations around the perimeter of the building. The Craven County cistern was monitored from May of 2005 through August of 2006.

A 19,680 liter cistern in Kinston, NC, (35°13'44.97"N, 77°36'49.97"W) collected water from a 406 m² section of rooftop, with the collected water used to wash vehicles. The harvested rainwater was pumped to a faucet at a vehicle washing station where signs clearly indicated that the faucet was supplied by rainwater. Within the same vehicle washing station, there were several faucets connected to the municipal water supply. Typically, pressure washers were used at the washing station to clean large commercial vehicles. The Kinston rainwater harvesting system was monitored from June of 2005 through August of 2006.

In Holden Beach, NC (an unused septic tank approximately 5,680 liters was used to collect runoff from a 78.5 m^2 roof top. The tank was fitted with a 186 Watt pump so that the homeowner could use the rain water to water vegetation in her garden and greenhouse. Because of the capacity of the pump the homeowner was restricted to a single spray irrigation system or hand watering.

Results and Discussion

Of the rainwater cisterns involved in this study, the most consistent usage was observed at the Raleigh, NC location. Because there were no other toilets in the vicinity and the rainwater harvesting system served as the only water supply to the facility's toilet, cistern water levels were largely governed by the number of people using the facility. Despite regular usage, the volume of water stored in the cistern only fell below 80% of capacity on one occasion during the monitoring period (Figure 1). Even during a historic drought beginning during the summer of 2007, the cistern maintained an adequate water supply. While the reliable water supply was beneficial, the ability of the rainwater system to capture runoff volume from the rooftop was greatly reduced. The majority of rainfall events resulted in overflow from the rainwater cistern located at this site. Monitoring of the rainwater harvesting system began before the facility was open to the public and educational programs and other functions that would use the facility were under development during the course of the study, which resulted in substantial variations in the number of building occupants. Beginning in February of 2008, workers at this facility installed faucets that were supplied by the cistern to use for irrigation around the property in an effort to better utilize the rainwater supply available.

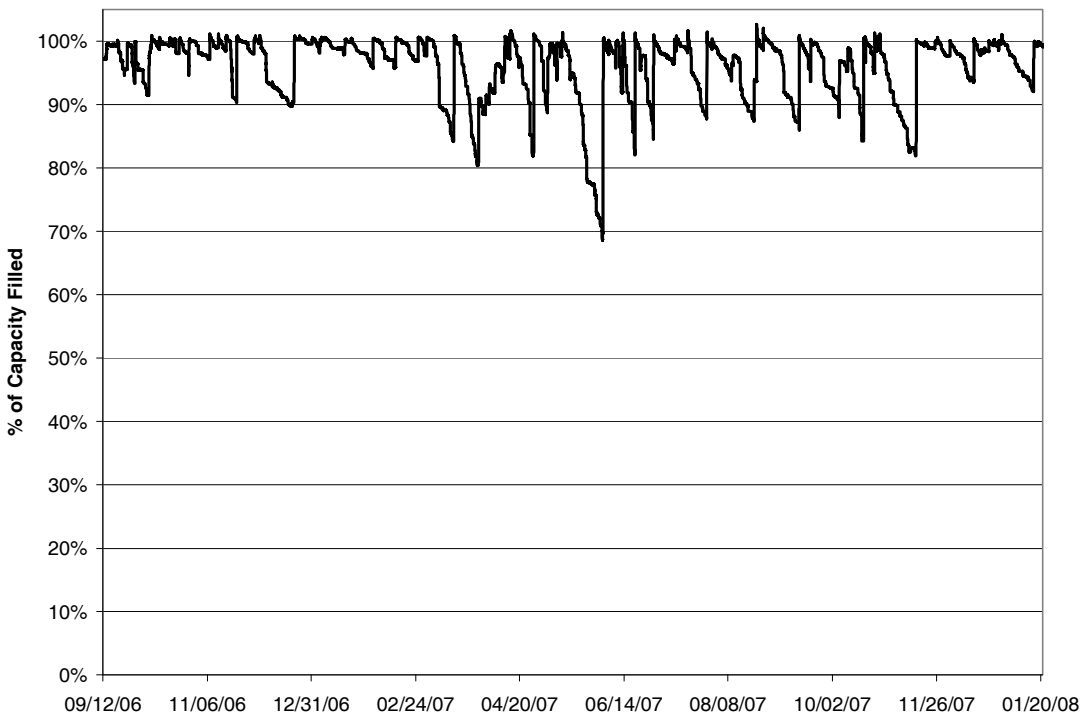

Figure 1. Percentage of cistern capacity filled by runoff storage at the Raleigh location

At the Craven County location, water use from the rainwater cistern was infrequent, with only 7 major uses occurring during the course of the monitoring study (Figure 1). Despite the infrequent water use, usage volumes were substantial. The largest of these uses depleted nearly 70% of the cistern's capacity; however, the fact that water levels decreased consistently over the course of several days suggests that the cistern may have been intentionally drained (Figure 2). Even with infrequent

usage, the volume of water stored in the cistern sometimes took several weeks or months to reach capacity. Part of the reason for the slow recharge is that a first flush diverter installed at this location prevented the initial runoff during a storm from entering the cistern. Limited usage during 2006 suggests that the cistern was used to hand water plants around the property and not used for large scale irrigation. Due to concerns over the cisterns appearance, the system was located on the opposite side of the building from the gardens it was originally intended to irrigate, which likely had substantial impacts on usage volume and frequency.

At the Kinston location, rainwater usage was minimal, with the cistern maintaining at least 80% of its capacity for the duration of the study (Figure 2). Observations at the site confirmed that water demand intended for the rainwater harvesting system was being supplied by municipal water. Vehicles were primarily washed with handheld pressure washers attached to the municipal water supply with water from the rainwater harvesting system used to meet small water demands. After better educating the facility workers on the use of the rainwater harvesting system in early 2006, rainwater usage increased. Even with this increased usage, the cistern remained near capacity, since municipal water was still used for much of the vehicle washing.

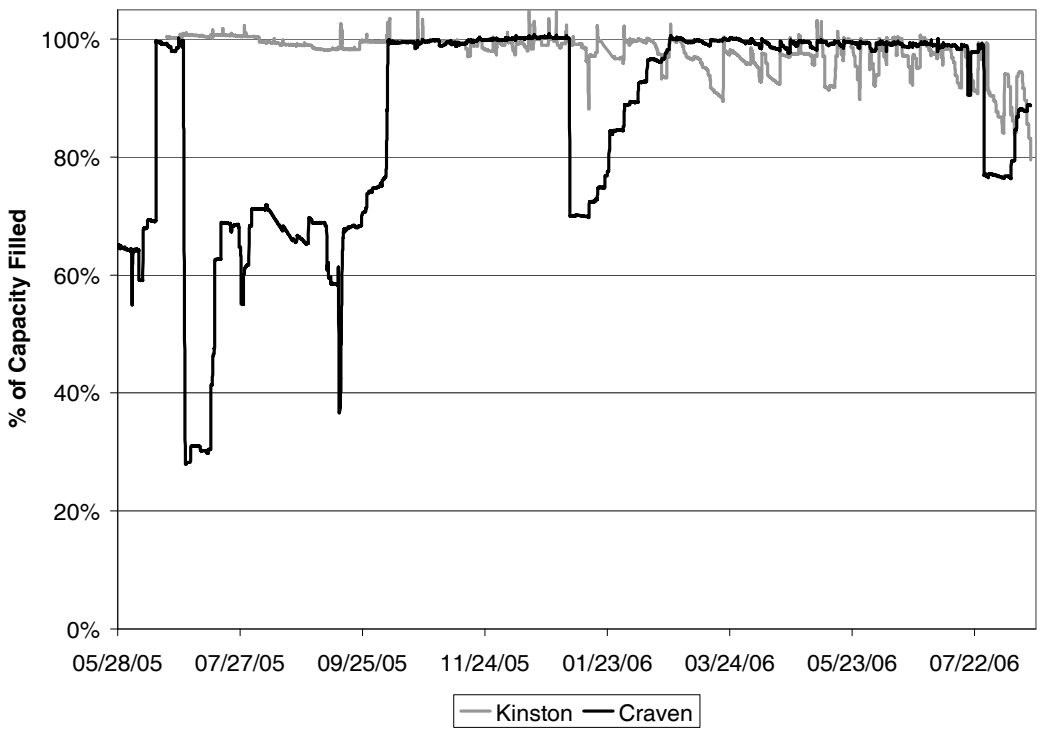

Figure 2. Percentage of cistern capacity filled at Kinston and Craven County sites

The irrigation demand for the Holden Beach water harvesting system was low, preventing the tank from completely emptying. Irrigation demand was lowest in February when 113 liters of water was used from the 5680 liter tank and highest in April when 6132 liters was used. The high demand in the summer was able to reduce the volume in the tank to approximately 20% on one occasion and 30% on two occasions (Figure 3). The prime factor in lowering the tanks internal water level,

however, was a crack in the tank 63.5 cm above the bottom of the tank that allowed the water to infiltrate into the surrounding soil until the water level in the tank was reduced to 63.5 cm. The presence of the rack proved to be in inadvertent benefit. Perhaps future designs for water harvesting systems should include intended "leaks" from the cistern, especially in lower water demand applications. This improved the performance of the Holden Beach system allowing more rooftop runoff to be captured due to the increase in storage volume. Irrigation demand was lowest in the winter months causing available storage to be less during that time with the capacity dropping below 60% on one occasion.

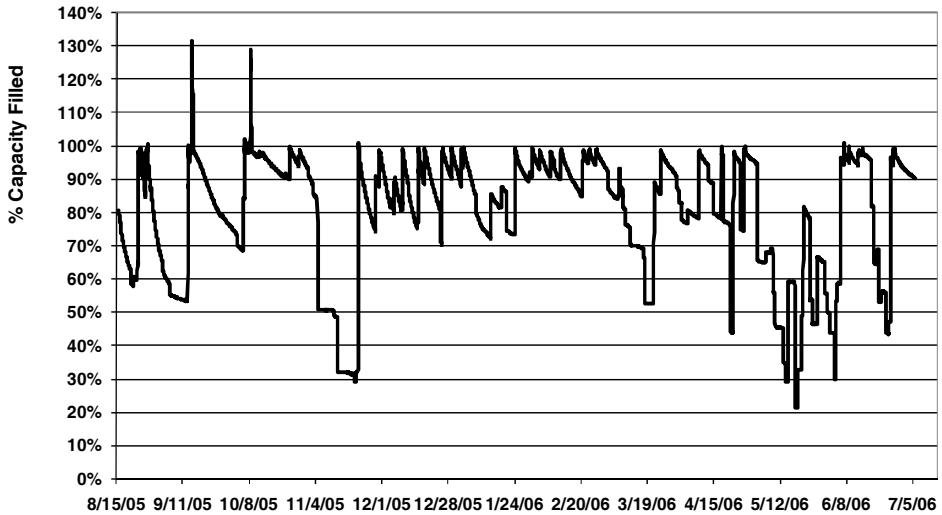

Figure 3: Percentage of cistern capacity filled by rooftop runoff at the Holden Beach location

Conclusion

Results of the monitoring study indicated that rainwater harvesting systems were consistently underutilized. Minimal usage of the captured rainwater greatly diminishes runoff volume reduction and economic benefits of a rainwater harvesting system. It is possible that with better education on the uses of captured rainwater and implementation of automatic usage systems, rainwater harvesting can be used as an effective LID tool in the southeastern United States. Rainwater harvesting systems that incorporate infiltration appear to be a viable design option.

When installing rainwater harvesting systems, knowledge of the anticipated water usage is imperative to ensure that an appropriately sized cistern is used. Because municipal water supplies generally provide a reliable backup to harvested rainwater, rainwater harvesting systems can be used to meet a variety of water needs, supplying substantial water volumes when properly designed. With increased planning, public awareness, and education, rainwater harvesting systems should serve as valuable tools in reducing the demand on municipal water supplies and the negative impacts associated with urban stormwater runoff at the same time.

Abstract

Decentralized wastewater treatment systems are of great importance to protect the environment and people's health in the areas without centralized treatment system. Utilizing laboratory cultivated inoculating microorganisms (suborder *Corynebacterineae* including *Agrobacterium sp.* and *Gordonia sp.*) in logarithmic growth stage, a deployable aqueous aerobic bioreactor (DAAB) system was developed for decentralized wastewater treatment. The system is flexible, deployable in a standard shipping container, quick to start, and capable of removing organic carbon, phosphorus and benzene from wastewater. Experimental results indicated that the inoculated consortium had a faster COD removal rate than sewage-born microorganisms during the startup of the system. During the startup period, the removal of total phosphorus in the aeration tank followed a pseudo first-order kinetics (R^2 = 0.90) with a rate constant of 0.027 hr^{-1}. The *Agrobacterium sp.* are likely responsible for the removal of phosphorus from wastewater. No ammonia removal was found in the aeration tank during the startup phase. After the system was in continuous operation with an average flow rate of 11.4 L/min, the removal efficiency of BOD_5 and total suspended solids (TSS) was 83±32% and 84±9%, respectively. The relative large standard deviation of the removal efficiencies is likely due to the small equalization capacity of a small treatment system to resist the variations of the incoming wastewater quality and shock loads. As an important supplement to the pilot studies, laboratorial tests by headspace analysis showed that the *Gordonia sp.* were able to degrade benzene from wastewater. After 26 hours, more significant biodegradation of benzene was found in sessile form (57±8%) than in planktonic form (25±11%) with minimal glucose. However, no benzene degradation was found in sessile form when no glucose was provided. The result suggested that the *Gordonia sp.* could not utilize benzene as the sole carbon and energy source.

Keywords: Decentralized wastewater treatment, biofilm, phosphorus, benzene, *Agrobacterium sp.*, *Gordonia sp.*

1. Introduction

Natural disasters such as hurricanes, tornadoes, floods and earthquakes can cause significant damages of civil infrastructures including municipal wastewater treatment facilities. When the treatment systems fail, human health and environmental quality are at risk. In addition, there are situations in which centralized wastewater treatment facilities are not available or unpractical, such as remote sites or small communities. Consequently, there is a need for technologies that can be rapidly moved into affected areas and put in operation to minimize the impacts or the damages and to provide support for the residents. Compared to centralized treatment system, decentralized systems appear to offer a number of potential advantages, such as flexibility, portability, quick response, easy operation, segregation of wastewater at source, and compatibility with local demands for wastewater reuse.

Although decentralized wastewater treatment systems are essential parts to protect the environment and human health and to support the sustainable development of the society, systematic studies of such systems are rather scarce [van Voorthuizen et al., 1995; Devi and Dahiya, 2008; Massoud et al., 2009; Butler and MacCormick, 2002]. As a result, the advantages and virtual potentials of decentralized wastewater treatment systems have not been explored significantly. Because of the challenges from the emergent situations such as post-disaster scenarios, the decentralized wastewater treatment system has to be well designed and capable of purifying both domestic and potentially recalcitrant and hazardous industrial wastewaters. Among various kinds of industrial wastes, the contaminants from gasoline are of special interests. The environmental pollution of gasoline is caused by accidental spills, leakage from storage tank, or improper disposal. Natural disasters may exacerbate the pollution of gasoline. As one of the major hurricane suffering areas, the US coast of Gulf of Mexico accumulates large amounts of oil exploration and refinery facilities. Therefore, the major aromatic constituent of gasoline, such as benzene is selected as the target industrial pollutant in this study, because benzene is one of compounds with a high water solubility relative to aliphatic constituents of gasoline [Deeb et al., 2001] and accounts for one of the major gasoline components that are found in the water-soluble fraction [Saeed and Mutairi, 1999]. Consequently, benzene is a common contaminant present in the waste stream in combination with the domestic wastewater. In addition, benzene has significant adverse health effects and environmental concerns. It is listed as a category A carcinogen according to USEPA.

In light of these challenges, a deployable aqueous aerobic bioreactor (DAAB) system has been developed utilizing laboratory cultivated microorganisms that are in logarithmic growth stage for a quick start of the treatment system; since seeding sludge is not always available near the treatment site. The whole system is designed to be deployable. It can be transported in a single C-130 aircraft or a 40-foot ISO container or trailer. For easy operation and simplification of the system, attached growth of biofilm was preferred over the suspended activated sludge system, because no sludge recycle is required. In addition, attached growth (sessile) system showed the advantage for fast degradation of benzene over suspended growth (planktonic) system as discovered in this study. In the DAAB, a hydrophobic plastic mesh medium was provided for the attached growth of biofilm. The microbes of suborder *Corynebacterineae* were carefully selected for primary irreversible adhesion to

medium, while others are selected for intercellular adhesion. Specifically, the suborder *Corynebacterineae* is comprised of seven microbes including well known genera, i.e., *Gordonia sp.*, *Caulobacter vibrioides*, *Enterobacter cloacae*, *Agrobacterium sp.*, *Bacillus subtilus*, *Pseudomonas putida* and *Pseudomonas stutzeri*. Among *Corynebacterineae*, the *Agrobacterium sp.* are able to remove phosphorus (Merzouki et al., 1999; de-Bashana and Bashan, 2004), while the *Gordonia sp.* possess the ability to degrade xenobiotics and industrial pollutants (Arenskotter et al., 2004). Many of the isolates of *Gordonia* have been derived from industrially influenced habitats and wastewater treatment systems (Arenskotter et al., 2004).

This study combined the pilot-scale tests to evaluate the overall performance of the system and bench-scale tests to elucidate the biodegradation of the hazardous compound. The main objectives of this study were (1) to explore the organic carbon (BOD and COD) degradation efficiency and TSS removal in the DAAB system; (2) to investigate the potential of nitrogen and phosphorus removal in the DAAB system; (3) to study the microbiological degradation of benzene.

2. Materials and Methodologies

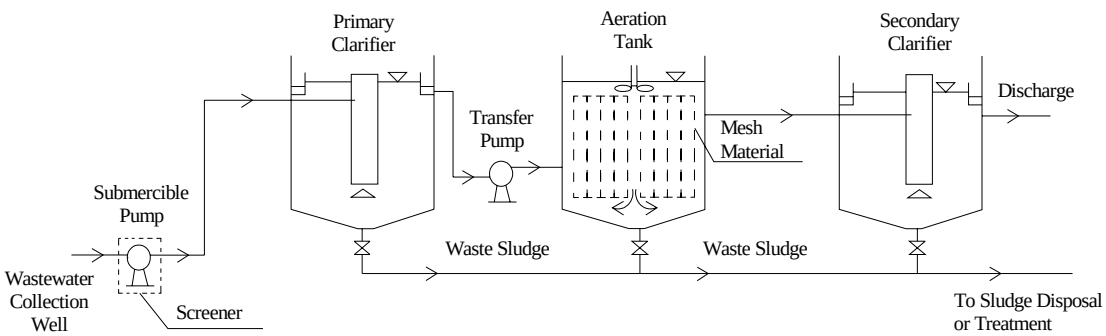

Figure 1. Diagram of the DAAB system.

2.1 The DAAB system

The basic DAAB system consists of a wastewater feed system, a primary sedimentation tank, an aeration tank, and a secondary sedimentation tank, as shown in Figure 1. Each tank was an oval cylinder with a dimension of about 2.4 (L) × 1.9 (W) × 2.0 m (H). The net volume of each tank was about 6.9 m^3. A transfer pump between the primary sedimentation tank and the aeration tank was equipped in order to provide a flexibility of the flow routing for varied topographies of the treatment sites. In this study, the transfer pump intermittently fed the aeration tank from the primary clarifier. The pump was running for about 5 minutes for every 20 minutes. In the aeration tank, the biomass is supported by a composite plastic mesh media to maximize the surface area of biomass. In contrast to conventional aerobic biofilm process (e.g., trickling filters and rotary biological contactors), fine air bubbles are provided through a patented aerator at the surface of the aeration tank for maintaining the desirable dissolved oxygen (DO) concentrations. The fine bubbles significantly increased the oxygen transfer efficiency due to the great surface-to-volume ratio and a long retention time of the air bubbles. In general, the DAAB system was mainly an attached growth system in a compact configuration that potentially provides efficient treatment of wastewater. Depending on the quantity and type of wastewater to be

treated, a DAAB system can consist of four to eight tanks in parallel or in serial fashions.

2.2 Wastewater sample analyses

Grab samples were taken from the DAAB treatment system, transported to the laboratory and analyzed typically within an hour for BOD_5 and total suspended solids (TSS) examinations according to the Standard Methods of USEPA. For COD, ammonia, and total phosphorus measurements, the samples were acidified by sulfuric acid to pH 2 and stored in refrigerator at 4 ºC following the Standard Methods of USEPA. An onsite analytical probe of the Quanta Water Quality Monitoring System (Hydrolab Corporation, Austin, TX) was used for DO, pH, turbidity, conductivity, and temperature measurements. Ammonia and total phosphorus were examined spectrometrically by using QuikChem 8500 Flow Inject Analysis (Lachat Instruments, Loveland, CO).

2.3 Benzene degradation experiments

*Cultures and media***.** Stock cultures of the *Gordonia sp*. (ATCC# BAA-558) were maintained in yeast extract glucose (10 g of Dextrose and 10 g of yeast extract per liter of distilled water) at 30 °C and 200 rpm for seven (7) days. Evaluation of benzene degradation was performed by inoculating cultures into either a minimal glucose media (5.0 g of dextrose, 6.0 g of Na_2HPO_4, 3.0 g of KH_2PO_4, 1.0 g of NH_4Cl, 0.5 g of NaCl, 0.12 g $MgSO_4$, and 0.01 g $CaCl_2$ per liter of distilled water) or into a minimal media supplemented with benzene (Fisher: B411-1 ≥99.0% reagent grade) as the sole carbon and energy source (87 mg/L C_6H_6, 6.0 g of Na_2HPO_4, 3.0 g of KH_2PO_4, 1.0 g of NH_4Cl, 0.5 g of NaCl, 0.12 g $MgSO_4$, and 0.01 g $CaCl_2$ per liter of distilled water). All media were autoclaved at 121 °C for 30 minutes. Benzene was added to the media after the autoclave cycle.

*Benzene degradation by planktonic (substratum-free) cultures***.** Experiments were designed to examine the capabilities of the *Gordonia sp.* to degrade benzene in the presence of a carbon source, as well as the ability of the *Gordonia sp.* to utilize benzene as the sole carbon source. A 100 mL aliquot of the medium previously described was transferred to the headspace analysis apparatus, described by Stalder et al. (1995), in a sterile laminar flow hood. A one milliliter aliquot of the seven-day stock culture was then transferred into either a minimal glucose media or into a minimal media supplemented with benzene as the sole carbon source. *Gordonia* cultures inoculated into the minimal glucose medium were incubated at 30 °C and 200 rpm for 24 hours in the headspace analysis apparatus prior to introducing benzene. The initial concentration of benzene added was 87 mg/L. For the experiments evaluating the ability of the *Gordonia sp.* to utilize benzene as the sole carbon source, a one milliliter aliquot of the seven-day stock culture was simultaneously added to the headspace analysis apparatus with benzene and incubated at 30 °C and 200 rpm. The initial concentration of benzene added was also 87 mg/L. The initial pH and DO before the addition of benzene was 6.1±0.2 and 1.9±0.6 mg/L, respectively.

Benzene degradation by sessile cultures. Examinations of the capabilities of the *Gordonia sp.* to degrade benzene adhered to a substratum were also performed. The steps were same as the descriptions of the planktonic test except that an autoclaved (at 134 °C for 30 minutes) hydrophobic polyethylene surface (5.1×5.1 cm) was initially placed in the solution of the headspace analysis apparatus before the tests. The initial pH and DO before the addition of benzene was 6.1±0.2 and 1.9±0.6 mg/L, respectively.

Examination of benzene. Benzene concentrations were determined by headspace analysis. The preliminary study indicated that the biodegradation activity of the *Gordonia* was below the rate of mass transfer between the gas and aqueous phases for benzene (Lincoff and Gossett, 1984; Peng and Wan, 1997; Prenafeta-Boldú et al., 2002). Therefore, the examination of benzene concentration in gas phase was used to indirectly reflect its aqueous phase concentration (Lincoff and Gossett, 1984). Samples of the headspace gas (1 mL) were withdrawn from the culture bottles using a Series A-2 gas tight syringe (Alltech, Nicholasville, KY) and were analyzed by a Hewlett-Packard 5890 gas chromatography equipped with a 5972 mass spectrometry and an Agilent DB-624 capillary column, 30m × 0.25 mm × 1.4 µm. The injector and detector temperatures were 250 °C and 280 °C, respectively. The initial oven temperature was programmed for 5 minutes at 35 °C then followed by a ramp of 10 °C/min to 126 °C for a total time of 14.10 minutes. All sample injections were made in the splitless mode. The carrier gas was He with a flow rate of 1 mL/min. Calibration curve was done with external standards.

3. Results and Discussions

3.1 System starting up

The system was fed on-site with municipal wastewater from Beaumont, TX directly from the raw wastewater well after the bar screen. The wastewater is mainly composed of domestic wastewater with a small portion of oil refinery wastewater. The general characteristics of the raw wastewater are listed in Table 1. As can be seen, the organic strength of the wastewater was 176±57 mg/L in BOD_5 and 365±128 mg/L in COD. The TSS level was 280±167 mg/L.

Table 1. The general characteristics of the raw wastewater treated by the DAAB system.

BOD_5 (mg/L)	COD (mg/L)	TSS (mg/L)	pH	Turbidity (NTU)	Conductivity (ms/cm)	DO (mg/L)	Temperature (°C)
176±57	365±128	280±167	7.1±1.0	137±46	0.8±0.1	0.3±0.2	15~28

As mentioned earlier, one of the key strengths of the DAAB system is quick startup, because seeding sludge might be difficult to find near the treatment site, especially during post-disaster scenarios. In this research, the degradation of COD from wastewater was compared with or without the inoculation consortium. The experiments were performed in the aeration tank in a completely mixed batch reaction mode. The aeration was kept on during the duration of the experiment. The plastic mesh media in the aeration tank had been pre-cleaned and dried before filling up the municipal wastewater in the aeration tank. The experiments started shortly after the

tank had been filled and well mixed with or without the inoculation consortium. The dosage of each type of the microbes was about 10^{12} counts based on the average of eight examinations. After that, the initial COD concentration of the mixed solution was measured as 183 mg/L and 223 mg/L for the inoculated and controlled test, respectively. DO was around 8 mg/L, pH was around 8.0, and the temperature was about 17 °C.

As shown in Figure 2, after seven hours of the reaction, 68% decrease of COD was observed with inoculation consortium compared to 58% reduction of COD without inoculation consortium. The inoculation of the seven microbes enhanced the COD removal by 10%. However, it was a little surprised to see that the COD removal (58%) without artificial inoculation was pretty significant. Two possible reasons might contribute to the COD degradation without inoculation. First, the plastic mesh media were hydrophobic and had a porous but compact arrangement inside the aeration tank. Consequently, the media might adsorb dissolved organics and catch particulate organic (and inorganic) matters from the wastewater with time. Second, the sewage-born microorganisms might become active and utilize dissolved organics from wastewater under the aeration condition.

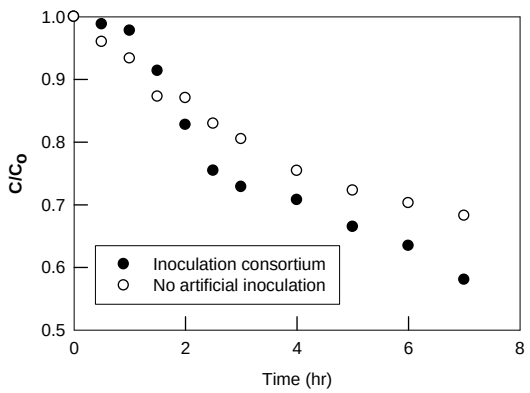

Figure 2. Comparison of COD removal in the batch reaction mode with or without inoculation consortium during initial startup of the DAAB system.

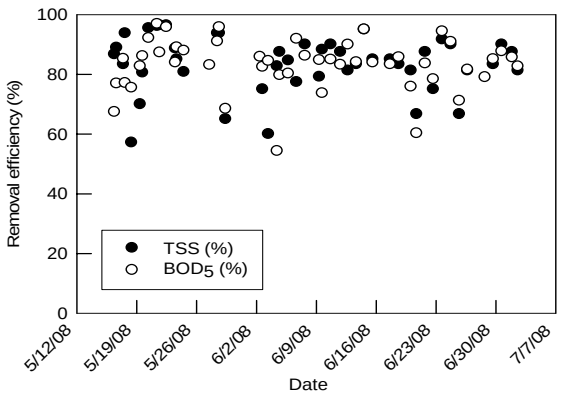

Figure 3. BOD_5 and TSS removal efficiency in the DAAB system.

3.2 BOD_5 and TSS removal

After the system had been started, we examined the treatment efficiency of the DAAB system for BOD_5 and TSS removal. In this set of experiments, the treatment performance was evaluated in continuous operation with an average flow rate of 11.4 L/min (i.e., 3 GPM). DO was 5.4±0.5 mg/L in the aeration tank. As shown in Figure 3, the BOD_5 removal efficiency of the DAAB system was 83±32%. For TSS, the removal efficiency was 84±9%. The effluent BOD_5 and TSS of the system was 28±13 and 42±32 mg/L, respectively. This means the average 30-day BOD_5 of the DAAB effluent met the US national standard for secondary treatment (i.e., 30 mg/L), while TSS was higher than the average 30-day national standard (i.e., 30 mg/L). In future work, a multi-media filtration is planed to be added to further polish the quality of the secondary effluent and to provide an option for wastewater reuse. The relative large variation of the treatment efficiencies is likely due to the fact that a small system like

the DAAB has a minute buffer capacity to absorb and equalize the fluctuations of the incoming wastewater quality and shock loads.

3.3 Ammonia and total phosphorous removal

The DAAB process is typically used to provide wastewater treatment prior to discharging to a receiving water body. To prevent eutrophication of the water body, nutrient, especially phosphorus removal is desired; because phosphorus is a limiting nutrient in most freshwater systems (Tchobanoglous et al., 2003). Therefore, the system needed to be carefully designed and operated to provide a high quality of the effluent. Accordingly, the removal of ammonia and total phosphorus was investigated during the startup period of the system, because the DAAB consortium was more dominated in this period. The experimental results shown in Figure 4 were obtained under a completely mixed batch reaction mode in the aeration tank of the DAAB system. In the batch reaction, the initial BOD_5 was 106 mg/L. DO was around 8 mg/L, pH was around 7.4, and the temperature was 18 °C. As can be seen, the degradation of ammonia was insignificant. During the duration of the batch test, the ammonia concentration in wastewater was constantly around 16.5 mg/L. In contrast, significant degradation of total phosphorus was observed. The total phosphorus concentration decreased from 93.0 initially to 33.1 μg/L after 33.5 hours. The degradation of total phosphorus followed a pseudo first-order reaction (R^2 = 0.90). The reaction rate constant was 0.027 hr^{-1}.

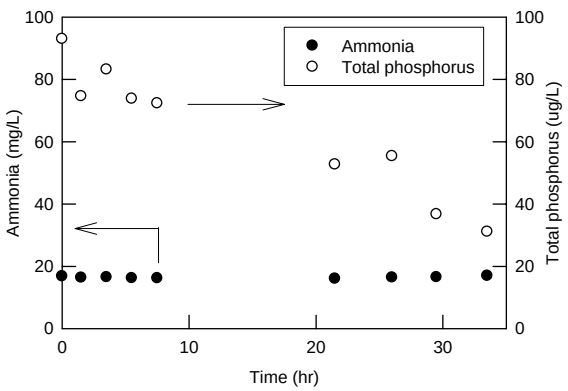

Figure 4. Ammonia and total phosphorous removal in the batch reaction mode during initial startup of the DAAB system.

The usual forms of phosphorus found in wastewater include the orthophosphate, polyphosphate, and organic phosphate. Biological phosphorus removal from wastewater is based on the activity of phosphorus-accumulating organisms (PAOs). In the anaerobic phase, PAOs take up readily biodegradable organic carbon substrates and store them as polyhydroxyalkanoates (PHAs) (Lee et al., 2001). The energy to this anaerobic process is derived from the hydrolysis of intracelluar polyphosphate and the glycolysis of glycogen followed by the release of ortho-phosphate to the bulk liquid (Mino et al., 1987; Okada and Sudo, 1986). In the subsequent aerobic phase, PAOs use the PHAs for generating energy for growth, glycogen synthesis, and phosphate uptake, where the PAOs take up phosphate more than released during the anaerobic phase (Lee et al., 2001).

Among the inoculation microbes used in the DAAB system, the *Agrobacterium sp.* are found responsible for the removal of total phosphorus from wastewater. *Agrobacterium sp.* are PAOs (Merzouki et al., 1999; de-Bashana and Bashan, 2004), which may utilize and store phosphorus inside the cells from wastewater. When the *Agrobacterium sp.* were dosed into the aeration tank from the oxygen-starvation condition (the microbes had been in pellet form), it started to grow and took up phosphate. In addition, it is also possible that total phosphorus could be partially removed through adsorption of organics and attachment of particulates from wastewater onto the plastic mesh media inside the aeration tank. However, compared Figure 4 to Figure 2, the removal rate of total phosphorus (22% removal in 7.5 hours) is much less than COD (32% removal in 7 hours). This fact suggests that biological removal of phosphorus played a role in the DAAB system.

Although there was not a separate anaerobic tank in the DAAB system, the biofilm system was spatially heterogeneous, providing spaces for both, aerobic and anaerobic processes (Gieseke et al., 2002). The biofilm of the DAAB system was exposed to varied DO levels as the transfer pump intermittently fed the aeration tank from the primary clarifier, which had a low DO of 0.3±0.2 mg/L. Once the biofilm was fully developed, the possible anaerobic zones inside the biofilm enabled the completeness of the two-stage cycle for biological phosphorus removal. Consistently, phosphorus removal was reported in attached growth system (Watanabe et al., 1995; Pastorelli et al., 1999; Morgenroth and Wilderer, 1999; Gieseke et al., 2002). After the DAAB system reached steady state and was in the continuous operation mode with an average flow rate of 11.4 L/min, DO in the aeration tank was 5.4±0.5 mg/L, a 43±25% removal efficiency of the total phosphorus was observed.

Nitrogen in municipal wastewater is mostly in the form of ammonium (NH_4^+) and organic nitrogenous compounds (amino acids, amino sugars and proteins) that together are reported as Total Kjeldahl nitrogen (TKN) (Tchobanoglous et al., 2003). Nitrogen can be biologically removed from wastewater by first oxidizing it to nitrate (nitrification by nitroso- and nitro-bacteria) then reducing it to nitrogen gas (denitrification by denitrifying bacteria). The results shown in Figure 4 indicated there was little ammonia removal in the aeration tank, simply because none of the seven inoculation microorganisms had a function of nitrification. In addition, ammonia has a small molecule and is highly soluble in wastewater, which is unlikely to be adsorbed onto the plastic mesh media. Moreover, considering the incoming sewage-born bacteria, nitroso- and nitro-bacteria grow much more slowly than heterotrophic bacteria. Especially in an attached growth system, nitroso- and nitro-bacteria can be easily outcompeted by heterotrophic bacteria when BOD level is not sufficiently low, because the heterotrophic bacteria have a higher biomass yield and thus can dominate the surface area of fixed-film systems over nitrifying organisms (Tchobanoglous et al., 2003). Consequently, nitroso- and nitro-bacteria were slow to grow in the treatment process. However, with the growth and accumulation of sewage-born microorganisms inside the treatment process, nitrification and denitrification might become possible with time.

As is evident from the description above, the DAAB system using the inoculation consortium was effective to remove BOD_5 and total phosphorus from wastewater. In a separate pilot study of industrial wastewater (Sam Houston State

University, 2006), the DAAB system achieved about 10% reduction of aromatic compounds, when the concentration of the influent contaminants was around 1 µg/L. However, the pilot tests were conducted in a very complex chemical system that was designed to include all possible influences and to evaluate the overall performance of the treatment system under real world conditions. The pilot study has less controlled experimental conditions (e.g., volatilization loss, adsorption and photolysis) and may bring environmental concerns if hazardous compounds are artificially introduced into the system. As a result, bench-scale tests were conducted to provide a more controlled environment that could be used to formulate a mechanistic understanding of the microbiological degradation of industrial and hazardous contaminants, such as benzene.

3.4 Biodegradation of benzene

In a preliminary study of the microbiological degradation of benzene by the seven inoculated consortium, the *Gordonia sp.* were the most active microbe to reduce benzene from the solution. Consequently, the *Gordonia sp.* were chosen to determine its capability to degrade benzene in laboratorial cultures. The bioremediation of benzene was investigated using a substratum with or without glucose minimal media and comparing that process to cultures without substratum.

3.4.1. Benzene degradation by planktonic with glucose minimal media

The results of biodegradation of benzene by the *Gordonia* in planktonic form (without a substratum) over a 26 hour time course are shown in Figure 5. The headspace was initially analyzed 20 minutes after 87 mg/L benzene was introduced to the glucose minimal media and bacteria and subsequently every few hours. The initial headspace concentration of benzene was about 15 mg/L. The concentration of benzene in the headspace after 26 hours decreased to 71±7%. This means there was a 29±7% reduction in the benzene concentration in live *Gordonia* cultures. The abiotic control, consisting of benzene and media only, exhibited a benzene reduction of 4±11% after 26 hours. Consequently, the net biodegradation of benzene by the *Gordonia* in planktonic form was 25±11%.

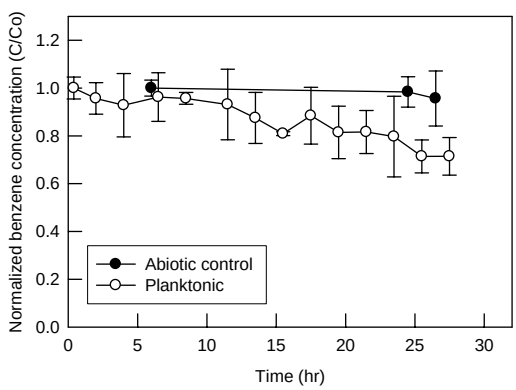

Figure 5. Degradation of benzene by the *Gordonia sp.* in planktonic form with glucose minimal media. The tests were performed in quadruplicates.

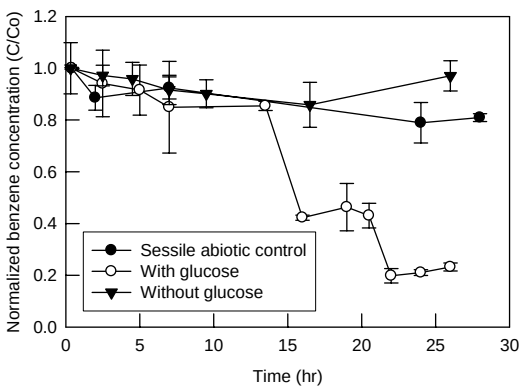

Figure 6. Degradation of benzene by the *Gordonia sp.* in sessile form with or without glucose minimal media. The tests were performed in quadruplicates.

3.4.2. Benzene degradation by sessile cultures

Figure 6 shows the degradation of benzene by the *Gordonia sp.* in sessile form from another quadruplicate study. The headspace was analyzed 20 minutes after 87 mg/L benzene was added to the glucose minimal media, substrate, and bacteria; the initial concentration of benzene was about 15 mg/L. The headspace benzene concentration decreased to 23±2% after 26 hours in that live shaking culture, a 77±2% reduction in the benzene concentration. In the abiotic control, consisting of benzene, substrate and media, benzene concentration decreased to 80±8%. The net biodegradation of benzene concentration in the headspace was 57±8%. The results are summarized in Table 2.

Table 2. Degradation of benzene by the *Gordonia sp.* in planktonic or sessile form with or without glucose studied by headspace analysis.

	Planktonic form		Sessile form		
Percent of the remaining benzene concentration (C/C_0) in the headspace after 26 hours (%)	Abiotic control	With minimal glucose	Abiotic control	With minimal glucose	Without glucose
	96±11	71±7	80±8	23±2	97±6
Net percentage removal after 26 hours (%)		25±11		57±8	0±8

Comparing the biodegradation of benzene by planktonic to sessile culture, it was evident that sessile culture provided much higher removal efficiency of benzene than planktonic culture. Cellular adhesion to a substratum is a critical function for many microorganisms and can be achieved by the use of fibrils or polymers (van Loosdrecht et al., 1990). Sessile organisms exhibit higher rates of uptake for many compounds when compared to planktonic organisms as well as also exhibit a higher rate of mineralization of organic carbon (Kirchman, 1983; Friedrich et al, 1999). Moreover, it is believed cellular adhesion by the *Gordonia* is mediated through the use of mycolic acids, which have also been shown to confer resistance to chemical injury, which makes the organisms of particular interest for utilization in biotechnological approaches for the treatment of industrial pollution (Kacem et al., 2004; Sokolovska et al., 2003). The results obtained in this study indicated the advantage of attached growth system over suspended activated sludge for degradation of hazardous compounds like benzene.

In addition to glucose minimal media, the bioremediation of benzene as the sole carbon and energy source was investigated (see Figure 6). The results indicated that benzene reduction was almost zero after 26 hours. This result reveled that the *Gordonia* were not active at all and could not utilize benzene as the sole carbon and energy source.

Development of Slow-release Chemical Oxidation Methods for Environmental Remediation

Stephanie Luster-Teasley, PhD and Patrick Onochie

North Carolina A&T State University, Department of Civil, Architectural, Agricultural and Environmental Engineering, Greensboro, NC 27411

Abstract

Chemical oxidation (chemox) is an emerging method used for treating subsurface water and soil. In chemox, highly reactive liquids or gases are injected into a contaminated zone where the oxidants rapidly react to oxidize and breakdown subsurface contaminants to less toxic byproducts. Examples of oxidants used in chemox include ozone gas, Fenton's Reagent, and crystalline permanganate or persulfate dissolved in water. Despite the effectiveness of chemical oxidation, there are drawbacks to current chemox technologies. These drawbacks include the need (1) to inject very strong gases or copious volumes of chemox liquids into the ground, (2) to reapply the oxidants into the subsurface to fully clean sites due to side reactions occurring with natural organic matter or plugging of the subsurface system with chemox precipitates, (3) to prevent explosion hazards caused by the rapid reactions, and (4) to protect workers from the health and safety hazards associated with use of these chemicals. A novel approach to improving chemical oxidation treatment is to develop slow-release, or controlled release systems, to deliver chemical oxidants for water and soil remediation. This paper addresses the development of slow-release oxidant prototypes which are able to delay the release of a chemical oxidants which can be used for various applications in water treatment.

1.0 Introduction

Controlled release (CR) methods to deliver drugs and chemicals are increasingly being employed for various fields such as surgery, pharmacology, agriculture[(Akelah 1996; Al-Zahrani 2000; Kakoulides and Valkanas 1994; Mogul et al. 1996; Quaglia et al. 2001; Segal 1991; Shaviv et al. 2003; Vert 2005)]. Examples of CR designs in the pharmaceutical industry include small non-toxic devices implanted under the skin and biodegradable CR polymers implanted in humans subjects [(Bruck 1990; Ding and Liu 1998; Kohn 1996; Lenz and Marchessault 2005; Nair and Laurencin 2006; Segal 1991; Uhrich 1999)]. In agriculture, CR biodegradable polymers and waxes are used for insecticide, fungicide and pesticide applications [(Akelah 1996; Al-Zahrani 2000; Mogul et al. 1996; Quaglia et al. 2001)]. Despite extensive medical and agricultural research for controlled release systems using environmentally benign and biodegradable polymers, few studies have investigated implementing these methods for environmental engineering applications. Several researchers have developed controlled release systems for soil and water remediation using clay, waxes, gels, and waxy polymers. Examples include slow release oxygen polymers for bioremediation, phosphate buffer encapsulation for polymers for pH control during denitrification of groundwater and sediment, alginate gel for Fenton photochemical oxidation, and

encapsulation of bacterial cells [(Brewster 1995; Gates et al. 1995; Kang et al. 2004; Ross et al. 2005; Schwartz 2005)].

Exploring the ability to use biodegradable polymers featuring controlled release capabilities for environmental remediation and treatment is an emerging concept. Like medical and agricultural systems, many environmental engineering treatments rely on mass transfer and delivery of chemicals. Fundamental research of CR applications for environmental protection, decontamination, and remediation therefore merits investigation. CR technologies can extend treatment methods for soil and water remediation. The existing body of literature for biodegradable polymers focuses on seeking affordable replacements for non-degradable, synthetic plastics and methods to increase physical properties such as tensile strength for the packaging industry [(Kaplan et al. 1993; Mayer and Kaplan 1993; Vert 2005)]. For environmental engineering applications, however, the benefit of using polymers which naturally degrade to deliver treatment chemicals provides a method for in-situ remediation that would not need to be removed after treatment is completed.

Chemical oxidants are highly reactive, non-selective chemicals that generate hydroxyl radicals able to degrade environmental contaminants. In current chemical oxidation methods, highly reactive liquids or gases are injected into a contaminated zone. Chemical oxidants rapidly react to oxidize and breakdown subsurface contaminants to less toxic byproducts. Examples of oxidants used in chemox include ozone gas, Fenton's Reagent and crystalline permanganate or persulfate dissolved in water. Despite the effectiveness of chemical oxidation, there are drawbacks to current chemox technologies. These drawbacks include the need (1) to inject very strong gases or copious volumes of chemox liquids into the ground, (2) to reapply the oxidants into the subsurface to fully clean sites due to side reactions occurring with natural organic matter or plugging of the subsurface system with chemox precipitates, (3) to prevent explosion hazards caused by the rapid reactions, and (4) to protect workers from the health and safety hazards associated with use of these chemicals.

The development of a controlled release delivery system for oxidants from a degradable shell has several advantages: (1) it stabilizes the solid oxidants for emplacement in soil, sediment or subsurface applications. The placement may vary from ones that form permeable reactive barriers, packing in a series of wells where contaminated water will flow past the pellets for remediation, packing in a reactor for a pump and treat system, emplacement in sediment or surface water, or augured into soil. (2) It reduces the need for maintenance associated with the gaseous and liquid oxidants. (3) It reduces the dangers associated with handling the oxidant by workers. (4) It extends the release of an oxidant without the need to re-inject the gas or liquid solutions. Therefore this new method has the potential to effectively extend the ability to provide chemox treatment in a fashion similar to using biodegradable medical implants to deliver drug formulations in the body to provide controlled and extended release of their active components.

This research focuses on the development of controlled release with the chemical oxidant potassium permanganate. Potassium permanganate is a purple crystalline oxidant that can be used to remediate trichloroethylene and was selected as the initial target oxidant for prototype development [(Kang et al. 2004; Ross et al. 2005; Schwartz 2005)]. Several researchers have investigated the ability to

encapsulate potassium permanganate for slow release remediation using waxes and chlorine based polymers[(Kang et al. 2004; Ross et al. 2005; Schwartz 2005)]. In the present work, several biodegradable polymers and polymer blends were investigated for their potential to produce slow release $KMnO_4$ for extended periods of time. These prototypes ranged in diameter size from 0.3-0.5 cm solid pellets capable of releasing $KMnO_4$ for over one month duration. This article presents the preliminary laboratory research conducted to produce encapsulated $KMnO_4$ using biodegradable polymers and examining the feasibility of this technology. A second prototype using an alternative "green" oxidant was explored and demonstrates the ability to remediate pathogenic material. This paper will summarize the results for the $KMnO_4$ development and discuss preliminary findings for using alternative oxidants for encapsulation.

2.0 Materials

Certified ACS $KMnO_4$ (Fisher Chemical, Fair Lawn, NJ) was encapsulated in a blend of inert biodegradable polymers. Due to legal constraints, the biodegradable polymers selected for the prototype design will not be disclosed in this article. The structures, henceforth referred to as controlled-release biodegradable polymers (CRBP), Polymer A (a hydrophobic biodegradable polymer), and Polymer B (a hydrophilic biodegradable polymer) were formed into 0.3-0.5 cm in size solid pellets capable of controlled-release of the oxidant. The polymer blends for Polymer A and Polymer B were designed based on three design mechanisms. These mechanisms include: type 1 – Polymer erosion of the CRBP, type 2 - diffusion controlled, and type 3 – combined control. In a type 1 polymer erosion based system, the polymer had a higher capability of dissolving in water to release $KMnO_4$. The type 2 diffusion controlled system was designed for a higher capability for the $KMnO_4$ to diffuse through the shell into water. The type 3 combined control is a combination of type 1 and type 2 systems. Potassium permanganate concentrations in solution were measured using a Spectronic Spectrophotometer at 525 nm wavelength. Trichloroethylene concentrations were analyzed using a HP 5890 Series II gas chromatograph with a flame ionization detector (GC/FID) and a capillary column (J&W Scientific DB-624, 0.53 mm id x 30 m length).

3.0 Results and Discussion

Prototype development was based on three criteria: (1) polymer shell compatibility with the oxidant, (2) the ability for diffusion of the oxidant through the shell boundary, and (3) the ability to form pellet structures feasible for use as fill material for a permeable reactive barrier or in a reactor system. Prototypes with various diffusion and erosion rates were investigated using batch studies with aqueous media. Studies were conducted to evaluate the prototype reaction with the encapsulated oxidant, release of the oxidant from the polymer, and remediation of 500 ppm trichloroethylene in batch reactors. Criteria for biodegradable polymer selection included the compatibility with the selected oxidant, the ability to form solid pellet structures ranging in size less than 0.3-0.5 cm, and the ability of the polymer to degrade or dissolve to release the oxidant. $KMnO_4$ was tested for reactivity with the biodegradable polymers and polymer blends. One concern for shell

material is to ensure the oxidant was not reactive with the polymer. If the $KMnO_4$ is reactive with the shell, visible evidence would be a brown discoloration caused by manganese oxide formation or visible degradation of the shell material. To determine the stability, $KMnO_4$ was encapsulated in biodegradable polymer shells and mounted on a glass slides. Photos at 40x and 100x were taken of the pellets using a digital microscope to observe any reactions or discoloration of the shell. Little to no reactivity was observed between the polymer material and the $KMnO_4$ demonstrating the shell is inert and able to stabilize the oxidant.

3.1 Release Studies for Encapsulated $KMNO_4$

Biphasic $KMnO_4$ release was observed from the encapsulated oxidant pellets. This is consistent with the observations seen in previous studies using wax and chlorinated polymers [(Kang et al. 2004; Ross et al. 2005)]. A rapid release of $KMnO_4$ occurred during the initial 1 – 3 days followed by a controlled and slower release of $KMnO_4$. Oxidant release was delayed by increasing the ratio of hydrophobic Polymer A to hydrophilic polymer B in the polymer blend. Prototype blends were identified as PAB-50, PAB-60, PAB-90, and PAB-100 contained 50%, 60%, 90%, and 100% of Polymer A to Polymer B, respectively. Therefore PAB-50 represented a 1:1 ratio of Polymer A to Polymer B. PAB-50 was observed to release $KMnO_4$ at a faster rate than PAB-60, PAB-90 and PAB-100. PAB-60 and PAB-90 appeared to exhibit similar release rates for $KMnO_4$ with PAB-90 releasing the oxidant slower during the first 20-minutes. PAB-100 demonstrated the slowest release of the oxidant. Homogenous mixing of the polymers and oxidant proved to be important to ensure diffusion of the oxidant from the shell at a controlled rate because the hydrophilic polymer will readily dissolve in water leaving pores in the hydrophobic shell. For example, an excess amount of hydrophilic polymer on the pellet surface led to rapid diffusion of the oxidant from the polymer. Pellets designed with only the hydrophobic polymer demonstrated the slowest rate of oxidant diffusion.

The diffusion based prototypes containing Polymer A proved to be the most effective $KMnO_4$ delivery without the formation of MnO_2 precipitates. The erosion based prototypes with Polymer B formed manganese oxide precipitates. The diffusion based and the combined prototypes were determined to be more feasible for long-term release of the oxidant subsurface. The prototypes with a higher ratio of Polymer B produced MnO_2 precipitate which decreased in formation as the ratio of Polymer A polymer increased in the pellet design. Because manganese oxide is a precipitate known to inhibit the ability to use $KMnO_4$ for trichloroethylene remediation, the PAB-100 prototype was evaluated for the media replacement, continuous release, and TCE remediation studies.

3.2 Replacement Media Study

In the replacement media study, PAB-100 prototypes containing 2% and 20% $KMnO_4$ by mass to polymer ratio were encapsulated in the polymer shell. In batch reactor bottles, 50 ml of DI water and 0.5 g of prototype pellets were sealed and stored for 3 – 4 days at 28°C and in the dark. After 3 – 4 days, the $KMnO_4$ concentration was measured using a Spectronic Spectrometer at 525 nm wavelength.

Following the $KMnO_4$ concentration measurement, the pellets and bottles were rinsed with DI water three times and 50 ml of fresh DI water was added to the bottles with the same pellets. This process was then repeated by storing the reaction bottles for another 3 – 4 days and a $KMnO_4$ measurement was performed. This replacement media study was designed to measure the steady-state release rate of $KMnO_4$ prototypes.

The prototypes demonstrated an initial rapid release of the oxidant followed by a slower, steady state release (Figures 1a and 1b). The 2% prototype exhausted the encapsulated $KMnO_4$ diffusing from the shell within 44 days. The 20% $KMnO_4$ structures however had not exhausted the oxidant within the 44 day period of the experiment.

3.3 Continuous Release Study

In the continuous release studies, PAB-100 prototypes containing 2% and 20% $KMnO_4$ by mass to polymer ratio were encapsulated in the polymer shell. A mass of 0.5 g of pellets were added to 50 ml of DI water in reaction bottles. Measurements for $KMnO_4$ were conducted every 3 – 4 days using a Spectronic Spectrometer at 525 nm wavelength. Following the measurements, the prototypes and the liquid sample were returned the bottles, capped, and stored for another 3 – 4 days at 28°C in the dark before the next measurement. In the continuous batch study, $KMnO_4$ release was observed to extend over a 46- 48 day period where 2% and 20% $KMnO_4$ by mass in polymer prototypes were measured for $KMnO_4$ concentration in water (Figure 2a and 2b).

Future studies to evaluate $KMnO_4$ release will entail optimizing the concentration of $KMnO_4$ (greater than 20% by mass) that can be encapsulated in the polymer structures and reducing the biphasic release observed in the prototypes. Additionally, alternative hydrophobic and hydrophilic polymer blends will be investigated. The surface area of the polymer structures can be enhanced using various shapes and geometries such as cylinder columns, saddles, or hollow tubes.

3.4 Reaction with Trichloroethylene

The prototypes demonstrated the ability to degrade trichloroethylene (TCE) in a batch system. The TCE contaminated water (500 ppm) was added to 25 ml serum bottles with 0.5 g of either the 2%, 20%, or 60% $KMnO_4$ prototypes. The bottles were overfilled and capped to prevent headspace air from being sealed in the bottle. This ensured all TCE would be dissolved in the liquid phase without the need to analyze headspace gas. TCE concentrations were analyzed using a HP 5890 Series II gas chromatograph with a flame ionization detector (GC/FID) and a capillary column (J&W Scientific DB-624, 0.53 mm i.d. x 30 mm length). Measurements were conducted every seven minutes for a total of 77 minutes. Trichloroethylene degradation for the 2% pellets reached 50% removal after 70 minutes while the 20% pellets reached 50% removal of TCE within 47 minutes. The TCE concentration reached 50% reduction in the 60% KMnO4 prototypes within 13 minutes however there was a large formation of MnO_2 (Figure 3). The TCE and $KMnO_4$ reaction demonstrated first order kinetics which is consistent with literature [(Schnarr et al. 1998)].

3.5 Challenges for $KMnO_4$ slow release remediation

There may be several factors that restrict the controlled release system. These factors include the quantity of potassium permanganate that will diffuse from the system, the production of MnO_2, and reaction efficiency may be limited. Prototype design and determination of an adequate quantity of pellets to remediate contaminants should help overcome these challenges. CRBP can overcome the need to inject copious amounts of liquid $KMnO_4$ into the subsurface which is the common practiced currently used for $KMnO_4$ and TCE remediation. Literature reports one of the limiting factors for chemical oxidation methods is the formation of precipitates that will "clog" the soil particles and reduce the effectiveness of transporting chemox liquids subsurface [(Siegrist et al. 1999a; Siegrist et al. 1965; Siegrist et al. 1999b)]. The formation of MnO_2 precipitates which, is also a significant problem for traditional $KMnO_4$ remediation, still remains an important consideration and potential challenge to overcome for CRBP remediation.

4.0 Future Work

Our future work for using chemical oxidants encapsulated in biodegradable polymers will include exploring alternative chemicals for encapsulation and investigating alternative hydrophobic and hydrophilic polymer blends to control degradation rates for the polymer/chemical pellets. We will continue investigate optimization of the chemical to polymer ratio, controlling and modeling chemical diffusion from polymer shells, encapsulation methods (i.e. micro-based and nano-based), and structure geometry. In particular, we are interested in exploring the use of alternative oxidants for treatment of environmental contaminants including various groundwater contaminants, pathogens, and pesticides. Our research efforts have progressed to investigating one alternative oxidant capable of reducing concentrations of pathogens in water. Release studies using the PAB-100 polymer demonstrate the ability to release the alternative oxidant for sustained periods of time. This work appears to be promising and will help promote future efforts in exploring controlled release technologies for environmental remediation.

Peracetic acid as an alternative disinfection technology for wet weather sewer overflows

Coyle, E.[1], P.E., L. Ormsbee[2], P.E., P.H. Ph.D., D.WRE, F.ASCE

[1]Environmental Engineer, Kentucky Water Resources Research Institute, 233 Mining and Minerals Resource Building, University of Kentucky, Lexington, Kentucky 40506-0107, (859) 257-8005, email:eecyole@juno.com; [2]Director, Kentucky Water Resources Research Institute, 233 Mining and Minerals Resource Building, University of Kentucky, Lexington, Kentucky 40506-0107, (859) 257-6329, email: lormsbee@engr.uky.edu

Abstract

Combined Sewer Overflows (CSOs) continue to be a significant source of wet weather flows (WWFs). Traditional technologies exist to address wet weather overflows but are many times cost prohibitive, can yield toxic by-products and in areas of older infrastructure, space for facilities to treat overflows is often limited if available at all. As such more cost effective technologies, requiring less space and producing less harmful by-products are currently being explored. One such possibility for alternative high-rate disinfection has been investigated using peracetic acid. The decomposition of peracetic acid results in only the non-toxic by-products of oxygen, methane, carbon dioxide and water, and the disinfection reaction occurs in a short contact time and with a high kill rate. Thus, this technology can prove not only valuable where space is limited, but is also extremely environmentally sound.

Introduction

Since the passage of the Clean Water Act (CWA) in 1972, the nation has spent considerable fiscal resources in an attempt to clean up the country's waterways. Following the passage of the Act, the initial focus of policy makers was on improving the treatment capacity and efficiency of the nation's wastewater treatment plants. Since that time, additional focus has been placed on addressing other sources of contamination such as non-point source runoff and intermittent discharges from wet weather flows (WWFs). In 1994, a coordinate attempt was made to address the problem with combined sewer flows through the development of nine-minimum controls and a subsequent long term control plan (USFR, 1994; USEPA 1995).

Rain induced wet weather flows (WWFs) consist of combined sewer overflows (CSOs), sanitary sewer overflows (SSOs) and stormwater (SW), all of which introduce pathogens to the surface waters when discharged. These waterborne pathogens consist of disease-causing bacteria, viruses, and protozoa. When people come into contact with the contaminated water, these pathogens can be transmitted resulting in severe problems of the digestive system, which can be life-threatening to the very young, very old, or those with damaged immune systems. In 2004 it was estimated that between 3,000 to 6,000 illnesses are caused nationwide on an annual level due to WWFs (EPA, 2004).

Combined sewer systems serve approximately 746 communities containing about 40 million people. Within these communities there are estimated to be around 9,348 CSO outfalls that are regulated by 828 NPDES permits. Most communities with combined sewer systems are located in the Northeast in the Pacific Northwest regions as well as in the Ohio and Missouri River valleys. In the state of Kentucky, there are currently 17 CSO communities with a total of 297 CSOs. The majority of these are associated with Louisville, Kentucky and the Northern County Sanitation District No.1 (see Figure 1 and Table 1).

EPA has estimated that approximately 850 billion gallons of untreated wastewater and stormwater are discharged from these outfalls (EPA, 2004). As of 2002, over $6 billion dollars had been expended in addressing these issues. At that time, it was estimated that an additional $50 billion dollars would have to be spent to achieve an 85% volume reduction of the existing CSOs.

Table 1. List of CSO communities in Kentucky

Community	KPDES Permit	# CSOs	Population Served
Louisville - MSD	KY0022411	115	430,000
N.KY Sanitation Dist. #1	KY0021466	74	335,000
Owensboro	KY0020095	8	54,000
Frankfort	KY0022861	15	50,611
Paducah	KY0022799	11	34,500
Ashland	Ky0022373	8	30,000
Henderson	KY0020711	14	29,500
Pikeville	KY0025291	3	10,000
Pineville	KY0024058	3	9,111
Maysville	KY0020257	11	8,950
Prestonsburg	KY0027413	1	4,800
Catlettsburg	KY0035467	17	4,100
Morganfield	KY0021440	2	3,850
Harlan	KY0026093	1	3,786
Worthington	KY0022926	3	2,168
Vanceburg	KY0021512	5	2,038
Loyall	KY0026115	6	1,332

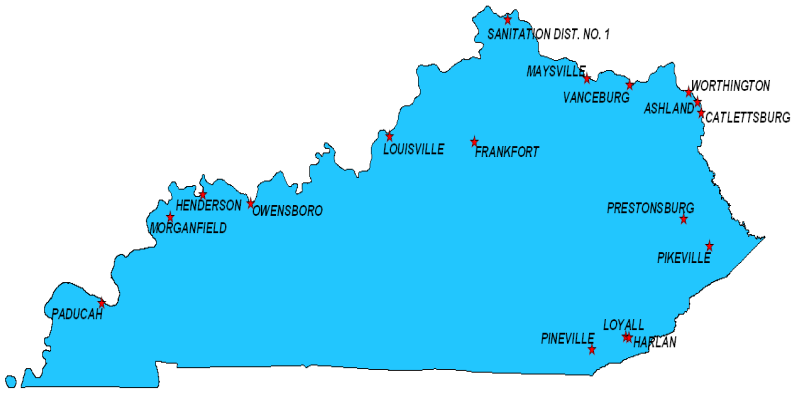

Figure 1. Map of CSO communities in Kentucky

Unlike traditional wastewater treatment plants, the quality and quantity of WWFs can vary significantly within minutes, as well as within hours, days, months and seasons (Wojtenko, et al., 2001) For example, after dry periods, a phenomenon referred to as the "first-flush" occurs during wet weather events, in which build up from the watershed or build up in the collection system, or both, are flushed from the watershed and system into the surface waters. This "flush" into the surface waters is much more concentrated with pollutants than flows that have been diluted throughout the wet weather event after the watershed and collection system have effectively been "rinsed off" by rain water. Another example is seen during the spring and summer seasons of high vegetative growth, when less runoff is introduced to the surface waters and collection system as opposed to more dormant fall and winter seasons when the volume of stormwater runoff is higher and of different character. In addition, the composition of WWF also varies from community to community depending on the characteristics of the individual discharges to the system. As such, not only do flow rate, volume and quality of WWFs vary temporally, they vary with location on a system by system, watershed by watershed basis.

The variation in quality can be seen in the range of constituents for "typical" WWFs. These ranges can be approximated from an examination of data from various sewer districts such as the Louisville Metropolitan Sewer District and Cincinnati Ohio WWF data (see Table 2 below).

Table 2: Representative WWF constituents

Constituents	Maximum	Average/Median	Minimum
E coli (col/100 mL)	10,000,000	501,187	31,623
TN (mg/L)	13	5.1	2.25
TP (mg/L)	2.5	1.5	0.5
TSS (mg/L)	500	150	45
COD (mg/L)	500	100	0
pH (SU)	6.5	7	7.5

As can be seen, the range of values varies depending on the constituent. It is also worth noting that the constituents do no vary directly with each other. Just because one constituent is on the high end of the range does not imply that others will be and vice versa. Due to the independent and highly variable nature of each of the WWF constituents, as well as the temporal and spatial variability of WWFs in general, the disinfection of WWFs is uniquely challenging.

Wet Weather Flow Technologies

The major technologies for addressing wet weather discharges can be grouped into five major categories: 1) operation and maintenance, 2) collection system controls, 3) storage facilities, 4) source reduction through low-impact development techniques, and 5) treatment technologies. This paper will be focusing on treatment or disinfection technologies.

Chlorine is the most commonly used wastewater disinfectant but as early as 1969, alternatives to the chlorination of wastewater were desired due to the costs and hazards involved in transportation, storage and operation, particularly in highly populous areas (Elwood, 1970). In addition, heightened public concern regarding the use of chlorine compounds which produce toxic, mutagenic and carcinogenic by-products has stimulated the desire for alternative disinfectants (Veschetti, et al, 2003). Thus, alternatives to chlorine disinfection are being sought due to the growing concern over safety in handling gaseous chlorine and possible toxic side effects of treatment with chlorine.

According to the USEPA guidance document, "Combined Sewer Overflow Control", methods that are generally referred to as high rate disinfection achieve "…high bacterial kills at lower contact times, using increased mixing intensity, increased disinfectant dosage, chemicals having a higher oxidation rate than chlorine, or a combination thereof" (USEPA, 1993). The guidance further indicates that an acceptable reduction in bacteria concentration of at least 4 log kills should be achieved at detention times less than the conventional values of 15 to 30 minutes. Further, "an ideal disinfection system should guarantee the maximum efficiency in pathogenic microorganism removal without generating toxic and undesirable by-products" (Veschetti, et al., 2003). Thus, alternative disinfectants for WWFs should meet the above criteria, however a 10 minute contact time is now often achieved with many of the leading alternatives.

In 1999, EPA published several publications addressing the issue of treatment of CSO discharges. These included publications for chlorine disinfection (USEPA, 1999a) and for alternative disinfectants (USEPA, 1999b). Potential alternatives include: 1) chlorine dioxide, 2) ozonation, 3) ultraviolet (UV) radiation, 4) electron beam irradiation, and 5) peracetic acid (PAA). This paper will investigate the potential effectiveness of PAA as applied to wastewater discharges from the Town Branch Treatment Plant in Lexington, Kentucky.

Peracetic Acid

PPA (CH_3COOOH) is a very strong oxidant having a oxidation capacity of 1.81 v. The equilibrium chemistry is shown in Figure 2. PAA is produced by combining acetic acid, hydrogen peroxide, and water. Sulfuric acid is typically used as a catalyst for the reaction. PPA residuals appear to be non-toxic and are readily biodegradable in receiving waters. The disinfection rate associated with PPA has also been found to be very rapid which provides an added incentive for application to WWFs.

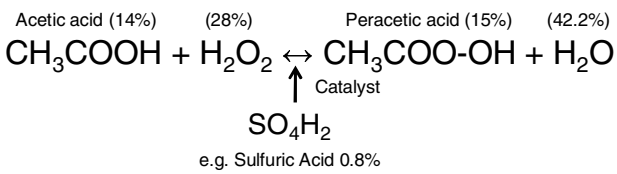

Figure 2: Equilibrium Chemistry for Peracetic Acid

Disinfection Studies

The potential application of PPA for use as a rapid disinfectant was tested using wastewater after primary treatment from the Lexington Town Branch treatment plant. The efficiency of the PPA was measured using Ecoli concentrations ranging from strong (> 1 million MPN/100 ml), moderate (> 100,000 MPN/100 ml, and weak (< 100,000 MPN/100 ml). For each strength, different combinations of contact time (i.e. 2, 5 and 10 minutes) and PPA concentration (i.e. 5, 10, and 15 mg/L) were evaluated.

Strong Wastewaters

Figures 3 and 4 show the disinfection efficiency of peracetic acid for water quality representative of strong WWFs with Ecoli concentrations ranging from approximately 1,000,000 to 2,500,000 MPN/100 ml. It can be seen that secondary water quality standards of 1,000 cols/100 ml is met with 10 - 15 mg/l of PAA up to 2,500,000 MPN/100 ml and that primary water quality standards of 100 col/100 ml is met with 15 mg/l up to 1,000,000 MPN/100 ml. With an increased dose of PAA higher initial concentrations were also brought down to primary water quality standards as show in figure 5. One of the more interesting things to note from each of these figures is that at the 10 and 15 mg/l peracetic acid dosages, the majority of the kill occurs in the first 5 minutes regardless of the initial concentration.

Moderate Wastewaters

Figures 5 through 8 show results from moderate strength WWFs. The primary water quality standard of 100 cols/100 ml is met consistently with the 10 and 15 mg/l doses and achieved or very closely approached with 5 mg/l. It is worth noting that at a contact time of 2 minutes, this standard is met with the 15 mg/l dose and that again, the majority of the disinfection occurs within the first 5 minutes (if not the first two) with the higher dosages. Finally, if a 10 minute contact time is desired such that less peracetic acid is used, it appears that 5 mg/l or a dose slightly higher would achieve primary water quality standards. All doses met secondary water quality standards of 1,000 cols/100 ml.

Weak Wastewater

Figure 9 shows results from an experiment with a weak WWF. As with the moderate strength WWF results, all three doses achieve primary and secondary water quality standards and the majority of the disinfection occurs within the first 5 minutes of treatment.

Conclusions

This study has demonstrated that PPA can be used as an effective disinfectant for WWFs as measured against discharges from an actual wastewater system. In addition to providing disinfection at a rapid rated, PAA requires no post treatment, since the chemical breaks down into harmless by-products.

Recycling of multiple waste streams for transportation fuel production via algae cultivation at wastewater treatment plants

Patrick J. Dunlap, Department of Civil Engineering, North Dakota State University
Andrew R. Shaw, Black & Veatch

Abstract

Increasing oil prices have led to recent initiatives to find domestic and renewable sources of transportation fuels. The cultivation of algae for biofuels production offers a uniquely sustainable option to utilize both greenhouse gases and wastewater as a valuable commodity. Algal cells contain lipids which can be converted to biodiesel by the same processes already used for other feedstocks. The most striking advantage over other feedstocks is the potential of algae; with theoretical production per area much higher than the currently favored feedstocks. Also as a non-food crop it will not have an effect on global food prices. Furthermore; the non-oil components of the algae cell also have value, such as cellulose which has the potential to be used for ethanol or methane production. With these advantages in mind, the steady flow of water and nutrients from a wastewater treatment plant presents an opportunity for effluent to be used in algae cultivation. The necessary carbon source could be supplied through a synergistic relationship with coal fired power plants needing to sequester greenhouse gases or as carbon from onsite anaerobic digesters. In any case, the coupling of a wastewater treatment plant with an algae cultivation system offers many exciting opportunities, such as low energy nutrient removal, valuable commodity production, and abatement of greenhouse gases. This paper reviews the current technologies and methods in algae for biofuels production, and suggests the feasibility of their future application to wastewater treatment plants.

Why Algae?

In recent years the push toward alternative and environmentally friendly transportation fuels has been highly visible. Policies, such as the former administration's policy of producing 132 billion liters (35 billion gallons) of ethanol by 2017 and 227 billion liters (60 billion gallons) of ethanol by 2030 (Sciences, 2007), and the funding and subsidies which have come about as a result of these and similar policies have led to immense growth in the biofuels industry in recent years. However, concerns have been raised about the actual versus the perceived impact of corn ethanol and other alternative fuel sources. For example the European Environmental Agency recently recommended that the current EU goal of 10% of transportation fuels being biofuels by 2020 be suspended over their concerns about net greenhouse gas abatement, natural resource utilization, and rainforest destruction; calling the goal "an experiment, whose unintended effects are difficult to predict and difficult to control" (Committee, 2008). It is also possible that biofuels production has been partially responsible for upsetting global food prices; leading to the ethical question should we really be treating food crops as a fuel commodity with the poorer citizens of the world impacted most?

In response to the push for increased alternative fuels production, microalgae has emerged in the public eye as a promising alternative. Serious research into microalgae cultivation for varied production purposes has been taking place for more

than three decades. What makes microalgae unique from other forms of biomass is its ability to convert solar energy so efficiently. Even the most conservative estimates say algae will produce about 20 times more biodiesel per area than soy, for example. Under optimized conditions algae can achieve energy conversion efficiencies much greater than other plant life resulting in a higher yield of fuel per land area. Unfortunately, application and realization of these yields has proven more elusive than theoretical figures might indicate. Algae can also be grown on land not suitable for the growth of other crops and with alternative water sources such as municipal and industrial wastewater, sea water, and saline aquifers. In addition, algae is not a food crop and will not have the impact on global food prices which have been associated with other biofuel feedstock options.

The purpose of this paper is to give an overview of current algae-biofuel technology. Some basics of algae cultivation and the history of its research will also be presented. Major hurdles will be summarized as well as commonly accepted strategies for overcoming those hurdles. Potential applications will be presented, along with their impact on wastewater treatment and water resources.

Basics

The term microalgae refers to microscopic unicellular algae species. It is a very general term for a very diverse group of more than 20,000 species which phycologists - those who study algae - even disagree on how to classify (Vymazal, 1995). Most of the interest has gone to a couple of well understood and promising groups such as members of the green algae genera Chlorella, Botryococcus, and Dunaliella; and the cyanobacteria genus Spirulina. (Benemann J. R., 2003) For practical purposes the major requirements for algal growth are Carbon, Nitrogen, Phosphorus, and water; though other macronutrients and micronutrients are required as well (Vymazal, 1995). pH, temperature, salinity, and insolation are also important factors in algal growth.

In a simplified view the constituents of algal biomass are cellulose, lipids, and proteins. This is significant as all components of the algae cell can be utilized, though traditionally the emphasis has been on maximizing the lipid fraction for increased biodiesel production. The lipids produced by algae are mostly triglycerides and through the process of transesterification can be simply converted to biodiesel as is done with the oil from other feedstocks.

Microalgae cultivation can be separated into two basic methods: open and closed systems. Each system has its own distinct advantages and disadvantages, with research still being performed on both. Open ponds (see Figure 1) have the advantage of being economical, scalable, and to some extant proven, as current commercial algae production for food, animal feed, pharmaceutical, and industrial applications utilize open pond systems. Even though they are more economical, the cost which these systems operate at is still prohibitively expensive for fuel. The disadvantages of the open ponds lay in their exposure to the atmosphere; making these systems susceptible to fluctuations in temperature, changes in salinity due to rain events and evaporation, and invasions by unwanted native species of algae.

Closed systems (see Figure 2) are commonly referred to photobioreactors (PBRs), and compared with open ponds are a relatively new addition to algae cultivation methods. They come in many different configurations, including hanging bags, horizontal and vertical arrays of plastic tubes, and even helix shaped. The advantage is that greater control can be exercised allowing the algae to approach theoretical photosynthetic efficiency, while the disadvantage is the prohibitive costs of the PBRs. It is also worth mentioning that in most concepts both open ponds and closed PBRs use CO_2 diffused through the water to supply a plentiful carbon source for the microalgae. This is necessary to achieve the high productivities commonly reported.

History

Early research into the culturing of algae saw potential for algae to provide a high protein and inexpensive food. Just as now, there was a lot of talk in the 1950s and 60s about algae saving the world, from food not fuel shortages. In the 1970s the Department of Energy (DOE) became interested in microalgae and first funded research for the low energy treatment of wastewater and the anaerobic digestion of the resulting biomass for biogas and ultimately energy production. (Benemann J. R., 2003)

In 1978 the DOE formed the Aquatic Species Program (ASP), which was focused on the cultivation of microalgae for biofuels production in open ponds fed by CO_2 from coal power plants. The ASP was in existence until 1996 and during that time it made many important breakthroughs, which today are considered by many to be the seminal work on the subject. The primary foci of the ASP were on selecting appropriate microalgae strains which were resilient to environmental variation and had high lipid content; increasing the lipid fraction of the individual algae cells; and the operation of open pond facilities to study algae production rates and CO_2 uptake levels (Sheehan, Dunahay, Benemann, & Roessler, 1998).

The 1990s also saw major research in Japan on the hardware of microalgae culturing. Closed photobioreactors were investigated as a means for CO_2 capture and synthesis of higher value co-products. The program was discontinued due to the high cost of these PBRs.

Early in this decade a member of the Aquatic Species Program named John Benemann published "Biofixation of CO_2 and Greenhouse Gas Abatement with Microalgae – Technology Roadmap" the purpose being to provide a guide for R&D which could produce applicable technologies within a decade (Benemann J. R., 2003).

In recent years research into microalgae for biodiesel production has taken a new direction. Government funding is still providing for research, but "clean tech" venture capital and petroleum industry wealth have become major sources as well. Within the last five years more that 50 venture capital companies have started in various areas of the algae-derived production chain; including algae biotechnology, open pond and closed PBR cultivation systems, and algae oil processing. Petroleum companies such as Shell and Chevron have staked claims and have partnered with some of the venture capital companies. Shell is working on an algae oil pilot facility

in Hawaii, and chevron has received funding from the Defense Advanced Research Projects Agency (DARPA) for the researching production of jet fuel from algae. In addition Honeywell, Airbus, and Boeing are other companies who have invested in algae technology.

With this recent research has come a lot of hype in the media, mostly spurred on by the new venture capital companies giving highly bloated figures on productivities, and claiming that algae will be running all our cars in a couple of years. For example in an article from CNN.com in 2008 the CEO of an algae oil startup company claimed that algae is about 50% oil and 0.4 hectares (one acre) of land used to grow algae can produce 380,000 liters (100,000 gallons) of biodiesel per year (Walton M, 2008). The first fact is wrong except under extreme circumstances and the second is actually thermodynamically impossible, but it was still published with no factual rebuttal of any kind. Naturally these sort of sensational stories recently have led to a much needed interest in algae, but with an overly enthusiastic optimism. A personnel favorite of the authors came on a recent American Airlines flight where the in-flight magazine contained an article on algae oil titled, "One Word: ~~Plastics~~ Algae" (Millar, 2008). This suggests the line from the 1967 film The Graduate and compares the venture capital-fueled world of algae oil today to the money to be made in the then emerging plastics industry.

Hurdles

Despite the recent influx of money coming at algae technology research and development, there are still obstacles to overcome. Like most new technologies, in the end it comes down to economic analysis. Algae did not become the food of the future because it could not be made competitive with other crop foods, and the Aquatic Species Program concluded that productivities needed to be higher and fossil fuels prices higher for the idea to work. If the profit from cultivating algae on a mass scale can be made significantly greater than the expenses while remaining socially and environmentally acceptable we will start to see algae oil facilities.

In order to achieve this economic viability, methods need to be found to decrease algae production costs and increase yields while developing new profitable ways to use the algae and the associated process. First it is necessary to analyze ways to keep production costs to a minimum. To achieve this, the open pond system currently appears to be the only feasible option. Millions of dollars of research was discontinued when the Japanese algae programs determined PBRs to be too expensive even for high value products (Benemann J. R., 2003). In 2007 an independent case study by Dr. Krassen Dimitrov used basic thermodynamic principles and conservative economical estimates to determine that a particular algae clean tech company's PBRs would not be competitive with fossil fuels unless crude prices reached $800/barrel (Dimitrov, 2007). John Benemenn from the ASP, a foremost expert on algae cultivation believes that PBRs are too expensive but could serve a role in inoculum production to seed the open ponds (Benemann J. R., 2003). In this way PBRs and open ponds could work together to overcome their individual inherent defects. The bulk of the growth could take place in the inexpensive ponds while changes in environmental conditions are buffered and invasive algae are kept

from taking over by a steady concentrated supply of the desired algae cultivated in a PBR. In addition to this, algae strain selection and genetic engineering could improve the efficiency of ponds in the future.

Another place where there is room for improvement is the optimization of the growth process in the ponds. While the necessary components to grow algae are straightforward, raw ingredients alone do not always constitute the desired recipe. Too many or too few nutrients can have a negative impact on growth, as can pH, temperature, or salinity if they are out of range. If the algae concentration is too high, the increased turbidity will block sunlight and slow the growth of more algae. Also, many see wastewater treatment as an advantageous co-process and if achieving a high quality wastewater effluent is another goal then controlling the process will become even more complex.

For the harvesting of microalgae; flocculation and sedimentation, centrifugation, microscreening, and flotation are all potential methods. Traditionally more energy intensive processes such as centrifugation have been used, and further research in this area could greatly impact microalgae biomass production economy. For example, bioflocculation is a process by which algae cells naturally form readily settling flocs under the right conditions. Flotation also seems to make sense as microalgae are already slightly buoyant due to oil content and if strains with higher amounts of oil are used flotation could be most effective.

Co-Products

Even with optimistic efficiencies and yield projections, the economic feasibility of algae to biofuels remains uncertain. It is popular belief that the best application of this process might lie in co-products and processes which can be produced and coupled with mass algae cultivation. At a WEFTEC 2008 algae committee meeting the idea of co-products and co-processes was a recurring theme. Likewise, this is one of the focuses of Benemann's 2003 roadmap, in which he states that current research should focus on the successes of past programs; such as the DOE's previous research into coupling with wastewater treatment and the production of high value co-products as was done in Japan and more recently by American private companies (Benemann J. R., 2003). Algae biomass and the process by which it is grown offer multiple opportunities to produce higher value products and receive greenhouse gas abatement credits. In this and the following section some of the co-products and co-processes which could create alternative income streams for algae cultivation are discussed.

There are several types of biofuels which can be produced from algae biomass, such as methane, biodiesel, ethanol, hydrocarbon chains, and hydrogen (Benemann J. R., 2003). The best known is biodiesel which simply requires the extraction of the lipid content and processing in the same way as with other feedstocks. The processing method is well established, but the costs associated with lipid extraction are high and more efficient methods are needed. A second biofuel option is to produce ethanol through fermentation of the algae's cellulose. Cellulosic ethanol is currently a hotly studied topic outside of algae research. If breakthroughs are made in this area it will also be a major breakthrough for algae oil research leading to a valuable co-product

to offset microalgae's expensive cultivation. A third biofuel production option is to anaerobically digest the remaining biomass for the production of methane (Benemann et al, 1977). The methane can be easily burned to produce electricity for the facility to help offset the high costs of the processes. This practice is applied at many wastewater treatment plants for their biosolids handling, and has been taken a step further at the wastewater treatment plant of Sunnyvale California where algae biomass used for treatment is harvested and anaerobically digested to produce biogas and ultimately electricity (Benemann J. R., 2003).

Other non-biofuel products include bioplastics which are potentially of higher value than fuels. Though this is still being researched they are currently seeing limited use in Europe and Japan. Algae oil and bioplastics technology each show great promise for the other's future viability. In addition unused biomass can also be sold as animal feed, and the nutrients which were absorbed by the algae can be reclaimed and recycled back to the algae ponds as needed or processed into a fertilizer.

Co-Processes

Another financial justification for algae cultivation comes from coupling it with other processes thereby increasing the efficiency of both. Some of the most promising of these appear to be wastewater treatment and CO_2 sequestration. The concept of growing algae as part of a wastewater treatment process has been around for decades. The most common method is shallow mixed ponds, termed high rate ponds, already used in many locations around the world such as the Sunnyvale Facility mentioned above. In high rate ponds raw wastewater is cleaned by a synergistic relationship between bacterial biomass and algae. Bacteria decompose the incoming organic matter releasing CO_2, Nitrogen, and Phosphorus; and form more bacterial biomass. With energy from sunlight the algae is able to use these components for the formation of more algal biomass and produce more oxygen to be used again by the bacteria (see Figures 3&4). The advantage of this over the conventional activated sludge process is in its energy efficiency, as aeration of the water is not necessary. The tradeoff is a much increased footprint as the surface area exposed to the sun now determines the power input into the system. In natural systems, phosphorus is usually the limiting element in algal growth, but in municipal wastewater it is usually carbon, and because of this limitation high rate ponds usually achieve 80-90% soluble BOD removal, 20-70% N removal, and 10-50% P removal (Lundquist & Benemann, 2007). When the purpose of the process becomes not only wastewater treatment, but also algae biomass production it is advantageous to increase algal production to its maximum, making the limiting factor the amount of sunlight. When CO_2 is diffused through the water to make up for the carbon deficiency, higher levels of treatment can be achieved at much lower costs than conventional nutrient removal systems (Lundquist & Benemann, 2007).

The greenhouse gas abatement potential of algae cultivation is also substantial. By the production of biofuels or improvements in energy efficiency GHGs which would otherwise have been released from fossil fuels are abated. Likewise; fertilizers have a very large carbon footprint associated with them but if they are produced as a byproduct of another process then they abate greenhouse gases. Lundquist estimates

an abatement potential of 455 kg of CO_2 per million liters (1.9 tons of CO_2 per million gallons) of wastewater treated. According to his research, coupling microalgae cultivation with wastewater treatment processes enhanced by CO_2 sequestration makes an economical impact which could lead to near term application for algae cultivation (Lundquist & Benemann, 2007).

Limitations

While algae technology shows a lot of promise there are some limitations to its application at larger scales. Technological and economical hurdles, as previously discussed can be solved on a more general level, but resource availability issues must be addressed for each individual site. The first and most obvious limitation is climatic; maximum solar radiation and high temperatures are desired for obvious reasons. Also, because of the large footprint needed for algae growth, land availability becomes a limitation as well, especially when attempting to couple the process with a wastewater treatment facility. There also is the issue of CO_2 supply. Ideally algae production facilities will be built near a coal fired power plant or some other industrial source of CO_2. If in the future serious legislation is passed regulating GHG emissions then it could become necessary for CO_2 emitting industries to transport and sequester their emissions making this less of an issue. This would however be extremely costly for such an industry to do.

Perhaps the most significant limitation to algae cultivation on the kind of scale needed to offset our nation's use of fossil fuels is the water resources required. For example, if we assume a very optimistic 94 m^3/hectare·yr (10,000 gal/acre·yr) production of biodiesel from algae and a conservative 1270 mm/year (50 inches/year) evaporation from the sunny areas where growth will take place, then to offset the 151 billion liters (40 billion gallons) of diesel used for transportation per year in the US the loss of water just due to evaporation would be almost 21,000 gigaliters/year (17 million acre·ft/year). Though this is not a problem in the near future; it shows the great impact that algae cultivation could have on water resources, and this is definitely something to be kept in mind in an age of water scarcity. In each site the water resources will need to be secured. In some instances wastewater will not be enough and alternatives such as saline aquifers and ocean water will need to be considered.

Because of these limitations, large scale algae cultivation will be only a niche application in the near future, being used successfully only where there is the appropriate intersection of land, water, solar radiation, and CO_2. This is will be the case unless either algae biofuels production proves itself very profitable at economies of scale or the government makes a concerted effort to utilize algae to limit oil imports. If either of these occurs then the infrastructure investment which is necessary might be paid for by petroleum companies, a US government agency, or some combination.

Conclusion

In summation the biofuels from algae cultivation shows incredible potential and advantages over other feedstocks currently used for fuel production, though the

technology has not yet been proven economical. If, however, production hurdles can be overcome, co-products and processes can be incorporated, and fossil fuels prices and security continue to be uncertain; then economic viability could be reached. Several technological advances and policy changes are indicators of this; such as cellulosic ethanol, biopolymer usage, and legislative policies toward greenhouse gas abatement. If massive scale cultivation becomes economical anywhere, it is likely to first occur at wastewater treatment plants due to the advantageous coupling of the two processes. However algae cultivation on the scale which would have an impact on our current imports of fuels is unlikely and would require either a very profitable situation or large government investment. This is due to infrastructure investment which would be necessary to supply the resources to the available land. Most opinions bring up a very vague figure of at least 10 years before algae could be driving our cars because no one really knows. Algae biodiesel could find niche applications where it is viable before this, but it is likely that long term production will fall short of optimistic hyperbole.

ABSTRACT

Under a Cooperative Research and Development Agreement (CRADA) established between the U.S. Environmental Protection Agency (EPA) and Harmsco, Inc., a prototype Community Water Security Filtration System for drinking water treatment using composite cartridges is being developed and tested at the EPA's Test & Evaluation (T&E) Facility in Cincinnati, Ohio. The filtration system incorporates a composite cartridge that combines physical pre-filtration with carbon adsorption and a cyst-rated final filter for removal of turbidity, specific chemical compounds, and some biological oocysts. The composite cartridge is then followed by ultraviolet (UV) light to provide short wave UV disinfection. The housing is constructed with a tangential inlet that induces a centrifugal motion to the water which aids filtratiom. The research has focused on optimizing the filtration media and housing configuration by testing the system using various biological surrogates and chemical compounds as contaminants. The current system configuration consists of a housing with two chambers; the upper chamber contains 8 (eight) composite cartridges for filtration, while the lower chamber contains six UV lamps for disinfection. Electrodes have been installed between the internal cartridge basket and the housing wall to provide an experimental electroseparation process to enhance particulate and pathogen removal and to determine if there is any pathogen cell disruption. Results of developmental tests conducted on single cartridges to optimize the composite cartridge media configuration show complete removal of Polystyrene Latex (PSL) beads (used as a non-biological surrogate for *Cryptosporidium)* which satisfies the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR) requirement of >3.0 log reduction of *Cryptosporidium*. Results of tests conducted on the 8-chamber full-scale unit show almost complete removal of MS2 bacteriophage as a surrogate for enteric virus satisfying the LT2ESWTR requirement of a 4-log reduction for viruses.

INTRODUCTION

The Water Supply and Water Resources Division (WSWRD) of the U.S. Environmental Protection Agency's (EPA's) National Risk Management Research Laboratory (NRMRL) has been conducting research on small drinking water systems since 1997 in response to the 1996 reauthorization of the Safe Drinking Water Act (SDWA) that established standards for drinking water systems and required EPA to assess treatment technologies relevant to small systems serving fewer than 10,000 people. The events of September 11, 2001, have further emphasized the need to develop water security appliances to remove physical, biological and chemical contaminants, resulting from deliberate or accidental contamination of the drinking water supply. Harmsco Filtration Products (Harmsco), based in North Palm Beach, FL, has developed a system combining physical filtration, adsorption and UV disinfection. Under a Cooperative Research and Development Agreement (CRADA) established between EPA and Harmsco, EPA guided and evaluated a multi-layer prototype cartridge at 15 gpm for whole-house water treatment at the EPA Test & Evaluation (T&E) Facility in Cincinnati, Ohio. The evaluation was conducted by Shaw Environmental, Inc. under a contract with EPA-NRMRL. The system showed effective performance in removing turbidity, *Cryptosporidium* size particles (2 - 5 µm), *E.coli*, 3.0 µm PSL beads (a non-biological surrogate of *Cryptosporidium*). The system also exhibited adequate removal of *B. subtilis* spores, but did not perform adequately in removing male-specific 2 (MS2) bacteriophage (a surrogate for enteric virus) (Muhammad, *et al*., 2008). The system showed effective performance in removing chlorine, diazinon and trihalomethanes (THMs) and adequate performance in removing methyl-tert-butyl-ether (MTBE) and haloacetic acids (HAAs) (Muhammad, *et al*., 2008). Based on the performance of the whole-house water treatment system, a larger system with multiple cartridges has been developed to provide filtration at a rate of about 100 gpm, suitable to meet the needs of a small community. The cartridges being developed for the larger system incorporate a different media to provide enhanced filtration. The system also included a UV system with higher wattage and electrodes to experiment with an electroseparation stage to potentially improve the microbial removal capability of the system. The results of tests conducted to date on the community filtration unit are summarized in this article.

SYSTEM DESCRIPTION

Figure 1 shows a cutaway cross-sectional diagram of a whole-house multi-layer single cartridge and the direction of water flow in the cartridge. The composite cartridge filter media is constructed in three layers surrounding a hollow core. The outer filter media is an anti-microbial, pleated, pre-filter designed for the removal of particles and sediment. The second filter layer consists of an extruded activated carbon core to adsorb chemicals (including disinfection by-products) and to improve

taste. The final filtration stage is a submicron, pleated filter media which is also anti-microbial. Figure 2 shows the community system housing and setup at the T&E Facility. The filter system housing consists of an upper chamber that houses eight composite cartridges and a lower chamber that functions as a UV sterilization chamber. The hollow core in each composite filter fits over a downspout that connects the cartridge filter housing to the lower UV chamber. The cartridge filter uses two O-rings to establish a seal between each cartridge and the associated downspout to prevent bypassing of the cartridge. Electrodes have been installed between the internal cartridge basket and the housing wall to provide an experimental electroseparation stage to enhance particulate and pathogen removal.

Water enters the upper chamber tangentially and flows rotationally between the electrode and the outer filter housing, rising upward and then through the composite cartridge filters. The housing is constructed with a tangential inlet that induces a centrifugal motion which aids filtration. Once the influent water has passed through all the filtration stages of the composite cartridge filters, it enters the complex UV reactor through each downspout. After UV treatment, the finished water exits the system housing. Figure 3 shows a cut-away view of the configuration of cartridges in the community filter system, while Figure 4 shows the star-shaped arrangement of the UV lights in the disinfection chamber of the Small Community Unit.

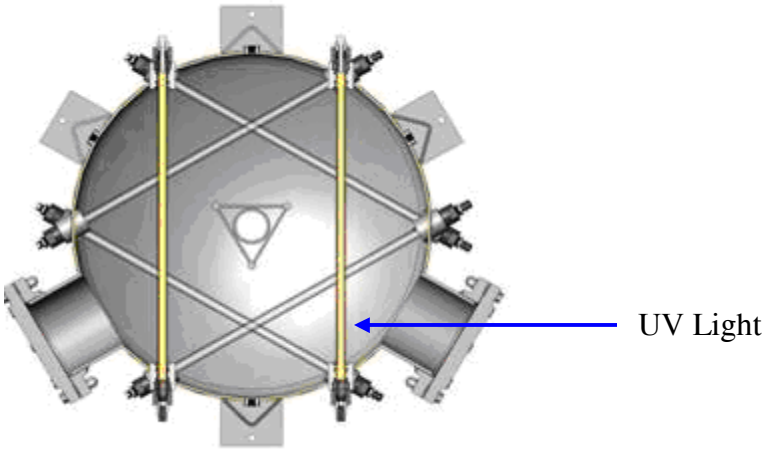

Figure 4. Cut-away View of Complex UV Chamber of the Small Community Filter

EXPERIMENTAL/ANALYTICAL METHODS AND MATERIALS

Evaluation and development of the small community filter system have to date included tests conducted to establish the construction configuration of the cartridges (i.e., the specific media type to be used in the various layers) and the efficacy of the complex UV disinfection using the unique, star-shaped configuration of the UV lamps in the lower disinfection chamber. A test stand was prepared and installed at the cartridge manufacturing location in West Palm Beach, FL to allow for rapid evaluation of various cartridge configurations in order to establish the media with the greatest likelihood of success when scaled up for use in the larger community filter. These experimental challenges were conducted using 3 µm PSL beads.

Concurrently, tests were conducted at the T&E Facility using MS2 bacteriophage to establish the degree of disinfection achieved by the UV lights in the system. The results of these tests could then be compared to collimated beam studies conducted on the same batch of MS2 bacteriophage to enable calculation of an effective UV dosage in the system.

Bench Scale PSL Bead Tests at Manufacturing Location

PSL beads in the size range of *Cryptosporidium* (3.0 µm) have been described by several researchers (Emelko & Huck, 2004; Li *et al*., 1997) as a suitable non-biological surrogate. To establish the cartridge construction configuration, seven small cartridges were manufactured using different proprietary media configurations and challenged with 3.0 µm PSL beads. Figures 5 and 6 shows the seven cartridges and the small cartridge housing used in these developmental tests. Each cartridge was tested individually, and, for each test, a stock solution of PSL beads was prepared using 0.01% Tween-20 that was added to a 14-gallon supply water tank to achieve a

final concentration of ≈ 10^5 PSL beads/100 mL. The water from the supply tank containing the beads was pumped through the cartridges at 6 gallons per minute (gpm) and influent and effluent samples (250 mL) were collected 2 minutes after the start of the test. At the conclusion of each test, the cartridge being tested was removed and the test stand was flushed for several minutes with another cartridge in place to remove any residual PSL beads from the system. A new test cartridge was then placed in the system and the system was operated for approximately 15 minutes prior to placing the PSL beads stock solution in the 14-gallon supply tank to initiate the test on that cartridge.

The PSL beads samples shipped to the T&E Facility and were analyzed following U.S. EPA Method 1622 (U.S. EPA 2001a). Log removal values were calculated comparing the influent and effluent bead concentrations.

Figure 6. Small Housing Used for Establishing Media Configuration

MS2 Bacteriophage Challenges

MS2 bacteriophage, described as a surrogate for pathogenic enteric viruses (Harrington *et al*., 2003), was used in this study to challenge the system to evaluate the performance of the system in removing viruses. The challenge tests were conducted on the community filter at two flow rates – 50 gpm and 100 gpm – using dechlorinated potable water. MS2 bacteriophage stock with cell concentration of ≈ 10^9 /mL was procured from BioVir Laboratory (Benecia, CA). The MS2 bacteriophage stock was mixed with 500 mL of 0.01% Tween-20 in a glass beaker to provide a stock solution which, when injected into the feed water stream to the community water filter system, would yield a target influent cell concentration of ≈ 10^5 /100 mL. The 500-mL MS2 suspension was injected into the influent stream of the filtration unit using a peristaltic pump. At the completion of injection, an additional 500 mL of 0.01% Tween-20 was injected into the feed stream to rinse out any residual MS2 in the beaker and feed tubing. The total injection time for the suspension and the rinseate was approximately 60 minutes. Grab samples (100 mL) from the influent and effluent stream were collected at 0 (T0), 5 (T5), 10 (T10), 20 (T20), 30 (T30) and 60 (T60) minutes after the start of the injection. The MS2 bacteriophage samples were analyzed using U.S. EPA Method 1602 (U.S. EPA, 2001b). Log removal values were calculated comparing the influent and effluent MS2 bacteriophage concentrations.

RESULTS AND DISCUSSIONS

Bench Scale PSL Bead Tests Results

Table 1 shows the results of the PSL bead tests conducted with the test stand at the Harmsco manufacturing location to establish the media configuration. The results show complete removal of PSL beads by all seven cartridges, and, the calculated log removal value (based on the influent concentration) ranged from 4.0 and 4.9. This removal performance satisfies the LT2ESWTR requirement of >3.0 log reduction for *Cryptosporidium* (U.S. EPA, 2006). Since all seven cartridges demonstrated complete removal of PSL beads in these preliminary tests, focus on the construction of the cartridges can be placed on the cost and ease of manufacturing.

Table 1. Results of PSL Bead Tests Conducted on the Test Stand for Establishing Media Configuration

Test ID	PSL bead Conc/250 mL		Log Removal	Avg. Log Removal

Tables 2 shows the results of MS2 bacteriophage challenges conducted on the community filter at 50 gpm and 100 gpm. The community filter achieved almost complete removal of MS2 bacteriophage at both flow rates, with an average log removal of 4.15. The performance of the community filter satisfied the LT2ESWTR requirement of 4.0 log removal of virus (U.S. EPA, 2006).

Table 2. Results of MS2 Bacteriophage Challenges Conducted on the Community Filter System

Figure 7 shows the UV dose response graph of the MS2 bacteriophage stock obtained from the results of collimated beam test conducted by BioVir Laboratory. The UV intensity, corresponding to 4.14 log reduction by the community filter, is 90 mJ/cm^2. The UV dosage is independent of flow rate and, therefore, independent of residence time in the system.

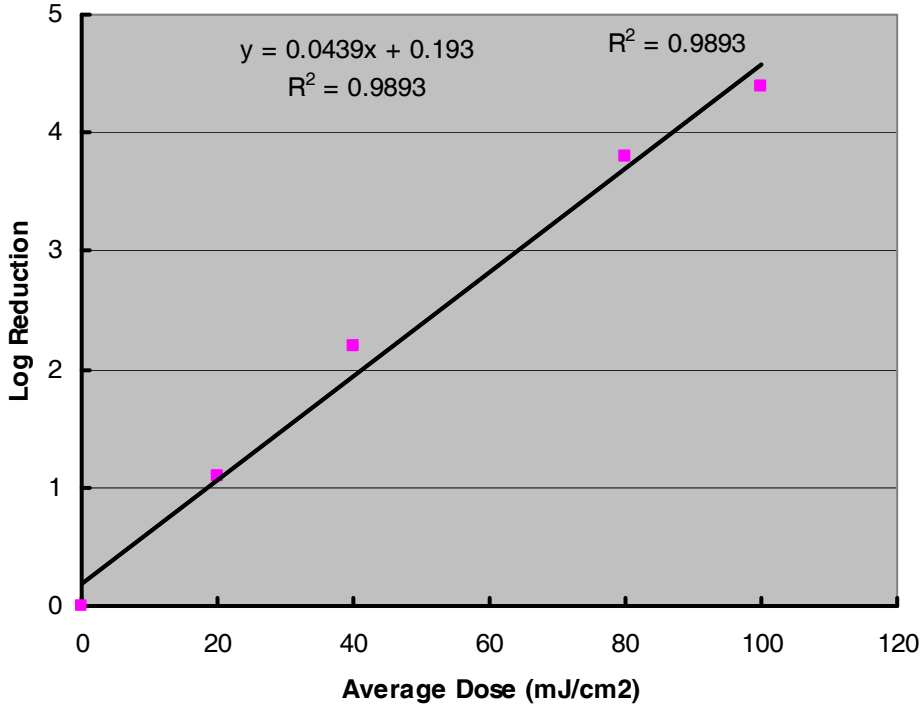

Figure 7. UV Dose Response Graph for MS2 Bacteriophage Stock

CONCLUSIONS

The test stand established at the manufacturer's location to perform preliminary tests provides a rapid and cost-effective methodology to establish cartridge configurations that can be selected for scale-up to the larger community filter system. On the basis of these tests, all the cartridges have shown equal removal performance for PSL beads indicating that other factors, such as ease of manufacturing, cost of materials, and pressure-drop development tests, should be used as the criteria for final cartridge selection. These efforts are currently ongoing and the final cartridge configuration will be tested in the near future on the community filter system to evaluate the removal of chemicals, such as mercury, tetracycline, triclosan and estradiol in addition to turbidity and cysts removal.

The UV intensity of the unit, based on the inactivation of MS2 bacteriophage, is 90 mJ/cm^2 which has been shown to be independent of residence time in this system. Additional MS2 tests are planned to evaluate whether the experimental

electroseparation provisions in the unit would enhance the system performance for removal of turbidity and MS bacteriophage.

ABSTRACT

EPA's Office of Research and Development is funding pilot-scale studies on MTBE contaminated groundwater using UV/ozone treatment technology (254 nm UV, 5.8 mg/L ozone). The pilot-scale treatment system consists of a GW well pump, a feed tank, a pretreatment system (water softener with iron reduction), a low-pressure UV/ozone treatment system, and GAC post treatment. Treatability studies have been conducted by graduate students at New Mexico State University to determine the effectiveness of UV/ozone treatment on well water contaminated by underground plumes of MTBE and other volatile organic compounds.

NMSU found UV/ozone treatment to be highly effective for removing MTBE and MTBE byproducts in groundwater. The MTBE concentrations after treatment were significantly lower (0.4-7.7 µg/L) as compared to the initial influent concentrations (127-251 µg/L). However, acetone was formed during oxidation of MTBE. Future field studies are planned to investigate the impact of enhanced ozone/medium-pressure UV on MTBE and MTBE byproduct removal and alternative technologies for acetone removal.

DISCLAIMER

The U.S. Environmental Protection Agency, through its Office of Research and Development, funded and managed, or partially funded and collaborated in, the research described herein. It has been subjected to the Agency's peer and administrative review and has been approved for external publication. Any opinions expressed in this paper are those of the author (s) and do not necessarily reflect the views of the Agency, therefore, no official endorsement should be inferred. Any mention of trade names or commercial products does not constitute endorsement or recommendation for use.

BACKGROUND

MTBE was first used in the United States in the late 1970s to enhance octane levels when the use of lead in gasoline was discontinued. MTBE helps gasoline burn more cleanly and reduces emissions of carbon monoxide and organic compounds into the air. Because it mixes readily with gasoline, has low production costs, and a high octane rating, MTBE became the oxygenate of choice for most gasoline producers facing State and Federal mandates (Clean Air Act 1990) to produce less-polluting gasoline (1).

The widespread use of MTBE in gasoline led to the contamination of both surface and ground waters in the U.S.. MTBE contamination is found in soils and groundwater wells near leaking underground storage tanks (UST), and in reservoirs used for public water supplies. MTBE is soluble in water and makes its way into drinking water wells more quickly than other chemicals in gasoline like Benzene, Toluene, Ethylbenzene, and Xylene (BTEX). MTBE is 30 times more soluble than benzene in water (2).

MTBE is classified as a possible human carcinogen and has a pungent taste and smell. MTBE is on the U.S. EPA's Contaminant Candidate List (CCL) of contaminants to be regulated (3). The EPA has issued a drinking water advisory of 20 to 40 µg/L (4), however, some States have established State levels that are lower. For instance, Texas established 15 µg/L MTBE as a target level used for cleanup after a fuel spill occurred in Lake Tawakoni (March 2000), a drinking water supply for North Texas (5). MTBE is currently listed on the CCL as a contaminant in need of both occurrence and research priorities (including health research, treatment research, and analytical methods research).

Occurrence of MTBE in Drinking Water Supplies

According to a 2001 United States Geological Survey (USGS) study (6), of 954 community water systems (CWS) sampled in the U.S., 0.5% of the systems contained MTBE levels at $\geq$5 µg/L. If we extrapolate this percentage to the 160,000 public water systems (PWS) in the United States, then roughly 800 PWS are likely to have MTBE contamination at levels $\geq$5 µg/L. The number of affected water systems may increase with time, as plumes from leaking gasoline-underground storage tanks begin to reach more groundwater systems (7). Private wells are also affected, although they are not currently regulated under the Safe Drinking Water Act.

Another nationwide USGS study (8) conducted in 1995 found concentrations of MTBE in urban and agricultural wells to be in the range of 0.2 to 23,000 µg/L. In Dallas/Fort Worth, Texas, 5 of 17 wells tested positive for MTBE and in Albuquerque, New Mexico 1 of 24 wells tested positive. The USGS study also looked at the frequency of

occurrence of MTBE in groundwater wells and found that MTBE was the second most commonly detected volatile organic compound (VOC) after chloroform. Of the wells tested, 28% had chloroform contamination followed by 27% with MTBE contamination. Additional VOCs found were tetrachloroethene 18%; trichloroethene 10%; cis-1,2 dichloroethene 7%; 1,1-dichloroethane 5%; and benzene 5%. These harmful VOCs can also be removed by advanced oxidation process (AOP) technologies.

Treatment Technologies and Cost

According to two new studies by the American Water Works Association and the Association of Metropolitan Water Agencies (9), the estimated cost to remove MTBE from public drinking water systems is in the range of $25-$85 billion. The California MTBE Partnership of 2000 determined that it would cost between $1 to $11 million dollars per well. These clean-up costs (capital and operation and maintenance costs), were determined using GAC adsorption over 30 years with influent MTBE levels of 200 µg/L and non-detect effluent levels.

Small water systems typically choose granular activated carbon (GAC) because it is the more affordable treatment technology. It makes sense for a small water system to purchase a small drum of GAC and pay for replenishing and processing of the carbon. For large groundwater systems, air stripping, granular activated carbon (GAC), and resin adsorbents are all capable of removing MTBE from the water supply (10).

It would not be cost effective for a small system producing only 10,000 gallons of water per day to purchase an air stripper intended to produce a million gallons of water per day. At MTBE concentrations of greater than 300 µg/L, air stripping becomes more economically feasible than alternative treatment technologies. However, much more air is required to oxidize MTBE at low concentrations in water and off-gas treatment adds significantly to the cost (2).

A low cost alternative for MTBE treatment in small systems utilizes an AOP technology that combines ultraviolet radiation (UV) with ozonation for oxidation of MTBE and MTBE byproducts from water as listed in Table 1.

MTBE Byproducts	Abbreviation	Formula
Methyl-tert butyl ether	MTBE	$CH_3OC(CH_3)_3$
t-butyl formate	TBF	$C_5H_{10}O_2$
t-butyl alcohol	TBA	$(CH_3)_3COH$
Isopropyl alcohol	IPA	$(CH_3)_2CHOH$
Acetone	Ac	$(CH_3)_2CO$
Methyl acetate	Mac	CH_3COOCH_3
Carbon Dioxide	CO_2	CO_2

Table 1. MTBE and MTBE byproducts

Benefits of UV/ozone treatment include low operating cost and destruction of MTBE and MTBE byproducts reducing residual handling costs. Both the UV light and ozone generation require minimal use of electricity for small drinking water systems.

INTRODUCTION

The EPA Water Quality Management Branch in Cincinnati, Ohio began evaluating pilot-scale studies by testing and evaluating MTBE and MTBE byproduct destruction using three oxidant combinations: hydrogen peroxide/ozone, ultraviolet irradiation (UV)/ozone, and UV/ozone/hydrogen peroxide. Pilot-scale studies conducted on dechlorinated Cincinnati tap water spiked with 300 µg/L MTBE showed that UV/ozone treatment removed 98% of the MTBE from tap water (at 254 nm UV, 5.8 mg/L dissolved ozone). The studies were setup to simulate real-world conditions at small groundwater systems (3 gallons/minute flow at 20 degrees C).

FIELD STUDIES

EPA, Shaw E&I, Inc., New Mexico State University (NMSU) and Souder and Miller Associates conducted MTBE treatability studies on contaminated groundwater combining low-pressure UV and ozonation technologies. A research trailer was customized with a well pump, a 110-gallon feed tank, a pretreatment system (water softener with iron reduction), and a UV/ozone treatment system as shown in Figure 1.

Figure 1. EPA research trailer with UV/ozone pilot unit and water softener

NMSU and Souder and Miller Associates approached the local community and owners of wells in Roswell, NM to request groundwater for these research studies. NMSU received approval to remove MTBE contaminated groundwater from the owners of Brewer Station 1 in Roswell as shown in Figure 2. After filling fourteen 5-gallon water containers, the groundwater was transported to NMSU in Las Cruces, NM to conduct the research studies. The groundwater containers had high levels of MTBE (ranging from 15 to 40 mg/L) that were diluted to less than 300 µg/L MTBE with uncontaminated groundwater for the treatability studies.

Figure 2. Removing groundwater for MTBE treatability studies

The UV/ozone pilot unit shown in Figure 3 was operated continuously to process ten 110-gallon batches of MTBE-contaminated groundwater. Flow rates of 1, 2, and 3 gallons per minute with corresponding contact times of 3, 1.5, and 1 minute were tested at recycle ratios of between 2.9 and 8.5 in the UV/ozone pilot unit. Samples were taken at time 0, 30, 60, 90 and 120 minutes. Daily operation and maintenance requirements were recorded and influent/effluent samples were analyzed as defined in the Quality Assurance Project Plan. The UV/ozone system cost, reliability, and ease of operation were documented during the treatability study (11). Treatability study average removal efficiency results are summarized in Table 2.

Figure 3. UV/ozone pilot-unit and GAC Drum

	MTBE	TBA	TBF	Ac	IPA	MAc
Influent	182	129	ND	3	7	ND
Effluent	2.3	25.4	0.2	85.9	1.7	0.9
% Efficiency	99	80	-	-	76	-

Table 2. Average removal efficiency of MTBE and MTBE byproducts

CONCLUSIONS

From the research conducted on low pressure UV light in combination with ozone, EPA and NMSU found that optimum treatment efficiencies were about 99% for MTBE and 80% for TBA with contact times between 1 and 3 minutes. The main organic oxidation byproduct was acetone increasing from 3 to 86 µg/L.

Because UV/ozone treatment destroys MTBE through oxidation, it does not require hazardous transport for processing. There is no need for chemical additives and processing of adsorbed contaminants when compared to GAC. Another consideration when selecting a drinking water treatment technology for MTBE is the disinfection capability of UV/ozone treatment to destroy organics and microbial pathogens simultaneously. Proper engineering controls for ozone emissions and UV radiation are necessary during operation of UV/ozone treatment systems to ensure worker health and safety.

PROJECT IMPACTS

VOC contamination of ground and surface waters is an on-going concern for environmental regulators. The project demonstrated the effectiveness of UV/ozone treatment for small groundwater systems. The project verified that AOP technologies, such as UV/ozone, are simple, affordable, readily available treatment alternatives for small groundwater systems affected by MTBE contamination.

Effective treatment technologies for VOCs in groundwater benefit the State primacy agencies and the Public. For instance, New Mexico drinking water supply is comprised of 95% groundwater systems that serve 85% of the population (1.8 million people). Texas drinking water supply is comprised of 80% groundwater systems that serve 6.4 million people daily (11). In both States, a majority of the groundwater wells are small drinking water systems that need affordable treatment technologies. Alternative treatment processes are vital for arid States such as New Mexico, which have on-going drought issues and desperately need clean water sources.

EPA, Shaw E&I, Inc, and NMSU plan to conduct additional studies to improve MTBE and MTBE byproduct oxidation with enhanced ozone/medium pressure UV lamps. Future studies will also address the formation and removal of acetone in water.

ACKNOWLEDGEMENTS

Field sample collection was carried out by Mr. David Ennis with Souder Miller, Inc under supervision of Mr. Craig Shapard with the New Mexico Environment Department. Experimental design, implementation and field analyses were coordinated by Ms. Maritza Macias-Corral, a graduate student in the Civil Engineering Department at NMSU. Dr. Bill Boyle with the Soil, Water and Air Testing Laboratory at NMSU performed the analytical work (11).

ABSTRACT

A pilot-scale evaluation to assess the application of direct current to a rapid sand filter (termed "electrofiltration") verified the theoretical effectiveness of electrofiltration in enhancing the performance of conventional filtration within a water treatment facility. The efforts which are described in this paper were based on prior bench-scale assessments of the electrofiltration process. The analysis, combined with the theory used to describe the phenomenon, was used to design and construct the pilot filter using sand from existing filters in the filtration plant. The filter was tested using effluent from a presedimentation basin, at influent turbidities typically around 30 nephlometric turbidity units (NTU). Initial tests verify that electrofiltration can improve the performance of a filter in terms of both particle removal and turbidity reduction. Results from the preliminary analyses and future plans are presented.

Introduction

Effective removal of waterborne particles is an essential issue in the drinking water treatment process. The particle removal mechanisms can be classified as gravity separation (sedimentation or flotation) and filtration. In order to enhance the removal efficiency, chemical additives, such as iron or aluminum salts and polymers, are widely utilized to eliminate the negative charges carried by particles in nature. After charge neutralization, these particles are ready to attach to each other or to other surfaces to form larger settleable particles, called flocs, which are easier to settle or be removed in the following filtration process (AWWA, 1997).

Chemical additives are essential to enhancing particle removal efficiency, but they result in solids residuals which must be disposed. The expense associated with residuals transport and ultimate disposal can be significant. One of the potential alternative methods to achieve filtration without the addition of chemicals is electrofiltration, where an external electric field inside of the filtration layer is applied to enhance the particle removal. The application of electric field on particle removal is widely applied in air-particle systems, such as electrostatic precipitators. However, in the liquid-particle system, it has received much less attention.

The electrofiltration process is presented schematically in Figure 1. In the electrofiltration process, charge neutralization is not necessary to enhance the particle removal efficiency; thus, the dose of chemical additives can be minimized, resulting in less sludge generation.

Electrofiltration can potentially benefit drinking water treatment plants either through direct filtration, where the need for coagulants could be minimized, or in conventional treatment to reduce coagulation needs and residuals formation.

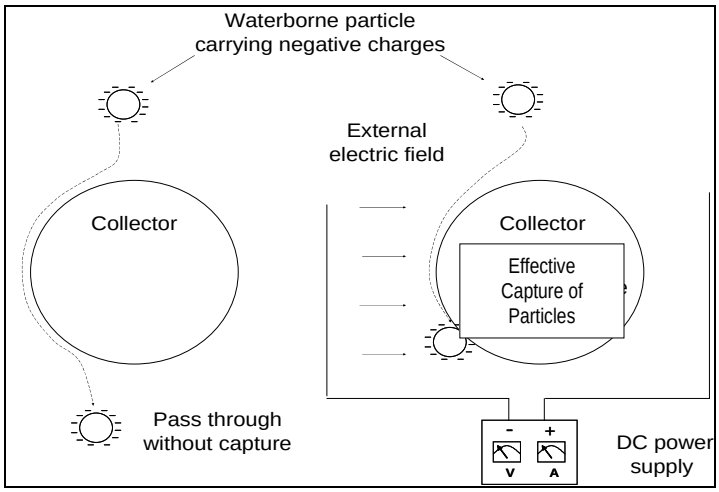

Figure 1. Schematic diagram of the particle motion with and without external electric field.

Electrofiltration has been utilized in the process of cake filtration, sludge dewatering and removal of particles in low ionic strength aqueous suspension (Lockhart, 1983, Ptasinski and Kerkhof, 1992, Zhang et al., 2000). Theoretical analysis regarding the beneficial effect of electrofiltration has been reported in the literature (Judd and Solt, 1989, Kulkarni et al., 2005). Bench-scale experiments conducted at Washington University (Kulkarni et al., 2005) using an external DC electric field applied on a cylindrical filter column resulted in significant improvement in the removal of test particles (kaoline and polystyrene latex beads) and the *Cryptosporidium* oocysts in three different types of media.

The results of the bench-scale analyses, while encouraging, were difficult to extrapolate to full-scale implementation. Thus, our team launched an effort to evaluate the efficacy of electrofiltration on a pilot-scale at a local water treatment plant. These experiments were conducted at the City of St. Louis Howard Bend Water Treatment Plant, in St. Louis, Missouri. The filtration media in the pilot filters was identical to that used by the full-scale facility. In addition, water applied to the filter was obtained from either the settled water basins, or the presedimentation basin, as described below.

Evolution of Experimental Setup

The initial efforts at scale-up followed the approach by Kulkarni et al. (2005). A cylindrical filter with a diameter of one foot was used in the tests. A single electrode was positioned in the center of the filter and the cathode was a solid sheet of stainless steel positioned around the inside wall of the filter. The distance between the anode and cathode was approximately six inches.

Initial pilot evaluations were conducted on-site using water from the full-scale plant's filter influent, (i.e. coagulated and settled but prior to filtration). Typically, this water had turbidity measurements less than 2 NTU. The pilot filter initial results showed that electrofiltration had little impact on the either the particle size removal or turbidity removal. In fact, initial results suggested that electrofiltration had a negative impact on filtered water quality, as shown on Table 1.

The research team assessed this performance and determined that two potential problems with the experimental setup contributed to the poor performance. First, it was determined that because the water applied to the electrofilter had already been coagulated using chemical additives, charged particles within the water had already been neutralized. Second, a mathematical analysis of the spacing between the anode and cathode revealed that the gap between the electrodes was too large to have much impact on particles passing through the filter, and the applied voltage was unnecessarily high.

Table 1. Results from initial electrofilter assessment

Test	Applied Voltage, V	Influent Turbidity, NTU	Filtered Water Turbidity, NTU	
			Control Filter	Electrofilter
1	0	4.80	0.50	0.94
2	20	5.94	0.27	1.23
3	40	5.69	0.29	0.76
4	60	6.31	0.30	0.77

Experimental Setup and Methods

The experimental design was revised to address those problems identified in the initial experimental setup. The schematic diagram of the reconfigured pilot-scale unit is shown in Figure 2. Twelve stainless steel mesh electrodes (12 in. × 24 in.) are embedded in the sand filter with 1 inch spacing. The electrodes are alternatively connected to the positive and negative output of a power supply. A water tank located on the top of the frame was utilized as a reservoir to maintain a constant hydraulic head, approximately 3 feet of water, to the sand filter.

Influent to the pilot unit is recieved from the water plant's pre-sedimentation basin, where settled water turbidity is typically 15 to 30 NTU. The filtered water (filter effluent) passes through a flow meter, which monitors both the flow rate and the total flow, and is then discharged to drain. During the interval of the runs reported in this study, the sand filter is backwashed by tap water to remove the captured particles.

The experimental plan on Table 2 presents the test conditions for the five tests. Only limited results are presented in this paper, as experiments with the test apparatus are continuing at this time. The first three tests (Tests 1 through 3) aimed to prove the effectiveness of the revised experimental set-up on filtration performance. For each of these first three tests, the influent flow rate was held constant while the power was turned on and off so that the enhancement due to the electric field can be determined. The filter

was backwashed in between each power on and off cycle. The fourth test sought to assess the impact of filter loading rate on electrofilter performance. The fifth test explored the effect of electrode voltage while maintaining a constant influent flow rate, in order to determine the applied voltage with the best efficacy. For all the tests, both influent and effluent samples were collected and analyzed in terms of turbidity, zeta potential, and particle counts.

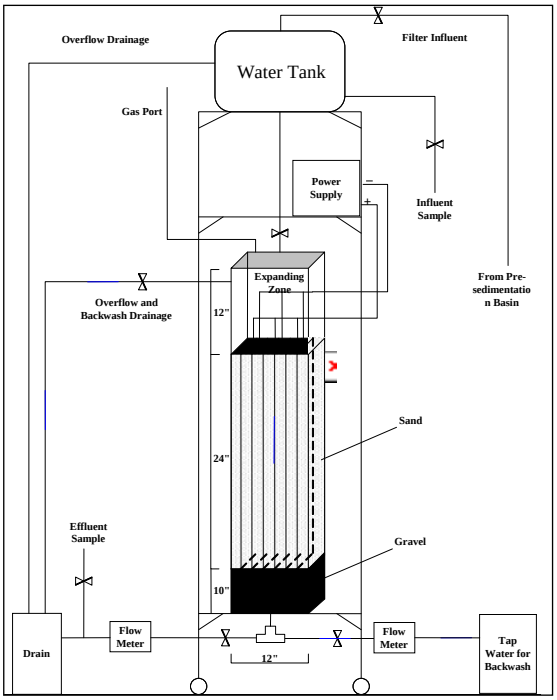

Figure 2. Schematic diagram of the pilot-scale electrofiltration setup

Table 2. Experimental plan

Test	Flow rate, Q (gal/min-ft^2)	Applied Voltage, U (V)	Description
1	0.6	$0 \leftrightarrow 8$	Power on and off alternatively
2	0.6	$0 \leftrightarrow 16$	Power on and off alternatively
3	1.2	$0 \leftrightarrow 24$	Power on and off alternatively
4	$0.6 \rightarrow 0.9 \rightarrow 1.2$	16	Consecutively increasing the flow rate
5	1.2	$0 \rightarrow 8 \rightarrow 12 \rightarrow 16$	Consecutively increasing the voltage

RESULTS AND DISCUSSION

Table 3 summarizes turbidity and zeta potential data for samples of river water and pre-sedimentation basin water. The turbidity of river water varied significantly from test to test, mainly due to weather changes. The treatment plant draws water from the Missouri River, which is notorious for rapid and large fluctuations in turbidity, along with other water quality parameters. Changes to the turbidity of the pre-sedimentation basin water,

and thus the water applied to the pilot filter, corresponds with fluctuations in river water quality; in general, the turbidity of the applied pilot filter water was about one order of magnitude lower than turbidity of the river water. On the other hand, the zeta potential did not vary much from test to test, and it only decreased slightly from the river water to the pre-sedimentation basin water. Since zeta potential is a critical parameter representing the surface change of waterborne particles, a higher value of zeta potential normally corresponds to a higher efficiency of electrofiltration.

Table 3. Summary of measured turbidity and zeta potential

Water Sample	Turbidity (NTU)				Zeta Potential (mV)		
	Test 1	Test 2	Test 3	Test 4	Test 1	Test 2	Test 4
River water	53	233	115	481	-16.5	-18.3	–
Pre-sedimentation basin water	12	32	12	37	-15.9	-17.1	-18.6

Proof-of-Concept Tests

The results of Tests 1 to 3 are shown in Table 4. The results clearly demonstrate that applying a voltage to the electrodes further reduced the turbidity and particle count of the effluent. The particle counts were reduced to approximately 59%, 62%, and 55% of the level without power, respectively. More importantly, most of the particle removal occurs with the smallest particles (2–4 μm). This is more clearly observed by comparing the particle size distributions of the effluent with or without power for a typical run, as shown in Figure 3. Thus, the results suggest that the electrofiltration process may be effective in targeting the removal of waterborne pathogens (e.g. *Cryptosporidium*) because most of pathogens are in the size range (2-4 μm) where electrofiltration works best.

Table 4. Electrofiltration results from proof-of-concept tests

Test	Water Sample	Turbidity (NTU)	Particle Count (#/ml)	2 - 4 μm (#/ml)	> 4 μm (#/ml)
Test 1	Influent	12.4	41638	34298	7340
	Effluent (0V)	0.66	2789	2385	404
	Effluent (8V)	0.47	1645	1348	297
Test 2	Influent	32.2	54968	37123	17845
	Effluent (0V)	8.25	2466	2002	464
	Effluent (16V)	5.05	1539	1253	286
Test 3	Influent	12	31787	22097	9690
	Effluent (0V)	0.97	2024	1438	586
	Effluent (24V)	0.95	1118	848	270

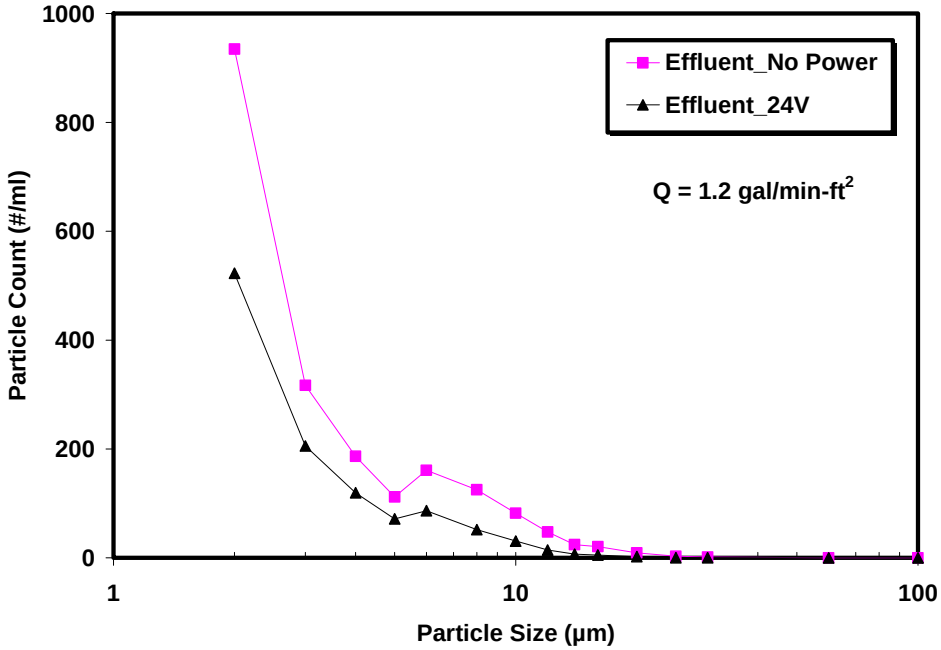

Figure 3. Comparison of particle size distributions of the effluent with or without an electric field for a typical run.

Effect of Filtration Flow Rate

One run was conducted to assess the impact of filter loading rate on electrofilter performance. During this run, no power was applied and the filter was operated at a steady-state filter loading rate of 1.2 gpm/ft^2. Filter power was set at 16 V until steady-state conditions were established, and then the filter loading rate was dropped from the initial rate to 0.9 gpm/ft^2, and finally to 0.6 gpm/ft^2. Further, the impact of applying power to the unit was demonstrated by turning off the power once steady-state is reached at the lowest applied power setting. The impact of flow rate on turbidity and particle removal is shown on Figure 4.

With data from only one run, a statistical comparison is not possible. Figure 4 shows that turbidity removal and particle removal improves as filter loading rate decreases during electrofiltraiton (applied voltage of 16 V). Further, both turbidity removal and particle removal decline once the power is turned off.

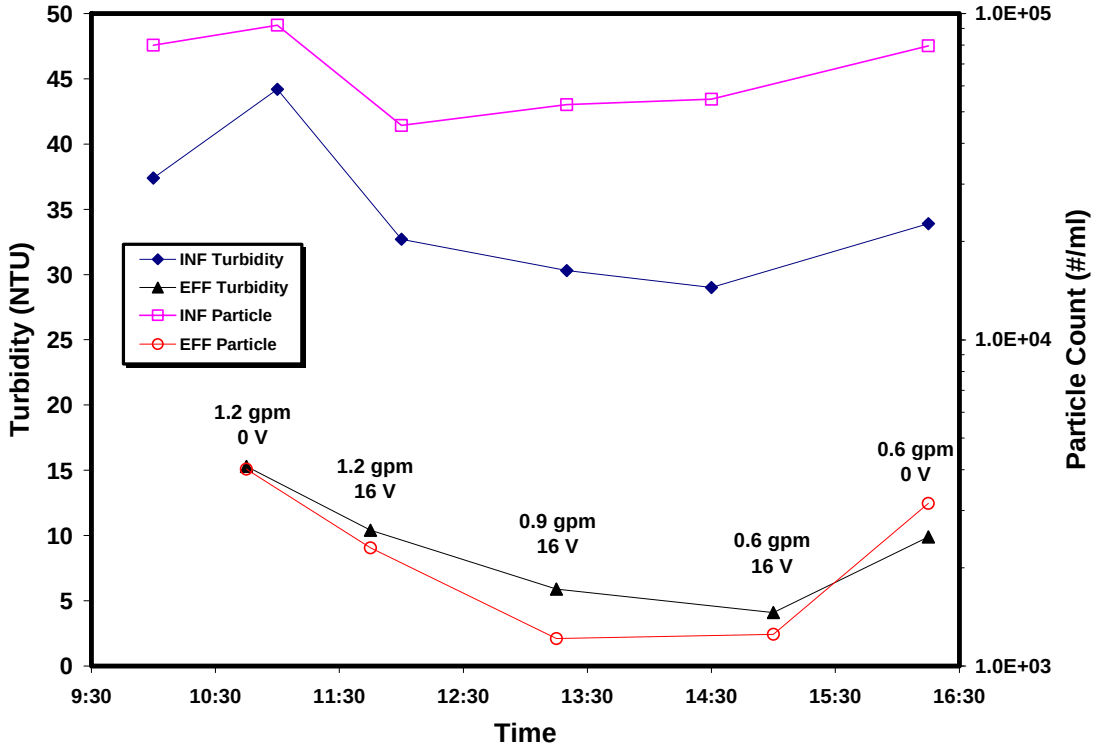

Figure 4. Effect of filter loading rate on electrofiltration

Effect of Electrode Voltage

Figure 5 shows the effect of electrode voltage on electrofiltration, while the filtration loading rate was maintained at 1.2 gpm/ ft^2. As shown in Figure 5, the power was off at the beginning and the end; during the test, the electrode voltage was increased from 8 V to 16 V in 4 V increments. Unfortunately, influent turbidity increased during the testing period; thus, it is not possible to make firm conclusions about filter performance. However, the effluent at 0 V at both the beginning and the end of the test had much higher values of turbidity and particle count than the corresponding values in the 8 to 16 V range. Thus, it is clear that the applied voltage enhanced the particle removal compared to the power off condition.

Estimate of Energy Consumption for Electrofiltration

The energy consumption of electrofiltration can be estimated from the voltage and amperage data recorded by the power supply. Table 5 lists the energy consumption at different applied voltages, based on a flow rate of 1.2 gal/min-ft^2. As the voltage increases, the energy consumption increases as a square function of voltage. The energy consumption at 16 V approaches the edge of economical consideration for practical applications. Based on the results on Figure 5, the particle removal efficiency at 16 V did

not improve significantly compared to 12 V. Hence, a range of 8 to 12 V may be the most cost-effective range for full-scale practice.

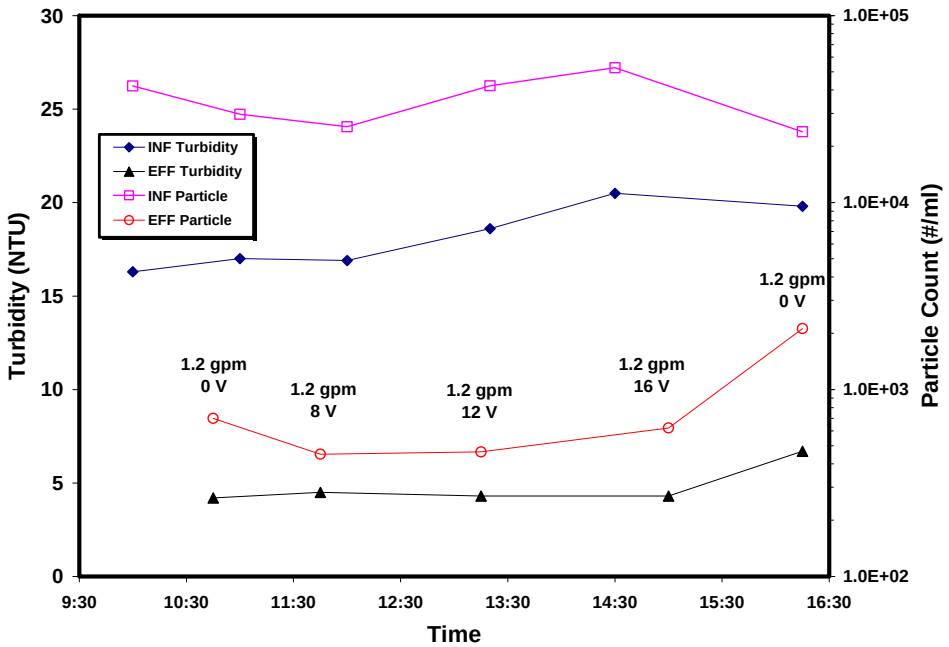

Figure 5. Effect of electrode voltage on electrofiltration.

Table 5. Estimated energy consumption for electrofiltration

Voltage (V)	Current (A)	Power (W)	Energy Consumption (kWh/Mgal)
8	3.4	27.2	378
12	6.2	74.4	1033
16	8.2	131.2	1822
24	14	336	4667

CONCLUSIONS AND FUTURE WORK

The current pilot-scale electrofiltration unit, equipped with vertical mesh electrodes embedded in a sand filter, has demonstrated its effectiveness in removal of waterborne particles. Both the turbidity and the particle count of the filter effluent were reduced when a voltage was applied across the electrodes, compared to the results with power off. When the electrofilter was operated at 8 V, the particle removal efficiency reached 97.2%, compared to 95.5% when the power was off. A separate theoretical analysis, along with prior work by others, has shown that conventional filtration processes often cannot reliably remove very small particles (< 4 μm). This study suggests that the electrofiltration technology can enhance the capture of such small particles. Future work

will focus on optimizing the applied voltage and filter loading rates. Based on the results described in this paper, an operating voltage range of approximately 8 V will be used in future work. Further, water from the presedimentation basin will be diluted in order to achieve an incoming water turbidity of approximately 5 NTU, while maintaining zeta potential at or below -10 mV.

ABSTRACT

Implementation of sophisticated SCADA systems in the water industry has given plant operators unprecedented capability to monitor and control all aspects of water production and distribution from a centralized control center. Sophisticated utilities recognize that SCADA need not be composed of one or more isolated "islands of automation" but can and should be a single system operating on a Wide Area Network, and integrated into their enterprise wide information technology system. The next logical step following implementation of a SCADA system is to leverage off this investment using state of the art software to allow predictive as opposed to reactive control of the water system. Resulting benefits can include improving water quality through reduced water age, minimizing energy costs and improved system operations without compromising operational reliability.

WaterOne, a quasi-municipal agency that provides water to more than 400,000 people, implemented an off-the-shelf software solution provided by Derceto Limited that achieved significant results in a very short amount of time. Using the software, WaterOne was able to save over $1 million in electrical costs in the first 18 months of operation, reduce greenhouse gas emissions by 4,800 tons/year, identify areas where further savings can be made, and streamline operation of its water treatment plant.

BACKGROUND

The control rooms of the 1950's through the 1970's were mainly filled with large panels full of gauges, chart recorders, alarm lights, and buttons driven directly from instruments and motor control centers. Commercial computers were large and expensive and even though some mini-computers such as PDP-11s were available their use was limited. Data from the gauges were recorder by chart recorders or sometimes by operators on paper. With the addition of Remote Terminal Units (RTUs) operating over radio links in the 1980's these systems enabled effective real time control of distributed systems from a single location. However, evaluating historical data was cumbersome and automating complex controls was difficult. Figure 1 shows a typical control room from this era.

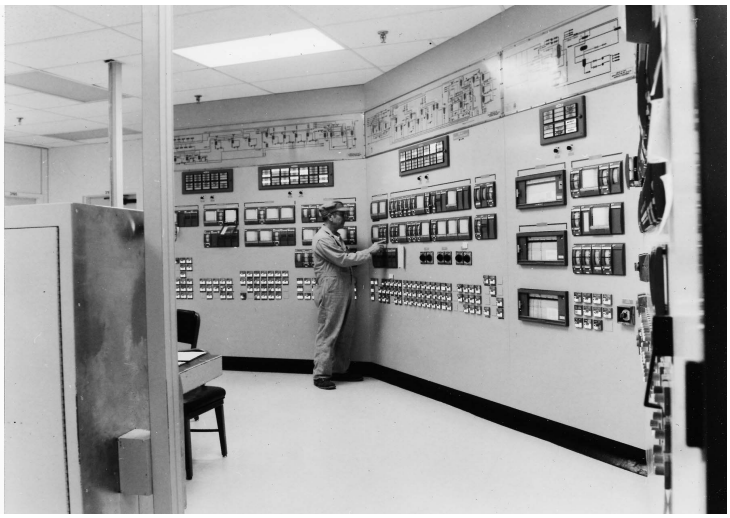

Figure 1. 1950's Control Room

With the introduction of Programmable Logic Controllers (PLCs) mixed automated and manual systems began to appear in the late 1970's. Efficiencies were gained in automation using computerized systems that piggy backed on the newly introduced Personal Computer (PC). The 1980's saw the advent of Supervisory Control and Data Acquisition (SCADA) systems. Automation of control and calculations as well as computerized storage of data brought efficiency to a much higher level. Large historical databases and smart instruments arrived in the 1990's, enabling integration with other business data to allow automated reporting of key performance and control indicators. This resulted in more timely and effective decision making and automation of complex control decisions. Figure 2 shows how large amounts of information flow from multiple plants to a common collection point where it is evaluated and boiled down by computer and delivered to decision makers in a timely and relevant manner.

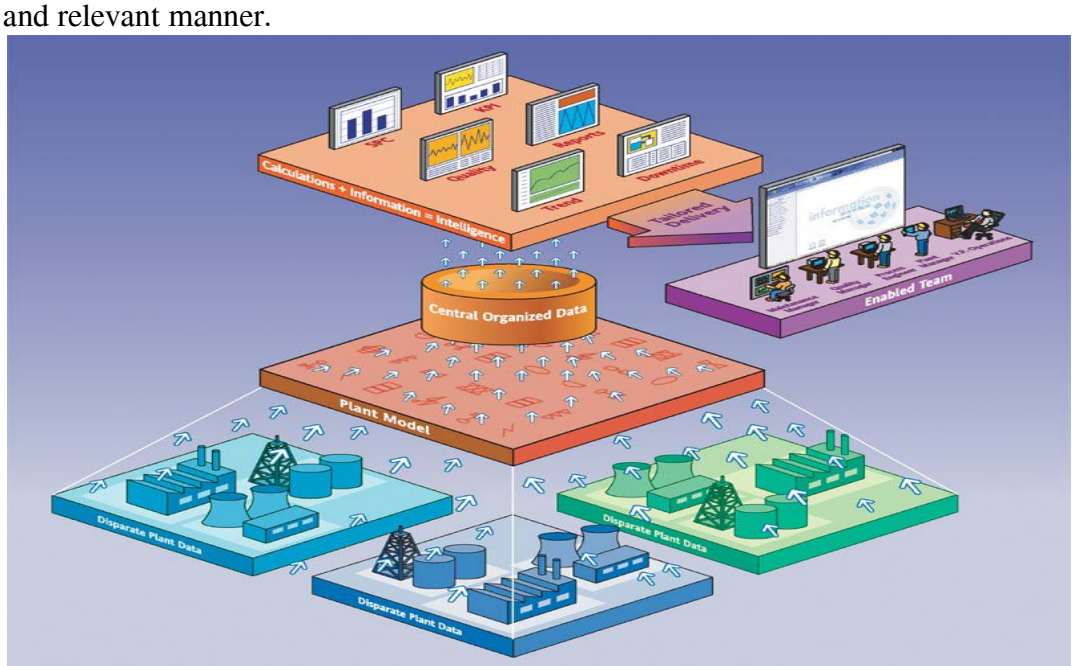

Figure 2. Information Flow

Figure 3 shows a typical modern control room. This control room is located at WaterOne. It was installed in 1991 and last upgraded in 2006. Derceto's Aquadapt software has takes the modern SCADA system one step farther by evaluating data gathered by the SCADA system, selecting the most cost efficient pumps to use in real time and then controlling pumps through the SCADA system. An understanding of WaterOne's system, energy use, and electricity supply tariffs is necessary to understand how Aquadapt software takes advantage of SCADA to achieve energy and cost savings.

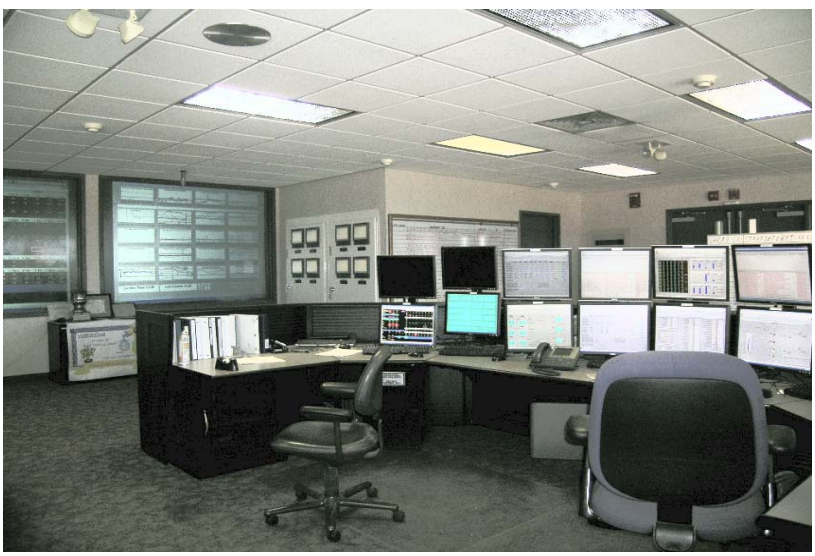

Figure 3. Modern Control Room

WaterOne is a quasi-municipal agency that provides water to more than 400,000 people. It serves residential and commercial accounts in 16 cities in the Johnson County area, has nearly 3,000 miles of transmission and distribution mains, covers a service area of more than 270 square miles, and a treatment capacity of 180 million gallons per day.

Over 84 pumps at 15 different pumping stations are used to deliver water from the rivers through the treatment process and distribution system to the service connections. There are two electric utilities with very different tariff structures serving these pump stations. With this many variables and constantly changing water system demand and other operational parameters, it's easy to see how difficult minimizing energy cost can be without using optimization software with SCADA.

Minimizing energy costs is a good strategic goal, as it is nationally one of the highest costs in producing the "next gallon of water." "The more than 60,000 water systems and 15,000 wastewater systems in the United States are among the country's largest energy consumers, using about 75 billion kWh/yr nationally – 3 percent of annual U.S. electricity consumption *(Palo Alto: 1999).*"

In 2005, WaterOne spent approximately 6.2 million dollars per year on electricity. Ninety-six percent of the electricity purchased is used to pump water. If even a modest 10% reduction was achieved, WaterOne could realize an annual savings $600,000 or more. This was the driver to investigate whether or not WaterOne's pump operations could be optimized with Aquadapt to achieve a reduction in energy costs. Current pump schedules, operational constraints, and electricity tariff structures were the key considerations in determining possible savings through optimization.

ENERGY TARIFFS

The tariffs have two main components, energy used in kilowatt-hours (kWh) and demand in kilowatt (kW). These are measured and priced separately. In the case of WaterOne the key controllable cost is the peak electricity demand occurring in any 30 minute period within a daily window of time set by the electricity supplier. Figure 4 illustrates a good car analogy for kWh and kW. The speed of the car is analogous to the instantaneous demand in kW and the odometer reading is analogous to accumulating use of electricity measured in kWh.

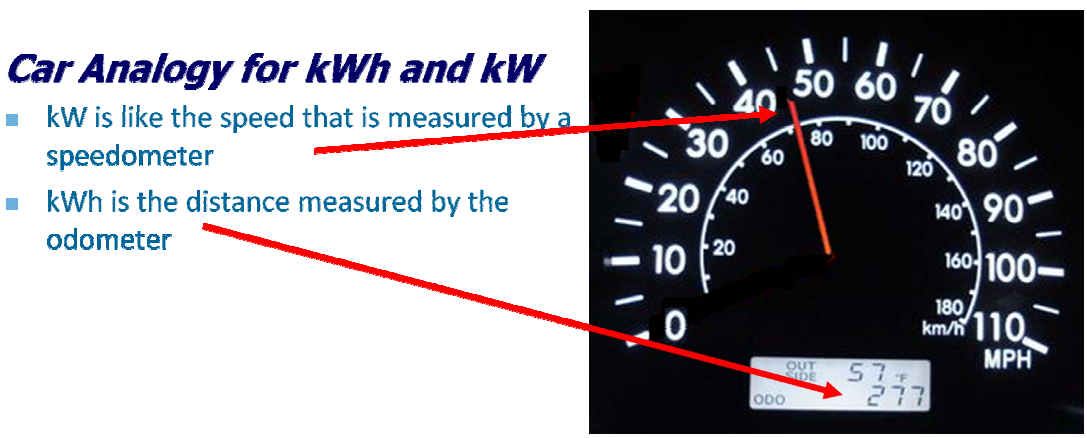

Figure 4. Car Analogy for Tariff Components

WaterOne's distribution system pump stations are primarily served by Kansas City Power & Light (KCP&L). Kansas City Power & Light has a flat kWH tariff and a flat demand charge (kW) that applies 24 hours a day 365 days a year. While this is easy to measure and bill it provides no incentive for load management. There are no options for time-of-use or real-time pricing. The last KCP&L tariff structure changes were made 10 years ago.

WaterOne's source water supply, treatment plant, and transmission pumping stations are served by the Board of Public Utilities (BPU) which also has a flat kWh tariff that applies 24 hours a day 365 days a year. The Board of Public Utilities demand charge however only applies 10 hours a day during weekdays. Demand charges are based on monthly peaks. Winter demand charges are billed as 70% of the highest summer peak, or the actual peak, whichever is greater. For WaterOne the summer peak is substantially more than winter peak and hence the 70% clause always applies and not

the actual monthly peak. This dominant summer peak means that essentially a 12 month ratchet clause applies to our single highest 15 minute period during summer.

There is therefore scope to make savings on the BPU tariff by controlling the summer peak load, although the smallest transgression for 30 minutes could eliminate an entire year's savings. It appears that the electricity market in Kansas is unlikely to change or deregulate any time soon.

DERCETO SOLUTION

Many attempts have been made to control a water utilities electrical load in response to water demand and electricity tariffs. While at first this might seem straight forward, solving the hydraulic equations with all the operational and electrical tariff variables is numerically impossible for all but the smallest systems. For example a water utility with only 11 pumps wanting an hourly schedule for a single day would have 2.96×10^{79} possible schedules to evaluate, which coincidentally is the same value currently accepted as the likely number of atoms in the universe. Given the numeric impossibility of solving this by brute force the following techniques have been attempted:

1. Localized optimization at each pump station using profiling or time triggers
2. Expert Systems using cascading rules
3. Advanced techniques using Genetic Algorithms
4. Multi-Objective Polynomial Systems (MOPS)
5. Dynamic Programming and Stochastic analysis

In order to solve the problem, these techniques still require a considerable amount of assumptions and relaxation of critical rules such as not overflowing or emptying storage tanks, both unacceptable to a modern water utility. The Derceto company felt the market was waiting for an off-the-shelf solution.

To meet this market demand, Derceto developed a "customized off-the-shelf" (COTS) software tool which works online and in real-time to reduce the costs of treated water distribution. Derceto's 'Aquadapt' software generates optimized pump and valve schedules on half hour boundaries for the next 24 to 48 hours with the goal to minimize distribution costs guided primarily by electricity tariffs. Direct connection to the SCADA system provides live data, which is then used by the Aquadapt system to enable it to choose the lowest cost scheduling solution for water production and distribution without breaching constraints These schedules are then automatically output directly to control pumps and valves, again via the SCADA system.

The optimization software calculates the minimum cost solution from the multitude of possible pump schedule combinations to meet the day's evolving demand while maintaining defined constraints such as water turnover and storage requirements. In the case of WaterOne the summer diurnal demand pattern can vary enormously day

to day, and even during the day based on weather and rainfall. Schedules created at the start of the day can have little relevance later on if the weather changes. The Aquadapt software generates a new optimized solution every half an hour as it adapts to changing conditions. The Aquadapt software also automates the entire water distribution process, providing consistent and reliable operation 24 hours a day.

WATERONE IMPLEMENTATION

The Aquadapt software runs on a pair of standard rack mounted server PCs. All user access is via thin client Windows applications running on the WaterOne Wide-Area Network (WAN). Figure 5 is a screen shot of one such application, the standard operator interface at WaterOne called the 'Operator Panel'.

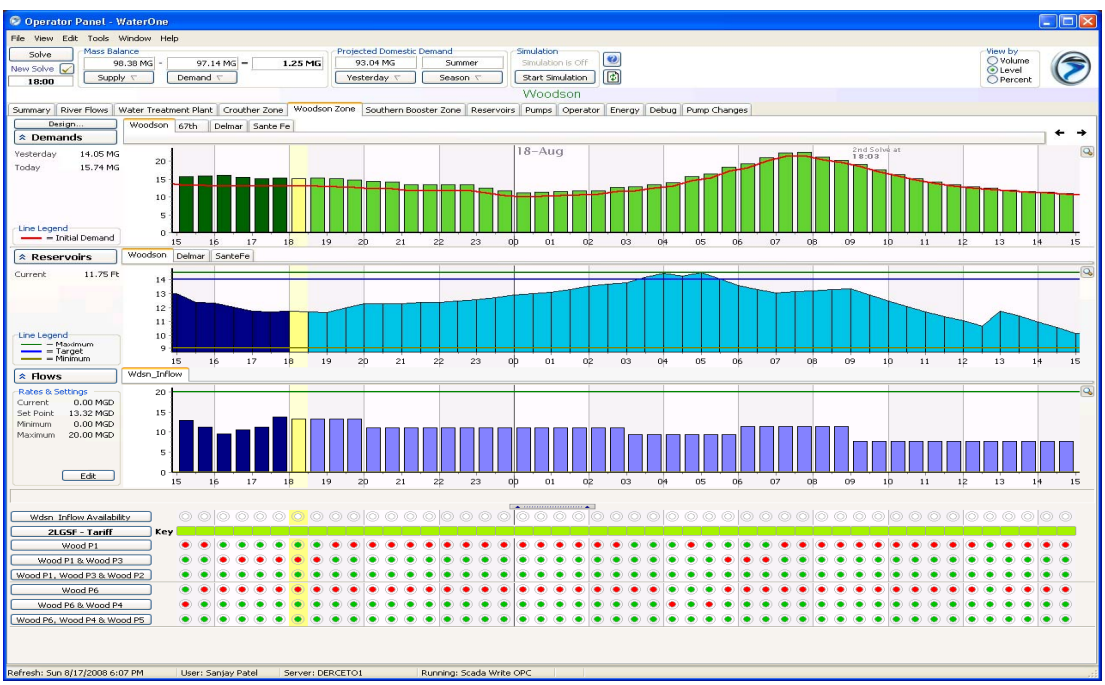

Figure 5. Derceto Aquadapt Operator Panel

This is a screenshot for a single pressure zone, and there are many similar pages for each of the other zones as well pages for the treatment plants, raw water sources, energy reporting data and miscellaneous supporting data. The top of the screen in Figure 5 reports summary information such as total system demand and supply, the time of the last update as well as access to operator inputs such as changing seasons or manually overriding setpoints. The Aquadapt software seeks to balance the supply and demand starting with the projected demand and then applying seasonal demand patterns for each zone with variations for weekday and weekends. The upper green graph in Figure 5 shows the actual and projected demand for water for this pressure zone for a 24 hour period. The yellow bar is the current time, with everything to the left of the bar being history and everything to the right being projected. The middle

portion shows reservoir levels and flows in half-hour increments for the next 24 hours. The bottom portion shows pump schedules for each pump in half-hour increments, with in WaterOnes standard red meaning ON and green means OFF.

PROJECT MANAGEMENT AND PERFORMANCE AUDITING

WaterOne started a three phase implementation of the Derceto Aquadapt software in June 2004. The timeline for the phases are as follows:

- Phase 1 - Feasibility Study - June 2004 to August 2004
- Phase 2 - Detailed Design - September 2004 to April 2005
- Phase 3 - Configuration and Testing - July 2005 to Mar 2006
  - Delivery, Implementation and Site Testing - April/May 2006

The feasibility Study determined that WaterOne could achieve $500,000 annual savings from peak demand reduction and lowest cost source selection. In particular, by reducing electrical demand at the facilities supplied by BPU during the hours of 10:00 a.m. and 8:00 p.m. on weekdays, WaterOne can lower the demand charge.

In order to accomplish the electrical demand reduction, WaterOne would need to vary its treatment plant production by as much as 100 MGD during each 24 hour period, increasing the flow as much as possible during night time hours and cutting back as much as possible between 10:00 a.m. and 8:00 p.m. on weekdays. This approach is contrary to conventional wisdom and operator training which desires to keep the treatment plant flow as steady as possible to prevent upsets in the treatment process.

WaterOne decided to proceed with the Detailed Design to investigate further whether or not changes to the operation of the treatment process could be made to accommodate the large flow swings, without adversely impacting treatment processes and water quality, and fine-tune savings estimates. The results of the Detailed Design showed that an annual savings of $810,000 could be achieved by shifting demand, the payback for implementing the changes would be less than 2 years, and that minimal hardware and equipment changes were necessary for integration with the SCADA system.

Implementation timing was critical to getting the 2 year payback. The software needed to be installed by May 2006 which is the beginning of the summer season for the BPU electrical demand. Otherwise the majority of the savings would be lost for 2006/07. The Derceto software was installed by and running effectively in May 2006.

WaterOne created and maintained an audit tool to measure savings on a monthly basis. The tool used a step function to determine, based historical data, what the

demand in kW would have been without Derceto software and compared it to the actual demand incurred when using the Derceto software. The difference was considered to be the monthly savings achieved with the Derceto software. Four years of historical data was used to develop a relationship between demand in kW and treatment plant flow in MGD. This approach to monitoring the savings allowed for changes in tariff in future years to be normalized in the evaluation.

RESULTS

Derceto helped WaterOne achieve a 20% electrical demand reduction resulting in a $90,000 savings that very first month. Figure 6 shows estimated daily demand reductions for the first month.

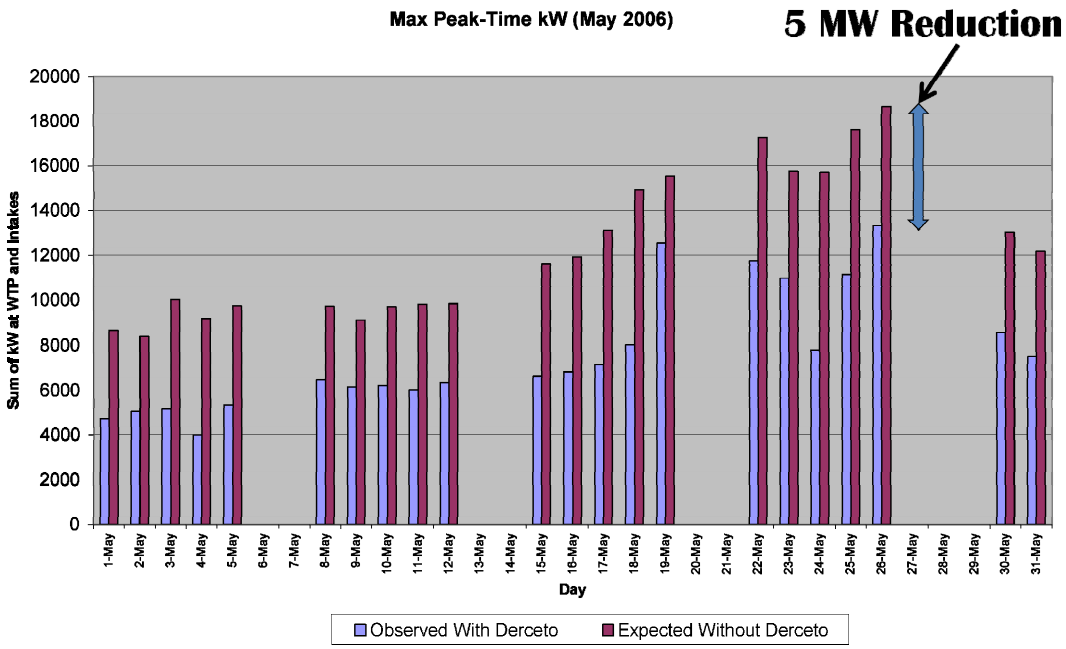

Figure 6. Electrical Peak Demand Reduction May 2006

Using the software, WaterOne was able to save over $1 million in electrical costs in the first 18 months of operation, reduce greenhouse gas emissions by 4,800 tons/year, identify areas where further savings can be made, and streamline operation of its water treatment plant. The reduction in energy use was so dramatic that BPU double checked their electric meters to make sure they were working properly and called WaterOne to verify that we had actually reduced our usage that much.

Operational changes were necessary to accommodate the flow swings that lead to the savings. The operators were involved from the very beginning to help ease the cultural change and shift in operating strategies. Before installing the software, Operators tested alternative ways to make the large flow swings and work out any

bugs and gain confidence that the new way of operating would work. Ongoing training and product enhancements have lead to even greater efficiencies and smoother operations. Although not required, some electric valve operators were installed to help with the flow swings. This minimal cost enhancement increased operator acceptance and more than paid for itself in manpower savings and efficiencies. Operators have gained so much confidence in their abilities to handle the flow changes that they have pushed the flow swings to a greater amount than originally anticipated and are achieving even greater energy savings.

WaterOne is currently using the Derceto Aquadapt software to evaluate energy savings by increasing distribution system storage and other system modifications.

CONCLUSIONS

The considerable investment in a Scada system is often hard to justify financially, but it is an essential tool. Utilization of the data and interfaces presented by a Scada system in areas such as planning and operations optimization can provide additional financial benefits. Even in an energy market that looked unfriendly to energy optimization, significant benefits were achieved.

Buying advanced software "off-the-shelf" reduces risk. Use robust systems to measure the benefits to avoid doubt. Operators need to be involved from start to finish; they know the treatment and distribution systems best. This is just one example of taking SCADA one step forward. Keep an eye on costs and benefits of integrating SCADA in other areas to best serve your customers.

ABSTRACT

Continued development of urban areas requires careful planning to ensure adequate resources are provided for growing industry and population while sustaining a healthy environment. This paper will discuss the on-going development of a GIS-based software tool, developed by the Atlanta Regional Commission (ARC), for projecting future development of the Atlanta Metropolitan Region. With this tool, the ARC can model growth of projected populations at fine scales, and thereby estimate future demands for transportation infrastructure, water, and other utilities.

The Atlanta metropolitan area is a 22-county region in the northwest corner of Georgia, with a burgeoning population of approximately 5 million. By land area, Atlanta is the fastest growing city in the world with some of the highest commute times in the United States. Continued development strains Atlanta's resources more and more. The ARC is dedicated to unifying the region's collective resources to prepare for a prosperous future. It does so through professional planning initiatives, the provision of objective information and the involvement of the community in collaborative partnerships.

To help adequately plan for future growth, the ARC has developed the ARC Population and Employment Allocation Disaggregation tool, an ESRI ArcMAP extension. The tool employs a two-step disaggregation procedure. Starting with a single region-wide population and employment projection (2000-2050) provided by a Regional Economic Models, INC (REMI) model, the tool first disaggregates this projection to large planning regions called super-districts. The ARC then adjusts the planning level projections manually to match their expectation for growth – and those of Atlanta's stakeholder community; city governments, developers, etc. The tool then disaggregates the superdistrict-scale projections to parcel scale by using map-based factors such as major roads and expressway ramps to estimate likelihood of development and allocating new growth to the most likely areas first. When the projection is at parcel scale, statistics for demands on the travel and utility networks can be calculated and used in forecasting future travel demands on the transportation system. The tool also provides a calibration procedure that compares modeled growth to actual growth and finds the set of model parameters that minimizes differences between the two.

INTRODUCTION

Continued development of urban areas requires careful planning to ensure adequate resources are available for growing industry and population while sustaining a healthy environment. This paper will discuss the on-going development of a GIS-based software tool, developed by the Atlanta Regional Commission (ARC), for projecting future development of the Atlanta Metropolitan Region. With this tool, the ARC can model growth of projected populations and employment at fine scales, and thereby estimate future demands for transportation infrastructure, water, and other utilities.

The Atlanta metropolitan area is a 20-county region in the northwest corner of Georgia, with a burgeoning population of approximately 5 million. By land area, Atlanta is the fastest growing city in the world with some of the highest commute times in the United States. Continued development strains Atlanta's resources more and more. The ARC is the municipal planning organization (MPO) dedicated to unifying the region's collective resources to prepare for a prosperous future. It does so through professional planning initiatives, the provision of objective information and the involvement of the community in collaborative partnerships.

This paper will discuss on-going development of the ARC Population and Employment Allocation Disaggregator tool in two sections, 1) algorithm description, and 2) technology description.

ALGORITHM DESCRIPTION

Step One: Disaggregation from Region-wide to Superdistrict scale.

The first disaggregation step starts with a regional projection provided by the ARCs Regional Economic Models, Inc (REMI) model, which includes 1) projections for 18 employment sectors, based on the North American Industry Classification System (NAICS) categories, and 2) projections for population by age, where there are 17 age categories. The NAICS employment projections are disaggregated to the 78 superdistricts by forcing the distribution of jobs across the superdistricts to follow the distribution observed in the base year – the first year of the time horizon.

The REMI model provides population projections as 17 population-by-age categories, which are first aggregated to a total population projection. To translate population into land use, the total population is translated to household size/income groups, where there are 6 household sizes (size is number of people in the household) and 4 income categories – giving a total of 24 household size/income categories. The households are also distributed across the superdistricts according to observed distributions in the base year.

Interactive Adjustment of Superdistrict-scale Projections

Once the tool has disaggregated the REMI projections to the superdistrict scale, users can make adjustments to the projections using the tool. The need for manual adjustments comes from 1) the tool assumes the base year distribution of jobs and housing will remain constant at the superdistrict scale over the projection time horizon, which may not be true, and 2) often, the ARC planners and the local stakeholders have accurate information about how development will occur in the short-range horizon (0-10 years) and medium-range horizon (10 -20 years). By allowing for manual adjustments, the tool can ingest this information. In the process, the tool can be used to build consensus on superdistrict-scale growth over the time horizon and can therefore raise confidence in ARC projections.

Of course, REMI-based regional totals of jobs and households – also know as control totals - must be matched. Manually adjusting projections will result in either a net increase or decrease in the total regional number of households or jobs. To conserve the control totals, the tool implements a re-balancing algorithm, which evaluates the total number of jobs or households moved by the user to a superdistrict and then compensates by removing a weighted fraction of jobs or households from the remaining superdistricts such that the total removed equals the total re-allocated.

Step Two: Disaggregation from Superdistrict to Parcel Scale

Once superdistrict scale disaggregation has been completed and approved, the second step of the algorithm is to further disaggregate projected growth to the parcel scale. At this point, the analysis becomes raster-based. In a year-by-year loop, the algorithm allocates projected growth first to employment land uses and then residential land-uses, emulating the actual development process, in which available land is occupied progressively over time. Figure 1 shows a schematic of how the algorithm proceeds through step two of the calculation.

The priority for allocation of new growth is driven by likelihood of development, which is evaluated for each raster cell according to a linear combination of map-based factors. For example, for a given scenario, the user might specify that commercial land use is most likely to develop in close proximity to interstate ramps, major roads, and in neighborhoods where commercial land use already exists. By bringing in map layers of interstates and major roads, the tool can evaluate a likelihood of development raster – called an L-raster. This L raster is calculated as the weighted sum of three rasters: 1) proximity to the closest major road, 2) proximity to closest freeway ramp, and 3) density of commercial land use in a neighborhood of raster cells around each grid cell. Figure 2 shows an example of an L-raster calculation for commercial landuse. The L-raster is the figure on the far right. Areas in blue represent the highest likelihood areas for commercial development to occur. New growth will be allocated to these areas first.

Each map factor is associated with a weight, which gives the importance of one factor relative to the other factors. The weights must add up to 1.0, and can be set by the

user. The choice of map factors and their associated weights is decided by the user, making the tool flexible for doing what-if scenarios and identifying the set of factors that are most influential to new growth – see the calibration section of this paper for more detail.

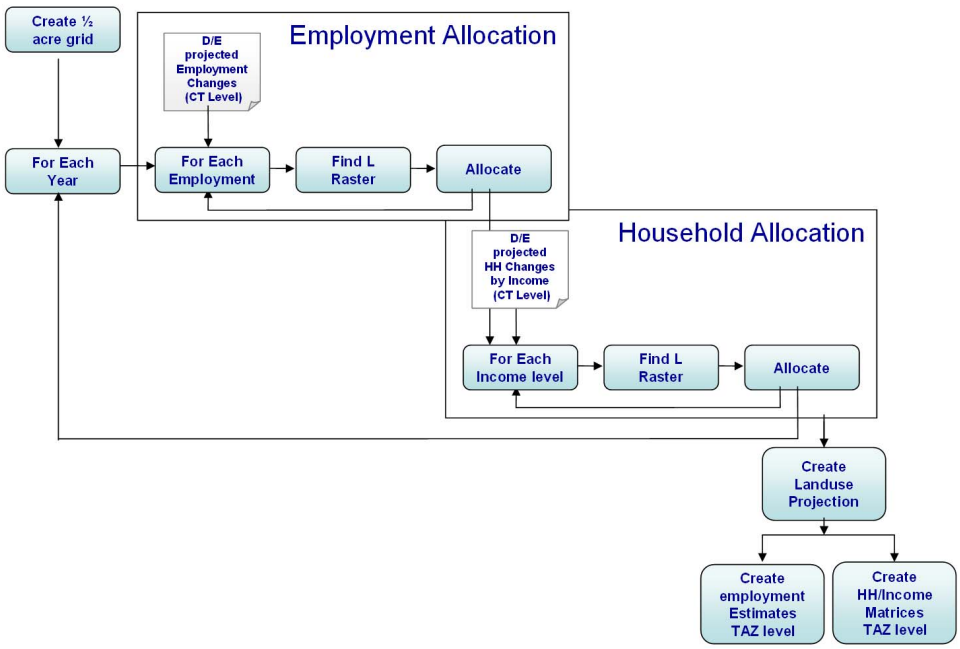

Figure 1: Schematic of Algorithm for Growth Modeling.

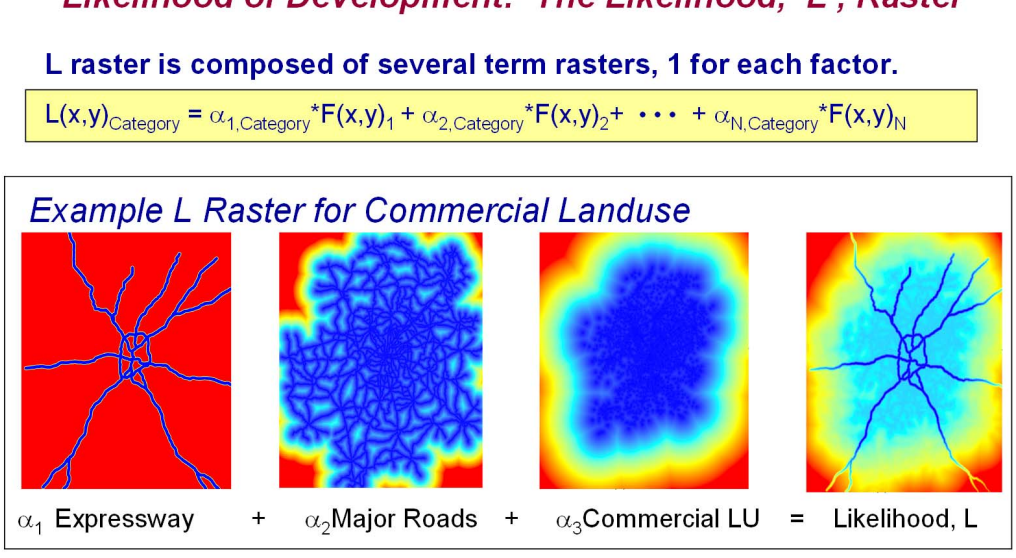

Figure 2: The L-Raster defines the likelihood of commercial or residential development at any given location by creating a weighted sum of user specified factors.

Translation from Employment and Households to Landuse

The superdistrict scale projections come in the form of numbers of new jobs and numbers of new households. As the algorithm allocates new growth by changing land use from vacant to developed, a suitable method for translating employment and households to land use is required. Using an ultimate build-out density map layer, the tool has an estimate at each location of the maximum density of jobs and households. The tool multiplies the number of new jobs or new households for any given year by the ultimate build-out density to arrive at a total number of acres required to contain the jobs or households.

Choosing the Raster Cell Size

In step two, the algorithm is converted from a vector-based to a raster-based calculation, where the vector-based shapes are converted to a grid. Using a raster-based approach is necessary because allocation during the second step must emulate the actual development process, where typically a developer will purchase and divide a large parcel into smaller ones and then develop multiple small parcels at a time in each given year. Converting to a raster-based analysis allows the algorithm to subdivide large parcels into smaller pseudo-parcels, in the form of raster grid cells.

An important aspect of converting to raster-based calculation is to choose the grid cell size of the rasters so that emulated development matches reality. Figure 3 shows the result of an analysis that found the size of actual changes in land use from 1999 to 2001. The rationale for the analysis is that changes in the land use polygons from year to year represent new development. We can set the grid cell size of the raster to match the most likely size of these changes. The implication is that 1) the growth modeling will be more accurate, as the chunks of land allocated to new development will match typical development, and 2) the calculation will proceed more quickly, as the basic grid cell size will be much larger than a single parcel.

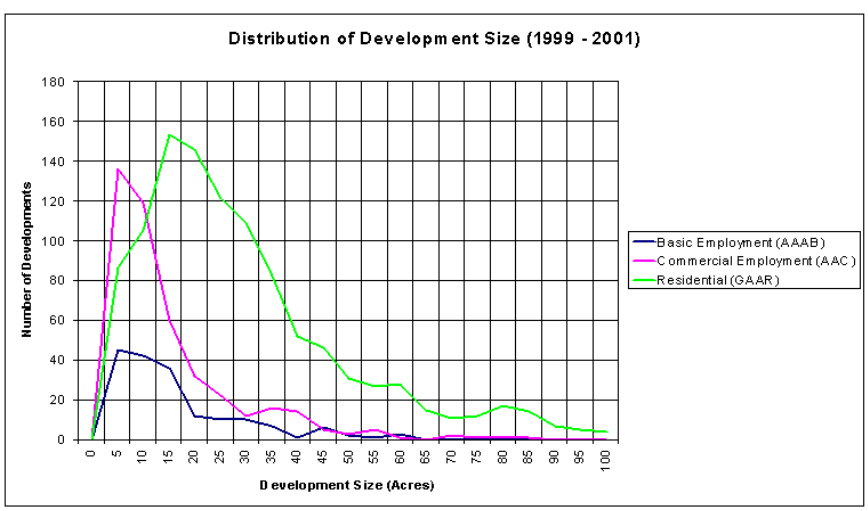

Figure 3: Distribution of Actual Landuse changes from 1999-2001.

For basic and commercial employment and residential landuse polygons, the difference in polygon sizes was calculated by essentially subtracting the 2001 polygons from the 1999 polygons. The distribution of the size of the changes was charted. From the Figure 3 on the preceeding page, we can see that for residential land use, the most likely size of new development is around 15-20 acres. Smaller average sizes for basic and commercial employment land use are found, 5-10 acres respectively. The grid cells size can be specified by the user in the ARC Population Disaggregation tool. The typical size used in our calculations has ranged from 500 ft (5.7 acres) to 1000 ft (23 acres).

Calculating Travel Demand Statistics

Once the algorithm has completed the two-step disaggregation process, a post-processing step is required to evaluate travel demand statistics for use in the ARC's travel demand model. The travel demand model requires employment and population estimates at the traffic analysis zone (TAZ) scale. The U.S. Census defines a TAZ as a special-purpose geographic entity delineated by state and local transportation officials for tabulating traffic related data from the decennial census, especially journey-to-work and place-of-work statistics. In the 13-county Atlanta metropolitan area, there are 1767 TAZs, with an average size of 1688 acres.

The tool calculates TAZ-scale totals for employment and households by income by translating the projected land use in each TAZ back to the NAICS employment and 24 category household size/income categories, ensuring that the distribution of jobs and housing matches that of the superdistrict.

Similar methods for aggregation of results to find demands for water, electricity, gas, and other resources can be added to the tool in the future.

Scenario-based Growth Modeling

In addition to the basic input data (map layers, REMI input, etc.), the user must specify the following to complete a run of the algorithm.

1. The time horizon of the analysis
2. The adjustments to superdistrict-scale projections
3. The map factors that influence development at the parcel scale for basic employment, commercial employment, and residential land uses.
4. The weights for the influential map factors

Collectively, this set of user specifications can be called a growth scenario. The ARC uses the tool to create multiple scenarios and compare the results. The intent can be to evaluate sensitivities to a certain map factor (eg. the effect of major roads), the effect of changing superdistrict scale projections to implement higher growth trends in one area versus another (eg. west Gwinnett County growing faster than east Gwinnett), and so on.

Calibration

An important question to answer in the course of growth modeling is whether the map factors chosen to define likelihood of development, and their respective weights, are reasonable. The tool implements a calibration algorithm to answer this question. The calibration process essentially consists of progressively adjusting weights of the factors until the difference in modeled and actual growth during an historic period is minimized.

The calibration algorithm requires a start year land use layer and end year land use layer. It calculates actual changes in land use by first converting the land use layers to raster form and then evaluating the number of grid cells that changed from vacant land to developed land. Then, the calibration procedure creates a set of possible weights for each map factor and runs the superdistrict to parcel scale disaggregation for every combination of those weights, evaluating the difference in modeled real land use change for each weight set.

The scale at which the comparison is made is dependent on the application. Currently, the comparison of actual and modeled growth occurs at the TAZ-scale, as the tool is being used for travel demand modeling. That is, the distribution of actual and modeled land use change is calculated for each TAZ. The region-wide comparison is made by finding the sum of squared errors (SSE) (ie. sum of differences between modeled and actual land use change) across all the TAZs for each of the three land use categories.

Simplex-based Calibration

The calibration method described above, where all combinations of possible weights are tested, is called the brute force method. Given it takes approximately 5 minutes to run a single growth modeling scenario on the ARC workstations, if there are as little as 3 map factors and the weight range is discretized into [0, 0.2, 0.4, 0.6, 0.8, 1.0], or six possible values, the number of runs of the scenario would equal $6^3 = 216$, which would require 18 hours to run. Given many more factors would normally be influential, and a finer discretization is preferred, a method for more quickly identifying the best set of weights is required.

The simplex calibration method is used to more quickly arrive at the best set of weights. Figure 4 illustrates the procedure. In the figure, 3 map factors are under consideration. The surface in the figure represents all the possible sets of weights that can be evaluated. Each black point on the surface represents a single set of weights. A triangle of neighboring points on the surface is called a simplex. First, the procedure evaluates the SSE for the 10, 8, 9 simplex. Point 10 - [0,1,0] results in the worst match between actual and modeled land use (largest SSE). The procedure then “flips” the triangle about the axis created by points 8 and 9, so that a new simplex is created of points 8, 9, and 6, and the SSE for point 6 is evaluated. The largest SSE is found to be point 9 for this simplex, and the triangle is again flipped to

make a new simplex of points 8, 6, and 7. The procedure continues until a simplex is found where there is no option to flip the simplex triangle and get a lower SSE. The point with the lowest SSE is thus identified as the best possible set of weights.

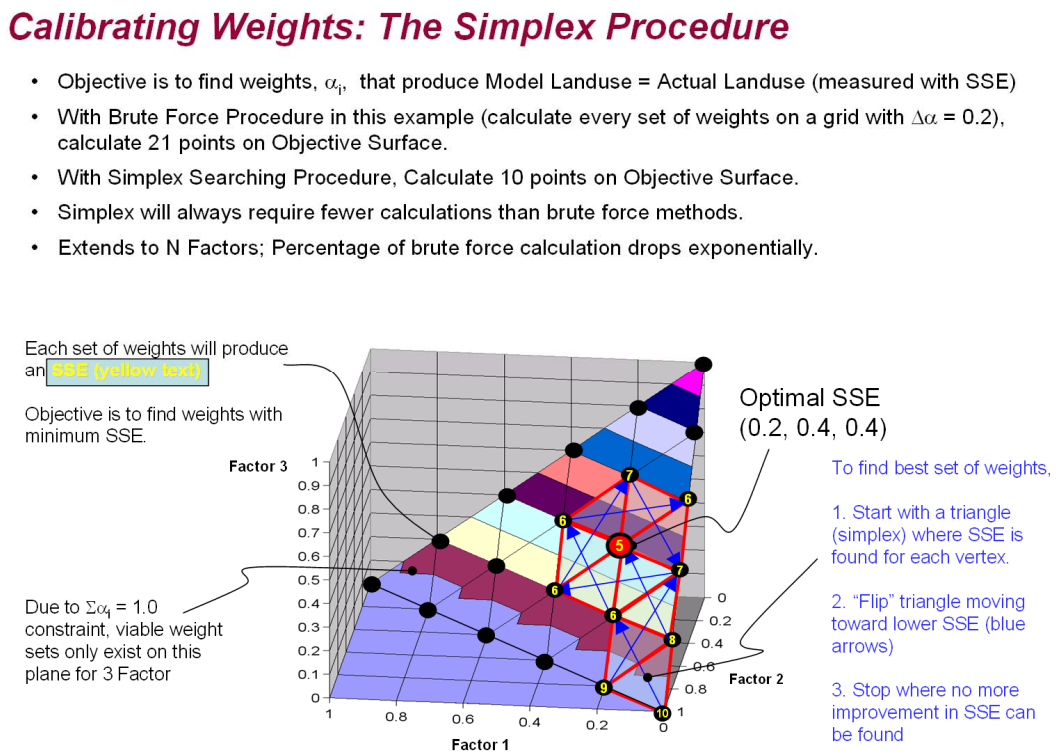

Figure 4: The simplex calibration procedure.

The simplex procedure reduces the calculation time substantially; savings increase as the number of map factors increases and the discretization of the weights becomes finer. A concern with using the simplex method is entering local minima in the SSE surface and not finding the global minimum as a result. To counter this, the algorithm is started from multiple simplexes. Moreover, once a minimum is found in the surface, the procedure "jumps" out of the minimum by moving randomly to a neighboring simplex and re-starting the search from this new point.

The calibration procedure is a powerful way of understanding which map factors are important in terms of new growth and which can be left out of the analysis. Moreover, the procedure provides some insight into the relative importance of each map factor. Finally, the calibration procedure provides some indication of how accurate the super-district to parcel scale disaggregation actually is. By comparing modeled growth to real growth, the ARC can understand how close these can actually come to projecting growth accurately, and conversely how much of the growth is not explainable with the growth model.

TECHNOLOGY DESCRIPTION

The ARC Population Disaggregation tool was created as an ESRI ArcMap 9.2 extension, so that it would work with the standard GIS platform used at ARC, the

platform the majority of ARC staff are trained in and use on a regular basis. Figure 5 shows a screen shot of the tool. The major components of the tool are a windows explorer-like tree that describes the growth scenario and allows the user to enter inputs and run the model, a context-sensitive information panel in the center of the screen that responds to the user clicking nodes in tree with information about the node and options for what you can do with the node, and a map on the far right. The map is the standard ArcMap map, and can be manipulated just as the standard map can.

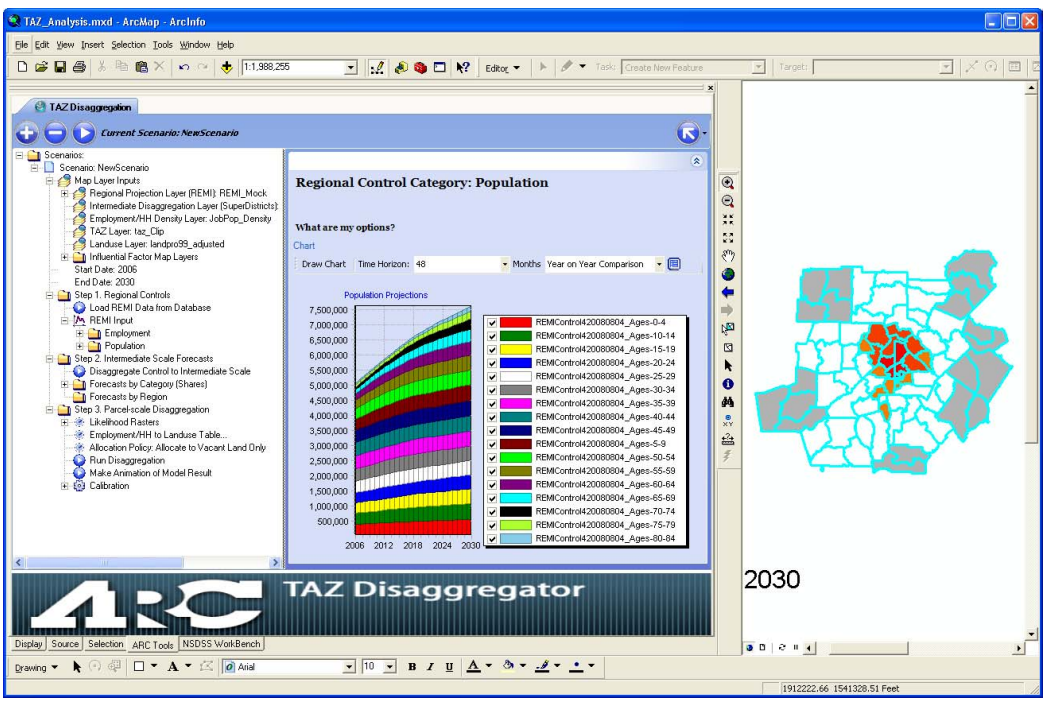

Figure 5: Screen shot of the ARC Population Disaggregator Tool.

Figure 6 shows a screenshot of the tree for a growth scenario. The tree is broken into four major sections 1) map layer inputs, 2) Step 1: Regional Controls, 3) Step 2: disaggregating from regional scale to superdistrict scale, and 4) Step 3: disaggregating from superdistrict scale to parcel scale. The user can create scenarios by clicking the scenarios folder at the top of the tree and clicking the "+" button on the toolbar. Once scenario is created, the user specifies which layers in the map should be considered the map layers to be used in the analysis (REMI layer, superdistrict layer, TAZ layer, etc.) and specifies the collection of map factor layers. The user can also enter the start and end date of the time horizon in this section of the tree.

Once the input data has been specified, the user can load the control data into the tool by clicking on the ***Load REMI Data from database*** node in the tree and choosing the load data option in the information panel. REMI data for the employment and population categories is loaded for the specified time horizon and can be charted as stacked time series charts (see figure 5). In step 2, the user then disaggregates the

regional control time series to the super districts. The results are displayed in a table in the information panel by category and by superdistrict. The user can adjust the projections directly within these tables, or they can select the superdistricts on the map and adjust the projections up or down.

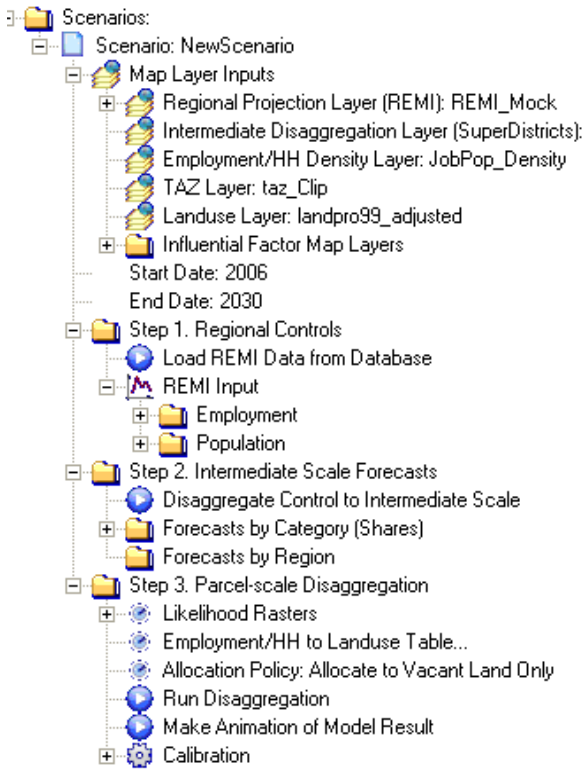

Figure 6: Scenarios for Growth Modeling are created in the Tree.

Finally, the user can run the disaggregation to parcel scale using step 3 in the tree. The user can set the weights for each factor in this part of the tree and set other modeling parameters. This disaggregation step is the most computationally intensive part of the algorithm and takes roughly 5 minutes on ARC workstations. The calibration procedure can also be run from this part of the tree if the user desires. Finally, an option for creating an .avi animation of the growth over the projection time horizon is included.

CONCLUSION

The ARC Population and Employment Allocation Disaggregation Tool is a powerful and flexible tool for GIS-based population projection. Using a combination of disaggregation steps that focus on 1) including the stakeholders in the projection process to build consensus, and 2) increasing accuracy in the modeling exercise through expert advice and calibration to historical pattern, the tool provides new insight into growth patterns in the Atlanta Metropolitan region.

How to Build a Broadly Useable GIS Toolset for Estuary Analysis.

ABSTRACT

Assessment of the health of coastal systems is difficult due to complex geomorphology, hydrodynamics and biogeochemistry. Traditionally, this assessment is tackled with commensurately complex supercomputer–based modeling tools. While these technologies provide useful results, their computational and financial expense renders them unavailable to most coastal professionals. In a pioneer effort to provide a more accessible method of analysis, a GIS-based database of spatial and temporal data that describe the environment, and an accompanying ESRI ArcMap-based toolset, together enabling the creation of a "virtual estuary", were developed for the St. Johns River Water Management District (SJRWMD) in northeast Florida.

The project was envisioned to be developed in a two-phase process. The first, or "Alpha," phase produced a prototype version, designed by a team composed of academic, government, and industry representatives. To ensure adequate and focused progress, the prototype was designed to tackle a single – but multi-disciplinary – problem using the virtual estuary, assessment of water quality. As of the writing of this paper, the Alpha phase of development has been completed. The second, or "Beta," phase (in planning) will put the prototype to the test to tackle several more diverse estuarine analysis problems. In the Beta phase, more institutions will be included to ensure a broad set of problems will be tackled, and to build the user community.

This paper will describe the collaborative committee-based process of project development used in the Alpha phase. The project team was composed of three parts: 1) a project management component – the SJRWMD staff, 2) a research and development component – the consulting water resources software developer, and 3) a design component – the steering committee. The development process consisted of 1) problem identification – assessing the region of influence for water quality sampled in an estuary, 2) a brainstorming session to form an initial set of requirements for what the toolset should do, 3) literature review – to synthesize the state of knowledge on estuary science and methodologies for estuary analysis, 4) rapid development of a prototype, 5) a brainstorming session to reflect on the first prototype and specify more detailed direction for development, 6) final development

of the prototype, and 7) documentation of the development process, the prototype solution, and lessons learned.

Critical decisions in the development process were 1) using nationally-recognized, vetted technologies such as Arc Hydro (Maidment, 2002) as building blocks for the technological solution, 2) ensuring the toolset was a GIS-based workbench for estuarine scientists (who will most likely not be GIS experts) to do simple analysis of estuaries from simple bulk parameter estimation to applying simple analytical models, 3) using brainstorming sessions to synthesize diverse opinions into a cohesive design and to reveal synergies between the experts that lead to novel ideas for tool development, and 4) using rapidly developed prototypes to provide the experts a concrete – and easily modifiable - model of their evolving, communal, design.

INTRODUCTION

Climate change, development pressures and other threats to coastal systems necessitate the continued efforts of environmental professionals to better understand and model these important systems. Relying solely on the most technologically advanced super-computer based models (e.g. Cerco, 2000) leaves most coastal professionals out of the active analytical process due to the financial and computational requirements of these models. Taking advantage of the continuing advancements being made in geographic information systems (GIS), and the nearly ubiquitous nature of this technology, a novel approach to coastal analysis using GIS was sponsored by the St. Johns River Water Management District (SJRWMD) in 2007. This paper will discuss the development of a GIS-based database of spatial and temporal data that describe the estuarine environment and an accompanying ESRI ArcMap-based toolset that together create a "virtual estuary" enabling simple analysis of estuary bulk properties and dynamics.

METHODS

Two-phase project development. An undertaking such as this would be doomed to failure if it was limited to a short project life cycle or if its scope was too broad at the outset. The complex geomorphology, hydrodynamics and biogeochemistry of coastal and estuarine systems suggest multiple potential applications in GIS. SJRWMD's interest in expanding its Arc Hydro water quality assessment application to coastal areas presented an opportunity to apply a progressive approach with a GIS solution. Any solution, let alone a simple one, to this expressed need would not be accomplished without an open mind for a creative solution, expertise in a broad spectrum of scientific and engineering disciplines and proper development timing. Although it was important to keep a broad-range vision in mind throughout, the project was best served with a two-phase development design. The first or "Alpha" phase was to address one coastal problem, preferably from a multi-disciplinary

standpoint to produce a prototype of the GIS solution. At the conclusion of an extensive QAQC process, the second or "Beta" phase will expand the prototype to several more diverse estuarine or coastal problems. During the Beta phase, the user community is expected to expand as more applications are developed.

Collaborative project development. Collaboration provides an efficient use of available knowledge and can result in novel ideas for development when diverse areas of expertise are represented in the collaborating team. Projects similar to the one described herein, ideally, are collaborative in nature – a consultant having been hired by an agency implies at least a working group of two. Add the agency's internal project management hierarchy and the group grows in number but not necessarily in active participation in the project development. What was intended was to invite a diverse group of interested parties from a variety of backgrounds beyond the ordinary agency work group to work on a creative solution for the project. Imposing structure on the collaborative process was essential to focus progress. For this project, the structure took two forms: division of the project team into specific task-groups and a unique project work plan that facilitated the collaborative process.

Task groups. To develop the GIS-based virtual estuary and toolset for SJRWMD, experts in estuarine science and engineering from academic institutions (University of Florida, University of Texas), a non-profit environmental agency (The Nature Conservancy), federal agencies (USGS, USACE) as well as from SJRWMD and PBS&J (the consulting water resources software developer), were invited to participate in the development and review of the new tool. The project team was composed of three parts: 1) a project management component – (SJRWMD staff), 2) a research and development component – (the consulting water resources software developer), and 3) a design component – the steering committee, which comprised the spectrum of experts and provided advice on design and reviewed the prototype. Individual roles necessarily overlapped but this clearly defined approach to task definition helped to clarify appropriate action during the project cycle.

Work plan. The development process or work plan consisted of 1) problem identification, 2) a brainstorming session to form an initial set of requirements for what the toolset should do, 3) literature review – to synthesize the state of knowledge on estuary science and methodologies for estuary analysis, 4) rapid development of a prototype, 5) a second brainstorming session to reflect on the first prototype and specify more detailed direction for development, 6) final development of the prototype, and 7) documentation of the development process, the prototype solution, and lessons learned. Figure 1 displays the process.

Step 1) Problem identification: By necessity, problem definition was preceded by the creation of the Statement of Work and its internal review by SJRWMD as indicated in Figure 1. This was the work of the "project management component" described above. Problem identification was undertaken by the research and

development component of the project team, assisted as needed by SJRWMD staff. Full discussion of the development of the problem identification process is beyond the scope of this paper and is fully presented in the project documentation (PBS&J 2007a, 2007b). In short, the expressed need of SJRWMD for an extension of Arc Hydro functionality to coastal and estuarine areas for water quality assessment required conceptual development to arrive at the problem to be addressed in the project. Simply stated, the standard view of "drainage to a point" fundamental to Arc Hydro does not work well in estuaries because of the influence of the tides. Water and pollutants can come from multiple sources as shown in Figure 2, the physical model of the estuary. The goal of the project was to create a prototype GIS-based tool to assess the region of influence for water quality sampled in an estuary. In order to do that the project team realized that the creation of a virtual estuary within GIS was a necessary first step.

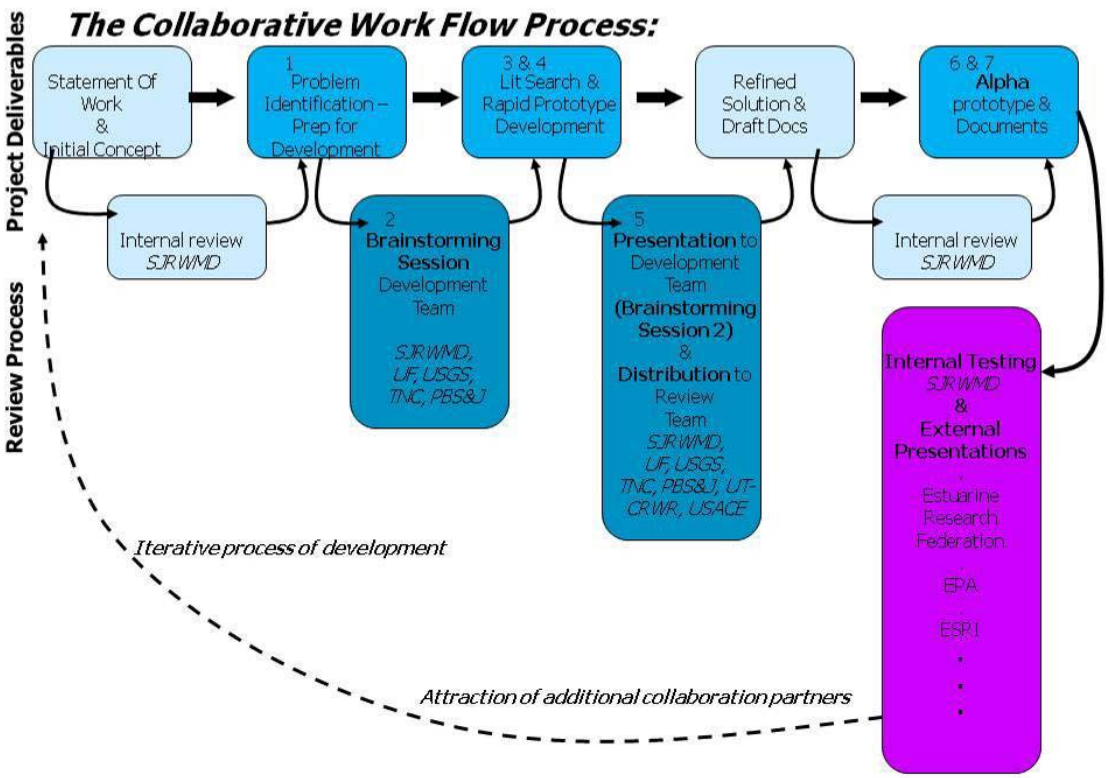

Figure 1. The collaborative work plan. *The seven key elements of the development process displayed in work flow format.*

Step 2) Brainstorming session 1*:* Once the team of estuarine science and engineering experts was assembled, and each member had an opportunity to review the project Statement of Work, an initial brainstorming session was convened in order to form an initial set of requirements for what the toolset should do. This first brainstorming session provided additional background to refine the problem definition and helped to

set the direction for project development. Available data for analysis was inventoried at this session, which led to the choice of a pilot estuary. Additionally, the major direction for the full literature review was determined, and a realistic plan for tool development was created. Lastly the high-level goals for an ideal GIS-based estuary analysis tool were set. The project team decided that the tool should be able to:

- Integrate data from multiple sources,
- Work with the existing district-wide Arc Hydro geodatabase,
- Allow creation of "virtual estuaries" in ArcMap,
- Estimate estuarine bulk parameters such as volume and flushing time, and
- Facilitate development and integration of other models into the same framework.

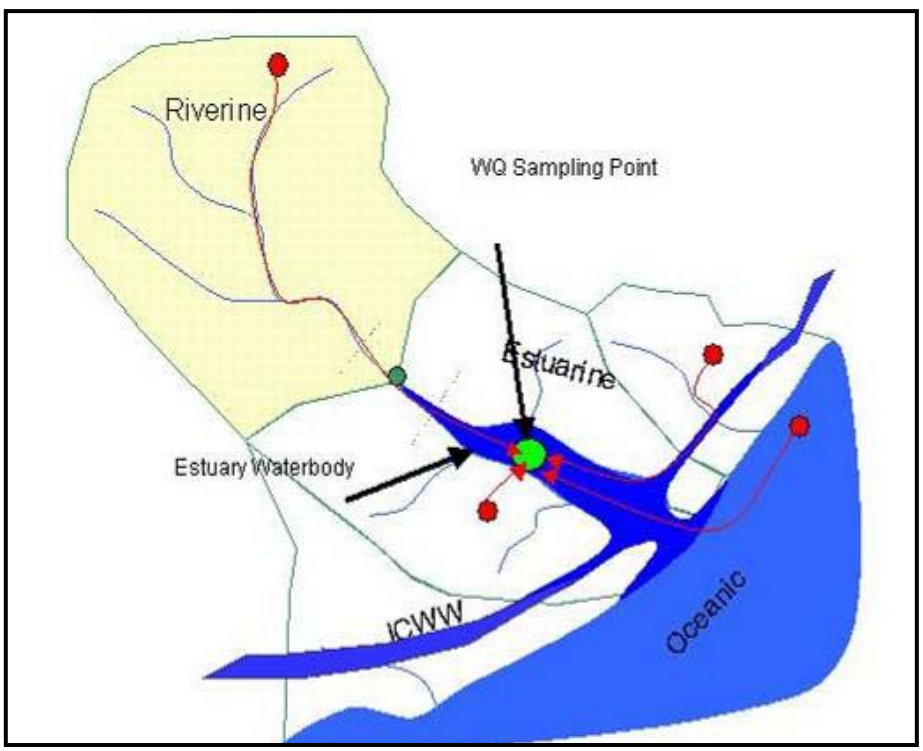

Figure 2. The estuary physical model: *A representation of the water quality assessment problem. The green dot represents the location of a water quality monitoring site. The red dots represent the various sources for pollutants that could travel to the site. ICWW = Intracoastal Waterway.*

These goals were kept high-level to provide only general direction. The goals did not detail how the tool should be designed – it's look and feel and underlying technologies – because the creative process was deemed best left to the research and development component that could forge ahead under the review committee's general direction. The research and development component envisioned that the toolset would be a GIS-based workbench specifically aimed for estuarine scientists (who will

most likely not be GIS experts) to use on their own to do simple analysis of estuaries from simple bulk parameter estimation to applying simple analytical models. Thus, the user interface and functional operation within the GIS were designed to be exceptionally "user friendly".

***Step 3) Literature review*:** Undertaken to synthesize the state of knowledge on estuary science and methodologies for estuary analysis, the literature review was extensive. The full literature review is included in the project documentation (PBS&J, 2007a). Because water quality in an estuary is influenced by the processes delivering pollutants to the estuary and the ability of the estuary to flush out the pollutants, the literature review focused on the following:

1) Methods for estimating estuarine properties, especially their geomorphology, hydrodynamics, and sediment transport properties,
2) Quantification of estuary properties and their relevance to water quality modeling on an estuary-by-estuary basis,
3) Water quality modeling approaches, their data needs, and which are pertinent to SJRWMD, and
4) Previous GIS-based approaches to water resource and environmental analysis.

Step 4) Rapid prototype development: The design approach for this project was based on a standard rapid prototype-based approach provided by PBS&J. Rapid prototype development as a component of GIS-based solution development comes from "rapid application development", a software development methodology, which involves iterative development and the construction of prototypes. The prototyping techniques are intended to accelerate software systems development, particularly important when technology is rapidly evolving. This approach has been implemented with success in several water resources technology software development projects around the country (Bourne et al, 2006; PBS&J, 2006). The rapid prototype concept is particularly helpful for driving creation of new software because it provides a functional version of the software very early in the project life cycle. The prototype can be used, scrutinized, and altered by representatives of the software's user base. This results in a much clearer picture of what is to be developed in the final solution, reduces misconceptions in scope definition, and enables the development of heavily used software.

Step 5) Brainstorming session 2: The second brainstorming session was intended to reflect on the first prototype and specify more detailed direction for development. The availability of the prototype was a key factor in the success of the second brainstorming session, by providing a tangible element to fuel discussions. The participants had something to view rather than just a description or a blueprint.

Step 6) Final prototype development: Refinements were made to the prototype following the second brainstorming session. These were subsequently reviewed by

the project management component (Figure 1). The resulting prototype tool is described in detail in Fox et al. (2008). The tool requires ArcMap at the full ArcInfo license, and both Spatial Analyst and 3-D Analyst extensions. Additionally, the tool creates an environment where data from diverse sources can be synthesized.

Step 7) Documentation: The literature review, committee recommendations, and eventual prototype solution design were documented (PBS&J 2007a; 2007b); the documentation was reviewed by the committee and approved.

CONCLUSIONS

The total number of participants in the original development team from the various agencies, academic institutions and industry was seventeen; additional reviews of prototype tool function and documents were provided by several others. A total of eight institutions were represented (SJRWMD, University of Florida, The Nature Conservancy, USGS, University of Texas, USACE, PBS&J and EPA). The respectable level of interest in participation at the outset of the Alpha stage suggested a need for an alternative to the complex supercomputer based approach to estuarine and coastal analysis. The collaborative development process, task groups and brainstorming-session infused work plan, resulted in a unique prototype GIS-based estuarine analytical toolset that has been described elsewhere (Fox et al., 2008). Opportunities for Beta development are being sought.

Several of the steps in the development process were not unique to this effort. Problem identification, literature reviews and documentation are standards in proper project management. It is worth noting here that the literature review was extensive, indicating the breadth of the effort to essentially use GIS in a way that hasn't been done before. In addition to the Conceptual Approach (PBS&J, 2007a) and the Requirements and Specifications (PBS&J, 2007b) documents that were previously mentioned, a Software User Manual was also provided (PBS&J, 2007c).

Unique to this process was the use of rapid prototype development and collaborative brainstorming sessions in the project development pathway. The prototype provided a central focus for the second brainstorming session, fostering a strong collaborative environment. It aided the development team to verify the requirements and to formally refine the data and process models. The brainstorming sessions were characterized by lively discussions that could have continued for an extended time had limits not been in place within the project management cycle. The second brainstorming session brought consensus on several important fronts (method of estuary polygon delineation, bulk parameter calculations, etc.) and furthered the discussion, although failing to reach accord on one issue (water quality modeling approach). The lack of agreement on the issue of water quality modeling underscored the requirement that the tool be designed to facilitate a wide variety of modeling approaches. However, the project timeline only allowed a single modeling

approach (multiple linear regression) for the initial development phase, although the entire project team recognized that a more sophisticated approach would ultimately be required, a fitting task for continued development. The brainstorming sessions facilitated discussions on a variety of subjects ranging from the various definitions of an estuary to the most effective way to do analytical modeling of water quality. These discussions were regarded by many as the best part of the development process, because they helped to clarify the review committee's recommendations on creation of the most useful tool. This benefited both the software developer, as well as the members of the committee itself.

Critical decisions in the development process were

1) Using nationally-recognized, vetted technologies such as Arc Hydro (Maidment, 2002) as building blocks for the technological solution,
2) Ensuring the toolset was a GIS-based workbench for estuarine scientists (who will most likely not be GIS experts) to do simple analysis of estuaries from simple bulk parameter estimation to applying simple analytical models,
3) Using brainstorming sessions to synthesize diverse opinions into a cohesive design and to reveal synergies between the experts that lead to novel ideas for tool development, and
4) Using rapidly developed prototypes to provide the experts a concrete – and easily modifiable - model of their evolving, communal, design.

ABSTRACT

This paper presents a novel data-driven method for modeling combined sewer overflows (CSOs) in real-time. This method treats CSO event generation as a threshold process that is triggered by increasingly intense rainfall events, and predicts the likelihood of a CSO given input conditions using a Bayesian network. The fusion of relevant data from multiple agencies into a unified data stream in real time is described, and a hierarchical modeling strategy is proposed that will facilitate the exploration of the causes of CSOs and direct research into the adaptive management of combined sewer systems using the Chicago wastewater system as a case study.

INTRODUCTION

In many municipalities, the wastewater infrastructure is divided into two systems, one that conveys municipal and industrial wastewaters (i.e. sanitary sewers) and one that conveys stormwater runoff (i.e. storm sewers). However, 746 communities located in 32 states, including many of the nation's largest cities, have combined sewer systems (CSSs) that rely on a common infrastructure to convey all wastewater [EPA 2004]. Precipitation events, in particular, cause critical loading of the wastewater infrastructure resulting in sewer "overflow" events (i.e. events where wastewater is discharged untreated into the environment in order to relieve pressure within the sewer system). From the 9,348 regulated combined sewer overflow (CSO) outfalls in the United States, the EPA estimates that about 850 billion gallons of untreated wastewater and storm water are released as CSOs each year [EPA 2004].

Recently, because of the health affects associated with the discharge of untreated wastewater by CSOs, there has been an interest in adaptive management of CSS. Such management, however, will rely on an understanding of the causes of CSOs throughout a CSS and the ability to forecast their occurrence. In CSSs, wastewater from a particular region is routed to a CSO connecting structure. Using an analogy to watersheds, the region drained to a CSO connecting structure is referred to as a sewershed. Wastewater entering this connecting structure can be either routed to the wastewater treatment facility (WWTF) via a sewer interceptor, or discharged, untreated directly into the environment as a CSO as shown in Figure 1. Fundamentally, CSOs occur when wastewater enters the CSO connecting structure more quickly than it can be leave via the interceptor; however, while this condition is overwhelmingly the result of intense precipitation [EPA 2004], the infrastructure-

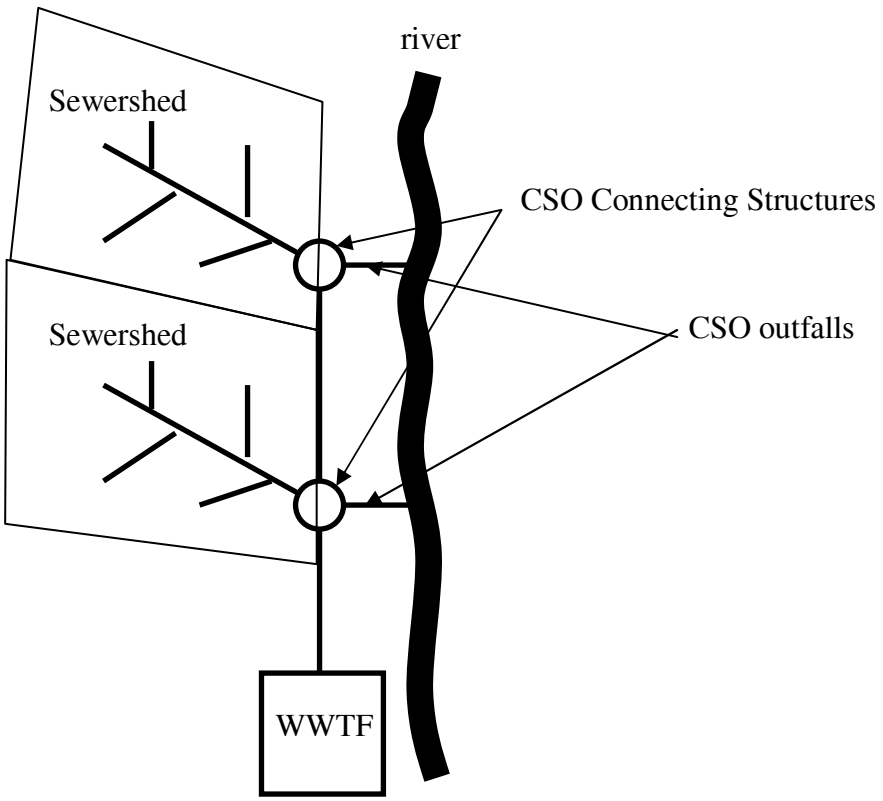

Figure 1. Diagram of a combined sewer system showing two sewersheds (A and B) that are connected to the same wastewater treatment facility (WWTF).

related causes of CSOs in a particular sewershed are often unknown, and likely to vary spatially (i.e., between sewersheds) and temporally.

This study will use modeling of CSOs to explore the causes of CSOs and to direct research into the adaptive management of CSSs using the Chicago wastewater system as a case study. Traditionally, CSOs models have employed complex physics-based flow routing models (e.g. Rouault et al. [2008]). Unfortunately, many such models cannot accurately represent the effects of special hydraulic structures (especially CSO connecting structures); resulting in significant uncertainties in their predictions [Garcia-Salas & Chocat 2006]. Additionally, as is the case in Chicago, CSO data needed to calibrate these models are often unavailable. For these reasons, this study employs a novel approach to CSO modeling that treats the CSO connecting structure as a low pass filter that transmits the stormwater from low and moderate intensity storms to the WWTP, while stormwater from more intense storms is only partially routed to the WWTP with the remainder being discharged as a CSO. This conceptual model, referred to as threshold filtering, has been successfully applied to other hydrologic systems in which behaviors are triggered by increasingly extreme conditions, such as rainfall-runoff modeling [Struthers et al 2007a and 2007b] and flooding [Kusumastuti et al. 2008]. Threshold filtering will be used to derive three increasingly complex models of CSO generation. In the first-order model, CSOs will be modeled as the result of locally intense (i.e., sewershed-scale) storms. The second-order model will extend the first-order model by adding global (i.e., CSS-scale) sewer loading to the first-order model, and the third-order model will extend the second-order model by adding time dynamics. The first- and second-order models will be

implemented using Bayesian Networks (BNs), and the third-order model will be implemented using a Dynamic Bayesian Network (DBN). This hierarchal modeling strategy will facilitate inquiry regarding the relative importance of spatial scale of influence (local vs. global), location (i.e. is the CSO generation process space invariant), and time (i.e. is the CSO generating process time invariant).

CASE STUDY

The Chicago wastewater system will be used to drive the derivation of the CSO models as well as a testbed to use these models to explore the causes of CSOs. In the 1970's Chicago began construction on one of the largest civil engineering projects ever undertaken—the Tunnel and Reservoir Plan (TARP). The TARP system, whose completion is anticipated in 2019, consists of over 100 miles of underground tunnels connecting several reservoirs which can be used during wet weather events to store excess wastewater until it can be treated and discharged into the Chicago waterways system. Phase I of TARP, which consists of the tunnels and structures tying TARP to the sewer system was completed in 2005 and provides over 2 billion gallons of storage. When Phase II is completed, the reservoirs will further increase the capacity of the TARP system by 15.6 billion gallons.

The goal of the completed TARP system is to drastically reduce the volume of untreated wastewater that is discharged into the environment by CSOs. However, observations since the completion of Phase I indicate that despite the currently available storage CSOs still occur at times when storage is available within the TARP system. For example, on Aug 23, 2007, a storm passed over Chicago dropping 1.9 inches of rain in 7.5 hours. The storm resulted in significant flooding in the Chicago area, 189 CSO events and forced the reversal of the North Branch of the Chicago river (a last-resort management decision, which had not been used for 5 years prior), however, at the conclusion of this storm, there was still approximately 500 million gallons (25%) of storage still available in TARP. Events such as this suggest that local behaviors, such as locally heavy rains or bottlenecks in the conveyance of wastewater may result in CSOs. Spatio-temporal analysis of CSO events from Nov. 2004–Dec. 2007 identified a subset of the Chicago sewersheds that generated significantly more CSO events than average. While many of these "critical" sewersheds are clustered in the northeastern region of the system, they are not spatially contiguous and are interspersed with non-critical sewersheds. This observation suggests that CSOs in the critical sewersheds are more influenced by local factors (e.g. local infrastructure differences or locally intense storms) than by system-wide sewer loading. In addition to a moderate seasonal trend, the spatio-temporal analysis also revealed distinct time periods in which CSOs were more likely to occur throughout the Chicago system, which tend to correspond with periods of unusually large quantities of precipitation. This result indicates the importance of precipitation variability to the generation of CSOs.

METHODS

The partitioning of stormwater runoff from a sewershed between sewer conveyance, storage, and overflow can be viewed as a hierarchy of threshold processes that are triggered by increasingly severe precipitation events. The first threshold corresponds to the storm intensity necessary to require the use of

wastewater storage, while the second threshold corresponds to the storm intensity necessary to trigger a CSO. Thus, during light precipitation events, all the stormwater can be conveyed to the WWTF via the sewer network. During moderate storms the system becomes conveyance limited and the wastewater that cannot be conveyed to the WWTF must be stored (if storage is available) until the conveyance limitation is lifted. Finally, during severe storms, the system is both conveyance and storage limited, thus, excess wastewater must be discharged as a CSO. While continuously valued properties (e.g. volume) can be attributed to a CSO, the overflow itself is a discrete temporal event (i.e. it has a well-defined beginning and end).

The models developed in this study predict whether or not the intensity of a given storm exceeds the CSO triggering threshold. Because of the variability in the processes that govern the generation and routing of wastewater through the sewer network, the threshold that triggers CSO events is uncertain. For this reason, it makes sense to model CSO events probabilistically. The probability that a CSO event occurs given the conditions described by a vector of random variables X can be calculated using Bayes' Theorem as

$$\mathrm{P}(CSO \mid X) = \frac{\mathrm{P}(X \mid CSO)\mathrm{P}(CSO)}{\mathrm{P}(X)} \tag{1}$$

where $\mathrm{P}(\cdots)$ indicates the (conditional) probability density function and CSO is a Boolean (yes/no) variable that indicates whether or not a CSO occurs. Thus, given a realization of $X = X'$, whether or not a CSO occurs can be predicted by determining if the likelihood that a CSO occurs (CSO=yes) is greater or less than the likelihood that a CSO does not occur (CSO=no) given X'. This can be expressed mathematically as

$$\arg\max_{CSO} \mathrm{P}(CSO \mid X = X') \tag{2}$$

BNs are graphical models that represent a set of variables and their dependencies as directed acyclic graphs, whose nodes represent the variables and whose arcs represent the conditional dependencies among them. The graphical structure of the BN facilitates Bayesian inference (i.e. solving Equation 2).

Creating a model of the form shown in Equation 2 requires a historical record of precipitation, TARP storage, and whether or not a CSO occurred. Since these data are measured at different spatial and temporal frequencies, it is first necessary to fuse these data (i.e. combine the diverse data sets into a unified data set that has a consistent spatial and temporal resolution). Because the models will be used for real-time forecasting, the fusion process must be automated to continuously process new data as it is collected. This study uses custom transformations that are implemented as a workflow within a semantically enhanced digital watershed to continuously fuse the data. These transformations define virtual sensors, as discussed by Liu et al. [2008], and result in new streams of data that can be used as input to the model or for updating the model parameters.

Historical records of the amount of water in the TARP storage and CSO events from 2004 through 2007 were provided by the MWRD. The storage data are encoded as a time series with irregular frequency, while the CSO data are encoded as event data (i.e. for every CSO event, a start and stop time was recorded). These data are fused to create a time series with uniform 10-minute intervals. The fusion process

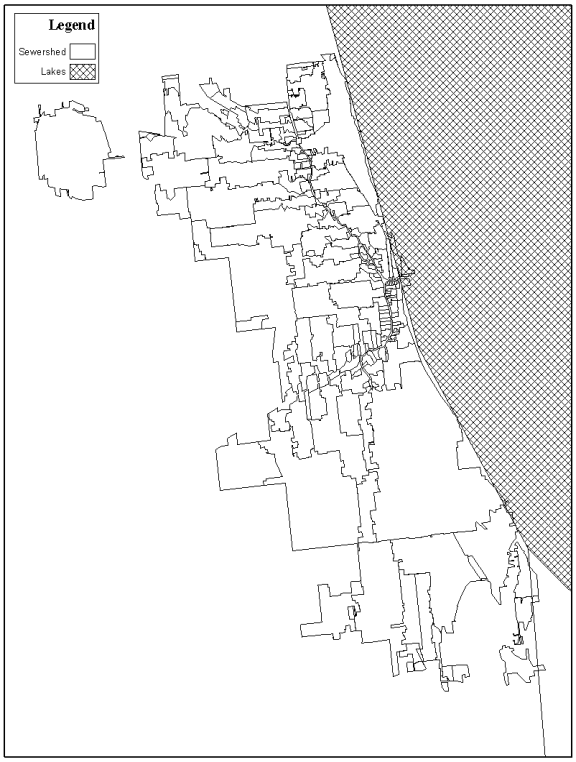

Figure 2: TARP sewersheds.

involved defining the discrete points to fall every 10 minutes starting at midnight (i.e. 00:00, 00:10, 00:20, etc.) and interpolating the CSO and storage records to these points.

The average rainfall rate over each sewershed was estimated using weather radar data from the Next Generation Weather Radar (NEXRAD) system, since, like many other cities [Vieux and Vieux 2005, Sempere-Torres et al. 1999], Chicago does not have a rain gauge network that is dense enough resolve the spatial heterogeneity of rainfall at the sewershed scale. Because no high level radar product (e.g. Level III or MPE) exists that can provide precipitation measurements at the space (~1 km^2) and time (~10 minutes) scales required for the CSO models developed in this study [Smith et al. 2007], NEXRAD Level II data are used. These data are the base reflectivity measurements made by the radar at irregular intervals (5, 6, or 10 minutes between scans), depending on the current operating mode of the radar [Fulton et al. 1998]. These data are georeferenced using a polar grid centered at the radar.

The City of Chicago occupies an area of approximately 525 km^2, which is subdivided into roughly 200 sewersheds that range in size from approximately 0.5 to approximately 70 km^2 as shown in Figure 2. The boundaries of the TARP sewersheds that drain the City of Chicago have been delineated by the Chicago Department of Water through analysis of the sewer network and field studies. These boundary data are encoded and georeferenced as vector polygons in Keyhole Markup Language (KML).

Integrating the NEXRAD and sewershed boundary data to determine the timeseries of spatially averaged rainfall for each sewershed requires several steps. First, a local grid is defined that discretizes the City of Chicago into 0.5x0.5 km

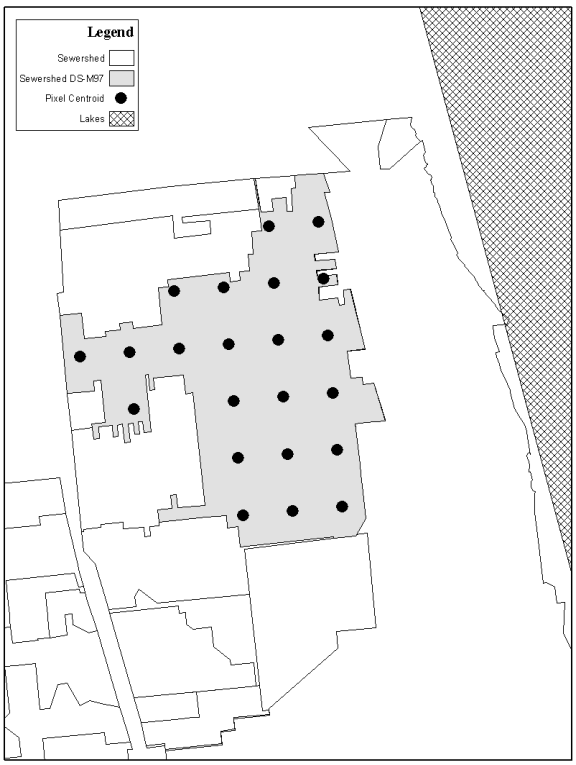

Figure 3: Centroids of the 0.5x0.5 km pixels within TARP sewershed DS-M97

pixels and is georeferenced using the same East-North-Up coordinate as the NEXRAD data. The pixel size for this grid was selected because Vieux and Farafalla [1996] noted that this resolution was sufficient to fill a rectangular grid from NEXRAD level II data. The average reflectivity of each pixel is then calculated using an inverse-distance-squared weighting technique suggested by Smith et al. [2007]. Then the polygon vertices of each sewershed are converted from World Geodetic System 1984 coordinates (used by KML) to the East-North-Up coordinates of the local grid, and a polygon filling algorithm is used to determine which pixels fall inside each sewershed. This algorithm parses the rows of the grid in South to North order once for each polygon, identifying the columns in each row through which an arc of the polygon passes. Assuming that the polygon falls completely within the grid, then processing the list of columns in East to West order quickly reveals the pixels that fall inside the polygon. The sewershed average reflectivity is calculated by averaging the reflectivity of the pixels falling in the sewershed polygon. For example, Figure 3 shows the 5.3 km^2 sewershed that drains into TARP dropshaft DS-M97 and the centroids of the 22 grid pixels that are used to calculate its average rainfall. The sewershed average reflectivity at each radar scan time *t* are then converted to rainfall rate in mm/hr using the standard convective rainfall-reflectivity equation [NWS-ROC 2003].

$$Z = 300R^{1.4} \tag{6}$$

where Z is the reflectivity and R is the rainfall rate. Finally, the sewershed average rainfall rate is averaged over 10 minute intervals to create a timeseries with a regular frequency.

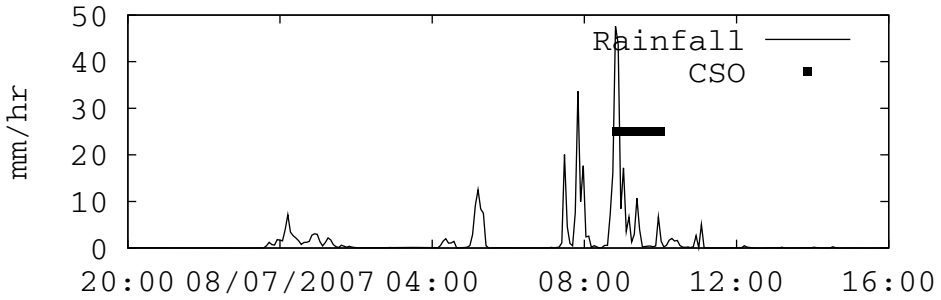

Figure 4: Fused CSO event and rainfall rate data from TARP sewershed DS-M97.

Figure 4 illustrates the result of fusing the CSO event and NEXRAD radar data. This figure shows a 24 hour window of the integrated CSO event and sewershed average rainfall timeseries for the sewershed that drains into TARP dropshaft DS-M97. During this window, there are 3 discrete storms, two low intensity storms that produce no CSOs, and one high intensity storm that results in a CSO event that lasts approximately 1 hour. This CSO event begins roughly halfway through the third storm (at about 9:00am) and is concurrent with the highest intensity rainfall peak in the storm of approximately 45 mm/hr.

The fused rainfall, CSO, and TARP storage timeseries will be divided into discrete storms using the criterion set up by the National Weather Service to define how much rain falls during a particular storm [Fulton et al. 1998]: storms are divided by periods longer than 1 hour where no rain falls. For example, if rain falls continuously from 10:00 until 10:30 and from 11:10 until 13:00 these rainfall events will be associated with the same storm. On the other hand, if rain falls continuously from 10:00 until 10:30 and from 11:35 until 13:00, these rainfall events will be defined as two separate storms. These data will be used to create three increasingly complex models of CSO generation as described in the remainder of this section.

First-Order Model: The first-order model assumes that causes of CSO events in a sewershed are well-described by the local (sewershed-scale) intensity of storms. Thus, the model does not resolve the effects of the storm in other sewersheds that may result in overwhelming the global sewer conveyance and/or storage capacity. These assumptions are valid if the causes of CSOs in a particular sewershed are only loosely dependent on the global system behavior (i.e. sewershed-scale factors drive CSO events), and success of the model to predict CSOs in a particular sewershed will indicate that global management strategies will be unsuccessful at alleviating CSOs in that sewershed, and local management should be pursued.

To characterize the intensity of sewershed-scale storm events the following properties are used: storm average rainfall rate over the sewershed i, storm duration t_r, and inter-storm period t_b. The average rainfall rate and the storm duration indicate the volume of wastewater generated within the sewershed, while the inter-storm period indicates the conditions of the sewer network prior to the storm, which is especially important when the local sewer system is capable of storing large volumes of wastewater.

As discussed so far, the BN model can predict whether or not a storm with characteristic variable values i', t_r', and t_b' will produce CSOs. However, it is often desired to know when a CSO event begins and how long it lasts. If it is assumed that a storm's behavior (i.e. rainfall rate and persistence) in the future is independent of the storm characteristic variables, the storm can be addressed incrementally. That is to say, a given storm S that lasts from time t_0 to time t_S can be decomposed into sub-storms where sub-storm s_t has duration t_0 to t and $0 < t \leq t_S$. Since the storm characteristic variable t_b is dependent only on the conditions leading up to the storm, it will be the same for all sub-storms s_t of storm S, and since the characteristic variables i, t_r only depend on the storm conditions up to and including time t, the BN model can be used at any time during a storm to predict the probability of a CSO occurring at time t during a storm using the incremental values of i, t_r calculated over the duration of the sub-storm s_t.

Second-Order Model: The second-order model builds on the local, first-order model by adding the effects of global storm intensity and global sewer system storage in TARP. This model assumes that global storm intensity only affects the CSO generating process in a particular watershed through the filling of the TARP storage. The volume of remaining storage in TARP will be represented by the variable S, and sewer system-scale storms will be characterized using the variables I and T_r, the average rainfall rate and storm duration over the entire sewer system, respectively. A variable representing the sewer system-scale inter-storm period is not necessary, because the TARP storage variable S provides the antecedent conditions of the sewer system.

Like the first-order model, the second-order model can be applied incrementally to a storm event (if it is assumed that a storm's future behavior is independent of the storm characteristic variables) to determine when a CSO event is likely to begin and how long it will last.

Third-Order Model: The first- and second-order models explore the spatial-scale of influence of the CSO generating processes. The first-order model includes only sewershed-scale processes, while the second-order model includes both sewershed and sewer-system-scale processes. These models can also be applied incrementally during a storm to investigate the temporal region during a storm where CSOs are likely to occur if it is assumed that the future behavior of CSO generating processes are independent of their previous behavior. This may not be a reasonable assumption. For example, if a CSO event occurs at time t, it may be more likely to continue at time $t+\Delta t$ than if a CSO event does not occur at time t. For this reason, the third-order model adds temporal dependencies to the second-order model. Since this model can explicitly represent the temporal dependencies in the system, it can be compared with the second-order model applied incrementally during a storm to test the assumption that the future behavior of CSO generating processes are independent of their previous behavior, which allows the second- (and first-) order model to be applied incrementally.

CONCLUSION

Modeling CSO events is important for understanding the causes of CSOs and for providing decision support to reduce their occurrence. This paper proposes the real-time fusion of heterogeneous data streams for inclusion in the modeling process and a hierarchal modeling strategy that will facilitate inquiry regarding the relative importance of spatial scale of influence (local vs. global), location (i.e. is the CSO generation process space invariant), and time (i.e. is the CSO generating process time invariant). At the conference we plan to present the results of this modeling effort and address the following questions:

How important are global factors in predicting CSOs? The first-order model assumes that CSOs are driven by the intensity (over the sewershed) of storms. Thus, it does not explicitly resolve the effects of the storm on other sewershed, which may result in reducing the conveyance capacity of the sewer system and/or filling the TARP storage. Thus, if the first-order model performs well at predicting the CSO within the sewer system, it will suggest that the global factors are less important than the local factors and that strategies to reduce CSO occurrence should be focused at the sewershed scale. On the other hand, if the second-order model performs significantly better than the first-order model, it would suggest that global factors are important to the generation of CSOs within a sewershed.

Are the CSO generating processes space invariant? After selecting the necessary model complexity (i.e. first-, second-, or third-order) the model parameters can be evaluated across many sewersheds. If the distributions of the random variables in the BN model are not significantly different between sewersheds, this will imply that the CSO generating processes are space-invariant. Thus, one model can be used to predict CSO events in all sewersheds. This is unlikely to be the case, however, it may be likely that sewersheds can be grouped into a small number of clusters in which the CSO generating processes are the same (i.e. the same model can predict CSO events in all the sewersheds in one cluster). Then by comparing and contrasting the sewersheds within and between clusters, it may be possible to determine the underlying features that make these sewersheds similar.

ACKNOWLEDGEMENTS

The authors would like to thank the Metropolitan Water Reclamation District of Greater Chicago and the City of Chicago, who provided data on the Chicago sewer system. This study was funded Adaptive Environmental Sensing and Information Systems (AESIS) initiative, which is supported by the University of Illinois at Urbana-Champaign Vice Chancellor for Research (VCR), the National Center for Supercomputing Applications (NCSA), and the Department of Civil and Environmental Engineering (CEE).

Abstract

In collaboration with Clermont County, the U.S. EPA's Office of Research and Development is developing watershed-wide load and transport models to account for stream processes at the Experimental Stream Facility (ESF) in Milford, Ohio. To better understand environmental stressors in stream flow and the structure and function of stream ecosystems, researchers are establishing continuous water quality monitoring stations along the Lower East Fork River and its tributaries. River and stream water quality are being automatically monitored and recorded every few minutes for: temperature, pH, dissolved oxygen, conductivity, stream flows (light levels, temperature and humidity), weather conditions (rainfall, solar radiation, temperature, humidity and barometric pressure) using remote sensors and weather stations. To transfer water quality data back to the ESF, high frequency data linking is being investigated for reliably and cost effectiveness.

EPA and the University of Cincinnati are examining the existing data telemetry software and suggesting a change in transmission protocol. The new protocol offers two important features: a built in CRC-16 for error correction and the ability to use the station as a digital repeater. Use of a protocol with a CRC will yield many benefits; the quality of transmitted data will be improved thus allowing the system to utilize higher baud rates, which translates into shorter transmission times and power savings. Use of the new protocol does incur additional packet length to accommodate addressing and the CRC as well as additional computational effort to validate incoming data by computing the CRC, so a comparison of protocols is merited. Also discussed are the benefits of 'digipeating' – by allowing each station to act as an addressable repeater transmissions can be broadcast over several hops to extend the range beyond simplex distance with the ultimate goal of meeting the 50 mile specification, though this is subject to the additional considerations of station density and use of directional antennas. Because each station is given a unique address there are possibilities for routing and redundancy in future projects

Keywords: Telemetry, Radio, AX.25 Protocol, Watershed Monitoring

Background

In 2007, Paul Dorsey prototyped a communications system that retrieved telemetry data from a sonde via FM radio in the High Frequency (HF) band [1]. This system allowed an operator with a terminal at the ESF station to remotely access equipment installed at the Shayler Crossing test site, approximately 4.7 miles away as the bird flies. Figure 1 shows that this 4.7 mile link traverses a variety of terrain and land use types, which present insurmountable obstacles to conventional "line of sight" systems, but can be overcome in the HF bands.

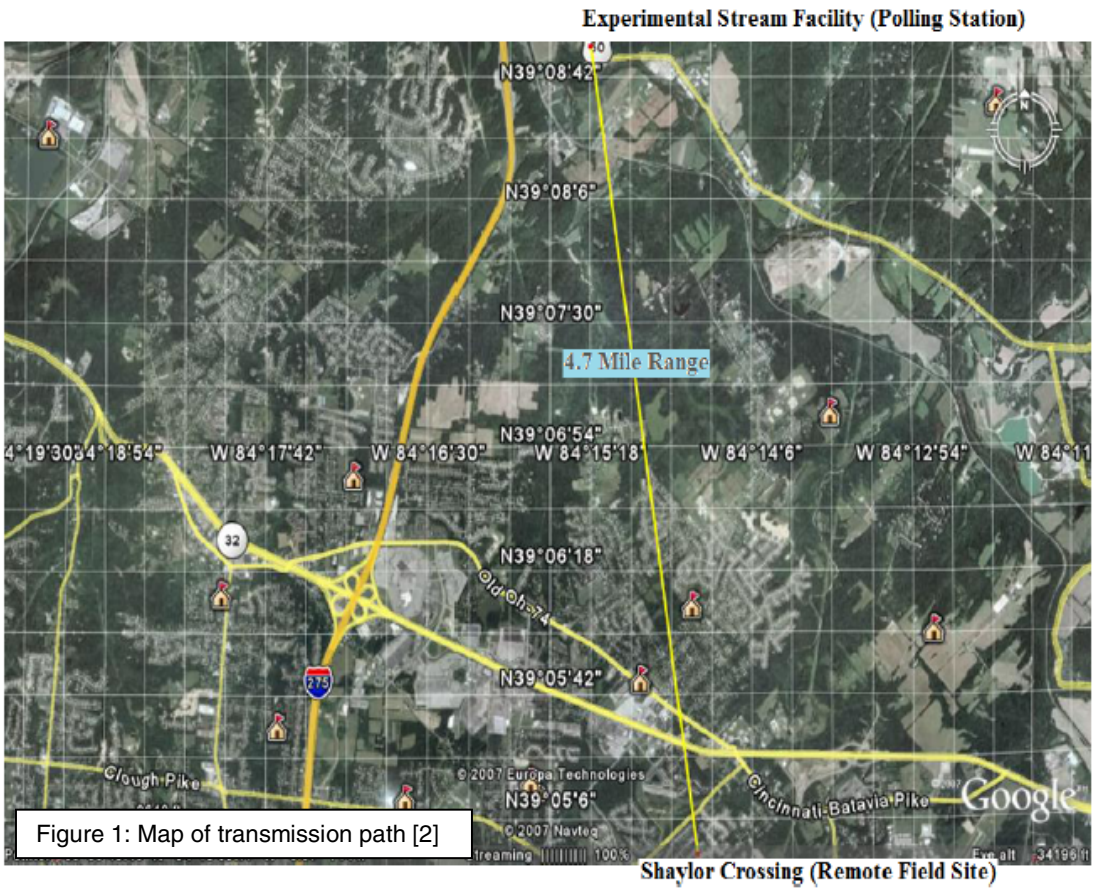

Figure 1: Map of transmission path [2]

This accomplishment is significant for several reasons; first, providing access the sonde data from the computer room means that operators would not have to travel to the site to collect it, thus saving time, vehicle costs – it is a 20 mile round trip, and reducing the risk of accidents associated with field operations [1]. Second, it eliminates the need for leased infrastructure. Third, it opens up the possibility for real time monitoring of data. Lastly, with some programming, it allows data to be collected automatically by a computer and analyzed or used as input into models.

Paul Dorsey was succeeded by Thuy Dang, who studied problems with the reliability of radio wave propagation in the system and determined that "with weak signals, the [Single Side Band

(SSB)] system will provide an intelligible signal where the FM system fails" [3]. By switching to SSB modulation, Dang reduced the system bandwidth and demonstrated performance increases over FM [3]. He also presented a MacroScheduler program that automated the data collection process.

Technical Details

Both endpoints of the system communicate using the RS232 protocol, so the equipment is selected around this. The first piece of equipment in the system is the KWM9612+ Terminal Node Controller (TNC), a modem designed to be used in a wireless environment. This device encodes the RS232 binary levels into an audio range Frequency Shift Key (FSK) signal with frequency components at 1300 and 2100 Hz. The FSK signal is input to the modulator stage of the Icom IC-746Pro radio so that it may be transmitted. The receiving station operates in reverse: the radio frequency FSK signal is brought down to audio frequencies by the receiving IC-476Pro and output to the TNC, where it is converted back to RS232 data. For intra-site communication, a Maxstream spread spectrum radio may be used when the required RS232 cable run would be too long or inconvenient. Figure 2 shows where each component fits into the larger system.

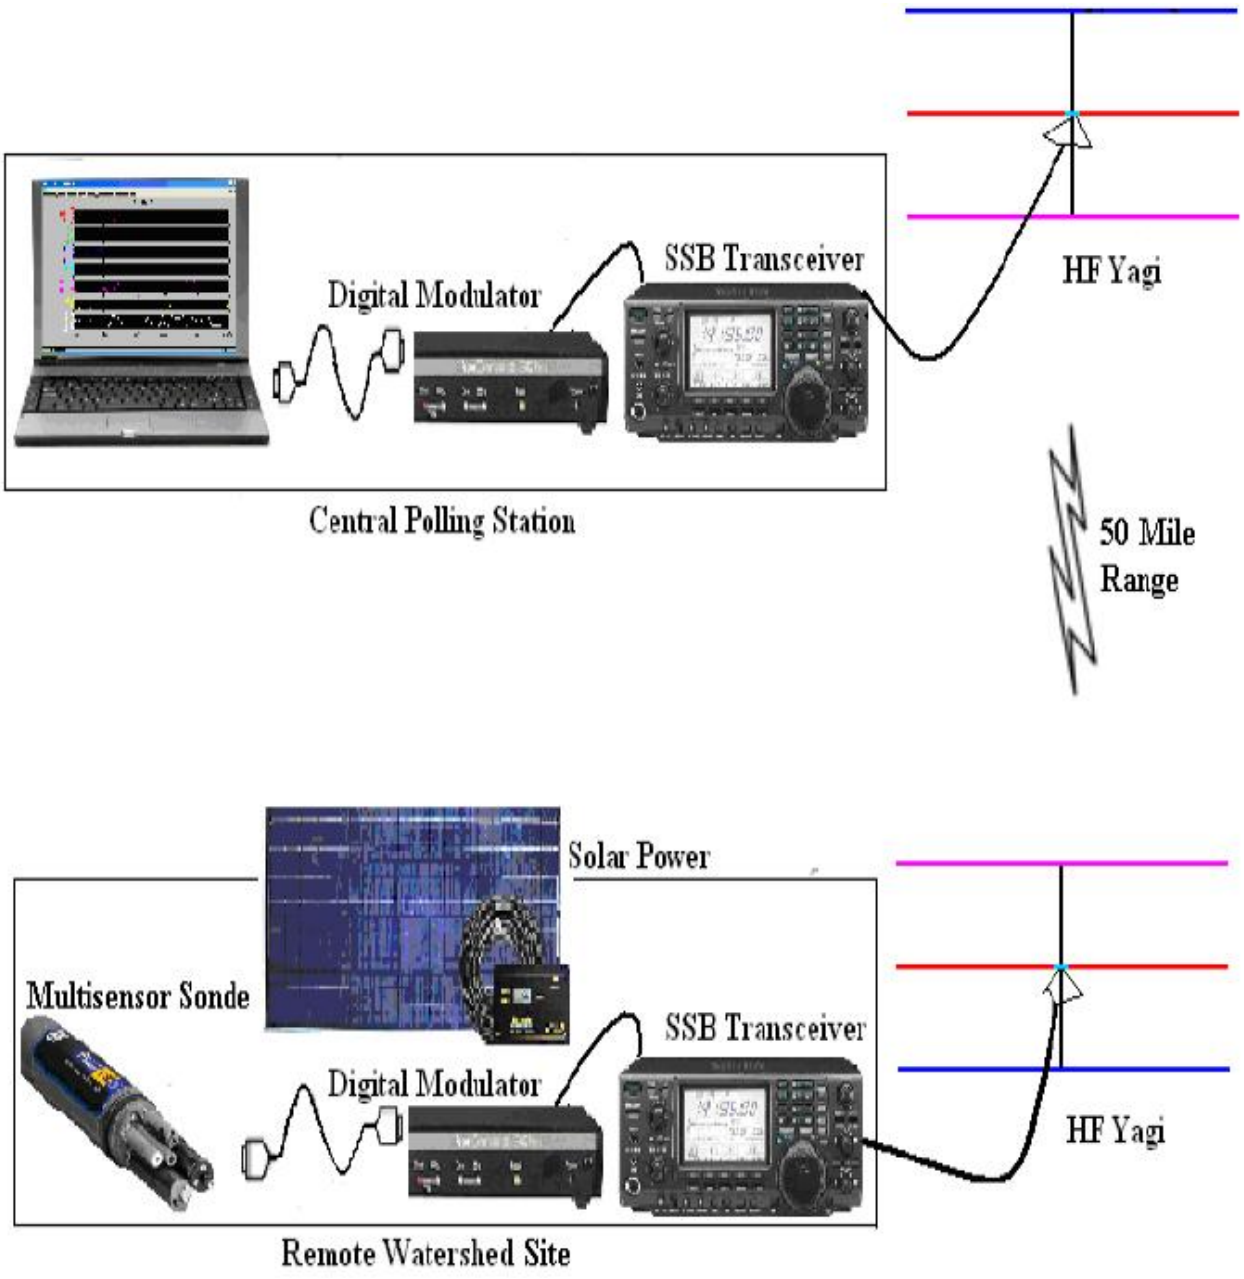

Figure 2: System Components [3]

In the original system, the TNCs are configured to use the Line Substitution (LINESUB) mode, which simply adds a start and end character to each packet before transmitting it [4]. It leaves addressing, error checking, and receipt of confirmation to the application. The TNC offers several other modes as well as support for the AX.25 packet radio standard.

Making Improvements

Reliability is the driving issue behind this set of improvements to the project. When using LINESUB mode, there is no guarantee of data accuracy; to reduce the occurrence of data corruption the baud rate had to be reduced to 300 bps, but even then, errors are fairly common. This issue is not discussed by Dorsey or Dang as the focus of their work on prototyping the radio link, however, in the configurations provided by Dang in Appendex C [3] the baud rate for transmission (HBAUD) is set to 300 bps.

Even so, the system did not work well enough to be relied upon for an unsupervised daily data transfer. The AX.25 protocol provides a CRC-16 check to ensure that data received is identical to data transmitted as well as a mechanism for retransmission when an error occurs [4]. With an error correction scheme in place, it becomes possible to increase the baud rate of the channel. The eventual goal is to reach the TNC's maximum data rate of 38400 bps, which is well over the sonde's maximum baud rate of 19200 bps, but will help to compensate for any additional overhead imposed by the AX.25 protocol.

Metrics of System Performance

Three variables are presented as good measures of system performance in this study: Power Consumption, Execution Time, and Data Integrity. The definition of these aspects of the system and the reasoning behind our interest in them is discussed in this section.

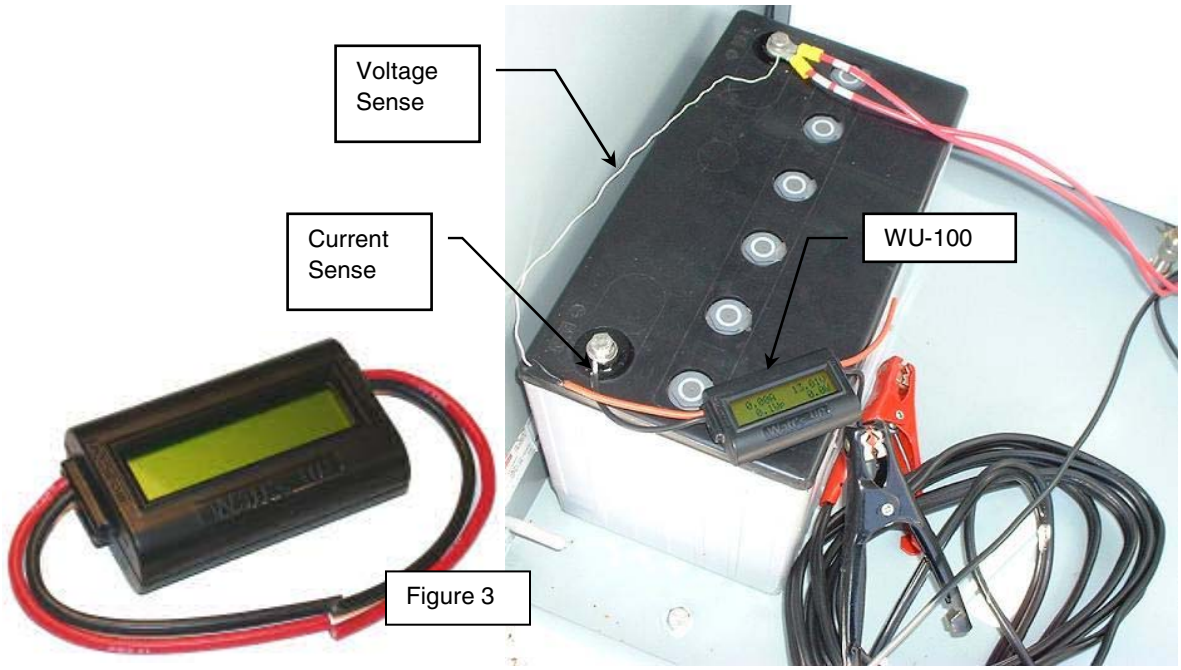
Power Consumption is crucial in a solar/battery powered system. Battery Capacity is measured in Amp-Hours (AH), but Watt-Hours (WH) present a more accurate picture of usage because they also considers the battery's voltage, which drops as its capacity is depleted and when the battery is under extreme load. For this study, both measurements are recorded, but Watt-Hours are considered the primary metric.

Execution Time affects several aspects of the system. A fast execution time means that the equipment is in operation for shorter periods of time, which will extend its useful life. It will also reduce the duty cycle of the battery, allowing it more time to charge.

Data Integrity is arguably the most important element of system performance. At best, bad data will lead to data entry problems and misleading models and trends. At worst, bad data can crash databases when unexpected control characters show up in unsterilized input. Most importantly, the system's usefulness is reduced if the data is unreliable.

Test Procedure to Determine System Performance

Three experimental variables will affect system performance over a given link: the program used to operate the system, the TNC mode (AX.25 or LINESUB), and the baud rate. To obtain an



accurate picture of how these factors affect performance, four configurations of the system have been tested with the parameters noted in Table 1. In each configuration, an identical data set of 277 measurements was retrieved, representing around 20KB of data or approximately one day's worth of samples. This test was executed 3 times for each Configuration to ensure representative sample data. The Program column shows which program was used to retrieve the sonde data; the Macro Scheduler program presented by Dang [3] or the AutoIt program that has been developed for this study. The TNC Mode column shows whether AX.25 or LINESUB mode was used in the run.

Table 1

	Program	TNC Mode	Baud
Configuration 1 (Baseline)	Macro Scheduler [3]	LINESUB	300
Configuration 2	AutoIt	LINESUB	300
Configuration 3	AutoIt	AX.25	300
Configuration 4 (Final)	AutoIt	AX.25	1200

Configuration 1 is the system demonstrated by Dang [3] and provides a baseline that can be used to measure changes in system performance; it is the control group. Configurations 2 and 3 are tested as lemmas: Configuration 2 is used to compare the performance of the programs and Configuration 3 shows that a cost is incurred by changing to a more complicated protocol. Configuration 4 tests the hypothesis that a net performance gain will occur when the baud rate is increased in spite of performance decreases in the previous Configurations.

A WU100 DC wattmeter/power analyzer, shown in Figure 3, is used to measure the power consumed by the system. When this device is installed in the system it continuously measures several variables: Source Voltage, Current, and Wattage. It also keeps track of Minimum (sag) voltage, Peak Amperage, Amp hours (current consumption), and Watt Hours (power consumption).

Left-most image courtesy of www.rc-electronics-usa.com

The two sets of leads on the WU100 are connected to the positive and negative sides of the Source and Load, though the three wire connection described later is preferred because it provides more accurate readings by removing the nominal power required by the meter from the measurement.

To install the WU100, as shown Figure 4, the negative lead to the system is disconnected from the battery and attached to the WU100 Load side negative lead. The WU100 Source side negative lead is then attached to the battery's negative terminal. This arrangement allows current to flow through the WU100's sensing element so that it may be measured. Next, the Source side positive lead from the WU100 is connected to the battery's positive terminal, allowing voltage to be measured. Note that the system is not disconnected from the battery's positive terminal and the WU100's Load side positive lead is left unconnected.

Power Test Setup

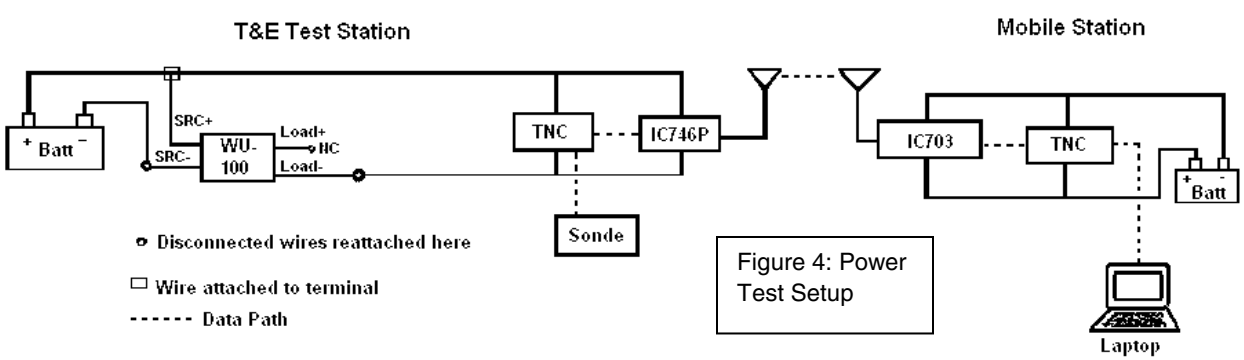


Figure 4: Power Test Setup

Execution time is determined using Microsoft's "timeit" utility available in the Windows Resource Tool Kit. The command to be timed is given to timeit as input and the elapsed time is output along with several other operating system related variables. Input and output for Configuration 2 are shown in Figure 5.

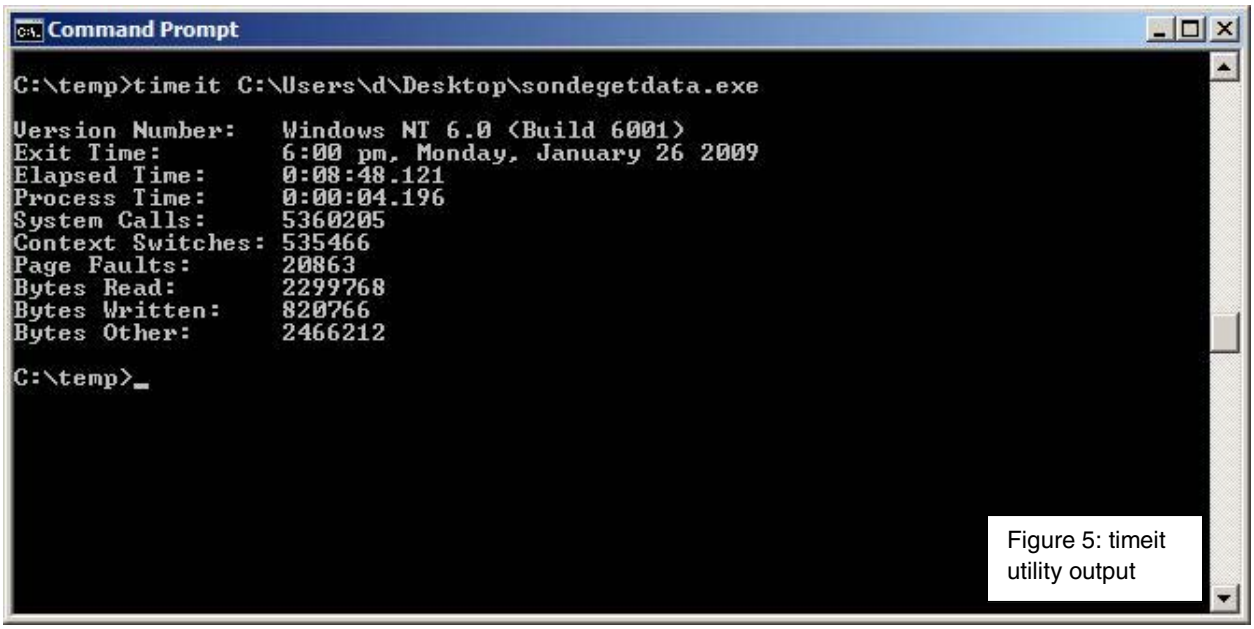

Figure 5: timeit utility output

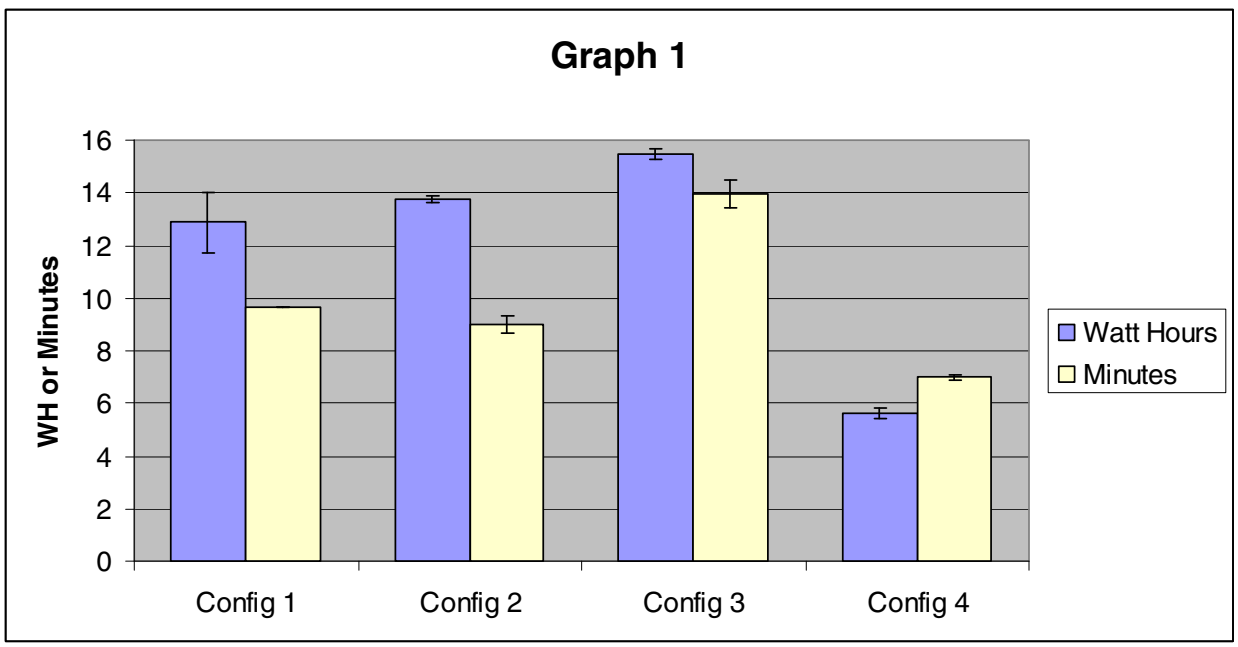

Data Integrity is paramount to this study, but measuring it is often difficult and subjective. For this test several error types are discussed in the results section and their presence or absence in the retrieved data is used to measure its quality.

Results: Power and Time

The results of the 12 metered tests are shown in Table 2 and Graph 1; note that the error bars in Graph 1 represent 2 standard deviations (95%). The values for Watt Hours, Amp Hours, and Execution Time are the mean of the data collected from the 3 test runs of each configuration.

Table 2

	Watt Hours	Standard Deviation	Amp Hours	Standard Deviation	Execution Time (mm:ss)	Standard Deviation
Configuration 1	12.9	.6	1.04	.05	9:39.160	0.196
Configuration 2	13.8	.1	1.13	.01	9:00.195	10.542
Configuration 3	15.5	.1	1.27	.01	13:57.833	15.470
Configuration 4	5.6	.1	0.45	< .01	6:59.522	2.886

Configuration 1, the system presented by Dang [3], shows very little variation in execution time. This is because MacroScheduler program performs minimal menu navigations and uses hard coded delays. Subsequent Configurations show more variability because the AutoIt program is able to determine when a transmission ends and begins the next one immediately. Configuration 2 executes in a shorter period of time for this reason; however, it uses more power because the program interacts more with the sonde's menu system, thereby sending and receiving more data. Comparing Configurations 1 and 2 shows that there is a power cost incurred by using a more complex program, but a savings in execution time has already been realized.

Appreciable degradation in both Power Consumption and Execution Time occur when the AX.25 protocol is implemented in Configuration 3. Additional power is used because transmitted data also includes meta-data required by the protocol and the TNCs are now required to make further transmissions for handshaking and packet acknowledgement. The AutoIt program must impose additionally delays when recognizing the end of a transmission as it now receives data in large packets instead of one byte at a time. This results in long Execution Times. However, the system now quite robust: it can detect errors in data, request that a bad packet be retransmitted, and it can interpret responses from the sonde.

In Configuration 4, the benefits of the added robustness are realized when the baud rate is increased. The higher baud rate means that it takes less airtime to transmit the same amount of data, resulting in savings in both power and time. The system consumes substantially less power: less than half of the power used by Configuration 1 and slightly more than a third of the power in Configuration 3. Execution Time has also been cut in half from Configuration 3.

Results: Data Integrity

Table 3 shows the types of problems encountered in the system presented by Dang [3]: Bit Errors, Sync Error Output, Missing Headers, and Incomplete Transfers. Figure 6 shows typical data integrity errors that occur during transmission. The red circles show where bit errors that occurred during transmission caused a space character (0x20) to become an “&” (0x26) and a “5” (0x35) to become a “-” (0x2D). It can also be seen that a synchronization error occurred near the end of the data transfer and caused the rest of the data to become non-printable characters (Sync Error Output). Runs 1 and 2 are also both missing the data header as well as some data (Missing Header error); an example of this error is shown in Figure 7.

Table 3

	Bit Errors	Sync Error Output	Missing Header	Incomplete Transfer
Configuration 1	Yes	Yes	Yes	Yes
Configuration 2	Yes	Not Displayed	Yes	Yes
Configuration 3	No	No	No	Yes
Configuration 4	No	No	No	Yes

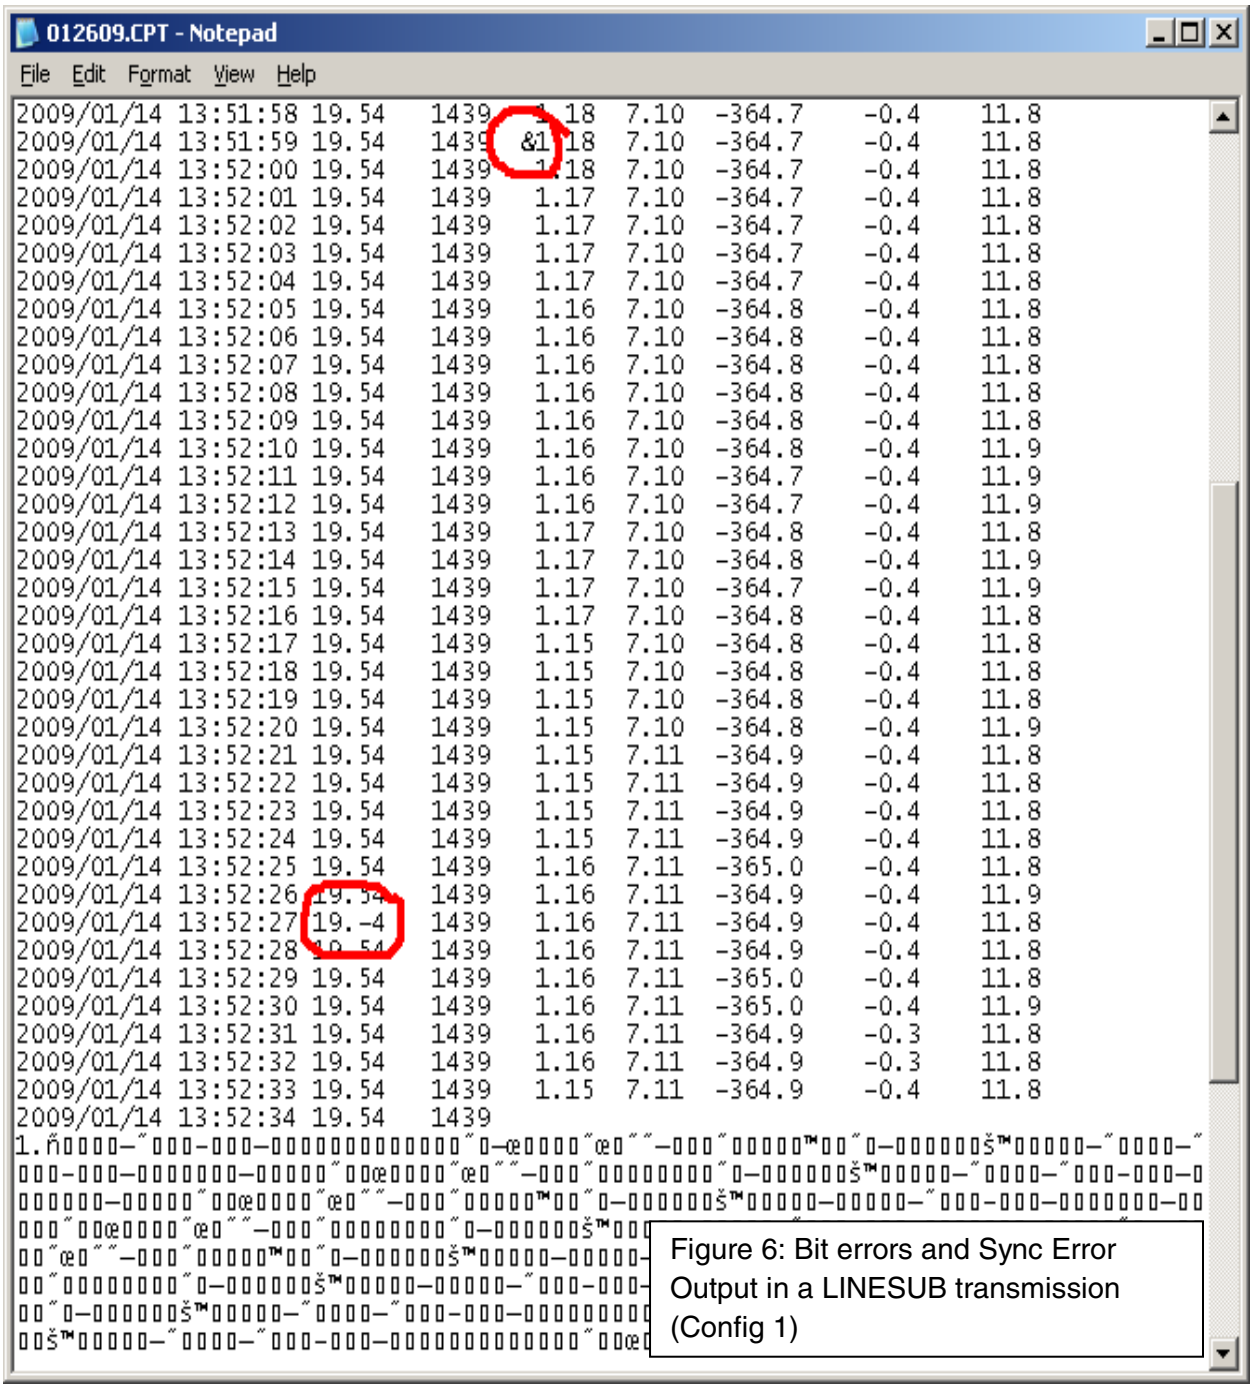

Figure 6: Bit errors and Sync Error Output in a LINESUB transmission (Config 1)

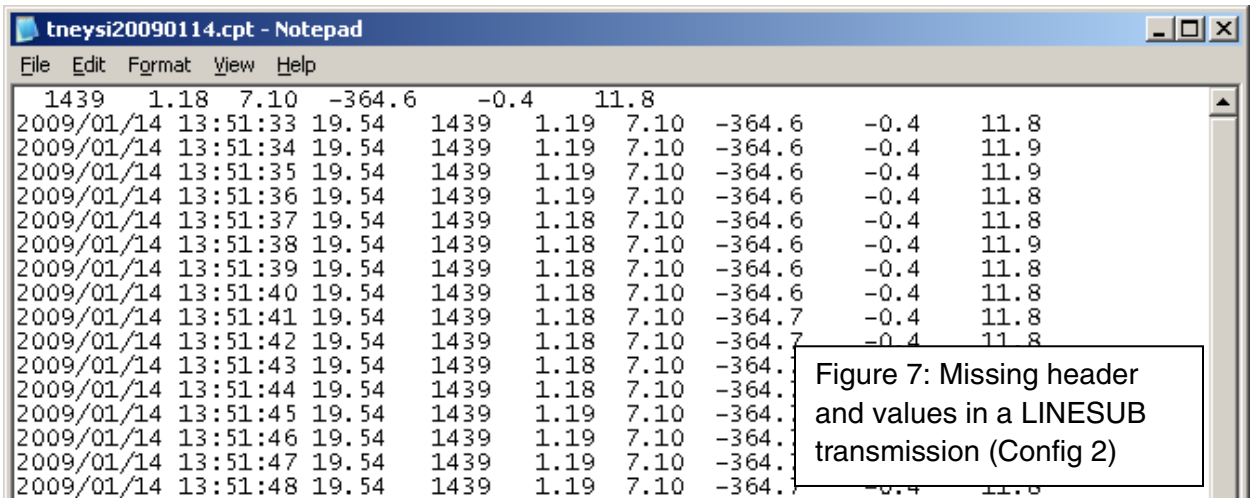

Figure 7: Missing header and values in a LINESUB transmission (Config 2)

It can be seen from Table 3 that switching to the AX.25 protocol (Configurations 3 and 4) eliminated the problems of Bit Errors and Missing Headers. The issue of Sync Error Output is more complex: the ComDebug application is used by AutoIt to communicate with the serial port in Configurations 2-4, while the EcoWatch application is used by MacroScheduler in Configuration 1. The ComDebug application used in Configurations 2-4 may not actually display the Sync Error Output. While this does remove the symptom, it does not solve the problem. However, Configurations 3 and 4 use packetized data with a CRC to ensure the integrity of the content; any packet containing erroneous non-printable characters would be dropped by the receiving TNC and retransmitted, which would prevent this type of error rather than obscuring it. Moreover, there is no reason that changing the supervisory program, the only difference between Configuration 1 and Configuration 2 (refer to Table 1), should prevent a Sync Error Output Error – especially since Configuration 1 exhibited this type of error.

This leaves the question of the Incomplete Transfers. An interesting phenomenon occurs in the in Configurations 3 and 4: all 3 runs of each Configuration produced files that were exactly the same length; Figure 8 shows that Configuration 3 yields files that are all 4356 bytes in size, while Configuration 4 results in files of exactly 7044 bytes. This suggests that the transmissions terminate predictably after the same number of bytes.

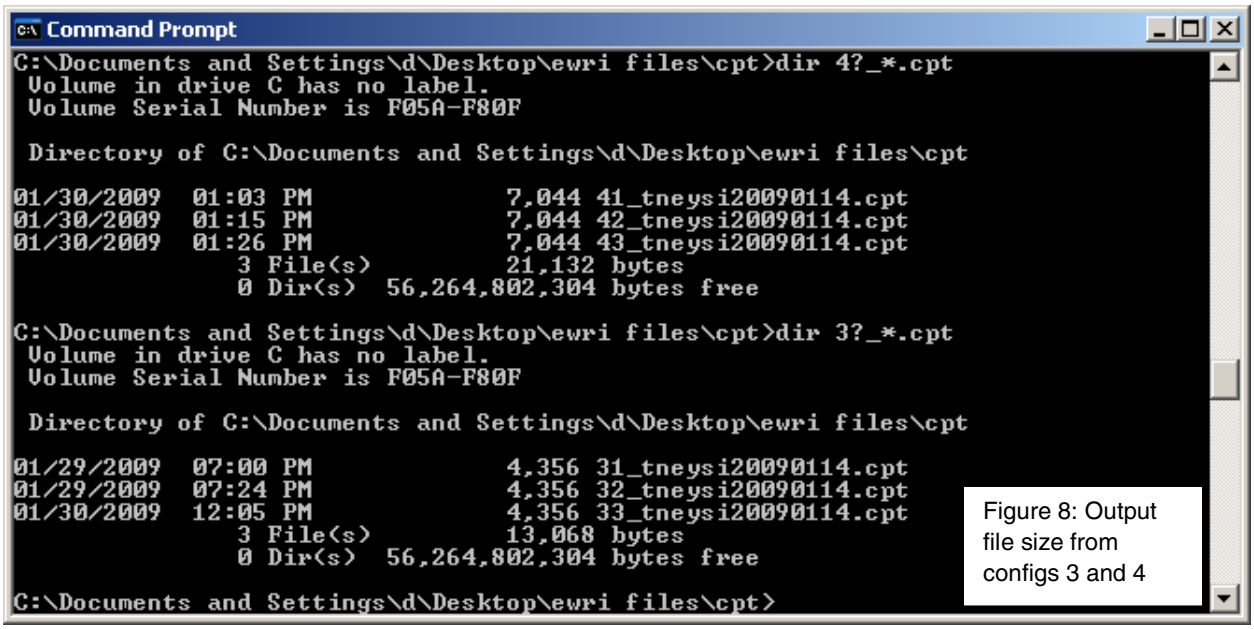

Figure 8: Output file size from configs 3 and 4

A possible explanation for this phenomenon could be that data is bottlenecking into the transferring TNC's receive buffer. The sonde is currently configured to expect a data rate of 9600 bps, which matches up with the 9600 bps setting on the digital side of the TNC (ABAUD setting). However, the modulated side of the TNC was set to either 300 bps or 1200 bps (HBAUD setting) for radio transmission. This creates a situation where the TNC is receiving data to send faster than it can send it, which may be causing either the sonde or the TNC to run out of buffer space and lose unsent data. Further testing is required to validate this hypothesis.

Recommendations

This study has shown that it is possible to attain substantial power and time savings while eliminating several types of transmission errors by adjusting system components for robustness and increasing the baud rate. The next step is to increase the baud rate further in order to realize even greater performance gains. The KWM9612+ TNC has a high speed port that allows baud rates in the range of 4800-38400 bps. Ideally, data could be retrieved hourly (or even more frequently) if the Execution Time and Power Consumption can be reduced far enough. Unfortunately, preliminary attempts to interface this port to the IC746Pro radio have been unsuccessful, but effort will continue in this area.

The issue of Incomplete File Transfers merits further investigation. It is possible that some research into the baud rate and flow control between the systems may yield a solution to this problem. Failing that, data can be retrieved in several smaller transfers instead of one large transfer.

Implementing the AX.25 protocol allows the system to take advantage of several features offered by the KWM9612+ TNC. The TNC offers remote access, repeating, and routing capabilities and all of these deserve consideration. Remote access allows an authorized user to change settings on a remote TNC; this is a useful capability for a central station to have and has been used extensively during testing. Repeating allows a station to pass along a message from another station. Some testing of the repeating capabilities of the TNCs has taken place, but how this capability can be applied for a topological advantage should be given consideration; astute placement of equipment may allow one station to monitor several sites instead of having one station per site. The TNC offers routing and networking features as well, which will become invaluable as the system expands from several stations to potentially several hundred or more.

Caveats

In practice, no test can be perfectly representative of any system and the procedures presented in this study are no exception, though every effort has been taken to assure that they are as accurate as possible. This section is provided for the sake of full disclosure and describes the shortcomings of the study.

The Autoit and MacroScheduler programs have both been modified so that they do not delete the dataset after they have saved it. This assures that each Run is conducted against the exact same data. However, it does mean that each program executes a few less commands and therefore runs shorter and consumes less power. This is mitigated by the fact that the data transfer is the biggest power consumer and takes the longest.

In the field, a pair of Maxstream XTend short range transceivers are used to send data between the sonde and the equipment cabinet. They have been excluded from this study because they are not part of the HF radio link; in practice they consume very little power (1W compared to the ICOM's 100W) and function at a very high baud rate, so their impact is likely negligible.

A smaller 33 AH battery had to be used instead of the normal 93 AH battery. This battery is not capable of sourcing as much current as the 93 AH unit. As a result, the power level of the IC-746Pro was reduced from the 100W used in the field to a level that the battery was able to handle by means of the RF Gain knob. Every effort was made to use the maximum possible transmission power at which the data could be intelligibly transmitted, in order to replicate field conditions.

The test was conducted between the station at The Test and Evaluation Facility and a mobile station in my car. Because walking between the station and my car takes time and the equipment is left running, the power consumed by the idle equipment appears in the metered results. To compensate, I timed 2 minutes on my Timex Atlantis wristwatch between resetting the power meter and executing the program and 2 minutes between the end of execution and the final reading. Thus, each metered result included 4 minutes of idle time. The idle equipment consumes 8.0 WH or .648 AH over the course of 20 minutes, which is divided by 5 to obtain a 4 minute average of 1.6 WH or .127 AH. The calculated 4 minute average was subtracted from each test result prior to calculating the mean and standard deviation values shown in the results section. This does not affect the measurement of execution time, which is the exact time the process was running as recorded by the timeit utility on the computer.

ABSTRACT

Recent advances in web technologies, such as those used by Google Maps (http://maps.google.com), have facilitated the development of more interactive geospatial mapping technologies. The technology behind these mapping tools is known as Asynchronous JavaScript and XML (AJAX), which is aimed at more stable functionality, fast interactivity between servers and clients, and cost-effective data exchanges between the servers behind the scenes. Although Google Maps takes full advantage of this recent technology, there are still many restrictions in terms of customization, source modification, and licensing issues. We propose to use ka-Map (http://ka-map.maptools.org/), which is a very powerful tool for customizing user components such as graphical user interfaces (GUI). Ka-Map can be coupled with MapServer (http://mapserver.gis.umn.edu/), which was developed at the University of Minnesota. Since both ka-Map and MapServer are open source web-mapping technologies that are compliant with Open Geospatial Consortium (OGC) standards, application of these tools for water resources management is of great interest.

INTRODUCTION

A geographic information system (GIS) provides a spatial framework to support decisions for the intelligent use of water resources. These days, applications of GIS are crucial in the sense that many water-related issues and man-made environmental problems can be analyzed and resolved through geospatial data analysis. For instance, many wise environmental decisions, such as how best to manage water resources in regional watersheds, involves geography and advanced geospatial web mapping to better disseminate information, manage resources, and respond to emergencies caused by extreme hydrologic events (e.g. flood and drought) and other cases (e.g. water-borne disease).

Many studies have been done to better manage water resources using GIS technologies from spatial analysis in modeling framework to web-based visualization over the internet (ESRI 2009). Web-based GIS applications, in particular, have grown

substantially over the past few decades. Thanks to advanced computer technologies and enriched GIS datasets, the field of geographic information continues to grow.

Web application platforms such as Google Maps/Earth are showing seamless performance by providing interactive maps to communicate our everyday activities around the world. These tools and technologies help us to improve our understanding of the environment, natural disasters, geopolitical complications, human activities and changes in natural resources. For hydrologic database management applications, the Consortium of Universities for the Advancement of Hydrologic Science, Inc. (CAUAHSI- http://www.cuahsi.org/) Hydrologic Information System (HIS) project has been initiated to facilitate data accessibility and visualize geographically distributed hydrologic data sources through the universities' alliances. The goal of CAUAHSI-HIS is to bring all water resource data, including precipitation, streamflow, water quality, and ground water levels together into a service-oriented architecture through "web services", known as specialized machine-to-machine communications via internet protocols (Maidment 2008). Such efforts are extremely important in providing seamless service for the widest variety of water data available to the research community and public domains. Hydrologic ontology defined in geospatial databases can be utilized to translate water observations data from various formats (e.g. text, excel, binary) into a single format compatible with an internet friendly hierarchical data structure (e.g. eXtensible Markup Language (XML)) that can be stored effectively (Maidment 2008). The water data discovery and acquisition system, called HydroSeek (http://www.hydroseek.org), is a good example of a geospatial database available on the internet.

In this paper, we propose to use ka-Map to visualize hydrologic drought information across the country. One major advantage of this tool is that all analysis output and dynamic maps of hydrologic information through data processing can be displayed efficiently on the web through an OpenGIS framework. Additionally, many different image formats of the maps (as users create them on their web browsers) are made available, including png, gif, tiff, and pdf formats Such visualization and customized maps are very useful for integrating and assimilating environmental datasets into digital watersheds along with other real-time data collections, including satellite-based remote sensing and/or automated wireless data networks. Additionally, local decision makers responsible for hydrologic event response plans and management can easily identify the spatial extent of areas vulnerable to upcoming hydrologic events, especially drought.

DATA ASSIMILATION

The United States Geological Survey (USGS) maintains 1,659 unregulated gauge stations, known as the Hydro-Climatic Data Network (HCDN) across the country to provide naturalized streamflow data for research activities related to climate change and other subjects (http://pubs.usgs.gov/wri/wri934076/1st_page.html). Records of unregulated streamflow (i.e., natural streamflow, as opposed to streams with upstream diversions or dam operations) are important in understanding the effects of hydrologic drought on regional water resources. A total of 1,009 unregulated gauge stations, a subset of 1,659 stations, were utilized for this study to visualize hydrologic drought information across the country. Selection criteria for streamflow gauge stations and data assimilation processes were determined based on a data quality assurance test. First, daily streamflow

data was downloaded from the USGS website (http://waterdata.usgs.gov/nwis/sw). Time horizons of the daily streamflow data was taken from as early as 1845 to the year 2005 and saved in text format, and then additional test was conducted to maintain data integrity. For instance, some stations that had duplicate records of streamflow within several unnecessary columns and whole segments of data missing were eliminated.

VISUALIZATION TECHNOLOGY

Open source based web-mapping platforms such as MapServer are commonly used by many water scientists wanting to publish maps online. Although MapServer is well suited for interactive web-mapping, MapServer alone is not able to accomplish a set of advanced actions such as enhancing robust and stable interactions between servers and clients. AJAX supports the functions of MapServer and is based on open standards, which means this technology is less dependent on any established or specific operating system and/or commercial software. The main advantage of AJAX is that it is very fast and reduces the time spent in (processing time) redrawing dynamic maps requested by the client within a web browser. AJAX accomplishes faster data processing by manipulating data via specific requests (e.g., event handling) rather than reading the entire page on the web. This high-speed mapping technology drives developers to integrate AJAX applications into web services. Figure 1 represents an integrated system of dynamic mapping technology within an open-source platform, including MapServer, geospatial database, and ka-map utilizing AJAX technology.

MapServer

Mapserver, an open source development environment, is widely used to implement web-based GIS solutions around the world since it was originally developed at the University of Minnesota (UMN) in collaboration with the National Aeronautics and Space Administration (NASA) and the Minnesota Department of Natural Resources (MNDNR). Although MapServer is not a full-featured GIS system, MapServer can visualize various formats of GIS data (e.g., images, raster, and vector data) through an internet gateway. Additionally, MapServer allows users to create and manage map files, which characterize individual map layers including data source, legend, scale, and metadata. In this project, MapServer will be enhanced to produce integrated maps along with drought prediction outputs as follows. First, all metadata will be customized to help the end users. A customization of metadata will help reduce the time required for map caching as it predefines analysis settings such as the queryable field, hyperlink information, color setting, and layer description. Second, the system should be able to operate conjunctively with the geospatial database to provide reliable web services in terms of time and quality. These components will enhance the dynamic mapping system through GIS technology, and help local decision makers identify the spatial extents of potential droughts via customized views.

Geospatial Database, PostGIS

A reliable geospatial database is another important key element in accomplishing the goals of this project. PostGIS (http://postgis.refractions.net/) is a tool used to support geographic objects within PostgreSQL (http://www.postgresql.org/), a powerful open-source relational database system. PostGIS enables the PostgreSQL server to be used as a

backend spatial database for geographic information systems (GIS), such as ESRI's ArcSDE and Oracle's spatial extension. PostGIS is also developed in an open-source environment so that it complies with Open-Source Geospatial Consortium (OGC) standards. Currently, PostGIS supports various geospatial data formats as well as data validations associated with geological coordinate systems. PostGIS can be used by implementing SQL routines to visualize the results via MapServer so that the interactive dynamic maps will be made available much faster over high-speed broadband internet connections.

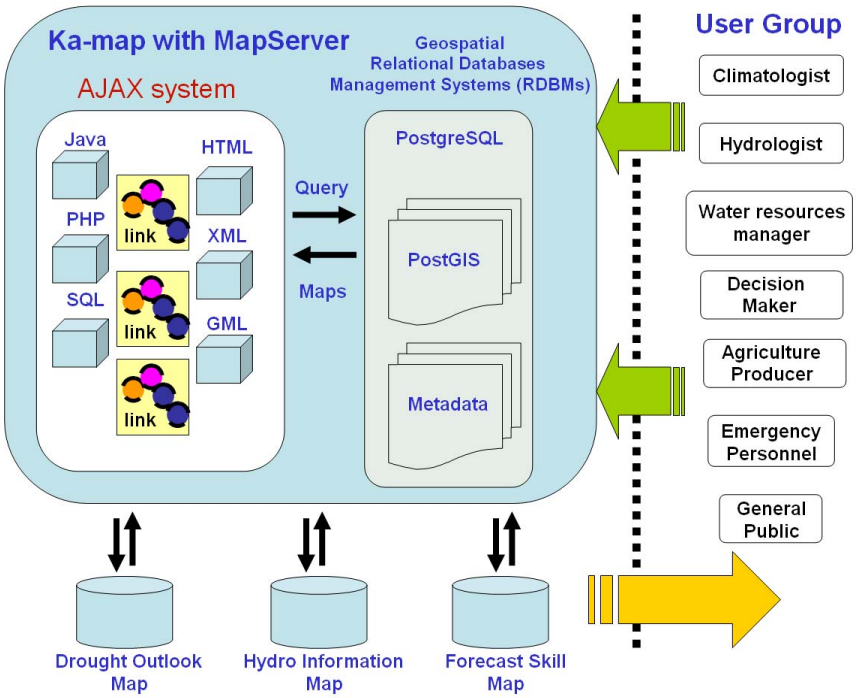

Figure 1. Integrating MapServer into ka-map utilizing AJAX technology

Ka-Map with AJAX technology

As an open source package, ka-Map will also be integrated with MapServer. Normally, a map is created by MapServer through map files (e.g., mymapfile.map) and then is made available on the web in cached form through ka-Map. Basic processing of these integrations is conducted through a simple cycle. MapServer is in charge of creating maps, and it waits for requests from users via a graphic user interface (GUI) in ka-Map. When a request is initiated by the user, both MapServer and ka-Map work together to generate and present new maps on the web. But when many duplicate requests are presented, only ka-Map is working on caching and redrawing the maps; MapServer sits idle and waits for the next batch of new calls. Traditionally, this process is done by a series of subsequent protocols including mouse clicks and/or zooming in, and then waiting for the entire map image, and waiting again for the web browser to publish maps, whereas the integration with ka-Map splits maps into several pieces when first requested and stores them on the server, then retrieves the map later for the user. This simplified cycle leverages system enhancements by improving the performance of the web browsers. Moreover, AJAX technologies facilitate the level of interactivity between servers and

clients, pre-rendering by caching the tile images stored in the server, and saving time by accelerating smooth panning and zooming.

DEMONSTRATION

For testing and demonstration purposes, we developed a mock-up to visualize raw geographic data (e.g. vector, raster, and coverage) on web-based GIS services (Web Service). Advantages of this service provide interactive communication tools between Web Service and end-users that require customizing geophysics applications. Figure 2 and Figure 3 show the main page of the mock-up and a sample of client's web service request, respectively. For instance, users can request the map for the area of interest to identify USGS gauge stations for further information. The graphical user interface (GUI) main page shown in Figure 2 allows the user to change the map sizes from the drop-down lists or enables them to zoom in or zoom out by clicking zooming tools built in ka-Map.

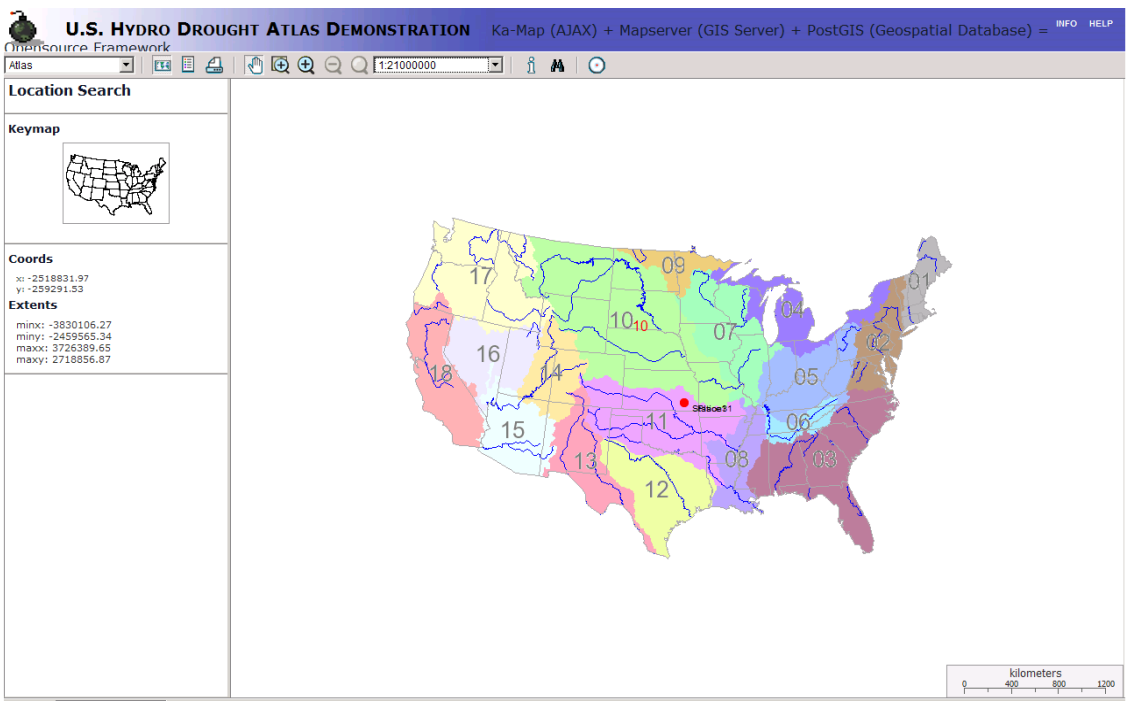

Figure 2: Main page with web-based GIS services. The color ramp in the main frame represents a total of 18 watersheds in the conterminous U.S.

The red circle on the left panel in Figure 3 indicates that the user has identified two USGS streamflow gage stations for further investigation.

Future Work

We created a mock-up of a web-based GIS service for data visualization to end-users using state-of-the-art geospatial mapping technologies, including AJAX and PostGIS. All these services comply with OGC standards so that many potential deployments to multi-disciplinary research activities are expected. The initial development activity is part of the first stage of an ongoing U.S. Drought Atlas project underway at the National Drought Mitigation Center (NDMC). A number of

improvements and enhancements are needed to pursue seamless Web Services for NDMC clientele. These activities may include: 1) stabilizing robust web service architecture in combination with geospatial database, PostGIS, to manage high volumes of geospatial datasets (e.g. raster, satellite images); 2) integrating current Web Services with other services, such as Web Map Service (WMS 2009) and Web Feature Service (WFS 2009); and 3) improving the GUI to better communicate and understand service availability and accessibility for advanced users, and seeking further information (e.g. metadata) for their research interests.

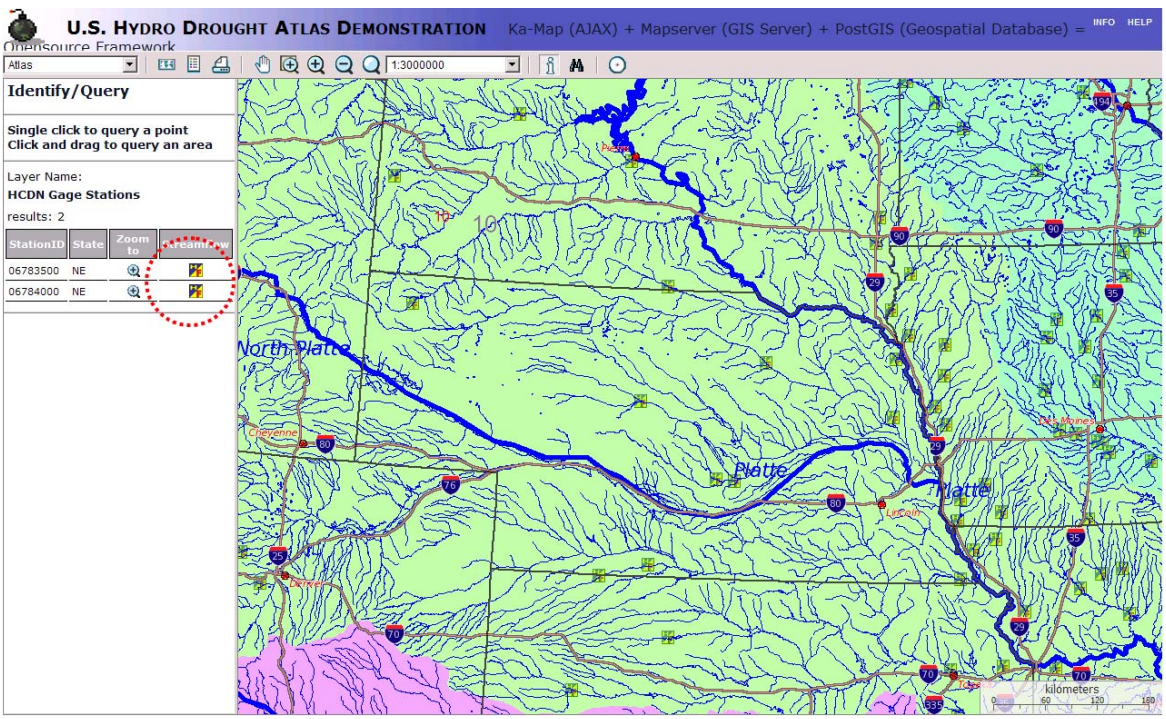

Figure 3: Web Services are customized for the client's view.

Abstract

Sewer hydraulic models are developed to reveal and simulate problem areas in sewer system networks. During model development precipitation input data, typically from rain gages, are applied and system parameters are adjusted until the calibrated model output matches the collected system flow meter data. The calibrated model is later used to evaluate problem areas and identify solutions to the system's deficiencies in order to comply with regulatory requirements, which are met by eliminating surcharge and overflow locations within the sewer system.

Calibration of the sewer system is only as accurate as its input rain data, so it should be a priority to use the best rain data attainable. While rain gages can be accurate and precise, they can only provide data at discrete points, resulting in low spatial resolution and ambiguity regarding how much rain has fallen in between gages. Installing denser networks of rain gages can help improve the spatial resolution of the gage data, but is expensive in terms of equipment fees, installation, and maintenance. For this reason, the City of Atlanta initiated a pilot program which uses a technique called Gage-Adjusted Radar Rainfall (GARR). GARR datasets are produced by taking regional NEXRAD radar data and calibrating them with co-located rain gages. GARR combines the high spatial and temporal resolution of radar with the volumetric accuracy of rain gages.

The study compared the hydraulic models that were developed using a GARR dataset, and a dataset consisting of rain gages only. Both datasets used information from 30 "tipping-bucket" rain gages from March 2001. The GARR analysis incorporated NEXRAD radar data on a 2x2 km grid, with a 15-minute sample rate. Correlations between the two precipitation measurement systems were strong. Rainfall timing was well matched. Incorporating the gage volumes resulted in lowering the radar rainfall estimated by 20%. The sewer hydraulic modeling results showed that the Flow (Q), Velocity (V) and Depth (d) response to the flow meter data matched more closely when GARR data is used as compared to the conventional rain gage data.

Because rainfall is the input variable with the largest impact on modeling sewer systems, it is also essential information for determining rehabilitation efforts and system upsizing. By using the GARR process to enhance real time rainfall data, the City of Atlanta will create more accurate models, attain a better representation of

storm frequency, intensity, duration, and improve future forecasting capabilities. Using GARR techniques will achieve a more accurate hydraulic sewer model, and better quantify inflows from storm events and their impacts on the system.

Introduction

Prior to 1915, the 19 square miles that comprised the City of Atlanta, and what is now the core downtown area, utilized a combined sewer system. As the City grew to its present total area of 132 square miles, the trend changed to a separate storm and sanitary collection system. The First Amended Consent Decree (FACD) imposed on the City of Atlanta since 1999 mandates the elimination of all unpermitted discharges and sanitary sewer overflows to achieve compliance with National Pollutant Discharge Elimination System (NPDES) permits. To accomplish this goal a Rainfall and Flow monitoring Plan were initiated to identify excessive infiltration and Inflow and to quantify peak flow factors for the macro system (Interceptor and Trunk) in a sanitary sewer model that would evolve through the years to include the micro system which will include outfalls and its tributaries. The model was deemed essential to assist in the development of operational procedures that may optimize system capacity, as well as to evaluate the impact of proposed system improvements. The rainfall plan is comprised of 32 rain gages operated by a consultant at strategic locations throughout the 10 city sewer basins, and an additional 16 rain gages operated by the City of Atlanta at Wastewater Treatment Facilities (WWTF) and Combined Sewer Overflow (CSO) facilities. The strength of a rain gage network is its ability to consistently estimate rain falling on a number of discrete points. Its weakness is the network's inability to estimate rain falling between the gages. Sewer hydraulic models are developed to reveal and simulate problem areas in sewer system networks. During model development precipitation input data, typically from rain gages, are applied and system parameters are adjusted until the calibrated model output matches the collected system flow meter data. The calibrated model is later used to evaluate problem areas and identify solutions to the system's deficiencies in order to comply with regulatory requirements, which are met by eliminating surcharge and overflow locations within the sewer system.

One of the main input data for a good calibrated model is rain data, so it should be a priority to use the best rain data attainable. While rain gages can be accurate and precise, they can only provide data at discrete points, resulting in low spatial resolution and ambiguity regarding how much rain has fallen in between gages. Installing denser networks of rain gages can help improve the spatial resolution of the gage data, but is expensive in terms of equipment fees, installation, and maintenance. For this reason, the City of Atlanta initiated a pilot program which uses a technique called Gage-Adjusted Radar Rainfall (GARR). GARR datasets are produced by taking regional NEXRAD radar data and calibrating them with co-located rain gages. GARR combines the high spatial and temporal resolution of radar with the volumetric accuracy of rain gages.

The study compared the hydraulic models output from March 3 2001 storm that were developed using a GARR dataset, and a dataset consisting of rain gages only.

Background

Currently, the City is served by approximately 1900 miles of sewer mains (15% combined and 85% separated). All sewage flow within the City is treated by three wastewater treatment facilities, to serve a population of 1.6 million approximately with a total average daily flow of 182 MGD. In addition to the flow produced within the City, there are six adjoining jurisdictions contributing flow to the City of Atlanta sewer system that comprise 45% of the total flow.

The City of Atlanta is divided into 260 sewersheds that join to form ten sewer basins. As defined by the First Amended Consent Decree (FACD) a Sewer basin contains all portions of the wastewater collection and transmission systems tributary to a trunk sewer entering a WWTP. The following ten sewer basins are separate from each other, but some of them are hydraulically-linked at the treatment plant: 1) Camp Creek (CMC); 2) Intrenchment Creek (INC); 3) Long Island (LIC); 4) Nancy Creek (NCR); 5) Peachtree Creek (PTC); 6) Proctor Creek (PRC); 7) Sandy Creek (SDC); 8) South River (SRV); 9) Sugar Creek (SGC) and 10) Utoy Creek (UTC).

Consent Decree Root

The FACD mandates the elimination of all unpermitted discharges and sanitary sewer overflows to achieve compliance with NPDES permits. This is accomplished through a number of plans under sections VIII.C.1, VIII.C.2. and VII.B.8.D of the FACD.

One plan is the System-wide Flow and Rainfall Monitoring Plan whose purpose is identifying excessive infiltration and inflow (I/I), quantifying peak flow factors, establishing sewer group priorities, and serves as a data source for hydraulic and hydrologic modeling. The City has submitted this plan to EPA/ GA EPD (Environmental Protection Division.)

To fulfill the requirements of the FACD, ADS Environmental Services was contracted in 1999 to install and maintain flow meters and rain gages, process and analyze the meter data and prepare monthly reports. Thirty-two 32 rain gages (tipping bucket) were installed throughout the City to provide a comprehensive network for establishing a rainfall record. Originally the selection of the preliminary rain gage locations uses a “circle of influence” methodology. Most rain gages are located at existing City owned /operated facilities such as libraries, fire stations, public schools, police stations, etc. These locations provide several favorable items such as ease of access, security, ease of connection to existing telephone lines and proximity to proposed flow monitoring locations.

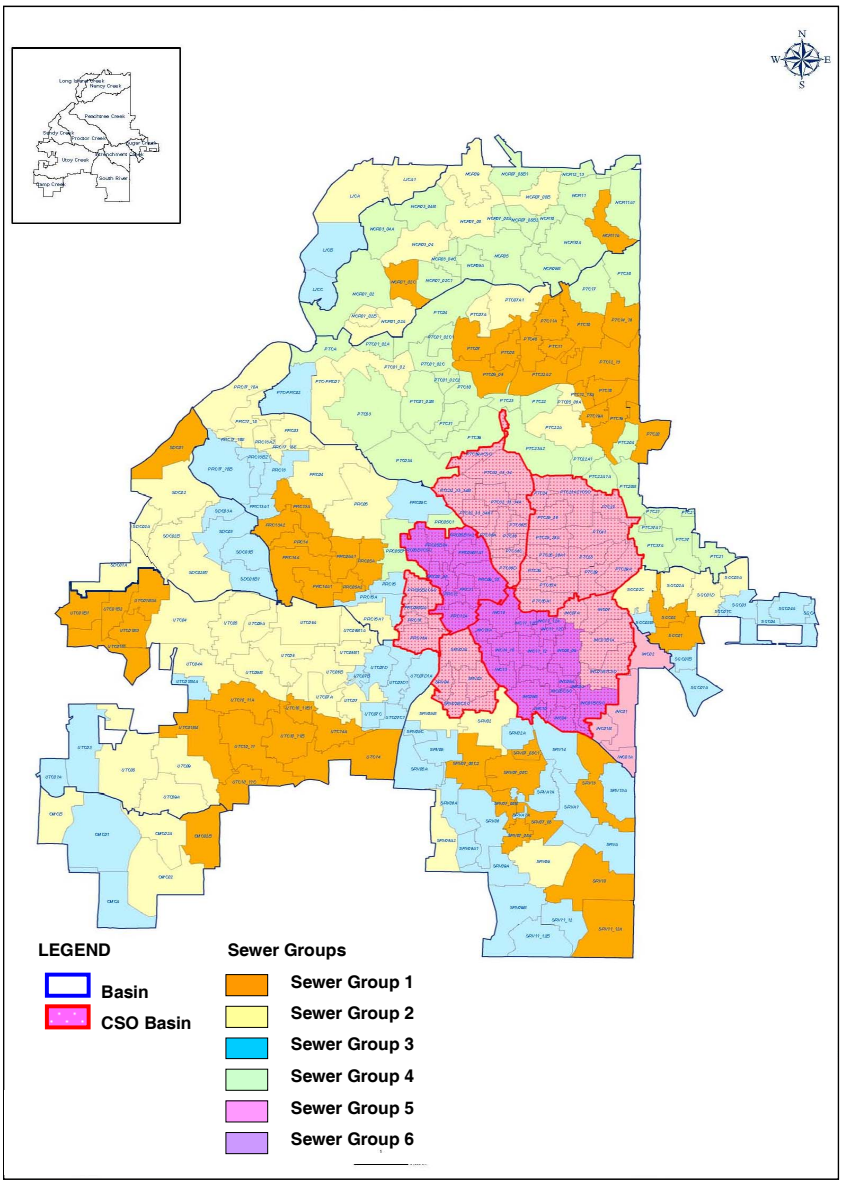

Figure 1. Prioritization plan by sewer groups.

The need for a comprehensive hydraulic model was realized early in the consent decree process through the requirement of a System-wide Hydraulic Modeling Plan. The model was deemed essential to assist in the development of operational procedures that may optimize system capacity, as well as to evaluate the impact of proposed system improvements. This plan is responsible for selecting the modeling software to be used and establishing the modeling approach, data verification, calibration methodology, performance and overall sensitivity. Infoworks CS (IWCS) is the current modeling software that the city uses.

As with other modeling software packages, IWCS dynamically simulates the flow within a sewer system by iteratively calculating flows in each pipe segment until it

converges on a solution at a predetermined tolerance such as (0.01 MGD) for flow and (0.01 ft.) for Depth. As all models, it is heavily dependant on the physical characteristics of the system including pipe diameter, length and slope, network connectivity, manhole coordinates, inverts and ground elevations, as well as sewer facility configuration such as Wastewater Treatment Plant, CSO facilities and Pump stations.

Modeling Approach

Due to the immediate need for a hydraulic model, the City's modeling approach consisted of a three step process to obtain the physical asset data. Initially, in 2000, a macro model was built for only the large trunk and interceptor sewers (i.e. greater than 24-inch in diameter). This basic model provided the City with an initial capacity assessment of the system. Following that over the next four years, one sewer group per year and all major outfalls (greater than 12-inch diameter) were added as defined in the Prioritization Plan. The criteria for the initial prioritization of the Sewer Groups took account of ten items that related to:

1) Frequency of Overflows,
2) Severity of Rainfall Dependent Infiltration/Inflow (RDI/I),
3) Risk to Surface Waters (Creeks),
4) Impact Failure,
5) Status of Ongoing Rehabilitation or Renewal,
6) Available Capacity in Sewers,
7) Judgment of Sewer Operation & Maintenance Division,
8) Relative Impact of RDI/I from Jurisdiction Outside the City's Control,
9) Proposed Development Intensity and
10) Location of Sewer Within the Combined System as shown in Figure 2.

Lastly, all sewer lines 8-inch and above are currently being added resulting from Sanitary Survey Evaluation System (SSES) work that began in July 2002 and is an ongoing task. The end result is a comprehensive model for the City.

Calibration

Once the physical attributes have been received from SSES and a model is built, the model network is loaded to simulate dry weather flow. As population and trade flow data (Commercial/Industrial) is not readily available, an average dry weather flow (ADWF) is obtained from meter data pertaining to the sewershed. The ADWF is then distributed throughout the model and loaded onto manholes. Diurnal patterns that vary according to the time of day were developed and applied to dry weather flows based on flow data gathered from the meters. The diurnal profiles are derived from the flow meter data. Approximately seven days of ADWF are needed for calibration. For dry weather calibrations, a 10% margin of error is allowed on the total volume and peak flow. To meet this performance tolerance, base flow loading and/or the diurnal profile may be adjusted to match measured flow data.

Wet Weather Flow (WWF) calibration is achieved by comparing peak flows, velocity and depth of metered data with a model's simulated results. Wet weather parameters, such as contributing runoff area, slope and width of drainage sub-catchments, are adjusted until an acceptable correlation between simulation results and metered data is achieved for at least three recorded storm events. Calibration storm events have the following desirable characteristics:

- Antecedent conditions - preferably 5 dry days preceding the rainfall event.
- Total rainfall depth – 1-inch to 2-inch total depth. Larger storms (>2-inch) may produce manhole overflows within the model simulation results. This simulated flood volume loss will not be reflected in the measured flow meter data. Smaller storms (< 1-inch) do not adequately mimic the effects of a design storm.
- Season of event – Spring storms are preferable due to their tendency to be larger in volume and duration.
- For wet weather calibration, a 20% margin of error is allowed.

Rain Data for Modeling

InfoWorks CS (IWCS), the modeling software used by the City, has a very flexible and effective way of handling rainfall data input into the model. The software has two basic methods for assigning rainfall input data. The first method is the conventional method that the city has been using and requires to geographically locate all discrete rain gages within a rainfall boundary area and identifying them with a profile number. The software then creates Thiessen polygon regions and assigns rainfall to the sub-catchments within that region. The disadvantage of this method is that when there are missing rain gage data, as is common with rain gage networks, there are no input data for the entire corresponding region defined by the Thiessen polygon.

The second method uses regions or polygons defined by the modeler to identify the different rainfall profile boundaries. The software can use multiple rainfall and regions provided that each rainfall profile is associated with a corresponding rain gage boundary region. For this study we decided to use the sewershed boundaries within the Peachtree Sewer Basin and assigned rainfall profiles corresponding to each sewershed boundary region as shown in Figure 2. Figure 2 shows both boundary regions for Thiessen and Radar Rain polygons. The GIS shape file was then created from the sewershed boundaries. These boundary regions were then supplied to OneRain, Inc. and the corresponding profile were populated with the GARR rainfall data. IWCS had a limitation in using regions defined by the sewershed polygons with multiple vertices, so the regions GIS shape file was manually adjusted using simplified polygons to cover each sewershed area. Since the rainfall input data were developed from the GARR data, the sewershed regions had rainfall estimates for every time step of the simulation.

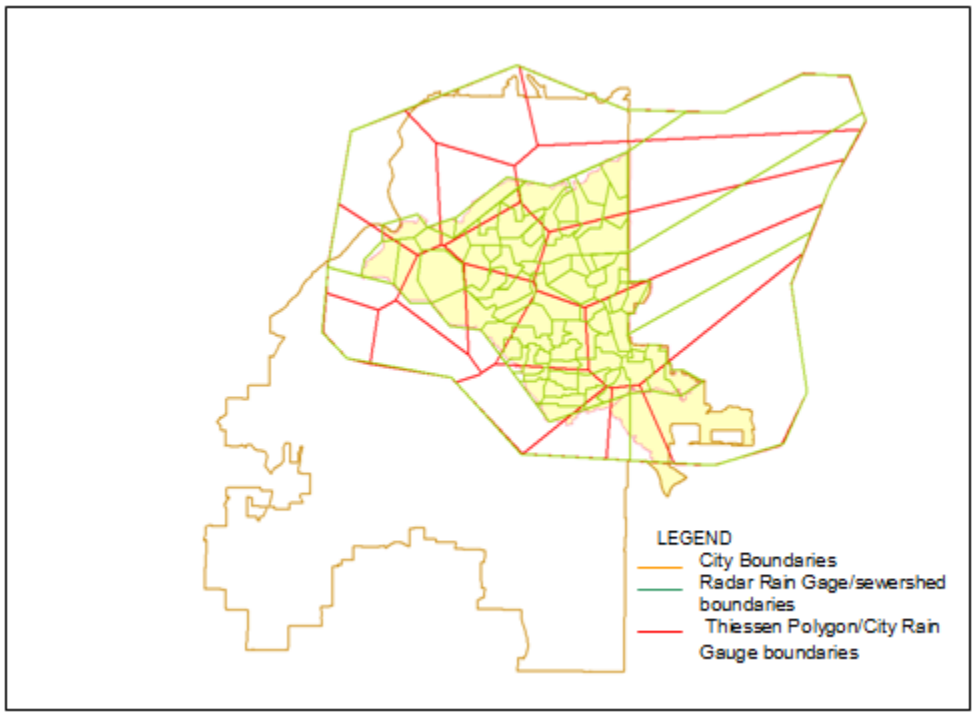

Figure 2. Comparison between Thiessen and Radar Rain Polygons for the Peach Creek Study Area.

Gage-adjusted Radar Rainfall Estimates

The GARR analysis incorporated NEXRAD radar data on a 2x2 km grid, with a 15-minute sample rate. Each radar image is a composite prepared using data from all National Weather Service WSR-88D radars covering the study area. The study area was based on the extents of the Atlanta city limits and what rain gages were available in and around that area. This area consisted of 783 2x2 radar pixels (29 rows and 27 columns) bounded approximately on the west by –84.6654° W longitude, on the east by –84.1491° W longitude, on the north by 34.0120° N latitude, and on the south by 33.4910° N latitude. A combination of 5-minute and 15-minute rain gage data for the study area were provided by the City.

The rain gage data were reviewed and checked for quality using several steps. First, six gages that failed to report rainfall for the entire study period were removed from the analysis. The next step was to divide the study period into separate rainfall events. Then scatter-plots were generated that compare the event gage volumes with their co-located unadjusted (raw) radar pixel rainfall estimate. Using these scatter-plots, under- and over-reporting gages tend to stand out from the rest of the group. During this step, the gages that recorded no rainfall and were paired with a radar pixel that did measure rainfall were removed from that period of the analysis. Figure 3 presents the scatter-plot comparing gage and (unadjusted) radar accumulations for the March 3-4, 2001 event. Gages circled in red indicate non-reporting gages and gages that appear to be under- or over-reporting for this event.

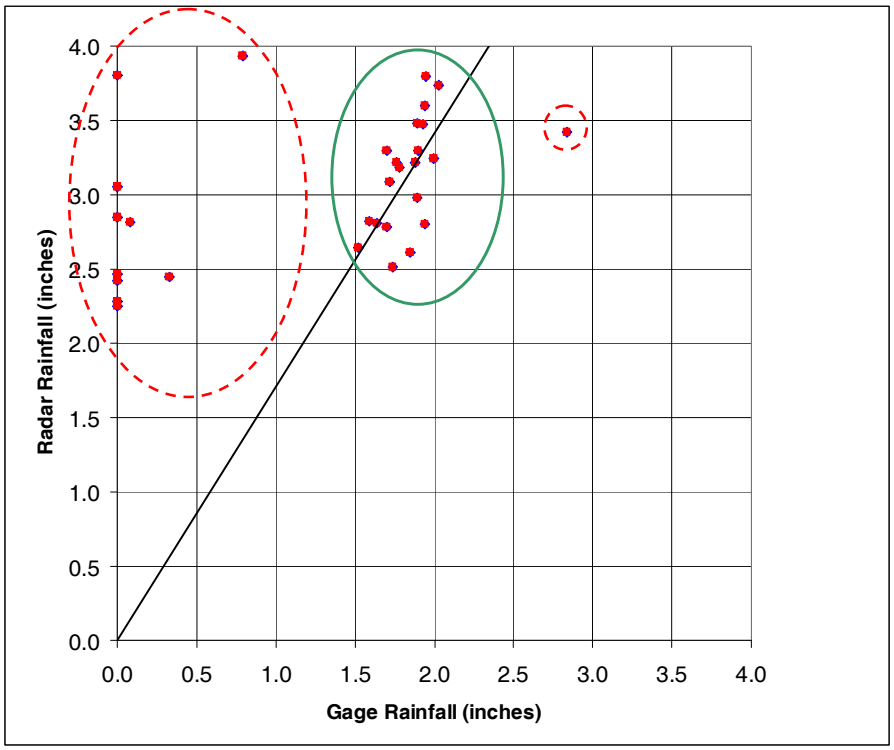

Figure 3. Comparing gage and radar accumulations for March 3-4, 2001 event. Suspect gages in dotted red circles required further investigation.

OneRain has developed tools to assist in the removal of these radar artifacts. However, initial analysis of the local Atlanta radar mosaic for March 2001 indicated that little filtering was required. For this pilot project, there was a much smaller number of discontinuities than typically exists. However, if further analysis is performed, a longer record of radar will be examined to determine necessary filtering. For this pilot study the only radar filtering performed was the removal of radar 'noise' or scatter that is common in raw radar. This noise in raw radar will appear as isolated short-term (usually less than 2 or 3 time-steps), stationary patterns that occur during times of no rainfall. Less than 0.4% of the 2784 radar frames required this type of filtering.

After the gages are checked and raw radar data has been filtered, comparisons and integration with gage data begins. A time-series was generated to compare each gage's data with its co-located radar pixel. At each pixel containing a gage location, an event gage/radar (G/R) ratio was computed by dividing the gage's measurement by the radar's during each event. Next, a Kriging-based interpolation technique was used to determine the appropriate geometry and distance-weighted G/R ratio for every other pixel in the domain. The G/R ratios were then multiplied by the filtered radar dataset for each time period during the study to determine the gage-adjusted radar rainfall amounts. This process was repeated for each event during the study period.

Figure 4 presents a block diagram description of the spatially variable gage-adjusted radar rainfall process.

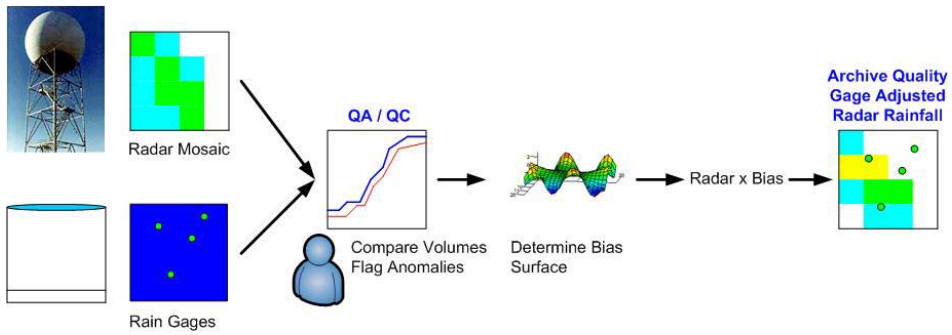

Figure 4. Block diagram depicting spatially variable gage adjustment process.

Gage-adjusted Radar Rainfall Results

Figure 5 shows the total rainfall accumulation across the City of Atlanta, study area for March 3-4, 2001. (This event became the focus of modeling results presented later in this paper.) For the entire study period, the central southern edge of the study area received the most rainfall. Pixel 15, counting from the bottom left of the image, along the southern study area boundary, received a gage-adjusted estimate of 12.0 inches of rainfall. The unadjusted radar estimates for that same pixel was 15.1 inches. Table 1 presents the ten highest rainfall intensities for time periods ranging from 15 minutes to 24 hours (start times are in UTC). The ten most intense 15-minute accumulations all occurred on March 12. The ten most intense one day totals occurred across four different days: March 3, March 11, March 12 and March 14.

Figure 6 shows the result of the gage-adjusted radar rainfall adjustment procedure. A G/R ratio was determined for each pixel and for each storm period before being multiplied by all of the raw radar rainfall estimates during those time steps. The result is a gage-adjusted radar rainfall dataset that matches the volume and timing of the rain gage network, but includes the spatial information from the radar. The Gages line shows the average accumulated rainfall for the gages with valid rainfall data and the Radar line shows the average accumulated rainfall from the radar pixels over the valid rain gages. The AdjRadar line shows the average gage-adjusted radar rainfall estimates for the pixels at the rain gages. In this figure, the AdjRadar line nearly matches the Gages line, indicating a good match between the rain gage and the gage-adjusted radar rainfall datasets. Overall, the gage-adjusted radar rainfall estimates were approximately 20% lower than the unadjusted radar estimates.

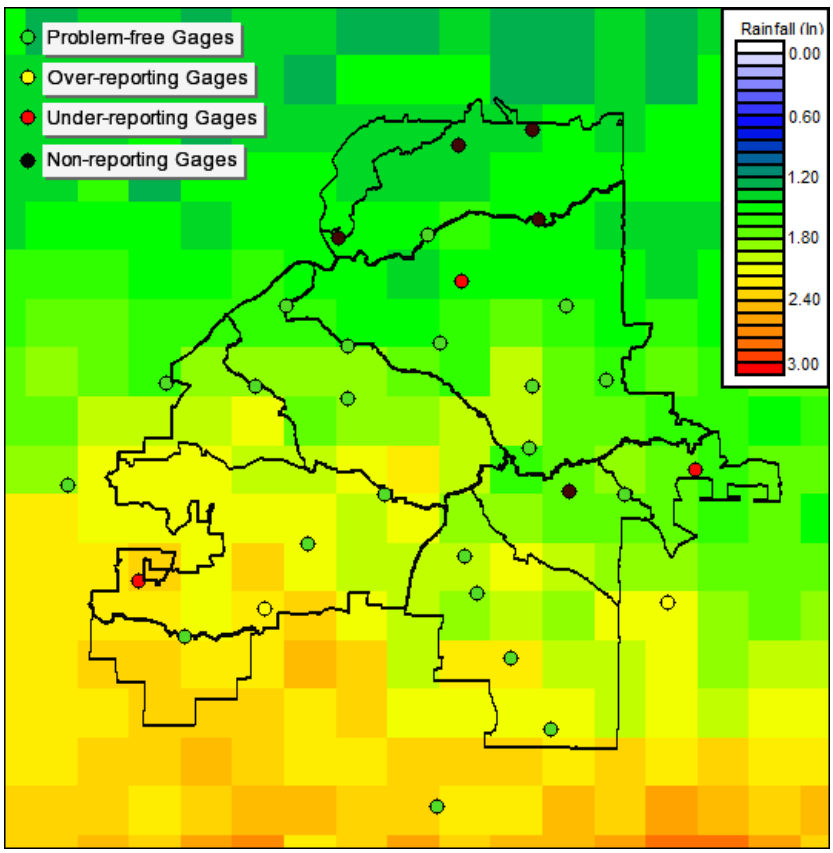

Figure 5. Gage-Adjusted Radar Rainfall estimates for March 3-4, 2001.

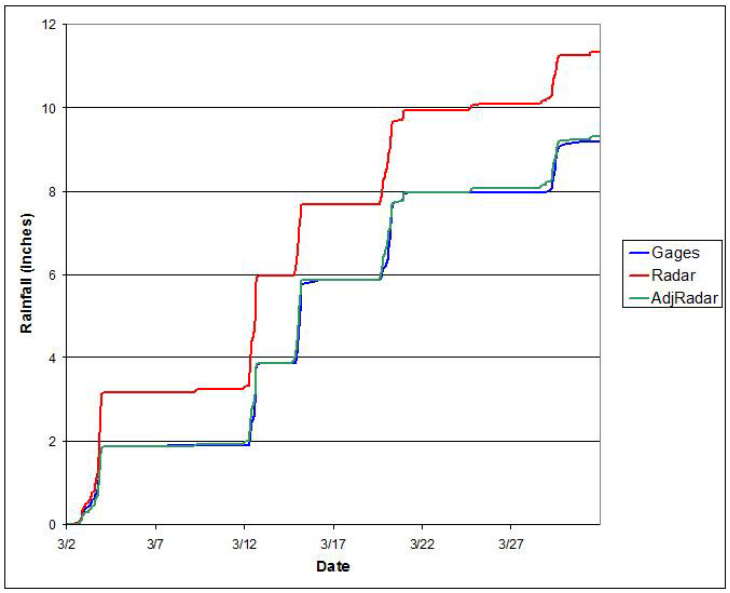

Figure 6. Average gage, raw radar, and gage-adjusted radar rainfall accumulation plot for March 2-30, 2001.

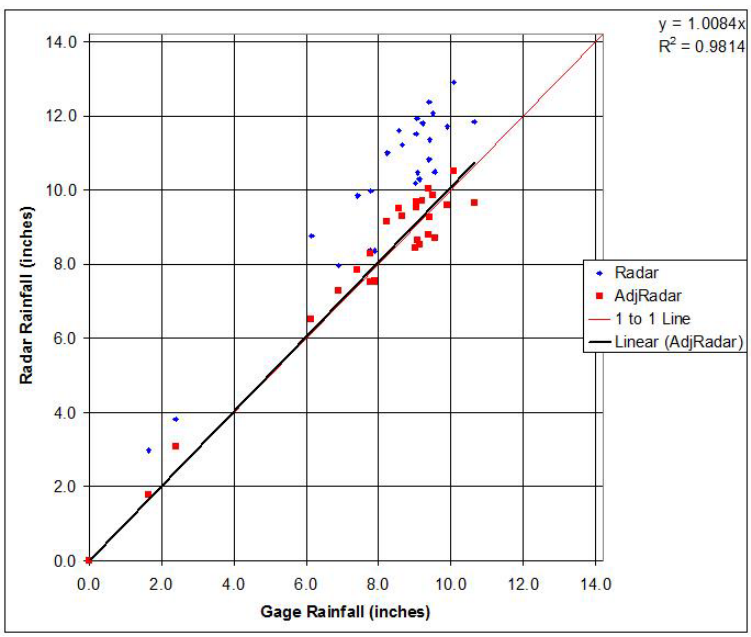

Figure 7. Scatter-plot of radar and gage-adjusted radar rainfall totals versus gage rainfall for each gage for March 2-30, 2001.

Figure 7 shows the scatter-plot of total rainfall measured at the gages compared to the radar and adjusted radar rainfall estimates at the pixels over the rain gages for March 2-30, 2001. If the gage and gage-adjusted radar rainfall estimates were identical, all points would lie on the 45-degree best fit line. However, due to scaling issues, measuring errors, natural variability, and other uncertainties, these values will not always match. Nevertheless, the gage-adjusted radar rainfall data are expected to

cluster around the 45-degree line. In summary, correlations between the two precipitation measurement systems were strong. Rainfall timing was well matched. Incorporating the gage volumes resulted in lowering the radar rainfall estimated by 20%.

Model Results

As stated earlier the current sewer modeling method is based on Thiessen Polygon distribution of rain gage boundaries that correspond to individual rain gages. When data for an individual rain gage is missing, the entire modeling results for the corresponding sewershed region is affected. An example of missing rain gage data occurred during the March 3-4 2001 rain event where flowmeter data were available. The total rainfall for the 38 hour event during this storm is around 2.8 inches with a frequency of less than 1 year and a maximum intensity of 1.15 in/hr. As mentioned earlier, in order to calibrate a sewershed, three (3) rain events with corresponding flowmeter data are required.

The GARR rainfall data were imported into each corresponding sewershed region profile of the Peachtree Creek Basin in the IWCS model. The rainfall profile was then used to run a simulation of sewershed PTC07A1 and calibrate it against the available flowmeter data. Figure 8 shows the simulation results for the flow from the model with the GARR calibrated input data and the Thiessen Polygon rain gage data. Both rainfall datasets are plotted versus the observed flow meter data for the period from 3/2/2001 to 3/4/2001.

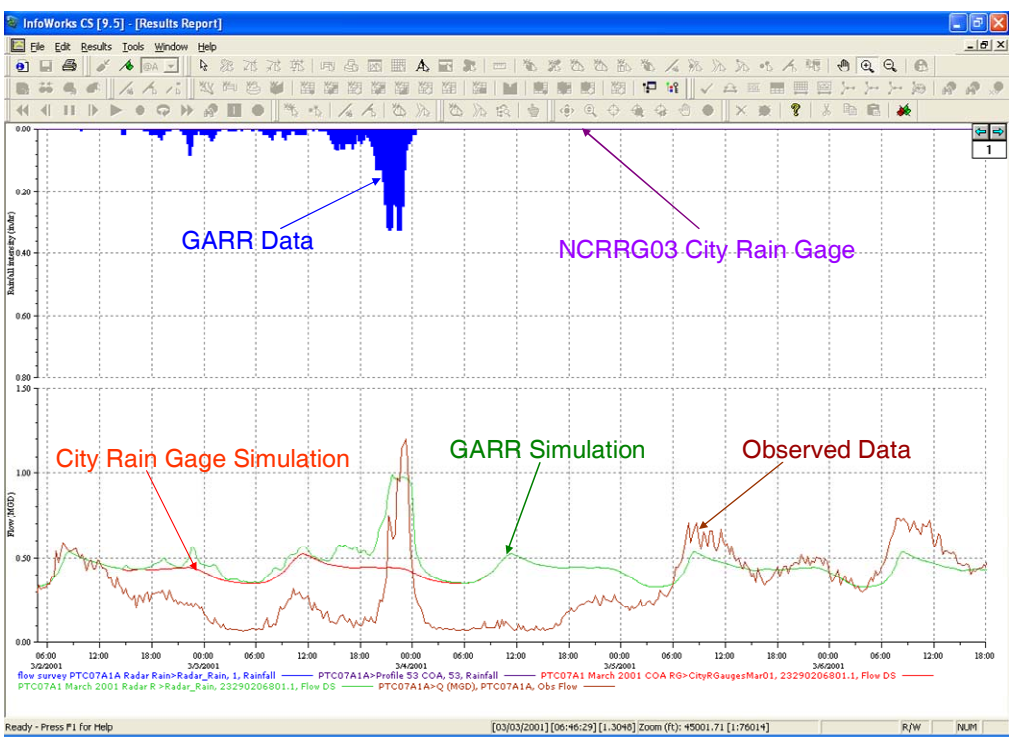

Figure 8. Comparing model results.

With the Thiessen Polygon method, modeling results for the sewershed were entirely dependent on rain data from the sewershed's single gage which recorded no data for the event. Therefore, the model could not be calibrated for the event. In contrast, the GARR rain data enabled us to populate the same storm event for that sewershed and to verify the model response to the observed ones.

Conclusion-Lessons Learned

GARR has made it possible to calibrate the sewer system model during periods when data from individual gages were unavailable. In addition, GARR rainfall datasets provide vastly improved spatial distribution of model input and more detailed characterization of rainfall events. This capability will become more and more critical as the City refines and adds detail to their system model.

This GARR Pilot Study provided valuable feedback on the quality of the gage data collection system. The system correlated well with the radar system and suggests that its data could provide the gage data foundation for additional historical analysis.

The success of this historical GARR analysis indicates it is good candidate for transitioning to a real-time application of GARR. Real-time GARR analysis uses a more simple algorithm called "uniform adjustment", which is based on the average gage/radar ratio over the preceding hour. Although spatially variable gage/radar ratios are not used, uniformly adjusted radar still integrates the spatial resolution of radar with the volume accuracy of rain gages. Real-time GARR, particularly when published on the web in real-time, can be a powerful tool for sewer system operations during rainfall events.

Another option for the City of Atlanta system is to implement gage-adjusted radar forecasting. Radar forecasting is typically based on the McGill Algorithm of Precipitation by LaGrangrian Extrapolation (MAPLE). MAPLE incorporates the past 90 minutes of radar movement to extrapolate the growth, decay, direction and speed of existing precipitation cells. MAPLE also attempts to determine the transition between rain, freezing rain, and snow. Once MAPLE forecasts are obtained, the gage/radar ratio over the preceding hour is applied to the data in order to calculate the forecasted GARR estimate. Forecasted GARR would better enable the ability to predict spills and flooding areas in the storm sewer system.

Rainfall is the input variable with the largest impact on modeling sewer systems. Its information is essential for determining rehabilitation efforts and system upsizing. By using the GARR process to enhance rainfall input data, the City of Atlanta will create more accurate models, attain a better representation of storm frequency, intensity, duration, and potentially improve future forecasting capabilities. By using GARR techniques, inflows from storm events and the resulting impacts will be better quantified.

Adaptive Long-Term Monitoring at BP Environmental Restoration Sites

Abstract

In partnership with BP, Summit Envirosolutions, Inc. has developed a unique set of software tools for reducing costs and improving effectiveness of long-term monitoring (LTM) through adaptive assessment to achieve remediation goals.

There are four components which comprise the software toolset. The first component, EPIPHINY®, is a database platform which gives the user the ability to quickly import and analyze analytical sampling data. The second, ModelBuilder™, creates and visualizes geostatistical models of spatial and temporal data, and identifies areas of significant data uncertainty which may benefit from additional sampling. The third, SampleOptimizer™, identifies redundant sampling locations and frequencies in historical data in preparation for future sampling events. SampleTracker™, the fourth component, enables users to create time-dependent site-wide remediation targets (e.g., expected reductions in mass) or well-specific targets (e.g., expected concentration trends) and to evaluate new data relative to those targets, as well as providing automated alerts of unexpected deviations.

This paper presents the long-term monitoring optimization (LTMO) results for two BP case study sites. The results are presented in the form of tradeoff curves associated with competing objectives: 1) minimizing the number of sampling locations; and 2) minimizing the maximum interpolation errors at all sampling locations which were recommended to be removed, as well as comparative visualizations showing the site concentrations before and after optimization.

1.0 Introduction

Routine long-term monitoring (LTM) is a significant component of overall operating expenditures at many private and public sector environmental restoration sites, with some estimating it as 30% of the average overall restoration project budget [ASCE 2003]. These costs not only include the cost of sample collection and laboratory analysis, but also the associated data management, data analysis, and reporting which is needed.

Numerous approaches to long-term monitoring optimization (LTMO) have been developed to optimize the selection of future samples to be taken in the next sampling round, in order to minimize the costs for sample collection and laboratory analysis [see ASCE 2003]. However, SampleOptimizer™ is unique in that it is the only approach which performs true mathematical optimization by utilizing a multi-objective genetic algorithm. Further, EPIPHINY® and SampleTracker™ enable their users to lower their data management, analysis, and reporting costs through automated importing, querying, and reporting modules.

This paper gives describes the technologies which comprise EPIPHINY®, SampleOptimizer™, and SampleTracker™, and presents the results of several case study analyses using these tools.

2.0 Technology Description

Experience indicates that the single largest component of data analysis budgets is usually putting the data into a form that can be analyzed. The environmental data industry still lacks a unified "data dictionary"; therefore, data formats differ between analytical laboratories, field equipment, and internet sources. The use of Microsoft® Excel® is currently the predominant repository of environmental data and is primarily used to prepare tables of data for reports.

2.1 EPIPHINY®

EPIPHINY® represents a new approach to "handshake" disparate data sources into a common database format. Import routines, data sets, and query results can all be saved and shared amongst EPIPHINY® users. Its powerful I/O algorithms can import and export data to and from text documents, spreadsheets, several database formats, as well as shape file formats utilized by ESRI ArcGIS®. The software provides robust data normalization and validation, parameter and location grouping, graphing, cross-tab table generation, intuitive interfaces for SampleOptimizer™ and SampleTracker™.

2.2 ModelBuilder™ and SampleOptimizer™

Both ModelBuilder™ and SampleOptimizer™ utilize algorithms from Data to Knowledge (D2K), a data analysis and optimization package created at the National Center for Supercomputer Applications (NCSA) at the University of Illinois [Welge et al. 2003]. ModelBuilder™ and SampleOptimizer™ were built to be powerful and customizable, yet their configuration is automatable and is thus easily accessible to everyday users.

As previously mentioned, SampleOptimizer™ employs a multi-objective genetic algorithm called NSGA-II, proposed by Deb (2002), to generate an optimal set of solutions between various competing objectives. This set of optimal solutions is known as a tradeoff curve or Pareto frontier. The advantage of using genetic algorithms to solve multi-objective problems is that the entire Pareto frontier can be generated in a single computational run. Figure 1, below, shows a set of snapshots of the Pareto frontier as developed by the software.

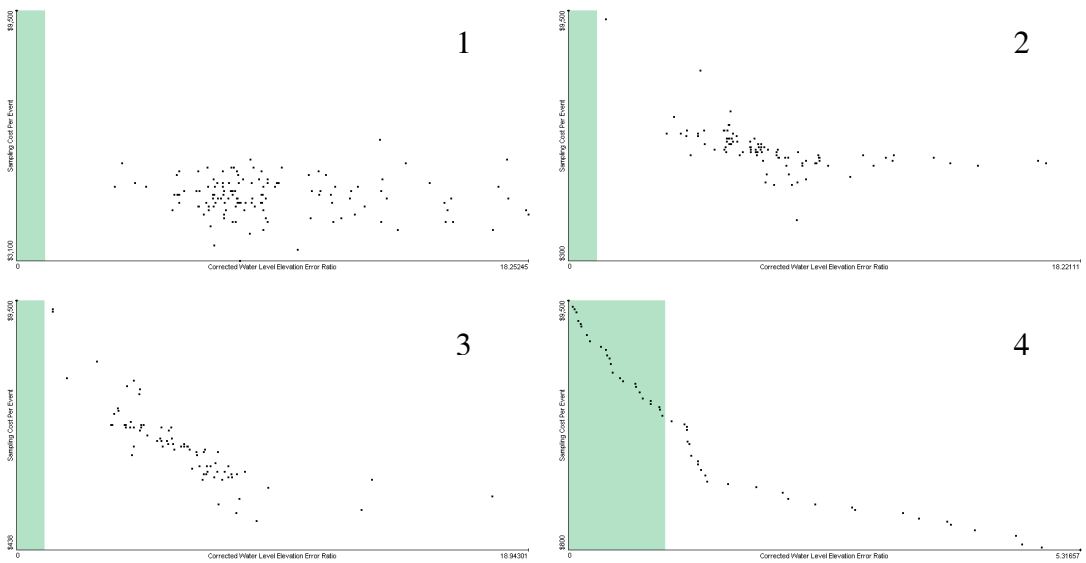

Figure 1: Progression of Pareto Frontier (shown chronologically, from 1 to 4)
The shaded areas highlight designs which fulfill the user defined accuracy objective.

ModelBuilder™ is a software module which assists the user in selecting a suitable interpolation model to use with their site data in SampleOptimizer™. In contrast to other interpolating packages which are strictly manually-configurable (such as ESRI® ArcView® Spatial Analyst), ModelBuilder™ automatically suggests a set of interpolation model parameters which are relevant to the site data. For example, when Ordinary Kriging is chosen as the interpolator, ModelBuilder™ suggests the values to be used for the theoretical variogram (nugget, spherical term, linear term).

After the model parameters have been chosen, ModelBuilder™ creates site visualizations which are easily customized to the user's choice of labels, symbols, and ranges. ModelBuilder™ also has the ability to calculate a mass metric value (based on summing the interpolated concentration values) for a site which can be inputted into SampleTracker™ for monitoring along with the values at individual sampling locations. Lastly, ModelBuilder™ has the ability to generate visualization maps of model and data uncertainty which can be used qualitatively utilized during site analysis to help decide if and where to site new sampling locations (see Figure 2, below). These uncertainty maps are created through a multi-step leave-one-out cross validation mechanism which is automated, and yet can be customized if needed.

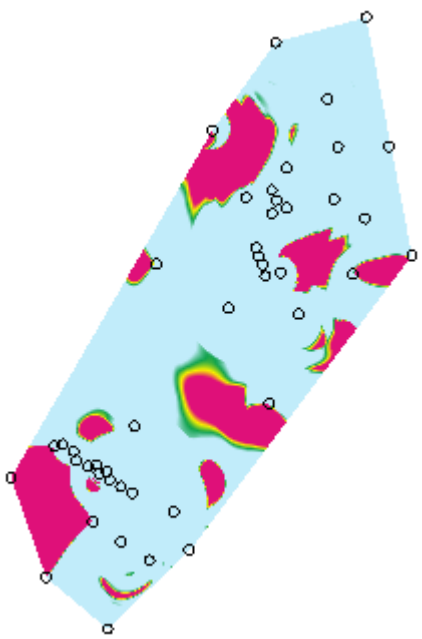

Figure 2: Example Relative Uncertainty Analysis Visualization
High relative uncertainty areas are highlighted in magenta.

2.3 SampleTracker™

SampleTracker™ is a complimentary application to both EPIPHINY® and SampleOptimizer™ which is designed to review current monitoring data against historical data and identify cases where current data deviates from expectations which are based on the historical dataset. These expectations are formulated in the form of bounds, which represent a statistical estimate of the range of values that might be expected in a specific sampling event, based on the historical data at that location.

Any current data value which is outside the bounds range for that location is reported to the user as being out-of-bounds (see Figure 3, below). Like ModelBuilder™ and SampleOptimizer™, SampleTracker™ makes configuration recommendations based on the site data which can be optionally customized by the user.

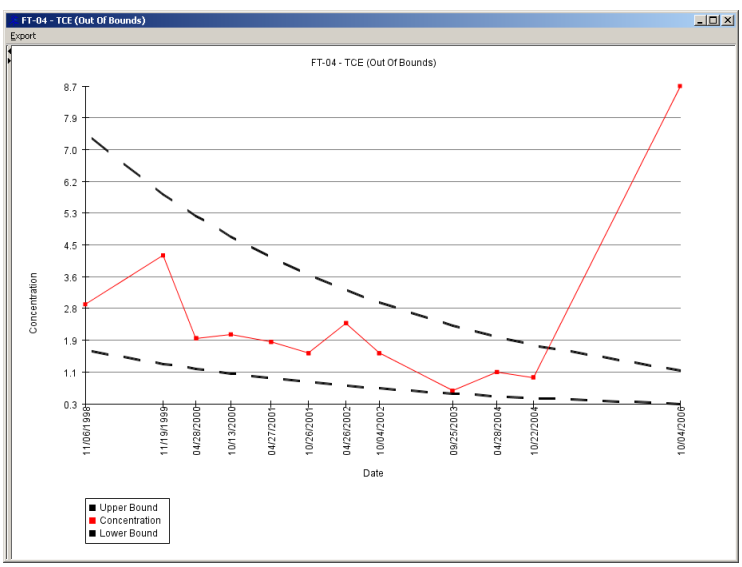

Figure 3: Example Unexpected Data Alert

4.0 Methodology

As with any data analysis tool, the quality of the analysis is dependent on the quality of the data. The spatial analysis of data generally requires basic information such as the geographic coordinates of the sampling location, the elevation of the sampling location (or, in the case of a monitoring well, the screened interval), and a result of analysis or measurement. The results of analysis using SampleOptimizer™ will be dependent on the level of understanding of the site conceptual model; it is generally not prudent to optimize data that are combined from multiple groundwater flow systems that are not hydraulically connected.

It is important to note that sampling at a site will usually be ultimately determined via discussions with the relevant stake holders, including any applicable regulatory bodies, and the results we provide here are the first step towards implementing a new sampling plan.

5.0 Results

5.1 Site 1 – Groundwater Elevation Sampling; Spatial Analysis

The site is sampled frequently during the year -- locations are regularly sampled at least quarterly; some locations have irregular additional sampling taking place on a monthly basis, and sometimes even more frequently. This site's geology is more complex, with a large recharge basin approximately half a mile off site, and active pumping taking place in the part of the site.

For this analysis, site data was first imported from two Microsoft® Access® database files into EPIPHINY®. One database contained the sampling results, and the other contained the well information (coordinates, depths, etc.). The import process was very straightforward and took approximately half an hour.

Next, after brief consultation with site personnel, a representative two-day sampling event in April 2008 which included 95 sampling locations was chosen to be the focus of the optimization. After about an hour of computation, the software presented the Pareto Frontier shown in Figure 4.

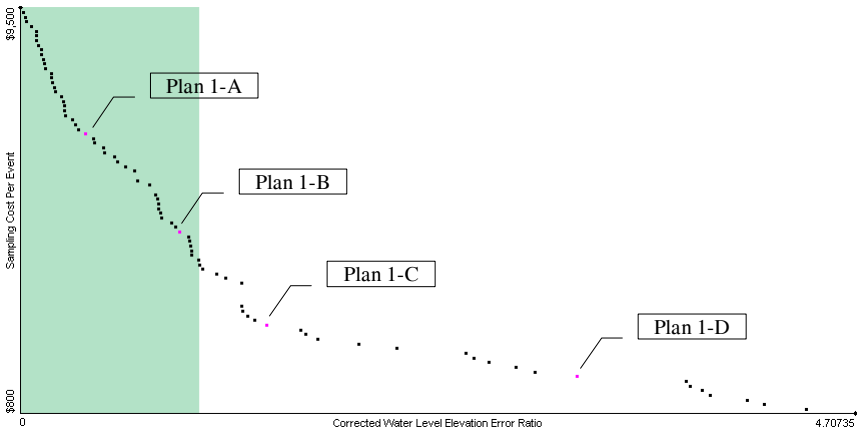

Figure 4: Site 1 Pareto Frontier

Next, various sampling plans in the Pareto Frontier were considered, and the four plans highlighted above were chosen for further consideration. Plume visualizations for each plan were created by ModelBuilder™, and are presented below in Figure 5.

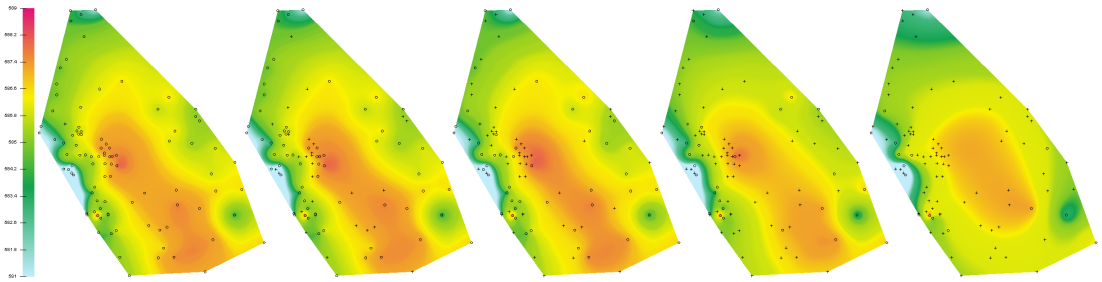

Figure 5: Selections from Site 1 Pareto Frontier
(From Left to Right: All 95 locations, Plan 1-A, Plan 1-B, Plan 1-C, Plan 1-D)

After viewing the plume visualizations, Plan 1-C was selected for proposal to the site team for consideration in future sampling events, since it offered very high savings in the number of samples taken (51%) while maintaining an excellent amount of useful information.

5.2 Site 2 – Benzene Sampling; Spatio-Temporal Analysis

This site uses regular semi-annual sampling, with approximately 50 samples per event and has an overall simple hydrogeology. There is no active pumping at the site, and there is a gradual hydraulic gradient present from the north east to the south west.

As with the previous site, the site data needed to first be imported from its native format. The data proved to require some basic reformatting in Excel®, but after less than an hour of formatting work, the data was ready to be imported into EPIPHINY®.

Once in EPIPHINY®, the data was queried and studied, and benzene was determined to likely be the driving COC at the site because of its levels relative to its USEPA MCL. After brief consultation with members of the site team, optimization of both the choice of sampling location as well as sampling frequency (called spatio-temporal optimization) was decided as the appropriate method. As a result, the seven most recent sampling events from 2005 through early 2008 were queried, and their data was easily exported into SamplingOptimizer™.

For Site 2, a novel approach for spatio-temporal analysis was chosen as an experiment. First, individual spatial optimizations were performed for each of the chosen sampling events. Next, a plan which was felt to represent an appropriate tradeoff between useful information and sampling cost was selected for each event. Next, the seven optimized sampling plans were tabulated in a spreadsheet, and analyzed as a group. After careful consideration, two most recent sampling events were weighted most heavily in deciding which frequency to recommend to the project team for consideration (see Table 1 for an example).

Plan #	464	71	1690	527	930	190	334	
Well ID	**Q1 2005**	**Q3 2005**	**Q2 2006**	**Q4 2006**	**Q2 2007**	**Q4 2007**	**Q2 2008**	**Recommended Frequency**
SW-2	On	On	On	On	On	Off	Off	Off
SWP-24	Off	Off	Off	Off	Off	Off	Off	Off
SW-8	Off	On	Off	Off	Off	Off	On	Annual
SW-14	On	Off	Off	Off	On	Off	On	Annual
SW-1	On	On	On	On	On	On	On	Semi-annual
SW-3	On	On	On	Off	On	On	On	Semi-annual
Sampling Reduction	34%	37%	40%	26%	33%	28%	20%	27%

Table 1: Example Frequency Analysis for Site 2
(Abbreviated for space consideration)

To check the results of the analysis, the proposed plan was visualized for the most recent sampling event (see Figure 6). While the amount of sampling reduction for this example (27%) is less than at Site 1, each sample at Site 2 is more costly to take since each one must be sent to a lab for analysis, and therefore such a sampling reduction would likely be worthwhile.

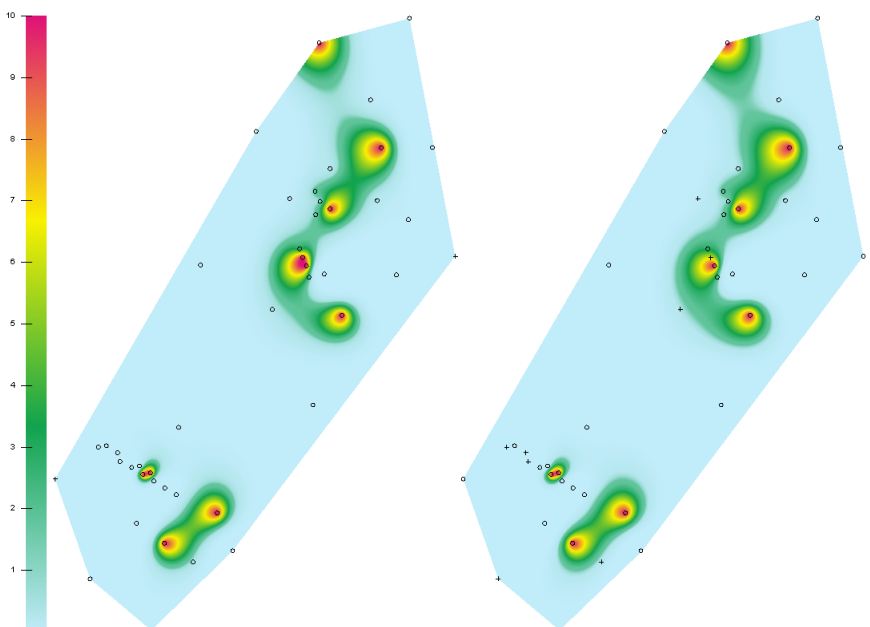

Figure 6: Site 2 Optimization (Q2 2008)
(Left - Before, Right - After)

6.0 Conclusions

At both sites, the use of the software tools was a success. EPIPHINY® was able to quickly and easily import site data, and made it easy for the user to export data to SampleOptimizer™. SampleOptimizer™ proved intuitive to use and found significant levels of potential sampling redundancy at both sites. Both of these sites will continue to be studied and future work will include results from using SampleTracker™.

Abstract

Multiple approaches (shear stress, discharge, stream power, etc.) have been developed for describing the rate of bedload movement, each with a means of being calculated in the field. One current approach relies on the mean virtual velocity of individual sediment particles. Virtual velocity is determined by dividing the displacement length of a particle by the sum of the rest and displacement times. The focus of this research is the application of a Radio Frequency Identification (RFID) system as a means to monitor individual and group particle displacement and rest times necessary for calculating the virtual velocity, so that the bedload transport rate can be predicted. An RFID system consists of programmed transponders and a corresponding reader that communicate using radio waves. This communication provides the ability to track individual particles with embedded transponders. By setting customized antennas in the flume to act as gateways, communication between the antennas and particles traveling over a known distance provides the time between antennas, allowing for the calculation of the 1-D virtual velocity. To develop this system, multiple obstacles needed to be overcome. Past RFID research has shown that transponder orientation and transponder signal collision can present large problems to the application of RFID technology to sediment transport research. These two problems have been accounted for by: 1) using particles consisting of two transponders oriented perpendicularly to each other, and by 2) using transponders that have anti-collision signal capabilities. The use of anti-collision capable transponders also provides the capability of tracking the flux of a group of particles. Tracking a group of particles allows for correction due to the flow field and the possibility of hiding. Cameras and image analysis tools will be used for confirmation of results.

Introduction

Many relationships exist for equating a quantifiable parameter to the rate of movement of bed material in a gravel bed stream to provide for future bedload rate prediction. One of the most popular parameters used for this prediction is the Shields parameter, a non-dimensionalized form of the critical shear stress (Shields, 1936). This shear stress value is commonly calculated using an erosion flume, where conditions (such as slope, flow depth, etc.) on a bed test section can be changed until incipient motion is achieved. Discharge is a second commonly used variable for predicting bedload rate (Schloklitsch, 1934), and can be measured using an acoustic doppler velocimeter along with surveying equipment to determine channel geometry. A third means of relating to bedload transport rate is stream power (Bagnold, 1966), which requires the same equipment as discharge to calculate. More recently, the virtual velocity of a particle has been used to develop such a relationship to account for the random nature of particle movement. The virtual velocity is given as the distance traveled by a particle divided by time the flow was capable of moving a particle of that size. The use of the total time flow capable of moving a given particle size instead of just the movement time for that particle accounts for the random aspect of particle movement (Haschenburger and Church, 1998); that for non-fully mobile beds, particles randomly experience periods of movement and rest dependent on localized flow conditions.

Due to its emphasis on individual particle movement, the use of virtual velocity as the independent variable requires a tracing technique for quantitative measurement. In the past, the painting of individual particles or groups of particles was widely used for tracing but the burial and hiding of particles during events strong enough for movement have often led to a low recovery rate. Low recovery rates result in an over-representation of the results of the located particles (in many cases, leading to an over-prediction of movement due to the loss of buried particles). In an attempt to increase the rate of recovery, many researchers have switched to tracing techniques that do not require a line-of-sight for discovery. One such technique is the use of particles equipped with radio transponders, as part of a radio frequency identification system.

Radio frequency identification technology is commonly considered to have first been developed during World War II, as a means identifying friendly aircraft. The technology then did not significantly further develop until the 1960s and 1970s, during which it started to be used for its most common application today, inventory tracking and supply management. The main mechanism for communication between a transponder (the combination of transponder and receiver, also commonly called a tag) and an antenna in an RFID system is the transmission of radio waves at a set frequency. The transponder consists of a small antenna, circuit for holding information, and capacitor that is charged when in the presence of the antenna's electromagnetic field. The reader acts to translate the radio waves received from the antenna in to a form usable by the operator and to send control signals to the antenna for transmission as radio waves to facilitate communication with transponder. For most applications of RFID technology near water and metal (both highly present in this research), the communication frequency used is 125 kHz, which has a longer wavelength than other RFID frequencies and thus does not get absorbed as easily by the two materials.

RFID technology has many benefits that make it well-suited for use as a particle-tracing tool: 1) particle communication is not dependent on sight for discovery, making detection during an event possible, 2) radio communication is possible through most bed materials, so detection of buried particles is possible, 3) the cost of individual particles is small, so, although recovery rate

can be very high, loss is not a serious limiting factor, 4) distance between particle and antenna does not matter as long as the particle is within the antenna's electromagnetic field, 5) the possibility of unique codes for each particle make individual particle tracing possible, 6) depending on the antenna configuration, particle detection can be treated as LaGrangian (i.e. finding each particle in the field) or Eulerian (i.e. each particle passing a set detection point).

Objectives

Prior RFID research in the field of sediment transport has focused on the issues of development of RFID as a tracer (Ergenzinger, Schmidt, & Busskamp,1989), use to measure step length and travel path (Habersack, 2001), and particle tracing in coastal environments (i.e. the transition from gravel to sand)(Allan, Hart, & Tranquili, 2006). The goal of this research is to present RFID as a tool for the prediction of bedload transport rates by using the virtual velocity of particles. Having a transponder-equipped particle move through a set up with multiple antennas spaced at known intervals could potentially yield time and reach-specific virtual velocity values. These specific virtual velocity values can allow a more precise calculation of the bedload rates. As opposed to real-time measurements, the use of RFID technology for tracing has largely been limited to gathering one final measurement after a particle-mobilizing event has concluded and the reach has drained. In this research, communication between the antenna and particle is only possible when the particle passes through the antenna coil. This setup provides the ability to determine, for the first time, the bedload transport rate in quasi-real-time without removing the particle from the system or visual tracking. However, due to the current limitations of RFID technology, the testing will be limited to the calculation of 1D virtual velocity values. 2D virtual velocity values will be gathered using video analysis and used for comparison.

Methodology

The experiments will be carried out in a 21.1 m long flume, with a 0.7m wide by 0.55 m high cross-section (Papanicolaou and Kramer, 2005). A simulated gravel bed consisting of five layers of 19 mm marbles packed in the densest possible configuration has been carefully placed in the bed in the flume (Papanicolaou and Schuyler, 2003). The necessary development length for a rough bed has been taken into consideration, with the test section located 10.9 m from the flume's entrance. For the test section, the top layer of marble-packed bed is made up of opaque white marbles, as to better contrast with the painted particles. The flow will be monitored by an electronic flow meter and controlled using two pumps with digital speed controls. Flow depth will be maintained using the flume's tailgate and exit rods to restrict the flow at the of the flume.

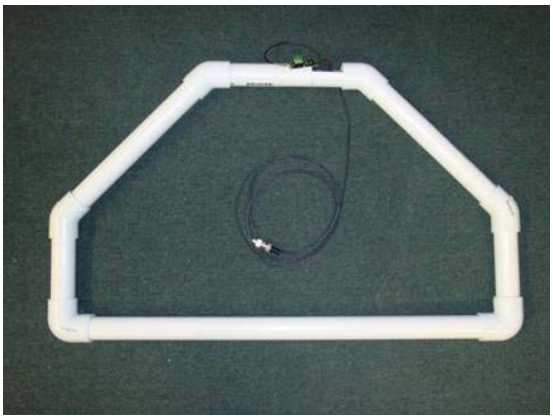

Fig 1. Antenna for RFID Reader

The RFID equipment located in and around the test section of the flume consists of four antennas, a reader, a computer, and 50 particles. The computer will be running a custom-built program developed using LabView software as a base. As a particle passes a given antenna, the program will display the identification code of the transponders in communication, the number of the antenna the transponders are in contact with, and the time of contact, all of which will be written into a text file for logging. The four antennas have been designed to fit within the cross-sectional dimensions of flume as well as be waterproof to a point safely above testing depth to avoid contact of the tuning electronics with the flowing water. These four antennas are connected back to the reader by means of a multiplexer and cable. Placing antennas as a cross-sectional gateway for the particles to travel through has not been tried before for RFID use in sediment transport research, but has been done in RFID research involved with fish tracking. The antennas will be oriented parallel to the cross-section of the flume to allow for detection of the particles as they roll through the antenna coil (providing quasi-real-time tracking of the particle).

Fig 2. Glass casing for transponders

Each test particle is made up of a glass case and two transponders. The glass cases were made from 25.4 mm glass marbles annealed to reduce the chance of cracking and then with the transponder holes drilled out. With the case prepared, two transponders programmed with unique identification codes were placed in the glass case, sealed in with outdoor silicone, and the whole particles were spray painted for easy numerical identification while testing.

To complete the experimental setup, three cameras have been placed around the flume to record both the plan and profile movement of particles through the test section. Two of the cameras will view the tests from the side through the flume's glass walls, and the third remote-controlled camera is mounted overhead to capture the plan view movement. Each camera has been connected to a computer for digital storage and analysis of video. To help ensure clear

video footage is captured, the flume wall opposite the profile-view cameras has been blacked out, and additional lights have been placed around the flume to remove shadows.

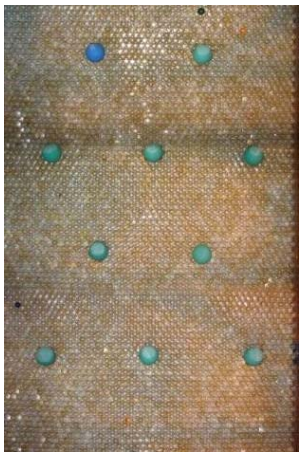

Fig 3. Potential Grid for 10-Particle Organized Test

Three feeding configurations are to be considered for the experimental tests, namely: 1) individual particles, 2) a 10-particle group organized upstream of the section corresponding at 2% packing density, and 3) a 10-particle group with no organization upstream of the section. The individual particles will be fed upstream of the test section using a feeder pipe designed to standardize release, provide for a quick release, and minimize flow disruption. The organized 10-particle group of tests is being run to account for the flow field within the flume. The non-organized 10-particle group of tests will be run to account for the hiding effect that will occur when particles start to group. Each group of tests will be run for a standard set of flow levels and flume slopes.

Discussion of RFID Complications, Solutions, & Expected Results

Prior research has revealed two serious impediments to the wider application of RFID technology to sediment transport: 1. Transponder orientation's significant effect on communication range between transponder and antenna, and 2. Signal collision due to multiple transponders in the antenna's electromagnetic field. These two impediments dictated the selection of the RFID system. Past experiments (Lauth & Papanicolaou, 2008) have indicated that particle orientation can have transponder orientation lead to nearly a 50% reduction in communication distance; unpublished trial tests put the reduction at closer to an order of magnitude. The reduction in signal strength is due to non-optimal direction of the tag antenna. With one of the main benefits of RFID particle tracking being the ability to detect and account for buried particles, the significant communication reduction could possibly lead to an over-reporting of buried particles as lost particles. To account for the effect of transponder orientation on particle communication, the transponders within the particle have been oriented perpendicularly to each other. While using two transponders in each particle will not guarantee at least one ideal orientation for communication, the potential loss in communication ability will be partially accounted for by the rotation of the particle while moving.

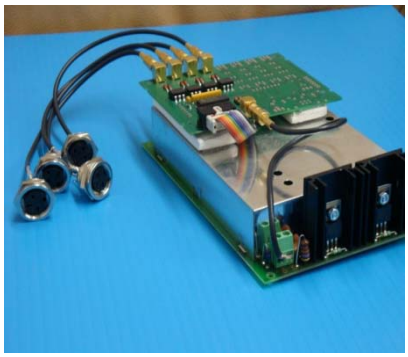

Fig 4. Uncased RFID Reader with Multiplexer

Previous testing with a RFID system has indicated that communication is not possible between an antenna and multiple tags. Because the reader does not have a system to distinguish a priority to which tag should be read when multiple are in the electromagnetic field, the reader fails to correctly identify any transponder, leading to communication failure (a condition known as signal collision). This problem can be solved in one of two ways, either by controlling transponder movement as to remove the chance of two transponders both being within the field at the same time, or by utilizing a system whose transponders and reader have an algorithm for assigning priority for transponder reading. Given the desire to use a two-transponder particle for testing, this research relies on a reader and transponders equipped with a priority algorithm.

One final impediment to RFID research not mentioned thus far in the sediment transport literature is the large effect that background electromagnetic interference can have on communication distance. A large component of RFID sediment transport research has taken place in natural streams and rivers (Nichols, 2002, Habersack, 2003, Lamarre, MacVicars, and Roy, 2005), many times in environments with little modern influence. However, the equipment developed for field research often requires development and initial testing in laboratory environments. These environments are at risk for background electromagnetic interference caused by poorly shielded electronics or electronics that emit irregular electromagnetic pulses (one prominent example is a digital flow controller). Such interference can be hard or expensive to detect, and may be systemic to the laboratory's power lines. This problem can be solved by removing the interference source, properly shielding the work environment (through use of a Faraday cage), or by using a reader that can filter out background interference. For this research, a reader with a filter was employed with attempts made to lessen the impact of interference sources.

The expectation for this research is that the transponders for each particle will communicate with each antenna the particle rolls through as the particle travels down the test section with each communication recorded. The timestamps from successive antenna passes along with the known distance between antennas will provide the 1D virtual velocity. Because the calculation of the virtual velocity will only be 1D, video files from the plan view camera will be analyzed using tracking software to determine the 2D virtual velocity for comparison. A recognized limitation of the current experimentation is that the packed simulated gravel bed will not allow for burial.

The use of RFIDs will potentially provide a finer resolution for the calculation of virtual velocity and thus bedload transport. These calculations could be made in real-time instead of after event. Furthermore, automation is possible where previously a large time dedication by a field researcher was required.

ABSTRACT

Automated monitoring systems are providing near real-time data at very high spatial and temporal resolution at a fraction of the cost of sampling programs. Significant improvements have been made in regards to reliability, maintenance intervals and ease-of-use that are making autonomous technologies the most cost-effective means of environmental monitoring. Data will be presented on the effectiveness of an automated vertical profiling system and a low-cost, autonomous underwater vehicle (AUV) used to transport a water quality monitoring package through a water column. Data from several case studies in drinking water reservoirs and natural environments throughout the world will be shown. Particular focus will be on the cost benefits of the vertical profiler in drinking water reservoirs and the AUV in environmental mapping applications. The profiling system provides near real-time data throughout the water column for a number of key water quality parameters such as temperature, algae biomass, turbidity, and dissolved oxygen. The data are being used to optimize water treatment and react to events, resulting in significant cost savings and providing better quality water. The AUV is used for a variety of water quality and bottom mapping applications. Monitoring agencies and consulting firms are using the system to provide very high-resolution data for point source and non-point source mapping, side-scan sonar surveys, and environmental impact projects at a fraction of the cost of current methods.

INTRODUCTION

The pressures on research groups, monitoring agencies and the private sector to expand and improve environmental data collection with limited resources have never been greater. At the same time an increased understanding of the high variability in natural systems (temporal and spatial) requires data to be collected at a higher resolution. Real-time monitoring of water quality offers a number of advantages over periodic spot sampling. The primary benefit is improved accuracy of the data and lower operating costs. As more real-time data is collected at shorter and shorter intervals, users are detecting greater and greater variation in natural environments, temporally and spatially. These variations are important to understand the environment, identify baseline conditions and thus recognize when conditions stray from baseline.

The evolution of field sensing equipment has resulted in increasing volumes of data with a decreasing level of effort. Manual monitoring in the field often involves vehicles, boats, multiple technical personnel, fuel and requires a significant amount of labor to collect a relatively small amount of data. In some cases the data resolution does

not provide information on daily variations and often misses events such as algae blooms, storms or natural disasters. Fixed-point continuous monitoring stations such as data buoys offer high temporal resolution data and larger sensor payload capacity, but from only one fixed depth. Automated vertical profiling platforms offer high temporal and spatial (vertical) resolution and can monitor in near-real time the dynamics of a water column which allows user to monitor dynamics and events on relevant time scales. These systems are able to track short- and long-term natural cycles and trends and in some cases forecast events (algae blooms), monitor events and the impact and recovery of events.

Autonomous mapping vehicles provide spatial coverage of water quality at unprecedented resolutions, allowing users to map water bodies and develop improved understandings of the dynamics of the system. They are also capable of bathymetric mapping that can be used to map bottom type, calculate water volume, and visualize bottom features. Due to the limitations of spot sampling and the growing importance of collecting environmental data at environmentally relevant time and spatial scales, YSI has developed two new autonomous water quality platforms which allow for detailed unmanned monitoring. Figure 1 presents results from the Vertical Profiler and the AUV.

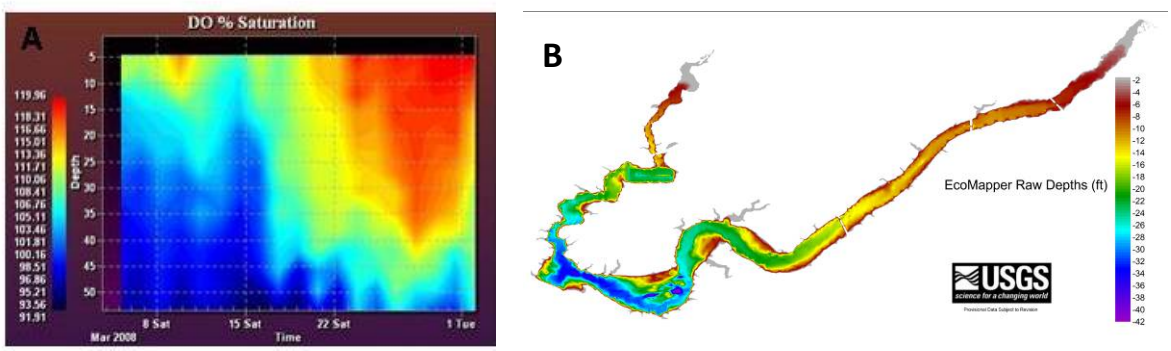

Figure 1. Two types of time-series data from (A) the Vertical Profiler showing variations in dissolved oxygen within a column of water over time and (B) an AUV mapping of depth of a lake.

Technological developments in the areas of in-situ sensors, data telemetry, and automated platforms have resulted in significant increases in system reliability and significant reductions in the cost of ownership. In regards to in-situ sensors, reliability has improved from new and more robust sensing methods, such as optical dissolved oxygen, as well as improved antifouling techniques that extend maintenance intervals thus reducing the cost of ownership. Data telemetry systems have evolved to plug-and-play systems that can post data to the web within minutes and requires no internal support, and monitoring platforms have developed to provide extremely high spatial and temporal resolution that would be extremely expensive or impossible to duplicate with other sampling modes.

This paper will focus on two automated platforms that are providing researchers, consultants and monitoring groups with tools to generate exceptionally high-resolution data that would have been cost prohibitive or impossible using more manual methods. The first platform is an automated vertical profiling system that provides water quality times-series data in near real-time throughout a water column. The systems are mounted

to fixed structures or to floating platforms and can be used in a variety of aquatic environments. The second platform is an autonomous underwater vehicle (AUV) designed specifically for water quality and bathymetric mapping. The vehicle collects data at 1 Hz as it moves horizontally and vertically through a water body at speeds of 1 to 4 knots. Both systems operate autonomously to carry a water quality sensor suite. The profiling system provides a time-series data set from multiple depths within a column of water. The system has been designed for extended maintenance intervals to maintain an affordable operating cost. The AUV runs missions on pre-programmed routes collecting data at a rate of 1 Hz. This allows an operator to map water bodies with 100% coverage. The autonomous operation of both systems results in a low cost of operation and high-resolution data.

AUTOMATED VERTICAL PROFILER

The Automated Vertical Profiler is a rugged monitoring platform that transports a YSI multiparameter water quality sonde through a water column at a user-defined interval. The system is capable of collecting water quality data in up to 100 m of freshwater or seawater. **Figure 2** presents a schematic of the Profiler. The water quality sonde is connected to a remote-controlled winch that raises and lowers the sonde to preprogrammed levels to collect vertical profile water quality data. The sonde is capable of measuring temperature, conductivity, salinity, specific conductance, dissolved oxygen, depth, pH, ORP, turbidity, algae biomass and blue-green algae biomass. A meteorological suite can also be installed. Considering the capabilities, there are a wide range of applications for the profiler including drinking water reservoir monitoring to improve treatment efficiency as well as lake/estuary/near coastal continuous monitoring.

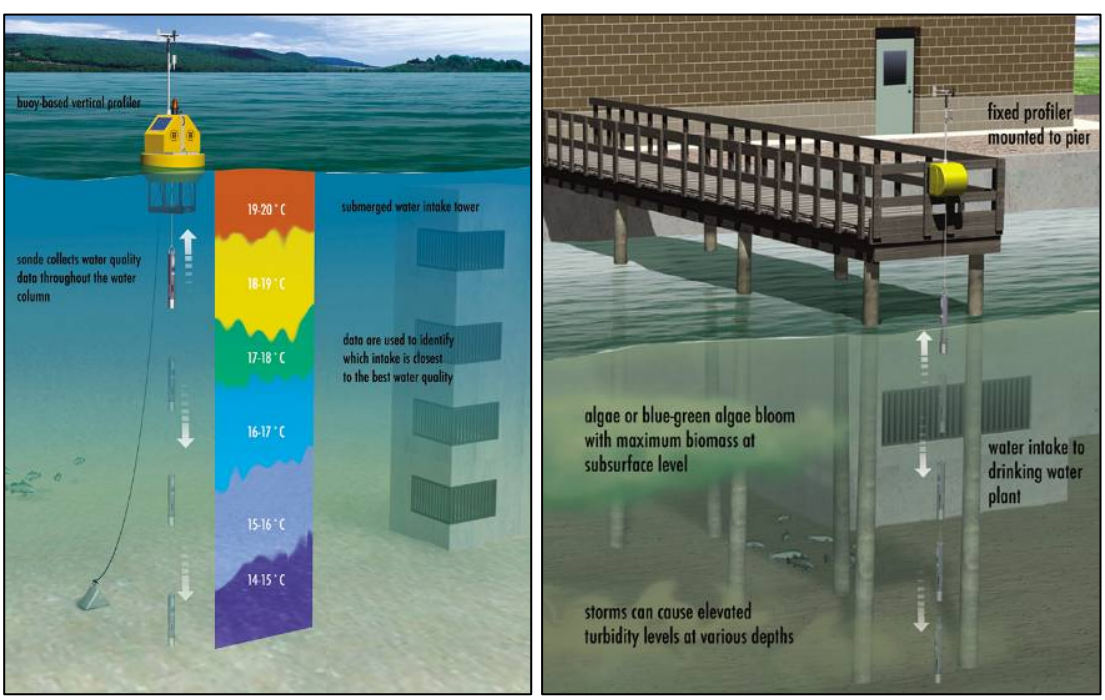

Figure 2 Schematic of the Vertical Profiler System installed near water intakes for drinking water plants; LEFT graphic of a profiling system mounted to a floating platform. RIGHT graphic of a profiling system mounted to a fixed platform such as a piling,

Of particular interest in recent years have been problems caused by blue-green algae (aka cyanobacteria) in drinking water reservoirs, often triggered by increased nutrient loading in watersheds. Blue-green algae are responsible for producing compounds (geosmin & MIB) that cause taste and odor problems in drinking water and in some cases producing toxins that can contaminate drinking water supplies. Planktonic algae, including blue-green algae, move throughout the water column and biomass in constant flux. The profiling systems allow plant operators to track total algae and blue-green algae biomass in near real-time in addition to other water quality parameters that can often stimulate an algae bloom or be impacted by algae growth such as temperature, dissolved oxygen, conductivity and pH. In reservoirs that have multiple water intakes to the plant, operators use the profiler data to identify the intakes with the best water quality thus increasing filter run-times, reducing chemical use and the likelihood of poor drinking water quality and customer complaints.

An important drinking water reservoir for the Raleigh, North Carolina area is Falls Lake. This lake serves 450,000 people and has been impacted by blue-green algae blooms for many years with blue-green algae making up to 75-95% of the algae population in the summer months (Werblow, 2008). A team at the Center for Applied Aquatic Ecology at North Carolina State University, working closely with the plant operators, has installed and maintained a continuous monitoring system for the past five years. The system is providing valuable data on blue-green algae dynamics during floods, droughts and storm events and saving the treatment plant operators money while improving water quality. The system is composed of multiple vertical profiling systems that profile the water column every 3 hours at 0.5 m depth intervals. The profiles are able to identify the chlorophyll maximum that guides where the optimal intake depths should be. The system also tracks algae blooms that can come and go with days or weeks and would likely be missed by manual sampling schemes. The profiler data are posted to a website (see Figure 3) that can be accessed by the public, researchers and plant operators to see the latest water quality information (www.ncsu.edu/wq).

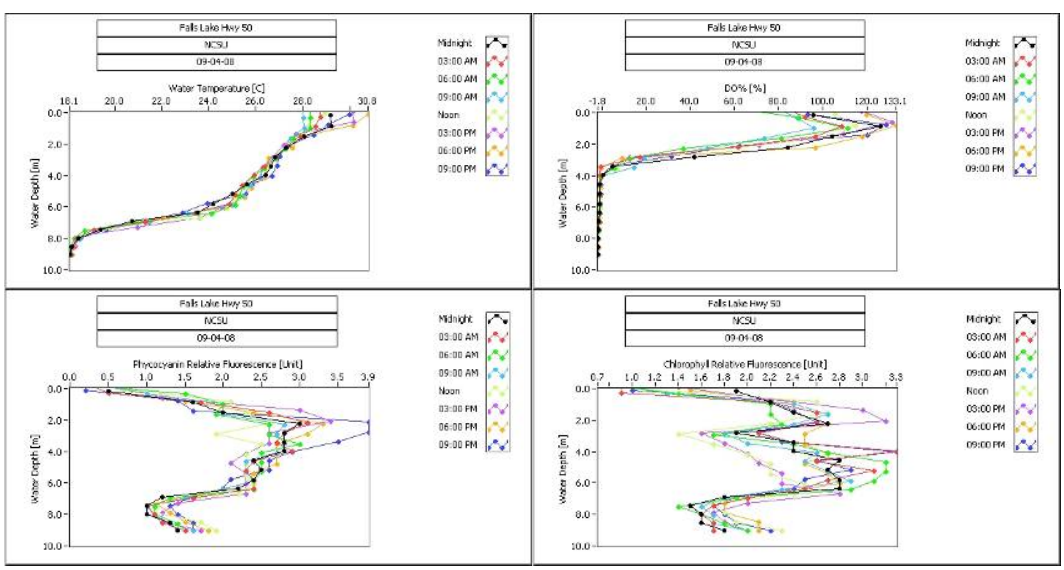

FIGURE 3: Examples of the daily profiler data posted to the web from Falls Lake. Graphs (from L to R, T to B) of temperature, dissolved oxygen, chlorophyll and blue-green algae.

A vertical profiling system offers significant cost savings. For plant operators, the near real-time data allows them to choose water intakes with the lowest blue-green algae biomass and therefore use less treatment chemicals, such as powdered activated carbon, needed for water with high blue-green algae biomass. In fact, plant operators have indicated that the cost of one fixed profiling system was less than the cost of one-week supply of PAC to treat high algae concentration. In other source water applications that use oxygenation systems, vertical profilers can result in significant power savings by providing continuous data on the dissolved oxygen levels and stratification. Profiler users in California have reported up to 50% savings in power consumption when the profilers have been installed. For researchers and monitoring groups, the price of the data is far less than using more manual methods.

AUTONOMOUS UNDERWATER VEHICLE

The EcoMapper™ AUV is a small, person-deployable environmental mapping vehicle that can operate in depths of <1 m and run for more than 8 hours on a single battery charge. These capabilities are coupled with a large sensor suite that requires only one field technician to deploy from shore, significantly lowering the operating costs. The data set that the vehicle is capable of collecting would be extremely challenging or impossible to collect from a boat or research vessel due to the EcoMapper's undulation and shallow depth capabilities and maneuverability. The EcoMapper has been designed to be an environmental mapping work horse capable of routine use in freshwater and near-coastal environments. The user loads pre-programmed mapping missions into the vehicle and the vehicle will operate completely autonomously to map an area, allowing the operator to conduct more technical work in the field.

The physical design allows for easy deployment from shore by one person. All external components on the vehicle can be easily replaced or installed in the field with the exception of the side-scan sonar. The external replaceable components include the water quality sensors, handle and balance assembly, vehicle antennae, control planes, propeller and cowling. This provides a more reliable system that can be repaired or re-configured in the field, saving the user valuable time and money.

The water quality sensors are located in the bow and are protected by the sensor guard. The field-replaceable water quality sensors suite (sensor payload is identical to the Vertical Profiler) is integrated into a sensor bulkhead which allows the user to add or remove sensors easily, providing a flexible payload that can be easily configured for a specific study. The EcoMapper antennae includes a GPS antennae, a charging plug for the internal lithium-ion power supply, optional cell phone and long-range radio antennas, and a series of LEDs that provide visibility to the vehicle while on the surface and indicate vehicle power and battery charging status. The four fins or control planes are field-replaceable as is the two-bladed prop and cowling. Figure presents a drawing of the EcoMapper.

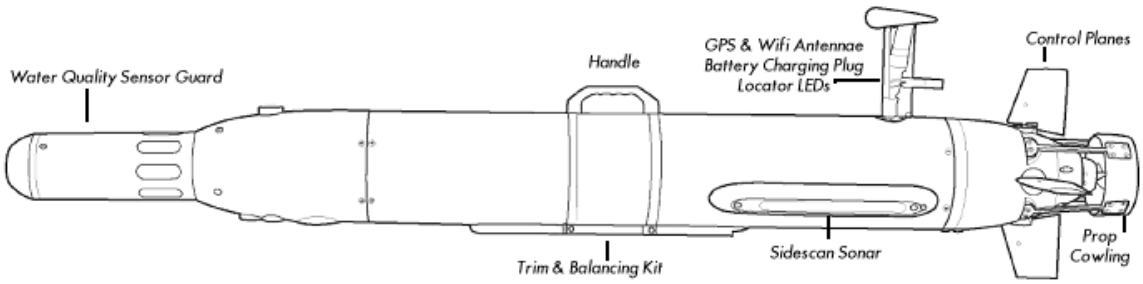

Figure 4. Technical drawing of the EcoMapper vehicle

Vehicle Specifications

Below is a list of technical specifications for the AUV. The AUV provides a flexible platform for water quality monitoring and hydrographic surveying. Options provide users the ability to monitor various water quality parameters as well as the ability to incorporate various bathymetry options making the AUV a valuable tool for lakes, reservoirs, estuaries and shallow coastal operations.

Dimensions: Length: 60.1 inches (152.65 cm);
Diameter: 5.8 inches (14.73 cm)
Weight (air): 45 lbs (20.41 kg)
Energy: 600 W-Hrs of rechargeable Lithium-Ion batteries (>300 cycles)
Endurance: 8 hours at speed of 2.5 knots (battery configuration dependent)
Speed Range: 1 - 4 knots
Control: Four independent control planes
External Connection: Data - wireless 802.11g Ethernet (up to 200m comm. distance)
Navigation: Dead reckoning via GPS (when on the surface)
Tracking: Internal data log (with programmable resolution)
Sensors: Conductivity, Temperature, Depth, height from bottom, 3-axis digital compass
Onboard Electronics: Low power X86 processor, 80 GB drive (data collection)
Software: Windows XP Embedded, GUI-based Navigation Suite
Communication: 2.4 GHz radio link (when on the surface)
Additional Options: Water Quality Sensors: Optical Dissolved Oxygen, Turbidity, Chlorophyll Fluorescence, Blue-green Algae Fluorescence, pH, ORP, Side-Scan Sonar: Imagenex 330 kHz or 330 / 800 kHz, DVL
Security System: Safety Tow Float

The EcoMapper is designed for fast deployment and ease-of-use and VectorMap mission planning software is a key feature to this capability. The software is loaded onto the user's PC and accepts a variety of geo-referenced map formats. The software allows the user to draw a mission directly on the map or image. For each leg of a mission, the user will program the location, vehicle speed, depth from surface or height from bottom or undulate between the two points, and which sensors to activate and log. Once a mission is created, a mission plan file is formed and transferred to the EcoMapper by loading it onto the UVC vehicle control software.

Communication with the vehicle is established via a Wi-Fi connection. The Wi-Fi antennae is located within the EcoMapper antennae and transmits a signal to the EcoMapper Communications Box, which is accessed by a wireless enabled PC or handheld device. The Communications Box is comprised of a rechargeable lithium-ion power supply, modem and Wi-Fi antenna. By running Windows™ Remote Desktop on a laptop or Pocket PC, the user can access the on-board computer and run the UVC vehicle control software. UVC is used to load missions, check diagnostics, transfer data and ~~to~~ take manual control of the vehicle when it is on the surface and within Wi-Fi range. After all vehicle missions, the EcoMapper creates a .log file. This file can be opened in mission planning software and overlaid onto the mission file to observe the vehicle's actual course.

Vehicle navigation occurs through the use of GPS position fixes at a series of surface waypoints. Between surface waypoints the vehicle 'dead-reckons' when it dives below the surface. If the vehicle is pushed off course between waypoints, the vehicle will detect this and travel back to the intended waypoint before continuing its mission. In areas with strong currents, more surface waypoints are required to keep the vehicle on course. An optional Doppler Velocity Log (DVL) will be available in the near future and will allow for very accurate sub-surface navigation in a range of conditions.

The EcoMapper has several safety features to minimize vehicle damage or loss in the case of unforeseen events. Internal detectors can detect a leak into the vehicle which will trigger the vehicle to surface and abort the mission. A series of safety rules are available to program vehicle behavior under specified circumstances such as; no forward progress, diving below specified depth, low power level, and mission length longer than specified time. A location pinger is standard in the event that the vehicle does not surface and a safety tow body is available that includes a large inflation device, depth sensor, additional pinger and control electronics if the AUV loses power and becomes stuck. A cell phone located in the vehicle can be used to track the vehicle when it is on the surface.

The EcoMapper has been deployed in a variety of environments over the past two years ranging from coastal to in-land waters and reservoirs to estuaries. In 2008 YSI worked with an agency in Illinois that required high-resolution water quality data at varying depths. The demonstration was conducted in one day and the purpose was only to demonstrate the EcoMapper's capabilities and not to conduct a scientific study. The EcoMapper mission was developed on site and required approximately 30 minutes to program and transfer to the vehicle. The site was a 4,900 acre lake surrounded by a recreation area that is a popular destination for fishing, water skiing, swimming, hiking and picnicking. The land and lake are owned by a power company that operates a nuclear power station in the area. The power station produces 1,043 net megawatts (electricity for ~1 million homes) and uses the lake to cool the plant's thermal discharge.

The lake is currently on the EPA's 303(d) list of impaired waters and classified as eutrophic. Sources of pollution are primarily agriculture, shoreline erosion and urban run off/sewers. There are currently no TMDLs reported for this water body and the source of impairment is listed as unknown. Groups monitoring the lake and the power company were both interested in the EcoMapper to autonomously produce high-resolution thermal and bathymetry maps of the lake in order to evaluate the lake's capacity to accept the thermal discharge and to study the ecological impacts of the discharge. Past thermal mapping was conducted through the use of aircraft and IR cameras, which provided a thermal map of the surface only. A preliminary mapping of the area around the power plant's thermal outfall was performed. The mission was 4 hours and 45 minutes with the

first half on the surface at a speed of 2 knots and the second half at 4 feet below the surface at a speed of 4 knots. The mission length was 11.1 miles.

Figure 5 shows some of the data collected. Image A displays the mission developed for the thermal outfall, where the dots indicate waypoints and the lines indicate the planned mission. Image B presents water depth, while Image C displays the water surface temperature with the thermal outfall evident from the hot water distribution. Image D shows subsurface temperature collected from 4 feet below the water surface. A clear difference in temperature distribution is seen between the surface (Image C) and subsurface data (Image D). Image E presents dissolved oxygen data at the surface while Image F highlights chlorophyll fluorescence at the surface. A clear pattern of lower algae biomass near the thermal outfall and increasing biomass away from the outfall was observed.

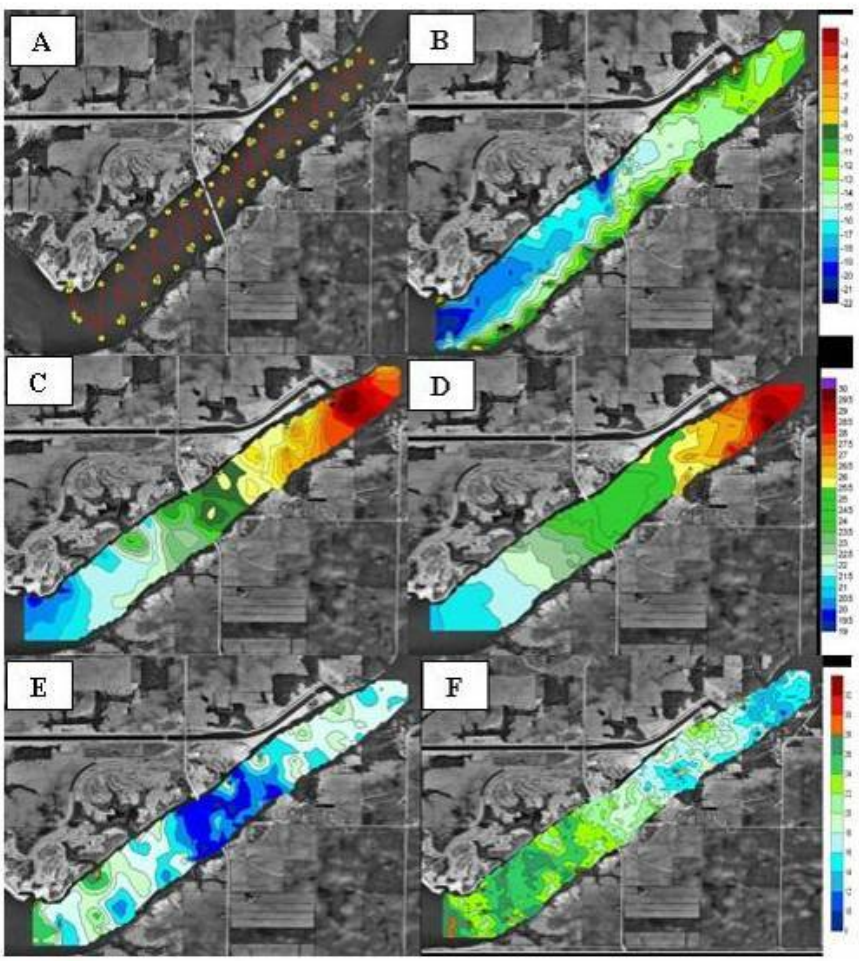

Figure 3. Test results from EcoMapper survey in a cooling lake

The second case study displays the potential of the EcoMapper for bottom mapping applications. The vehicle provides an exceptionally stable platform for side-scan sonar studies when it is navigated below the water surface. A lake was chosen as a test site for bottom mapping applications, where the EcoMapper was tasked with mapping a submerged aggregate plant. Charts of the location of the plant were made available and

the EcoMapper mission was planned to navigate approximately 5 m above the site (FIGURE 4). Two missions were planned; the initial mission was used for target location and the second mission was used for a more detailed target mapping. Within one day the EcoMapper was able to lock in on the target and map the submerged plant. Image A presents an original photo of the old aggregate plant at the bottom of the lake; metal structures that remain today can be observed in the photo. Image B displays a geo-referenced technical drawing of the plant; the purple lines are contour lines, while the orange lines and dots represent the AUV mission. Image C presents side-scan sonar images from the AUV mission; it can be observed from the data collected that there is an old grate present for aggregate sorting, as well as the concrete walls and steel girders from the aggregate plant. Lines indicating plant walls are wavy due to the navigation of the AUV.

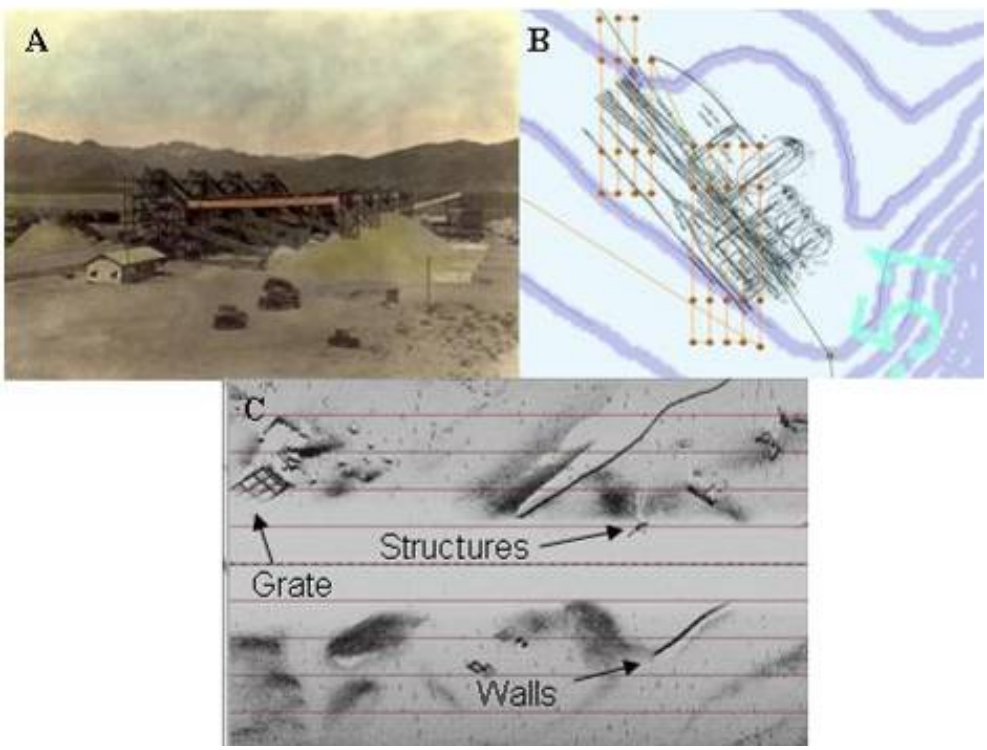

Figure 4. Side-scan sonar data from submerged aggregate plant in Lake Mead, NV

The EcoMapper AUV is a cost-effective platform for applications that require high-resolution spatial mapping of water quality. Applications for which the vehicle is well designed include baseline environmental monitoring, hypoxic zone mapping, algae bloom tracking, source water mapping and volume measurement, shallow water mapping, point-source studies, dye tracer studies, temperature and stratification studies, rapid response, environmental impact studies, and port and harbor security. In addition the EcoMapper can provide accurate bathymetry mapping with the depth standard and optional side-scan sonar package.

CONCLUSIONS

Both autonomous environmental monitoring systems presented here are capable of producing unique, high-resolution data that would be exceptionally difficult to generate with more manual methods. The Vertical Profiler provides a long-term time-series data set with important insight into the vertical dynamics of water body. The system is designed for continuous use with infrequent maintenance visits and remote troubleshooting capabilities. Given the size and cost, an EcoMapper provides a platform to efficiently collect three-dimensional data that were previously unattainable or cost- and time-prohibitive to operations personnel and scientists alike. EcoMapper missions can be run with only one person from shore and more technically demanding work can be completed while the vehicle is collecting data. In addition, the EcoMapper is designed for frequent use and can be deployed daily with rapid mission planning, fast battery re-charge, and field-replaceable sensors. Groups tasked with environmental monitoring or mapping should evaluate the cost of ownership and operation of field sensors and monitoring platforms carefully and consider how the use of autonomous systems such as those discussed here can provide high-resolution data at low operating costs.

Abstract

The South Florida Water Management District (SFWMD), one of five water management districts in Florida, is responsible for regional flood control, water supply and water quality protection as well as ecosystem restoration in the Southern portion of Florida. The SFWMD is partitioned into water control systems (WCS). Analogous to watersheds in that vertical fluxes of water enter through rain and exit through evapotranspiration, the WCSs differ in that they have control structures to regulate horizontal flux through a system of canals. Efficient control of these structures ensures that SFWMD's multiple water resources objectives are met. SFWMD is currently building an operations decision support system (ODSS) for control of its water-control systems. A possible source of information for the ODSS is a water-budget-based real-time assessment of WCS system state, which is implemented as the WCS Tracker application.

The WCS Tracker application is a computer software solution that comprises 1) an extension to ESRI's ArcMap software, 2) an enterprise geo-database, and 3) a windows service for real-time calculation. Through a SCADA system, the WCS Tracker application receives real-time measurements of gage and radar-based rainfall, gage-based evapotranspiration, and flow and stage measurement of the WCS control structures. By way of various interpolation schemes, this input is re-analyzed into a regular time interval and used in a water budget equation to evaluate the storage of water in the water control system. This storage term is an indicator of oncoming overland flow and thus provides advanced warning to aid in control structure decisions.

The WCS Tracker has been developed over three year-long phases in 2005, 2006, and 2007. Over the first three phases, the WCS Tracker application was transformed from a research proof of concept, to a raw prototype, to a matured workbench that allows operators to create and configure new WCSs, calibrate them with historical data, enroll them in real-time services, and explore their water budget model results.

The current phase of the WCS Tracker (2008) focuses on integration into the SFWMD enterprise through technology and knowledge transfer. First, the WCS Tracker will be enhanced to provide direct access to historical data from SFWMD's DBHydro database. DBHydro represents the best store of meteorological and hydrological information for calibration of WCS water balance models. A fast and user-friendly means of accessing this data directly from the WCS Tracker tools is essential for ongoing water budget modeling. Second, the WCS Tracker will be made more accessible to SFWMD operations and research staff by migrating the application to SFWMD's Citrix environment. Third, the WCS Tracker will be stabilized and tested for quality assurance. Lastly, the WCS Tracker will be thoroughly introduced to SFWMD operators through one-on-one training workshops. Through these workshops, the WCS Tracker will be refined based on operator preferences to ensure comfort with the tool and successful acceptance by its users.

Introduction

The South Florida Water Management District (SFWMD), one of five water management districts in Florida, is responsible for regional flood control, water supply and water quality protection as well as ecosystem restoration in the Southern portion of Florida. The SFWMD is partitioned into 168 water control systems (WCS) that are managed by the Operations and Management group. Analogous to watersheds in that vertical fluxes of water enter through rain and exit through evapotranspiration, the WCSs differ in that they have control structures, such as pumps, gates and weirs, to regulate horizontal flux through a system of canals. Efficient control of these structures ensures that SFWMD's multiple water resources objectives are met.

The Operations division of SFWMD is charged with controlling the structures at the outlets and inlets of the WCSs to avoid flood damage and to ensure the highest available water supply during drought. As part of meeting its charge, the Operations division is building the operational decision support system (ODSS). A possible source of information for the ODSS is a water-budget-based real-time assessment of WCS system state, which is implemented as the WCS Tracker application. The WCS Tracker does nowcasting of the storage of water in the WCSs. Nowcasting is real-time modeling of the WCSs to determine current WCS system state.

The WCS Tracker has been developed over three year-long phases in 2005, 2006, and 2007. During this first phase, the Arc Hydro Enhanced Database (AHED) was developed by the SFWMD information technology department as the GIS database of record for the District. This GIS enterprise database is based on the basic Arc Hydro design, but extends the design for the purposes of providing the business groups at SFWMD with a useful framework for production of tools like the WCS Tracker. It was determined in the first phase that the AHED database would provide the geo-spatial foundation for the WCS Tracker.

In the second phase, the alpha version of the WCS Tracker was developed and installed on O&M machines. With this operational version of the WCS Tracker, real-time calculations of the water budget models for the pilot area commenced. A new database, specifically intended for operational purposes called OpHydro was built. The OpHydro schema design started with replicating the Arc Hydro Enhanced Database (AHED) schema. The schema was then extended to add data structures for real-time water budget modeling. The addition of supporting data structures to store time-series facilitated the use of OpHydro as a unifying spatial platform that could store data from the SCADA OASys system, IMS, and the DBHYDRO databases.

The third phase of development matured the WCS Tracker to a workbench that allows operators to create and configure new WCSs, enroll them in real-time services, and explore their water budget model results. Additionally, it provided a more accurate water budget calculation procedure, an optimization-based means of calibrating WCSs with historical data from the District's DBHydro database, and an enhanced user experience through user friendly interface design, animation of recent rainfall and storage data, and enhanced time series processing capabilities.

This paper will describe the current phase of the WCS Tracker (2008) which focuses on integration into the SFWMD enterprise through technology and knowledge transfer. First, the WCS Tracker will be enhanced to provide direct access to historical data from SFWMD's DBHydro database. DBHydro represents the best store of meteorological and hydrological information for calibrating WCS water balance models. A fast and user-friendly means of accessing this data directly from the WCS Tracker tools is essential for ongoing water budget modeling. Second, the WCS Tracker will be made more accessible to SFWMD operations and research staff by migrating the application to SFWMD's Citrix environment. Third, the WCS Tracker will be stabilized and tested for quality assurance. Lastly, the WCS Tracker will be thoroughly introduced to SFWMD operators through one-on-one training workshops. Through these workshops, the WCS Tracker will be refined based on operator preferences to ensure comfort with the tool and successful acceptance by its users.

WCS Tracker Application

A WCS is composed of a land portion on which overland flow occurs and a water portion, which may be composed of natural rivers and lakes or man-made canals. The land portion is known as the water control catchment (WCC). The water portion is known as the water control unit (WCU). Figure 1 schematically illustrates a WCS.

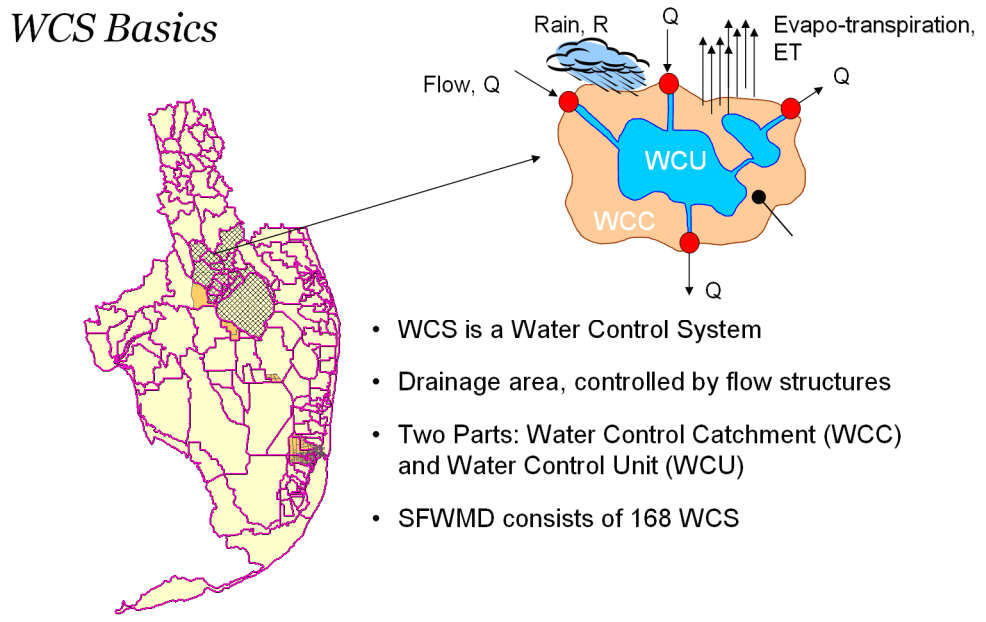

Figure 1. The basic WCS contains two regions, the terrestrial water control catchment (WCC) and the water conveying water control unit (WCU).

A water budget can be applied to each WCS by deriving a water budget equation for the WCC and WCU separately and then subtracting the two equations to produce a single, solvable, water budget equation. The remainder term of the final water budget equation is equivalent to the storage within the WCC plus an additive error term:

$$S_{wcc}(t) = (R_{wcc}(t) - ET_{wcc}(t))A_{wcc} + (R_{wcu}(t) - ET_{wcu}(t))A_{wcu} + Q_s(t)\Delta t - S_{wcu}(t) + S_{wcu}(t-1) + S_{wcc}(t-1) + \varepsilon$$

where

S	=	Storage volume (l^3)
R	=	Rainfall accumulation during interval $\triangle$t (l)
ET	=	Evapotranspiration accumulation during interval $\triangle$t (l)
A	=	Area (l^2)
Qs	=	Flow through Control Structures (l^3/t)

The WCS Tracker application is a computer software solution that comprises 1) an extension to ESRI's ArcMap software, 2) an enterprise geo-database, and 3) a windows service for real-time calculation. Through the SFWMD supervisory control and data acquisition (SCADA) system, the WCS Tracker application receives real-time measurements of gage and radar-based rainfall, gage-based evapotranspiration, and flow and stage measurement of the WCS control structures. By way of various interpolation schemes, this input is re-analyzed into a regular time interval and used in the water budget equation above to evaluate the storage of water in the water

control system. This storage term is an indicator of oncoming overland flow and thus provides advanced warning to aid in control structure decisions.

The workbench for the WCS Tracker application is shown in Figure 2. The extension is embedded into the ArcMap software as a contents view control. A windows-explorer like tree, called the WCS Tree, is the central control. This tree provides an organized hierarchical view of the WCS(s) currently selected. As the user selects nodes in the tree, contextual information and options about the node are presented in the informational panels (see figure 2). The map and chart present cartographic depictions and time series depictions of the WCS respectively and are driven by selection of nodes in the tree that apply to the WCS and its inventory of time series.

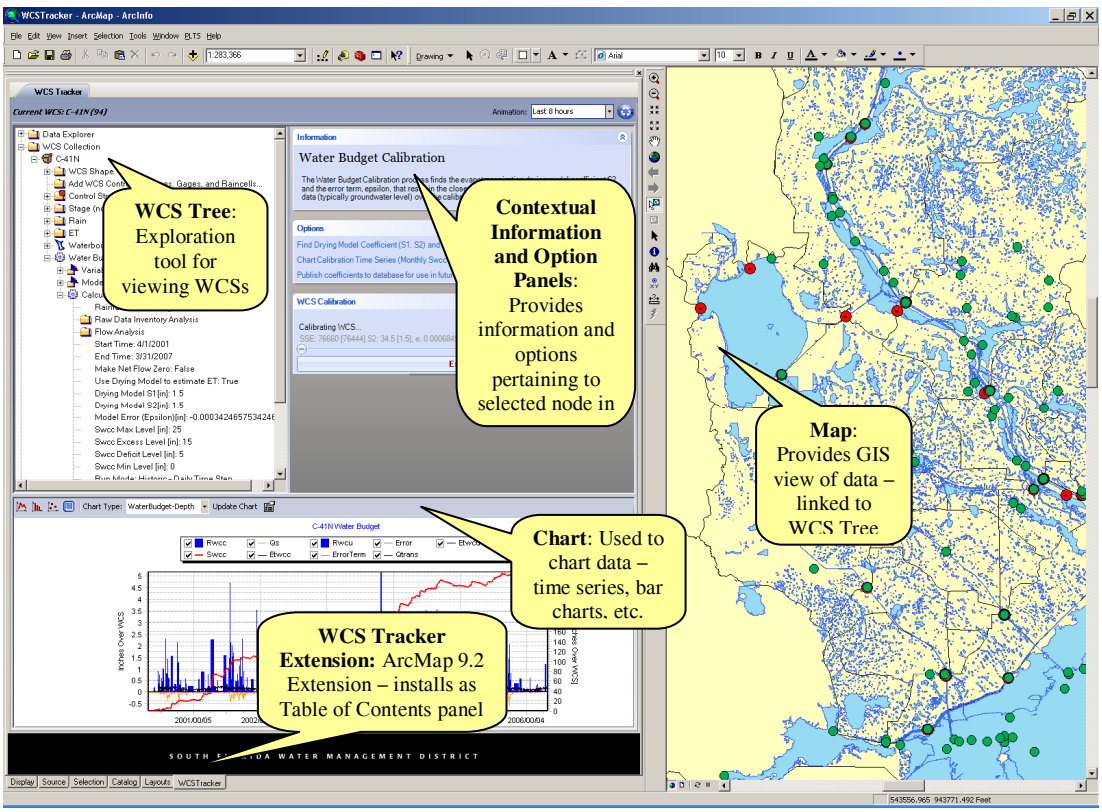

Figure 2. WCS Tracker workbench within ESRI's ArcMap.

WCS Tracker Phase IV (2008)

The current phase of the WCS Tracker (2008) focuses on integration into the SFWMD enterprise through technology and knowledge transfer. This was accomplished by 1) providing direct access to historical data from SFWMD's DBHydro database, 2) deploying the application to SFWMD's Citrix environment; 3) on-going stabilization and testing, and 4) on-site comprehensive training workshops.

Access to DBHydro Database

The introduction of the ability to calibrate and configure WCSs has underscored a need for automated access from the WCS Tracker to sources of historical data. Previously, data for calibration was collected manually from SFWMD's DBHydro database and imported to the OpHydro database. The DBHydro database represents the best store of meteorological and hydrological information available for use in WCS historical calibration. A fast and user-friendly means of accessing this data directly from the WCS Tracker tools was deemed essential for ongoing WCS modeling.

During the current phase, a functional component was developed for direct access to the DBHydro database from the WCS Tracker user interface enabling SFWMD users the ability to explore, visualize, and download any data within DBHydro. From a user's perspective, the WCS Tracker interface will allow them the ability to select a monitoring point or structure and desired variable: stage, rain, ET or flow. The WCS Tracker GUI will then display a list of all DBKeys that fit the user's requirements. DBKeys are unique identification keys for every time series stored in the DBHydro database. The user can then select a DBKey and the time series data will be charted. If the user desires, they can associate DBKeys with monitoring points or control structures in the OpHydro database. By associating the DBKey with the monitoring point/structure it can now be used for calibration purposes.

Access to the DBHydro database is accomplished through activating stored procedures contained in the OpHydro database. These stored procedures in turn execute procedures in the DBHydro database for retrieving DBKeys and their time series. Figure 3 shows the processes for: 1) searching for data in DBHydro; 2) accessing historic time series data for specified DBKey from DBHydro; and 3) storing the time series data to OpHydro through the WCS Tracker interface.

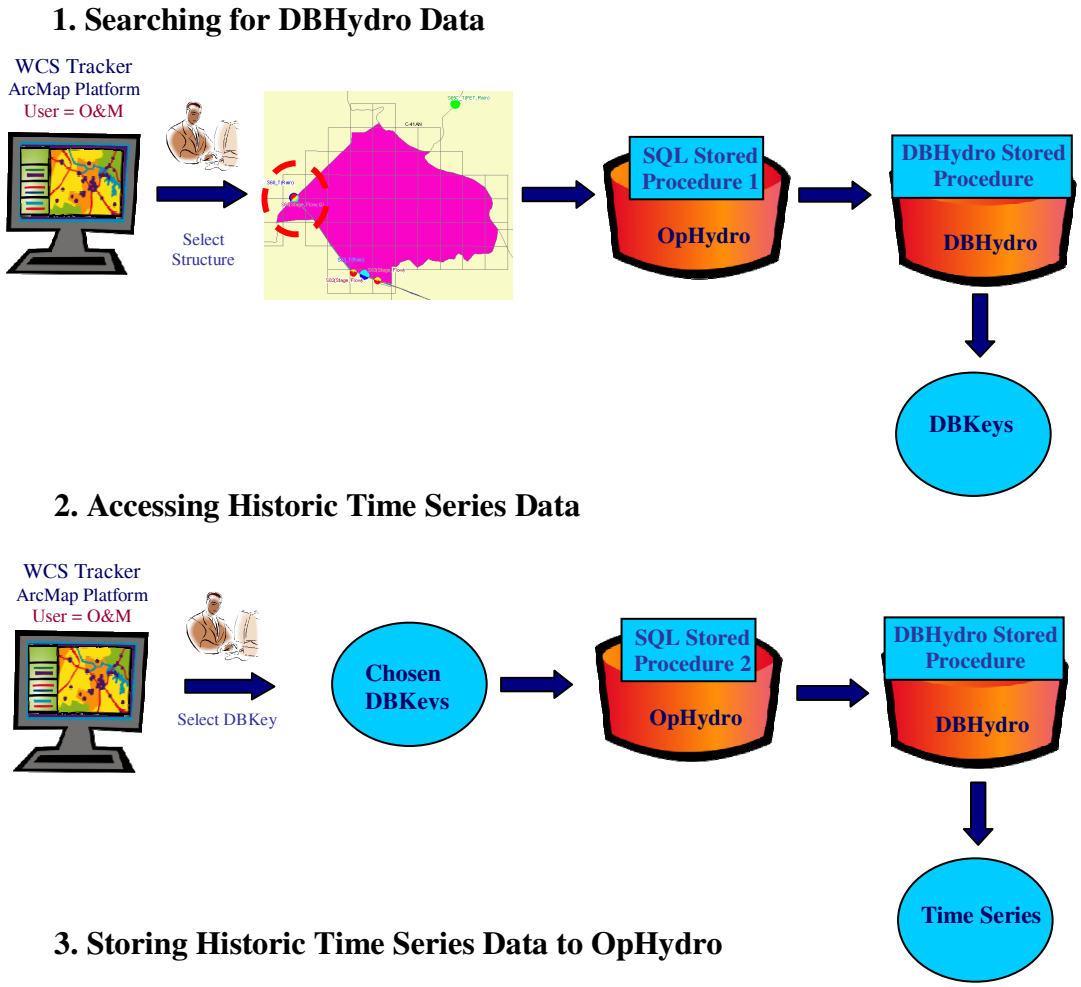

Figure 3. Schematic showing the three processes for: searching for DBHdyro data; accessing historic time series data for specified DBKey from DBHydro; and storing the time series data to OpHydro through the WCS Tracker interface.

Migration to Citrix Environment

Building the WCS Tracker user base is essential. Previously, the WCS Tracker application needed to be installed on each user's computer. Since the application is an extension of ESRI's ArcMap, ArcMap must also be installed on each computer. This limited the number of users that could access the WCS Tracker application. In this phase, the application has been made more accessible to SFWMD operations and research staff by migrating the application to SFWMD's Citrix environment. The Citrix environment allows multiple users to log on and run applications in separate, protected sessions on a single server without having them installed on their local hard drive. Since the application resides on a single server, it allows for an easier, faster and more reliable deployment, maintenance and upgrade, in addition to providing mass availability.

In order for the WCS Tracker application to successfully run on SFWMD's Citrix environment several coding conventions were required. The most significant requirement was that the application could not be coded to read or write to a specific drive. In addition, the SFWMD protocol for Citrix migration required a multi-stage process of development and testing on several servers prior to full deployment to the Citrix environment to ensure minimal conflicts with other Citrix environment applications. The greatest challenge in successfully migrating the WCS Tracker to the Citrix environment was how to handle multi-user access and editing of the same database, OpHydro. This was accomplished by enforcing through the WCS Tracker tool a single-editor policy, where only one editing session can be opened on the OpHydro database at a time.

Testing and Stabilization for Quality Assurance

Testing was conducted through-out the current phase to ensure that any application and architecture modifications were functional and stabilized for quality assurance. This consisted of integration testing of a series of use cases to ensure that each functional requirement of the application is performing as it is supposed to. Each use case was described in a table that listed the functionality, the actor, the flow of events, any alternative flow of events, pre-conditions, post-conditions and user interface components. Table 1 provides an example of a use case for searching for DBHydro data within WCS Tracker.

Table 1. Example integration test for searching for DBHydro data within the WCS Tracker application

Use Case:	**Search for DBHydro Data**
Description:	User searches for historic data in DBHydro database. WCS Tracker displays a list of historic time series data based on proximity to monitoring point/structure of interest and parameter of interest.
Actors:	Operator

Flow of Events:	1. User clicks on a monitoring point under the Data Explorer node in WCS Tree 2. User selects the *Rain* parameter from the drop down menu in the Time Series Explorer panel 3. User clicks the *Find DBHydro data close to this monitoring point* contextual option 4. A list of available historic time series data close to the monitoring point from DBHydro appears within the Time Series Explorer panel
Alternative Flow of Events:	1a. User clicks on a control structure under the Data Explorer node in the WCS Tree 2a. User selects the *Flow* parameter from the drop down menu in the Time Series Explorer panel 2b. User selects the *Stage* parameter from the drop down menu in the Time Series Explorer panel 2c. User selects the *ET* parameter from the drop down menu in the Time Series Explorer panel 3a. User clicks the *Find DBHydro data close to this control structure* contextual option 4a. A list of available historic time series data close to the control structure from DBHydro appears within the Time Series Explorer panel
Pre-conditions:	Valid ArcMap MXD is open with OpHydro databases set. User has searched for existing data in OpHydro database.
Post-conditions:	
U.I. Components	WCS Tracker Tab. WCS Tree with contextual options and nodes for Data Explorer.

Training Workshops

The addition of the direct link with the DBHydro database from the WCS Tracker interface and the deployment of the application to SFWMD's Citrix environment during the current phase brought the WCS Tracker tools to a point where they could be used widely by the operators at the District. Therefore, a comprehensive on-site training program was developed to encourage full adoption of the tool in day-to-day usage.

The training workshop was conducted to demonstrate the application, validate its stability, resolve issues, and train SFWMD staff on the application's use. Training was done with the O&M water management team to demonstrate functionality through pre-defined usage scenarios that string together functionalities in a manner resembling everyday use. The workshop occurred over two days during morning sessions. Any application stability issues and additional refinements identified during the morning sessions were addressed in the afternoons in preparation for the next day

of the workshop. We have found great success with this kind of intense workshop in the past with other development projects. The result of the workshop is a refined tool that works exactly how the water managers expect.

Conclusions

The WCS Tracker is a real-time water budget application for assessing the current state of a Water Control System (WCS) within SFWMD. The WCS Tracker has been developed over four year-long phases in 2005, 2006, 2007 and 2008. Over the first three phases, the WCS Tracker application was transformed from a research proof of concept, to a raw prototype, to a matured workbench that allows operators to create and configure new WCSs, calibrate them with historical data, enroll them in real-time services, and explore their water budget model results. Over the last and current phase, the WCS Tracker application has undergone further enhancements by providing direct access to the DBHydro database, SFWMD's best store of historic data. In addition, the application has been migrated to SFWMD's Citrix environment allowing increased accessibility to users. Testing was conducted throughout the phase for quality assurance and to ensure a stable and functional application. Lastly, a comprehensive one-on-one training workshop provided technology and knowledge transfer to SFWMD users. Building the WCS Tracker user base is essential for continued development of the application. In the future, more hands on training workshops will be crucial to the successful transfer of the WCS Tracker application to SFWMD's Operations and Management group.

Coordinating and implementing a graduate course on interdisciplinary modeling for water-related issues

Laurel Saito,[1] M. ASCE

[1] Graduate Program of Hydrologic Sciences, University of Nevada Reno, Mail Stop 186, 1664 N. Virginia Street, Reno, NV 89557; PH (775) 784-1921; Fax (775) 784-4583; email: lsaito@cabnr.unr.edu

ABSTRACT

The science and management of water-related issues is inherently interdisciplinary, involving hydrology, atmospheric science, water quality, geochemistry, sociology, economics, environmental science, and ecology. Although these issues are increasingly being addressed in an interdisciplinary manner, education and training in interdisciplinary approaches in higher education face challenges that include: engaging faculty from different disciplines to teach a course, attracting students from different disciplines to participate in a course, and finding effective teaching approaches that work for diverse academic backgrounds. A graduate-level course on interdisciplinary modeling for water-related issues was recently offered by 17 faculty from three institutions with an overall objective of *engaging interdisciplinary discourse in modeling aquatic ecosystems*. Students were introduced to models available in different disciplines and how such models might be applied together to address water-related issues, and issues in implementing interdisciplinary approaches. Students also worked in interdisciplinary teams to apply interdisciplinary modeling approaches. This presentation describes the development, implementation, and outcomes of the course, including some of the challenges, rewards, and lessons learned.

INTRODUCTION

The science and management of water-related issues is inherently interdisciplinary, involving hydrology, atmospheric science, water quality, geochemistry, sociology, economics, environmental science, and ecology. Models are useful tools for addressing water-related issues, but there are many challenges in implementing interdisciplinary modeling approaches (Saito et al. 2007). A primary challenge that this paper addresses is the need for education and training in interdisciplinary approaches (Nicolsen et al. 2002; USGS 1999). Education and training in interdisciplinary approaches in higher education face challenges that include: engaging faculty from different disciplines to teach a course, attracting students from different disciplines to participate in a course, and finding effective teaching approaches that work for diverse academic backgrounds. In 2005, a workshop funded by the National Science Foundation was held to develop a curriculum for a graduate-level course on interdisciplinary modeling for aquatic ecosystems. The outcomes of that workshop were extremely positive (Saito et al. 2007) and led to the first course offering in July 2008, as described in this paper.

COURSE DESCRIPTION

After the workshop in 2005, faculty from the University of Nevada Reno (UNR) and the University of California at Davis (UCD) worked together to provide an offering of a graduate course on interdisciplinary modeling that could be attended jointly by students from UNR and UCD. This offering occurred in Summer 2008 at the Tahoe Center for Environmental Science (TCES), a facility located between the two campuses in which both universities have office and meeting space. There was a lead coordinator at each university, seven co-instructors, and eight guest lecturers from UNR, UCD, and the Desert Research Institute (DRI) who participated in teaching the course. The course was held 8 hours each day for 15 days (a three-week period), and generally followed a format of lectures in the morning, followed by related laboratory exercises in the afternoon. Students worked in teams of four to complete an interdisciplinary modeling project that was started in the second week of the course. There was one field trip to learn more about the topics of the interdisciplinary modeling projects. A wiki was used to allow continual updates of the course website with materials from lectures and exercises and to share data for the projects. Topics covered ranged from disciplinary approaches such as watershed modeling, algal modeling, economic modeling, and atmospheric modeling, to issues with interdisciplinary modeling such as modeling uncertainty and issues of scale. Some case studies of interdisciplinary modeling projects were also presented.

OUTCOMES

Although eight students from UNR participated in the course, no students from UCD participated. The students in the course were graduate students in economics, political science, hydrology, environmental science, and ecology. Thus, despite the small class size, there was great diversity in the backgrounds of the students. Faculty were very impressed with the modeling projects, not only because of the amount of work completed in such a short period of time, but also because of the innovation and creativity used to approach the projects. Student evaluations of the course were overwhelmingly positive. Students especially liked being exposed to so many different disciplines during one class, using the wiki as an instructional tool, and the interdisciplinary modeling project.

CHALLENGES, REWARDS, AND LESSONS LEARNED

A number of challenges were involved in implementing the course, including finding faculty willing to participate in such a course for little or no compensation or course credit, finding students to participate in the course from diverse disciplinary backgrounds to enable interdisciplinary dialogue and interaction during the course, and coordinating and designing the lectures and exercises among diverse faculty. Despite the extra effort required to implement the course, the rewards for faculty included the opportunity to see lectures and exercises from other disciplines and opportunities for interaction among themselves to discuss research and possible collaborations. The students gained valuable skills in interdisciplinary communication

and dialogue, as well as an appreciation of the amount of resources available to them from other disciplines in water-related modeling. Among the many lessons learned was the need for adequate housing when the course is offered far from campus, which was especially true for potential UCD students. In addition, one student was taking the course pass/fail, which affected group interactions in her modeling group. In the future, students will not be allowed to take the course pass/fail so that all students are invested in doing the interdisciplinary modeling project.

Experiences Teaching a Multi-Disciplinary Course

Daniel P. Loucks

School of Civil and Environmental Engineering, Cornell University, Ithaca, NY 14853
PH (607) 255-4896; FAX (607) 255 9004: email: Loucks@cornell.edu

ABSTRACT

Cornell University offers a two-year professional masters degree program in public administration. This program attracts participants who have had work experience and interests in furthering their careers in consulting and in government and non-governmental organizations, mostly dealing with economic development, public finance, and environmental protection. They are an incredibly bright and interesting group of individuals (for example one recent student had 17 years of experience managing the Indian railroad!) but typically they have not had much training in quantitative methods, and specifically model building and use. In fact many will almost do anything to avoid such work. We who plan courses for these individuals have decided that their academic program should include at least three courses in quantitative analyses, including the use of statistics and systems analysis methods. I offer one of these courses that focuses on the art and science of building and solving models to aid in the identification and evaluation of alternative plans or policies for addressing public policy issues and problems.

INTRODUCTION

Public System Modeling is a course designed for students enrolled in our professional master's degree program offered by Cornell University's Institute for Public Affairs. Students who are admitted to this program come from many different disciplinary backgrounds, but few have the training in mathematics and physics that engineers typically have. Few have had statistics, probability, calculus, or even the economics that would be ideal prerequisites for this course in public systems modeling. And few if any are really interested in getting such a background. The faculty of CIPA believes some background and experience in the use of simulation and optimization modeling should be a requirement of the master's degree program. Many CIPA alumni tell us the organizations they work for use such methods applied to economic development, financial planning, and environmental resources management. So, the challenge is how to offer these subjects in model building and use an effective way without taking too much of the available time students have for the study of all the courses they want to take during their two years at Cornell.

COURSE CONTENT

The course is designed to be an introduction to the art model building and use, especially related to public sector planning and management issues. This includes environmental policy issues as well as other public sector problems in administration, management and development. The course introduces for the first time to many students the quantitative systems approach for identifying, evaluating and estimating the physical, economic, environmental, and social impacts of decisions planners and managers are asked to make when addressing specific issues of concern. The problems examined in this course are not likely to be those any of the students will address after graduation, but are designed to help individuals develop the skills of building and using quantitative models to address and analyze problems. Students call this a puzzle solving course. By the end of this one-semester course students should feel competent in the development and use of computational and modeling tools for generating information useful to those making decisions typically addressed by public administrators and policy makers.

The quantitative methods introduced in this course include various deterministic and probabilistic optimization and simulation approaches and models, and decision analysis. They require some knowledge of differential calculus useful in economic analyses. Multi-objective modeling approaches for generating efficient tradeoffs among different system performance criteria are also introduced. All of the quantitative mathematical methods involving calculus, statistics, probability theory and systems engineering or operations research are at the level of undergraduate introductory courses in those subject areas. The aim of all of this 'modeling technology' is to facilitate the identification and evaluation of the impacts of alternative courses of action and the communication of that information in ways that result in more informed decision making.

The public sector ‘puzzles’ examined in this course include, but are not limited to, those involving public health, air and water quality, military strategies, timber and water yield management in watersheds, transportation planning, location of public facilities, privatization of public utilities, environmental economics, enhancing police and fire services, public infrastructure expansion and maintenance policies and urban development. Benefit-cost analyses and an introduction to engineering economics are also included.

The course involves the use of several computer software packages, none of which require computer programming. Yet interestingly, students have more trouble understanding how to construct flow diagrams that outline some search procedure, for example, than learning how to perform a Monte Carlo simulation.

Homework exercises are assigned and students are encouraged to, work on them with others in the class. The end-of-course project is a team effort, but each member of each team is graded based on the team's work and the recommendations of others in the team. This is intended to simulate a typical consulting experience where teams consisting of professionals often from different disciplines are assigned to address a problem. The course includes one test to evaluate how much each individual has learned in the course without outside help. A teaching assistant provides considerable outside class time help to those who desire it.

STUDENT RESPONSES

Just how well is this course working? Perhaps one measure of this is the end-of-course responses provided by the students. Each year almost everyone cites the enormous work load and time spent on the homework exercises, yet at the same time they comment on how enjoyable and valuable the course has been for them. The teaching assistants I've had have been critical to the degree of success this course has had. Being available when students want help considerably contributes to how they feel about the course.

Clearly I've learned in my some 40 years of teaching here and elsewhere that at least I can't please everyone all the time, and perhaps some never. On the positive side a sampling of comments from this past Fall semester's course include:

> "The course succeeded in bringing a mathematical subject to mostly non-mathematical students, in a rapid fashion, using well chosen examples and carefully using the essential math tools without overburdening them with excessive rigor.
>
> The course itself is very useful for anyone interested in policy planning. The subject matter is very strong, teaching some very helpful and dynamic modeling concepts.
>
> The homeworks assigned were drawn from real-life situations and were very applicable to my academic requirements as a Public Administrative student.
>
> The course content is very useful, and it seems to be helpful when taking other courses such as economics or finance.
>
> The group work was helpful in that it taught us to work well in a group.

On the negative side a sampling of comments from the same class of students included:

> "Too many methods to learn. I need more time and easier exercises to digest them.
>
> It'd be helpful to have real world application in mind or more of a big picture, rather than just seemingly random problems on the homework, especially since most of the class is comprised of policy-minded people and not science-based people.
>
> Even as someone with a background in advanced calculus and statistics, homework exercises still took me a VERY long time to complete, even with added help.
>
> The lectures for me were not very helpful. First of all, the time of the class was too early, from 8:00 am to 10:00am. For such an intense and difficult course, it was hard being so attentive so early in the morning.
>
> I really liked the course content, but I think it could have been explained better.

> There were too many assignments. Instead of weekly assignments, bi-monthly assignments would've been better. It would have given us more time to concentrate on and understand each assignment better.
>
> The course is more valuable for students with a good mathematics background, hence graduate level math or calculus should be made a pre-requisite for the course."

DISCUSSION

Many multidisciplinary courses are taught by a team of professors, each a specialist in his or her discipline. In this Public Systems Modeling course I pretend I know something about a wide variety of public policy issues but clearly I do not have any in-depth knowledge of all of them. (But I'm learning!) Obviously I can and should improve my teaching methods and style and student comments are perhaps a useful guide for learning what needs improving. Yet the dilemma is that students with different backgrounds require different amounts of time and instruction to learn what is being taught. In this situation it is not possible to require all students to take prerequisite courses in various disciplines to prepare them to take a course like this. Cornell offers a web-based course covering some of the fundamentals of mathematics and statistics the summer before students arrive at Cornell, and encourages CIPA applicants to take it if they feel the need for it and have the opportunity to take it. In any case we can not assume everyone in the class will have had those subjects. Many who have had calculus and statistics early in their academic careers, claim that by the time they become CIPA students they have forgotten them. What this generally leads to is more outside class time devoted to helping those having weaker backgrounds.

I also teach a junior undergraduate engineering class and a graduate engineering class at Cornell. While it is dangerous to generalize, and there are exceptions, I have to say that my experience in front of CIPA students seems much more enjoyable than when I'm in front of engineering students – those in my own discipline! CIPA students ask more questions in class and argue more with me. They talk more. They make me think. I learn something from them that I don't when students are very quiet and not interacting with me. Perhaps by the time I see those engineering students in my classes they are exhausted from all the chemistry, physics and engineering pounded into them that diminishes the creativity and curiosity they came to Cornell with. They also typically have not had the work experiences that CIPA students have. In my view this says something about the advantages of a more liberal education and perhaps some job experience prior to entering a graduate program to get a degree in engineering. See for example the papers on water resources education in the Special issue of Journal of Contemporary Water Research and Education on *A Creative Critique of U.S. Water Education* (Issue 139, June, 2008).

CONCLUSION

I've described a public systems modeling course I teach to students enrolled in a professional master's degree in public administration. These students have had a variety

of work experiences and were trained in a variety of disciplines. The multi-disciplinary interactions among these students as they struggle together to develop and apply analytical models as aids for analyzing a wide variety of public policy problems or issues are probably the most educational aspects of this course. They know they benefit from this experience, probably because they know how such tools and approaches together with different disciplinary inputs could have benefited them in the jobs they had prior to coming to Cornell.

The challenge of course is just how best to provide and enrich this learning experience. Hopefully the discussion that this talk motivates will provide all of us some ideas we can explore that could improve the effectiveness of not only this course but other multi-disciplinary courses as well.

Water Resources in Sudan: Enhancing Rainfall Harvesting Methods for Water Supply

S. Mohamed-Ali[1], S. Luster-Teasley, PhD[1], and E. Nzewi, PhD, PE[2]

[1]North Carolina A&T State University, Department of Civil, Architectural, Agricultural and Environmental Engineering, 1601 E Market Street, Greensboro, NC 27411

[2]Southern University and A&M College, Department of Civil & Environmental Engineering, Suite 321 Pinchback Building, Baton Rouge, LA 70813

Abstract

In Sudan, the climate ranges from arid in the north and northwest to wet-and-dry tropical weather in the southwest. In semi-arid zones in Sudan such as West region, safe drinking water is rare. In particular, areas in North Darfur and South Kordofan States rely on groundwater supply (wells) or water storage methods called *hafir* or earth dams for their water supply. *Hafir* are small lakes constructed in low lying areas to allow water to be stored during rainfall events. Improved water supply methods, to provide adequate water quality and water supply, are acutely needed for this region. Rainfall collection is one of water sources in Sudan and rainwater harvesting (RWH) methods can be implemented to improve the production of crops and livestock in the region. In Sudan, rainfall decreases from south to north, the annual average varying from 120 cm (47 in) in the south to less than 10 cm (4 in) in the north. Agricultural production and domestic water needs would be very difficult to sustain without the use of locally viable rainwater harvesting techniques to enhance water supply; and the reduction of water demand by water conservation. In North Darfur, where the rainfall is concentrated over short periods of time, rainwater harvesting techniques have been developed for various types of water collection schemes by implementing domestic rain water harvesting.

The potential to greatly improve water supply and water quality in Sudan exists. This can be achieved by designing and implementing modified rainwater harvesting methods from the United States and other regions that may be applicable in Sudan. This paper presents the water supply problems in Sudan and proposes RWH solutions tailored for the region. It also includes strategies for improving current RWH methods that are being used in developing regions.

Introduction

Sudan is the largest country in Africa covering a total area of 2,505,813 square kilometers. It is divided into nine regional boundaries which are Northern, Eastern, Darfur, Khartoum, Kordofan, Central, Upper Nile, Bahr El Ghazal, and Equatoria (Figure 1 and Figure 2). In Sudan, the climate ranges from arid in the north and northwest region to wet-and-dry tropical weather in the south and southwest region. Table 1 provides a summary of the rainfall zones and average rainfall for Sudan regions and states.

The desert regions of the Northern, Eastern, and Western regional boundaries

include the northern border of the Northern State, Nile State, Red Sea State, Kordofan and Darfur which experience an average of 0 – 75 mm of rain during two to three months of the year. The southern portion of this region ranges from semi-desert to sandy, low-rainfall savannah with 75 – 400 mm of rainfall. Agricultural production starts in semi-arid zone which includes the southern state borders of the Nile, Northern, and Red Sea and the northern border of Kassala. The states included in the sandy low-rainfall savannah include Khartoum, the south borders for Kassala, and the north border of Gedaref.

The Western regional boundary of Sudan encompasses Darfur (i.e. Northern Darfur, Western Darfur, and Southern Darfur) and Kordofan (i.e. Northern Kordofan and Southern Kordofan). In this region the average rainfall is from 0 to 900 mm and the region is classified as an arid desert to high savannah rainfall zone. The arid, or desert, rainfall zone includes Northern Darfur and Northern Kordofan. The semi-arid rainfall zone of Western Darfur additionally has a water supply from Jabal Marrah Mountain. In Northern and Western Darfur water is acquired from small water pools called *wadis* water sources that will become dry during the winter months. An isolated region in the northwest region of Northern Darfur called the *jizzu* experiences sufficient winter rainfall in January and February to support animal grazing. The sandy, low-rainfall savannah in the Western regional boundary averages between 300 to 400 mm of rainfall within a three to four month rainy season. This rainfall zone extends across the middle of the Western Regional Boundary states such as Western Darfur, Western Kordofan, and the southern borders Northern Darfur and Northern Kordofan. During the rainy season, Southern Darfur, and Southern Kordofan is covered by grass known as *goz*.

The Central Clay Plains regional boundaries of Sudan can be divided into the northeast central clay plains region and the southern clay plains region. The central clay plains include the Central and Upper Nile Regional Boundaries which include Gedaref, Sennar, White Nile, Blue Nile, Upper Nile and Jonglai state. The states located in this region are classified as a clayey, low-rainfall savannah. The southern clay plains region range from clayey, high-rainfall savannah to tropical rainfall zones and include the south border of Southern Darfur, Bahr El-Ghazal and Equatoria Regional Boundaries. The rainfall ranges between 1000 and 1 500 mm and the rainy period between seven to eight months in duration.

Water collection methods in Sudan

Water resources in Sudan are significantly impacted by the regional climate, access to water sources, and rainwater harvesting opportunities. For example, major cities in Sudan are primarily located near the banks of the Nile River due to the adequate water resource while Sudanese villages are primarily located in semi-desert and savannah area and have limited access to water. People who live with limited access to water resources support their water needs by living nomadic lives and travel to find water sources, living in villages but travel extended distances to transport water back to the villages, or use community water harvesting methods such as hafirs or earth dams.

Hafirs and earth dams represent two traditional, low cost water harvesting methods currently used in the western and eastern regions of Sudan. In the semi-arid

zone the rainfall is concentrated over short periods of time that people in this region try to collect the water by making local reservoirs known as hafir (Figure 3). In Sudan the 'hafir' is the primary RWH method used to store runoff water during the rainy season and the collected water is stored for use during the winter months. The hafir is a natural or manmade (hand or machine) deep catchment area with an approximate 3.5 m average depth. The hafir is recharged with water through manmade canals. The hafir's water is used by the community, farmers, nomads, and animals. To prevent sediment, solid materials and silt from entering the collected water, a trap is built before the inlet pipe. This trap is a deep trough to clear water by leaving the silt and solid materials at the base and tapped off the water in the top to the hafir by the inlet pipe.

Figure 3: The Azagarfa hafir in Darfur

Earth dams, or check dams, are built in a stream of a narrow valley or across a gully or riverbed with length range from 50m to 1000m (Figure 4 and Figure 5). The slow moving water through the dams allows for storage of this water. Dam designs may also include spillways, sluice gates, channels and embankments to allow control of the water .

Methodology

Limited written resources, such as journal articles, are available regarding water sustainability in Sudan. Therefore, to obtain information regarding RWH, representatives from Sudanese based water action groups were contacted by phone and by e-mail in Sudan and the United Stated. The representatives were interviewed to discuss water sustainability in the Sudan, to explain current RWH methods, and were asked to provide documentation or photos about the methods. The North Carolina Department of Environment and Natural Resources (NCDENR) and the Division of Water Quality (DWQ) "Technical Guidance: Storm water Treatment Credit for Rainwater Harvesting Systems" provides a resource for developing RWH system. Using this guidance document, a **rooftop rainwater harvesting** system was

designed for use in the Sudan with some modifications to meet the needs of Sudanese people.

Interviews

Mr. Hashim Altayeb, the **Quality Assurance Manager** (Practical Action Organization-Sudan), was interviewed by phone. He was able to provide background information for RWH methods in Sudan, photos, and discuss the feasibility of improving RWH methods. Mr. Mohamed Saleh Farah, **Senior Programs Practical** (Practical Action Organization-Sudan), was interviewed by phone and discussed the problems specifically related to implementing RWH methods in Sudan such as climate, resources, and economic feasibility.

Plan Development

The potential to greatly improve water supply and water quality in Sudan exists. This can be achieved by designing and implementing modified rainwater harvesting methods from the United States and other regions that may be applicable in Sudan. Based on the information provided by Practical Action Organization – Sudan and the NCDENR guidance document, a RWH system was designed to address four goals:

1) Generalizing the idea and the concept of RWH methods for Sudan to the people in all regions to collect clean rainwater.

2) Help people in western Sudan (Darfur and Kordofan), eastern Sudan and southern Sudan by designing rainwater harvesting modifications for public buildings (i.e. schools, government buildings) thus creating a central rooftop RWH system in each village.

3) If implementing rooftop methods in Sudan, local Sudan developers need to be educated about RWH methods that can be used to increase water collection. Additionally builders from developed countries interested in helping improve water resources in third world countries must consider the economic and resource limitations in countries such as Sudan.

Results: Proposed Design

In the United States, rooftop RWH methods are used to collect water for non-potable water systems such as vehicle washing and toilet flushing. In Sudan however where potable water supply is the primary concern, a RWH system combined with a water treatment systems would be necessary to collect water which would be safe to use for drinking, cooking, and daily water without the threat of illness. Based on the climate, local Sudanese resources, economic feasibility, and architectural design for Sudanese homes, rooftop RWH systems are feasible for water collection in Sudan. Rooftop systems would need to be modified to meet the needs the Sudanese cities or villages. Figure 6 provides and example of a basic rainwater harvesting system design developed by the NCDENR.

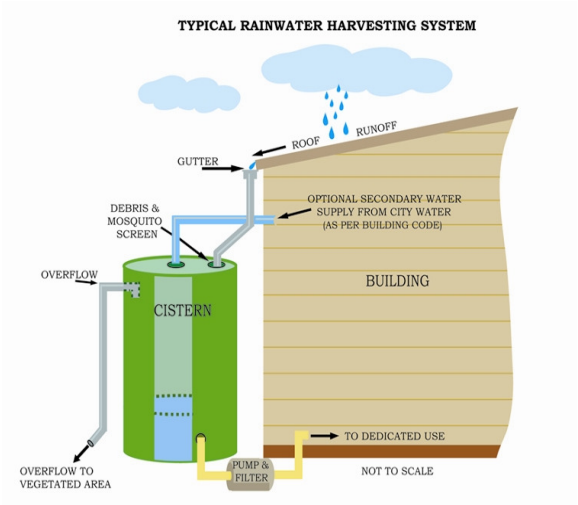

Figure 6: Schematic of a rainwater harvesting system (Source: NCDENR)

Sudanese Resources

One of the main purposes of this paper is to recommend methods for RWH systems which could be used in all the Sudanese houses and in various Sudanese regions feasible for RWH systems. Due to limited resources in the Sudan, materials used for the RWH system would need to be very simple, inexpensive, and a resource available within the village or country. Most Sudanese families will possess basic materials such as plastic barrels, mesh, pipes, and filtration material such as sand and rocks. Supplies that would be readily accessible in Sudan which could be used for a RWH system include:

1- **Plastic Barrel:** The Plastic barrel is the above ground that holds the rainwater The plastic barrels are available in the most of Sudanese houses because families will collect and store extra water supplied by the city in barrels in case of water rationing or limited water supply from the city.
2- **Roof Surface**: Suitable surface such as metal or clay/wood surface with slope.
3- **Pipe (gutter):** Install a gutter system along the roof edge to convey the rainwater from the roof to the cistern or plastic barrel to another pipe fixed at the end of the sloped pipe to the cistern or plastic barrel.
4- **Small piece of mesh**: It has a circular shape and fixed at the entrance of the rain water pipe in the roof to filter the rainfall water from leaves, coarse dirt or any others solid materials that may come with water from roof.
5- Filtration System: A small, slow sand filtration system can be built by filling a plastic barrel with pebbles and coarse sand to filter water from the small pieces of materials that may not filter using only mesh.
6- **Water Purification**: Sudanese currently use two methods for water treatment. These include Aluminum Sulfate, called shub, and a regional plant called Morina oleifera.
7- **Tap:** install on the plastic barrel for treated water access.

Modification of Roof Top Rainwater Harvesting System for Sudan's cities

Most of the Sudanese's homes located in cities are made of clay, rocks, or concrete (Figure 7). The roof is sloped to one side to discharge the rainfall water through holes located on the edge of the roof. These holes allow water to drain from the rooftop. A small modification would need to be made to the roof such that a sloped gutter system is installed along the roof edge to help direct rainwater flow for harvesting. Using a sloped pipe, the rain water can be collected from the roof and transported through this pipe to a collection barrel designed to operate like a slow sand filter. The barrels should contain pebbles at the bottom and coarse sand on the top to filter the collected water. Filtered water can be stored in a separate barrel. This water can then be filtered a second time and boiled before using for cooking and drinking.

Figure 7: Photo of typical Home in Sudanese city

Modification of Roof Top Rainwater Harvesting System for Sudan villages

In the poorer villages in Sudan such as Amdrosa, Nur Alhuda and Omar teina (western Sudan) most homes will be made with thatched roofs and homes that would not be able to support the addition of a metal roof (Figure 8). The cost of replacing the roof with concrete or metal-like material may prove to be too costly for villagers to pay for individual home systems. Therefore a centralized, RWH rooftop system or "Water Center" would help the entire village collect and store the daily water needed. The roof of the RWH building would need to be cleaned and maintained especially during the rainy months from April to December. Before diverting the rain water into the storage tank or open well/bore, a slow sand filter would be needed to treat the water. At the individual homes, this water would then be used after a final filtering step and boiling before using for cooking and drinking.

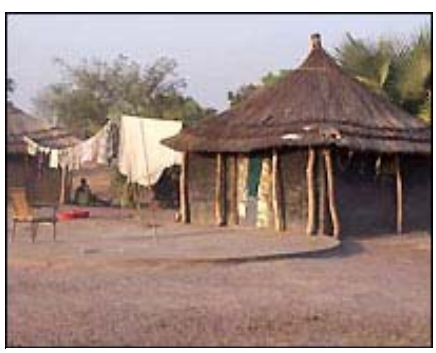

Figure 8: Photo of home in Sudanese Village

In the sandy areas of Sudan where water percolation occurs such as in the Western Region (e.g. Darfur and Kordofan), rainwater from the roof can be diverted to shallow recharge structures such as percolation pits, recharge trenches, and shallow/small recharge wells. In the clay area such as Eastern Region (e.g. Gerdef and Kassala) where the soil is impervious, rainwater would need to be diverted to the deep recharge structures system such as percolation pit with boreholes, recharge trench with boreholes and deep/large recharge wells. All of these methods would be needed for deep percolation into the underlying sandy layer.

Sudanese Water Treatment

In Sudan water there is a greater need for potable water than palatable water. Sudanese, in both cities and villages, use a native material called ***shub*** to treat collected water. ***Shub*** rocks are traditionally added to collected water to settle sand or any other fine particles. The water is then filtered and boiled. The scientific name for ***shub*** is **Alum** (Aluminum Sulfate $Al_2(SO_4)_3$) and is commonly called filter alum. Additionally, there is a native plant called Moringa oleifera used for water treatment (Figure 9 and 10). Moringa oleifera leaves are used as filter material to treat water. The chemicals released by the leaves are traditionally used in Sudan to treat stomach problems as well as mild forms of malaria. Thus using shub or Moringa oleifera in rainwater harvesting designs provides a low cost, native material to treat water for Sudanese RWH systems.

Figure 9: Moring oleifera plant

Figure 10: Seeds from Moringa Oleifera

Conclusion

The potential to greatly improve water supply and water quality in Sudan exists. This can be achieved by designing and implementing modified rainwater harvesting methods from the United States and other regions that may be applicable in Sudan. The implementation of rooftop collection designs for rainwater harvesting in Sudan cities would be feasible by attaching a gutter system to the roof to help direct rainwater from the roof top for home rainwater harvesting systems. In villages, where homes have thatched roofs due to economics and location, a centralized rainwater harvesting system on a community building, such as a school, could be used for rainwater harvesting. Following rainwater collection by the roof, slow sand filtering the water and treating the collected rainwater using local and native Sudanese resources such as Moringa and shub can provide alternative water for potable use.

RWH therefore can help both individual homes and communities where water supplies are limited or scarce. Currently hafir, earth dams, and wells are the primary methods used to help increase water supplies for the various Sudanese regions. These options however require people to travel to the hafir, earth dam, or well water source. In western and southern Sudan villages, women and girls in the villages are responsible for traveling long distances to water sources to bring back water for drinking, cooking, and washing body and clothes. It is not uncommon for women and children to travel for hours during the day to collect water. The lives of these women can be improved by applying the RWH methods because instead of spending time walking to collect water, women and children could have time for other village tasks and education.

Using creative RWH designs, considering the economic feasibility of a country, and the public need for water, there are many options for exploring sustainable designs to improve the lives of people. Education for RWH methods and

efforts from developed countries to improve water resources in third world countries is important to help improve the lives of people in these regions. As the interest in green technologies and sustainability increases, many of the technologies being using in developed countries have broad based applications that can be applied to many regions in the world.

Table 1: Rainfall zones and average rainfall for Sudan Regions and State

Rainfall Zones	Regions	Average rainfall (mm)	RWH Method
Desert	Northern region :North border of Nile State and Northern State	0–75	No RWH used
	Western region: North border of Northern Darfur state; Northwest border of Northern Kordofan		
	Eastern region: Red sea state		
Semi-desert	Northern region: South border of Nile State, South border of Northern State	75–300	Hafir and Earth Dams
	Western region: Middle part of Northern Darfur, North Border of Northern Kordofan		
	Eastern region: Southern border of Red Sea state; North border of Kassala State Central Region: Khartoum		
low-rainfall savannah (sandy)	Eastern region: South border of Kassala state, North border of Gedaref State	300–400	Hafir and Earth Dams
	Western region: Kordofan, southern border of Northern Darfur, central region of Western Darfur		
	Central clay plains region: North border of White Nile and Gezira States		
low-rainfall savannah (clayey)	Eastern region: Gedaref State and Southern border of Kassala State	400–900	Hafir and Earth Dams
	Western region: Southern border of Western Darfur, Southern Darfur, Southern border of Northern Kordofan, and Southern Kordofan		
	Central clay plains region: Southern border of Gezira, Sennar, White Nile, White Nile, Blue Nile, and Upper Nile States		
	Southern region: Jonglei, Northern border of Eastern Equatoria, Lakes, Northern Bahr El-Ghazal; and Western border of Western Bahr El-Ghazal and Unity State		
High-rainfall savannah	Western region: Southern border of Southern Darfur State	900–1300	No RWH used
	Southern region: Southern border of Eastern Equatoria, Bahr El-Jabal, Western Equatoria, and Southern border of Northern Bahr El-Ghazal and Western Bahr El-Ghazal States		
Tropical	Southern region: Far southern border of Western Equatoria and far south border of Central Equatoria	Above 1300	No RWH used

Environment and Water Resources in 2050:
The Challenge for Engineering Education

Jeff R. Wright[1]

[1]Dean of Engineering, School of Engineering, University of California, P.O. Box 2039, Merced, CA 95344; PH (209) 228-4410; email: jwright@eng.ucmerced.edu.

ABSTRACT

The evolution of the field of environmental and water resources engineering over the next half century will both shape and be shaped by, changes in the formal education of tomorrow's technical workforce in this domain. While predicting *anything* 40 years into the future is initially daunting and ultimately humbling, this paper presents a framework for anticipating the changes that will be needed in the way we educate environmental engineers. Particular attention is given to the expectation for new and emerging information and computational technologies, and opportunities and challenges for developing new educational pedagogies.

PERSPECTIVE

Endeavoring to evaluate attempts to predict the future with respect to important societal concerns Princeton physicist Gerard K. O'Neill made the observation that forecasters tend to underestimate the rate of technical change, and overestimate the rate of social change (O'Neill, G.;1981). This appears to be consistent with the rapid pace at which engineering innovation over the past several decades has provided technologies and methodologies that can improve water resources assessment and management, as well as the sluggishness with which widespread incorporation of such advances are mandated for use within comprehensive resource management programs. Slower still is the rate at which this innovation has motivated widespread changes in the undergraduate engineering curriculum.

Within this framework, a number of prognostications from the perspectives of *technological change*, *social change*, and *educational change* are offered describing the challenges and opportunities for water resources professionals and educators between now and 2050.

TECHNOLOGICAL CHANGE

Sustainable Distributed Energy Sources. Recent attention to concerns of energy independence, sustainability, and global warming will drive massive R&D investments in renewable energy sources and dramatically improve distribution and control systems (Sayigh, 2008). This investment will produce cost effective, modular and scalable sources of high quality energy that will enable increasingly reliable

water monitoring, assessment, management and control systems. Improved efficiencies, reliability, and maintainability of these systems will dramatically reduce the overall relative cost of providing sustainable water resources to all sectors. New technologies for energy storage will enable much more efficient load shifting and balancing that will allow enhanced optimization of production and delivery systems.

Ubiquitous Environmental Sensor Technologies. New sensor technologies and methodologies for use are being created at an ever increasing rate (Kanouin, O. and Trankler, H.R.;2004). Advances in modern sensor technology across all spatial and performance scales will continue and accelerate over the next 40 years. Smaller and more efficient sensors will be adaptable to widespread environmental and water resources monitoring systems, and. more readily integrated into physical infrastructure to monitor performance and condition, which will improve service and dramatically reduce the cost of systems maintenance and operation. Sensor networks will become increasingly energy independent and able to collect and transmit data reliably and continuously as needed.

Remote Sensing and Earth Observation. Remote sensing and related earth observation technologies will advance quickly with much higher resolution and reliability. High resolution technologies will enable daily image capture from all populated areas with higher frequency data collection from sensitive or critical areas. Custom image capture perspectives and schedules will be readily available to engineers, scientists, and water authorities. Large scale data storage and central repositories will enable widespread access to these data stores.

Intelligent Visualization and Image Analysis Systems. New and continuously improved intelligent and adaptive systems will be created to perform real time analysis of images and sensor signals. The information from the analysis of these images will be combined seamlessly with data from distributed sensor networks to provide immediate and reliable measurements of the condition and health of environmental and water resource systems. Autonomous learning agents and adaptive systems will form the structure for intelligent scene-driven data analysis algorithms, providing opportunities for the development of more cost effective and responsive early warning systems.

Adaptive Modeling Systems. Modeling will remain an important component of water resources planning and management and environmental engineering (Loucks, 2008). While innovation will continue in the design and development of next generation modeling technologies and methodologies, major advances must be made in the utilization of this innovation. New model applications development environments will emerge rapidly over the coming decades that will enable new opportunities for rapid prototyping of water resources models utilizing fully emerging computing architectures including virtual distributed client-server networks and grid computers. Prototyping will enable rapid integration of state-of-the-art simulation and optimization algorithms as well as inferential algorithms. New gigapixel hardware output display devices such as 3D powerwalls, caves, and other immersive media systems (including networked systems supporting multiple users across space and time) will emerge rapidly enabling exploratory evaluation of complex images for use

by systems managers as well as water resources engineers and scientists (Grant, et.al; 2008). These modeling and systems technologies will expand greatly the rate at which modern shared vision modeling environments can be developed for, and used by, water resources stakeholders.

Commonplace Open Information Management Systems. The interactive access and use of water resources models and data will be facilitated greatly by Open Information Management Systems (OIMS) which will become widely available and commonplace enabled by explosive growth in the development and use of free and open source software. Transparent interfaces for the spectrum of input and output devices will enable systems to be designed and implemented by engineers and administrators without the need for extensive and expensive computational support staffs.

SOCIAL CHANGE

Increased Public Awareness of Water Issues. Expanded pressures on water resources from continued population growth (see Table 1) and environmental pressures will become much more visible to the general public, with growth in size and number of better informed citizens action groups that will hold municipalities and water authorities much more accountable for sharing information and water resources forecasts, and providing regular updates on water related and environmental issues. Daily water reports will become commonplace in print, broadcast and online media, and other public forums.

Increased Public Pressure for Water Sustainability. Because of increased availability of water resources information and the need for improved stewardship of this valuable resource, the society demands for the sustainability of reliable and high quality water sources will be much more visible on the public agenda. The decisions by water agencies and public officials responsible for water resources will be under increased scrutiny because of a larger and better informed citizenry. Water related public expenditures and the stewardship of public infrastructure will be more visible and will provide the basis for citizen choices in public elections.

Table 1. Projected growth and change in U.S. population demographics by 2050:

Year	2005	2050
[1]Population (millions)		
World	**6,426**	**9,309**
United States	**296**	**438**
[2]Shifts in U.S. Racial/ethnic groups		
Foreign-born	12%	19%
White	67%	47%
Hispanic	14%	29%
Black	13%	13%
Asian	5%	9%

[1]U.S. Census Bureau (2008)
[2]Passel and Cohn (2008)

EDUCATIONAL CHANGE

Universal Technical General Education. The perspective on general education by most of our universities is that technical students must have broader backgrounds in the arts, humanities, and the social sciences. While certainly true, in this increasingly technical and complex society it will become increasingly

important for non-technical students to obtain, through their formal education, a deeper understanding of technologies and sciences that impact their lives. This is nowhere more true than in areas of public welfare such as health care, environmental sustainability, and water reliability and quality assurance. Universities will be under increasing pressure to provide technically-based learning experiences to all students, driven by the country's need to attract more K-12 students into technical careers, or careers that involve the management of technology. Stronger and more effective linkages and networks will be created between universities, community colleges, and K-12 institutions to improve the seamless transition of students into career paths that are more compelling for them because of the impact they will have on society.

Technical Workforce Diversification. The next 40 years will experience not only rapid world and U.S. population growth but dramatic demographic shifts (Bergman, 2004; El Nasser, 2008; Passel and Cohn, 2008) as reflected in Table 1. Most dramatically, the U.S. will no longer have a majority Caucasian population in this country, with the fraction of White citizens dropping from 67% to 47% at the same time that the Hispanic population will increase from 14% to 29%. With the Hispanic representation in the current U.S. engineering workforce at less than 5.5% and the current enrollment in engineering undergraduate degree programs at fewer than 3 . 5% of total engineering students (NSF, 2005), increasing Hispanic participation in engineering will be a top priority in the coming decades. Doing so will result in an influx of new talent and important new perspective into the engineering workforce at the time when this is essential for the country. Strong and targeted recruitment pipeline facilitation efforts will emerge nationally, particularly in the U.S. southwest.

Standard 5-year Requirement for Engineering. By 2050 the majority of engineering programs in the U.S., particularly those disciplines that address most directly engineering problems in the public sector (e.g. civil engineering, environmental engineering, etc.) will transition to 5-year programs; many offering streamlined BSE/MS emphasis programs. For water resources and environmental engineering students, this will enable broader exposure to information management and networking communications technologies, modeling and model development tools and techniques, data and database development technologies, and collaboration systems. Valuable internship and co-op experiences will become a formal and required component for most of these programs

Global Learning Communities. Recent interest in the development of national and international learning communities will continue (Smith, et.al.,2004; Palloff and Pratt, 2007) and become commonplace within the engineering community. These collaborations will include educational/research universities at multiple locations working as approriate with leading private sector firms and government organizations. Curricula will become increasingly experiential learning-based, and be configured in a manner that will reduce the overall cost and redundancy of staffing and equipping more narrow, but higher quality programs. Courses will consist of flexible module choices within a connected theme, and will adapt most directly to specialized learning needs rather than teaching needs. The resulting curricula for a particular degree or certification will be offered by the very top faculty and professionals in the area regardless of physical location.

Lifeline Learning. Universities and learning communities will become an increasingly important part of a student's formal professional development throughout one's career. With improved networked communications methodologies and infrastructure, students will be able to remain linked to their formal education continuously and formally. Academic programs will transition from being a foundational experience for formal engineering education to one that is viewed explicitly as part of one's *lifeline learning* (Wright, J.R.; 2000); students will stay "connected" with their learning roots, and will nourish, as well as be nourished by that foundation.

Environmental and Developmental Risks and Stressors Impacting a 2050 Vision

Walter M. Grayman[1]

[1]W.M. Grayman Consulting Engineer, 321 Ritchie Ave., Cincinnati, OH, 45215,
PH: (513) 761-1722, email: grayman@fuse.net

Abstract

A vision of what our water resources and environment may look like in the year 2050 must consider the increasing risks and stressors facing our planet. Recent papers, reports and books are used as the source and basis for identifying the range of future challenges facing the world's water resources and environment. They reflect domestic and international views from people in government, academia, institutions, and private practice. The issues have been distilled down into the following major issues/topics: (1) Aging infrastructure; (2) Population growth and demographic shifts; (3) Public health; (4) Economic development; (5) Energy use and production; (6) Climate change; (7) Sustainability; (8) Pollution of our environment; (9) Security; and (10) Institutional issues such as public participation, regulations, environmental justice and utility governance. Each of these topics is assessed in terms of their potential impacts on future water resources and environment and the challenges we will face over the next 40 years in fulfilling a shared vision of the environment and water resources in the year 2050.

Keywords
Risk, stressors, future, water resources, environment

BACKGROUND

The EWRI Emerging and Innovative Technology Committee (EITC) recently formed the Environmental/Water Resources Vision 2050 task committee. The specific goals of this task committee are to develop a vision of what the state of our natural and constructed environment and water resources could and should look like in the year 2050, and identify the actions needed now and on into the future to make that state a reality. These actions would include both the technical and policy advancements that need to be made in order to achieve the identified 2050 view. As such, it will serve as a very rough research agenda for the coming 40 years. The task committee will enlist a wide range of experts in the environmental/water resources field in the development of this vision.

Our world and society are dynamic systems that continuously change and evolve. Therefore, an important consideration in the development of future vision is an understanding of the risks and stressors that are and will be facing our planet and society over the coming 40 years.

Several recent papers, reports and books have addressed issues related to trends, risks and stressors that may impact the water resources and environment around the world. These publications serve as a source and basis for identifying the range of future challenges. Following is a partial list of some of the key documents that were reviewed in order to identify the range of trends/risks/stressors that are likely to impact future water resources and environment in the United States and around the world.

- The World's Water 2006-2007: The Biennial Report on Freshwater Resources (Gleick, 2006).
- The United Nations World Water Development Report (UNESCO, 2006).
- AwwaRF Update of Strategic Assessment of Future of Water Utilities: Trend Paper (McGuire and Patrick, 2005; Means et al, 2005).
- TECHNEAU: Trends Regarding Future Risks for Water Supply Systems (Rosen and Lindhe, 2007).
- Sustainable Water management in the City of the Future [SWITCH] (Khatri et al, 2007).
- U.S. Drinking Water Challenges in the Twenty-First Century (Levin et al, 2002).
- Wastewater Management in the 21st Century (Daigger, 2007).
- Integrated Water Management for the 21st Century (Bouwer, 2002).
- Innovative Urban Wet-Weather Flow Management Systems [Sustainability Principles for Urban Infrastructure] (Heaney et al, 2000)

These reports and papers form a diverse set of views on future trends and important issues in the water resources/environmental area. They reflect domestic and international views from people in government, academia, institutions, and private practice with backgrounds in the various areas of water resources and the environment. There are many commonalities and also some subtle differences among the various papers. The issues raised in the papers have been distilled down into the following ten major issues/topics related to our water resources and environment. Each of these topics is examined in greater detail in terms of the major trends and their applicability within the fields of water resources and the environment. However, it is the intersection of the various trends that together present the greatest challenges to the future water resources and environment.

- Aging infrastructure
- Population growth and demographic shifts
- Public health
- Economic development
- Energy use and production

- Climate change
- Sustainability
- Pollution of our environment
- Security
- Institutional issues

SUMMARY OF STRESSORS

Aging infrastructure

The American Society of Civil Engineers (ASCE, 2005) report card on America's comprehensive infrastructure assessed the state and needs of public infrastructures and drew the following conclusions: "$1.6 trillion is needed over a five-year period to bring the nation's infrastructure to a good condition. Establishing a long-term development and maintenance plan must become a national priority." Of the 15 general infrastructure areas, the water resources categories received a grade of either D or D-, marks indicating the failing condition of these infrastructures and the urgency for immediate repair, rehabilitation and replacement.

The estimated direct costs associated with repairing and/or replacing the nation's water resources infrastructure are well documented (USEPA, 2002; USEPA, 2005). The likely implications and impacts of not making needed replacement or repair include:

- Significant and ever increasing operations and maintenance costs
- Increasing drinking water and water pollution violations due to the inability of the infrastructure to function properly
- Inability to meet water use demands
- Health concerns due to contaminants entering into water distribution systems or untreated or improperly treated wastewater discharging into water bodies
- Inability to support future growth and development

Population growth and demographic shifts

Population is a major factor in influencing the quantity of water that is used and the amount of wastewater that is generated and as a result, will impact the balance of water availability and the adequacy of the water resources infrastructure in the future. The United Nations (2004) projects total world population to rise from 6.1 billion in 2000 to a range of 7.4 to 12.8 billion people in year 2050 depending upon differing fertility and life expectancy scenarios with most of the increase occurring in less developed countries. The U.S. Census Bureau's Population Projections Program projects an increase in population in the U.S. from 282 million in 2000 to 420 million in 2050 (U.S. Census Bureau, 2004-2005). They also project a large spatial variation in population increases across the country with the largest increases generally occurring in areas where water use is already the most stressed. Figure 1 shows the projected percentage changes in population by state for the period from 2000 to 2030.

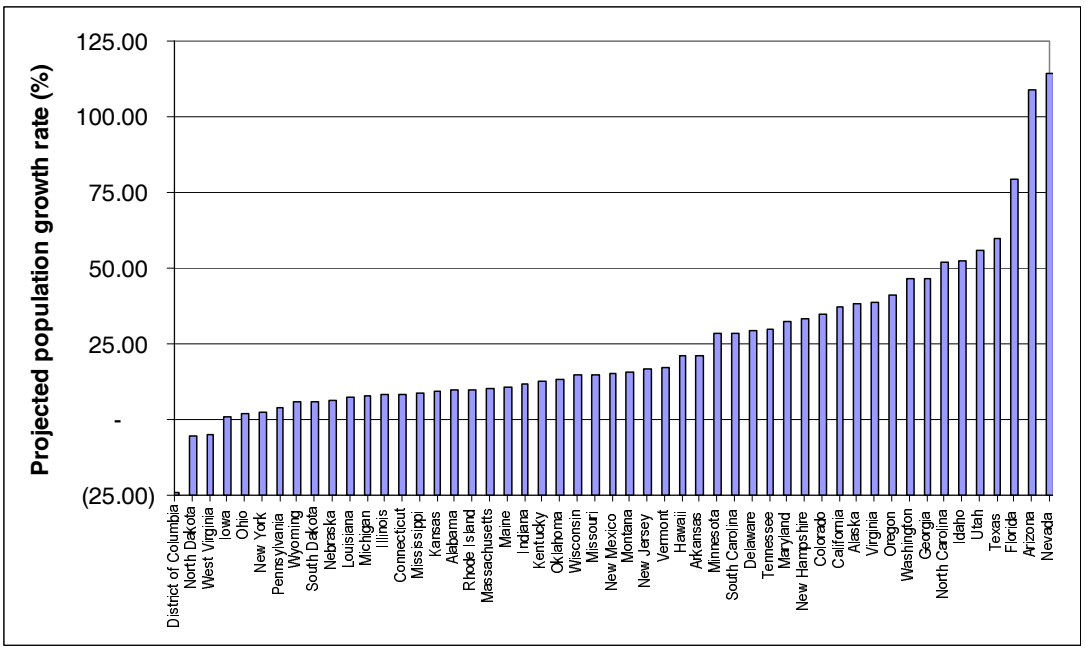

Figure 1. Projected population changes by State for 2000 to 2030

The AwwaRF sponsored futures workshop, included U.S. population and demographic shifts as one of the top ten major trends that will affect how water industry operates in the next 20 years (Means et al, 2005). Specific implications include:

- Communities with burgeoning populations will have to find the resources to fund new facilities while areas with static or shrinking populations face the challenge of diminishing customer base, resulting in a limited rate capacity to replace aging water infrastructure.
- In areas of burgeoning population, utilities will need to consider the contaminant loading from additional human activity and manage this loading to minimize deleterious effects on water quality and treatment.
- Other demographic aspects that may impact water resources management include: an aging customer base, a more educated population, ethnic shifts in population, and increasing income gap

Another demographic change deserving greater attention is the population shift that has resulted and will continue to result in under utilized water infrastructure capacity serving a dwindling customer basis. Examples include rust-belt cities and even a sudden cessation of phenomenal population growth such as in Las Vegas. The nature of the population-induced stress to water infrastructure is different from those with a burgeoning population. Increased water residence time and greater water quality deterioration in drinking water distribution system, for example, has come to the front page of challenges facing water industry. The question of asset management in a dynamic population environment within the service time of a built environment remains unexplored at this stage, and deserves better understandings.

Public health

Public health was the primary driving force in the United States in the 19th and 20th century for the establishment of both public drinking water supplies and municipal sewer systems and treatment plants. As a result of these advances, the most serious waterborne diseases such as cholera and typhoid were virtually eliminated in the United States. However, waterborne infectious disease (WBID) is still a significant concern in the U.S (Levin et al, 2002) and in many of the less developed countries, waterborne disease is still rampant, killing millions of people on an annual basis. Specific public health impacts include:

- The full extent of WBID in the U.S. is not known and current incidence estimates are likely to be several orders of magnitude greater than estimates by the CDC.
- There is emerging evidence that disinfection by-products such as trihalomethanes resulting from chlorination may be carcinogenic and have other possible health effects.
- A multi-barrier approach is needed to address some of the most common waterborne pathogens (e.g., *Giardia, Cryptosporidium*, and some viruses).
- There are trends throughout the world in the emergence and resurgence of diseases including some waterborne diseases. This includes waterborne pathogens that have developed resistance to antibiotics or increased in virulence.

Economic development

Like population increases, economic development generally results in increased (and more spatially concentrated) water usage, increased wastewater production, and more increased stormwater runoff and non point source pollution. Much of this is associated with the urbanization process that generally accompanies economic development. However, there is significant uncertainty in the impacts of future economic development in the United States because of the increasing trends towards globalization, shifts in agricultural water practices, and the possible effects of technological change. Technological change could foster further development that could increase the strain on the water resources infrastructure or, more optimistically, could provide methods for mitigating the impacts of development. Daigger (2007) emphasizes this in his statement that, "further technological developments are crucial to fully and effectively implement new approaches to urban water management that are inherently and significantly more sustainable and that better serve the full range of people irrespective of their economic situation."

Energy use and production

Gleick (2006) observed that there is a strong linkage between the water and energy sectors since water is required to produce and use energy, and energy is used to clean, transport and use water. Most water supply and waste water systems are dependent upon pumping and most water and waste water treatment plant components need sources of energy to perform their functions. According to the Alliance to Save Energy (2002), the water and wastewater sectors are responsible for about 2 to 3% of global energy use. However, in the absence of a comprehensive energy policy for the United

States, there is much uncertainty in the likely impacts of energy on the water resources infrastructure. Some potential impacts include:

- Significantly increased water usage in parts of the country to accommodate agriculture and processing costs associated with bio fuels.
- Increased construction costs due to increased energy costs and petrol-based products such as PVC and HDPE pipes.
- Potential (unknown) impacts of renewable energy methods (wind, solar, hydro power) and increased nuclear power generation.
- Increasing global energy usage and its likely impact on energy availability and cost. This may force water and wastewater utilities to achieve greater energy efficiency in order to offset energy costs.
- Energy shortages may occur with increased frequency and water (and wastewater) systems will need increased capability to switch to alternate or backup energy supplies (Means et al., 2005)
- New energy-intensive treatment technologies may not achieve their expected potential despite their advantages (Means et al., 2005)

Climate change

The area of climate change and the potential impacts of human activities on climate change has been an active area of research, debate and concern for well over a quarter of a century. Modern studies are generally based on mathematical and statistical analyses and a physical understanding of the processes involved in climate change. However, there is still uncertainty in climate change modeling and analysis and most reputable studies attempt to qualitatively or quantitatively assess or express this uncertain. The most recent report issued by the Intergovernmental Panel on Climate Change (IPCC, 2007) concluded that:

- Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level
- Most of the observed increase in global average temperatures since the mid-20th century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations.

Some of the potential impacts of climate change on the water resources of the United States are identified by Levin et al (2002), Cromwell et al. (2007), Miller and Yates (2006), and Buchberger et al. (2008) and include:

- Changes in hydrologic cycles shifting the timing, intensity, seasonality and spatial distribution of precipitation
- Perturbation of stressed ecosystems
- Droughts followed by severe weather events can result in more polluted runoff to surface waters and less infiltration to replenish aquifers and could destabilize natural biological controls of pests and pathogens.
- Warmer temperatures of surface water sources may contribute to increased harmful algal blooms resulting in taste, odor and toxic (e.g., cyanobacteria) impacts on water.

- Warmer temperatures and heavy precipitation events may result in increased sediment and non-point source pollutant loadings to watercourses. This may cause higher microbial and nutrient loadings in drinking water supplies and make water treatment more difficult.
- Throughout the U.S., temperature and hydrology changes may result in changes in watershed vegetation and aquatic ecology. Potential impacts of this will be increased wildfires, pest infestations, and reservoir eutrophication.
- Rising sea levels will increase the risk of coastal flooding to wastewater facilities and coupled with lower freshwater base flows will increase salinity in coastal aquifers.
- Heavy precipitation events may result in increased sediment and non-point source pollutant loadings to watercourses. This may make water treatment more difficult.
- The increased variability due to global warming in key parameters affecting water quality and quantity will put a premium on good long-term planning for water and wastewater utilities. Reevaluation of the entire utility portfolio from source to tap with respect to adaptation strategies is needed.

Sustainability

The Brundtland Commission, formally the World Commission on Environment and Development (WCED), was convened by the United Nations in 1983. The Report of the Commission, *Our Common Future*, was published by Oxford University Press in 1987 and contains the following definition for sustainable development, "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (Bruntland, 1987). It recognizes that land, water, air, and minerals are all essential but finite natural resources that contribute to a healthy planet and society. UNESCO (2006) established a goal to ensure environmental sustainability. The report recognizes that "healthy ecosystems are essential for the maintenance of biodiversity and human wellbeing" and that "we depend upon them for our drinking water, food security and a wide range of environmental goods and services". It sets a target to "integrate the principles of sustainable development into country policies and programmes and reverse the loss of environmental resources". Overextraction of groundwater and depletion of other key resources are other significant examples of non sustainable development.

Pollution of our environment

There are many pathways by which our water resources and environment can be compromised through pollution. These include air pollution, point and non point sources of water pollution, salt water intrusion into existing aquifers, and other related pathways. "Pollution of water bodies alters chemistry and ecology of rivers, lakes and wetlands; greenhouse gas emissions produce dramatic changes in runoff and rainfall patterns" (UNESCO, 2006).

Bouwer (2002) addresses the potential impacts of non point sources on our groundwater resources. "Since almost all liquid fresh water on the planet occurs underground, groundwater will be used more and more and, hence, must be protected against depletion and contamination, especially from nonpoint sources like intensive

agriculture. A significant nonpoint source of groundwater pollution is agriculture, with its use of fertilizer, pesticides, and salt containing irrigation water that contaminate the drainage water as it moves from the root zone to the underlying groundwater. The problem can be expected to get worse in the future as agriculture must intensify (including use of more agricultural chemicals) to keep up with the demands for more food and fiber by increasing populations."

Saltwater intrusion is a natural process that occurs in coastal aquifers, where there is hydraulic connectivity between the aquifer and the seawater. This is a natural process but the rate of saltwater intrusion will increase (or decrease) due to a changing imbalance in the freshwater aquifers and the sea levels. Increasing ground-water withdrawals from these aquifers can cause further lateral and vertical intrusion of surrounding saltwater. Similarly, sea level rises that have been discussed as a potential effect from climate change, can result in increased saltwater intrusion. The impacts of salt water intrusion include more intensive water treatment requirements and/or decreased availability of fresh water for various uses including agriculture.

Security

Water utilities have historically been concerned with security issues such as accidental pollution spills into their raw water source, and vandalism or other criminal activities resulting in damage to equipment. The twenty-first century has brought an increasing concern over intentional acts directed against water and wastewater utilities. These include physical damage to utility facilities and purposeful contamination of the water supply. Means et al (2005) list the following implications to increased security concerns facing the drinking water industry. Most of these also apply to the wastewater area.

- The need for improved physical security has been accepted by drinking water utilities following the September 2001 terrorist activities.
- Utilities now need to examine the nature and capabilities of the real threats faced by the water industry.
- Utilities are becoming increasingly vulnerable to security breaches on information technology systems by both internal and external threats.
- Risk and cost tradeoffs are not well understood by a traditional mindset.
- Utilities will require a sophisticated workforce to understand the risks and use the required tools for responding to these risks.

Institutional issues - Public participation, regulations, environmental justice and utility governance

Gleick (2006) notes that there has been a dramatic change in the way that water decisions are made around the world moving from decisions by a small number of technical or engineering experts to significant involvement by the public. This is only one of several trends in the area of institutional issue that are and will affect the operations and decision-making in the water resources field. Other issues in this area include privatization of water systems, customer expectations concerning the safety and reliability of their water supply, communications of information to water customers, water as a human right, valuation of water, and creative partnerships between water/wastewater utilities and other sectors. Conflicting water resources and

environmental regulations lead to inefficient or insufficient management of the resources.

SUMMARY AND CONCLUSIONS

Our planet and society are not static. There are pressures, risks, and stressors that continually affect and change it. This dynamic behavior must be considered whenever we do future planning so that we are not building a blue print for a situation that will no longer exist. Though there is always uncertainty in the future, an understanding of potential and likely stressors is an essential element in developing a vision for our water resources and environment in the year 2050.

ACKNOWLEDGEMENTS

Much of the information in this paper was derived from an EPA sponsored research project at the University of Cincinnati called the Water Resources Adaptation Program (WRAP). I would like to acknowledge my fellow members of the WRAP team (Steven Buchberger, Robert Clark, and Zhiwei Li) for their insights and contributions and to our EPA Project Officer, Jeffrey Yang, for his vision and technical guidance.

ABSTRACT

Today the United States faces increasing annual flood damages and climate change will only exacerbate this problem. In spite of nearly 73 years of flood control and 41 years of floodplain management, the challenge continues. This paper provides a positive vision of how the floodplain of 2050 might appear if appropriate measures were taken by governments and the public at large in the years ahead. It is based on the output of the 2007 ASFPM (Association of State Floodplain Managers) Foundation Gilbert F. White National Flood Policy Forum that examined this topic.

YEARS OF FLOODS

Floods have been a part of American history. Early Eastern colonists battled overflows from the Delaware River into nearby agricultural lands. Early in the 18th century, the founders of New Orleans initiated levee building to protect the growing city. Over time, as the nation moved to the west, it established its towns and cities alongside rivers, the principal highways for movement of goods and people, and, as the cities grew, the problems of periodic flooding became more evident. By the middle of the 19th century, the federal government began its involvement in attempting to reduce flood losses. Shortly after the turn-of-the-century it had begun to actively assist states and local communities in dealing with the flood challenge. Major floods in 1927 and 1936 caused the Congress to reevaluate the federal role and legislate a national approach to flooding that would drive federal and state efforts for the rest of the 20th century. The Flood Control Act of 1936, in its name, defined the method by which engineers would address flooding-***control*** the waters by keeping them off the land, storing them behind dams, and speeding them to the oceans through channel work and floodways. The 1936 Act and a 1928 Act, targeted at the lower Mississippi Valley, were focused on preventing disasters-no more destructive flooding-and led to the construction of large systems such as the Mississippi River and Tributaries project that protects the lower Mississippi Valley from Cairo Illinois to the Gulf of Mexico against inundation, and the countless smaller projects designed to protect individual communities, agricultural areas, and critical infrastructure.

The environmental movement of the 1960s, coupled with the growing knowledge of the work of the University of Chicago geographer, Gilbert F. White, that focused on adjusting human use of the floodplain as opposed to protecting humans in the floodplain from flooding, began a slowdown in the construction of flood control

structures and a search for alternative approaches- nonstructural methods - to deal with flooding. These methods included land-use controls to prevent unwise development in the floodplain, floodproofing and elevation of structures, acquisition of most frequently flooded lands, use of natural storage of flood waters in upstream wetlands, development of early warning systems to permit evacuation of flood hazard areas, and provision of insurance to those at risk. In 1968, Congress passed the National Flood Insurance Program (NFIP) that has grown to include today over 20,000 communities and over 5.7 million policyholders.

In 1993, the Midwest was devastated by massive flooding that took 38 lives and caused over $16 billion in damages. Because the flooding was extensive-eight Midwestern states-and water remained in homes and on the land in some places for over six months, the nation was exposed through evening news and other media coverage to the devastation and human trauma that resulted from this flood. Calls for action were heard in the Congress and by the Administration and led to a White House study of the causes of the flood and the development of recommendations to deal with future such events. The report, which was issued in 1994, indicated that although the flood was a significant event, floods of that magnitude were natural events and would continue to occur (IFMRC 1994). It pointed out that national flood damages continue to grow and that people and property are at risk across the country. It noted that occupation of the floodplain and attempts to protect those in the floodplain had caused significant environmental damage and threatened ecosystems that provided rich goods and services to both the natural and human environment. It acknowledged that flood control structures had prevented $18 billion in damages during the 1993 flood. The report recommended that, in moving forward with efforts to reduce flood damages, the nation should not only strive to reduce flood losses but also concurrently protect and enhance the natural environment of the floodplain. The report offered a vision for the future of the floodplain that would carefully balance the use of both structural and nonstructural methods to bring about both sustainable use of lands that were already the home for many long settled communities and important for the conduct of commerce, as well as ensuring that the loss of riverine ecosystems was reversed. Although there was some support for action on the recommendations, other national priorities moved on to the scene and the report was soon forgotten.

INTO THE 21ST CENTURY

While non-governmental organizations, such as the Association of State Floodplain Managers, continued to point out the growth in flood losses in the latter half of the 20th century, entreaties for a retrospective look at the national approach generally fell on deaf ears. While the these organizations were unable to promote any detailed examination by the Congress of the flood problem, they were at least able to convince the Congress to support a $1 billion modernization of flood mapping by the NFIP in order to more accurately depict the threat faced by those who live in and near the floodplain.

On August 29, 2005, Hurricane Katrina smashed into the Louisiana-Mississippi Gulf Coast and inflicted massive damages on the people and the built and natural environment of the region. Over 1800 people lost their lives. The costs of property losses, response and recovery operations and insurance claims payouts have not been completely identified but likely will exceed $100 billion. Over 120 mi.² of the wetland buffer that existed between New Orleans and the Gulf were also destroyed by the hurricane. Three and one half years after the hurricane, only 70% of the pre-Katrina population has returned to the region and many parts of the city of New Orleans and the Gulf Coast have yet to be restored or have plans made for their eventual resettlement or reuse. Once again just as it occurred after the 1993 Flood, the outcries about the need to deal with flooding were loud and the promises great. Some initial debate about alternative approaches to the restoration of below-sea level areas of New Orleans (move people out) were quickly seen to be impolitic and the President of the United States appeared in that city with a promise to make " the flood protection system stronger than it has ever been (Bush 2005)." Since 2005, the focus of federal effort in New Orleans has been on restoration of the hurricane protection system (levees, pumps and other structures) to a level that would protect the city against the 100-year (1% annual chance of occurrence) flood event, a level that is far less than the approximately 400-year Katrina storm surge event.

Questions about why levees failed in New Orleans during the hurricane and why the destruction along the Mississippi coast line was so complete did bring calls for investigations, reviews, and studies and did result in Congressional hearings. Two reports by the US Army Corps of Engineers (USACE) dealt with the technical issues surrounding the levee failures as well as the flaws in the decision-making from Washington to New Orleans over the 40 year history of the New Orleans hurricane protection project (IPET 2008; Woolley and Shabman 2007). The IPET report was supplemented by reports from the American Society of Civil Engineers (ASCE 2008) and a blue ribbon panel of the National Research Council (NAE/NRC 2006). The Federal Emergency Management Agency (FEMA) commissioned an Interagency Levee Policy Review Committee (ILP RC 2006) to examine how levees were treated in the NFIP. The net result of the conduct of these studies, together with the attention of ASFPM and the National Association of Flood and Storm Water Management Agencies (NAFSMA), was the identification of the fragile nature of thousands of miles of levees across the entire nation and the need for evaluation of the condition of these levees (a conclusion also reached in the 1994 IFMRC report). This attention eventually led to the passage, in the Water Resources Development Act of 2007, of provisions to establish a national levee safety program (NCLS 2009).

FLOOD RISK MANAGEMENT

In recognition of the gradual shift away from a structural-only approach, during the last decades of the 20th century organizations such as the Federal Emergency Management Agency (FEMA) and the US Army Corps of Engineers (USACE) began to drop use of "flood control" in favor of "flood damage reduction" in describing

activities related to management of the floodplain. But in Europe, the approach was to move even farther away from flood control.

Under flood control, those responsible for reducing damages chose a level of protection for areas in danger based on either an economic analysis that determined that the benefits of providing the protection (flood damages avoided) exceeded the cost of constructing the protection, or a national policy such as "no more floods." Following the disastrous floods in 1953, the government of the Netherlands took action to prevent recurrence of such catastrophic events and eventually established a 10,000-year level of protection for coastal areas (and in 2008, a Delta Commission recommended that the level be increased to 100,000-year protection.) The European Community began however to consider a different approach, flood risk management. Under this approach, the risk to a given area would be defined by examining the probability that the flood might occur, the probability that whatever protection system existed would function as designed, and the consequences should the area actually flood. Establishing a risk-based approach not only identified the level of risk faced by each community but also offered a method of prioritization in carrying out protection efforts. It became clear, using flood risk management, that the risk could be reduced not only by increasing the probability that the protection system would do the job, but also by taking steps within the protected community to reduce its vulnerability to flooding through use of nonstructural methods including the avoidance of development. While Europe moved ahead with this concept, it was not until Katrina, that it began to be examined in any detail in the United States (Galloway 2008). Now, as USACE and FEMA move to deal with post-Katrina flood vulnerability, they have both adopted a flood risk management paradigm.

WHAT ABOUT THE FUTURE?

With flood damages increasing each decade, the population of the nation increasing at a high rate and moving to coastal and riverine areas, and climate change promising an increased potential for flooding even in areas where total rainfall may decrease, it became obvious to the professionals in the floodplain management business that something needed to be done. In 2007, the ASFPM Foundation decided to conduct a Gilbert F. White Flood Policy Forum, the foundation's vehicle for addressing critical issues in floodplain management. The Forum would examine what actions needed to be taken to ensure that by 2050 the flood risk situation found at the start of the 21st century would be mitigated.

In November 2007, the Foundation brought together for two days in Washington 75 national and international flood experts to discuss what the floodplain might look like in 2050 if no action were taken to slow the growth in damages and what it might look like if specific actions were taken to move in the opposite direction. The group quickly agreed that an unchecked 2050 would present the nation significant problems and would threaten the lives and property of those living in and near the floodplain as well as the economic viability of the nation as a whole. They also agreed that if the nation was willing to address the challenges it faced in managing the floodplain,

future damages could be reduced, the ecology of the floodplain could be rejuvenated, and the nation could benefit.

GILBERT WHITE'S THESIS

In defining a broader than structures-only approach to dealing with floods, Gilbert White identified eight adjustments that could be made to floodplain use that would reduce the potential for losses and ensure long-term sustainable use of the riverine environment (White, 1945):

- Elevation. Raising structures above the expected flood level.
- Flood abatement. Using measures "taken outside of stream channels with the effect of reducing the crest of flood flows or changing the debris load for a flood event."
- Flood protection. Using engineering works to minimize the impacts of flooding.
- Emergency measures. In areas already occupied, taking actions to mitigate floods that do occur through temporary evacuation, the adjustment of services, and flood fighting.
- Structural adjustments. Designing buildings and other structures to reduce losses when floods occur.
- Land use. Permanently removing property and services beyond the reach of floods.
- Public relief. Using public grants and direct rehabilitation to relieve the impact of flood losses.
- Insurance. Mitigating the financial effects of flooding on structure owners and businesses through use of insurance.

During the Forum, participants examined the eight methods of adjustment to determine if White's original list was still relevant, and where it was not or where he was not fully useful in the 21st century and what changes might be made to increase its modern utility. They were also asked to identify new adjustments that might be added to White's list to better address the needs of the country in the future.

A SUSTAINABLE 2050 FLOODPLAIN

Not surprisingly, forum participants determined that the adjustments posited by White in 1942 largely remain relevant today. They also identified several areas where new adjustments measures could be added to those developed by White. The Forum participants concluded that, should action be taken in accordance with a suite of adjustment measures, the floodplain of 2050 would be far less dangerous, environmentally more suitable, and overall more sustainable than it would be should no action be taken to deal with the impending challenges.

In a looking forward to 2050 in light of the White adjustments to flooding, participants saw that the more sustainable floodplain would see:

- Land-use in which all states would have comprehensive land-use planning that effectively identified their land and water resources and the natural hazards and that development would be permitted only when there would be no adverse impact on flooding or on the natural and beneficial functions of the floodplain.
- Building and development standards targeted at avoiding new construction in flood prone and residual risk areas behind levees and below dams to reduce the exposure to flood damages. Where structures were built, the nature of their construction would reduce the potential for losses should floods occur. Those who took actions that increased their flood risk would not be rewarded with federal benefits.
- Elevating structures in the floodplain would no longer be considered as the best or even desirable solution since structure surrounded by water pose a risk to both those in the structures and those that must be concerned about the condition of those that occupy the structures.
- All-hazard insurance would be mandatory throughout the United States.
- Structural flood protection would only be used to deal with existing development where no other alternatives existed. The first choice would be nonstructural.
- Emergency measures would be based on robust pre-disaster mitigation activities that took full advantage of the lessons learned in previous flooding events.
- Disaster relief and assistance would be available to all as a backup to other adjustments but the public at large would understand the limits of such relief and assistance.
- Watershed planning would clearly identify the impacts of upstream activities on those downstream and vice versa. Every effort would be made to ensure maximum natural storage of flood waters.

While 21st-century consideration of Gilbert White's eight adjustments would certainly go a long way to ensure that the floodplain of 2050 was more sustainable, the participants also recognized that four additional adjustments should be considered. They believe that the nation must also consider:

- Providing room for rivers and oceans by choosing not to occupy flood prone areas and thus avoiding the hazard as well as precluding unintended adverse impacts on ecosystems. This adjustment would ensure that development would routinely place distance between human occupation of the landscape and rivers and oceans.
- Requiring exercise of personal responsibility by recognizing the hazards that are faced, the risks that are taken in dealing with these hazards and the need to become concerned with the sustainability of the environment.
- Recognizing the geographic interdependence of floodplain activities and taking steps to minimize the impacts of these interdependencies. Damages to one community, business, or industry may have significant economic and social impacts at locations far from the flooded area.

- Ensuring national awareness of the flood hazard and education of the population on flood processes, mitigation and avoidance. Those who are well-educated are far more likely to take appropriate action to reduce their vulnerability to flooding or to totally avoid placing themselves at risk. 21st-century information technology offers the rare opportunity for near real-time distribution of hazard information to the entire population.

Attention the above adjustments would result in a 2050 Floodplain where: "… *in spite of rapidly growing populations and a changing climate, both flood risk and land and water resources are being managed towards more sustainable outcomes. The nation views land and water as precious resources, and therefore protects the natural and beneficial functions of floodplains, wetlands, and coastal areas. Because these areas have been reserved—and in some cases, restored—a maximum amount of natural mitigation of flooding takes place continually. Integrated water management is an accepted practice. All new development is designed and built so that it has no adverse impact on flood levels, sedimentation, erosion, riparian or coastal habitat, or other community-designated values. The market strongly favors sustainable development, which means that floodprone construction rarely occurs. Private and public losses due to floods are indemnified through a government-backed but private system of universal insurance coverage that encourages mitigation. Floodplain management programs are funded from fees charged for development impacts, a highway trust fund, or other secure sources. Risk communication through all levels of government has become advanced enough that local decision making is well informed; policy decisions are based on sound science." (ASFPM Foundation 2008).*

GETTING TO 2050

New approaches don't just happen. Even though flood professionals may strongly endorse modified White-developed adjustments and the addition of other adjustments to deal with the uniqueness of our current situation, these approaches must be understood and accepted by the population at large and they must find their way into clear and holistic public policies that treat land and water is important natural resources/ As the forum report notes, the twin goals of these policies must be "to protect people and property from flooding while also protecting flood prone lands from people." Even with new policies there remains a need for dealing with the nation's fragmented system of water resource management, disaster relief and mitigation. Efforts must be made to eliminate disincentives to correct action, duplication of programs and minimization of costly and time-consuming litigation. Moving to a safe and sustainable 2050 floodplain will require access to accurate and comprehensive data about our natural resources, the hazards we face and integration of these data with the increasingly available data and information about all their aspects of society *(ASFPM Foundation 2008).*

A movement to this better floodplain of 2050 will also require adequate funding to not only with proper siting and construction of future development and removal of

unwise past development, but also with the need to maintain the infrastructure that currently exists and that provides protection for many areas.

The Forum report points out that the circumstances that surround early 21st century development are unique and represent the opportunity for significant change in the way in which we do business. The report concludes with by providing six guidelines that "capsulize the new ways of thinking and operating that will be needed to achieve safe and sustainable relationships with our water resources," and lead to the safe and sustainable floodplain of 2050. These guidelines ask that decision-makers and the public at large to:

- **Make room for rivers, oceans, and adjacent lands.**
- **Reverse perverse incentives in government programs that make it more profitable to act unwisely than to recognize the need for long term safety and sustainability.**
- **Restore and enhance the natural, beneficial functions of riverine and coastal areas.**
- **Generate a renaissance in water resources governance and development of the policies and organization that will support this renaissance.**
- **Identify risks and resources and communicate at public and individual levels.**
- **Assume personal and public responsibility for their actions in the floodplain** *(ASFPM Foundation 2008).*

IMPLICATIONS FOR CIVIL ENGINEERS

According to ASCE's *Vision 2025 (2007)*, "Entrusted by society to create a sustainable world and enhance the global quality of life, civil engineers serve competently, collaboratively, and ethically as master

- planners, designers, constructors, and operators of society's economic and social engine—the built environment;
- stewards of the natural environment and its resources;
- innovators and integrators of ideas and technology across the public, private, and academic sectors;
- managers of risk and uncertainty caused by natural events, accidents, and other threats; and
- leaders in discussions and decisions shaping public environmental and infrastructure policy."

Moving from where we are today in floodplain and flood risk management to the future described above will require civil engineers to live up to the aspirational expectations of *Vision 2025*. Implementation of the modifications of Gilbert White's original adjustments to floodplain use, the suggested new adjustments, and the guidelines proposed in the report on the Gilbert F. White forum will demand from

civil engineers full exercise of the knowledge, skills and attitudes needed to serve the nation in the manner described above. It is important that, as floodplain professionals define a visionary state for 2050, civil engineers are prepared to support this effort and see it through to its fulfillment.

IN SUM

The United States faces major challenges in dealing with flooding. Damages from disastrous floods are on the rise people and property remain at risk. Over the next 40+ years, if action is not taken to deal with the problem, it will grow substantially worse. Climate change, population growth, unbridled development in hazardous areas, and a lack of personal responsibility on the part of individuals subject to flooding will lead to an untenable situation by the middle of the 21st century. Since the federal government became involved with flooding in the early part of the 20th century, it has moved from trying to control the floods to jointly to addressing the problem through use of both structural and nonstructural means and recognizing the need to see flooding as a risk. Gilbert White's seminal work identified what actions could be taken to deal with the flood threat and proposed eight adjustments that have stood the test of time. Those attending the ASFPM Foundation 2007 Forum identified four additional areas where human adjustment might result in even better future conditions. With attention to these opportunities, the American floodplain of the future can be far different than it is today. Civil engineers are at the nexus of this challenge and must, along with their many other responsibilities, take on the challenge of flooding 2050.

ACKNOWLEDGMENTS

The author would like to acknowledge the great efforts of the ASFPM Foundation team that planned and carried out the 2007 Flood Policy Forum, synthesized its results and prepared the report of the Forum: Doug Plascencia, Bruce Baird, Diane Brown, Larry Larson, Dale Lehman, Jackie Monday, and Edward Thomas. Their work made possible this paper.

ABSTRACT

During the past 40 years, urban stormwater management has evolved from focus on drainage and flood control to inclusion of stormwater quality associated with nonpoint pollution. This paper projects what the urban stormwater field could look like in the year 2050. The projections are based on our best judgments as to the internal and external drivers that are expected to change the field during the next 40 years. Relevant projections by other stormwater groups are reviewed. Anticipated changes include the growing interest in stormwater reuse, on-site control of stormwater using a variety of low impact development alternatives, generation and accretion of recalcitrant residuals, toxics and chemicals as well as changing temporal and spatial phenomena of the urban hydrologic cycle due to changes in climate and patterns of urban settlement. Key expected drivers of changing attitudes are the greatly increasing relative cost of providing water and energy; greater concern about developing more sustainable green materials and infrastructure systems; and technological advances that will allow proactive management of urban stormwater systems using real time control and including source controls.

INTRODUCTION

As early as the 1960's, urban water experts were advocating the need to take an integrated systems view of water supply, wastewater, and stormwater (Heaney et al. 2000). While these investigators were able to scope out the problem, they lacked the essential computational and measurement tools to conduct these evaluations. Since the 1960's, computational power and models such as SWMM, geographical information system (GIS) tools and computational fluid dynamics (CFD) have been coupled with advances in urban water chemistry and particulate measurements, and imaging technology at scales ranging from x-ray tomography to satellite imaging for water chemistry indices to flood depths. This paper focuses on urban stormwater management with the notable exception of flood control that is described in a companion paper by Galloway (2009). A literature review of sustainability concepts and related efforts to forecast future stormwater systems is presented in the next section. Then, methods of analysis are described. Lastly, our forecasted major shifts in stormwater management are presented.

LITERATURE REVIEW

Innovative Urban Water Systems. Heaney et al. (2000) list the following principles for sustainable water infrastructure systems for the 21st century based on a thorough review of the literature on urban water systems:

- Individual urban activities should minimize the external inputs to support their activities at the parcel level. For water supply, import only essential water for high valued uses such as drinking water, cooking, showers and baths. Reuse wastewater and stormwater for less important uses such as lawn watering and toilet flushing. Minimize the demand for water by utilizing less water intensive technologies where possible. For transportation, minimize the generation of impervious areas, especially directly connected impervious areas, for providing traffic flow and parking in low use areas.
- Minimize the external export of residuals from individual parcels and local neighborhoods. For wastewater, export only highly concentrated wastes that need to be treated off-site. Reuse less contaminated wastes such as shower water for lawn watering. For storm water, minimize off-site discharge by encouraging infiltration of less contaminated stormwater and using cisterns or other collection devices to capture and reuse stormwater for lawn watering and toilet flushing.
- Structure the economic evaluation of infrastructure options to maximize the incentive to manage demand by using commodity use charges instead of fixed charges. For stormwater, assess charges based on the cost of providing stormwater quality control for smaller storms and flood control for larger storms. Charges should be based on the imperviousness with higher charges for directly connected imperviousness and the nature of the use of the impervious areas and their pollutant potential. Some charge should be assessed for pervious areas. Credit is now being provided for on-site storage and infiltration. However, the credit needs to be subject to quantifiable system behavior for hydrologic restoration and load management.
- Assess new development for the full cost of providing the infrastructure that it demands, not only within the development, but also external support services.
- Implement policies to make drivers pay the full cost of using personal automobiles through appropriate taxes on gasoline.

Blue Water in Green Cities. Novotny (2006) organized an NSF sponsored workshop on urban water systems of the future. He lists the following nine drivers of the change to more sustainable urban water systems.

1. Population growth and migration
2. Global climate change
3. Land stewardship and ethics
4. Increasing living standard and leisure time
5. Multiple use and overuse of urban waters
6. Change in hydrology
7. Long distance transfer of water and sewage
8. Improved efficiency of wastewater and stormwater runoff treatment
9. Limits have been reached and developing remedies is urgent

The ongoing downturn in the United States and world economy has modified the extent to which Novotny's drivers apply, e.g., our standard of living may be declining. However, this list is still current. Novotny (2006) summarizes the results of an international interdisciplinary workshop of experts that described visionary concepts on how to ensure that cities and their water resources can become more sustainable within the broader concepts of green cities and smart growth. This paradigm will evolve from the concept of the total hydrologic water and mass balance where water supply, stormwater, and wastewater will be considered and managed in a closed loop. The paradigm will include making the landscape hydrologically and ecologically functional. Selected papers from this workshop are presented in Novotny and Brown (2007).

IWA/IAHR Joint Committee on Urban Drainage: An international group of experts affiliated with the IWA/IAHR Joint Committee on Urban Drainage prepared a position paper on current conditions and expected future developments in this field (Marsalek et al. 2007). They discuss the following four future scenarios: 1) Business-as-usual; 2) Privatization; 3) Technocratic; and 4) Green. The Green option is viewed by the authors as synonomous with decentralization of urban water systems in order to maximize the reuse of treated wastewater and stormwater. They correctly caution that these Green approaches have not been implemented on a large scale and significant potential public health issues need to be considered.

EPA Research Plan. US EPA (2007) developed a research plan directed at encouraging innovation and research for water infrastructure for the 21st century. Most of their suggested topics deal with existing infrastructure issues. This plan is somewhat limited by the lack of a federal water agency that can take a holistic view of urban water in general and urban stormwater in particular. For example, US EPA deals with urban stormwater quality issues while the Corps of Engineers is responsible for flood control.

URBAN STORMWATER MODELS, SENSORS AND METHODS

Elliott and Trowsdale (2007) analyze and compare ten simulation models for evaluating urban stormwater systems with emphasis on decentralized systems. Weinstein et al. (2006) show how low impact development systems can be simulated. Heaney and Lee (2006) and Lee et al. (2005) describe a simulation and optimization model for decentralized urban stormwater systems. Modeling decentralized low impact development systems is much more challenging than modeling centralized traditional systems for several reasons including:

- many more controls to analyze, e.g., hundreds of small storage-release systems as opposed to a single neighborhood detention pond;.
- the reliance on infiltration greatly increases the uncertainty regarding performance;
- control can be exercised anywhere in the stormwater systems, thus blurring the distinction between the transport/storage and control elements in the model;
- increased questions regarding liability in the case of system "failures", e.g., allegations that flooding was caused by overland flow from nearby parcels;

- increased complexity regarding the expected water quality changes associated with subsurface phenomena;
- increased complexity from the non-stationary coupling of water chemistry, variably-saturated phenomena and the fate/transformation of chemicals and particulates in such systems;
- by design, decentralized systems are high surface area systems resulting in systems of higher reactivity and therefore greater temporal variability and also spatial variability;
- measurement practices adopted from centralized steady flow wastewater treatment systems; and applied to decentralized systems, or single/multiple unit operations subject to unsteady runoff loadings (Sansalone and Kim 2008).

Present and projected computer hardware and software will allow modeling of these more complex decentralized systems. For example, SWMM and CFD can be coupled and validated to predict the fate of chemicals and particulates whether in centralized or newer decentralized systems once the constitutive properties of the system are known (Kuang et al. 2008). While the hydrologic parameter inputs to such models have developed and matured over the last 50 years, a similar evolution is progressing for rainfall-runoff chemical and particulate phenonema, in particular with respect to coupling unit operation and process concepts (Sansalone 2005). New sensor and more fundamental measurement systems and methods are essential to accurately monitor urban stormwater systems and institute proactive adaptive controls. Experimental urban watersheds with state of the art representative monitoring and modeling are an essential element of selected future systems in order to find the optimal mix of centralized and decentralized systems.

Whether our urban water systems are centralized or decentralized, the complexity and uncertainty of rainfall-runoff relationships requires more progress towards continuous simulation that couple hydrology, chemistry and treatment. Beyond event-based modeling and design load concepts for unit operation and process (UOP) and low impact development systems which still provides heuristic and instructive insights and examinations; the long-term performance and viability of such systems is completely unknown and requires continuous simulation. Longer term assessments also require the coupling of rainfall-runoff relationships with coupled constitutive relationships for chemical, particulate and thermal regimes. For example, is transport of particulate matter a first-order process (a mass-based first-flush) or zero-order process as a function of hydrology (Sheng et al 2008)? Modeling also requires that the signature of a UOP or low impact development system must be generated for rainfall-runoff as well as for chemical, particulate and thermal regimes, recognizing that the signature changes (non-stationary), as these systems age and are not maintained (Kim and Sansalone 2008). While the hydrologic responses of a UOP or low impact development system have been effectively modeled under saturated or unsaturated conditions with existing models, modeling of the hydrodynamic, chemical, particulate and thermal regimes is more complex and not as common. The simple steady-state signature, the more complex event-based signature, or the much more challenging non-stationary signature of a UOP or low impact development system that includes chemical transformation, pollutant re-mobilization and scour can be developed with CFD. CFD is arguably one of the most powerful tools for assessment of UOP and LID systems since the introduction of continuous simulation

modeling. However, as with any powerful tool, CFD has liabilities. CFD requires far more representative data and monitoring than what is currently collected. For example, accurate particle size distribution (PSD), whether monitored in-situ or ex-situ is required. Additionally, CFD requires validation. As we move forward towards 2050 tools such as continuous simulation modeling, SWMM, GIS and CFD modeling will be coupled, providing an even more significant advance for urban water cycle management.

URBAN REUSE AND POLLUTANT INVENTORY

Reuse and urban pollutant inventories will continue to grow as we move toward 2050. Pollutant load inventories in urban control systems (including UOPs and low impact development) can be mobile and leachable while representing an inventory that requires recovery and management. Additionally, pollutant inventory in conventional urban conveyance systems and urban land uses requires recovery, quantification and management; otherwise this load becomes part of the urban water cycle. This is particularly important with respect to stormwater and wastewater reuse as a component of the urban water cycle. As we move toward 2050, source controls and pollutant recovery from urban source areas such as pavement cleaning can make a very demonstrable difference to reduce loads with a commensurate reduction in operation and maintenance requirements for centralized or decentralized systems. Load management is required to reduce phenomena such pollutant leaching from urban load inventories. As our technologies and infrastructure systems are improved to provide treatment, greater quantitative management and credit for such management will need to be provided. Management of such systems is a critical issue for persistent chemicals, in particular metals, which accrete at the aqueous-particulate interface and have a history of ecological impacts in urban civilizations. In addition to metals, modern chemicals include xenobiotic and organic chemicals used in the manufacture of materials from asphalt pavement to plastic water bottles; chemicals that are leached into to the urban water cycle and in some cases directly into the food web (Sansalone 2008).

Management of rainfall-runoff requires recognition that hydrology and chemistry are coupled phenomena in urban environs, and it is only with restoration of the hydrologic cycle and management of the urban water cycle that these cycles will be sustainable at the urban interface. The success or failure of reuse is dependent in large part upon our understanding and application of hydrologic processes and treatment controls as an integral part of the urban water cycle. Water reuse is now a critical and important component of the urban water cycle. This reuse is currently dominated by highly treated wastewater but also includes stormwater in selected urban areas. The need for such reuse will continue to increase. Distributing reuse water makes sense on a volumetric basis; however more attention is required for the chemical and microbiological loadings that are cycled back to urban areas by reuse water; becoming part of the hydrologic and urban water cycles. Persistent chemicals in runoff and runoff residuals include metals, organics, endocrine disrupting compounds (EDCs) and nutrients. Transport and fate are a function of land use, land use activity and infrastructure conditions. Unless reuse runoff is specifically treated for the aqueous fraction of these species, such chemicals have the potential to be redistributed back to the urban environs. The particulate residual fraction

must be separated and also be managed due to the potential of leaching or volatilization of these chemicals. Urban runoff contains pathogens and will require disinfection before reuse. While highly treated wastewater as reuse may have very low gravimetric levels of TSS and BOD_5 and provided with a disinfection residual; concentrations of nutrients, salts, EDCs and emerging contaminants must also be significantly reduced before re-introduction into urban hydrologic cycle. States such as Florida and California lead the nation with respect to reuse on a volumetric basis, and it is a logical extension to extend this leadership to urban chemical cycling management.

FORECASTED CHANGES

Heaney et al. (2000) developed urban water budgets for Denver and New York City to provide a first approximation on the expected utilization of wastewater and stormwater for non-potable purposes. Urban stormwater varies in relative importance because of climatic variability. Water budgets indicated that annual urban runoff was about 20 % of water use for Denver while it was about 100% of water use for New York City (Heaney et al. 2000). However, seasonal shortages can be expected due to timing issues; thus, on-site storage would be needed in most cases. Effective use of soil moisture storage can reduce the need for constructed storage facilities including cisterns, rain barrels, and rooftop storage.

Per capita indoor water use is expected to decline from historical levels of about 70 gallons per capita per day (gpcd) to as low as 40 gpcd with current technology especially high efficiency toilets (Aquacraft 2005). On the other hand, outdoor irrigation usage is increasing in many areas due to larger landscape areas and the use of automatic sprinkling systems that encourages higher application rates. Outdoor water use exceeds indoor water use in many of the warmer, more arid, parts of the country. Outdoor water use also contributes to the peak demands. Virtually all of the indoor water use ends up as wastewater that is treated along with infiltration and inflow (I/I) to the sewers. Thus, wastewater supply including I/I is a fairly steady 80-120 gpcd year round. This wastewater supply can be expected to decrease to 50-75 gpcd due to decreased indoor demand and more effective I/I controls. Irrigation demand decreases as precipitation increases so there is a mismatch between irrigation demand and the available supply of stormwater for reuse as irrigation water. A continuous simulation model can be used to estimate the amount of storage that is needed to provide irrigation water from reuse sources (Asano et al. 2007).

The quantity of stormwater per capita increased dramatically during the 20th century due to (Heaney et al. 2000):

- more automobiles which required more streets and parking and created additional pollutant sources
- larger houses on larger lots that increased runoff quantity and pollutant loads
- Growth of suburbia and much lower population densities
- More contemporary urban area was devoted to parking than to human habitat and commercial activities.
- Low density urbanization generated over three times as much stormwater runoff per family than did pre-automobile land use patterns.

Major trends during the 21st century can be expected to decrease the demand for urban stormwater systems:

- "Green developments" that increase population density and reduce urban sprawl
- Major modifications in our energy policies that increase the relative cost of energy compared to its historically very low costs in the United States (Friedman 2007)
- The reduced demand for more larger homes and landscapes due to changing economic conditions and public attitudes towards sustainable lifestyles
- The availability of advanced modeling and data gathering techniques that will enable the direct measurement of stormwater fluxes throughout the urban area and the resultant ability to implement proactive real time control systems that optimize performance for the entire contributing watershed.

These trends should have a very positive impact on urban water systems in the following ways:

- Higher gasoline costs will reduce the demand for automobile travel that is the largest source of directly connected impervious areas in cities. This will reduce stormwater runoff generation and the associated pollutant loads.
- Higher energy costs will encourage higher density urban development and reverse the trend over the past 50 years towards lower density urban sprawl that has greatly increased urban stormwater generation.
- Higher density urban development will reduce the irrigated area per person and higher energy costs will reduce demands for irrigation water.
- Higher energy costs favor the development of decentralized urban water systems because water distribution and collection systems constitute the majority of the cost of urban water systems.

SUMMARY AND CONCLUSIONS

During the past 40 years, urban stormwater management has evolved from focus on drainage and flood control to inclusion of stormwater quality associated with nonpoint pollution and how the demand for off-site stormwater services can be reduced by on-site management, primarily through infiltration. This paper projects what the urban stormwater field could look like in the year 2050. Recently developed similar projections by other stormwater groups were reviewed. Anticipated changes include the growing interest in stormwater reuse, on-site control of stormwater using a variety of low impact development alternatives, and changing patterns of urban runoff due to changes in climate and patterns of urban settlement. Key expected drivers of changing attitudes are the greatly increasing relative cost of providing water and energy; greater concern about developing more sustainable green systems; and technological advances that will allow proactive management of urban stormwater systems using real time control. Sustainable green systems will also require management of pollutant loads from reuse and active control and management of recalcitrant or toxic residual inventories generated in urban environs and activities. Source controls and green materials can improve the sustainability of such systems.

ABSTRACT

Population growth, coupled with increased standards of living and growing resource limitations, is creating water shortages and necessitates changes form the "linear" urban water management approach historically used. Fortunately, evolving approaches and enabling technologies allow integrated 21st century urban water management systems to be assembled which require the removal of much less water from the natural environment, can achieve energy neutrality (no net energy input to the water management system), and provide significant nutrient recovery. They incorporate increased efficiency, use of local water resources, and much greater recovery and recycling. These systems provide further advantages, including easier expansion, reduced urban heat island effects, and dramatically increased urban aesthetics. Our existing "linear" systems can be transformed by aggressively incorporating these modern concepts into new developments and when redevelopment occurs. Education and professional practice must be transformed to break down historical barriers between drinking, storm, and waste water. Economic analysis requires careful consideration of marginal effects.

INTRODUCTION

The current approach to managing water in urban areas has been used for millennia and was codified in modern cities in the late 19th and early 20th century. It is a "linear" system that involves removing large quantities of water from the environment, transporting it often long distances to the urban area, treating it to potable water standards, distributing it to meet all urban water uses (even those for which different water qualities would be more than sufficient), collecting used water for treatment to meet water quality standards, and remote discharge. Likewise, urban stormwater is collected and conveyed out of the urban area. This 20th century approach has been highly successful in meeting its original objective of protecting the public from enteric disease and flooding when the population of the planet was less than 2 Billion people and the population was mostly rural. However, by 2050 the population of the planet will be approaching nearly 10 Billion people, the vast majority will reside in urban areas, and they will be experiencing a significantly elevated standard of living which will place severe strains on the resources of the planet unless current resource consumption patterns are altered (Daigger, 2007a; NRC, 2003). Under these circumstances the current "linear" 20th century urban water and wastewater management systems will no longer be sustainable as it contributes to water stress (the lack of sufficient water supplies to meet human needs), environmental degradation (due to "dehydration" of the environment), excessive

resource consumption, and the dispersal of nutrients into the aquatic environment (Daigger, 2008).

Fortunately alternate urban water and wastewater management approaches are developing which use water much more efficiently (require significantly less water to be abstracted from the environment), use less resources (energy and chemicals), and better manage nutrients (Daigger, 2008, 2007b; Daigger and Crawford, 2007). These new 21st century approaches capture local water resources through techniques such as rainwater harvesting and distributed stormwater management, reduce net water use through use of water conservation and water reclamation and recycling technologies, can become energy neutral by both reducing energy use by distributed urban water management and by extracting energy and heat from the wastewater stream, and recover nutrients. The distribution of potable and non-potable water and separation of wastewater components at the source contribute further to energy and nutrient recovery objectives and offer the potential to significantly improve public health protection. 21st century approaches can also enhance the urban environment by retaining water in the urban landscape and creating natural areas that are not only amenities but also reduce urban heat island effects.

This paper outlines the individual technologies and approaches which form the basis for the 21st century urban water (and wastewater) management systems and demonstrates how they can be integrated into more highly performing systems. The year 2050 is chosen for this analysis for two reasons. First, planning for water management systems must be long-term in nature due to the long life of water management infrastructure. Second, the year 2050 represents an expected plateau in the human population, growing through the first half of the 21st century to reach a global population of approximately 10 billion (450 Million in the US), and remaining at this level through the second half of the 21st century (Daigger, 2007a; UN, 2005).

Transition from the current "stove-piped", "linear" system to a more integrated system will require significant changes to urban infrastructure, urban water management institutions, and professional practice (Daigger, 2008; Daigger and Crawford, 2007). This transition will require integrated action but can be implemented aggressively in areas where new development is occurring and in existing urban areas as redevelopment occurs. Over time both expanding needs can be met and existing urban areas can be transformed into this higher performing approach to urban water and wastewater management. Elements of this transition will be described.

ELEMENTS OF THE 21st CENTURY APPROACH

Table 1 summarizes key approaches and technologies that enable the 21st century approach to urban water management (Daigger, 2008). A wide variety of water conservation technologies are available, and more are expected in the future. Experience in water short areas indicates that application of these technologies can reduce domestic and commercial indoor water use substantially from over 400 L/capita-day to between 120 and 150 L/capita-day. This is the obvious starting point as reduced water use also means significantly reduced used water volumes, which can facilitate added innovations as will be discussed below. Reduced water consumption

means that local water sources can become a higher proportion of the urban water supply. One such source is local rainfall, which can be captured by a wide variety of means and stored in either constructed storage or in local aquifers. Even if the rainwater is not reused, infiltration into the local groundwater by a wide variety of techniques (as illustrated in Table 1) provides a local groundwater source which can replenish local streams and enhance the local environment (Strecker, *et al.*, 2005).

Table 1. Approaches and Technologies Enabling the 21st Century Approach to Urban Water Management.

Approach	Example Enabling Technologies
Water Conservation	Low-Flush Toilets, Low-Volume Showerheads, Washing Machines, Dish Washers, Xeriscape, Drip Irrigation
Distributed Stormwater Management	Rainwater Harvesting, Green Roofs, Porous Pavement, Rain Gardens, Vegetated Strips
Water Reclamation and Reuse	Membrane Bioreactors, Advanced Oxidation, Ultra-violet Disinfection
Source Separation	Dual Distribution Systems, Urine Separating Toilets
Distributed Water Treatment	Membranes, Advanced Oxidation, Ultra-violet Disinfection
Heat Recovery	Heat Pumps
Organic Management for Energy Production	Anaerobic Treatment, Microbial Fuel Cells
Nutrient Recovery	Crystallizers, Struvite and Calcium Phosphate

Water reclamation and reuse produces another local water source which can contribute significantly to meeting urban water needs (Daigger, 2007b). Used water can be treated to meet essentially any quality requirement, including for potable consumption or even for industrial applications requiring ultra-pure water. Table 1 lists some of the technologies which are making this approach cost-effective (Daigger, *et al.*, 2005; Daigger, 2003). An evolving approach is source separation, which recognizes that different water qualities are appropriate for different uses. This general concept has been used for several decades with dual distribution systems where reclaimed water is distributed for urban irrigation. It is now being extended recognizing the small proportion of water which actually needs to meet potable water standards – on the order of 30 to 40 L/capita-day. If the small needed amount of potable water is produced from fresh water sources and non-potable and irrigation water is supplied by rainwater harvesting and water reclamation and reuse, net water removal from the external environment can be reduced by more an order of magnitude. More extensive treatment, perhaps at a more local level to minimize deterioration in the distribution system, can be applied to the small amount of water which must meet potable water standards. This is the concept of distributed water treatment.

Source separation can be extended further to the collection of used water from domestic and commercial sources. Grey water is relatively uncontaminated and, consequently, can be treated without chemicals and with relatively little energy to produce non-potable water that can be used for a variety of sources. Importantly, this

is the largest proportion of domestic and commercial water use. Further separation of black water (feces) from yellow water (urine) segregates the majority of the organic matter (which can be used for energy production) from the majority of the nutrients in the waste stream. Figure 1 illustrates the typical distribution of organic matter (as expressed as five-day biochemical oxygen demand – BOD_5) and nutrients in the domestic waste stream. When it is recognized that the black water (and kitchen waste if it is also combined) represents a relatively small proportion of the waste volume, and yellow water may represent only about 1 L/capita-day, one can see that separation of these waste sources results in not only smaller volumes but much higher concentrations can be processed in different ways. Due to the higher concentration the resulting organic matter stream can be subject to direct anaerobic treatment and the biogas collected for energy production, rather than being subject to aerobic treatment which requires energy. In the future it may be possible to directly produce electricity from the organic matter contained in this waste stream using microbial fuel cells (Logan, *et al.*, 2006). The concentrated yellow water can be separately treated to recover nutrients and to remove pharmaceuticals (which are also concentrated in this stream).

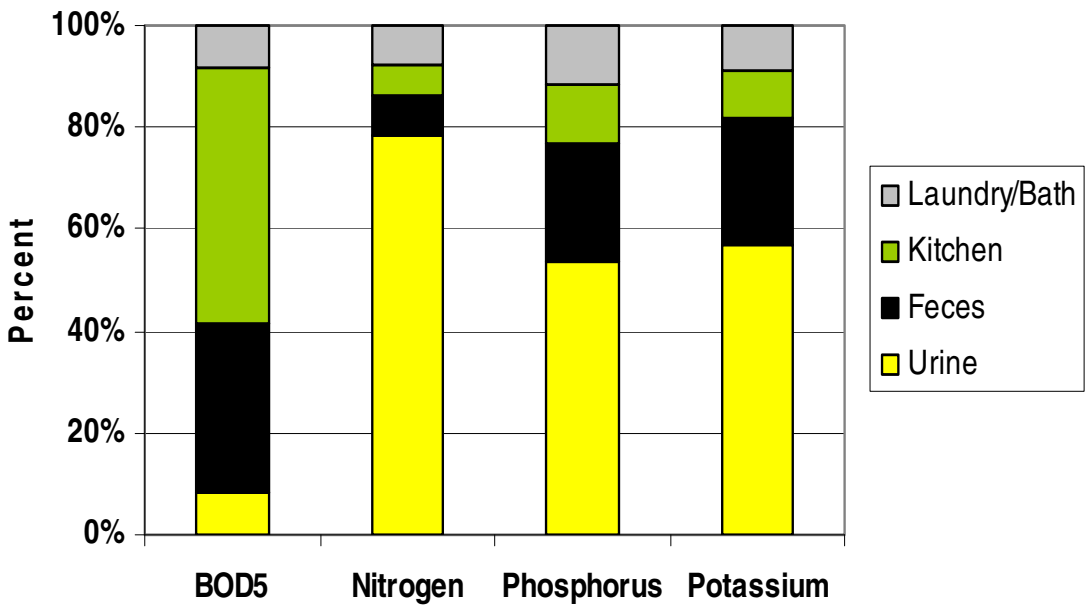

Figure 1. Distribution of Organic Matter and Nutrients in a Typical Domestic Waste Stream (From Henze and Ledin, 2001).

Not only can energy be produced from the organic matter contained in the waste stream, the thermal mass of the water and waste stream can also be used productively. Heat exchangers and heat pumps can be used to extract heat from the waste stream for space heating, and heat can also be rejected to this stream for space cooling as well.

These technologies and approaches represent a significant departure from the traditional linear approach described in the introduction. These elements can be

further combined into integrated systems with further enhanced performance characteristics.

INTEGRATED 21st CENTURY URBAN WATER MANAGEMENT SYSTEMS

When developing integrated urban water, organic matter, and nutrient management systems it is necessary to recognize the appropriate scale for various activities. Development of the stormwater, water treatment, and wastewater reclamation technologies listed in Table 1 allows water management to be accomplished on a more distributed basis. This offers at least two advantages. First, transmission distances (and consequently pumping energy requirements) are minimized when rainwater is captured and reclaimed water is produced closer to its use. Second, production of high quality reclaimed water facilitates extraction of heat from or rejection of heat to the waste stream to meet local needs. At the same time, economical energy production and nutrient recovery from the waste stream requires relatively large quantities of organic matter and nutrients, suggesting that these functions be accomplished on a more centralized basis.

Integrated urban water management systems must also comply with a set of guiding principals and constraints, as summarized in Table 2. The guiding principals help to conceive of systems alternatives, while the constraints must be complied with for any alternative that will perform acceptably on the long-term.

Table 2. Integrated Urban Water Management Systems Guiding Principals and Constraints (From Daigger, 2008).

Guiding Principals	Constraints
Protect and Use Local Water Resources	Maintain Water Balance Under Dry and Wet Conditions
Mimic Local Hydrogeology	Maintain Salt Balance
Provide Multiple Barriers to Protect Public Health	Maintain Nutrient Balance
Minimize Resource Consumption and Maximize Recovery	Collect and Manage Residuals

Figure 2 provides an example integrated 21st century urban water management system intended to use only local water supplies. Potable and non-potable water are supplied separately for the reasons outlined above. Potable water is supplied by local water resources, in this example assumed to be by a potable water aquifer which will provide suitable capacity due to the relatively small amount of potable water required when potable and non-potable needs are met separately. Non-potable water supply is provided by rainwater harvesting and water reclamation and recycling. Non-potable water storage (to balance demand with production) is provided by another local aquifer. Salt build-up is a possibility in a closed system such as this, which can be controlled by the export of brine (produced through reverse osmosis treatment of a portion of the reclaimed water) to a saline water aquifer.

Figure 3 provides an example integrated 21st century urban water management system intended to minimize energy requirements and maximize nutrient recovery. Potable and non-potable water supply is separated, this time to minimize pumping distances

and, consequently, also the pumping energy for potable and non-potable water distribution. Local water supplies (rainwater, grey water wastewater reclamation) are used for non-potable water supply because of the lower resulting energy consumption, as discussed above. Separate collection of black water and yellow water allows the concentrated black water stream to be treated anaerobically for biogas production and for recovery of nutrients from the yellow water stream. The thermal mass of the waste stream is used locally as a heat source for space heating and to reject heat for space cooling, depending on the season.

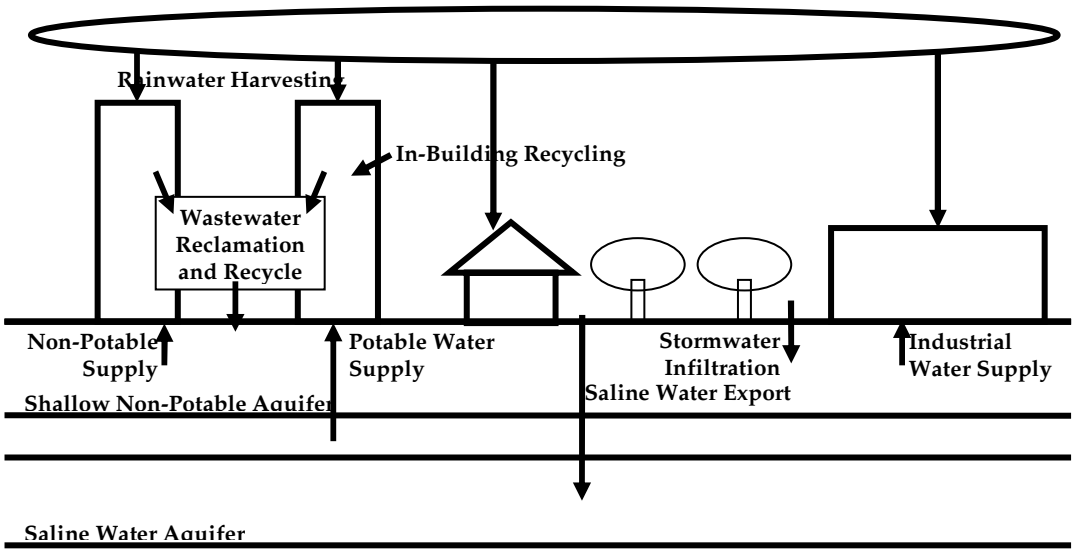

Figure 2. Example 21st Century Urban Water Management System Which Minimizes Net Water Removal From the Environment.

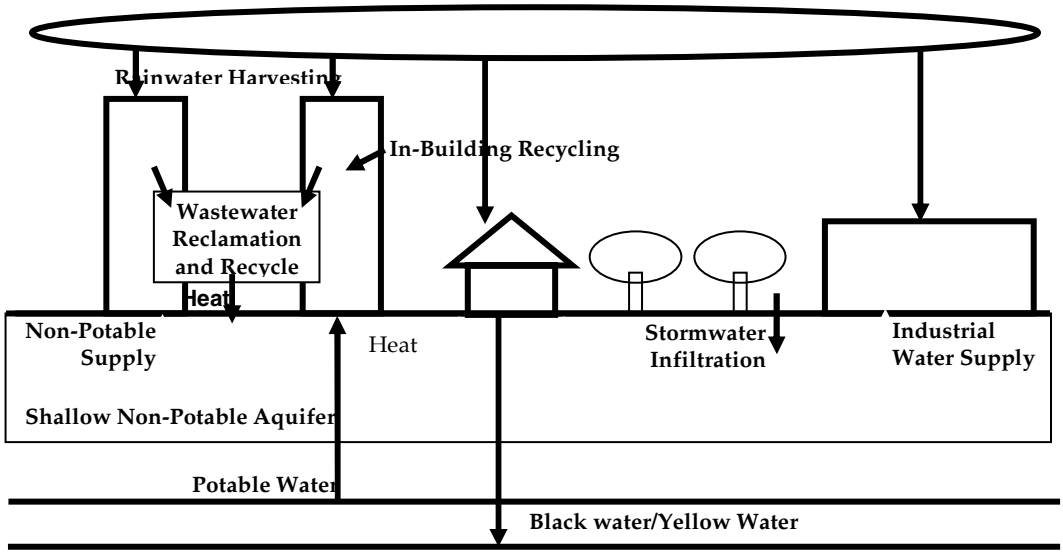

Figure 3. Example 21st Century Urban Water Management System Minimizing Energy Use and Maximizing Nutrient Recovery.

Analysis of systems such as these demonstrates that they can significantly reduce net water use, which makes water available to meet growing needs based on population

and economic growth; to achieve energy neutrality (no net energy input required), and significant nutrient recovery. They provide further benefits to the urban area, including reduced heat island effects (due to the increased vegetated cover) and greatly improved aesthetics. The monetary value of these benefits is often not reflected in cost-benefit analysis, but they are real. These examples are just two of the many possible.

TRANSITION TO 21st CENTURY SYSTEMS

When the high efficiency, closed loop 21st century integrated urban water management systems illustrated above are compared to our current, linear 20th century systems, one may ask "How can we transform our existing systems?". Said another way, what will we do with our "legacy" systems. When phrased in this fashion, the answer becomes obvious as we have significant experience in many contexts dealing with legacy systems and phasing them out while phasing in new generation approaches. We do it by aggressively incorporating 21st century approaches into new developments and also when we redevelop existing urban areas. Recognizing that the US population is expected to grow by 50 percent from the current 300 Million to about 450 Million by 2050, simply incorporating 21st century approaches into new development will result in one-third penetration of the new approaches into the water management infrastructure that will exist in 2050. Recognizing the urgent need for repair and replacement of much of our existing urban water management infrastructure, aggressively incorporating 21st century approaches as this infrastructure is redeveloped will result in significant conversion of our entire infrastructure. The key is to begin now, as it will provide two benefits. One is accelerating the transition from 20th to 21st century approaches which will allow us to capture the benefits of these new approaches as quickly as possible. The second is that aggressively incorporating these approaches will provide the practical knowledge that will allow the "fine tuning" of these new approaches and drive a research and development (R&D) agenda that will lead to their further advancement. The modular nature of 21st century infrastructure is another advantage as it can be easily added and expanded in response to demand and thereby facilitating financing.

Institutional arrangements are certainly a key to accelerating the transition to routine implementation of 21st century approaches (Daigger, 2008; Daigger and Crawford, 2007). In many areas urban drinking water, waste, and stormwater are managed by separate utilities. Even when they are managed by the same utility they are often not managed in an integrated fashion. Examination of the example systems presented above illustrates that this will not be possible in the future as the integrated systems simply consider that "water is water". This may lead some to conclude that integrated 21st century systems can only be implemented when a single utility is responsible for all forms of water within the urban area. Fortunately, numerous examples exist where separate utilities successfully cooperate, indicating that utility reform is not a necessary precursor. In fact, the principal constraint may be the structure of our historic educational approaches and our professional organizations which emphasize the separate management of drinking water, wastewater, and stormwater. Better integrating our approaches to education and expanded cooperation by our professional organizations can create an integrated vision for urban water

management, which can carry into professional practice. This historic division may be the reason that so many utilities with combined responsibilities currently fail to act in an integrated fashion.

Economics are a key to enabling rapid transition to 21st century integrated urban water management approaches (Daigger, 2008; Daigger and Crawford, 2007). There are two important aspects to this. First, the benefits of these integrated approaches can be broad and must be evaluated properly. For example, the cost benefits of options which reduce net water demand (such as water conservation, rainwater harvesting, and water reclamation and reuse) should not be compared to the average cost of delivering potable water. Reduced demand will allow the most expensive water supply option to be retired or implementation of the next most expensive water supply option to be avoided (depending on whether the options being considered will reduce demand or meet growing demand). In other words, the marginal cost, rather than the average cost must be considered in the evaluation. This concept is well known to professionals routinely engaged in evaluating water reclamation and reuse options, but not by water management professionals in general. Multiple benefits can also be generated by these measures – for example a reduction in both water supply and waste management costs – and all of these benefits must be considered in the evaluation. In other words, we must be careful to perform a "global" rather than "local" optimization. We must also include broader benefits such as reductions in heat island affects and reductions in greenhouse gas (GHG) emissions in the overall evaluation.

At the same time, the costs and benefits for various options may not be uniformly distributed between the responsible parties. Such issues can be dealt with through inter-agency or inter-departmental charges. It may also be necessary to change the basis for financing urban water management utilities. In many instances urban drinking water and waste management utilities are financed based on user charges based on the volume of water sold or wastewater generated. Obviously, this penalizes utilities for reducing water use and wastewater generation, steps which are contrary to our general objectives. Moreover, since utility costs do not go down in proportion to the volume of water sold or wastewater processed. This challenge has been faced by many electric utilities and has been solved by at least partially separating the revenue that the electric utility receives from the quantity of electricity it sells. The more enlightened approach compensates electric utilities for causing increased efficiency of electricity use, along with the total amount used. The same approach could be applied to urban water management utilities.

CONCLUSIONS

The traditional, 20th century approach to urban water management may be described as "linear" and involves removing large quantities of water from the environment, transporting it often long distances to the urban area, treating all to potable water standards, distributing it to meet all urban water uses (even those for which different water qualities would be more than sufficient), collecting used water for treatment to meet water quality standards, and remote discharge. While this linear 20th century

approach has successfully protected public health, several factors are creating the need to transform our approach to urban water management, including:

- **Global population** from, from less than 2 Billion in the first half of the 20th century to approximately 10 Billion by 2050 (US population growth from less than 100 Million to approximately 450 Million).
- **Urbanization**, from less than one-third of the total population in the first half of the 20th century to more than half today and to more than two-thirds of the total population by 2050.
- **Increased living standards**, which are necessary to allow global population to stabilize.
- **Resource availability**, from a period of apparently excess resources in the 20th century to resource limitations in the 21st century.

As a result, widespread water stress is developing both globally and within the US.

Fortunately, higher efficiency, closed loop approaches are available which can:

- Dramatically reduce the quantity of water urban areas must remove from the external environment.
- Achieve energy neutrality (i.e., no net energy input required).
- Achieve significant nutrient recovery for reuse.

These 21st century approaches incorporate (1) increased water conservation and efficiency, (2) distributed stormwater management which captures and uses rainfall, (3) source separation, (4) water reclamation and reuse, (5) distributed water treatment, (6) heat recovery, (7) organic management for energy production, and (8) nutrient recovery. To achieve full benefit, these approaches must be developed into integrated urban water management systems where a variety of qualities of water are produced and used and collected for reuse. The transition from linear 20th century to closed loop 21st century approaches can be implemented by aggressively incorporating 21st century approaches into new development and as redevelopment occurs. The modular nature of these technologies facilitates incremental additions in response to growing demand. Changes in professional practice and our educational system are required to develop practitioners capable of developing and implementing these integrated systems. Economics must be carefully examined, often considering marginal cost impacts. Collaboration between utilities will be required, including approaches to financing them.

Challenges of Managing California's Sacramento-San Joaquin Delta

Jay R. Lund#, Ellen Hanak*, William E. Fleenor#, William A. Bennett#, Richard E. Howitt#, Jeffrey F. Mount#, Peter B. Moyle#
University of California – Davis, Center for Watershed Sciences

"Once a landscape has been established, its origins are repressed from memory. It takes on the appearance of an 'object' which has been there, outside us, from the start." Karatani Kojin, *Origins of Japanese Literature*, Duke University Press, 1993, p. 34.

The Sacramento–San Joaquin Delta is the hub of California's water supply system and the home of numerous native fish species, five of which already are listed as threatened or endangered. The recent rapid decline of populations of many of these fish species has been followed by court rulings restricting water exports from the Delta, focusing public and political attention on one of California's most important and iconic water controversies.

In our previous report, *Envisioning Futures for the Sacramento–San Joaquin Delta*, we explored the alternatives available for the long-term management of this multifaceted resource. We concluded that change is inevitable for the Delta and that retaining the current policy of exporting large amounts of water through pumps in the southern Delta was both risky and unsustainable. We examined nine long-term strategies for managing the Delta from the perspectives of environmental, economic, and water supply performance.

In this report, we continue the theme of analyzing how the Delta will change in the future and how California can respond to expected changes to meet state economic and environmental objectives. We focus on a central question for long-term Delta policy: Which water management strategies best meet the goals of environmental sustainability and water supply reliability? Many other decisions concerning California's water management, the Delta aquatic environment, and Delta land use depend on the answer to this question. We provide an integrated analysis of these issues in a series of technical appendices and summarize the results and their policy implications in this report. These analyses allow us to arrive at some firm conclusions regarding the desirability of various long-term alternatives for the Delta from a scientific and technical perspective.

Managing the Inevitable

Although the Delta is the focus of growing controversies regarding fish and water supplies, it is also being subjected to major physical forces that are at odds with

current Delta policy. These physical forces are sea level rise, land subsidence, changing runoff patterns, and earthquakes.

The Delta is a product of sea level rise over the last 12,000 years. At the end of the last Ice Age, the current Delta was only a confluence of rivers flowing to a delta outside of the Golden Gate Bridge. As the sea level rose, the Delta began to form as higher tides began to flood the area of confluence about 6,000 years ago. Continuing sea level rise can be seen in the last century of tidal records worldwide and for San Francisco. With climate warming, sea levels and Delta water levels are expected to increase by one to three feet, perhaps more, over the coming century. Without large investments to raise Delta levees, this rise in sea level will cause many levees to fail, pushing seawater into the Delta. Even if the levees could be sustained, sea level rise would increase the salinity of Delta waters.

Land subsidence—or the sinking of Delta islands—began when the marshlands were first diked and drained in the late 1800s and it continues today as the peat soils oxidize and erode. Most islands are below sea level, many by more than 20 feet. Subsidence increases seepage into the islands, raises the likelihood of levee failures, and increases the costs and consequences of catastrophic island flooding.

California's runoff patterns are changing. Over the last 50 years, there has been a shift toward less snow and more rain in the Sierra Nevada mountains. These shifts—probably associated with climate warming—have increased winter inflows to the Delta. Climate models indicate that this trend will continue, with even larger and more frequent floods in the future. The increases in winter flood flows also will increase island flooding.

Earthquakes are probably the greatest unavoidable threat to today's Delta. Several authoritative investigators have concluded that a major earthquake, such as the 1906 San Francisco earthquake, will likely cause the failure of many Delta islands simultaneously, with a two-in-three chance of such an earthquake occurring within the next 30 years. Such failures would directly threaten water supplies and would affect thousands of roads, bridges, homes, and businesses at the same time. The water supply costs of such an event are estimated to be in the tens of billions of dollars. The likelihood and costs of earthquake-related failures increase significantly with sea level rise and land subsidence.

The Delta also faces a powerful biological driver of change—the invasion of aquatic and terrestrial species from all over the world. Today, nonnative species dominate the Delta, threatening the survival of remaining native species, changing the way the ecosystem functions, and making the ecosystem and the services it provides less predictable. Unfortunately, new species continue to arrive at a high rate, adding a new wild card to the management deck every time one becomes established.

These factors alone are sufficient to conclude that the Delta of the future will be very different from the Delta of today and the Delta of the past, regardless of what management and policy actions are taken and what happens to California's environment and economy. Californians cannot go back to the Delta that existed before its marshy tracts were diked and drained; it would require 3.4 billion cubic yards of material to fill subsided islands alone. Nor is it possible to return to the agricultural Delta of early 20th century; the levee upgrade costs are too great, and salinity will intrude farther into Delta waters even with higher levees. This salinity will decrease the productivity of millions of acres of farmland that depend on Delta

waters and will raise water treatment costs and public health risks for the two-thirds of Californians who rely on the Delta as a source of drinking water. Salinity intrusion can be delayed for a time by releasing more fresh water into the Delta, but it cannot be delayed indefinitely. As these changes transform Delta water and landscapes, invasive species will continue to alter the Delta ecosystem.

Even if California could sustain the current Delta against these forces, would it be in the best interests of the state's residents and environment to do so? As found in our earlier report and confirmed by recent events, the current Delta is performing poorly from almost everyone's perspective. Given the potential for catastrophic failure of the system, it is important to examine strategic alternatives for managing the Delta. Although the Delta problem is extremely complex, it is unrealistic to seek solutions to all issues simultaneously. California needs to develop a strategic direction for the Delta before working out all the details of how to get there.

Water Exports: A Central Issue in the Delta

This report focuses on a central question for Delta policy: how to manage Delta water supplies and, in particular, water exports. This question lies at the heart of the wider debates over meeting environmental and economic goals for the Delta. Export policy decisions will drive environmental actions and regulations, determine investments in Delta levees and the ecosystem, and ultimately shape much Delta land use.

In broad terms, there are only four long-term strategies for managing Delta water exports: (1) continue pumping exports through the Delta (the current policy), (2) divert water upstream and convey it around the Delta through a peripheral canal, (3) combine the current through-Delta pumping strategy with a peripheral canal (so-called "dual conveyance" or "dual facility"), and (4) end exports altogether. All Delta water export policies, including those examined in our earlier report, are variants of these four basic strategies. The use of most other tools available to California's water managers to meet water supply needs— including conservation, groundwater and surface storage, transfers, recycling, and desalination—depends significantly on this strategic decision.

A wide range of environmental management tools could improve conditions for the Delta's threatened aquatic life. Reducing or ending the use of the southern Delta pumps could prevent fish entrainment and the altered water flows that harm fish. Increasing the volume of water flowing into the Delta and rebuilding variability in Delta water flows are two strategies for creating a more diverse and beneficial aquatic habitat. Ample opportunities also exist to expand aquatic habitat on the Delta's fringes and within the Delta itself, particularly given the likelihood of island flooding. Methods also are available to improve the design and management of aquatic habitat and to suppress harmful invasive species. The suitability of these tools, and their potential performance, will be significantly affected by the water export strategy employed.

Likewise, many land use, road, rail and other infrastructure decisions in the Delta will largely depend on the state's long-term strategy for Delta water exports. The present strategy of responding to emergencies only as they happen puts California in the position of making Delta policy by default rather than by deliberate consideration of the best long-term alternatives.

Evaluating Strategic Decisions

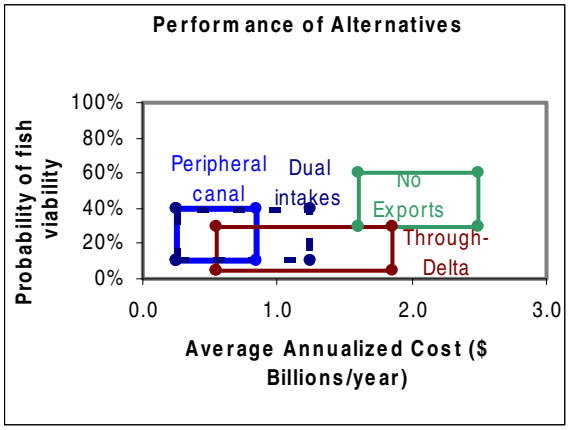
Because the strategic decision of how to manage water exports is of central importance for so many other management decisions, we focus our analysis on the quantitative comparison and evaluation of the four approaches to exporting water from the Delta. Decisionmaking for other related issues seems likely to become easier once the log-jammed decision on a sustainable long-term Delta export policy is established.

The four alternatives are examined in terms of the two co-equal objectives for the Delta suggested by the governor's Delta Vision Blue Ribbon Task Force: environmental sustainability and water supply reliability. To represent environmental sustainability, we focus on the likelihood of sustaining viable populations of desirable fish species, including native species and others that do well under similar conditions. We assess water supply performance in terms of statewide economic costs and benefits.

To facilitate explicit comparisons among export alternatives, we employ a method known as "decision analysis." This method allows us to explicitly consider a range of possible outcomes, account for major risks and uncertainties, and examine how the water and environmental management system would likely respond to major failures in these alternatives.

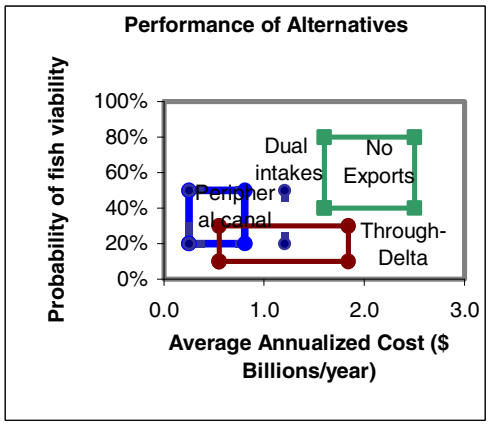
For the economic analysis, many aspects of the water export decision can be quantified, making it possible to draw clear comparisons among alternatives. Elements used in the assessment include capital and operating costs, the costs of water shortages, the costs resulting from an extensive Delta levee failure, and the costs of repair after an extensive failure. We also compare alternatives in terms of water quality costs for drinking water treatment and agricultural production. We estimate ranges of answers to reflect the uncertainty in these costs.

The viability of fish populations under different water management alternatives is more difficult to assess. However, California is fortunate to have many experts on the Delta ecosystem and its fishes, and years of studies have improved understanding of these issues. We surveyed a group of experts on the Delta ecosystem to help us understand how each export alternative would likely affect the viability of fish populations. We complemented these results with an analysis of conditions under which different groups of fish species thrive and our own assessment of how Delta fish species would likely be affected by long-term changes in Delta conditions. This allowed us to establish ranges for the likelihood that fish populations would be sustained for each of the four water export alternatives.



In comparing alternatives, we also consider major risks. For example, if a peripheral canal were built and listed fish species did not recover, legal and political actions would be likely to seek reductions in water exports through the canal. Another uncertainty is the timing of an earthquake or flood that will cause an extensive failure of levees in the Delta, disrupting exports that pass through the Delta.

Comparing the Water Export Alternatives



When this information on costs, risks, and likely performance of Delta fish populations is integrated in the decision analysis, it produces estimates of the likely ranges of economic costs and fish population viability for each of the four export management alternatives. A summary of our analysis appears in Figure S.1. Fish population viability estimates are presented for two key Delta species—the delta smelt and fall-

run Chinook salmon. For delta smelt, viability is defined as achieving sufficient recovery to avoid Endangered Species Act restrictions on water exports. For fall-run Chinook salmon, viability is defined as maintaining adequate populations to support commercial and recreational fisheries.

For some alternatives, the range of likely economic performance is quite broad. A dual facility has likely costs as low as $250 million and as high as $1.4 billion per year. For continued through-Delta pumping, the range is even larger, with a low of $550 million and a high of $2 billion per year. These ranges reflect considerable uncertainty. For through–Delta pumping, a major uncertainty is how soon the system will be damaged by a large-scale levee failure. A dual facility would become much more expensive if extensive investments were made to maintain the through-Delta export channels. For fish, the ranges reflect the considerable uncertainties about species performance, depending in part on how carefully the ecosystem components of any Delta alternative are managed, as well as on influences from external sources (i.e., for salmon, the ocean and upper watershed).

(a) Delta smelt

(b) Fall-run Chinook salmon fishery

Figure 1 - Range of costs and fish population viability for Delta export alternatives in 2050

Despite these uncertainties, some clear comparisons emerge. In terms of statewide economic cost, the most likely ordering of alternatives is a peripheral canal (best), followed by dual conveyance, continued through-Delta exports, and, in last place, ending exports. Even if a peripheral canal faced relatively high construction costs (on the order of $10 billion) and could export only 60 percent of current levels because of endangered species restrictions, its total costs would not exceed $1 billion per year. Dual conveyance is potentially more costly than a canal alone, because it will likely entail additional infrastructure costs to continue through-Delta pumping. Dual conveyance costs also could be somewhat higher because the lower water quality pumped from the Delta increases costs for urban and agricultural users.

Several key drivers make continued through-Delta pumping relatively costly. First, by mid-century, the increased salinity of Delta waters imposes water treatment costs on the order of $200 million to $1 billion per year, every year. Second, this alternative requires significant investments, initially to fortify key levees and to improve Delta

channels and, ultimately, to build a peripheral canal when the levee system fails.[1] Third, a catastrophic failure of key levees would cause large one-time costs of $8 billion to $15 billion. The no exports alternative, in contrast, involves considerable costs outside the Delta itself, as water users develop alternative, higher-cost sources and reduce water use, particularly for agriculture in the southern Central Valley. Our estimates assume that water users have time to prepare for an end of exports. The costs would be considerably higher—more like those of a catastrophic failure—if they had no time to prepare.

The most likely ranking of alternatives is quite different for fish viability, with no exports being the best, followed by a peripheral canal and dual conveyance (tied), and continued through-Delta pumping in last place. A broad consensus exists among estuarine experts that ending exports is likely to be best for a range of desirable fish species—ending the harmful entrainment and unnatural flow patterns generated by the southern Delta pumps, as well as providing more water for aquatic habitat. A peripheral canal provides the first two of these benefits; our estimates of fish viability assume that a peripheral canal would be designed and operated to minimize new entrainment problems at the upstream intake. Although in principle dual conveyance offers some additional flexibility for water management, we do not believe that it will have appreciably different outcomes from a canal-only alternative for either delta smelt or salmon. Finally, continued through-Delta pumping is the least beneficial for fish, given the problems of entrainment and disruption created by the southern Delta pumps. Through-Delta pumping also prevents the more flexible management of environmental water flows to increase aquatic habitat variability.

How do the alternatives compare when environmental benefit and economic performance are considered together, as co-equal objectives?

- The peripheral canal and dual conveyance alternatives are very likely to perform better than continued through-Delta export pumping on both objectives. The peripheral canal has a two-thirds chance of outperforming through-Delta pumping; these chances exceed 50 percent with a dual facility. In contrast, through-Delta pumping has less than a 5 percent chance of outperforming the two canal-based alternatives on both co-equal objectives.
- There seems little reason to prefer a dual facility over a peripheral canal. The two alternatives are likely to perform equally from the perspective of desirable fish species, and dual conveyance is likely to be more costly. Nevertheless, for an interim period, it may be valuable to maintain some through-Delta pumping as part of a dual system, to aid water quality for Delta farmers and provide additional flexibility for exports and environmental operations. With time, the through-Delta portion of dual conveyance will probably become less reliable and more expensive as a result of endangered species regulations, sea level rise, and island failures. A dual conveyance alternative with significant investments to support through-Delta pumping is unlikely to be worth the additional costs, given the water quality and environmental risks of through-Delta pumping.

[1] Our analysis finds that a peripheral canal would be built after massive levee failure, because this would be the least expensive response. If, instead, a decision were made to rebuild the failed levees or to end exports, the expected cost of the through-Delta strategy would be higher than the range presented here.

- A clear tradeoff exists between a peripheral canal and dual conveyance and the alternative of ending exports. A peripheral canal and dual conveyance are better in terms of costs to the economy, but ending exports is better for fish. Selecting between these alternatives will require a value judgment. The tradeoff may be easier to make if some of the economic benefits of a canal-based alternative could be used to support enhanced ecosystem investments in the Delta, thereby improving environmental outcomes.

Selecting an export strategy does not, in itself, solve the Delta's problems; it is only a necessary step toward a solution and should provide a framework that improves subsequent decisionmaking. Many technical, regulatory, financial, governance, and policy decisions must accompany the implementation of a long-term strategy. In particular, no matter which export strategy is selected, there will have to be investment in improvements of aquatic habitats within the Delta to increase the likelihood of fish recovery. As indicated by the range of costs and likelihood of restoring fish populations to health, the implementation details will be at least as important as the specific strategy selected.

Policy and Regulatory Implications

Almost a century of Delta regulations, laws, policies, and agreements have revolved around the historical policy of maintaining the Delta as a largely freshwater body and exporting water through the Delta. This situation no longer serves the interests of the state's environment or economy. An institutional framework is required for establishing, operating, regulating, and financing a new Delta strategy. Successful new institutional arrangements are unlikely to emerge from a stakeholder-led process. Large numbers of parties with divergent interests are ill-suited to crafting workable solutions without outside leadership. The governor and the legislature can provide the necessary leadership to make such profound institutional changes to prepare for and manage the Delta of the future.

Conclusions

Our conclusions can be summarized in four broad areas.

1. **Fundamental changes are inevitable in the Delta.** "Restoring the Delta" is an unrealistic notion given the historical changes that have occurred and the immutable forces that will affect the Delta in the decades to come.
   - Sea level rise, earthquakes, continued land subsidence, and higher winter flood flows will increase the frequency and costs of Delta island failures.
   - Maintaining all Delta islands is not cost-effective.
   - The Delta of the future—with large bodies of open water—will significantly differ from the Delta of yesterday or today.
   - California is unprepared for the changes that will occur in the Delta.
2. **The conditions for the Delta's fish can be improved.** Naturally occurring improvements include greater aquatic habitat as islands become permanently flooded. Managed changes in water intakes, water operations, and habitat also can improve conditions for fish but the following issues must be considered:

- Rebuilding large, self-sustaining populations of desirable Delta fish species will require large and carefully designed ecosystem investments.
- More diverse habitat is fundamental to improving conditions for desirable fish species, with greater variability in Delta water flow and salinity as part of this strategy.
- Water export alternatives matter for fish, and the current export alternative is almost certainly the worst for desirable fish species.
- Preventing new invasions of alien species and better control of existing problem invaders are needed to create a more predictable and favorable environment.
- Some species in the Delta are likely to be sustained only with heroic efforts.

3. **For water exports, time favors a peripheral canal and is unfavorable to other alternatives**. Figure S.2 presents a conceptual view of how export alternatives are likely to perform over time and the choices California will face. Water exports are currently declining from historical high levels as a result of court rulings regarding endangered species. Additional species listings are likely to cause further export reductions in the near term. The accumulating effects of land subsidence, sea level rise, worsening floods, and earthquakes will make continuation of through-Delta pumping less reliable and more costly over time but it will leave peripheral canal exports relatively unaffected. However, it will take some time before a peripheral canal can be constructed. How well a dual conveyance alternative ultimately performs will depend on the size of the canal component. If the canal were sufficiently large, it could take an increasing share of exports as through-Delta pumping became less viable. As the figure highlights, the ability of each alternative to support fish populations also significantly affects its ability to support exports.
4. **A peripheral canal is a necessary component of a long-term solution that serves economic and ecosystem objectives co-equally.**
   - Sea level rise will make Delta export pumping increasingly unattractive and eventually infeasible.
   - The long-term water export choice is between building a peripheral canal (which is best for the economy) and ending Delta exports (which is best for fish).
   - A potential compromise is to allocate some of the savings generated by a peripheral canal to enhanced ecosystem investments.
5. **A successful long-term Delta solution will require governance, regulatory, and finance arrangements that allow decisions to be made in a timely way.**
   - To be viable, a peripheral canal or dual conveyance would require effective governance, regulatory, and financing mechanisms.
   - Governance mechanisms can be devised to provide appropriate environmental safeguards for a peripheral canal.
   - Financing mechanisms are available to cover the range of water system needs.
   - It makes economic and environmental sense to involve upstream diverters, as well as users of exported water, in providing more water to the Delta.
   - Establishing these arrangements requires involvement from the legislature and governor.
   - The current regulatory framework is not prepared to deal with the Delta of the future.

Recommendations

The Delta of the future will be very different, and the costs of inaction are high. California needs to prepare for this changed future to direct it more favorably. This means charting a new strategic direction for Delta water management, planning environmental investments from the vantage point of a changing Delta, and developing strategies to manage levee failures. Preparing for the future through governance and regulatory reforms is also essential.

1. **Initiate a planned transition away from through-Delta pumping to other export strategies.**
   Table 1 summarizes the role of the four alternatives in the context of such a transition. Continued through-Delta exports are already demonstrably harmful to the environment, and with time they become unviable for the state's economy. The transition away from through-Delta pumping will occur over time, whether planned for or not. A more expeditious, planned transition would be less susceptible to the rapid, costly changes accompanying earthquakes, floods, and levee failures.

Table 1 - Summary Comparison of Water Export Alternatives

Alternative	Role
Continued through-Delta exports	Increasingly unstable and costly solution
Dual conveyance	Interim solution for transition to peripheral canal
Peripheral canal	Potential to provide both cost-effective water supply and improved fish viability
No exports	Best for fish but most costly to the economy; ultimate outcome without a peripheral canal

2. **The most promising strategy for meeting co-equal long-term state environmental and economic objectives is a peripheral canal. This strategy should include the following elements:**
   - Export water users commit up front to pay for a peripheral canal and water export facilities.
   - Safeguards on the operation of a peripheral canal are provided through governance and ownership institutions rather than by limits on the physical capacity of the canal, to enable better environmental and water supply performance
   - Export water users and upstream diverters commit funds and water to improve the ecosystem. Although upstream diverters have more senior water rights, both groups of users are partially responsible for declines in the Delta ecosystem.
3. **Actively prepare for a changing Delta ecosystem.** Habitat conservation planning needs to consider the effects of sea level rise, climate warming, permanent levee failures, and new invasive species. A rigidly negotiated habitat conservation plan is unlikely to succeed; experimentation and detailed modeling studies to inform a decision-capable governing framework will be needed.

- Ecosystem management should favor diverse habitat and flow conditions for multiple species.
- Hydrodynamic modeling needs to consider sea level rise, permanently flooded islands, and the potential for managing Delta flow patterns to favor desirable fish species.

4. **Move away from levees as the primary means of managing Delta land and water.** Prepare for island failures. Provide major state levee investments only for those Delta islands that have a cost-effective statewide interest; devise mitigation strategies for land owners on other islands.
5. **Develop a new framework for governance and regulation of the Delta.** In addition to developing workable governance and finance institutions for water supply and ecosystem management, policymakers need to anticipate regulating a very different Delta environment.
   - The regulatory consequences of sea level rise and island failures need to be addressed now, so that flexible water management tools are readily available to help California meet its environmental and economic goals,
   - The number, importance, and urgency of problems associated with a Delta transition require a decision-capable governance and regulatory system and one that is at least somewhat more centralized than the current, highly decentralized system. The current governance system is effective at tinkering with the status quo but will likely be ineffective in overseeing any sort of major transition.

Charting the Future for a Changing Delta

The ongoing and increasingly rapid changes in the Delta pose a long-term challenge to California as a whole, as well as to all parties involved in this perennial source of conflict. All parties seeking to achieve the Delta Vision's co-equal objectives of environmental sustainability and water supply reliability have an interest in making a peripheral canal part of a long-term solution for the Delta. This strategy must be embedded in a comprehensive set of actions to improve aquatic environments in the Delta and the greater watersheds of the Sacramento and San Joaquin Rivers. To be viable, a long-term solution must include governance, regulatory, and financial arrangements to ensure that various goals are well served, including water supply, environmental management, and the state's local interests in the Delta. It is unlikely that local and regional stakeholders can negotiate such arrangements on their own in a timely way, given the complexity of the problem and its innumerable stakeholders. Pursuit of a grand consensus solution for the Delta's many issues is likely only to continue the deteriorating status quo. Leadership from the governor and legislature will be needed to create conditions for reasonable governance of the new Delta, with cooperation from local governments and federal agencies that regulate and manage water and land use.

Characterization of Water Resources and Environmental Disasters

Walter M. Grayman[1]

PH: (513) 761-1722, email: grayman@fuse.net

Abstract

When you think about water resources and environmental disasters, some of the recent events that come to mind include Hurricane Katrina, the 2004 Indian Ocean tsunami and the Exxon Valdez oil spill. However, other than concluding that "I know a disaster when I see one", what can we do to better characterize and rank disasters? Some potential criteria include: economic damage, environmental damage, fatalities, reconstruction cost, aesthetic damage, disruption of normal activities, destruction of irreplaceable objects, and long-term or permanent loss of species. This paper explores past water resources/environmental disasters and provides a rough comparison of their impacts in terms of a range of criteria. It also provides a taxonomy of disasters in terms of causes (natural events, human induced), predictability and potential impacts.

Keywords
Disasters, water resources, environment

DEFINITION OF DISASTERS

Following are several definitions of the word "disaster" resulting from a search on the Web:

- A disaster (from Middle French désastre, from Old Italian disastro, from the Greek pejorative prefix dis- bad + aster star) is the impact of a natural or man-made hazard that negatively affects society or environment. http://en.wikipedia.org/wiki/Disaster
- An unexpected natural or man-made catastrophe of substantial extent causing significant physical damage or destruction, loss of life or sometimes permanent change to the natural environment; An unforeseen event causing great loss, upset or unpleasantness of whatever kind. http://en.wiktionary.org/wiki/disaster
- A serious disruption of the functioning of a community or a society causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources. www.adrc.or.jp/publications/terminology/top.htm

- Any occurrence that causes damage, ecological destruction, loss of human lives, or deterioration of health and health services on a scale sufficient to warrant an extraordinary response from outside the affected community area. www.nhtsa.dot.gov/PEOPLE/injury/ems/emstraumasystem03/glossary.htm
- A sudden, unplanned calamitous event, which causes loss and hardship to all or part of an enterprise and thereby significantly impacts its ability to deliver essential services for some period of time. www.state.mn.us/portal/mn/jsp/content.do
- An occurrence, either natural or man made, that causes human suffering and creates human needs that victims cannot alleviate without assistance. http://wps.prenhall.com/chet_langan_preparing_1/0,9681,1613226-content,00.html
- An event that causes major disruption on the economy, society and the environment. Its origin or causes may be directly derived from natural phenomena, i.e. geophysical (as volcanic or seismic events that cause collapse of infrastructure, landslides or liquefaction, etc.) or climatic (as hurricanes, typhoons, tornadoes, major variation in rainfall both in terms of excess or deficit causing drought). Although usually not covered by the methodology, disasters may also have a "human" or anthropic origin as chemical spills, industrial accidents, or voluntarily caused events such as war, terrorist actions, etc. Disaster consequences or damage will always be associated with human intervention before, during and after the event (the "disaster cycle"). http://magic.un.org.mx/www2/desastres-capacitacion/wbi/GLOSSARY.doc

Though each of the definitions differs slightly, there is a rather clear consensus that disasters are natural or human events, usually unexpected, that result in significant impacts in terms of a variety of metrics.

WHAT CONSTITUTES A DISASTER?

Other than concluding that "I know a disaster when I see one", what can we do to better characterize and rank disasters? Obviously, statements such as "my hair is a disaster today" or "that party was a real disaster" are only frivolous uses of the word "disaster". On the other hand, most people would agree that the "Great Flood of 1993" that hit the Upper Mississippi River (Johnson et al., 2004), as described in the following paragraph, constitutes a real water resources disaster.

> "The magnitude and severity of the resulting flood event was overwhelming. The areal extent, intensity, and long duration of the flooding makes this one of the greatest natural disasters ever in the United States. At least 48 people lost their lives as a result of this extreme flood. Over 500 river forecast stations in the Midwest were above flood stage at the same time. Nearly 150 major rivers and tributaries flooded. Banks and channels of many rivers were severely eroded, and sediment was deposited over large areas of the flood plains of the Mississippi, Missouri, and Illinois Rivers. Economic damages approached $20 billion. Levees were broken; farmland, towns, and transportation routes were destroyed; and more than 50,000 homes were damaged or destroyed. Water-quality threats to public health and safety were of paramount concern. These threats included contamination of drinking-

water supplies, disruption of wastewater-treatment plant operations, failure of septic systems, and risks associated with the inundation of facilities that handle hazardous materials."

Water resources/environmental disasters can vary significantly in terms of characteristics, time scale, likelihood and impacts. These topics are discussed in the following sections.

CATEGORIZATION OF DISASTERS

Disasters may be categorized in various dimensions. One way of categorizing disasters is by the cause of the disaster. In broad terms, disasters may be categorized in the following broad classes:

- Natural disasters: Disasters caused by natural events
- Human-induced accidents: Accidental events that are the result of human activities
- Disasters at the intersection between natural and man-induced: Events that are caused in part by natural events and in part by human actions
- Voluntary disasters: Intentional events purposely caused by humans

In some cases, the lines between categories of disasters are fuzzy. For example, a wildfire could be a natural disaster (e.g., caused by lightning), a human accident or an intentional event. Similarly, there is still some debate as to whether climate change is a purely natural event, an accidental by-product of human actions, or an intersection of natural and human actions. Impacts of floods may result from natural precipitation events intersecting with the failure of dams and/or levees. Table 1 lists examples of disasters and a suggested categorization of events into one of the four categories.

Table 1. Types of Disasters

Natural	**Human accidents**	**Natural-human**	**Voluntary**
Hurricane	Infrastructure failure	Flood	War
Tornado	Chemical emission	Drought	Terrorist act
Volcano		Epidemics	
Tsunami		Famine	
Heatwave		Wildfires	
Earthquake		Landslides	
Blizzards		Environmental	
Meteor		Climate change	

In many cases, these categories may be further sub-divided. For example, following is a list of potential categories and examples of environmental disasters (http://en.wikipedia.org/wiki/List_of_environmental_disasters):

- Agricultural (Salinization of the Fertile Crescent)
- Biodiversity (Extinction of American megafauna)
- Coal (Martin County, Kentucky sludge spill)

- Human health (Infectious diseases introduced by Europeans colonizing America)
- Industrial (Minamata, Japan mercury poising)
- Mining (Ok Tedi environmental disaster in Papua, New Guinea)
- Oil industry (Environmental issues in the Niger Delta relating to the oil industry)
- Nuclear (Chernobyl and Three Mile Island accidents)
- Pollution
- Air (The Great Smog of 1948 in London)
- Land (Dust bowl in U.S. and Canada in 1934-1939)
- Water – fresh
- Water - marine (Environmental threats to the Great Barrier Reef)

Another form of categorization relates to the time-scale of the event and resulting impacts. Most disasters involve relatively short timescales (on the order of minutes, hours or days). For example, an earthquake may only last less than a minute and the impacts are largely immediate. Slightly longer timescales are associated with events such as floods which may move through a river basin over a period of days to weeks. Droughts, famine, epidemics and war may occur over and result in impacts spread out over months or years. Climate change could result in impacts over several decades or even centuries.

METRICS FOR EVALUATING DISASTERS

Various metrics can be used to assess and rank the seriousness of disasters. Following is a list of some potential metrics.

- Economic damage
- Environmental damage
- Fatalities
- Reconstruction cost
- Aesthetic damage
- Disruption of normal activities
- Destruction of irreplaceable objects
- Loss of species
- Homelessness
- Illness

Some of these metrics are more amenable to quantification than others. For example, economic damage may be quantified in terms of dollars (losses or reconstruction cost) while environmental damage may be loosely categorized as severe, moderate or low, or in a more quantitative sense by the number of acres or square miles of land or sea that have been impacted. More specific metrics may also be used in evaluating impacts such as the gallons of oil that were spilled.

Examples of different metrics being used to rank disasters are shown in Tables 2 and 3. In Table 2, the top ten deadliest natural disasters are ranked in terms of loss of

human life. In Table 3, hurricanes hitting United States are assessed and ranked by two different metrics, damage (in dollars) and loss of life.

Table 2. Top 10 Deadliest Natural Disasters

Rank	Event	Location	Year	Death toll (estimate)
1	China floods	China	1931	2,000,000 – 4,000,000
2	Yellow River flood	China	1887	900,000 – 2,000,000
3	Shaanxi earthquake	Shaanxi Province, China	1556	830,000 +
4	Bhola cyclone	Bangladesh	1970	500,000
5	India cyclone	India	1839	> 300,000
6	Antioch earthquake	Antioch, Turkey	526	250,000
7	Earthquake/tsunami	Indian Ocean	2004	229,866
8	Tangshan earthquake	Tangsha, China	1976	242,000
9	Haiyuan earthquake	Haiyuan, China	1920	240,000
10	Baqiao dam failure	Henan, China	1975	231,000

Adapted from http://en.wikipedia.org/wiki/List_of_natural_disasters_by_death_toll

Table 3. Top 10 U.S. Hurricanes

	Ranked by Damage			Ranked by Number of Deaths		
Rank	Name	Year	$ Billions	Name	Year	Deaths
1	**Katrina**	2005	200	Galveston	1900	9000
2	Andrew	1992	44	Florida	1928	1800
3	Charley	2004	15	**Katrina**	2005	800
4	Ivan	2004	14	NC to NY	1938	600
5	Hugo	1989	12	Florida	1935	423
6	Agnes	1972	11	Audrey	1957	390
7	Betsy	1965	11	Miami	1926	373
8	Frances	2004	9	Louisiana	1909	350
9	Camille	1969	9	Gulf Coast	1919	287
10	Diane	1955	7	New Orleans	1915	275

Adapted from http://www.epicdisasters.com/

Examination of the two alternative metrics for ranking hurricanes shows that there is only one hurricane (Katrina) that is in the top ten in terms of both metrics. This illustrates the importance of selecting a metric that reflects the specific characteristic of interest. Examination of the two lists also shows that nine out of the ten worst hurricanes in terms of damage occurred in the past 50 years while nine out of ten of the worst hurricanes in terms of deaths occurred over 50 years ago. This certainly suggests a trend in the United States of increasing economic damage and decreasing loss of life from natural disasters.

IMPENDING DISASTERS

In most cases, we cannot accurately predict the time and extent of specific natural or human-induced disasters. However, in many cases we can assign a probability or likelihood of a particular type of disaster at a specific or general location. For example, USGS in cooperation with other agencies issued a report (USGS, 2007) stating that:

- California has more than a 99% chance of having a magnitude 6.7 or larger earthquake within the next 30 years, according to scientists using a new model to determine the probability of big quakes.
- The likelihood of a major quake of magnitude 7.5 or greater in the next 30 years is 46% and such a quake is most likely to occur in the southern half of the state.

The Times-Picayune (the primary New Orleans newspaper) published a five-part series in 2002 (3 years before Hurricane Katrina) containing the following opening paragraph: "It's been almost 40 years since a major hurricane inundated New Orleans. Since Hurricane Betsy's storm surge poured into the city in 1965, our landscape has been sinking and our coastline disappearing. Despite billions of dollars spent on higher levees and flood control, this is no place to be when The Big One inevitably hits (Times-Picayune, June 23, 2002)." This was a sentiment that was widely shared by the water resources and disaster management profession.

Leatherman et al. (2007) discussed the likelihood and consequences of a disaster impacting Lake Okeechobee in Florida as follows: "Lake Okeechobee is a disaster waiting to happen, just like New Orleans when Hurricane Katrina struck in 2005. The dike that is keeping the nation's second largest lake from overflowing the low-lying areas to the south has a high probability of failing during the next major hurricane. It failed back in 1928, when a hurricane whipped up waves and surge that breached the earthen dike, generating an estimated 15-foot high wall of water that drowned 2,500 people. Now there are 40,000 people living in small towns that are in danger during hurricane season".

For many water resources phenomena, events have traditionally been classified probabilistically by their expected frequency. For example, a 100-year flood is expected to occur, on average, once per one hundred years. Many hydrologists are now questioning the true stationarity of such events and, as a result, the probabilistic manner by which extreme events are predicted. Matalas (1998) expressed such concerns in the following statement. "Among the uncertainties affecting the management of water resource systems are those that derive from the lack of knowledge as to how hydrology will unfold in the future, more specifically over the time bound by the economic time horizon. Interest in the hydrologic past is driven in expectation of shedding light on the hydrologic future."

Other potentially disastrous events are largely unpredictable in terms of location, extent or timing, and, in fact, whether they may occur. Following the events of

September 11, 2001, it was widely held that some form of intentional terrorist event would be attempted towards a water or wastewater facility in the United States. Will such an event occur and, if so, when, where, and how? These are all questions that cannot be answered either definitively or even probabilistically. Rare natural events such as collisions between large meteors and the earth, and even more common events such as tsunamis do not lend themselves well to predictability.

SUMMARY AND CONCLUSIONS

Though there are many definitions for the word "disaster", there is a rather clear consensus that disasters are natural or human events, usually unexpected, that result in significant impacts in terms of a variety of metrics. Disasters may be categorized by the cause of the disaster: (a) natural disasters; (b) human-induced accidents; (c) disasters at the intersection between natural and human-induced; and (d) voluntary or intentional disasters. They may also be categorized by their timescale ranging from seconds or minutes (e.g., earthquakes), to hours or days (e.g., floods), to months to years (e.g., drought), or even very long-term such as climate change that may span decades or centuries. Various metrics can be used to assess and rank the seriousness of disasters including: economic damage, fatalities, environmental, ecological or aesthetic damage, and homelessness. Examination of disasters in the U.S. over the past century, suggests a trend of increasing economic damage and decreasing loss of life from natural disasters.

In most cases, we cannot accurately predict the time and extent of specific natural or human-induced disasters. In many cases we can assign a probability or likelihood of a particular type of disaster at a specific or general location. Other potentially disastrous events are largely unpredictable in terms of location, extent or timing, and, in fact, whether they may occur. Planning for disasters should consider both the likelihood of occurrence and the consequences of the events. For those events that have a high probability of occurrence over a relatively short timeframe (i.e., disasters waiting to happen) or even those events with a lower probability but a high consequence if they occur, actions to mitigate or reduce the likelihood of the events are appropriate.

How Reliable is New York City's Water Supply?

Daniel P. Loucks

School of Civil and Environmental Engineering, Cornell University, Ithaca, NY 14853

ABSTRACT

The New York City water supply system provides drinking water to over 9 million customers. It operates almost entirely by gravity and is delivered to the city via a system of aqueducts and tunnels, some constructed over 100 years ago. Currently the system's safe yield exceeds the demand, but demands are expected to increase, and major system outages are possible, especially in the Delaware water supply aqueduct. NYC receives about 55% of its water supply from the Delaware component of their system. The current leakage from the aqueduct exceeds 40 mgd, and folks living some 700 feet above the tunnel on the surface are seeing new lakes and streams created by that leak. The city is facing a major challenge, how to repair the leaks and not cause a total collapse of the tunnel. This talk will discuss some of those challenges and the possible consequences and options and what is being done about it.

INTRODUCTION

Early Manhattan settlers obtained water from wells, even for fire protection. By 1830 wooden pipe distribution systems were replaced with cast iron pipes As the population of the city increased, the well water became polluted and supply was insufficient. The supply was supplemented by cisterns and water drawn from a few springs in upper Manhattan. This was followed by impounding Croton River water and transporting it to the city via an aqueduct. This aqueduct, known today as the Old Croton Aqueduct, had a capacity of about 90 million gallons per day (mgd) and was placed in service in 1842. In 1883 a commission was formed to build a second aqueduct from the Croton watershed as well as additional storage reservoirs. This aqueduct, known as the New Croton Aqueduct, was placed in service in 1890.

In 1905 the city decided to develop the Catskill region as an additional water source. The Catskill System, included the Ashokan Reservoir and Catskill Aqueduct, was completed in 1915. The remaining development of the Catskill System, involving the construction of the Schoharie Reservoir and Shandaken Tunnel, was completed in 1928.

In May 1931 the Supreme Court of the United States upheld the right of the city to augment its water supply from the headwaters of the Delaware River. Construction of the Delaware System began in March 1937 and was placed in service in stages: The Delaware Aqueduct was completed in 1944, Rondout Reservoir in 1950, Neversink Reservoir in 1954, Pepacton Reservoir in 1955 and Cannonsville Reservoir in 1964.

Figure 1. New York City's Water Supply System (DEP, 1999).

Water for the system is impounded in three upstate reservoir systems which include 19 reservoirs and three controlled lakes with a total storage capacity of approximately 580 billion gallons. The three water collection systems were designed and built with various interconnections to increase flexibility by permitting exchange of water from one to another. This feature mitigates localized droughts and takes advantage of excess water in any of the three watersheds. Approximately 95% of the total water supply is delivered to the consumer by gravity. Only about 5% of the water is regularly pumped to maintain the desired pressure. As a result, operating costs are relatively insensitive to fluctuations in the cost of power. When drought conditions exist, additional pumping is required.

Today New York has one of the world's most robust water systems (Figure 1). Eight million residents in the city, and another one million upriver, daily consume 1.2 billion gallons that flow through a network of reservoirs and aqueducts stretching from the Delaware River watershed to the Connecticut border almost 100 miles to the southeast.

The Croton system in Westchester County, which began providing water in 1842, meets about 10 percent of the city's needs. The Catskill system, built in the first quarter of the 20th century, provides 40 percent. The remaining 50% or 600 million gallons a day also come from the Catskill Mountains, through the Delaware Aqueduct system, which was finished in the 1960s. This system includes the Rondout-West Branch tunnel, completed in 1944 and promised to last at least a century. The Rondout-West Branch tunnel is 45 miles long, 13.5 feet wide, up to 1,200 feet below ground and responsible for transporting half of New York City's water supply from reservoirs in the Catskill Mountains.

Since 1842, there have been no significant interruptions of service other than brief annual shutdowns for the purpose of routine inspections during the period from 1842 to the Civil War. Clearly water supply planning in NYC has been quite foresighted and successful. Today however this record of reliable water supplies is potentially threatened because of leaks in the tunnels (aqueducts) that bring upstream water to the city.

LEAKS IN THE SYSTEM

The city was aware of the extensive leaks in the Rondout-West Branch tunnel 20 years ago. For most of those 20 years it has been leaking over 20 million gallons a day. In 2004 the city's Department of Environmental Protection (DEP) hired consultants to assess the extent of the problem. They discovered the leaks had increased to about 40 million gallons per day. When in 2007 residents of the small community of Wawarsing located above the tunnel reported cracks in building foundations and sinkholes in their yards, mold, wells contaminated with E. coli and basements that flooded even on dry days, the city's Department of Environmental Protection initiated a five-year, $240 million project to prepare to fix the tunnel. The challenges are to keep water flowing through New Yorkers' faucets and prevent tunnel collapse during the repairs. The most immediate job is to fix a valve at the bottom of a 700-foot access shaft so pumps will eventually be able to drain the tunnel, and to ensure that the tunnel does not crack or collapse while it is empty due to the hydrostatic pressure outside the tunnel.

For this, the city has employed deep-sea divers to work 700 feet below the surface in 12-hour shifts, with each diver taking a four-hour turn hacking away at concrete to expose the valve. The story of these divers and what they must do to prepare themselves for this work and what they must go through after their work has been the subject of a number of newspaper articles. These articles are finally informing the public about these leaks and what is being done to reduce if not eliminate them (Belson, 2008; Zale, 2008).

ISSUES AND OPTIONS

NYC's DEP estimates the earliest the city might dewater the tunnel is in two to three years because of all the preparatory work required. As the divers study the underwater pumps, the city is investigating where, how and whether to build a bypass tunnel, and how much to expand the filtration system that will permit lower quality water to be pumped from the Croton system.

Another option is to build another tunnel across the Hudson River connecting the four Delaware system reservoirs to the Catskill reservoirs. This tunnel would be more expensive than a smaller bypass, but would give the city more flexibility by connecting two giant water systems. But building water tunnels can take decades: One known as New York City Tunnel No. 3 was started nearly 40 years ago and is not scheduled for completion until 2015.

The city is not only focusing on supply reliability but also on demand reduction. DEP has been quite successful in reducing the average daily water consumption which in the 1980s was about 200 gallons per person to the current consumption of about 150 gallons per person by repairing leaky pipes and through subsidizing water use conservation measures such as water leak surveys, water saving shower heads and lawn sprinklers, more efficient clothes dryers, and low-flush toilets.

There are a number of other options not yet discussed in the press that are being considered, but one thing is clear, an unplanned failure of the Delaware Aqueduct over an extended time period will result in major shortages of water for the city. Sure, everyone can buy bottled water, and more groundwater can be pumped from aquifers in the area, but each of those options has its negative impacts. And neither will provide much fire protection without an extraordinarily high energy cost. Addressing this issue is not only a challenging engineering problem, it is also a political one. Everyone expects a failure sometime. It's a question of when and how much. Will the city be ready for it?

What ever options are taken to alleviate any unplanned shortfall in water supply as a result of a tunnel failure, the city recognizes those options will have economic, environmental and social impacts that have to be traded off against the risks and consequences of experiencing that shortfall. Clearly these decisions are not going to be easy, but indeed now is the time to think about what should be done before any unplanned event occurs, and then hope there will be enough time to do it before any unplanned event occurs.. With the help of engineering consultants and panels of 'experts' this is exactly what the city is doing. The city hopes it will have the time and resources to be ready for an unplanned event – and indeed create a planned shortfall before an unplanned one occurs.

Standby folks, the story is just beginning.

ASSESSING POLLUTANT LOADS AND EVALUATION OF TREATMENT SYSTEMS TO ACHIEVE WATER QUALITY GOALS FOR LAND DEVELOPMENT PROJECTS

Steven D. Trinkaus, P.E., CPESC, CPSWQ, Trinkaus Engineering, Southbury, CT

ABSTRACT:

It is widely acknowledged that all types of land development have some type of impacts on the environment. Most of these impacts adversely affect our environment, such as those from non-point sources, such as storm water discharges. In the past 10-15 years, the adverse impacts on water quality from non-point source pollutants have become very significant. These pollutants have adversely affected our natural and in particular our aquatic environments. Most municipal land use agencies are unaware of the types of pollutants in non-point source runoff and the negative effects that they have on our environment. The commissions are also not aware how various storm water treatment systems remove pollutants associated with non-point source runoff.

The preparation of a pollutant loading analysis is one tool that can be used to not only determine the amount of pollutants associated with development, but how effective the storm water treatment systems are at the removal of the pollutants.

NON-POINT SOURCE POLLUTANTS – WHY THEY MATTER:

Numerous studies have shown that the amount of pollutants discharged from a development site in the storm water is directly related to the extent of the impervious cover. Recent studies by Tom Schueler of the Chesapeake Stormwater Network in the State of Virginia have also shown that the runoff from disturbed soils can also contribute to non-point source runoff. The following is a description of the common pollutants found in non-point source runoff.

Total Suspended Solids:

Total Suspended Solids (TSS) is particles that are dissolved in water. Sources of TSS in the undisturbed environment are silt, decaying plant and animal matter. On a developed site, the sources include soil erosion, sand used for winter sanding operations, atmospheric deposition and debris found on impervious surfaces. TSS is leading cause of turbidity in water bodies. TSS in water bodies block light from reaching aquatic vegetation, with less light in the water, photosynthesis is reduced. As photosynthesis is reduced, less oxygen is produced by the vegetation thus affecting many aquatic species. As dead vegetation decomposes, more oxygen is used in the decomposition process thus further reducing oxygen levels in the water. TSS can also clog gravel substrate in breeding streams, affecting insect larvae and fish eggs.

Nutrients:

Nutrients, such as Total Nitrogen (TN) and Total Phosphorous (TP) in storm water can have adverse impacts on receiving water bodies. While these nutrients are necessary for growth by aquatic plants, excessive levels of these nutrients do cause excessive growth these plants, especially algae. This excessive growth leads to eutrophication of surface waters. Nitrogen is a limiting pollutant in tidal areas, while

Phosphorous is a limiting pollutant in freshwater systems, particularly ponds and lakes. The common sources of TN and TP are the application of inorganic and organic fertilizers for crop production, lawn fertilization and the disposal of waste residues (biosolids, animal manure, and compost). As noted above, decomposition of excessive vegetated growth, leads to lower dissolved oxygen levels in the water. Dissloved Inorganic Nitrogen (DIN) is also a concern in the environment.

Metals:

Common metal pollutants, such as zinc (Zn), copper (Cu) and cadmium (Cd) are highly toxic to aquatic life. These pollutants can not only kill some forms of aquatic life, the metals can bioaccumulate in higher forms of aquatic life. Human beings can be adversely affected by these pollutants thru the consumption of these higher aquatic species. The most common source of metal pollutants is the transportation system. These metals are found in brake linings, vehicle exhaust, tire and engine wear. After they accumulate on impervious surfaces, they are easily washed into the storm drainage with the next rain event, likely attached to TSS particles.

Hydrocarbons:

Vehicles are also the source of hydrocarbon pollutants. Petroleum hydrocarbons (TPH), such as oil and grease are one type. Vehicle exhaust that is deposited on the road surface contributes polycyclic aromatic hydrocarbons (PAHs). PAHs also result from the incomplete burning of fossil fuels and can be deposited by atmospheric deposition on an impervious surface. Both TPH's and PAHs are highly toxic chemicals which attach themselves to sediment particles, which are then washed off the impervious surface during rainfall events. They are not easily removed from the environment.

WATER QUALITY STANDARDS:

Many states have begun to set limits for Total Maximum Daily Loads (TMDLs) for many impaired streams, rivers and lakes from pollutants over time. As defined by the EPA, "a TMDL is a calculation of the maximum amount of a pollutant that a waterbody can receive and still meet water quality standards, and an allocation of that amount to the pollutant's sources." Increased discharges of pollutants will increase the impairment of the waterbody.

Some state agencies have begun to adopt removal goals for various pollutants in storm water. The most common pollutant being regulated is TSS. Due to chemical bonding, particles of other pollutants, such as nutrients, pesticides, bacteria, metals and hydrocarbons become attached to small sediment particles. It has been widely noted in literature that if TSS is being removed by a treatment system, it is extremely likely that the other pollutants are also removed, but this is not always the case. Many municipal land use commissions have difficulty determining if this goal will be met for land development projects.

TYPES OF WATER QUALITY MODELS:

Two very technical water quality models are the SLAMM (Source Loading and Management Model) and the P8 model (Program for Predicting Polluting Particle Passage through Pits, Puddles and Ponds). These two models were developed to

assess pollutant loads from development and to determine the removal efficiencies of treatment facilities. They can be cumbersome for design community to use and are difficult for the regulatory community to evaluate. Both the SLAMM and P8 model requires continuous hourly rainfall and daily air temperature data which is not readily available to the design community. SLAMM is a model used to understand the common sources of urban storm water pollutants and the control of these pollutants. It is based upon actual field observations and must be calibrated prior to use. Both of these models are more difficult to use in many parts of the country, where the necessary input data is not readily available.

There is one model that can be used to easily estimate annual pollutant loads from typical land development projects. This model is the Simple Method as developed by Tom Schueler in 1987. Based upon simple inputs, such as annual rainfall, drainage area, percent impervious cover and pollutant concentration, the annual pollutant load in pounds can be calculated. This equation can be used for all of the typical pollutant associated with land development projects, such as TSS, TN, TP, Zn, Cu, TPH and DIN. The equation can also be used to calculate the pollutant load for a given storm event, such as the 90% storm (a storm which provides 1" of rainfall or less).

THE SIMPLE METHOD:

In 1987, Tom Schueler developed the Simple Method as a way to estimate pollutant loads for various chemical pollutants on an annual basis. The Simple Method requires a small amount of information to be utilized; annual precipitation, pollutant concentrations, percent impervious cover and subwatershed areas. The formula of the Simple Method is as follows:

$L = [(P)(Pj)(Rv)]/12(C)(A)(2.72)$ or reduced to $L = 0.226(P)(Pj)(Rv)(C)(A)$, where

L = Pollutant load in pounds
P = Rainfall depth over desired time period (inches)
Pj = Factor that corrects P for storms that produce no runoff, use Pj = 0.9
Rv = Runoff coefficient, fraction of rainfall that turns to runoff, $Rv = 0.05 + 0.009(I)$
I = Site Impervious coverage (percent)
C = Flow weighted mean concentration of pollutant (mg/l)
A = Area of site (acres)
0.226 = Unit Conversion Factor

The Simple Method provides reasonable estimates of changes in pollutant amounts resulting from different types of development. There are three aspects of the Simple Method that engineers need to keep in mind when using the equation.

1. It only estimates the pollutant load from storm events and does not consider pollutants from baseflow volumes. For large low density residential developments, where I < 5%, up to 75% of the annual runoff volume may be comprised of baseflow, the annual nutrient load associated with the baseflow may be equal to the annual load associated with the development.

2. Its primary usefulness is for calculating and comparing the relative storm water pollutant loads from various development concepts.

3. It provides an estimate of the pollutant loads that are likely close to the "true" but unknown value for a development project.

One area of concern to calculating pollutant loads on annual basis is the fact that neither the engineer nor the land use agencies can evaluate how the annual load is reaching the receiving wetland or waterbody. However, there is a solution to this issue. The Simple Method can also be used to calculate the pollutant load for a particular storm event. If you wanted to calculate the pollutant load for the 1" rainfall event, which comprises approximately 90% of the annual rainfall events, you would simply set P = 1". This will allow the calculated loads to be related to the 1" rainfall event, thus providing the regulatory agency with values that are easier to comprehend.

You can also take the annual load and divide it by the number of annual rainfall events for the area which will yield a pollutant load per storm event. Both these methods will yield a value that is more understandable to local regulatory agencies.

STORM WATER POLLUTANT CONCENTRATIONS:

Concentrations for the various storm water pollutants were originally developed from the studies conducted under the National Urban Runoff Program (NURP) in various parts of the country. Over time, additional research condand overseen by Robert Pitt, P.E., PhD at the University of Alabama; Roger Bannerman at Wisconsin Department of Natural Resources and the Center for Watershed Protection have provided confirmation of many of the NURP numbers, while providing documentation for adjusting pollutant concentrations per different types of land use. The National Stormwater Quality Database (NSQD), Version 1.1 prepared by Alex Maestre and Robert Pitt of the University of Alabama and the Center for Watershed Protection (September 4, 2005) provides pollutant concentrations based upon monitoring data, which was part of the EPA's National Pollutant Discharge Elimination System (NPDES). This study looked and evaluated data from 1992 to 2002 from 3,765 events on 360 sites in 65 communities throughout United States.

Reliable pollutant concentrations are provided for TSS, TN and TP for various types of development in addition to natural ecosystems. For various land uses, the total and disconnected impervious areas are provided. This information is very helpful for the engineer in assessing which pollutant concentration to use for a particular land use practice. The engineer needs to verify that the proposed impervious cover for a project is consistent with the value provided for a given pollutant concentration. The following table is a sample of these concentrations for different types of land use.

Residential	TSS	TP	TN
2-8 units/acre	60 mg/l	0.38 mg/l	2.1 mg/l
8+ units/acre	60 mg/l	0.38 mg/l	2.1mg/l
Commercial	58 mg/l	0.25 mg/l	2.6 mg/l

Industrial	80 mg/l	0.23 mg/l	2.1 mg/l
Paved roads	99 mg/l	0.25 mg/l	2.3 mg/l
Deciduous Forest	90 mg/l	0.1 mg/l	1.5 mg/l

(NSQD, table 55, 56, 58, 60 and 61)

STORM WATER TREATMENT PRACTICES:

There are three major types of storm water treatment practices:

A. Conventional Systems, which includes catch basins, dry detention ponds, stone and vegetated swales, wet ponds and oil/grit separators.

B. Manufactured Systems, such as hydrodynamic separators, underground filter and infiltration systems.

C. Low Impact Development (LID) systems, such as bioretention, extended wet detention ponds, constructed wetlands, gravel wetlands (submerged horizontal flow systems), vegetated filter strips, and surface sand filters.

While some development sites may have limitations for Conventional systems, these same sites are likely able to can accommodate multiple types of LID systems in a treatment train configuration.

POLLUTANT REMOVAL RATES FOR TREATMENT PRACTICES:

In order to address the changes in pollutant loads, engineers have many tools at their disposal to treat the storm water to reduce the pollutant loads. These tools consist of Conventional, Manufactured and Low Impact Development systems noted above. By the application of pollutant removal efficiencies for the different treatment systems, the engineer can demonstrate how effective the storm water treatment system will be at their removal of a given pollutant.

The efficiency of any storm water treatment system is usually provided as a removal efficiency rate, which refers to the change in pollutant load from the inflow to outflow of the treatment system. There are two types of computational methods to determine this removal efficiency, the event mean concentration (EMC) efficiency and mass efficiency.

EMC efficiency gives equal weight to both large and small storm events and averages the incoming and outgoing concentrations for all storm events. The mass efficiency is affected by the volume of water in the system and water losses that may occur within the practice. Examples of water loss in the practice are infiltration and evapotranspiration. This method is based upon a summation of incoming and outgoing loads and is considered a more accurate method than EMC efficiency. The EMC calculation generally results in lower removal rates and thus can be considered to be more conservative in this application.

There are four sources for pollutant removal efficiencies. The first is the International BMP Database (ASCE/EWRI) of October 2007. The BMP Database provides inflow and outflow concentrations for each pollutant considered, from which removal efficiencies can be calculated.

The second and third are the National Pollutant Removal Performance Database for Stormwater Treatment Practices, 2nd Edition (March 200) and Version 3 (September 2007) by the Center for Watershed Protection. While median removal rates are provided for the practices, it is important for the engineer to evaluate the

supporting data for each system. The number of studies conducted for a given treatment system along with whether or not actual pollutant concentrations were measured as part of the study need to be assessed to provide the engineer with a comfort level regarding the published removal rate.

The fourth is the two annual reports from the University of New Hampshire Stormwater Center for 2005 and 2007. Dr. Robert Roseen, P.E. and his colleagues of the University of New Hampshire Storm Water Center (UNHSC) has been generating very impressive data on how Conventional, Manufactured and LID systems function in a northern climatic area. Dr. Roseen's research has shown that those treatment practices associated with LID have much greater removal rates than many of the Conventional and Manufactured systems and that the LID systems work very well during the winter months. His research has also demonstrated that many of the manufactured systems, such as hydrodynamic separators which claim high removal rates of TSS (based upon lab tests) are significantly less efficient at TSS removal in the real world.

The monitoring of Best Management Practices (BMPs) is an emerging field of research and therefore, the number of studies of certain treatment practices is limited at this time.

ASSESSMENT OF POLLUTANT LOADS AND EVALUATION OF REMOVAL EFFICIENCIES:

In order to assess changes in pollutant concentrations, the engineer must first calculate the pollutant loads for the undeveloped site. Even if there is some amount of impervious cover on the site, the engineer needs to assume that the impervious area does not exist and use a natural undisturbed land cover type to calculate pollutant loads for the natural condition.

The most important consideration in the preparation of a pollutant loading analysis for proposed conditions is the use of the appropriate pollutant concentration for the proposed land use. The engineer needs to evaluate the proposed percentage of impervious cover for a given land use to ensure that it is consistent with the pollutant concentration data. If there are substantial differences in the percent impervious cover for a specific land use when compared to a pollutant concentration from the Database, the engineer needs to determine how to account for this change. One way would be to separate out the roadway area from the lots in a residential subdivision. This would allow the engineer to use appropriate pollutant concentrations for each land use.

The following example will demonstrate the analysis and computations necessary in the preparation of a pollutant loading analysis for TSS. The area of concern for water quality issues is the large wetland in the east central portion of the site (right central area in Figure 1 below).

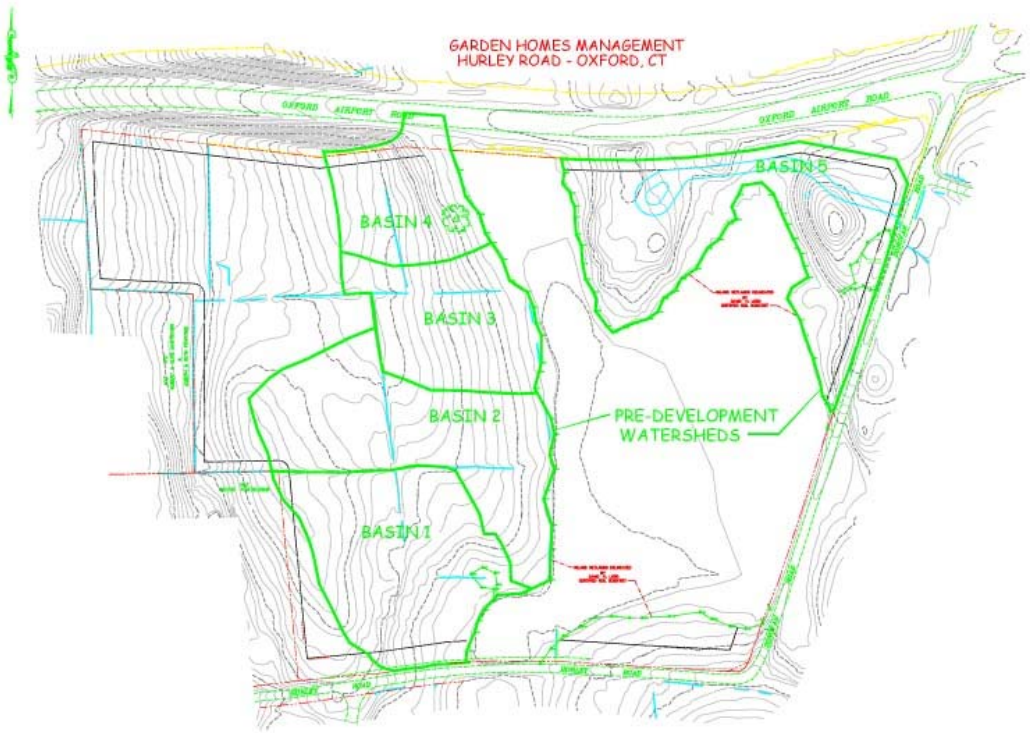

Figure 1- Oxford Commons Existing Conditions

The site is currently vacant and consists of dense meadows/brush areas. That portion of the site tributary to the central wetland area was divided into five watershed areas. Utilizing the Simple Equation, and site specific information for each watershed area, the pollutant loads were calculated for the existing conditions for each watershed area for TSS.

Watershed Area:	Basin 1	Basin 2	Basin 3	Basin 4	Basin 5
Annual Load of TSS (lbs)	179.7	193.3	113.4	91.8	175.3

Total TSS Annual Load for Natural Conditions is 753.5 pounds.

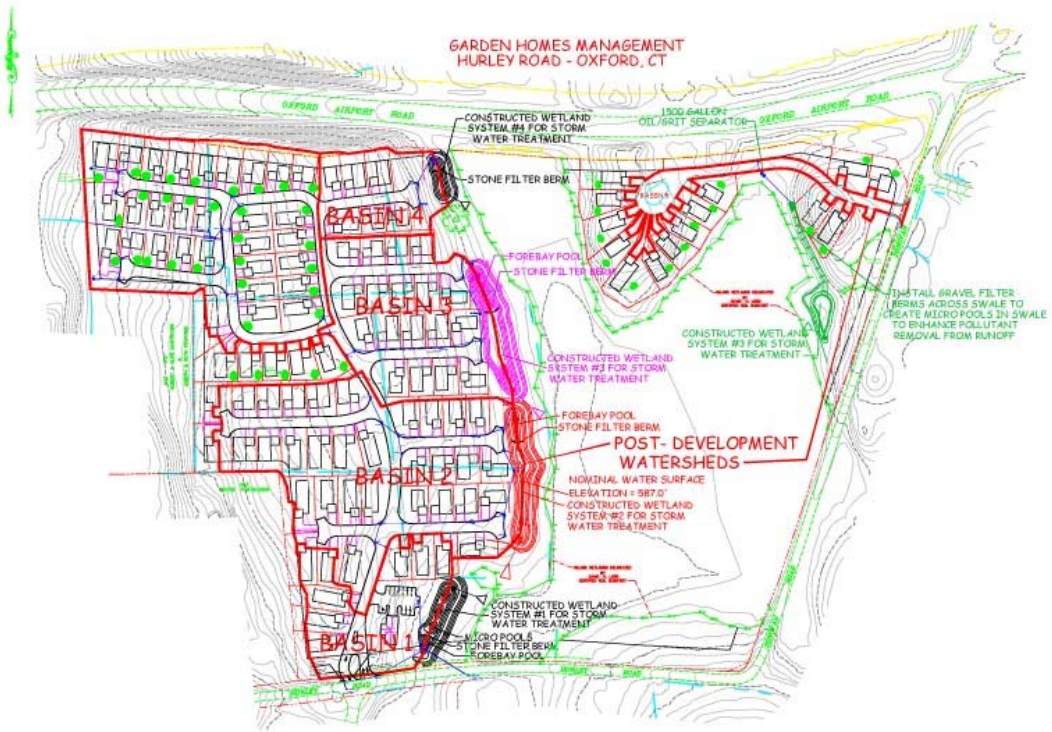

Figure 2 - Oxford Commons Future Conditions

The future conditions on the site will consist of the following land uses: Manufactured housing units on lots which average 7,000 sq.ft. (6 units per acre) accessed by 24' wide paved roads. The watershed boundaries shown in Figure 2 above reflect the proposed site grading.

Pollutant loads were calculated for the future conditions for each watershed area for TSS.

Watershed Area:	Basin 1	Basin 2	Basin 3	Basin 4	Basin 5
Annual Load of TSS (lbs)	576.6	1948.3	1068.2	368.0	672.1
Net Change:	+396.9	+1755.0	+954.8	+276.2	+496.8

Total TSS Annual Load for Future Conditions is 4,636.2 pounds.

You can see that the annual load for TSS substantially increases the site. For Basins #1 through #4 the storm water treatment train consists of the following systems: catch basins with 24" sumps [last CB with 48" sump & hooded outlet], 4' deep forebay at inlet of Extended Detention Ponds (EDP). The runoff from Basin #5 is treated by catch basins with 24" sumps [last CB with 48" sump & hooded outlet], Oil/grit separator, Wet Swale (WS), and Extended Detention Shallow Wetland (EDSW).

The Extended Detention Ponds are long linear, and shallow systems designed to increase the flow time of the runoff within the basin. The Water Quality Volume (WQV) is maintained as a fixed volume within the bottom of the basin. The bottoms of the basins will be planted with native emergent species to enhance the removal of pollutants from the runoff.

The Wet Swale has a minimum base width of 8', along with the installation of gravel filter berms within the swale. The filter berms will create micro pools within the swale, enhancing pollutant removal, reducing flow velocities and allowing infiltration to occur.

The removal rates for TSS for each component of the treatment systems are stated below:

CB with deep sump	EDP	EDSW	WS	Oil/grit separator
25%	80%	69%	1%	0%

Calculate total removal rate for TSS for Basin #1:
Deep catch basin with hooded outlet = 576.6*0.25 = 144.15 lbs.
Extended Detention Pond = (576.6-44.15)*0.80 = 345.96 lbs.
Total TSS removed = 144.15+345.96 = 490.11 lbs or 490.11/576.6 = 85.0%

Calculate total removal rate for TSS for Basin #2:
Deep catch basin with hooded outlet = 1948.3*0.25 = 487.07 lbs.
Extended Detention Pond = (1948.3-487.07)*0.80 = 1168.98 lbs.
Total TSS removed = 487.07+1168.98 = 344.08 lbs or 1656/1948.3 = 85.0%

Calculate total removal rate for TSS for Basin #3:
Deep catch basin with hooded outlet = 1068.2*0.25 = 267.0 lbs.
Extended Detention Pond = (1068.2-267.0)*0.80 = 640.9 lbs.
Total TSS removed = 267.0+640.9 = 907.9 lbs or 907.9/1068.2 = 85.0%

Calculate total removal rate for TSS for Basin #4:
Deep catch basin with hooded outlet = 368.0*0.25 = 92.0 lbs.
Extended Detention Pond = (368-92)*0.80 = 220.8 lbs.
Total TSS removed = 92.0+220.8 = 344.08 lbs or 312.8/368.0 = 85.0%

Calculate total removal rate for TSS for Basin #5:
Deep catch basin with hooded outlet = 672.1*0.25 = 168.0 lbs.
Oil/grit Separator = (672.1-168)*0.0 = 0.0 lbs.
Wet Swale = (672.1-168.0-0)*0.60 = 302.4 lbs.
Extended Detention Shallow Wetland = (672.1-168.0-0-302.4)*0.69 = 139.2 lbs.
Total TSS removed = 168.0+0+302.4+139.2 = 609.6 lbs or 609.6/672.1 = 90.7%

In this case, the goal of 80% removal of TSS at the limit of the delineated inland wetland area would easily be achieved by the storm water treatment practices proposed for this project. Similar analyses can be performed for TP, TN, Zn, Cu and other pollutants of concern.

As you can see multiple treatment practices in series (treatment train) can significantly improve the percent removal of a given pollutant versus a single treatment practice. There are simple ways to increase the pollutant removal efficiency for some treatment systems. As an example, the use of 48" deep sumps and hooded outlets on a catch basin will increase the TSS removal to 25% from 15%.

CONCLUSION:

It can be seen by the application of the Simple Equation and easily obtained site data how a design engineer can evaluate the changes in pollutant amounts and then apply appropriate removal efficiencies to determine whether a land development project will achieve water quality goals.

ABSTRACT
Conventional methods of subsurface assessment for remediation or monitoring purposes often involve field sampling and laboratory analyses of soil and water samples for specific contaminants species. Even though these procedures are well established and produce reliable results, they have a number of disadvantages. Among others, they are not measured in real time, and they are sometimes destructive because excavations are needed to obtain soil samples. Furthermore, the sampling and testing processes can be quite laborious and expensive. Various investigations have been carried out to develop alternative, nondestructive methods for such routine measurements. The application of artificial neural networks (ANN) in environmental site characterization has proved to be an effective modeling method for the prediction of migration paths of environmental contaminants. However, the uses of ANN modeling for the migration of explosives-related contaminants (in particular perchlorate) in water and soil, have not been widely reported in the literature. For this reason, this study will explore the potential use of neural network modeling for predicting the amount and distribution of perchlorate at military installations.

Introduction

Testing and training ranges are essential to maintaining the readiness of the armed forces of the United States. Recently, concerns have arisen over potential environmental contamination from residues of energetic materials at impact ranges. Jenkins, et al. (2001) concluded that the current state of knowledge concerning the nature, extent, and fate of contamination is inadequate to ensure sound management of ranges as sustainable resources. The potential for environmental impacts, including contamination of drinking water supplies, mandates that the Department of Defense (DOD) demonstrate responsible management of these facilities in order to continue testing and training activities.

The application of artificial neural networks (ANN) in environmental site characterization has proved to be an effective modeling method for the prediction of migration paths of environmental contaminants (Mryyan & Najjar, 2005; Dowla & Rogers, 1995 and Rizzo et al. 1996). However, the uses of ANN modeling for the migration of explosives-related contaminants (in particular perchlorate) in water and

soil, have not been widely reported in the literature. For this reason, this study will explore the potential use of neural network modeling for predicting the amount and distribution of perchlorate at military installations, specifically the Massachusetts Military Reservation (MMR).

Background of Study Area

MMR is a site that has been associated with military operations for several decades. This site was utilized for many purposes, one of which led to the presence of perchlorate in soil, sediments, surface water, and groundwater. The data used in this study was obtained from this site.

Although the MMR is a large area of land, the area of concern is only 7.4 acres. This site is referred to as Demolition Area One (Demo 1) and is located on Camp Edwards, approximately 2 miles northeast of the Otis Rotary in Bourne, Massachusetts. Demo 1 is located in a natural topographic depression that covers approximately one acre at its base and lies 45 ft below the surrounding grade.

Demo 1 was established in its current location between 1986 and 1989 as a heavy demolition site. Its primary use was for training engineer and explosive ordnance disposal units and for the destruction of various types of unexploded ordnance. Such ordnance (that include perchlorate) included explosive charges of C-4, 2,4,6-trinitrotoluene (TNT), and det-cord with a weight limit of 40 lbs, Bangalore torpedoes, and claymore mines (AMEC, 2001). According to Pennington et al. (2002): In January, 2000, the U.S. Environmental Protection Agency (EPA) Region I issued an Administrative Order for Response Action in the matter of Training Range and Impact Area, Massachusetts Military Reservation to the Massachusetts National Guard. The purpose of the Order was to require the respondents to undertake Rapid Response Actions and Feasibility Studies, Design and Remedial Actions to abate the threat to public health presented by the contamination from past and present activities and sources at and emanating from the (MMR) Training Range and Impact Area.

In 2004, the MMR implemented a program to correct the negative impacts of perchlorate contamination at the Demo 1 site. Two extraction, treatment, and recharge (ETR) systems were installed within the area of contamination. These wells pump the contaminated groundwater out, remove explosives and perchlorate contamination from the water, and then reinject the treated water back into the wells. This is done at a rate of 110 gallons per minute (USACE, 2006). This process continues to date.

Pre-Existing Data

At the start of this research, perchlorate laboratory analysis data were available for the years 2000–2005. The ANN model was developed, tested, and calibrated using the available data from the MMR facility. A total of 459 samples were collected and analyzed at the Demo 1.

In accordance with the Administrative Order for Response Action, the U.S. Army Environmental Center (EC) collected water quality samples at 51 monitoring wells in 33 locations. Site investigations at and down gradient (west) of Demo 1 included the collection of approximately 650 soil samples and the installation of monitoring wells in 33 locations (USACE, 2006). Data from all monitoring wells were utilized in this study. Water quality samples were collected by the EC between August 2000 and December 2005. These samples were analyzed for over 200 compounds to include explosives, volatile organic compounds, semi-volatile organic compounds, pesticides and herbicides, polychlorinated biphenyls (PCBs), polychlorinated naphthalenes, dioxins, and heavy metals.

Model Development

Back-propagation networks were developed using the TR-SEQ1, a three layered ANN training software package developed by Najjar (2001). The purpose of the ANN model is to predict the concentrations of perchlorate at the MMR from appropriate input parameters.

Determination of Appropriate Model Inputs

This section will discuss the process used to determine the selection of input parameters for the ANN models. The determination of the appropriate model inputs is a process that requires a great deal of consideration. Huang (2006) states, "Whereas in physically-based models the necessary input parameters are specified by the equations that describe the physical, chemical, or biological process being simulated, there is no such specification in ANN models." Because of this, it is imperative that there be an adequate amount of relevant input data to train the ANN model.

Based on the available MMR data, backpropagation neural network was chosen as the most-appropriate ANN for developing the site profiling prediction model. The back-propagation approach used by Najjar & Mryyan (2005) and Dowlas & Rogers (1995) has proven successful in past environmental site profiling because of its ability to accurately predict the amount and distribution of environmental contaminants at a given site.

The performance of a network is dependent on the following factors: The number of hidden layers and nodes. For ANN mapping, one hidden layer was used between the input layer and output layer. The number of hidden nodes in the hidden layer was determined by adaptive training

and online monitoring of accuracy measures on the testing datasets. This was done by varying the number of initial hidden nodes, in the hidden layer, until the network was able to best learn the patterns involved in the testing datasets. Fully connected internal structure, where every node in one layer connects to all the nodes in the next layer, was used. (Mryyan and Najjar,2005)

It is worth mentioning that the input domain of the network was determined by a trial and error approach, because there is no reference in the literature that could provide guidance for selection of the inputs. The number and type of nodes in the input layer. Given the MMR data, the following nine potential input parameters were considered:

X east, Y north, Sample depth from sea level (Z), Groundwater elevation (G), Cumulative number of days since 1/1/2000 (T), Cumulative amount of rain since 1/1/2000 (R),Amount of water injected back to groundwater at the Pew Road well (INJ1), Amount of water injected back to groundwater at the Perking Road well 2 (INJ2), and Amount of water injected back to groundwater at the Perking Road well 3 (INJ3)

In order to determine the domain of input parameters for the optimal ANN model, the effect of input parameters on the output and the performance evaluation criteria (statistical accuracy measures and graphical evaluation) are utilized to identify and distinguish the most important parameters that contribute to the best perchlorate prediction. Various training and testing trials, eliminating different input parameters, were conducted in order to identify the most important input parameters. In the initial step, all nine potential input parameters (X, Y, Z, G, T, R, INJ1, INJ2 and INJ3) were used to develop the desired perchlorate prediction model. In the second step, one parameter was eliminated to arrive at eight inputs (X, Y, Z, T, R, INJ1, INJ2 and INJ3. Groundwater (G) was not included. In the final step, seven input parameters were used (X, Y, Z, T, INJ1, INJ2 and INJ3. Rain (R) and groundwater elevations (G) were not included. (See table 1)

Based on previous environmental site profiling knowledge (Mryyan & Najjar, 2005;Mryyan & Najjar, 2006 and Mryyan & Najjar, 2007), input(s) with minimal impact on the accuracy of ANN model prediction were eliminated from the input domain in trial cases. If the statistical accuracy measures were improved by eliminating one input parameter, the effect of eliminating two input parameters at the same time was investigated further. This procedure was repeated until the statistical accuracy measures did not improve by eliminating more input parameters. The purpose of this procedure was to obtain the optimal ANN model—the highest statistical accuracy with the least number of input parameters. In this study, based on the two stages approach, it was

determined that all of the nine potential input parameters (X, Y, G, Z, T, R, INJ1, INJ2 and INJ3) were necessary to accurately predict the amount and the distribution of perchlorate at Demo1. Table 2 to 4 show the statistical accuracy for each of the three trial cases.

Model Training and Testing

In order to obtain the best perchlorate prediction model, the database used for training should represent all possible features and sub-features that the network is required to learn. This study adopted a two-stage training methodology for every ANN model trial structure. In the first stage, the entire database was divided into training, testing and validation sub-databases at the ratio of about 50%: 25% : 25%. The training sub-database contained all the datasets with the maximum or minimum value of each input and output parameter. Using the training and testing datasets for training and testing respectively, the least-error-structure is selected based on the following statistical accuracy measures (Tables 2, 3 and 4): Averaged Squared Error (ASE), Mean Absolute Relative Error (MARE) and Coefficient of determination (R^2) on the testing datasets. Then the network was trained, tested, and validated at its least-error structure with the corresponding sub-databases.

Felker (2005) reported that if the statistical accuracy measures at the least-error structure for training, testing, and validation data sets were found to be comparable, then the second stage of training is not necessary. Otherwise, this indicates that the developed net does not recognize some of the features in the database. In this case, the second stage training was carried out. In the second stage, all datasets in the database were used to re-train the least-error structure identified in stage one. A total of three cases were investigated in order to obtain the optimal ANN model for perchlorate prediction. The optimal ANN structures for all cases are listed in Table 2.

Model Selection

The best model is considered as the one with the highest statistical accuracy. Statistical (MARE, R^2 and ASE) accuracy measures were adopted to select the optimal network models. Tables 2 to 4 show the accuracy measure obtained for each trial case. The statistical accuracy measures, ASE and R^2, were improved by training on all data at its optimal ANN structure (obtained from stage I). It was found that the 7 input case and the 8 input case are comparable, however, the 9 input case outperformed the 7 and the 8 input cases in all other statistical accuracy and graphical measures. It was then decided to select the 9 input case as the optimal ANN model for this study.

In summary, for the MMR perchlorate prediction model, it was determined that the optimal network model contained 9 input parameters,

9 hidden nodes, and 1 output parameter (9-9-1). The corresponding accuracy measures for this network based on stage II training is listed in table 2.

Data Banks

Once the optimal network model was determined to represent the MMR site, the network was used to predict the values of perchlorate contamination at any desired location. The only parameter required in order to provide needed predictions is the input data vector (X, Y, G, Z, T, R, INJ1, INJ2, and INJ3).

The Demo 1 site was divided in the x, y, and z directions using $\Delta x = \Delta y = 25$ ft. The grid system generated in the (x, y) plane produced 4,527 grid points. These coordinates were used for z = -50 ft, -25 ft, 0 ft, 25 ft and 50 ft, generating a total of 22,637 grid points. For each of the generated grid points, the perchlorate concentration values were predicted using the corresponding (x, y, z) coordinates via the optimized 9-9-1 network (Table 2). Predictions were made using data representing one specific date in time. This means that values for the parameters G, Z, R, INJ 1, INJ 2, and INJ3 remained constant for specific time, although z varied for any given x and y coordinate.

Excel Application

Once the ANN model was developed, the optimal network parameters (9-9-1) was used to create an Excel and Visual Basic software program called MMR perchlorate level determination (MMR-PLD). To make the program user-friendly, a graphical user interface (GUI) was developed. To find the perchlorate level at any certain x and y coordinate throughout the Demo 1 site, all the user must do is enter the desired date (t) and desired depth (z). The program will then return the perchlorate level for x,y and z.

Contour Maps

It is often difficult to analyze large amounts of contaminant data in relation to a specific area such as Demo 1. By taking known data and creating a contour map, a visual graph of the study area can be created. This allows for easier interpretation and comparison of given data. For this reason, contour maps of the Demo 1 site were created using version 8 of Surfer® software (2007) to assist in the visualization of perchlorate contamination from years 2000 to 2005. This was done using the results obtained from the 9-9-1 ANN model, as described before.

The contour maps had (x, y) as a variable and (z) as a constant. Figures 4–33 indicate perchlorate concentrations at z = -50 ft, -25 ft, 0 ft, 25 ft and 50 ft for years 2000 to 2005. By creating contour maps for each year and each depth, trends in the concentration of perchlorate

contamination over time and at different depths can be tracked easily. Such images also allow for easy identification of contaminated areas.

In all contour maps (Figures 4 to 33), a red color reflects a high value of perchlorate and a light color represents a low perchlorate value. Consequently, a red color means that a high value of perchlorate concentrations above the regulatory limit of 1 part per billion, and a white color indicates no perchlorate concentration. Color ramp is used between the red and white colors to map intermediate perchlorate concentration values according to scale shown on the figures.

As stated before, 3-D contour maps were generated at depths of -50 ft, -25 ft, 0 ft, 25 ft and 50 ft for the years 2000 to 2005. For the purposes of comparison, these depths will be divided into three categories: below sea level (-50 ft and -25 ft), sea level (0 ft) and above sea level (25 ft and 50 ft).

Before the implementation of the Extraction, Treatment and Recharge (ETR) methods in 2004, high levels of perchlorate were noted in groundwater samples as demonstrated in the contour maps for years 2000 to 2003. This finding is consistent with known natural migration patterns of perchlorate in groundwater. The highest levels of contamination for these years were noted below sea level, as shown in Figures 4–6 and 10–12. At sea level and above, levels of contamination decreased but were still present, as shown in Figures 16–18, 22–24, and 28–30.

With the implementation of the ETR wells, the pattern of perchlorate contamination changes. Groundwater that has been drawn off and treated by the ETR system no longer contains perchlorate. When this treated water is reinjected into the wells, it is reinjected below sea level. This causes a significant decrease in the levels of perchlorate. On the contour maps for 2004 and 2005, at a level 50 ft below sea level (Figures 9 & 9), there is no evidence of perchlorate contamination. At -25 ft, levels of perchlorate contamination begin to increase (Figures 14 & 15), with the greatest amount noted at 25 ft above sea level (Figures 26 & 27).

Concluding Remarks

The ANN-modeling used in this paper demonstrates the neural network's ability to accurately predict perchlorate contamination using multiple variables. When comparing the trends observed using the ANN-generated data and the actual trends identified in the MMR 2006 System Performance Monitoring Report, both agree that perchlorate levels are decreasing due to the use of the ETR systems. This proves that the ETR systems were both effective and necessary for the removal of perchlorate contamination at the Demo 1 site, as demonstrated in the contour maps.

This study has proven that it is possible to utilize backpropagation ANN-modeling to accurately predict groundwater and soil contamination using limited known data. This allows for the study of not only small sites, but larger sites such as the Demo 1 site. By utilizing ANN methodology, more similar in-depth studies can be performed at a lower cost due to the decreased need for sampling data.

ABSTRACT

Ozonation of organic chemicals generally can result in less toxic and more bio-degradable products. It is proposed to use ozone as a potential decontaminant in case of chemical spill in surface waters. CCHE2D chemical model, a two-dimensional depth-averaged and process-based chemical fate and transport model, was developed for simulating multiple decontamination tests including two-chemical-reaction processes. In this study, toluene decontamination by ozone was selected as an example. Both chemicals' transport, fate and the reactions between these two are all taken into consideration. The model is also used to investigate the effectiveness of decontamination on the water quality by comparing the simulation results of a self-decay case with scenarios of ozonation. The hypothetical case demonstrated the model's capability to represent not only the chemical fate and transport but also the decontamination operations.

INTRODUCTION

Recently, there is a rising awareness of water infrastructure security. Surface water quality can be deteriorated by chemical spill incidents caused by natural or manmade disasters such as extreme flood, transportation accidents, willful dumping, etc. There is an increasing need to assess the environmental impact of the chemical spill incidents and to evaluate the mitigation and control measures to counteract the negative effects. Numerical models have been extensively used as an assessment and evaluation tool. Some examples are the modeling of the chemical spill on the Rhine River in November 1986 (Mossman *et al.*, 1988); the simulation of the long-term impacts of heavy metals or PCBs in both fresh and coastal waters (Thomann et al. 1993, Ji et al., 2002, QEA, 1999).

The CCHE2D chemical model (Zhu et al., 2006) has been developed and validated to simulate chemical fate and transport. It is a two-dimensional depth-integrated and process-based model for simulating advection, dispersion, settling and erosion of sediments, partition between dissolved and particulate phases of chemicals, mass transfer between the water column and sediment bed, and chemical decay through volatilization, photolysis, hydrolysis, and biodegradation, etc. It was integrated with CCHE2D hydrodynamic and sediment transport model (Jia and Wang, 1999; Jia et al., 2002). The model uses a finite element numerical scheme and staggered quadrilateral meshes. It has been developed for simulating free surface flows, sediment/pollutant transport and channel morphological changes. The model has been verified and validated vigorously using analytical solutions, physical model data, and field data.

In this study, the CCHE2D chemical model was extended to simulate the reactions between two chemicals in addition to their individual fate and transport. The purpose of this new development is to study the decontamination measures in case of a chemical spill incident using numerical simulation. The selected study case here is the ozonation of spilled toluene resulted from a hypothetical spill incident.

Toluene (C_7H_8 or $C_6H_5CH_3$) is a common solvent and can be used as additive to gasoline, adhesive and cleaning agent, and as a raw material in the production of benzene and polymers (ATSDR, 1994). By inhalation or ingestion, toluene can cause acute and chronicle health problems, and also poses as a cancer threat (ATSDR, 1994, USEPA, 1999). Toluene is a colorless, flammable, refractive liquid, which is slightly soluble in water (The Merck Index, 1989) with the solubility of 0.47 g/l at 20^{o}C. The Maximum Contaminant Level (MCL) of toluene in drinking water suggested by the USEPA is 1 ppm. Over 100 toluene spill incidents have occured since 2000 (NRC, 2009). One of the major incidents occured in March 1993, when 65,000 gallons of toluene was spilled into the Ohio River.

Ozone has been widely used to reduce the concentration of aromatic organic pollutants such as toluene, benzene, etc., in wastewater and drinking water. The advantage of ozonation is that it generally results in less toxic, more bio-degradable products. Ozone itself decomposes into oxygen if not consumed by the pollutants. In the drinking water industry, the only regulated ozonation by-product in United States (USEPA, 1998) and Europe (EU, 1998) is bromated, which is formed by the ozonation of bromide-containing waters. The reaction products of ozonation of toluene are not well documented in literature. Wibau et al. (1950) reported that formic, acetic, oxalic acids, carbon dioxide and water may be formed in the ozonation of toluene. Recently, Pi et al. (2005) proposed a reaction pathway for the reaction of ozone and some aromatic compounds, including toluene and the products of toluene ozonation would be short chain hydrocarbons, which are more bio-degradable and less toxic than toluene. Hence, it is proposed to use ozone to clean the spilled toluene in a natural water body.

REACTION MECHANISM

In aqueous phase, ozone oxidizes toluene by two major mechanisms (Hoigne and Bader, 1976; Langlais et al., 1991, von Gunten, 2003): one is the direct oxidation

of toluene by ozone molecules; and the other is indirect oxidation by hydroxyl radical reactions. Toluene reacts with ozone in the following form:

$$\eta O_3 + C_6H_5CH_3 \rightarrow \text{products}$$

in which, η is the stoichiometric ratio ranging from 1-2.5 with the maximum measured in the laboratory condition of 5 (Hoigne and Bader, 1983).

Ozonation of toluene occurs by direct and indirect oxidation. The reactions can be written as:

$$-dC/dt = k_T\, C_{ozone}\, C$$

$$-dC_{ozone}/dt = (\eta\, k_T) C_{ozone} C$$

in which, C is the toluene concentration, C_{ozone} is the ozone concentration, and k_T is the overall rate constant.

Kuo and Chen (1996) carried out a traditional ozonation test at pH values varying from 3 to 11 at 25°C. The initial concentration of ozone is from 0.00013 to 0.0002 mol/l (6.24 mg/l to 9.6 mg/l), and toluene concentration varies from 0.0005 – 0.002 mol/l (46 mg/l to 184 mg/l). The overall rate constant ranges from 2.34 l/(M s) to 29.41 l/(M s) (The pH ranges from 3.0 to 9.0). The oxidation kinetics is first-order with respect to the ozone concentration, and the reaction order in toluene varies with pH ranging from 0 to 1 (0 for pH over 10.0; 0.5 for pH between 7.0 and 9.0; and 1 for pH below 5.4). The measured stoichiometric ratio is 1 in their study. The oxidation rate is determined by both the direct and indirect mechanisms in distilled water (initial pH of 5.2-5.4) and other weak acids.

In natural waters, ozone can be consumed not only by the spilled pollutants but also by a lot of organic and inorganic compounds existing in the background. The rate of dissolved ozone consumption can be written as:

$$-dC_{ozone}/dt = wC_{ozone}$$

in which, w is the specific ozone utilization rate, a function of the pH and chemical composition of the water matrix.

Yurteri and Gurol (1988, 1989) did different experiments using synthetic water samples from several rivers and groundwater. Various chemical consumptions have been tested (pH = 6.8 – 9.0; TOC (total organic carbon) 0.3-5.3 mg/l; alkalinity = 10 – 500 mg/l as $CaCO_3$). The temperature was controlled at 20±1°C. The initial ozone concentration was set around 10 mg/l. The experiments were carried out in a headspace-free reactor made of dark glass so that volatilization was limited. The specific ozone utilization rate was found to be

$$\log w = -3.98 + 0.66\text{pH} + 0.61 \log (\text{TOC}) - 0.42 \log(\text{alkalinity}/10)$$

in which, w is in /hr.

GOVERNING EQUATIONS OF THE MODEL

The chemical model simulates the ozonation of toluene by solving three transport equations simultaneously: two for the toluene transport in the water and bed

respectively; and the third for the transport of ozone in the water. The transport equation in the water is written as:

$$\frac{\partial C}{\partial t} + \frac{\partial}{\partial x}(uC) + \frac{\partial}{\partial y}(vC) = \frac{\partial}{\partial x}(E_{xx}\frac{\partial C}{\partial x}) + \frac{\partial}{\partial y}(E_{yy}\frac{\partial C}{\partial y}) + S_k + S_{load}$$

where C is depth-averaged concentration for either ozone or toluene (mg/l); u , v are depth-averaged velocities in x and y direction (m/s), respectively; E_{xx} and E_{yy} are components of dispersion tensor E (m^2/s); S_k is kinetic source term (mg/l/s); and S_{load} is the external loading (mg/l/s).

The kinetic source term for ozone is mainly due to the consumption of toluene and background organic and inorganic compounds:

$$S_{ozone} = wC_{ozone}$$

The kinetic source term for toluene comprises of chemical source/sink due to net settling or eroded sediment flux, vertical diffusion, decay (volatilization and biodegradation) and decomposition by ozonation.

$$S_{toluene} = S_{load} + S_{sed} + S_{v-diff} + S_{decay} + S_{ozonation}$$

where S_{sed} is chemical source/sink due to net settling or eroded sediment flux (mg/l/s); S_{v-diff} is vertical diffusion flux at the water-sediment interface (mg/l/s); and S_{decay} is chemical decay term (mg/l/s).

$$S_{ozonation} = k_T C_{toluene} C_{ozone}$$

It is assumed that the convection and dispersion in bed sediments are negligible. The governing equation for the bed sediments in the conservative form is:

$$\frac{\partial (C_s \times D_{sed})}{\partial t} = S_{load,s} - S_{sed} + S_{v-dif} + S_{decay,s}$$

where C_s is the toluene concentration in bed (mg/l); D_{sed1} is the depth of sediment layer (m); $S_{load,s}$ is the external load to bed (mg/l/s); and $S_{decay,s}$ is the chemical decay rate in the bed (mg/l/s).

SIMULATION OF TOLUENE OZONATION SCENARIO

In this study, a hypothetic toluene spill incident was assumed to occur in a reservior. The reservoir is about 18 km long and 4 km wide with the water depth of about 4 m in the main channel. It was assumed that 270 tons of toluene was spilled into the middle of the reservoir over a period of 12 hours due. In order to clean the spilled toluene, the following numerical ozonation operation procedures were designed:

1. Identify the highest toluene plume in the reservoir, which can be found out using the simulation results of the toluene spill incident.
2. Set up an ozone barrier in the reservoir close to the plume with high concentration of toluene. The ozone barrier shall move at a similar

speed with the traveling velocity of the toluene plume so that when it passes by, toluene can be degraded more efficiently. The traveling velocity of the plume can be estimated from the flow simulation results. The length of the ozone barrier is set about the width of the plume. Two barrier width and two ozone generation capacity were tested in this study, which makes four operations in total.

3. Analyze the efficiency of ozonation using the simulation results of the chemical model. Adjust the location and ozone generation capacity of the ozone barrier if necessary to achieve favorable cleaning effects.

Flow simulation was conducted first to obtain the flow field (flow velocity, water depth, and eddy viscosity). With the input of flow field, the CCHE chemical model was then used to simulate the fate and transport of toluene spill incident, which provides the temporal and spatial toluene concentration in the reservoir and also serves as the background level without ozonation. Finally, four ozonation operations were simulated and analyzed.

Flow Field Simulation

The simulation domain was descretized into a 70 by 174 numerical mesh. Steady flow condition was assumed with the flow discharge at upstream being 120 m^3/s and water surface elevation at downstream 90.25 m. Manning's roughness coefficient was set as 0.025. Mixing length model was used for the turbulence closure. The steady flow was simulated at a time step of 20 seconds using the CCHE2D model. Figure 1 shows the bathymetry of the reservoir, locations of inlet, outlet and toluene spill, and local flow field near the spill site.

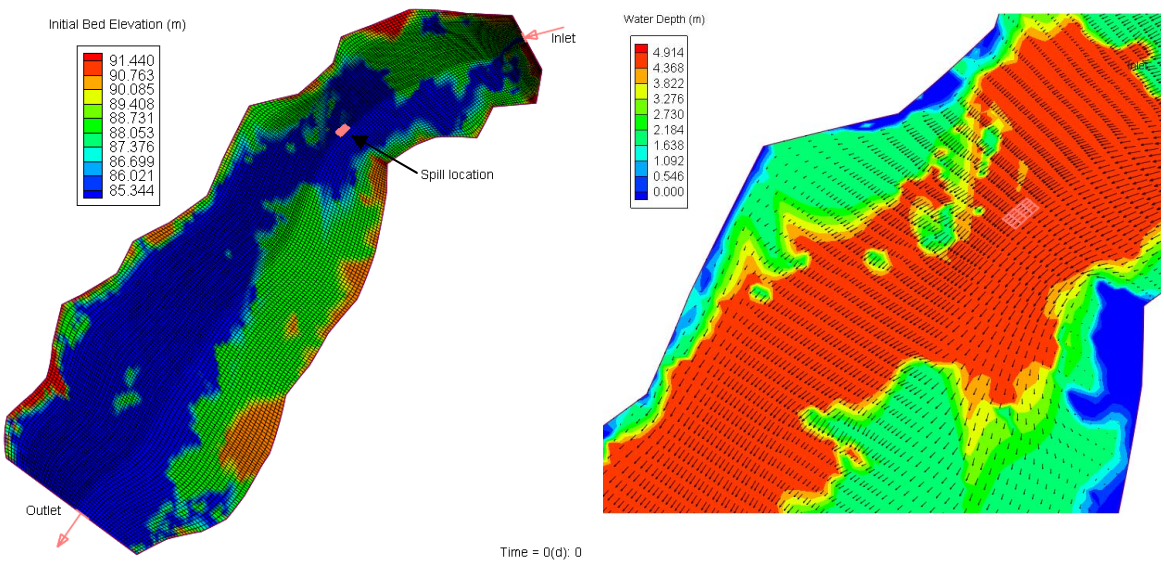

Figure 1 Numerical domain (left) and local flow field (right)

Simulation of Toluene Spill

The hypothetic toluene spill incident was simulated for 10 days. The parameters for simulating toluene decay processes and interaction with sediments are listed in Table 1.

Table 1 Parameters for simulating toluene

Biodegradation rate (s^{-1})	1.30787E-006
Partition coefficient	100
Vertical diffusion (m^2/s)	1E-007
Gas phase transfer rate (m/s)	1E-005
Henry's constant (atm m^3/mol)	0.00664
Suspended sediment concentration (mg/l)	10
Bed porosity	0.4

Toluene concentration still exceeds EPA's MCL at the end of 10 days although due to the decay processes, it has decreased from 298 mg/l (at the end of first day after spill) to 7 mg/l (at the end of 10 days after spill) (shown in Figure 2).

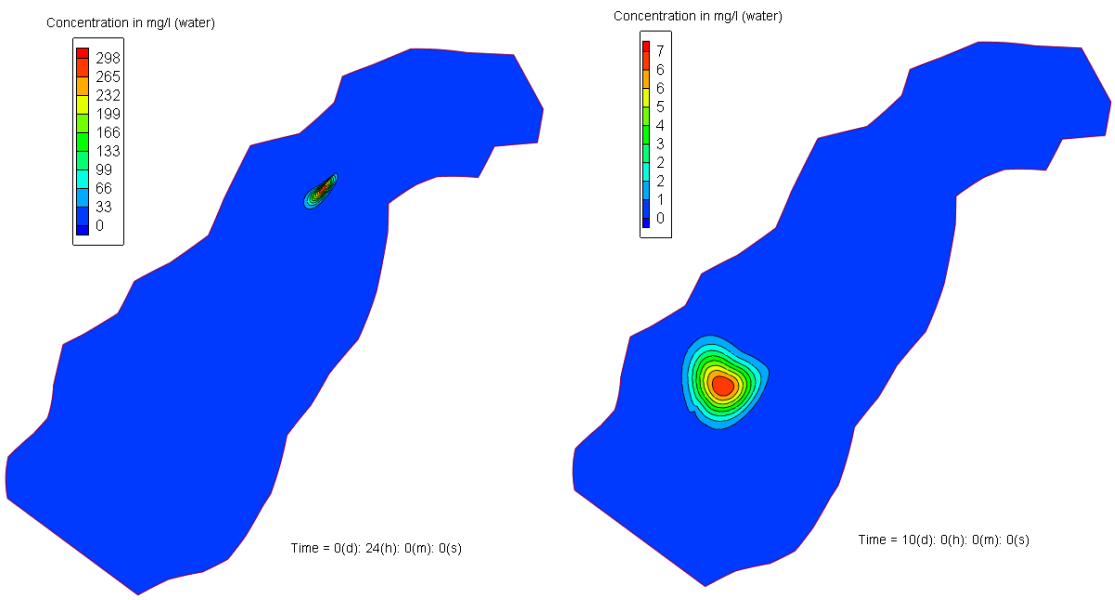

Figure 2 Toluene concentration distributions after the spill

Simulation of Ozonation Options

The hypothetic ozonation was designed to start right after all toluene was spilled into the reservoir, i.e. after 12 hours of the spill. Four options of ozonation barrier were summarized in Table 2. The barrier moves downstream with the tolune plume at an average speed of 0.013 m/s.

Table 2 Ozonation Operation Parameters

Options	1	2	3	4
Barrier width (m)	80	160	80	160
Ozone generation capacity (g/s)	650	650	1650	1650

The reservoir water is neutral with pH value of 7 and it is assumed that during the simulation period the water temperature is at 20°C. To simplify the problem, it is also assumed that the consumption of ozone was mainly by toluene. The overall rate constant of ozonation was set as 0.0002 s^{-1}. The stoichoimetric ratio was set at 1. Four ozonation options were simulated using the same flow, environmental condition, and ozonation rate constant. The simulation results of Option1 and 2 are found to be similar and that's the case for Option 3 and 4, which suggests that ozone generation capacity is the dominant factor to increase the toluene removal rate. Figure 3 shows the toluene concentration distributions at the end of day 3 after the spill. It can be seen that with higher ozone generation capacity, option 3 can clean the spill site faster.

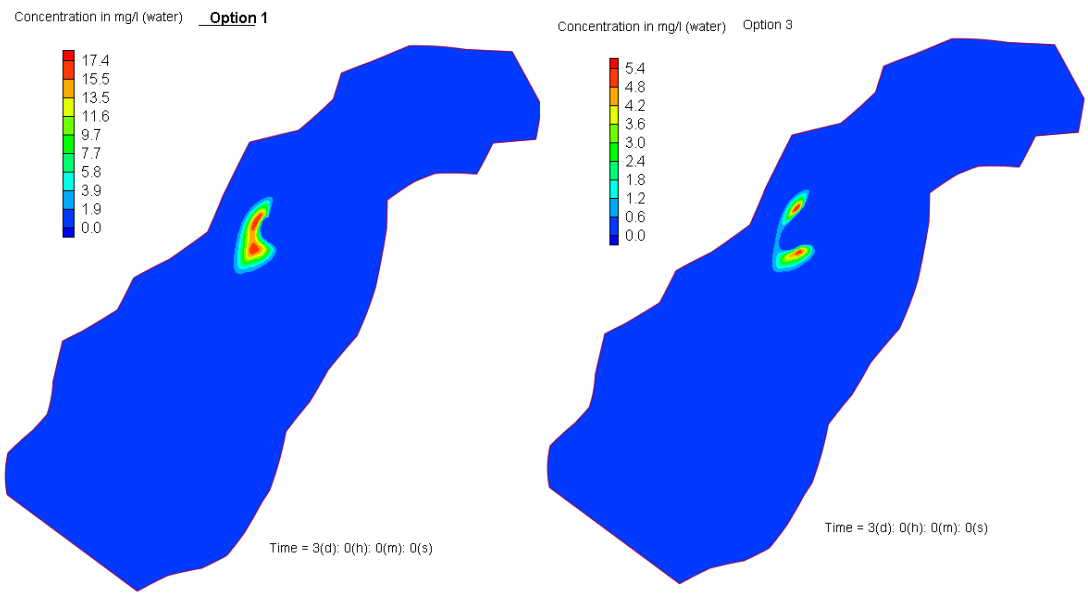

Figure 3 Toluene concentration distributions with ozonation

Total mass of toluene in the reservoir was calculated as the ozonation went on to show the removal rates for each option (Figure 4). Again, Option 1 and 2 has the similar mass reducing pattern, which is also true for Option 3 and 4. In Option 3 and 4, the toluene mass reached zero after 100 hours, while it took about 200 hours in Option 1 and 2.

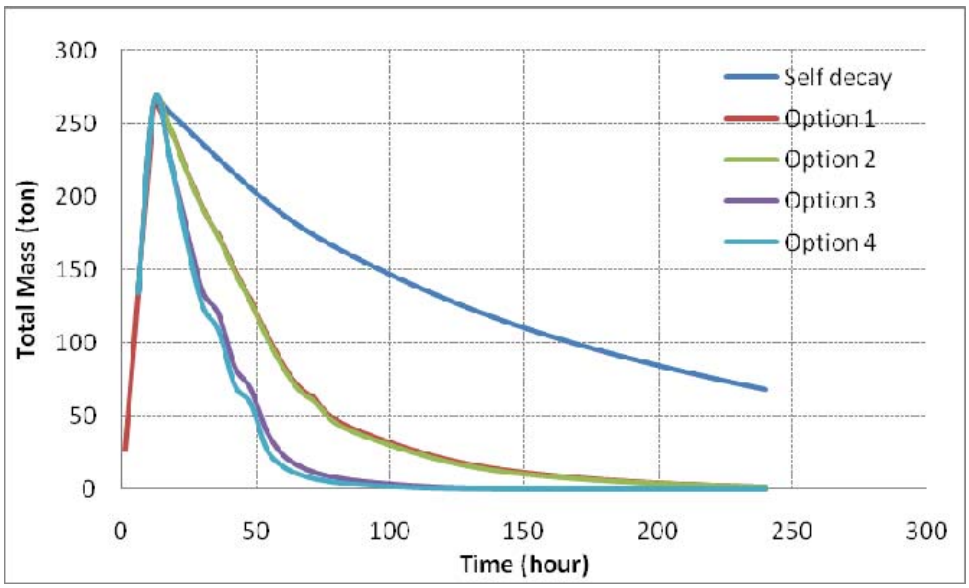

Figure 4 Toluene removal rate of four ozonation options

The water is considered safe if everywhere in the reservoir the toluene concentration is below the MCL (1 ppm). Figure 5 shows the days it took for each option to bring the water back to the safe level. After ten days, the toluene concentration still exceeds the MCL if no ozonation was conducted. Using Options 3 and 4, the water quality can recover the soonest within 5 days.

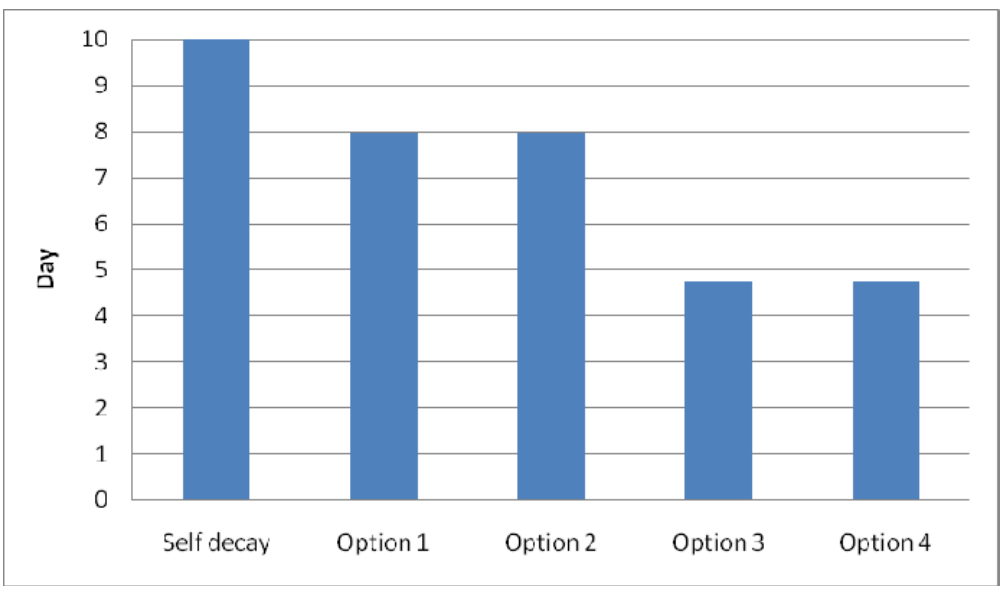

Figure 5 Toluene clean-up time

CONCLUSIONS

A hypothetic toluene spill incident in a reservoir was assumed and the clean-up operations by means of ozonation were designed and simulated using the CCHE chemical decontamination model in this study. The process-based model simulates major decay processes of toluene in the surface waters including ozonation, volatilization, biodegradation and interaction with suspended sediments and bed sediments. As this study emphasizes the simulations of toluene ozonation, the hydraulic condition was simplified as steady flow and the toluene decay processes were represented using those from literature. The spatial and temporal concentration distributions of toluene and ozone were obtained from the simulation results.

The impact of ozonation on toluene distributions can be found by comparing the toluene transport scenarios with or without ozone. With the ozone barrier moving with the toluene plume, the spilled toluene can be decontaminated at least twice as faster compared with that of self decay case. The model is also able to investigate the effectiveness of different ozonation options. It was found through the simulations of four options that the width of ozone barrier has very limited impact on the toluene removal rate. However, the ozone generation capacity plays an important role. With higher ozone generation capacity, the total mass of toluene decreases faster and the reservoir would be cleaned up in about half of the time compared with the lower capacity options.

Although this case study is hypothetical, it demonstrates that the model is a useful initial tool to help design and evaluate clean-up operations. The practical layout of ozone device needs more study in the future taking into account of factors such as device size, device movement, and cost etc. This would further enhance the effective removal of toluene or other contamination removal under consideration.

Abstract

Air pollution is one of the most important environmental issues of the populated cities, which is seriously threatening human health. This is caused by several factors, such as climo-physiologic characteristics of the region, deficiency of perennial plants, vehicles-mobile pollution sources- and also stationary sources including factories and power plants. Vehicles' gas emission is the major source of air pollution which is related to the type and magnitude of fuel they consume. In comparison, the stationary sources only contribute one fifth of the total pollutant emission.

In this study, the effect of fuel consumption increase on Tehran (Iran's capital) air pollution is evaluated. Obviously, weather patterns have also considerable role on air pollution which are considered in the proposed simulation model. For this purpose, the most effective parameters on Tehran air pollution are identified and selected as the input of simulation model. Then, Artificial Neural Network (ANN) models are chosen due to their efficient power and robustness in identifying the nature of complicated phenomena which air pollution is one of them. Tehran is selected as a case study because of its higher violation to the air pollution standards and being one of the five polluted cities around the world. Results show that the proposed model can be implemented successfully to monitor the air pollution changes and consequently makes it possible for associated managers to develop appropriate policies against the air pollution.

1. INTRODUCTION

Today, human because of fundamental changes in world population, technology and industry has more interaction with environment than he had in past. For the first time in human history, more people are living in towns and cities than in rural areas. As a result, the demand for land in and around cities is becoming acute; urban sprawl is re-shaping landscapes and affecting people's quality of life and the environment as never before. Overall consumption, energy use, water use and waste generation go along with a growing number of urban households. Consequently, the huge detrimental human activities influence greatly on environment.

Urban environment, in its general sense, consists of resources, human and processes through which the later can convert the former into products and services. It is a mélange of natural, human-made and socio-economic environments due attention to each of which is required in order to avoid imbalance in the whole. Hence, coordination and interaction between all these three dimensions of environment ought to be aimed in any urban management policy. Today, ever-increasing problems of urban environments, particularly in developing cities, have brought a significant importance to urban management. Human impact on the environment is determined by three main factors: the materials standard of living, the applied technology and the number of people. (Fenger et al, 1998)

Air pollution is one of the challenging outcomes of human impacts and technology growth which is very important because of its direct effect on the health of people, specially in developing cities. Two decades of unparalleled growth have, however, come at a cost. Swelling urban population and increased concentration of industry and automobile traffic in and around cities have resulted in sever air pollution, threatening human health and undermining the productivity of the urban population. (Shah et al, 1997)

The prediction and simulation of air pollution concentrations is not an easy task as it involves non-linear relationships and variables of uncertainty. Several models have been developed and can be classified as either deterministic or empirical models. Deterministic models such as the Urban Airshed Model (UAM) and Canadian Hemispheric and Regional Ozone and NO*x* System (CHRONOS) are Eulerian-based models that require several inputs such as meteorological data, topographical data and emissions inventory. A difficulty encountered with such deterministic models is that emissions from natural and anthropogenic sources, such as industry and traffic, are often uncertain and not normally available. Also, deterministic models are computer intensive. (Mintz et al, 2005)

Ozone (O_3) is one of the main components of photochemical pollution which has become a major concern for public health in recent years. A study conducted in 20 US cities failed to find an association between O_3 concentration and mortality from either all causes, cardiovascular (CV) disease or respiratory disease. In contrast, more recent studies carried out in Hong Kong, Santiago de Chile, and Montreal (Quebec) reported a

significant correlation between O3 concentration and short-term mortality. (Parodia et al, 2005)

In this study, attempts have been made to explore the relationship between Tehran air pollution parameters (Ozone: O_3, Sulfur Oxide: SO_2, Nitrogen Oxide: NO_2, carbon monoxide: CO and particle matters PM) and meteorological variables and fuel consumption to analyze the role of different factors on Tehran air pollution. Having selected appropriate predictors, Artificial Neural Networks (ANN) models are developed. In next section a brief introduction of Tehran air pollution problem is given, then the ANN models used in this research are introduced. Finally, the results are discussed with some details and conclusion is given.

2. TEHRAN AIR POLLUTION

2-1. TEHRAN AT A GLANCE

Tehran, a mega city now, was once a rural area the pleasant and congenial climate and rich nature. In 1775, it was chosen as the capital city. At the beginning of 1921, as a result of the development of urban sights, the foundation of public buildings such as offices and banks could perhaps be credited as the most essential as it transformed Tehran from a traditional town to a modern city. From 1955 to 1962, Tehran turned to the industrial and administrative pole of the country as a result of which a torrent of immigrants flew into the city seeking better life standards. The trend of physical expansion in Tehran which has always been under the pressure of economic, social and political issues, one can infer that its growth has never followed a systematic, well-planned strategy in harmony with its natural capacities.

Today, Tehran metropolitan area is 655 square kilometer and the population is over 8 millions. 22 districts each of which has a municipality work under the supervision of the municipality of Tehran. Figure 1 illustrates a map of Tehran and its 22 districts.

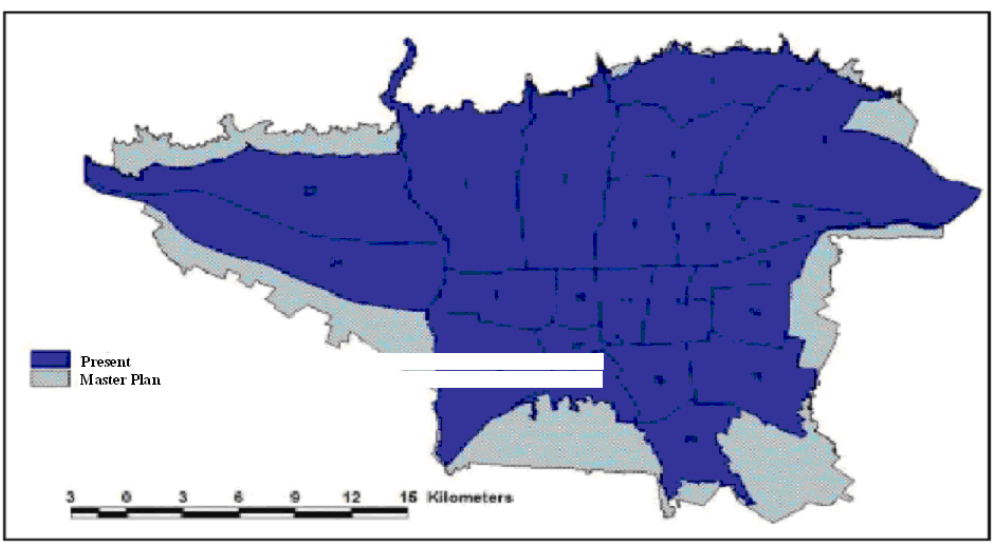

Figure 1. Map of Tehran and its municipality districts

Among all environmental issues of Tehran, air pollution is by far the gravest as it not only smudges the face of the city giving it an ever looking grey sky, but also puts the health of the inhabitants into serious jeopardy. Hence, both people and authorities are extremely concerned about it.

Tehran is located in a deep and valley-like space embraced by mountains from three different angels only allowing wind blows from the south and southwest. In terms of climate, Tehran is considered to be sited in dry Mediterranean zone. The direction of wind blow in the west of Tehran is typically from west to east and in the east from south to north. Being quite a vast city, Tehran has a variety of climates. Since the west of Tehran has a less stable climate and enjoys winds twice as fast as the ones blowing in the east, it is less prone to the effects of pollutants than the east where winds usually blow with a steady pace. Winds are generally supposed to blow faster in the first months of year than in the last ones; however, as mentioned above, this is not the case in the east of Tehran, which might be why its weather is polluted with pollutants in cold months of the year.

2-2. SITUATION OF AIR POLLUTION IN TEHRAN

Density of air pollutants increases during climatic extremes, both in cold and warm months of year, due to certain climatic changes in winter and increase in the amount of fuel consumption in summer. Investigations carried out by Tehran municipality show that in 2004, the number of unhealthy days reaches 108 and in 2006, even though declines to 67 days(Table 1), but was still very critical compared to the once a year occurrence standard released by the Environmental Protection Agency. Figure 2 illustrates the distribution of Tehran air pollution in critical days in a critical and normal day.

Table 1, Tehran air pollution regarding PSI

Year	Good	Moderate	unhealthy	hazardous
2003	10	194	159	2
2004	16	241	108	0
2005	22	251	93	0
2006	29	269	67	0
2007	31	316	18	0
2008	5	310	50	1

2-3. TRANSPORTATION AND IMPACTS ON AIR POLLUTION

Today, there are around 3 million cars traveling in Tehran. The share of transportation in air pollution of Tehran is around 88%. Vehicles manufactured before 2000 specify 70% of the pollution to themselves; whereas the ones entering the market after 2004 only produce 20% of the pollution. 75% of pollution is due to light vehicles while only 21% belongs to motorcycles and only 2% is produced by bus transportation system and the

rest is caused by other sectors. Constant expansion of urban societies and the growth of car manufacturing enterprises urge the need for a proper transportation system which utilizes the latest technological advances. (A report on ecological situation of Tehran, An insight to current trend and future actions, 2008), (Hesami, 2007)

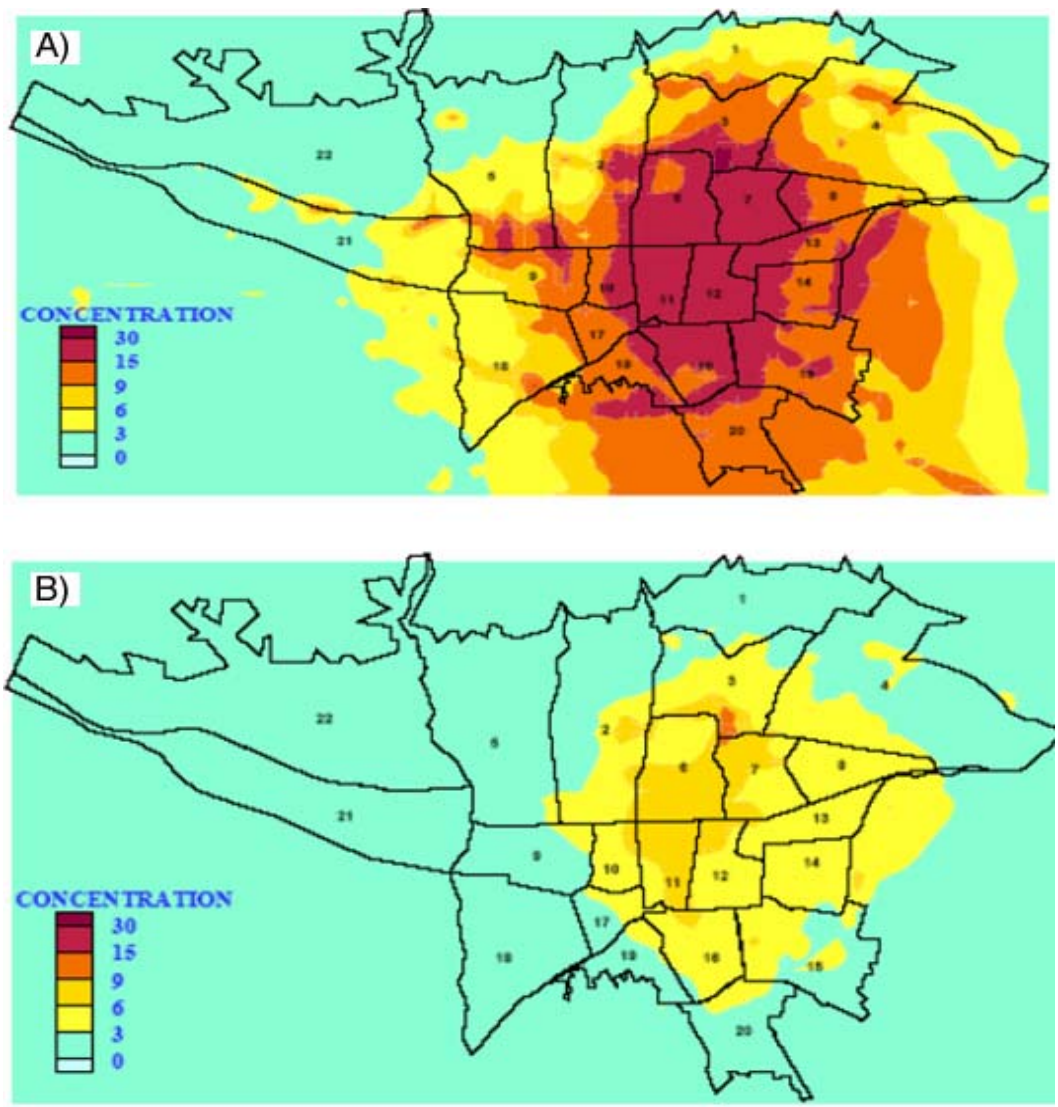

Figure 2. Critical air pollution distribution state in A) a critical day and B) Relatively normal conditions.

There are many air pollution gauges in Tehran operated by Air Quality Control Company of Tehran Municipality in order to monitor the air pollution continuously throughout the year. The air pollution data body used in this study is provided by this center. Meteorological data was collected by Iran Meteorological Organization and Air Quality Control Company of Tehran Municipality.

3- SIMULATION MODEL

3-1- ARTIFICIAL NEURAL NETWORKS

The architecture of ANNs is adapted from biological neural networks, which recognize patterns and learn from their interaction with the environment. Figure 3 shows the components of a typical three-layer feed forward artificial neural network. As shown in this figure, each node j receives incoming signals from every node i in the previous layer. Associated with each incoming signal (x_i) to node j, is a weight (w_{ji}) in order to give a large level of flexibility in the model formulation of the hidden layer that corresponds to the hidden or artificial variables. Since the input-output relation is easy to be computed, the neural network model can be considered as an effective technique in any descriptive or optimization procedure. (Karamouz et al, 2006)

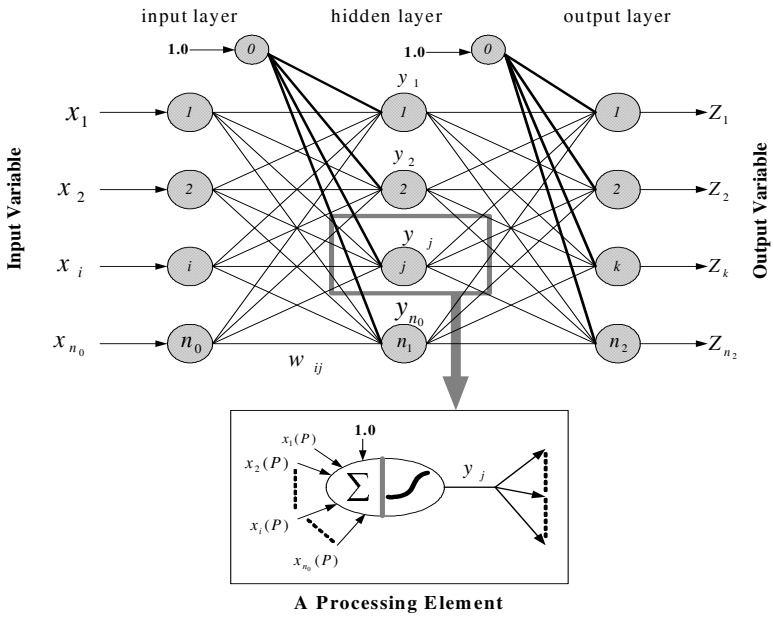

Figure 3. Typical three-layer feed forward artificial neural network (Hsu et al., 1995)

3-2. INPUTS OF SIMULATION MODEL

The relation between monthly records of O3, CO, NO2, PM-10 and SO2 as air pollution indicators and the weather parameters and also fuel consumption has been computed to find the best predictors for the simulation model. We chose average of maximum

relative humidity, average of minimum relative humidity, average of wind speed, monthly sunshine hours and monthly precipitation as the weather parameters which have strong effect on air pollution indicators and benzin, gasoil, kerosene and fueloil as the fuel consumption indicators.

The results of the best correlation obtained for each air pollution indicator are presented in Table 2. As shown, there is a significant relationship between predictors and ozone, one of the most factors of air pollution that seriously affect the health of inhabitants. The NO2 and SO2 indices can also be considered as indicators of Tehran air pollution. We didn't find strong relationship between CO and PM with the predictors in the period of 2001 to 2005.

Table 2: Correlation of each air pollution indicator with weather and fuel consumption indicators

Index	Kerosene	Gasoil	Average of Relative Humidity	Monthly Sunshine Hours	Benzin
O3	0.75	0.65	0.77	0.83	0.56
NO2	0.5	-	-	0.31	0.61
SO2	0.56	-	0.4	-	0.7

3-3. RESULTS OF ANN MODEL

Three different ANN models of Multi-Layer Perceptron Neural Network (MLP), are trained using three sets of data classified in Table 2. In first model, monthly time series of Kerosene, Gasoil, average of relative humidity, sunshine hours, and Benzin are given as inputs and Ozone as model output. In other two models, three of 5 variables are given and NO2 and SO2 are simulated.

In order to find the structure of these models, we have developed MLPs with tansig and Pureline activation functions in hidden and output layers respectively. The number of neurons in hidden layer is selected using cross-validation technique. For this purpose, all 52 set of input and output are divided into 26 chunks. Then, the MLP model is trained 50 set of data and validated by the 2 remaining sets. This is repeated for each of the chunks. The error of calibration and validation are obtained averaging the errors of all 26 trains. These steps are repeated for number of neurons from 2 to 15. Now, there are two errors of calibration and validation for each number of neurons in hidden layer. To quantify the ANNs performance, Root Mean Square Error, RMSE index has been calculated. Table 3 shows the calibration and validation errors for O3, NO2, and SO2 for different number of neurons in hidden layer.

Table 3. Cross-validation results for selecting optimum number of neurons in hidden layer

Neuron	O3			NO2			SO2		
	Err-Calib	Err-Valid	MinMax	Err-Calib	Err-Valid	MinMax	Err-Calib	Err-Valid	MinMax
2	7.15	1.58	7.1	2.83	0.97	2.83	6.94	1.97	6.94

To select the optimum number of neurons in hidden layer, we tried Min-Max approach. According to this method, NO2 and SO2 models have 5 and 6 neurons respectively, and in case of O3 following the Min-Max method we should have selected 13 neurons, but since the variation of train error for neuron numbers of greater than 8 is almost the same, we select the number of neuron with small validation error. Therefore, we selected 3 neurons for O3 model (Table 2).

After the selection of model architecture, the models are trained for 80 percent of data and validated by rest of the data. The RMSE error index of 1.97 and 1.37 obtained for validation periods of both O3 and NO2 models with 1000 epochs, respectively. This was 2.56 for SO2 model which obtained with 5000 epochs. Learning rate for all the models is considered 0.001. The time series of observation against the forecast for training and validation periods are given in figures 4 to 6 which show the robustness of the developed models in test period.

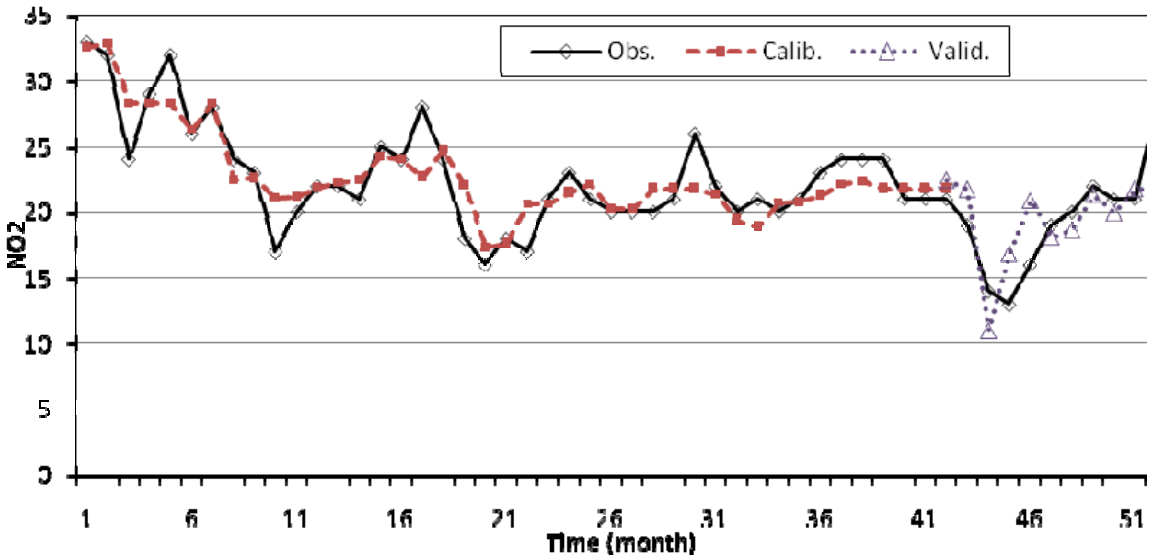

Figure 5. Simulated and observed time series of NO2 (Sep. 2001-Dec. 2005)

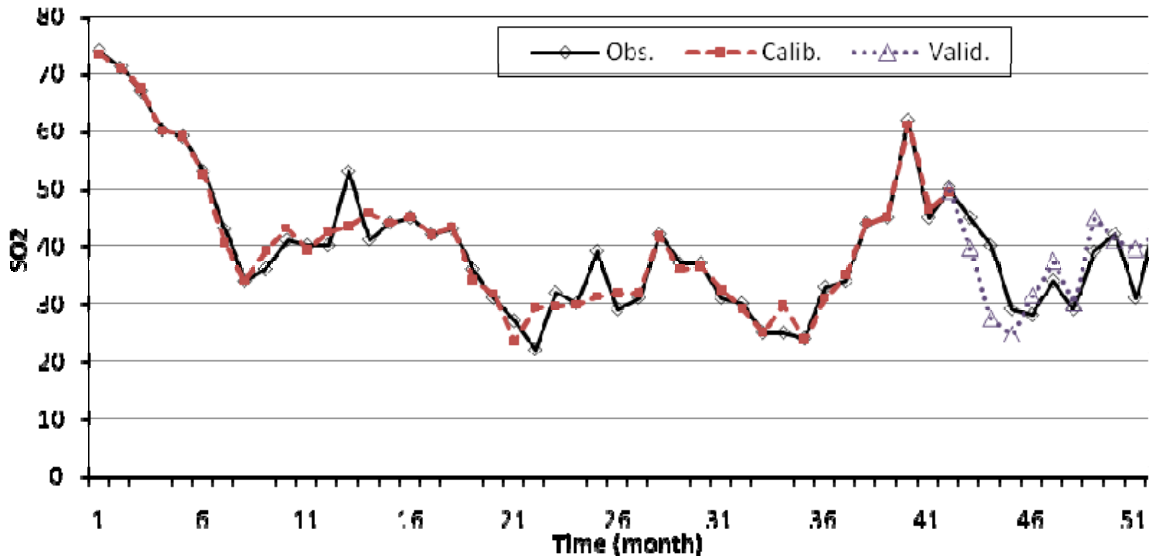

Figure 6. Simulated and observed time series of SO2 (Sep. 2001-Dec. 2005)

4- CONCLUSION

The purpose of this study is to analyze Tehran air pollution problem focusing on impacts of vehicles' portion of pollution and its relation with fuel consumption and weather patterns. For this purpose, the correlations between fuel consumption indicators (benzin, gas oil, kerosene and oil), weather parameters and Tehran air pollution indicators (Ozone, Sulfur Dioxide, Nitrogen Dioxide, Carbon Monoxide and particle matters) have been computed. Five fuel consumption and climate indicators highly correlated with pollution indices have been used as air pollution predictors and as input of three different MLP models. These models are used to simulate Ozone, Sulfur Dioxide, and Nitrogen Dioxide. Results show that even though there is short length of recorded data available, developed models simulate the Tehran air pollution effectively and can be used for making different traffic policies in city in order to reduce the air pollution. Using these models for different cloud coverage, humidity rates and fuel consumption air pollution of Tehran are simulated. Since the climatic variables can be predicted and the fuel consumption of Tehran has some special patterns it is also to predict the air pollution conditions in Tehran in advance and consequently protective policies for its reduction.

ABSTRACT

States own numerous dispersed facilities, many in remote locations. These facilities could be potential locations for renewable energy generation systems, using the power to offset the electricity use at the locations with excess being sold back to the utilities, i.e. the grid. In efforts to initiate renewable energy generation at state facilities, the State of Missouri undertook a study to erect a combined photovoltaic (PV) array and wind turbine renewable energy project at a highway patrol facility. In this study, a new rapid site evaluation for wind power potential was undertaken. The annual energy generation was estimated to be 22,800 kilowatt hours (kWh) (12 month x 1,900 kWh/month). The PV/wind turbine system installed and operational in under five months from project initiation.

Based upon electricity offsets alone, an economic analysis estimated that the wind turbine part of the project would have a payback period of 18 - 25 years. When considering the Carbon Credits (CC) that could be generated, the payback period was reduced. Carbon Credits are largely an unknown and misunderstood commodity. The current trading price of $3 to $4 per CC equivalent is expected to increase to around $12 in the short term, and within the payback period of this project, carbon credits are anticipated to reach $20-30. Carbon Credit finance is still largely an untested market for entities such as a state, and the economics covered in this talk are not easily attained on small projects. This talk will discuss how agglomeration of the small projects could lead to marketing of these credits to help the economic analysis of the individual projects.

INTRODUCTION

At a time when energy costs are escalating and energy security is a concern nationally, renewable energy is clearly a part of the national future. In this future, many entities are looking to enter the energy production efforts, including farmers, private companies, schools and private companies. State institutes are also interested in pursuing renewable energy projects, but the diversity of state facilities and of each individual application, hinders the ease of entering into a renewable energy project for individual facilities. As part of an effort to focus on the siting and implementation

processes, the State of Missouri Division of Facilities Management, Design & Construction teamed with Missouri University of Science and Technology to deploy a small demonstration project. Critical factors in the project planning were rapid sight evaluation and power projections, particularly for the wind project, which was completed using novel methods based on readily available weather data. Small, distributed energy generation systems will be located at various state facilities to primarily offset electricity produced from fossil fuel and not be sited for ideal wind resources, which is done for most wind energy projects. For each small project in dispersed locations, detailed and expensive wind studies that can take months to years to complete are impractical.

In utilizing wind turbines or PV arrays for renewable energy sources, the electricity generated is the primary commodity produced and has the greatest economic value. As a result of future regulatory action on the market valuation of carbon emissions, the costs of fossil fuel generated electricity will almost certainly increase, with many projections suggesting increases of two to three fold, particularly in Missouri where energy is currently very inexpensive. Concurrently, the value of carbon credits and renewable energy credits are projected to increase, offering other revenue streams from the renewable energy sources. The market value of carbon credits in particular is highly volatile. For example, the value of carbon credits (based on offsetting or sequestering one tonne of CO_2) on the European market, climbed to $30 a tonne and then fell to almost 0 within a year. Developing an understanding of these markets and how to capitalize on the economic potential is essential for renewable energy projects as evolution of carbon credit markets is clearly a contributor to the financial feasibility for renewable energy technologies. The sale of carbon credits can be carried out in a variety of methods, including open markets or direct purchase by companies, states or industries. The credits can also be sold to organizations like EcoSecurities, who develops projects and offer guaranteed purchase agreements and builds an agglomerated portfolio to market later. As a whole, carbon credits are an emerging source of income to those generating alternative energy which modestly adds to the economic returns from the project currently and may be a considerable revenue stream in the future.

Site Assessment and Implementation Siting studies which include the collection of wind and/or solar data at candidate locations are routinely performed during feasibility studies for wind and/or solar farms which generate energy for utility company purchase. One of the major challenges associated with installing relatively small renewable energy systems at existing facilities is that the facilities may not be located in areas with high potential for renewable energy (especially wind) generation. A second challenge is that the cost of installing a weather station to measure the available wind and solar resources at the facility location may cost a significant fraction of the renewable energy systems. The annual energy generation was estimated to be 22,800 kWh (12 month x 1,900 kWh/month). The use of non-specific wind velocity data from regional databases may provide reliable wind turbine performance predictions. Details of this methodology are presented in recent

publications on small wind turbine prediction modeling (Elmore and Gallagher, 2009). This methodology will be applied for the project outlined in this paper.

Obtaining an interconnection agreement with the local municipality was also an unexpected hurdle. The local municipality required the interconnection participant to carry liability insurance in order to enter the interconnection agreement. The State of Missouri, however, is self-insured. Both entities, the state and local utility, were cooperative, but the novel aspects of the renewable energy project had not been considered in previous experiences for both state and utility personnel. The interconnection agreement was completed, and the lessons learned on how to address liability issues on this novel project will hopefully aid in future similar projects. The PV and wind turbine selection, installation, and interconnection was completed in roughly five months. The resulting system is described below in Table 1 and shown in Figure 1. Some preliminary lessons learned:

1. Review the local utility interconnection permit because the requirements may vary significantly from utility to utility. For this project there were some unanticipated costs: a PE was required to develop a one line electrical diagram; two shutoff switches (one for the wind and one for the PV) were required on the line from the inverters to the utility connection; and the utility requested approximately $1,000 to install a net meter. These items were not required for similar projects in other jurisdictions.
2. Ask the tenant to participate in the project financially to prevent escalation of installation costs related to potential modifications to the facility. For example, the tenant requested extra grounding of the system and that utilities be installed without cutting a light duty asphalt driveway. These actions were not technically required, and the tenant may not have made such requests if they shared in the costs.
3. The instrumentation vendor needs to provide a statement of qualifications indicating that they have instrumented the exact wind turbine and PV models being installed.
4. The tenant should be prepared for significant public interest.

Table 1. Equipment list along with the manufacturer and model numbers for the project at the Missouri State Highway Patrol Troop I Headquarters.

Item:	Manufacturer:	Model Number:
Solar Panels (x 10)	Sharp	ND-216U2

Temperature Probe	Fat Spaniel Technologies	439/259

Renewable Energy Performance Methodology The performance of the photovoltaic (PV) array is currently being monitored using a data feed from Fat Spaniel Technologies. After the solar power is converted in the Frionus IG 2000 inverter, the power produced, in kilowatts (kW), is monitored by the Fronius EZ Card. The data is averaged every minute and posted to the data feed where the results can be viewed. To obtain the daily energy produced, in kilowatt hours (kW-hrs), the daily sum of the minute averages must be calculated. When divided by sixty this converts the power to kW-hrs for that particular day.

Figure 1 Photo of completed wind turbine and PV solar array.

The performance of the wind turbine is currently being monitored using a data feed from Fat Spaniel Technologies. After the wind turbine power is converted in the Gridtek 10 inverter, the power, voltage and current produced are monitored using a current transducer. The minute averages of the power are sent to a data feed, and the voltage and current values are sent to a website produced by Fat Spaniel. The daily energy produced can be calculated by taking the daily sum of the minute averages of the power and dividing by 60.

Carbon Credit Finances Carbon credit trading is currently a voluntary program in the US. As such, there is no single approved methodology for quantifying or exchanging CCs. Numerous methodologies and marketing approaches are available. In all of these methods and approaches, the basic premise for CC generation in renewable energy projects is that the energy is used to offset use of electricity from a fossil fuel source emitting greenhouse gasses (GHG), whereas the renewable energy does not emit GHGs. The protocols used for quantifying the CCs vary in the specific methodologies used to quantify and market GHG emissions mitigated in the project. Three of the most common types of projects for CC quantification, validating, and marketing are listed in Table 2 below.

Table 2 Three common methodologies for carbon credit quantification, validation, and marketing.

CC Methodologies	Summary	Reference
CDM - Clean Development Mechanism	From Kyoto, very complete, widely accepted	CDM 1
CCX – Chicago Climate Exchange	Linked with CCX market, "arbitrary" values	CCX
CCAR – California Climate Action Registry	Newest, limited project types, widely accepted	CCAR

Protocols for Carbon Credit Determination and Verification CDM Protocol is based on standards intended for use with the "Clean Development Mechanism" program from the Kyoto Protocol. CDM protocols are very thorough and transparent, including numerous tools for calculating baseline, additionality, and other important factors that affect a project's quality and market value. CDM standards are available for most types of acceptable GHG reduction or mitigating projects. Verification of a CC project is usually completed by a third party, but can also be done by the aggregator (if it has the technical expertise) or by the trading platform, both of which are usually done for a set fee ($/CCE). As verification processes can be tedious and quite complex for some types of projects, it can also be quite costly. Often the verification can include a new mechanism or methodology for measuring the carbon sequestration or mitigation. Relating this mechanism or methodology to true carbon credits can be brought into question and can be accepted/not accepted under the different protocols. Acceptance by one is not acceptance by all. In the case of mechanical (wind, hydro) or PV electrical generation, the verification is rather straight forward based upon the power generated and the source of electricity that was offset.

Credits that are quantified and verified following CDM protocols are certified emission reduction (CER) credits, each equivalent to one tonne of CO_2. These CERs can be traded and sold, and used by industrialized countries to meet a part of their emission reduction targets under the Kyoto Protocol. If not within the Kyoto framework, the credits are voluntary and do not need to prescribe to the CDM standard. Reductions can be part of a subscribed voluntary program, such as the Chicago Climate Exchange, in which members are legally bound to emissions reduction schedules. The protocols for such programs are terms as a Voluntary Carbon Standard (VCS), seeking to provide a credible but simple set of criteria that will provide integrity. Credits verified using the VCS result in voluntary emission reductions (VERs) that are independently verified and represent real, quantifiable, additional and permanent project-based emission reductions. In a regulatory framework or a cap and trade system, CERs are backed by a recognized framework and institutions, i.e. the UN for the Kyoto Protocol, to ensure that real greenhouse gas emission reductions take place, as well as providing a clear audit trail. In the US, the CCX is established as the largest voluntary market and for the CCX trading, these

VCSs are adequate. CCX standards and protocols are available for most types of emissions reductions or sequestration projects, but can be very specific in nature. CCAR Protocol is the newest of the three protocols available and although it is not as well established, it rapidly becoming accepted. In summary, a "carbon credit" does not always represent the same quantity or assurance of emissions reduction.

Marketing Carbon Credits In a regulatory framework of a cap and trade system, entities are held to emissions levels through the capping process to determine the allowable emissions for each entity (government institute, private company, or industrial facility). Caps can then be met by direct reductions or by buying offsets wherein another entity can show the reduced emissions. Through this mechanism, the most financially advantageous emissions reductions should result. In such a model, the trading is done in an open market to let market pressure determine the monetary value of the emissions reductions. In such a market, all emissions reductions must be 'equal' and thus the rigor of the CERs as noted above. In the Kyoto Protocol framework, the European Climate Exchange (ECX) is the market where the trading of carbon credits takes place. Trading can also occur directly between those supplying the emissions reductions and those needing the credits to meet their cap, but the CERs are still required.

In the voluntary market of the US, there is no set standard. Members of the CCX have voluntarily joined and followed the prescribed reductions schedules of the CCX. Under these schedules, members of Phase I and II have legally committed to reach 6% below their initial baseline from 2003 – 2010 (CCX, 2009). For projects that market VERs, the VCS protocols are adequate and generally used. VERs can also be marketed directly to parties interested in offsetting their carbon emissions, such as business travel. There are many entities marketing emissions reductions directly to 'consumers' (Ecobusinesslinks, 2009). In such cases the consumers buying the offsets may be taken with marketing of such projects of tree plantings, but in reality there may be little or no credibility. In research by the Financial Times, the voluntary carbon credit business was filled with fraudulent activity and lacking verification using approved protocols (Fidler Harvey, 2007). In the same study, the regulated market was noted to hit $68 billion annually by the year 2010. Certainly there is value in carbon credits as this value is expected to increase.

Carbon Credit Values Projections for carbon credits range widely, and will certainly be driven by any cap and trade programs in the US. Many estimates have such legislation appearing in 2011 or 2012. In 2008, the discussion of the Warner Leiberman bill on a proposed cap and trade system in May-June 2008 caused a clear increase in the CCX market to over $7, more than $2 above the previous high, see Figure 2. The bill proposed a cap and trade program in place by 2012 and to curb US emissions by 50% by 2050; however, the bill was not passed by the Senate.

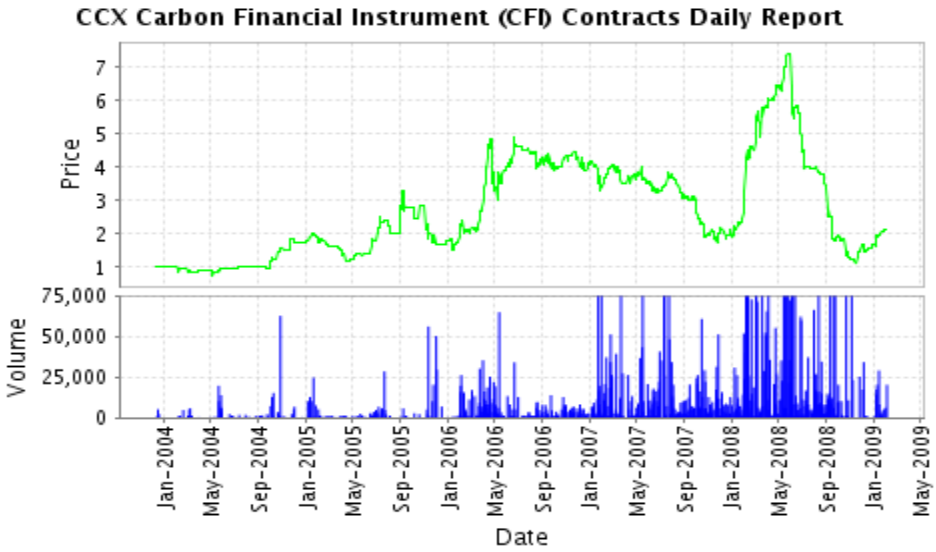

Figure 2 CCX prices for carbon credits showing a high during discussions of the Warner Leiberman bill (CCX.com).

Carbon Credit Revenues for the Troop I Project In this project, the revenue that can be generated over the life of the project will be modeled under a variety of scenarios, where electricity values ranges from 0.02 to 0.14 $/kWh, and where the carbon credit pricing ranges according to the projections shown in Figure 3. These projections were generated in collaborations with personnel at EcoSecurities, a carbon credit brokerage firm, as part of a project on the financial benefit of using livestock waste digestion to produce methane and subsequently electricity (Grover, 2008). Many estimates are that carbon credit prices will initially be listed at $10 – 15 when allocations are initially set, should cap and trade legislation be in place by around 2012. While this is a highly volatile market and not yet well understood, the projections cover almost all scenarios we have investigated, short of no climate change action by the US, or carbon credits hitting the extremes of existing projections, which were above $60.

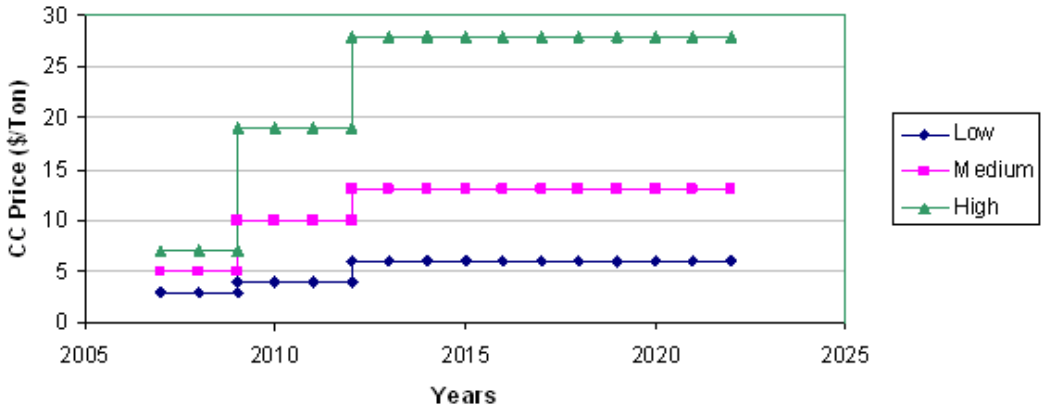

Figure 3 Carbon Credit projection scenarios based upon a variety of actions proposed at the federal and state level. (Grover 2008)

In projecting the carbon credits generated in this project, the CCX emission factors will be utilized (Boyt, 2007). Currently, the emissions factors for this region of the country are 0.68 tonnes CO_2/MWh. Based upon the estimated electricity generation of 22,800 kWh annually, estimates are that approximately 15 tonnes of carbon credits will be generated, representing $100 – $320 annually for the range of carbon emissions anticipated.

The electricity produced is estimated at a value of $1,400 to $2,700 annually for the range of electricity rates expected during the payback period of this project. Overall, electricity offsets represent about 90% of the estimated financial benefit of the renewable energy project. These projections are conservative in estimations and once a reasonable data set of energy production is available (typically 6-12 months), a true evaluation of the carbon credit revenue potential can be fully completed.

ACKNOWLEDGEMENTS

This project was funded by the Missouri Office of Administration Division of Facility Management, Design, and Construction. The authors would like to acknowledge the contributions of may that assisted with this project. Numerous staff at Rolla Municipal Utilities, Missouri State Highway Patrol Troop I headquarters, Missouri S&T were all instrumental in assisting to complete administrative paper trail and physical installation of this system is astonishingly rapid fashion for a project with so many entities involved. We also thank Missouri S&T student Sarah Seigfried for commentary and input on the carbon credit mechanisms.

DRIVE FOR ZERO NET CARBON IMPACT

Presented By: Jessica Lamb & Ashlynn Horras
In association with Luke Fencl, Courtney Warren, and Sebastian Medina

Today we are challenged with increasing concerns over global climate change, dependency on depleting hydrocarbon forms of energy, the growing scarcity of water resources to support quality of life infrastructure, and sustainability of infrastructure development on natural resources under current technologies and practices. Our future depends upon the development and commercialization of technologies in the field of renewable energy sources for cogeneration or combined heat and power (CHP). These renewable sources could include biomass, biogas, synfuels, and solar power.

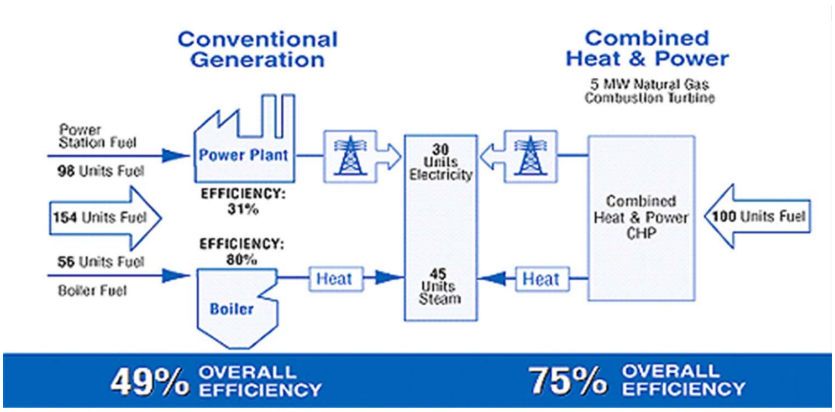
CONSUMER/GOVERNMENTAL POSITIONS

There is no doubt that the way society views the environment is changing. Seventy-six percent of Americans believe it is important that their electric utility offers power produced from renewable sources. Fifty-six percent felt it was so essential that they would pay a small fee to cover the cost of energy generated from renewable sources. Forty-two percent of Americans can now name at least one form of renewable energy, whereas only 20% of Americans could do this last year.'

An MRA commissioned survey of key clients shows that utilities believe that a cap and trade system and a federal Renewable Portfolio Standards (RPS) mandate are inevitable and the clients are correct.[2] The government will play a major role in how the industry interacts with the environment in the near future. It's nearly certain governmental restrictions on greenhouse gas emissions will become more severe. President Barack Obama proposed a market-based cap and trade system in efforts to reduce greenhouse gas emission significantly by 2050. President Obama aims to reduce greenhouse gas emissions 80% by 2050. This means that in the near future, greenhouse gases such as carbon and methane will actually be worth money — to simply allow them to enter the atmosphere as waste heat will essentially be burning money. However, when these gases are sequestered and used to make a process self sufficient, a profit can be realized. President Obama also campaigned on the promise to invest in a new digital utility grid to accommodate current and future energy requirements as well as incentives for research and development of the next generation of renew-able energy technologies.

Energy in the U.S. costs on average $0.089/kWh in 2008. However, if energy prices rise according to the current trend, electricity could cost nearly $0.50/kWh by 2050, an increase of more than 500%.[3] Natural gas prices follow an even steeper climb. Natural gas prices have more than doubled this decade from $5.77 per 1000 ft^3 at the beginning of 2000 to $13.23 per 1000 ft^3 in May of this year.[4]

With consumers quickly becoming aware of climate change, the increase of oil based energy costs would open the market up for renewables. As soon as gas prices surpass the cost of renewables, the economic drawback would no longer exist. The social and environmental incentives would place green technologies as a high priority.



WHAT IS CHP?

The production of combined heat and power (CHP) uses one source of fuel to generate power and thermal heat— CHP is more efficient and cleaner than utilizing conventional generation.

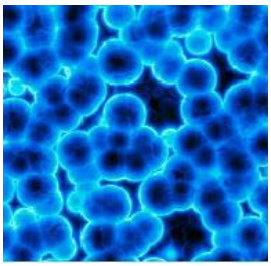
What differentiates CHP from conventional generation is the use of waste heat. On average, fossil-fueled power plants lose two-thirds of their energy in the form of waste heat. The release of this heat contributes to global warming, caused by gases such as carbon dioxide (C02) and air pollutants like nitrogen oxides (NOx) and sulfur dioxide (S02) being emitted into the air. However, CHP systems implement waste heat recovery technologies to capture large quantities of the heat and, because of this, achieve efficiencies of 60%-80% for producing electrical and thermal energy. This is what makes cogeneration a great application. Instead of releasing waste heat and its intrinsic greenhouse gases, which are likely to have a dollar value soon, the heat is reused to create a sustainable process. The higher efficiencies of CHP systems translates into: lower operating costs, reduced emissions of all pollutants, increased reliability and power quality, and reduced grid congestion and avoided distribution losses.

Because there are many technologies that may be employed to generate CHP, the site-specific efficiency can only be determined once the technologies are installed. The system's efficiency actually depends on the technology used to generate heat and power. However, six commonly installed technologies which provide rather standard ranges of achievable efficiencies are:

- Steam Turbine: 80%
- Diesel Engine: 70-80%
- Natural Gas Engine: 70-80%
- Gas Turbine: 70-75%
- Microturbine: 65-75%
- Fuel Cell: 65-80%

One of the many economic benefits to utilizing CHP is that it can offer stability in opposition to unstable energy prices by allowing the user to supply its own power during times when electricity prices are very high.

CHP & RENEWABLE ENERGY



Wastewater treatment plants have specific needs for heat and power, making them a perfect candidate for CHP. Heat can be used for anaerobic digesters, building heating, and cleaning solutions for membranes. Power is required for pumping, compressed air, blowers, UV treatment, ozone generators, instrumentation, and varying process equipment.

The concept behind cogeneration is to provide reliable, efficient, environmentally responsible energy sources. When looking at renewables, five major categories exist: wind, hydropower, geothermal, solar and biomass. Wind and hydropower lack direct applications of heat, while geothermal would involve specific location requirements.

Waste production must be kept at a minimum, and energy production should be lower than retail cost. Furthermore, contaminants must be eliminated for public health. Our criteria of meeting the Triple Bottom Line led us to focus on biogas, biomass, concentrated solar power, and microbial fuel cells. These produce power along with utilizing waste either in the form of heat or sludge.

BIOGAS

Biogas is a naturally occurring byproduct from wastewater treatment. Microbial organisms break down the organic matter in the water during anaerobic digestion; this process releases biogas. With methane as its main component, biogas has the potential to run in current natural gas engines, making it a prime candidate for renewables and CHP. However, due to the sensitivity of the equipment, contaminants must be removed before combustion. The three main contaminants plaguing biogas usage are carbon dioxide (C02), hydrogen sulfide (H2S), and siloxanes.[5] C02 is the other major gaseous component of biogas. C02 decreases the BTU capacity of the gas, lowering the methane concentration. H2S is highly reactive acid which can corrode and eventually destroy equipment when in contact with moisture. Also, there exists a maximum workplace concentration of H2S of 5 ppm in order to avoid toxic levels. Emerging around 2000 siloxanes are a new contaminant in biogas. Siloxanes oxidize to form silicon dioxide during combustion, creating deposits in piping and engines. When left untreated, siloxanes can damage equipment to the point of needing replacement after a couple of months of usage. Furthermore, if siloxanes were to be added to the CAA's partic-ulate list, the EPA would require cleaning, even with flaring. In order to use in engines, treatment of all three contaminants is suggested. For the possibility of selling back to the natural gas pipeline, all three must be treated.

CLEANING

In keeping with the mission statement, cleaning processes were examined by eco-friendly standards while making sure waste is kept to a minimum. Current treatment options often contain a media which the gas passes through or expensive chemical processes which need to be continually fed. This fails the criteria of waste reducing, considering the media has to be disposed of and replaced on a regular basis. We opted for a biological solution, which eliminates the need for expense chemicals while providing an environmentally responsible solution.

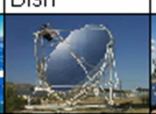
Biogas provides a solution to the rising consumer concern over climate change…

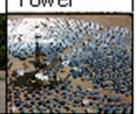
For the treatment of C02, water scrubbing is recommended. This is based on C02 being more soluble in water than methane. The water absorbs the C02, leaving behind a higher concentration of methane.[5] This is a fairly tested treatment option and could be implemented immediately. A biological solution is recommended for H2S. Thiobacillus, a chemtroph, has been found to use carbon and energy produced from the oxidation of H2S to grow new cells.[7] This meets the requirement of a green solution along with minimal waste. However, the technology is untested and in the early stages of development. Investment in research and development is suggested to obtain concrete evidence and implementation requirements. For siloxanes, chilling prior to cleaning is recommended.

Chilling to -40°C removes up to 90% of the siloxanes along with moisture in the gas.[5] This can be achieved through trigeneration, in which excess heat from the engines is used as an absorption chiller by evaporating a refrigerant to create a cool sink. This is CHP at the next level, using heat, instead of intensive electricity consumption, for power. To treat the remaining siloxanes, a molecular sieve by ATF is suggested. A pilot plant of trigeneration combined with a molecular sieve is recommended. Additionally, studies have indicated that siloxanes, like H2S, may be able to be broken down by bacteria.[8] Investment in research and development on the effectiveness of varying bacterium is recommended.

BIOMASS & SYNFUELS

Non-gasified bio-mass as a renewable energy source for cogeneration includes limited options. However, one application for biomass as a renewable CHP source is through a process called fast pyrolysis. The biomass used for fast pyrolysis could include domestic refuse, sludge, wood-chips, or feedstock. This can allow for the reuse of valuable carbon and methane gas to produce another fuel as opposed to flaring and releasing waste heat. Fast pyrolysis is the chemical decomposition of organic material induced by heat in the absence of oxygen. This process is exemplified by its short residence time, usually 0.5 seconds - 2.0 seconds. This is what differentiates pyrolysis from gasification, which has a much longer residence time.





The pyrolysis process will produce combustible gases such as carbon monoxide, hydrogen, methane, and other hydrocarbons. Theses gases will condense to liquid form and will have produced oil/char and contaminated water, which will require particulates to be removed by equipment such as fabric filters or wet scrubbers. The oil from pyrolysis is showing promising signs of being an effective substitute for petroleum. There have been successful demonstrations that show pyrolysis oil can be fired in boilers to produce a suitable amount of steam for the demonstration. As with any emerging technology, there are a few limitations. Due to rapid heating, the biomass must be ground into fine particles and contain extremely low moisture content. Correcting these drawbacks may simply raise the treatment costs at specific sites. Nevertheless, this is an up-and-coming technology that is showing promising signs.

CONCENTRATED SOLAR POWER

Solar technology has long had great public perception. The sun is an infinite and powerful source of energy and has been researched for decades. Concentrated solar power (CSP) works similarly to the photovoltaic cells most people are familiar with. CSP is different in that it concentrates the solar rays using mirrors or lenses to achieve maximum solar efficiency.

There are five main types of CSP listed in the table. The table also includes basic information and specifications for each type to be used for comparison.

After evaluating the specifications of each type of CSP technology, it is clear that two of the five suit the

	Parabolic Trough	Parabolic Dish	Linear Fresnel	Concentrated Photovoltaics	Power Tower
Example					
Capital Costs	$4,200/kW	$6,000/kW	$3,400/kW	$7,500/kW	$4,500/kW
Minimum required footprint	580 acres	0.165 acres	900 acres	0.140 acres	520 acres
Power Output	100 MW	25 kW & up	200 MW	25 kW & up	50 MW
Operating Costs	$58/kW/year	$56/kW/year	NA	NA	$56/kW/year
Storage Capabilities	None at small size	None currently	None currently	None currently	6 hours

needs of water or wastewater treatment plants. Water is costly to pump long distances and because of this, treatment plants are located near concentrations of people. Hundreds of acres are simply not available in an urban or suburban area. For that reason, only the Parabolic Dish and Concentrated Photovoltaic (CPV) technologies are suitable. Another benefit of the Parabolic Dish and CPV technologies is that they can be scaled up or down to meet the needs of each unique plant.

Neither of these technologies have been established in a long-term solution. The Parabolic Dish technology needs to be mass-produced, to improve upon reliability issues, and tested with high-wind conditions before it becomes a standard solution with cogeneration. CPV has fewer issues, but still needs to show long-term proof before it is standardized.

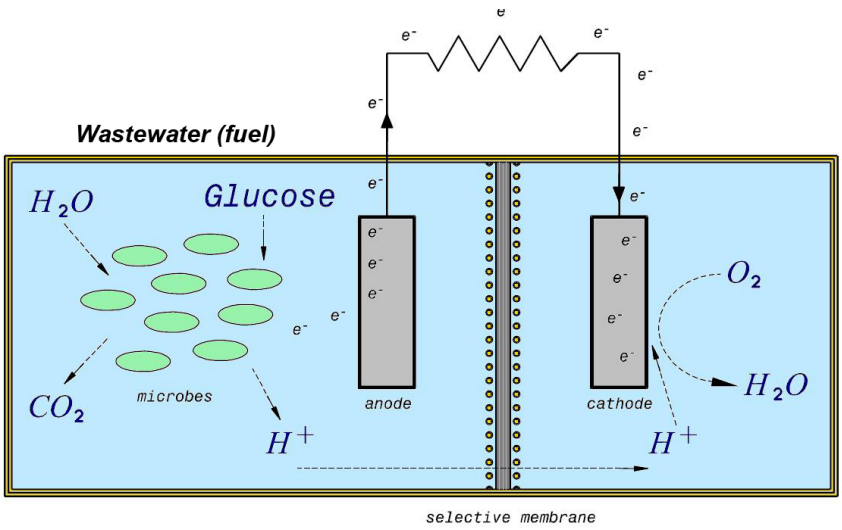
Another issue to keep in mind with CSP is that it requires direct sunlight, as opposed to reflected sunlight. Because storage technologies are not currently viable, CSP must be used in conjunction with one or more base load sources. Even so, solar power has the potential to greatly lessen the cost of powering a water treatment plant.

The use of solar power is both environmentally and economically beneficial. The two smaller CSP technologies listed above can provide free energy with little or no maintenance costs, no fuel costs, and no transportation costs after capital investment, in addition, the use of solar energy generates no carbon emissions, a factor that will become pivotal when Carbon Trading becomes a reality.

FUEL CELLS

A fuel cell is an electrochemical conversion device that produces electricity from fuel (on the anode side) and an oxidant (on the cathode side), which react in the presence of an electrolyte. The reactants flow into the cell, and the reaction products flow out of it, while the electrolyte remains within it. Fuel cells can operate virtually continuously as long as the necessary flows are maintained.

This fascinating technology has been around and under research for over 100 years. Chemical fuel cells are extremely expensive due to requiring catalysts to speed up the reaction and increase efficiencies. This catalyst is usually platinum or nickel. Another problem facing chemical fuel cells is extremely high operation temperatures, which eventually damage the device, resulting in constant maintenance.



One type of genuine fuel cell that has long-term potential is the microbial fuel cell (MFC). Unlike other fuel cells, which use hydrogen, methanol or ethanol as a fuel, MFC uses bacteria to generate electricity by converting bio-chemical energy into electrical energy. In other words, microbial fuel cells operate on waste. As the bacteria consume the pollutants, they shed electrons, which flow through a circuit and generate electricity. In the process, pollutants are broken down, with the sole byproduct of clean water.

With constant inquiries done at Penn State, Washington University in St. Louis and Ghen University (Belgium), research groups found varying efficiency results. The device's maximum system power generation depends on the electron donor substrates. In similar MFC systems, 494 mW/m^2 was produced with glucose" and 506 mW/m^2 with acetate[72], but only 305 mW/m^2 was achieved with butyrate", 261 mW/m^2 with swine wastewater", and 146 mW/m^2 with domestic waste-water". However, just like chemical fuel cells, microbial fuel cells could be stacked in order to meet the required operating voltage.

Energy recovery from wastewater is the next step towards sustainability. An MFC would be used in a treatment system as a replacement for the existing energy-demanding bioreactor (such as an activated sludge system), resulting in a net energy-producing system. However, it is not yet clear how to economically scale up an MFC or what the costs would be to replace a conventional system with an MFC-based design. Scale-up and materials issues are the greatest challenges in applying MFCs for wastewater treatment.

In the U.S., approximately 4% of the electricity produced is used for the operation of the whole water and wastewater infrastructure[75]. A treatment system based on an MFC provides a great opportunity to develop the technology, because the substrate is "free" and wastewater must be treated. At a modern treatment plant, the wastewater may contain 9.3 times as much energy as is used to treat it[6].

MFCs represent a promising technology for renewable energy production; their most likely near-term applications are as a method of simultaneous waste-water treatment and electricity production. However, a great amount of research has proved they can be further utilized in other specialized applications as well—for example, as power sources for environmental sensors and environmental bioremediation. With modifications, MFC technologies could find applications ranging from H_2 production to renewable energy production from agricultural biomass.

MICROBIAL FUEL CELL

The Penn State research group is now ready to begin the phase of demonstrating pilot-scale prototypes. Even though it is too early to predict the price of this apparatus in commercial applications, MFCs are rapidly evolving technologies that will fascinate scientists and engineers who are challenged with waste technologies and energy production in the coming decades.

ABSTRACT

EPA implemented new regulations for confined animal feeding operations in 2003. They were revised in 2008 based upon a court decision. Many confined feeding operations above a certain size are required to obtain a NPDES permit under the Clean Water Act. The 40 Code of Federal Regulations Part 122, Section 122.23 describes the permitting requirements for confined animal feeding operations. The paper discusses the main points of the regulations along with some of the challenges in nutrient management planning.

INTRODUCTION

In February of 2003, EPA issued revised Clean Water Act (CWA) permitting requirements and effluent limitations for confined animal feeding operations (CAFOs). These were the first revisions to the CWA for CAFOs since it was passed in 1972. In February 2005, the Second Circuit Court of Appeals issued its decision in the Waterkeeper Alliance versus EPA regarding legal challenges to the 2003 rule. The court directed EPA to remove the requirement for all CAFOs to apply for National Pollutant Discharge Elimination System (NPDES) permits and added requirements for Nutrient Management Plans (NMPs). EPA published rules in June 2006 and March 2008 describing how they would address the Second Circuit Court of Appeals decision (EPA, 2008).

In the 2003 rule, all CAFOs were required to apply for NPDES permits. The revised rule instead requires only those CAFOs that discharge or propose to discharge to apply for a permit. In the discussion of the revised rule, EPA further clarifies how operators should evaluate whether they discharge or propose to discharge. A CAFO owner or operator can determine on a case by case basis as to whether the CAFO does or will discharge from its production area or land application site based upon an objective assessment of the CAFO's design, construction, operation and maintenance. The final rule also provides for a voluntary no discharge certification option for CAFOs that do not discharge or propose to discharge.

The revised rule requires CAFO operators to submit NMPs along with their NPDES permit application. CAFO operators were already required to develop and implement NMPs under the 2003 rule, but they could be done after the NPDES permit was granted. In the new rule EPA removed the provision that allowed new source swine, poultry and veal calf CAFOs to use containment structures designed for a 100-year, 24-hour storm to fulfill the no discharge requirement. Such CAFOs may now meet the no discharge requirement with site-specific best management practice effluent limitations.

CODE OF FEDERAL REGULATIONS APPLIED TO CAFOs

The Title 40 of the Code of Federal Regulations (CFR) is the 'Protection of the Environment' that includes federal requirements of environmental control. The 40 CFR Part 122 provides the requirements of the EPA NPDES permit program and the implementation by various states is conducted through the requirements of 40 CFR Part 123.

The 40 CFR Part 122, Section 122.23 includes the permitting requirements of CAFOs and the 40 CFR Part 412 provides the effluent guidelines and standards of the CAFO point source category agricultural livestock operations. The animal feeding operation (AFO) is defined as "a lot or facility (other than an aquatic animal production facility) where animals (other than aquatic animals) have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period, and crops, vegetation, forage growth, or post-harvest residues are not sustained in the normal growing season over any portion of the lot or facility." The CAFO is an AFO defined as large, medium, or small based upon a specified number of animals housed at the operation. The agricultural activities related to CAFOs are included in the Table 1 along with the applicable Standard Industrial Classification (SIC) and North American Industry Classification System (NAICS) codes, and the specified sizes of CAFOs are shown in Table 2.

The standard industrial classification identified in Table 1 is not comprehensive, however, the CAFO facilities must review the rule applicability criteria under the 40 CFR Section 122.23. A CAFO that is not a large or medium size as included in the Table 2 above is designated as a 'small CAFO'. The EPA and/or the states that are delegated by the EPA will review and make the CAFO designations and depending on wastewater or process water pollutants contributing to the impairment of waters of the United States.

A NPDES permit would be required by an owner or operator of a CAFO as defined above that discharges or proposed (or potential) to discharge wastewater from the production or land application area, and are point sources. A factual objective assessment on the CAFO is needed of its design, construction, operation, and maintenance, to see whether a wastewater discharge will be possible. As defined in 40 CFR Section 122.23, a CAFO may be identified for one group of livestock operation but, however, the NPDES requirements will be applicable to all animals and manure, litter, and process wastewater caused by those animals of that confinement. Additionally, the 'land application area' is also defined by the rule as land that could be owned, rented or

leased by the owner or operator for application of manure, litter, or process wastewater from the CAFO. Thus, the owner or operator of the CAFO shall apply for a NPDES permit, or submit a notice of intent to cover their operation under a general permit category if one can be issued by the regulating agency and, if not, a NPDES permit application must be applied and the permit shall be obtained.

Table 1. The regulated CAFO entities and their NAICS and SIC codes as included in 40 CFR Section 122.23 (Federal Register, 2008).

Regulated CAFO Entity	NAICS	SIC
Beef cattle feedlots including veal calves)	112112	0211
Beef cattle ranching and farming	112111	0212
Hogs (Swine)	11221	0213
Sheep and Goats	11241, 11242	0214
General livestock except dairy and poultry	11299	0219
Dairy farms	11212	0241
Broilers, fryers, and roaster chickens	11232	0251
Chicken eggs	11231	0252
Turkey and turkey eggs	11233	0253
Poultry hatcheries	11234	0254
Poultry and eggs	11239	0259
Ducks	11239	0259
Horses and other equines	11292	0272

Table 2. The regulated CAFOs and their defined sizes of operation (GCS, 2009).

CAFO	Large	Medium
Mature dairy cows, whether milked or dry	700	200-699
Veal calves	1,000	300-999
Cattle other than mature dairy cows or veal calves (and is not limited to heifers, steers, bulls, and cow/calf pairs)	1,000	300-999
Swine each weighing 25 kg or more	2,500	750-2,499
Swine each weighing less than 25 kg	10,000	3,000-9,999
Horses	500	150-499
Sheep or lambs	10,000	3,000-9,999
Turkeys	55,000	16,500-54,999
Laying hens or broilers (AFO using a liquid manure handling system)	30,000	9,000-29,999
Chickens (other than laying hens) (AFO using other than a liquid manure handling system)	125,000	37,500-124,999
Laying hens (AFO using other than a liquid manure handling system)	82,000	25,000-81,999
Ducks (AFO using a liquid manure handling system)	5,000	1,500-4,999
Ducks (AFO using other than a liquid manure handling system)	30,000	10,000-29,999

The 'process wastewater' is defined as "water directly or indirectly used in the operation of the AFO for any or all of the following: spillage or overflow from animal or poultry watering systems; washing, cleaning, or flushing pens, barns, manure pits, or other AFO facilities; direct contact swimming, washing, or spray cooling of animals; or dust control. Process wastewater also includes any water which comes into contact with any raw materials, products, or byproducts including manure, litter, feed, milk, eggs, or bedding." The 'production area' is defined as "that part of an AFO that includes the animal confinement area, the manure storage area, the raw materials storage area, and the waste containment areas. The animal confinement area includes but is not limited to open lots, housed lots, feedlots, confinement houses, stall barns, free stall barns, milkrooms, milking centers, cowyards, barnyards, medication pens, walkers, animal walkways, and stables. The manure storage area includes but is not limited to lagoons, runoff ponds, storage sheds, stockpiles, under house or pit storages, liquid impoundments, static piles, and composting piles. The raw materials storage area includes but is not limited to feed silos, silage bunkers, and bedding materials. The waste containment area includes but is not limited to settling basins, and areas within berms and diversions which separate uncontaminated storm water. Also included in the definition of production area is any egg washing or egg processing facility, and any area used in the storage, handling, treatment, or disposal of mortalities."

The NPDES permit application and its contents requirements are included in the 40 CFR Part 122 Section 122.21. The applications of CAFOs must complete the Form 2B, in addition to completion of other required forms and data submission(s). As per the requirements of 40 CFR Section 122.21(i), the application shall contain: name of the owner or operator; facility location and addresses; latitude and longitude of the production area (including the entrance to production area); topographic map showing the location of production area(s); specific data on the number and type of animals; type(s) of containment and storage and total capacity for manure, litter, and process wastewater storage (tons/gallons); total number of acres available for land application of manure, litter, or process wastewater; estimated amounts of manure, litter, and process wastewater generated per year (tons/gallons); estimated amounts of manure, litter, and process wastewater transferred to other persons per year (tons/gallons); and, a certification that a 'nutrient management plan (NMP)' is completed and will be implemented by the effective date of the NPDES permit-issuance (GCS, 2009).

As the NPDES permit application requirements of CAFOs are included in the 40 CFR Section 122.23, the process wastewater effluent guidelines and standards are included in the 40 CFR Part 412 – CAFOs Point Source Category. However, a CAFO that discharges process wastewater to publicly owned treatment works (POTW) will need to comply with the requirements of 40 CFR Part 403 – General Pretreatment Regulations for Existing and New Sources of Pollution. The 40 CFR Part 412, Subparts A, B, C, and D, include the applicable best practicable control technology currently available (BPT), best control technology for conventional pollutants (BCT), best available control technology economically achievable (BAT), new source performance standards (NSPS), and pretreatment standards for new sources (PSNS) to: horses and sheep, ducks, dairy cows and cattle other than veal calves, and swine, poultry, and veal calves, respectively.

The BPT, BAT, and NSPS limitations are applicable to 'large' CAFOs. The 40 CFR Section 412.4 provides the requirements of best management practices (BMPs) for land application of manure and, however, these requirements are applicable to dairy and beef cattle other than veal calves (Subpart C), and swine, poultry, and veal calves (Subpart D) CAFOs (GCS, 2009).

The NMP shall be prepared based on the applicable requirements of 40 CFR Sections 122.42(e) and 412.4(c). The NPDES permit for any CAFO will include a NMP with the BMPs and the operational measurements toward complying with the applicable process wastewater effluent limitations and standards. The permitted CAFOs shall have the NMPs developed and implemented by February 27, 2009. All new CAFOs or CAFOs that apply for a NPDES permit after February 27, 2009, shall have a NMP developed and implemented by the effective date of the permit. The NMP shall be prepared "based on a field-specific assessment of the potential for nitrogen and phosphorus transport from the field and that addresses the form, source, amount, timing, and method of application of nutrients on each field to achieve realistic production goals, while minimizing nitrogen and phosphorus movement to surface waters" (GCS, 2009).

The application rates for manure, litter, and process wastewater applied to land must minimize phosphorus and nitrogen transport to surface waters as per the applicable and identified technical standards, and those technical standards of nutrient management shall include a field-specific assessment of the potential for nitrogen and phosphorus transport, the methodology of nutrient management to comply with the applicable standards, such as multi-year application of phosphorus on fields that will not play a significant role in the phosphorus runoff to surface water, and phased implementation of phosphorus-based nutrient management, etc., as required. The manure, at a minimum, needs to be analyzed once annually for nitrogen and phosphorus content, and the soil analyzed once every five years for phosphorus content. The results of these annual manure and soil analyses need to be used in the determination of manure, litter, and process wastewater land application rates. The equipment used for land application of manure, litter, and process wastewater must periodically be inspected for leaks and as needed. A setback of 30.5 m need to be observed between the manure, litter, and process wastewater land application, and surface waters to possible conduits to surface waters, such as, open tile line intake structures, sinkholes, and agricultural well heads. As an alternative, the CAFO may use a setback of 30.5 m with a 10.7 m wide vegetated buffer, "a narrow, permanent strip of dense perennial vegetation established parallel to the contours of and perpendicular to the dominant slope of the field for the purposes of slowing water runoff, enhancing water infiltration, and minimizing the risk of any potential nutrients or pollutants from leaving the field and reaching surface waters, where applications of manure, litter, or process wastewater are prohibited." However, additionally, if possible, as a compliance alternative, the owner or operator of the CAFO can demonstrate to the regulator that a setback or buffer is not required and the alternative conservation practice or characteristics of the field of land application provides pollutant reductions equivalent or better than the usage of 30.5 m setback (GCS, 2006).

APPLICABLE REQUIREMENTS FOR HORSES, SHEEP, AND DUCK CAFOs

For horses and sheep CAFOs, except for the applicable NPDES stormwater discharge requirements, the existing point sources shall not discharge any process waste to navigable waters. However, the process waste may be discharged to navigable or the U.S. waters via overflows caused by the 10-year, 24-hour rainfall event for the geographic location of CAFO (Ref. 40 CFR Sections 412.12, 412.13, and 412.15) (GCS, 2009).

For ducks, the existing dry and wet lot operations shall comply with the BOD5 and fecal coliform BPT limits of maximum daily of 1.66 kilograms per 1,000 ducks and a maximum monthly average of 0.91 kilogram per 1,000 ducks, and 400 MPN per 100 mL at any time, respectively. As per the NSPS requirement, any new source shall not discharge process wastewaters to U.S. waters; however, the process wastewater may be discharged to navigable or the U.S. waters via overflows caused by the 25-year, 24-hour rainfall event for the geographic location of CAFO (Ref. 40 CFR Section 412.25). The PSNS requirement is that no discharge of process wastewater to a POTW; however, the process wastewater may be discharged to a POTW via overflows caused by the 25-year, 24-hour rainfall event for the geographic location of CAFO (Ref. 40 CFR Section 412.26) (GCS, 2009).

APPLICABLE REQUIREMENTS FOR DAIRY COWS AND CATTLE CAFOs

The BPT limits require the existing point sources of no discharge of manure, litter, or process wastewater to U.S. waters. However, an overflow of manure, litter, or process wastewater may overflow to U.S. waters via the runoff and the direct precipitation from a 25-year, 24-hour rainfall event. But the production area need to be operated as per the additional measures and records maintained under 40 CFR Section 412.37(a) and (b) – *visual daily and weekly inspections* of water lines and stormwater facilities, and manure, litter, and process wastewater impoundments and containment structures; and usage of *depth markers* indicating the minimum capacity necessary to contain the runoff and direct precipitation of the 25-year, 24-hour rainfall event, and 100-year, 24-hour rainfall event in the case of new sources. However, the CAFO can also request 'voluntary alternative performance standards' that could be useful based on site-specific alternative technologies and duly submitting the supporting information (as included in 40 CFR Section 412.31(a)(2)(i)) and for land application areas (40 CFR Section 412.31(b). The applicable BCT and BAT limits of this CAFO production and land application areas are the same as BPT requirements under 40 CFR Sections 412.31(a) and (b). The NSPS requirements of *new sources* are also same as the BPT, BCT, and BAT, except that the applicable discharge limits and permit requirements shall be attained by the effective date of the CAFO NPDES permit. And the new sources commenced between April 14, 1993, and April 14, 2003, must comply with the BPT standards of 40 CFR Sections 412.31(a) and (b), after the completion of compliance period as required by the 40 CFR Section 122.29(d)(1). The 'additional measures' for new sources (if the effluent limits of Swine, Poultry, and Veal Calves NSPS of 40 CFR Section 412.46(a)(1) are applicable) also include 'that all open surface manure storage structures shall include a *depth marker*

indicating the minimum capacity to contain the maximum runoff and direct precipitation with the design storm used for no discharge.' The animal mortalities of the CAFOs shall not be discharged to the liquid manure or process wastewater streams (40 CFR Section 412.37(a)(4)). Additional recordkeeping requirements are applicable for the production and land application areas and the records shall be maintained for five-years from the date of creation (40 CFR Sections 412.37(b) and (c)) (GCS, 2009).

APPLICABLE REQUIREMENTS FOR SWINE, POULTRY, AND VEAL CAFOs

The BPT, BCT, and BAT requirements of existing CAFOs production and land application areas are same as 40 CFR Sections 412.31(a) and (b) and discussed above except that the CAFO shall comply with the limits and requirements by February 27, 2009. The NSPS requirements of new sources are: no discharge of manure, litter, or process wastewater pollutants to U.S. waters; usage of BMP effluent limits based on site-specific evaluations of the entire CAFO production area; proper design and operation of open manure storage for rainy seasons and additional capacities for chronic rainfalls and the land application measures consistent to the NMP; evaluation toward the adequate capacity of the manure storage structure using the recent version of Soil Plant Air Water (SPAW) Hydrology Tool and 100-year local climate data, or usage of an approved technical evaluation based on site-specific data; and the additional measures as included under 40 CFR Sections 412.47(a) and (b) that are discussed in the above section and same as the 40 CFR Section 412.37(a) and (b). The new sources of CAFO land application areas shall comply with the limits and requirements same as BPT. However, the new sources shall comply with the permit limits and requirements from the effective date of the permit. And the new sources commenced between April 14, 1993, and April 14, 2003, must comply with the BPT standards of 40 CFR Sections 412.43(a) and (b), after the completion of compliance period as required by the 40 CFR Section 122.29(d)(1). Moreover, the new sources that are commenced wastewater discharging between April 14, 2003, and January 20, 2009, and have these NSPS applicable requirements shall continue to comply with the requirements for the duration of time as specified in 40 CFR 122.29(d)(1). The additional measures for the new sources are as discussed in the above section (Dairy Cows and cattle other than Veal calves) and as included under the 40 CFR Section 412.37(a) through (c) (GCS, 2009).

The Form 2B of the NPDES permit application is used for applying toward 'permit to discharge wastewater – concentrated animal feeding operations and aquatic animal production facilities.' This Form 2B requires: owner and/or operator and facility contact information; facility status – new or existing; type and number of livestock and operation; generation rates of manure, litter, and process wastewater; land application area, and transfer of waste to other facilities or persons; type of waste containment, storage, and capacity; details and status of the NMP; BMPs to be practiced; and a certification of details by the facility responsible person or official.

The requirements of the preparation and maintenance of a NMP are included in the 40 CFR Part 122 Section 122.42(e). Some of the requirements are new and effective as of December 22, 2008, besides the existing requirements promulgated by 2003 and

modified thereof. The NMP shall have the methodology, such as, the BMPs necessary to comply with the applicable waste discharge limits and standards, in compliance with the 40 CFR Parts 122 and 412 and applicable sections. Primarily, the NMP shall ensure: adequate storage and operation of manure, litter, and process wastewater facilities; proper management of animal mortalities; prevention of any contact of livestock with U.S. waters; proper selection and usage of chemicals and not discharged to manure, litter, or process wastewaters unless those chemicals are designed toward in the waste treatment; observation of buffer zones to control runoff; protocols for testing of the manure, litter, process wastewater, and soil; protocols for proper land application of manure, litter, and process wastewater toward a specific nutrient management practice; requirements of implementation and management of elements of NMP; record keeping requirements including transfer of waste to other parties; annual reporting requirements of CAFOs waste (manure, litter, and process wastewater) generation and land application acreage; certification of the NMP by a certified nutrient management planner; actual crop(s) planted and actual yield(s) for each field, and the amounts of nitrogen and phosphorus taken up by crops, for the previous 12-months; and compliance terms or requirements of the NMP with respect to the CAFOs NPDES permit, such as, land application rates of manure, litter, or process wastewater in a linear or narrative-rate approach. Any changes to the NMP shall be handled through the requirements of 40 CFR Section 122.42(e)(6) (GCS, 2009).

NUTRIENT MANAGEMENT PLANS

CAFOs are required to develop and implement a NMP. Manure is to be applied at rates that meet crop needs while avoiding over application that could lead to water quality degradation. The new regulations require that each field that receives manure be evaluated using a risk assessment method to determine the extent of risk of nitrogen and phosphorus losses from the field. The risk assessment methods vary from state to state. If the risk from phosphorus in runoff is low then manure application rates may be applied at nitrogen based agronomic rates. For phosphorus risk assessment the state may use the phosphorus index, soil phosphorus threshold or soil phosphorus test (Davis, 2003). The phosphorus index considers both transport and source factors. Producers may lower their index by changing manure application method or installing BMPs or changing the feed formulation. If phytase is added to swine or broiler feed the content of the phosphorus in the manure may be reduced from 25 to 30% (Sutton and Humenik, 2003). The soil phosphorus threshold level sets a threshold level for soil test phosphorus above which manure application must be stopped or the application rate is based on crop phosphorus removal rates. Delaware, Maryland and Pennsylvania require manure must be applied at phosphorus crop removal rates if the soil test high or very high in phosphorus. One of the challenges in nutrient management is interpreting the soil phosphorus test because different laboratories use different test methods and different extractants, which will give different results. The soil test phosphorus approach uses the standard fertilizer recommendations found in state agronomy guides for manure application that may generally be obtained through the Cooperative Extension Service. When the phosphorus recommendation is zero either no manure is applied or it is applied at rates that replace crop phosphorus removal.

In some states there is too much manure produced in some areas to be applied at agronomic nitrogen or phosphorus rates. When this happens, the manure has to be transported or alternative uses found for the manure. This problem can occur in certain areas of the Delmarva Peninsula for broiler litter. In response to this problem, both Delaware and Maryland have started programs for relocation of poultry manure. Delaware pays up to $0.11 per 1000 kg per km for raw manure with a cap of $18 per 1000 kg for raw manure and $0.049 per 1000 kg per km for processed manure. In 2007 the average cost was $10.65 per 1000 kg. . In 2001, when the program started 20.7 x 10^6 kg was relocated or went for alternative uses. In 2007, 84.8 x 10^6 kg was relocated or when to alternative uses. The challenge for Delaware and Maryland in a tough economic climate is to find money to pay for the program.

Some of the challenges Oregon (State CAFO Organization, 2009) is facing in their NMP regulations are:

- How do you train staff to review and enforce NMP requirements?
- Do you have an adequate tool to calculate application rates?
- What do you look for in inspections and how much staff time will they take.
- What are the requirements for land application during adverse weather conditions at permitted sites?
- Do you have a tool to determine when and what type of enforcement is appropriate?

FINANCIAL ASSISTANCE

The 2002 and now the 2008 Farm Bill offers several voluntary conservation programs producers can use to help comply with the new CAFO rules (Cohen et al., 2003). The largest program is the Environmental Quality Incentives Program (EQUIP). EQUIP pays up to 75% in cost share funds to assist producers in implementing conservation systems and addressing regulatory requirements. By statue, at least 60% of EQUIP financial assistance funds must be used for livestock and poultry operations. Fifteen states have the Agricultural Management Assistance Program (AMA) including Delaware, Maryland, Pennsylvania and New York. CAFO operators may use AMA funds to develop and implement NMPs. Other programs, such as, the Conservation Reserve Program, Conservation Reserve Enhancement Program, and Wetlands Reserve Program may also support CAFO operators to implement conservation programs.

CONCLUSIONS

In 2003, EPA implemented new permitting regulations for CAFOs. The regulations are meant to be more effective in protecting and restoring water quality than the original regulations implemented under the Clean water Act in the 1970s. Some CAFOs are exempt from obtaining a permit if they can prove they have no discharge. Along with the NPDES permit CAFO operations must also develop NMPs. In many areas land application rates for manure will be based upon phosphorus because the soil tests high in phosphorus or there is a great potential for runoff. Manure application rates based upon

phosphorus crop needs may present problems in some areas to find enough land to apply the manure. In these cases manure must be relocated or alternative uses found for it.

ABSTRACT

Water quality is an important factor for preservation of human life and aquatic ecosystem. In rivers, water quality is affected by the environment, climate condition, seasonal variation, land-use, natural and man-made pollution of watershed. Considering growth of water use for different consumptions and discharge of pollutions in rivers, several water quality parameters are usually monitored along rivers in different periods. However, there is a need to combine results of such measurements in the form of composite indices which are understandable to decision makers and general public. For this purpose, some indices for classification of water quality in rivers have been applied world wide recently. In this paper, two Water Quality Indices (i.e. National Science Foundation of the USA and Council of Ministers of Environment of Canada) were trialed for the case of Karun River system which is the most important river of Iran. These indices were calculated using existing data and their variations have been analyzed and compared in 9 stations, located along the river, for different periods. Results showed that application of these simplified indices was satisfactory for the educational case study and could be replicated for other communities in Iran.

Keywords: Water Quality, River, Water Quality Index, NSF WQI, CCME WQI

INTRODUCTION

Water quality is an important factor for preservation of human life and aquatic ecosystem. Even if water may be available in adequate quantities, its un-suitable quality limits the uses that can be made of it. Although the natural ecosystem is in harmony with natural water quality, any significant changes to water quality will usually be disruptive to the ecosystem (WHO, 1996).

Quality of surface water is affected by the environment, climate condition, seasonal variation, land-use, natural and man-made pollution of watershed. Considering growth of water use for different consumptions (e.g. domestic, agricultural, and industrial) and discharge of wastewaters in rivers, several water quality parameters are usually monitored along rivers in different periods. However, there is a need to combine results of such measurements in the form of composite indices which are understandable to political decision makers, non-technical water mangers and general public (Simoes, et al., 2008).

A number of indexes have been developed to summarize water quality data in an easily expressible and easily understood format (Sanchez, et al., 2007). A water quality index provides a convenient means of summarizing complex water quality data and facilitating its communication to a general audience. Furthermore, it provides a platform for comparison of the water quality among different sites with an ultimate view of classification of water quality in rivers.

National Sanitation Foundation of the USA developed the Water Quality Index (NSFWQI) in 1970. This standard method was used for quantifying and comparing water quality in various parts of that country. This index is the aggregate score of water quality parameters, commonly used by state regulatory agencies to provide general water quality descriptions (excellent, good, average, fair, poor).

The Canadian Council of Ministers of the Environment also developed a Water Quality Index (CCMEWQI).This simple tool has been devised as an alternative for traditional reports on water quality trends which typically consisted of variable-by-variable, water-body-by-water-body statistical summaries (CCME, 2001).

The objective of this paper is to assess the water quality in the Karun River system which is the most important river of Iran. In the absence of any local index, the NSF WQI as well as CCME WQI has been trailed for this purpose in the case study and results were compared with each other.

BACKGROUND & METHODOLOGY

The NSF Water Quality index comprises nine parameters. These are dissolved oxygen (DO), Fecal Coliform, pH, Biochemical Oxygen Demand (BOD), temperature, total phosphate, nitrates, turbidity and total solids. According to score of each parameter, a "Q-Value" is assigned to each parameter from figures or tables of test results. The weighted average of these values is introduced as the NSF WQI. This combined index can vary in the range of 0-100, 0 being "Very bad" and 100 as the "Excellent" (Willkes University , 2009).

The CCME Index incorporates three elements: Scope (F1) - the number of variables not meeting water quality objectives; Frequency (F2) - the number of times these objectives are not met; and Amplitude (F3)- the amount by which the objectives are not met. The CCME WQI is then calculated as:

$$CCME\ \ WQI = 100 - \frac{\sqrt{F_1^{\,2} + F_2^{\,2} + F_3^{\,2}}}{1.732} \tag{1}$$

The index produces a number between 0 (worst water quality) and 100 (best water quality). These numbers are divided into 5 descriptive categories to simplify presentation. The CCME WQI allows the index user to select the objective set on which to compare measured water quality. This is a design feature that increases the versatility of the index considerably but allows for misuse (CCME, 2001).

Table 1. Ranges of Water Quality Classification by NFS and CCME

NSF Water Quality Index		CCME Water Quality Index	
Range	**Quality**	**Range**	**Quality**
90-100	Excellent	95-100	Excellent
70-90	Good	80-94	Good
50-70	Medium	65-79	Fair
25-50	Bad	45-64	Marginal
0-25	Very bad	0-44	Poor

In the absence of any local index, the NSF WQI as well as CCME WQI has been trailed for Karun River System in Iran. Most of the existing data for calculation of these indices were collected form the Khuzestan Water and Power Authority (KWPA) and Iran Water Resources Management Company (IWRMC). A list of water quality parameters for calculation of CCME WQI for Karun River is given in Table 2. The Objectives, mentioned in this Table, were adopted from Krenkel and Novotny (1980).These indices were calculated using existing data and their variations have been analyzed and compared in 9 stations, located along the river, for different periods. For calculation of the CCME WQI, a spread sheet in EXCEL developed by CCME in 2001 was employed.

Table 2. List of water quality parameters for calculation of CCME WQI in Karun River

Parameter	Objective	Sampling Period	Parameter	Objective	Sampling Period
Dissolved Phosphorous Total (mg/L)	0.03	2002 - 2008	Total Lead (mg/L)	0.05	2006 - 2008
pH	6.5< >9	2002 - 2008	Dissolved Iron (mg/L)	1	2006 - 2008
Dissolved Oxygen (mg/L)	5	2002 - 2008	Total Zinc (mg/L)	0.1	2006 - 2008
Dissolved Nitrogen (mg/L)	20	2002 - 2008	Total Dissolved Solids (mg/L)	500	2002 - 2008
Fecal Coliforms No./100ml	200	2004 - 2008	Dissolved Sulphate (mg/L)	250	2002 - 2008
Dissolved Chloride (mg/L)	150	2002 - 2008	Dissolved Sodium (mg/L)	100	2002 - 2008

STUDY AREA

Karun River, located in South West of Iran, is the most important river of the country. Major projects have been constructed or are under construction on this river including five large dams with a total storage capacity of about 13 BCM (IWPCO, KWPA, 2008).

The flow rate of Karun river, measured at Ahwaz station, are 90 m^3/s in low water seasons, 2500 m^3/s high water season and about 5000 m^3/s in maximum floods

(AWWC, 2006). This River suffers from discharge of pollution loads from industrial, agricultural, agro-industrial and domestic sources. Increasing water withdrawal from and wastewater discharge to the river has endangered the aquatic life of this important ecosystem. Furthermore, the drinking and in-stream water quality standards have been violated in many instances. (Karamouz et al., 2008).

The Karun River System consists of Karun River and Dez River. This system feeds Khuzestan plain which is located down stream of Gotvand Dam. Figure 1 depicts the study the area between the Gotvand Dam and Khoramshahr City including 9 water quality monitoring stations (Table 3).

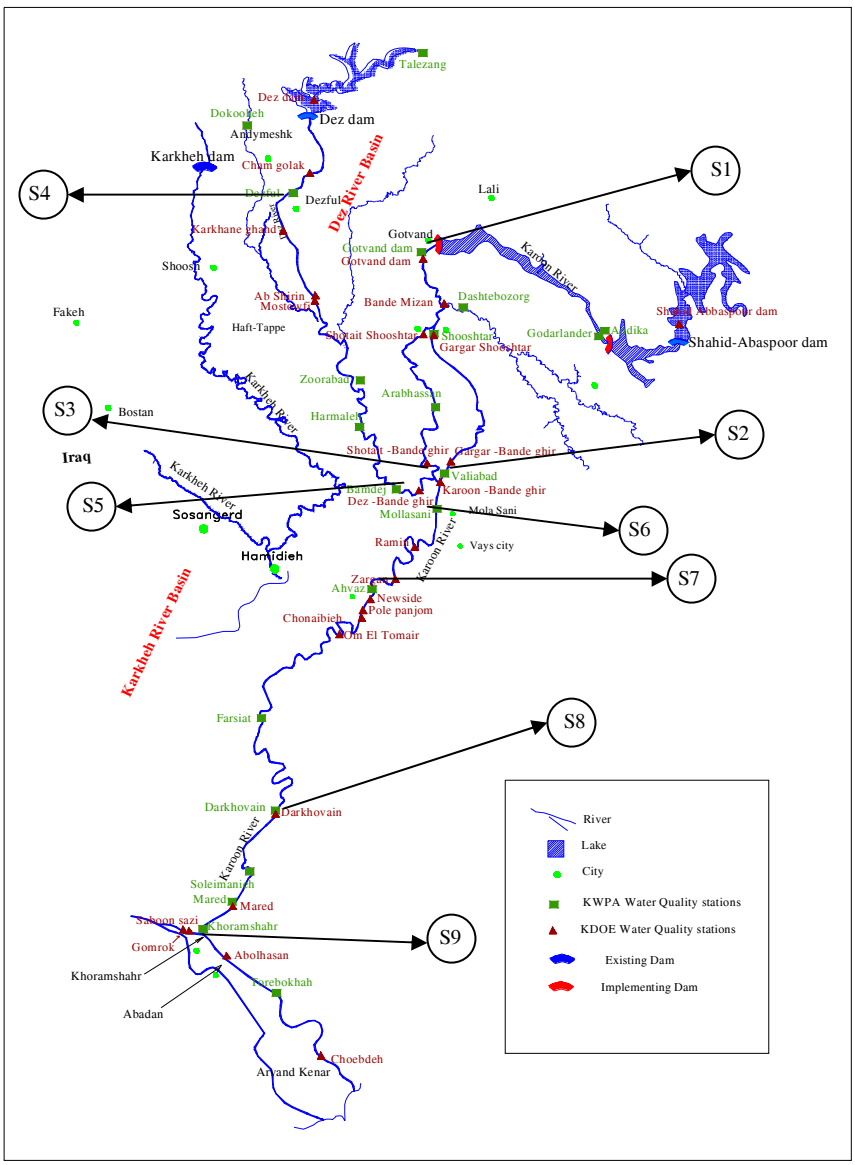

Figure 1. Karun River System (Karamouz et al. , 2008)

Table 3. Water Quality Monitoring Stations along Karun River System

Name of River	Name of Station	Code
Karun	Gotvand Dam	S1
GarGar	Valiabad	S2
Shotait	Bandeghir	S3
Dez	Dezful	S4
Dez	Bamdej	S5
Karun	Mollasani	S6
Karun	Ahvaz	S7
Karun	Darkhovain	S8
Karun	Khoramshahr	S9

RESULTS & DISCUSSION

In the Karun River, BOD, DO, Na, Cl parameters were found to be in an acceptable range, with respect to water quality criteria. The high value of Focal Coliform is an indication of un-treated wastewater discharge to this river. Furthermore, the TDS value is also considerably higher than the water quality criteria. This is attributed mostly to drainage of agricultural return flow and is to an extent stemmed from salinity of parts of the upper watershed.

Figure 2 depicts temporal variation of the CCME water quality index for 9 stations located along the Karun River system. The temporal trend lines of this index are found to be generally similar, despite their locations. Some minor discrepancies are attributed to missing data. Each line shows a rapid decline in the 2nd half of the study period which is classified as "Marginal" and "Poor". This is because of inclusion of heavy metal and Focal Coliform parameters data which has decreased the value of the index. Typically, the Water Quality Index decreased towards the downstream end of the Karun River. The lowest values were observed at Stations 2, 7 and 8 because of some local wastewater discharge and agricultural return flows. The Index at these stations is considered to be in "poor" category according to CCME classification. Further to decline of WQI in 2006-2007, a more rigor policy for the Karun River protection was enforced by the Department of Environment of Iran.

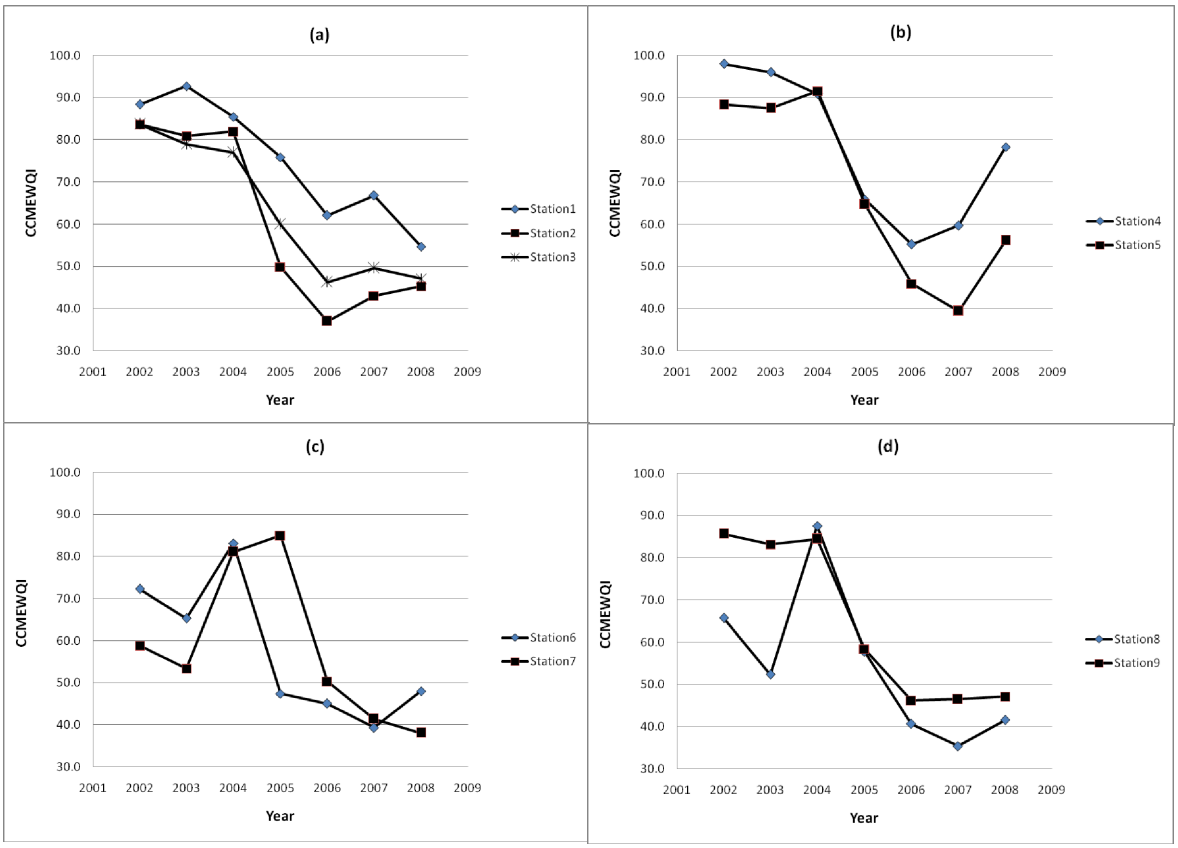

Figure 2. Spatial & temporal variation of CCME WQI for Karun River system

The NSF WQI was also calculated at the 9 stations along the Karun River for 2006-2008 and the results were plotted in Figure 3. This index did not vary significantly and therefore remained in the "Medium" category. A comparison of these results with the CCME WQI at a given station showed lower values for the latter frequently. This difference can be attributed to the fact that NSF WQI does not include heavy metals and divergence of parameters and method of calculation. Therefore, the range of classification of WQI for NSF and CCME differs with each other.

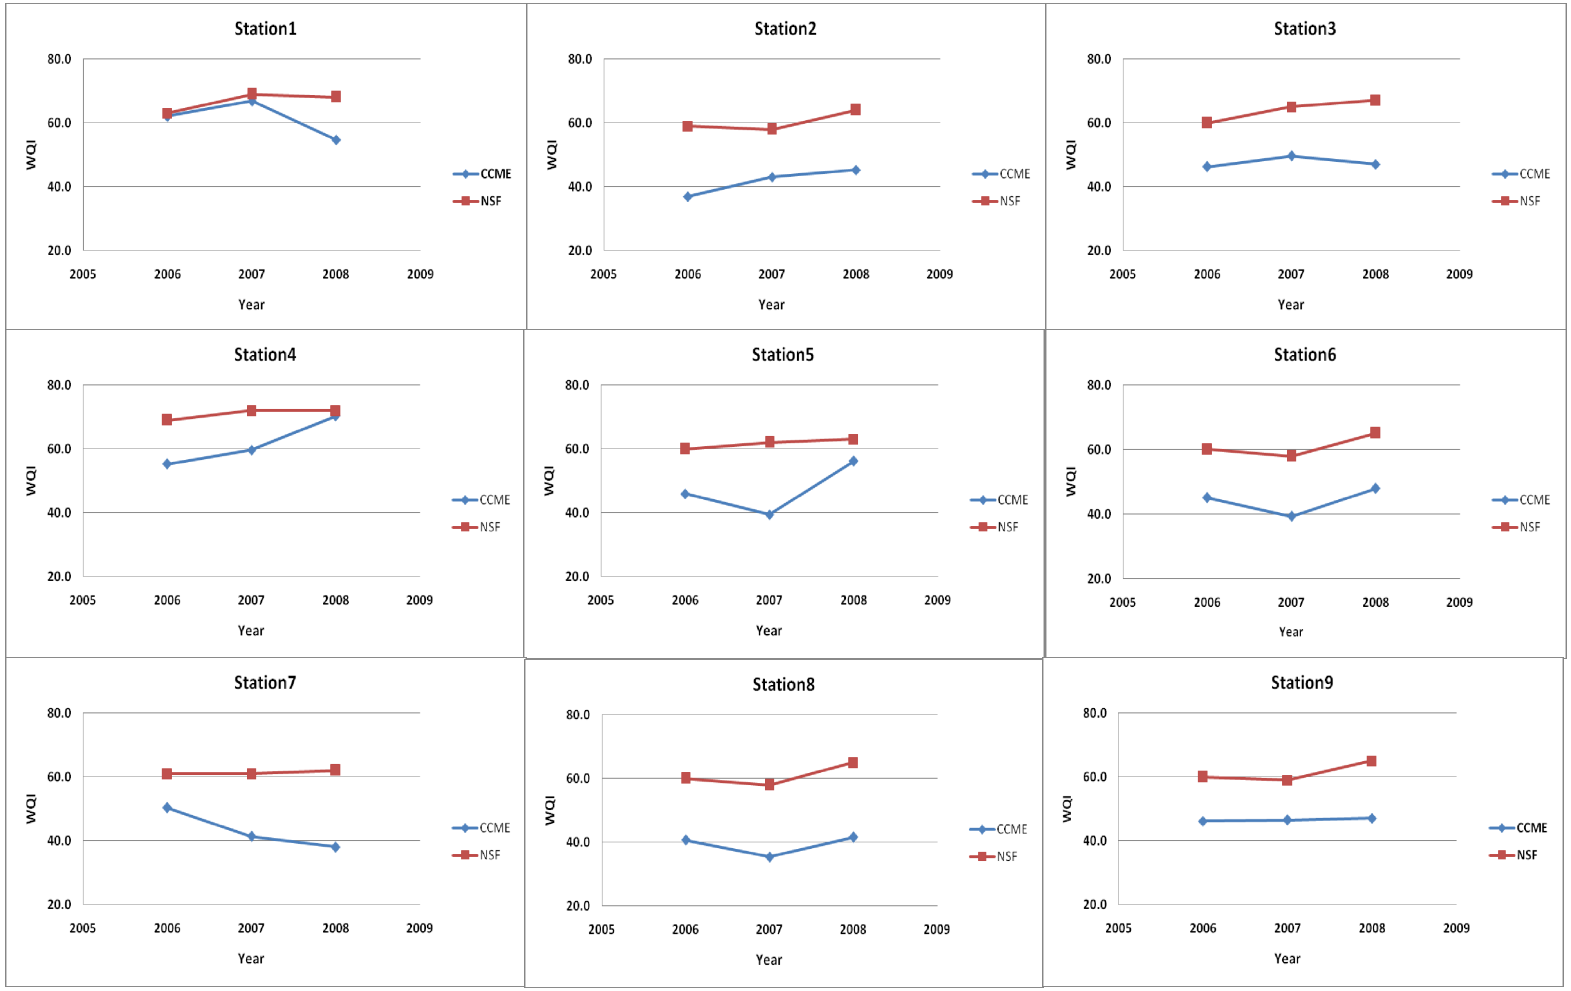

Figure 3. Comparison of NSF WQI and CCME WQI along Karun River syste

CONCULSION

In this paper, two Water Quality Indices (i.e. NSF and CCME) was trialed for the case of Karun River, in the South Western part of Iran. Results showed that:

- In the absence of any local water quality index, application of NSF WQI as well as CCME WQI for the case study in Iran was found satisfactory, despite some differences in environmental protection standards.
- The Karun River was considered in "Medium" category by NSF whereas "Marginal" to "Poor" in CCME classification. Regardless of such a difference, they can be both valid for practical purposes.
- To make the most of such a case study for rivers in Iran, it is useful to develop local bench marks for water quality variables.

ACKNOWLEDGMENTS

The authors are grateful Khuzestan Water and Power Authority (KWPA), as well as and Iran Water Resources Management Company (IWRMC) for providing the water quality data.

ABSTRACT

New technologies are not only critical in supporting military and industrial success, but also play a significant role in advancing sustainable development. With the current global economic challenges, effective tools and partnerships which streamline the design and dissemination of these technologies are more important than ever. Accordingly, the systems environmental engineering approach utilized by the Urban Operations Laboratory (UOL), [comprised of M2 Technologies, Kansas State University, and CABEM Technologies], has facilitated innovative research, training, assessment, and product design for DoD and other stakeholders. Through strategic life-cycle environmental assessments (LCEA); programmatic environment, safety, and occupational health evaluations (PESHE); Health Hazard Assessments; and other proactive studies and reports, UOL has helped foster successful development and deployment of non-lethal technologies. More specifically, these efforts provide a framework for addressing complex environment, safety, and occupational health (ESOH) risks that affect personnel, infrastructure, property, and natural/cultural resources. Integrated analyses (comprehensive and transdisciplinary) involving flexible groups of subject matter experts, are employed in support of public and private collaborations with a focus on inputs, hazards, and constraints. This paper highlights the UOL process which can translate into advantages for a variety of projects (e.g., environmental, water, energy, infrastructure, etc.).

URBAN OPERATIONS LABORATORY

Background

In 1989 Congress appropriated funds to establish the Center for Hazardous Substance Research at Kansas State University, which later spearheaded the formation of the Nonlethal Environmental Evaluation and Remediation (NEER) Consortium in 2001. The successful public-private consortium was subsequently expanded into the UOL to support dynamic military needs through practical environmental assessments, software tool design and development, and innovative technology (product, service, or activity) development. UOL performs environmental analysis for its military partners in accordance with international, federal, state, and local regulations and policies, including: DoDI 5000.02 (Operation of the Defense Acquisition

System) (DoD, 2008), DoD Military Standard MIL-STD-882D (Practice for System Safety) (DoD, 2000), the National Environmental Policy Act (Congress, 1970), and Executive Order 13423 Strengthening Federal Environmental, Energy, and Transportation Management (CEQ, 2007), among others. Further information is available at www.uol.ksu.edu.

Approaches and Tools

Working closely with DoD Integrated Product Teams and the Joint Non-Lethal Weapon Directorate (JNLWD) Human Effects Review Board, UOL provides technical input and assistance throughout the design and development process. Through an iterative approach involving multidisciplinary professionals, including engineers, scientists, toxicologists, safety professionals, legal/regulatory advisors, financial planners, and military analysts, UOL is able to effectively leverage a variety of resources and methods. In addition to the Environmental Knowledge and Assessment Tool (EKAT) (M2 Technologies, 2008), various DoD databases and Environmental Protection Agency (EPA) models are utilized with special attention to green engineering principles. Empirical multimedia sampling and analysis are often performed by the team to supplement available experimental data and simulated and predictive data sets.

Technologies and Capabilities

To date, several innovative technologies, devices, and systems have been successfully evaluated at various phases of acquisition. Given the established user need for these nonlethal technologies and their integration, the capability to assess these systems in the context of unintended human health and ecological impacts is paramount.

U.S. MILITARY AND THE ENVIRONMENT

Transformation

Early in the 19th century, aspects of environmental management were integrated into the American military mission, including the Lewis and Clark Expedition (Corps of Discovery). As military activities, equipment, and facilities became more complex and mechanized, the need for effective natural resource conservation and environmental stewardship emerged. The history of the chemical weapons program illustrates the conundrum of unanticipated consequences (Allen, 1997). In terms of environmental quality and prioritization, there has been a transformative progression from early command and control approaches with regulatory drivers, to more recent preventive measures with overarching sustainability objectives. For example, the Air Force is now actively working to institutionalize sustainability into its design and construction philosophy, requiring military construction (MILCON) capable of achieving the U.S. Green Building Council's Leadership in Energy and Environmental Design (LEED) Silver level of certification (Mesick, 2009). Similarly, in 2008, the Army issued its first sustainability report, which is the first report from any major federal agency to follow the Global Reporting Initiative's sustainability reporting framework (DA, 2008).

Four Focus Areas

Military environmental programs are administered through four primary focus areas: 1) conservation, 2) restoration, 3) compliance, and 4) pollution prevention. The tremendous technical and financial challenges of investigating and remediating historic/legacy contamination sites demonstrate the need for strategies and tools that integrate environmental considerations much earlier in the technology development cycle (DoD, 2002).

ENVIRONMENTAL KNOWLEDGE AND ASSESSMENT

The Environmental Knowledge and Assessment Tool (www.ekat-tool.com) is an automated web-based tool designed by the UOL Consortium to identify, research, and evaluate environmental and pollution prevention options, and safety-related issues for products and systems (Boguski, 2007). Originally a concept jointly developed with the Marine Corps System Command in order to better integrate environmental requirements into the systems acquisition program, to support DODI 5000.2, the tool's features also make it useful to other public and private sector organizations. EKAT is organized to conveniently compile basic information on technical and regulatory requirements and serves as a resource center linking to other references, tools, and databases to assist in research efforts to minimize any unintentional safety and environmental effects associated with product use. Key modules and capabilities of EKAT include the following:

- Environmental screening. The environmental screening feature allows the user to evaluate chemicals or materials for potential environmental compliance and safety and health issues by comparing chemicals to federal environmental regulations and other pertinent lists.
- NEPA Decision Tree. The National Environmental Policy Act (NEPA) module assists military users in meeting federally-mandated requirements to consider environmental and related issues in proposed actions.
- EmisCalc. EmisCalc allows the user to estimate actual air pollutant emissions or calculate the potential emissions for processes using EPA-approved air emission factors from the EPA Factor Information Retrieval database.
- TRACI for EKAT. TRACI for EKAT Tool is a modified version of the EPA software tool, The Reduction and Assessment of Chemical and Other Environmental Impacts (TRACI), which allows the user to evaluate the environmental impact of releases to air and/or water over the lifecycle of a product, helping the individual understand and mitigate future liability.
- PESHE Report Generator. Military users utilize the Programmatic, Environmental Safety and Occupational Health Evaluation (PESHE) module to guide analysis and preparation of the comprehensive ESOH report, as required by the Department of Defense for all programs, in support of DODI 5000.02.
- EKAT Wizard. The EKAT wizard feature is set up in a question and answer format to guide users and help them determine which assessments, tools and other EKAT resources can help best address their requirements.

EKAT contains additional research options, including information resource documents and guides, providing the user with quick access to myriad resources for investigating material

properties, reviewing specific ESOH regulations and databases, finding pollution prevention alternatives, as well as providing links to other Internet resources on topics of interest.

LCEA METHODOLOGY AND APPROACH

Initial Characterization

The first step is to ensure that the team clearly understands the proposed technology concepts, materials and byproducts, and intended uses. Determining potentially applicable regulations and acquiring key data (screening and scoping) are performed with tools such as EKAT. Potential impacts are qualitatively estimated and baseline inventory information is compiled.

Evaluating Impacts

Evaluating the effects or impacts for a proposed action or technology is at the heart of the UOL systems process. Interdisciplinary teams of subject matter experts carefully collect and evaluate theoretical and empirical data to further predict, quantify, and assess any unanticipated impacts. At this stage, information is synthesized to ascertain the level of significance. Preliminary findings and ranking are then analyzed, along with any needed mitigation measures.

Decision-Making

Tentative recommendations are shared with military and technology leaders for preliminary input with respect to selecting the proposed action or technology.

Documentation

Based on proponent feedback, draft reports, such as an LCEA or PESHE, are cooperatively completed. As part of this process, monitoring and oversight plans are incorporated. Programmatic recommendations are completed and used as technical resources for further site-specific/geospatial evaluations and local public involvement. As Figure 1 outlines, the steps are iterative with feedback loops; the concepts are mindfully integrated throughout the system development and procurement life cycle. The acquisition continuum provides several opportunities for both formal and informal environmental analysis, as illustrated in Figure 2, thus contributing to technology maturation while addressing environmental quality.

During initial planning and design, UOL professionals review the capabilities and requirements. ESOH experts are part of the IPT from the beginning. Efforts are initiated on PESHE construction prior to system development and demonstration. Environmental specifications and attributes are an integral part of prototype development. During field testing, data are collected to update and confirm predictions and verify compliance with standards. Considerations for deployment, transportation, and storage activities are carefully implemented. Before fielding and production, formal program assessments are completed. This information is provided to military installations for site-specific analysis. Given the holistic procedure, demilitarization and disposal actions are proactively evaluated to minimize waste generation and

maximize reuse and recycling back into the technology sphere.

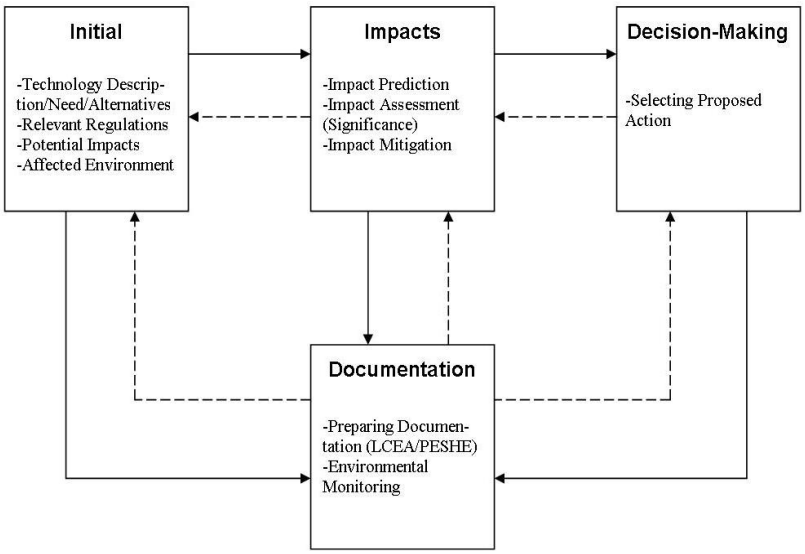

Figure 1. Conceptual Framework for Life-Cycle Environmental Assessment.

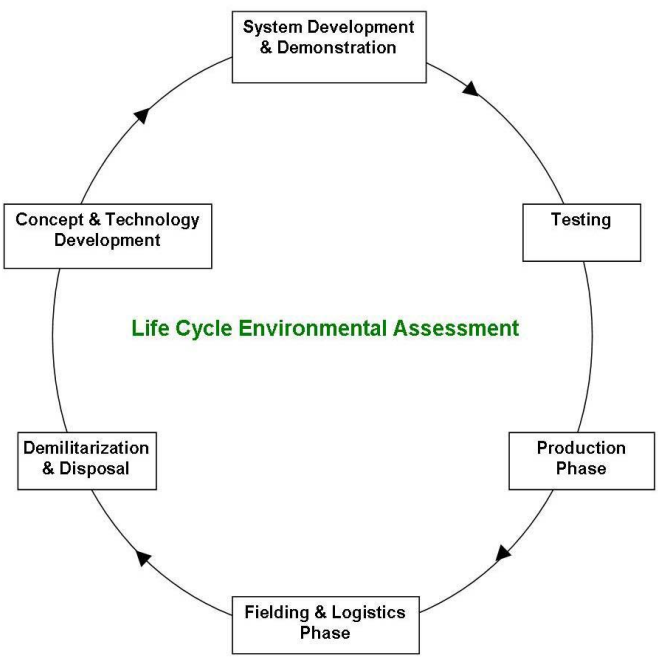

Figure 2. Acquisition Continuum and Integrated Life-Cycle Environmental Assessment.

ENHANCING ENGINEERING OPPORTUNITIES

Given the current economic and energy challenges (e.g., global recession, precarious and emerging markets, geopolitics, climate change, etc.) facing the U.S. and the international community, life-cycle strategies to improve cost and schedule efficiencies, while reducing liabilities are crucial. Many public projects aim merely to achieve regulatory compliance, regretfully missing fecund (sustainability) options, while many privately driven analogs often have even less rigorous macro requirements (limited by near-term profit metrics). However, if myopic perspectives are reframed/enhanced, various emerging as well as more established projects, from concept to implementation and beyond, present lucrative opportunities to use systems-based methodologies and determine fully burdened costs. In particular, pre-operation (strategy and planning, research and development, product/process design); operation (raw material acquisition, manufacturing, transportation, use, waste/emissions, recycling); and post-operation (demobilization, decommissioning, remediation, and restoration) hazards and risks can be addressed. Moreover, technology and policy dimensions can benefit by incorporating these concepts into early tradeoff analysis. By bringing together diverse teams of experts and users/customers for scoping and holistically mapping processes, unintended impacts can be identified for further evaluation and stakeholder engagement/input. This can facilitate technical, regulatory, and social (cross-functional) dialogue; thereby galvanizing empowerment and creative problem-solving for long-term societal needs.

NON-LETHAL TECHNOLOGIES

Background

Prior to 1995, non-lethal technologies had been used primarily in specialty law enforcement applications. The successful utilization by U.S. Marines in 1995, to assist the safe withdrawal of United Nations Peacekeepers in Somalia, served as a pivotal event in establishing the efficacy of their use. The Pentagon issued a policy directive codifying the development and employment responsibilities for non-lethal weapons systems (DoD, 1996). It designated the U.S. Marine Corps as the Executive Agent and provided official definition, "Weapons are explicitly designed and primarily employed so as to incapacitate personnel or materiel, while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment." The following year, the DoD Joint Non-Lethal Weapons Program (JNLWP) was created. Asymmetric and decentralized threats have further contributed to the need for these enhanced security capabilities (e.g., crowd control; checkpoint and convey operations; humanitarian relief; etc) (DoD, 2007). Partnering with the JNLWP, UOL has supported the advancement of several non-lethal systems and tools, of which three are highlighted below (UOL, 2008).

Mobility Denial System/Anti-Traction Material

The Mobility Denial System/Anti-Traction Material project is a Marine Corps led program using a water-based slippery gel material which when sprayed on surfaces is designed to preclude and/or minimize access to designated areas by individuals and vehicles. UOL evaluated early formulations and identified potential chemicals of concern. Support activities included developing a geographic information system (GIS) suitability training tool, sampling and analysis, risk assessment, installation consultation, etc. Based on findings, the gel material

was optimized, and personal protective equipment and best management practices were incorporated.

Aroma and Odor Compounds

Aroma and odor compounds are foul-smelling mixtures used for targeted delivery as area clearing mechanisms. UOL identified problematic constituents in formulations and reviewed conventional and novel delivery subsystems for various DoD agencies. Release scenarios were estimated and safe concentrations were calculated to assist technology development, Figure 3 provides an example of a conceptual exposure estimate. Recommendations for payload enhancement, ecotoxicity testing, and controlled release delivery were completed.

Flash-Bang Grenades/Non-Lethal Airburst Munitions

For this joint forces program, early small-arms launch platforms and payloads were assessed by UOL. Based on input, problematic compounds were eliminated, including perchlorate (Saulters, 2006). Improved flash-bang pyrotechnics have been developed as the basis for these versatile systems. Limited field sampling and analysis, in test chambers and ambient conditions, were completed. Innovative metal-based payloads, fuzes, and activators are currently being analyzed. UOL is involved with several variations, including: hand delivered, single shot, and multiple fire applications of this multisensory (light, sound, and heat flux) technology.

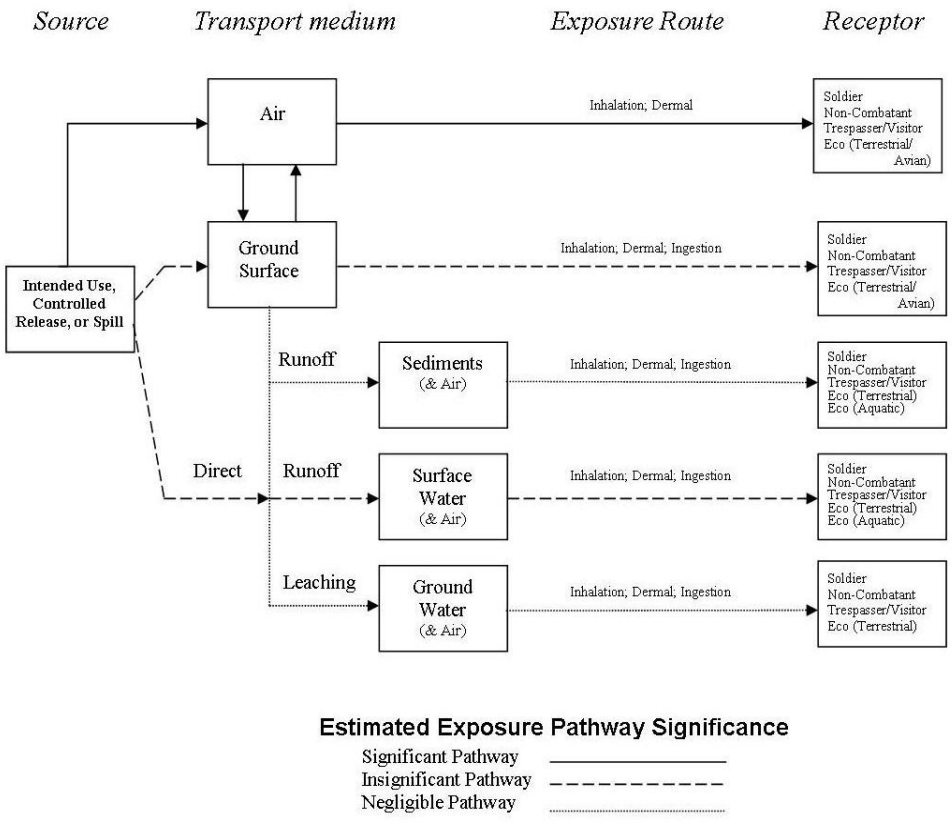

Figure 3. Conceptual Exposure Pathway Estimates for Aroma and Odor Technologies.

CONCLUSIONS

Based on the successful public-private framework followed by UOL, several instructive advantages can be derived.

1) A strong commitment to stewardship and sustainability from organizational leaders contributes to an enduring ethos of quality and dynamic balance (top down).

2) Strategic life-cycle environmental assessments, integrated during systems development and procurement, have been demonstrated to elevate triple bottom line priorities (environment, economics, social) while also driving innovation at the operations level (bottom up).

3) Early partnership and cooperative involvement are essential to effective planning and implementation, utilizing both multidisciplinary teams and robust data tools. These upstream collaborative efforts can lead to improved products and processes, while minimizing unintended environmental and safety consequences (proactive rather than reactive).

4) Efficiencies can be captured by streamlining and leveraging efforts between stakeholder groups with similar objectives, thereby fortuitously breaking barriers, building capacity, and creating synergy. Examples include: joint services testing requirements rather than fragmented redundancy; combined environment, safety, and occupational health data sharing; transdisciplinary research, development, and knowledge dissemination (doing more with less).

Overall, with growing economic, environmental, and energy constraints throughout society, pragmatic approaches to product development and decision-making, such as the UOL methodology are vital.

ABSTRACT

The environmental impact generated from coffee processing effluent was assessed by comparing reference sites with downstream locations. The physico-chemical parameters of coffee effluent on average consists of very high amount of BOD (2200mg/l), NO_3 (26.4mg/l), low pH (4.3), and zero DO values. Thus, BOD values as high as 1900mg/l and 1700mg/l were found at the downstream sites of Bore and Fite rivers, respectively. The cluster analysis was effective in clustering the downstream sites of Fite and Bore rivers. Based on the principal component analysis, fresh water loving species of Heptagenidae and Hydropsycidae had higher weighted average for oxygen while pollution tolerant species of Chironomidae and Oligocheata had higher weighted average for BOD. The habitat score of the study sites was in the range of 29% (very poor) up to 84% (excellent). In general, the integrity of most of downstream sites was impacted by the coffee processing activity in the area.

1. INTRODUCTION

Coffee is the most important commodity in the world (Chanakya and Alwis, 2004) and in Ethiopia it is produced on small and large scale farms, which can produce more than 226,971 tons of coffee per annum (CSA, 2005), making Ethiopia the largest coffee producer and exporter in Africa. In addition, the presence of cheap labor market coupled with the high demand for wet processed coffee has increased the number of coffee processing stations in the country.

The process of separating the beans from coffee cherries during wet processing generates enormous volumes of waste material (solid and liquid). These by-products of coffee processing (coffee pulp and processing effluent) result in bad odour in the surrounding areas, breeding of disease vectors, when dumped around the processing

plants and pollution of ground water and surface water bodies through leaching and run-offs, respectively (Mbru *et al*.,1994). In addition, the composition of coffee pulp is organic and mainly contains carbohydrates, proteins, fibres, fat, caffeine, polyphenols, and pectins (Gathua *et al*., 1991). Thus, the decomposition of this organic waste in the rivers makes the water unsuitable for various uses and damages the aquatic ecosystem. However, the lack of the hitherto enforcement of environmental assessment before issuing the permit to the newly established processing stations and failure of monitoring and evaluation activities of the existing processing stations have resulted in the generation of huge amounts of processing by-products around major rivers used for coffee processing in Ethiopia.

Human activities degrade water resources by altering one or more of five principal groups of attributes: water quality, habitat structure, flow regime, energy source and biotic interactions (Karr and Chu, 1999). Therefore, simple chemical monitorings may not detect an integrative health conditions of water environments due to degradations of physical habitat and flow modifications (Judy *et al*., 1984). But, the most direct and effective measure of the integrity of a water body is the status of its living system (Guye *et al*., 2004). Therefore, an effective method for the assessment of ecological integrity must integrate physical and chemical parameters and ecological processes (Harper *et al*., 2000).

The present study is therefore an assessment of the ecological integrity of environmental quality around processing stations using physico-chemical data, macroinvertebrate community structure and qualitative habitat evaluation index (QHEI).

2. MATERIALS AND METHODS

2.1. Study area and location of sampling sites

Gomma woreda (Fig 1) is one of the 13 woredas in Jimma zone (district) known for predominantly growing coffee. It is located 390 km south west of Addis Ababa and about 50 km west of the Jimma city.

Gomma woreda enjoys well distributed annual rainfall. The average annual rainfall (15 years) is 1524 mm (IPMS, 2007). Agroecologically, Gomma woreda is classified as 96% wet midland and 4% lowland. Altitude in Gomma ranges from 1387 to 2870 m.a.s.l (IPMS, 2007). The three dominant soil types in the woreda are Eutric Vertisols, Humic Alisols and Humic Nitosols, of which Nitosols are the most abundant covering about 90% of the woreda. Many perennial rivers exist as a result of the topography, vegetation and rainfall pattern in the woreda (admnistration unit). Cheseche, Kota, Awetu, Urgessa, Fite, Janje, Sunde and Bore rivers are the prominent rivers found in the woreda. The rivers drain to Ghibe/Omo to the east and Dedesa River to the north (ORG, 2003).

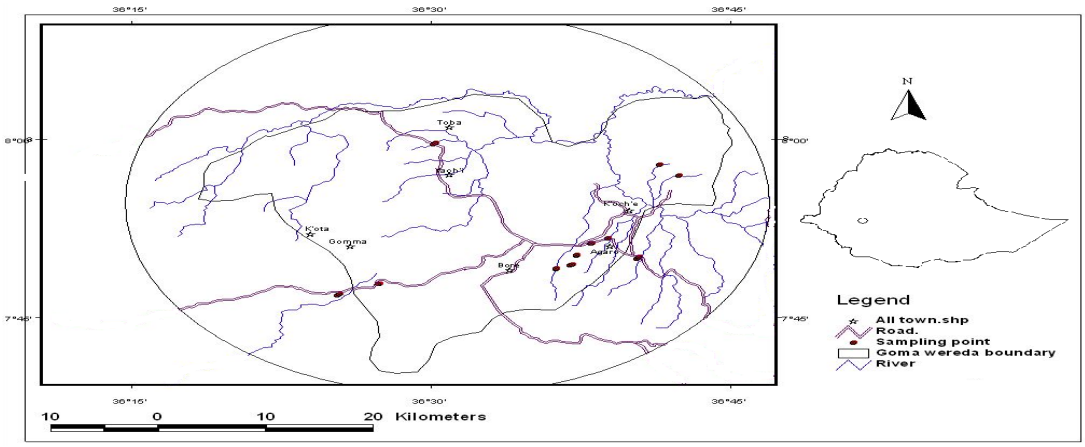

Figure 1. Location of the study area, its rivers, towns, roads and sampling points.

2.2. Water sampling technique

In this work, environmental impact generated from wet coffee processing effluent was conducted by using the technique of comparing upstream reference sites (Control sites without any impact from the effluent and other possible pollutants because of their location above processing stations) and downstream (locations below coffee processing stations which are effluent receivers) locations. Two samples from each site were taken once. Therefore, eleven processing stations (22sampling sites) were used in order to assess the environmental impact arising from these processing stations. Biological and physicochemical river water quality assessment was conducted in November 2007 (peak coffee processing month). Riffle sites of homogenous habitat were chosen (Gerth and Herlihy, 2006) and used for water and macroinvertebrate sampling for physico-chemical and biological analysis. The location of the sampling points at the lower course of the study rivers were placed sufficiently downstream from 50 to 300m below effluent entry points to ensure dispersion of the effluent over a wide cross section of the river.

2.2.1. Water Sampling and analysis

A composite sampling technique was employed to take water samples and samples were taken at three sampling points across the width (Bartram and Balance, 2001). The water samples were collected by inserting the bottles to a 21 to 30 cm depth to the opposite direction of the course of the river flow. The samples were kept in ice boxes and were immediately transported to Environmental Health Laboratory of Jimma University for chemical analysis following the standard methods (APHA, 1998). NO_3-N was determined by Phenoldisulfonic acid method. NH_3+NH_4 by Phenate method, PO_4^{-3}-P by Ascorbic acid method, TDS by Gravimetric standard method and TSS by filtration. BOD_5 (Biological Oxygen Demand) was determined by the Azide modification of the winkler's titrimetric method by determining DO (Dissolved Oxygen) contents of the samples before and after 5 days incubation at 20 ^{0}C. Nutrient analyses were performed in triplicate, and BOD was analyzed in duplicate. In-situ measurements of pH and water temperature were taken using

pH/mV/thermometer (*Model HI 8424*NEW) while DO was measured at the site using dissolved oxygen meter (*Model HI-9143*).

2.2.2. Macroinvertebrate sampling and counting

A triangular D-frame kick net with a 250 μm mesh size was used to collect macroinvertebrate in the riffle site by disturbing the river bed using kicking action over a distance of 10 meters for 3 minutes (Parsons and Norris, 1996). Macroinvertebrate sampling was conducted only once from each riffle sampling sites. After three minutes all the contents of the net were transferred in to a five liter collecting jar. To each jar 70% ethanol was added and transported to Jimma University Environmental Health laboratory for sorting and identification. In the laboratory, the collected samples were transferred into a bowel containing sufficient amount of water, agitated and sieved with 500 μm mesh to discard the mud and retain the macroinvertebrate. This was repeated until all the macroinvertebrates were washed from the mud. The samples were then transferred to wheel trays to easily pick them up using forceps. All macroinvertebrates were sorted and identified using binocular dissecting microscope and identification key (Bouchard, 2004) and assigned to their respective taxonomic levels.

2.3. Habitat survey

The habitat conditions of the sampling sites were assessed using a qualitative habitat evaluation index. Six habitat parameters were used for evaluating QHEI, based on the references widely used (Rankin, 2006). It is composed of six variables: substrate, instream cover, channel morphology, riparian zone and bank erosion, pool/glide and riffle/run quality, and gradient. Each principal parameter was divided into metric components and summed to provide the total QHEI site score of 100.

2.4. Multivariate Statistical Methods

2.4.1. One Way Analysis of Variance

Differences in physicochemical variables among sampling sites were assessed by analyzing one-way analysis of variance (ANOVA) using MSTAT software.

2.4.2. Cluster Analysis

The Bray –Curtis similarity index was used to calculate the distance between sampling sites and single link clustering method was used to cluster sampling sites (Quinn and Keough, 2002). Biodiversity professional® software (1997) was used to construct the cluster.

2.4.3. Principal Component Analysis

Relationships between the environmental and biological data were assessed using canonical multivariate analysis with the software program CANOCO 4.5 (ter Braak and Smilauer, 2002). First, Detrended correspondence analysis (DCA) of square-root transformed taxa abundance, with downweighting of rare taxa, detrending by segments and non-linear rescaling was used to determine the biological turnover, or gradient length, of the species data set. DCA for taxa (species) abundance of the second axis was less than 2, implying that taxa abundance exhibit linear response to environmental gradients (ter Braak and Smilauer, 2002). For this reason, principal component analysis (PCA) was used in the ordination of taxa abundance, environmental variables and sampling sites.

3. RESULT AND DISCUSSION

3.1. Physico-chemical parameters

There was a variation in physicochemical parameters along the course of the rivers and among the rivers (Table 1).

Table 1. Mean Physico-chemical characterstics of water samples of rivers of Jimma zone at locations above and below coffee effluent discharge points with their QHEI values.

Rivers	No.		BOD		DO		pH*		NO_3		QHEI	
	U	L	U*	L*	U	L	U	L	U	L	U	L
Sugo	1	2	1.5	600	5.98	5.98	7.0	7.0	2.51	2.13	27	39
Sunde	3	4	4	330	6.82	6.54	7.1	6.5	2.28	2.51	52	54
Chisech	5	6	1	2.3	6.6	6	6.8	7.3	0.48	1.58	75	75
Songa	7	8	270	150	5.4	5.4	6.7	6.6	1.83	2.05	81	75
Urgessa	9	10	0.8	200	7.64	7.13	7.8	6.9	1.28	2.55	84	78
Janje	11	12	1	600	5.15	6.87	6.7	7.3	1.64	2.09	76	47
Fite	13	14	1.3	1700	7.02	6.35	7.2	6.9	1.43	2.13	83	75
Guracho	15	16	6	5.3	6.15	5.71	6.8	6.7	0.94	1.03	67	59
Funtule	17	18	110	2.5	5.15	3.93	6.7	5.9	1.25	2.50	67	46
Bore	19	20	2.3	1900	6.49	0	6.9	5.8	2.41	2.80	81	59
Chore	21	22	1.9	3.2	6.04	3	7.2	6.5	1.42	1.39	78	79

U*: upstream sites; L*: downstream sites; all units except pH and QHEI are in mg/l.

BOD levels extend from 0.8mg/l at upstream site of Urgessa river to 1900mg/l at downstream sites of Bore river. The BOD values at the downstream sites of Bore and Fite rivers reached to 1900mg/l and 1700mg/l values from 2.3 and 1.3mg/l levels at the upstream sites. These BOD values were close to the average BOD content recorded for the diluted raw effluent (2200mg/l) just before it entered into the river

(Table 2). The high BOD content at the downstream sites of Songa and Urgessa rivers might be partly explained by the high BOD levels of their upstream sites and this might be related to other pollution sources such as erosion from the nearby agricultural fields. Additionally, the BOD values were even higher after the discharge of the effluent into the river which had increased the organic load of the river further.

Janje and Fite rivers that contain high BOD values despite the opposite relationship between DO and BOD (Meyrick, 2005) and these high DO values might be related to the discharge of the rivers that have high potential to dilute the organic effluent entered into the river and a continuous aeration along its way to downstream sites (Giller and Malmqvist, 1998). Nevertheless, the very high BOD content was mainly related to organic enrichment from the coffee processing effluent (Von Enden and Calvert, 2002) and its effect was much more pronounced at the downstream sites of Bore and Fite rivers. In general, most of the downstream sites were impacted from coffee processing effluent so that the average BOD value was 499mg/l which according to Von Enden and Calvert (2002) should be reduced to less than 200mg/l before its entrance to natural water ways.

The upstream DO values of all sampling sites were found to be more than 5mg/l (Table 1). There was a drastic change in DO at the downstream sites at Bore river (0 mg/l), and Chore river (3mg/l) with the decrease of 100%, and 50% of their respective upstream sites. The lowest DO level recorded was 0mg/l at the downstream site of Bore river while the highest was 7.64mg/l at upstream site of Urgessa river. There was a significant variation between DO values of the study sites as expected ($P<0.05$). Therefore, the main ecological effect of organic pollution in a watercourse is the decrease in oxygen content (Murthy *et al*., 2004).

Table 2. Summary of average physical and chemical values for upstream and downstream sites with their statistical values and raw effluents data.

	pH	Temp	BOD	DO	TDS	TSS	NO_3	NH_3
Upstream	7.03	17.68	36.35	6.22	132.27	115.05	1.59	0.33
Downstream	6.74	17.89	499.34	5.17	170.45	91.45	2.07	0.506
Significance	0.02	0.09	0.00	0.00	0.00	0.00	0.16	0.00
Raw Effluent	4.3	-	2200	0	1810	252	26.4	11.9

*Environmental variables with significant P value ($P<0.05$); all units except pH are in mg/l.

A general pattern of NO_3 increment at downstream sites compared the upstream sites was observed during the sampling periods. Similarly, Ammonia concentration (Table 1) increased following the effluent discharge. Although raw coffee wastewater contains 26.4mg/l NO_3, the lowest and highest NO_3 content of the downstream samples were within the range of 0.487 (Chiseche) to 2.547mg/l (Urgessa). A decrease in Nitrogenous pollutants may be associated with flow rate and dilution effects of the river water. Large volume of water has the capacity to reduce BOD and other organic pollutants.

On the basis of QHEI score, the habitat score of the upper streams was in the range of 27% (poor) upto 85% (excellent). Accordingly, the upper stream sampling sites of Chiseche, Songa, Urgessa, Janje, Fite Bore and Chore displayed scores more than 70% and evaluated as excellent. Likewise, the sampling sites at Gurracho, and Funtule were found as good (55-69); whereas Sunde was valued as fair (43-54) and Sugo as poor (32-42). Similarly, the downstream sampling sites of Chiseche, Songa, Urgessa, Fite and Chore were evaluated as excellent. Likewise, the sampling sites at Gurracho and Bore were valued as good; whereas the sampling sites at Sunde, Janje and Funtule were in a fair condition. In addition, the sampling sites at Sugo remained in a poor condition.

In general, the comparison between upstream and downstream sites clearly demonstrated the deterioration of water quality in most downstream sites. As a result, the downstream sites of Janje, Urgessa, Fite and Bore rivers were impaired by the coffee processing activities of the area during the study period. However, the construction of lagoon for the containment of coffee pulp and coffee wastewater around Chiseche rivers and the placement of processing station at a considerable distance from Songa river made these sites relatively unimpacted. A different level of impact was found on the remaining rivers.

3.2. Biological Analysis

3.2.1. Cluster analysis

In order to show the relationship of each cluster to all others and similarity/dissimilarity levels of each cluster, dissimilarity analysis of the macroinvertebrate composition was undertaken in all river sampling sites.

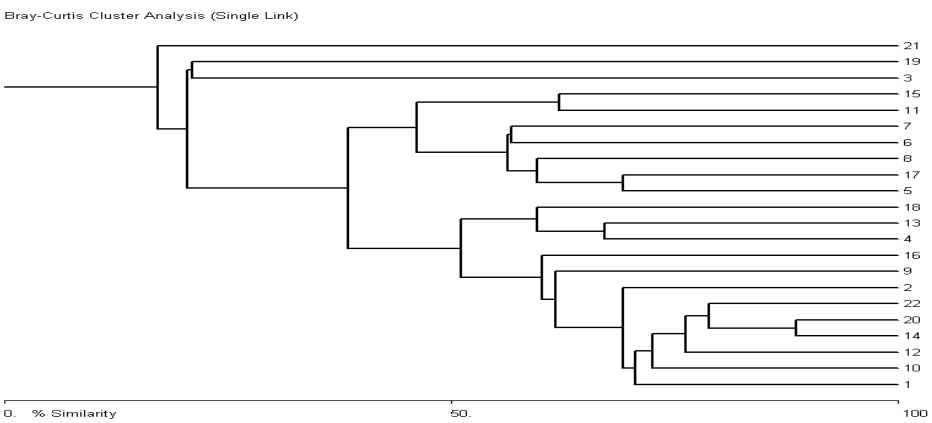

Figure 2. The hierarchical clustering of sampling sites using macroinvertebrate taxa composition

This analysis (Fig. 2) revealed that the highest similarity was found between the downstream sites of Fite (14) and Bore rivers (20) while the lowest similarity was found between the upstream sites of Sugo (1) and Chore rivers (21). In addition, the

downstream sites of Urgessa (30) and Janje (33) rivers were clustered together. These sites were also found to have a similar diversity index.

3.2.3. Principal Component Analysis

Although slight difference was observed for the results of environmental variables and biological indicators to depict the pollution gradient along the river separately, the combination of both were able to clearly define and explain the pollution gradients (Figure 3).

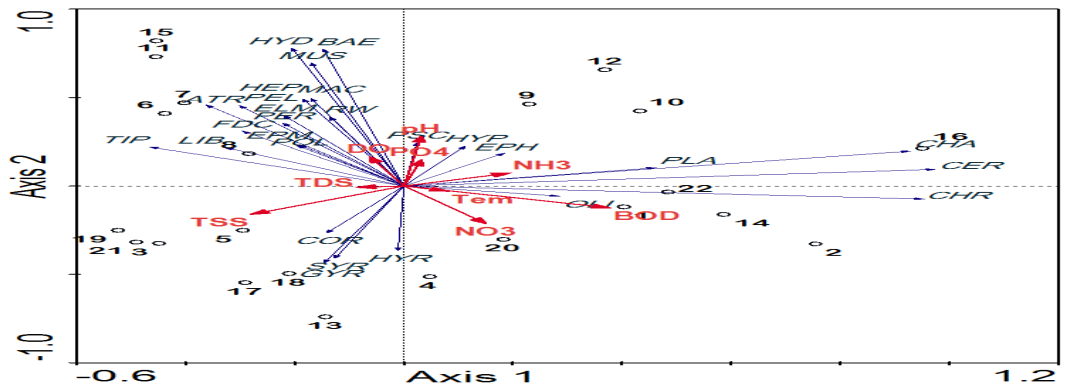

Figure3: PCA triplot of samples, macroinvertebrates and environmental variables based on the first two axes

In the ranking of the projection points, the origin (0, 0) indicates the global average of the variable. (ter Braak and Smilauer, 2002). Therefore, TDS, Temperature and PO_4 did not change much (short arrow length) and hence their influence were minimal as compared to BOD, TSS, NO_3, pH, and DO environmental lines which displayed the maximum rate of change across the diagram. Therefore, variations in macroinvertebrate composition were strongly correlated with these environmental variables.

Although slight difference was observed for the results of environmental variables and biological indicators to depict the pollution gradient along the river separately, the combination of both were able to clearly define and explain the pollution gradients. The high oxygen weighted average for oxygen loving species (Hydropsychidae, Baetidae, Heptagenidae, Perlidae and Psychodidae) is as expected since Heptagenidae is in Ephemeroptera family while Hydropsychidae, Perlidae and Psychodidae are in Trichoptera family. Ephemeroptera, Trichoptera and Plecoptera are considered to be abundant in oxygen rich water very sensitive for pollution and used as a water quality monitoring index in Ethiopia (Worku Legesse, 2000). Therefore sites 8 (Sugo lower), 6 (Chiseche lower), 7 (Songa upper), 11(Janje upper), and 15(Gurracho upper) had higher DO values than the rest sites.

On the contrary organically polluted sites were found to be dominated by pollution tolerant species of Chaoboridae, Oligochaeta, Ceratopogenidae and Chironomidae

taxa and except the taxa of Oligochaeta, all the species are in the Diptera family. The special characteristics of the above mentioned taxa are their ability to flourish in very low oxygen (high BOD) level and dominate the entire site with great abundance (Gallardo *et al*,. 2006). Sites 14 (Fite lower) and 2 (Sugo lower) and 20 (Bore lower) had the highest BOD values than the rest sites. Therefore the species-site-environment PCA triplot diagram clearly discriminated unimpacted sites from the severely impacted ones.

4. CONCLUSION

The results of this study revealed ecological impairment of most of the downstream sites due to the activities of processing stations. Measures of physico-chemical parameters, macroinvertabrate community and QHEI analyses indicated the significance environmental impact around most of wet coffee processing stations. Therefore, the downstream sites of Urgessa, Sugo, Sunde, Janje, Fite and Bore rivers were impaired by the coffee processing activities in the area during the study period. However, the construction of lagoon for the containment of coffee pulp and coffee wastewater around Chiseche rivers and the placement of processing station at a considerable distance from Songa river made these sites relatively unimpacted. A different level of impact was found on the remaining rivers.

How to Save the Second Aral Sea?

Rysbekov Yusup Khai. [1]

[1]Department of Management, Scientific-Information Centre of Interstate Coordination Water Commission of Central Asia, 100187, 100187, Tashkent, B-11, Karasu-4, Uzbekistan PH (99871) 265-1659; FAX (99871; email: yusuprysbekov@icwc-aral.uz

ABSTRACT

In the beginning of 1960s Aral Sea had water area more than 66000 km^2. Now Aral Sea was divided into three Seas, and has the total area 20000 km^2, including Eastern Aral Sea (EAS) - 11000 km^2, Western Aral Sea (WAS) - 5000 km^2, Northern Aral Sea (NAS) - 3300 km^2. Now only NAS (Kazakhstan) has real chances for survival.

Preservation of WAS (Uzbekistan) is impossible without creation of artificial flowing ecosystem "WAS - Amu Darya River delta". There is a line of concomitant factors for benefit for WAS preservation, in comparison with EAS:

- WAS has the large depths, the smaller area and water volume;
- WAS' water have smaller mineralization

The offered proposal has by innovative part the connection of Western part of NAS with WAS, construction of channel NAS-WAS and dam, which will separate WAS from EAS. Idea's realization will be favorable for Kazakhstan also.

INTRODUCTION

Intensive development of irrigation in the Amu Darya River Basin (RB) and Syr Darya RB in 1970-1980s has caused sharp reduction of water level in the Aral Sea, and hope for reception of additional water from Siberia were not justified. According to the available data, average multiyear river flow in the Aral Sea Basin (ASB) in 1911-1960 made about 117 km^3/year, including for Amu Darya RB - 80 km^3, and for Syr Darya RB - 37 km^3. In this period the Aral Sea received on the average about 56 km^3 of water per year, including 42 km^3 from Amu Darya River and 14 km^3 from Syr Darya River.

Next decades sharp decrease of inflow in the Aral Sea is observed: in 1961-1970 it has decreased till 30.0 km^3/year, 1971-1980 - up to 16.7 km^3, 1981-1990 - up to 3.5 km^2, 1991-1999 - till 7.6 km^3/year on the average. In 1980-2001 per separate years waters of Amu Darya and Syr Darya did not reach Aral Sea. Accordingly, sea level has decreased from 53 m (beginning of 1960s) up to 41 m (1985-1986), and 30 m (2001).

In 1985-1986 Aral Sea was divided into Large Aral Sea (LAS) and Northern/Small Aral Sea (NAS), later the LAS was divided into Eastern Aral and Western Aral Seas (EAS and WAS).

In the beginning of 1960s the Aral Sea had water area more than 66000 km^2 (see Figure 1) now total area of three Seas makes less than 20000 km^2: EAS, with gulfs - less than 11000 km^2, WAS - about 5000 km^2, and NAS - about 3300 km^2) (see Figure 2).

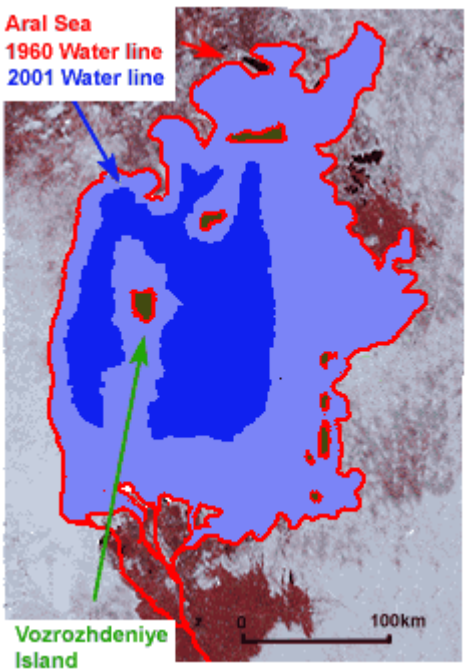

Figure 1. Dynamics of the Aral Sea level for 1960-2001.

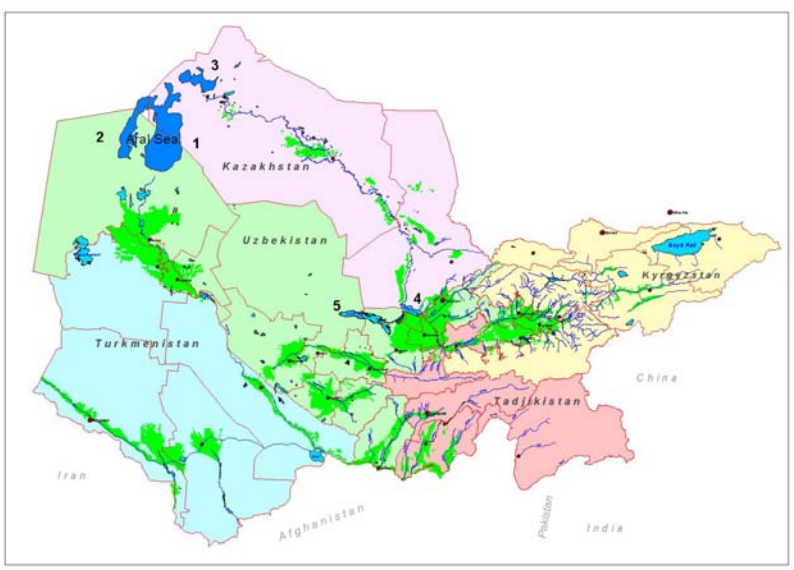

Figure 2. Aral See Basin (1 - Eastern Aral Sea, 2 - Western Aral Sea, 3 - Northern Aral Sea, 4 - Shardara reservoir, 5 - Arnasai Lake ecosystem).

Now, as a result of realization of the appropriate measures by Government of Republic of Kazakhstan (construction of Kokaral dam in the Berg' strait, maintenance of constant inflow in the Sea), only NAS has real chances for survival.

In the whole, the tragedy of the Aral Sea was caused by inept management and ignoring water requirements of the ecosystem. In middle of 1980s the Amu Darya River and Syr Darya River water shortages downstream were recognized by the Soviet Government (by Moscow) as a critical water management situation that was exacerbated by the lack of a unified water management body. As a consequence and according to the appropriate political decisions (1984, 1985, 1986, and 1987) the Basin Water Organizations (BVO) "Syr Darya" and "Amu Darya" were established. These BVOs were responsible for water allocation between the Central Asian states and operation of the associated interstate hydraulic structures. However, it was established that if in the Amu Darya River and the Syr Darya River water availability is higher than estimated, water may be accumulated in the reservoirs, and under very high water, a share of water may be released downstream to the Aral Sea. This was a short-sighted decision and a political mistake, which resulted in aggravating the health of the Aral Sea.

BASIC RESULTS OF THE PREVIOUS RESEARCHES

In last 20 years a line of researches was carried out in the context of saving of the Aral Sea (or its separate parts). The basic accent in them was made on preservation of wetlands of the rivers (Amu Darya and Syr Darya) deltas and separate parts of the Aral Sea (NAS, WAS, EAS) in the limited borders, which would ensure their steady existence. So, according to Nachtnebel P. et al. (2006), Shutter J. and Dukhovny V. (2006) and other sources, the offered ways for preservation of water ecosystems in coastal zone of Aral Sea are reduced to the following basic variants (other variants do not leave for frameworks resulted below):

1. Reduction of total area of Aral Sea (with variants);
2. Reduction of area of Aral Sea, but with NAS' liquidation;
3. Separation of NAS and WAS;
4. Separation of NAS and WAS, at reduction of WAS' area;
5. Preservation of NAS and WAS, at separating of EAS;
6. Preservation of reduced LAS and NAS;
7. Preservation of reduced LAS, but NAS is salty reservoir;
8. Preservation of reduced EAS, but WAS and NAS are salty reservoirs;
9. Preservation of reduced WAS and NAS, but EAS is salty reservoir;
10. WAS exists, EAS is completely separated;
11. EAS exists, WAS is completely separated;
12. EAS and WAS continue to exist in natural condition, without human intervention.

4. Variant # 13. Water of Amu Darya is directed to WAS.

Analysis shows, that most expedient, attractive and possible to realization is the variant №13, which can be accepted for a basis for preservation of WAS.

But this idea, which was offered by Academy of Sciences of Uzbekistan, is not considered as correct by authors of the report under the Project INTAS - 0511 REBASOWS (Nachtnebel P. et al., 2006).

If we shall distract from definition "reduced", and we shall take into account that the task on preservation of NAS is practically solved, variant #13 is close to variants # 5 and # 9. This task (preservation NAS is solved) can be advanced and is put in other plane only, namely - in context of maintenance of national interests of Kazakhstan and Uzbekistan in ecological sphere in future.

OFFERED IDEA AND ITS POSITIVE PRECONDITIONS

Considered in present analysis zone is known under "Southern Prearalie", which includes of Amu Darya River delta in the whole and adjacent with WAS and EAS areas in territory of Uzbekistan. EAS receives waters from Amu Darya River after satisfaction of needs of its delta, which includes system of wetlands and numerous lakes. In turn, WAS receives water only in case of water surplus in EAS (having poured from EAS).

It is necessary to note that Amu Darya River delta and its wetlands not receive always water in quantities, which are sufficient for its steady existence, is especial - in dry years (in particular, in 2000, 2001) and this circumstance complicates management of water ecosystems of river delta and coastal zone. Earlier realized projects in this zone do not give the concrete answer to the question on sustainable management of Amu Darya River delta and coastal zone of WAS and EAS.

In developing situation it is necessary to recognize (Rysbekov Yu., 2006, 2007) that a preservation of WAS is impossible without creation artificial dynamical (flowing) ecosystem "Delta - delta" (in our case - "Delta of Amu Darya River - WAS"). If the problem of WAS' preservation will not be solved, the parameters of water ecosystems in River delta will sharply vary depending on receipt of water (as a whole - dry or wet year), and it is senselessly to reason on their sustainable existence. Offered idea consists in connection of western part of NAS (Kazakhstan) with WAS (Uzbekistan) by means of construction of the artificial channel "NAS - WAS" that will allow:

- To supply a fluidity of water and to reduce of water mineralization of NAS on all to its length (now sea waters mix up badly, as a fresh river water runs into it of its eastern part, while water of western part of NAS has higher mineralization),
- Considerably to expand vital space and to supply more favorable conditions of duplication both residing of freshwater and sea fishes in NAS,
- To exclude dump of river fresh waters (from Syr Darya River) in EAS, which can be used for filling of WAS and improvement of water quality in it.

We shall result while as minimum 3 factors for the benefit of offered variant:

- (1) WAS has the large depths, than EAS. EAS is flat natural depression and has depths 3-4 m. The maximal depths of WAS make more than 40 m,
- (2) WAS' waters have smaller mineralization, than EAS' waters. According to available data, mineralization of WAS waters was stabilized at level of 80-90 g/l (on other data - it has reached 100 g/l). At the same time, mineralization of EAS' waters makes not less, than 140 g/l,
- (3) WAS has smaller area and water volume, than EAS. It will ensure stability of management of the Sea after its restoration.

At acceptance of the decision about preservation of WAS, there are 2 hypothetical routes for construction of the artificial channel to WAS (Rysbekov Yu. and Tillaiev B., 2008), namely:

- Through Sudochie lake - Southern channel,
- Through Lakes Rybachie and Muinak - Northern channel.

Analysis shows that the construction of the Southern channel is preferable from the point of view of technical practicability, smaller financial charges and future efficiency. Thus, in addition 2 factors testify for the benefit of WAS' preservation:

(4) Realization of technical measures (construction of dams etc.) will be cheaper,

(5) Channel from delta of Amu Darya will pass on the route including lake Sudochie - object of the Ramsar the Convention that is one of important factor.

For achievement of offered idea it is necessary to change the approaches to management by coastal zone of WAS and delta of Amu Darya River with purposes of creation of uniform flowing water ecosystem "Delta-Sea".

For this purpose it is necessary to determine:

- Minimal river flow, which will supply a flowing regime for sustainable functioning of new artificial ecosystem.

This water volume can not be used for other needs (irrigation, etc.) in downstream zones of Amu Darya River,

- Optimum quantities of wetlands and lakes in delta of Amu Darya, which necessary and can be saved.

It is necessary resolutely to refuse a number of wetlands (Akushpa etc.), which have few chances for survival, and which parameters do not promote steady management by them in view of an economic efficiency (small areas and depths, high mineralization, low biological productivity, etc.),

- Optimum water level (OWL) in WAS as bases for necessary calculations.

OWL can be determined after acceptance of decision about water limits (requirements) for ecosystem "Delta-Sea". It is possible to accept for base of this water limits the volumes of collector-drainage waters, which are dumped (without benefit) in the EAS, and sanitary water releases to the Amu Darya delta,

- (4) Development of necessary measures on service by ecosystem "Delta-Sea", for maintenance of its functionality

As a rule, it is an operational measures,

- (5) Volumes of bio-efficiency (fish, vegetation etc.)'s restoration.

These volumes will depend from quantity and quality of water, which flows in new ecosystem "Delta-Sea", proceeds on it and accumulates in WAS,

- (6) Volumes of artificial wood landings (area, kinds of vegetation etc.) in adjacent to system "Delta-Sea" areas.

These measures will allow to lower negative pressure on new ecosystem and will promote common improvement of zone,

- (7) Other necessary measures on maintenance of stability of ecosystem "Amu Darya Delta - WAS".

There are following positive preconditions to the offered idea's realization:

- (1) Fresh water surpluses from Syr Darya River very are dumped in the practically dead sea (EAS) through Kokaral water-regulating structure.

So, according to IFAS (International Fund for Aral Saving)'s data, in 2003 mineralization of water, which flow down from NAS to EAS, makes 1.7-1.8 g/l. At the same time, average mineralization of NAS' water is equaled bout 15 g/l. This river water do not improve an ecological condition in EAS, which has water mineralization about 140-150 g/l. Valuable and practically fresh water is dumped in EAS at the sharp water deficiency in Syr Darya RB only with the purposes for safety of Kokaral dam.

- (1.1) Experts will confirm that in EAS is dumped fish with water (direct damage for Kazakh fishermen), most part of which doomed on extinction in EAS,

- (1.2) Volumes of dumped water are huge.

So, in 2003 NAS has received 9.0 km^3 of river water from Syr Darya, from which 7.3 km^3 (more than 80 %) is dumped in EAS. This water volume (7.3 km^3) is enough for irrigation about 700 000 - 800 000 ha.

- (1.3) It is necessary to say that in 2003 the EAS has received about 6.3 km^3 collector-drainage water from Amy Darya part,

- (2) Waters of EAS supersede waters of high mineralization from EAS to WAS, and it worsens quality of EAS' waters. EAS' waters is intensively spent for evaporation (small depths of EAS),

- (3) Fresh river water from Syr Darya is accumulated in the east part of NAS (excepting a river flow from the mouth of Syr Darya to the Kokaral dam), as waters with higher mineralization of NAS' rest (to west) part do not promote an intensive mixing the rather fresh water (mineralization - 1.5-1.8 g/l) and sea salty waters (15-18 g/l) of medial and western part of NAS,

- (3.1) More fresh and easy river water from Syr Darya (in comparison with sea water) is dumped to EAS always. As the consequence, most part of fishes will be to live in the east part of NAS.

Accordingly, the Kokaral dam supports ecological stability and steady fish craft only of small (east) part of NAS. presentations in conference proceedings.

REALIZATION OF IDEA

Realization of proposed idea assumes the complex approach, in view of the stated above rules, in particular:

a) preservation of WAS by means of creation of uniform ecosystem "Delta of Amu Darya - WAS");

b) construction of Southern channel for maintenance of WAS by collector-drainage waters from irrigated lands,

c) construction of the artificial channel "NAS-WAS".

d) construction of dam (Uzbek part) between EAS and WAS, which will separate EAS from WAS.

It is represented to expedient a preservation of WAS' water level on considerably higher marks, than EAS (presumably, the excess should be not less than 6-7 m).

Difference in absolute marks between WAS and EAS will depend on the decision, at what level for preservation of EAS is expedient. Volume of civil works depends on the accepted water level in EAS also. All rest (dam's parameters, hydraulic engineering structures) requires forwarding research and engineering substantiation.

Dam between WAS and EAS should be equipped with water-regulating structures, in particular - for passing of water by higher mineralization from the bottom layers of WAS and for catastrophic dump. In start period it is possible to supersede waters of high mineralization (up to 90-100 g/l) in process of receipt of collector-drainage water of smaller salinity from delta of Amu Darya (5-7 g/l) and NAS (up to 15 g/l), and further it is necessary to adjust and support an acceptable level of water mineralization in WAS. It is represented expedient to provide in system of hydraulic engineering structures an opportunity for construction of pump station for pump out from NAS the strong-salty waters from depths 15-20-30 m for further prospect, and it will promote further desalinization of NAS' water.

The question of use of drying up coastal zone of EAS requires an expert analysis (production of salt, restoration of vegetation - wood planting etc.).

Now WAS and EAS completely have lost such important function as a place for the craft fishes. The following conditions for survival of alive organisms in water environment can be accepted as base for step-by-step revival of fish craft in EAS:

- (1) Separate kinds of seaweed maintain salinity up to 280 g/l, and of microorganisms (bacteria) - from 120 g/l and higher;
- (2) Intervals of salinity from river up to ocean waters are considered as favorable conditions for the majority of alive water organisms.

In particular, salinity of ocean's water makes about 35 g/l on the average, water of the Caspian Sea (excepting rivers' mouths) - 13 g/l. It is wide known that a flounder was delivered from the Caspian in the Aral Sea; the flounder can live and give posterity at water salinity in limits 20-60 g/l.

CONCLUSION

The Aral Sea Basin was quoted by the UN Environmental Program as one of the most staggering disasters of the 20th century, and the Aral Sea region is referred to as an ecological disaster zone on a global scale. Restoration of WAS will doubtless give the positive social-political, socioeconomic and ecological effects. In particular, the economic benefit will be reflected in revival of fish and hunting craft, and a greatest feedback should be from fish-cultivation that positively will have an effect on a socioeconomic situation of the local population of contiguous areas.

Coming back to Figure 2, it should be noted that the preservation of the WAS will allow to solve a line of tasks connected with to operation of Shardara reservoir (Kazakhstan) and Arnasai Lake System (Uzbekistan) (Rysbekov Yu. and Tillaiev B., 2008), which are in of the Syr Darya River Basin. ALS was formed in 1969, when about 22 km^3 of water was dumped in it and this water volume makes more than half of the multi-year water resources of the Syrdarya River Basin.

In last 40 years the Arnasai was used as a receiver of superfluous water with the purposes of protecting the territory of Kazakhstan against high waters, as the Shardara reservoir could not contain the water and the Syrdarya River could not pass water surpluses to the Aral Sea.

Before dividing of the Aral Sea into the Large (LAS) and Small Seas (NAS) water of Amu Darya and Syr Darya flew in one sea, with successful realization of the proposed project they will flow also in one Sea - WAS. But it is already a philosophy.

In 1993 in Kyzyl-Orda the Heads of Central Asia States (CASs) have signed the Agreement, in which they have recognized as general tasks, in particular:

a) "guaranteed maintenance of water submission in the Aral Sea in the volumes allowing to support its reduced, but steady water area at an ecologically acceptable level and preservation thus seas as natural object";

b) "restoration of balance of broken ecosystem…, first of all - in territory of deltas of Amu Darya, Syr Darya and contiguous sites…, creation here the artificial steady landscape complexes".

In this plan, the realization of offered idea answers political will of the Head of CASs to stabilize a situation in the Aral region.

Air – Borne Heavy Metal Contamination to River Ganga (India)

J. Pandey*, K. Shubhashish & Richa Pandey
Center of Advanced Study in Botany, Banaras Hindu University
Varanasi, India – 221005

ABSTRACT

A two year study was undertaken at Ganges basin of India to evaluate the atmospheric input of six heavy metals to river Ganga. Atmospheric bulk deposition was collected on a fortnightly basis at 8 river sites from April 2006 through March 2008 to determine atmospheric loading of heavy metals to river Ganga. The sampling protocol consisted of bulk collectors placed at 24 locations (3 at each site) selected along a 20 km long tract of river Ganga at Varanasi, India. The atmospheric fluxes of six heavy metals to river Ganga were estimated as (g ha^{-1} y^{-1}) : Cd – 0.56 – 20.15; Cr – 0.34 – 8.87; Cu – 1.63 – 58.17; Ni – 0.21 – 7.32; Pb – 1.80 – 124.00; Zn – 124.15 – 477.18. Atmospheric deposition of all the elements was lowest at Adalpura (site 1) and highest at Rajghat downstream site (site 8) receiving maximum down – wind urban industrial emissions. Zinc alone contributed to more than 68 % of total measured heavy metal input. For season, the atmospheric fluxes were measured highest during winter followed by summer and rainy seasons. Data on heavy metal concentrations in mid – stream water showed significant correlation with their respective values received through atmospheric deposition. Corresponding to the atmospheric deposition, except for Zn, highest concentrations of Cd, Cr, Cu, Ni and Pb in mid – stream were recorded during winter followed by summer and rainy seasons. Concentrations were recorded highest for Zn followed by Ni, Cr, Pb, Cu and Cd. Concentrations of all the heavy metals were high in down – stream sampling locations. Although the concentrations of Cr, Cu and Zn remained well below their maximum admissible concentrations (MAC), more than 80 % of water samples of 7 out of 8 locations sampled, showed Cd, Ni and Pb levels above their respective MAC. Heavy metal loading to mid – stream implicates the adjoining urban agglomeration of Varanasi as the principal emission source area. The atmospheric loading to the river will continue to rise with the completion of Ganga Express highway. This may lead to serious health implications in long – run since Ganga water is also used for drinking purpose by a large population.

Key words : Atmospheric deposition, contamination, Ganga basin, heavy metals, pollution, Varanasi

INTRODUCTION

The solute chemistry of a river depends on a number of processes occurring within its catchment. Some chemical constituents are imported into the river system through weathering and surface run – off. A number of other elements and ions including those of potentially toxic heavy metals are added into the system through surface discharge and atmospheric deposition. The impact of long – range atmospheric transport and deposition of pollutant aerosols on terrestrial environment is well documented from long back, impact of aerially – driven pollutant aerosols on lotic systems have received attention only recently (Thornton and Dise, 1998). Some earlier studies have shown sizable atmospheric input of trace metals to lake systems (Bragazza, 2006). In India, the

data so far available on these lines have been mainly confined to the deposition and effects of acidic components of the atmosphere (Kumar *et al*., 2001). Far less attention has been paid towards atmospheric deposition – linked heavy metal contamination to river systems. During recent years anthropogenic activities have dramatically increased the atmospheric deposition of pollutant elements even in areas far – away from the direct human influence (Pandey and Pandey, 2005). Although the problem of atmospheric deposition of pollutant elements is of global concern, this problem is rapidly rising in developing countries including India due to newly establishing industries coupled with fastened urban growth and lack of efficient control measures (Borbely – Kiss *et al*., 1999; Pandey and Pandey, 2009).

Atmospherically – driven heavy metals have been shown to significantly contaminate soil and dietary vegetables causing a serious risk to human health when plant – based foodstuffs are consumed (Pandey and Pandey, 2009). Furthermore, dietary intake of trace elements depends also on irrigational water use. There exists a strong relationship between the concentrations of trace elements in irrigational water supply and their accumulation in agricultural crops (Sharma *et al*., 2006). Thus, the deposition of heavy metals on water bodies could doubly increase the human intake through food chain as well as through drinking water use. Most of the surface discharge sources contaminate soil and water bodies under limited spatial range, aerial emission which often follows long – range atmospheric transport, contaminate wider range of ecosystems down – wind to emission sources. Furthermore, unlike surface discharge, where stream – flow restricts mid – stream contamination, atmospheric deposition directly adds contaminants on to the water surfaces. Thus, despite all efforts to reduce surface – discharge – linked heavy metal contamination, addition of atmospherically driven toxic metals will continue to contaminate surface water resources even to those water bodies situated away from the emission sources. At a time when a human health has become a global priority, a better understanding of atmospheric deposition – linked heavy metal contamination of fresh water resources seems to have particular significance.

In the present study, an attempt was made to examine the variations in the concentrations of six heavy metals in mid – stream water of Ganga river in relation to their inputs through atmospheric deposition at Varanasi. Recent studies conducted in India have indicated the rising atmospheric transport of trace elements derived from distant sources, variations in the regional deposition patterns of these elements and, their significance with respect to contamination of terrestrial environment including agro – ecosystems (Singh and Agrawal, 2005; Pandey and Pandey, 2009). However, there is a general dearth of studies explicitly addressing the atmospheric transport of potentially toxic heavy metals in Indian river systems and their significant role in contaminating these fresh water resources. This investigation is an effort in this direction with a view to examine the magnitude of contamination of mid – stream Ganga water at Varanasi in relation to atmospheric deposition of some important heavy metals.

MATERIALS AND METHODS

The study area

The present study was conducted at selected sites of Ganga river at Varanasi between April, 2006 to March, 2008. The study area is situated between 25^0 $18^/$ N latitude and 83^0 $1^/$ E longitude in the midst of eastern Gangetic plane at 76.19 meter above msl. Eight sampling locations selected at 20 km long river site for this study

extends from Adalpura to 3 km down – stream of Malviya bridge at Rajghat (Table 1). The climate of the region is tropical monsoonal with dominant westerly winds.

Methods

The bulk atmospheric deposition was collected using bulk samplers which combine the precipitation and dry fallout in the same container. These collection systems were maintained at a height of 2 m and were devised to avoid bird nesting as described in Pandey and Pandey (2009). After collection, samples of atmospheric deposition were acidified with HNO_3 (Merck), filtered and stored in dark at ambient temperature before analysis. Heavy metals in atmospheric particulates were extracted following ternary acid digestion procedure (Allen *et al*., 1986). Mid – stream sub-surface water samples were digested with HNO_3 at 80^0 C (APHA, 1987). The concentrations of Cd, Cr, Cu, Ni, Pb and Zn in digested filtrates were determined with an atomic absorption spectrophotometer (Perkin Elmer model 2130, USA). A quality control has been performed using acidified water blank for checking the contaminations during field collection and during sample treatment in the laboratory.

Effects of sites and seasons were assessed using analysis of variance (ANOVA) following appropriate transformations whenever required. Correlation coefficients (r) were computed to test the linearity of relationships and temporal variability was determined by calculating coefficient of variation (CV) across time.

RESULTS AND DISCUSSION

The bulk atmospheric deposition was observed highest for Zn (124.15 – 477.18 g ha^{-1} y^{-1}) and lowest for Cd (0.56 - 20.15 g ha^{-1} y^{-1}). Atmospheric deposition of Pb (1.80 - 124.00 g ha^{-1} y^{-1}) also remained high. On spatial scale, the atmospheric deposition appeared higher at source oriented sites in comparison to those of the non – source oriented locations, the values being lowest at Adlpr (site 2) and increased almost consistently up to Rjght (site 8). Except for Zn, depositions of all the heavy metals were observed highest during winter (Fig. 1). Seasonal as well as between – site variations in the atmospheric deposition were significant ($p < 0.001$) (Table 2). Atmospheric deposition recorded in this study are, in general, comparable to those observed in earlier studies conducted in other parts of Indian tropics receiving similar atmospheric loadings (Singh and Agrawal, 2005; Pandey and Pandey, 2009).

Heavy metal concentration in mid – stream water showed large differences and followed a trend almost similar to those observed for atmospheric deposition. With few exceptions, concentrations of these metals increased almost consistently down – stream from Adlpr to Rjght (Fig. 2). Concentrations in mid – stream water were recorded maximum for Zn (26.70 – 198.60 µg L^{-1}) and minimum for Cd (ND – 8.60 µg L^{-1}). Similar observations have been made by Eder and Offiong (2002) for Lower Cross River Basin, Southeastern Nigeria. Except for Zn, concentrations were recorded highest during winter (Fig. 2b). For Zn, concentrations were recorded highest during summer (Fig. 2b).

In the present study, the concentrations of Cr (1.50 – 29.60 µg L^{-1}), Cu (2.41 – 18.45 µg L^{-1}) and Zn (26.75 – 198.60 µg L^{-1}) in mid – stream water of all the eight locations were well below their respective maximum admissible concentrations (MAC) of 50, 1000 and 5000 µg L^{-1} (Table 3). However, the concentrations of Cd (ND - 8.60 µg L^{-1}) were found to be greater than its MAC (3.0 µg L^{-1}) in 7 out of 8 locations sampled. Similarly, Pb concentrations (0.28 – 16.80 µg L^{-1}) in 7 out of 8 locations were higher than its MAC of 1.5 µg L^{-1}. Eighty seven percent of total water samples had Pb concentrations

above the MAC of 1.5 µg L^{-1}, while 82 % of the water samples showed Ni in excess of its MAC (20 µg L^{-1}). This may lead to serious health implications since Ganga water is also used for drinking purpose by a large population.

The patterns of spatial variations bear great significance in establishing source – receptor relationships. Site – wise variations of heavy metal concentrations in mid – stream river water as indicated by ANOVA was significant (Table 2). Correlation analysis indicated significant ($p < 0.01$) relationships between mean concentrations of Cd, Cr, Cu, Ni, Pb and Zn in water and their respective rates of aerial deposition (Table 4). Similar observations have been made by Thorton and Dise (1998) in a number of streams in English Lake District of Cumbria. The total aerial metal input which was computed as Cd + Cr + Cu + Ni + Pb + Zn, ranged from 160.12 – 643.35 g ha^{-1} y^{-1} and, with few exceptions, increased almost consistently from site 1 (Adlpr) to site 8 (Rjghtds). These atmospheric fluxes of total metals observed for Ganges although were significantly lower than those observed very earlier for Lake Michigan (Eisenreich, 1980), a corresponding trend in total metal concentration in mid – stream water (34.70 – 336.10 µg L^{-1}) is an indicative of the role of aerially – driven input of heavy metals in mid – stream water contamination. Temporal variability remained higher (cv = 0.123 – 0.336) for mid – stream heavy metal concentration in comparison to that of the atmospheric deposition (cv = 0.115 - 0.326). However, the differences between mean cv values of these two functions were not significant. This further support that the atmospheric deposition is the main contributor to mid – stream water contamination. Low temperature, calm wind and concurrent formation of inversion during winter could restrict dispersal and consequently raise the deposition of atmospheric aerosols. Zinc appeared exception due probably to added atmospheric loading of soil- borne particulates during summer months. Mid – stream heavy metal concentration showed almost similar seasonal pattern. Relatively high concentration of Zn during rainy season could be linked to surface – borne metal added through run – off.

The main sources of these elements into the atmosphere are urban – industrial emissions in adjoining areas (Pandey and Agrawal, 1994). Re - suspension of the land – deposited particulates coupled with predominant westerly winds could further substantiate deposition of heavy metals (Pandey and Pandey, 2009) towards down – wind locations. These inputs are in addition to the urban flushing and surface run – off being added to the river. However, since stream flow restricts cross – stream lateral mixing of surface – fed materials, atmospheric deposition could be considered as the major forcing factor responsible for mid – stream heavy metal contamination of Ganga river. A comparison of Adlpr site with rest of the sampling locations shows that more than 86 % of mid – stream water samples of the latter showed about 1.5 to 36 fold increase in the heavy metal concentrations under the influence of anthropogenic emission sources. Except for Adlpr (site 1), the remaining 7 locations fall into medium to high concentration zones (Eder and Offiong, 2002).

Our observations clearly indicate that Ganga river at Varanasi receive sizably high atmospheric inputs of Cd, Cr, Cu, Pb and Zn. The spatial and temporal patterns of atmospheric deposition strongly implicate the western and north – western periphery of river Ganga at Varanasi as the primary emission sources. Concentrations of these metals in mid – stream water showed significant correlations with their respective inputs through atmospheric depositions. This indicates that the atmospheric deposition is the major

contributor to mid – stream heavy metal contamination of Ganga water at Varanasi. The study suggests that the aerial catchment can sizably contribute to surface water contamination of potentially toxic metals. These observations form the first report on atmospheric deposition – linked mid – stream water contamination of Ganges. Furthermore, more than 82 % of water samples of 7 out of 8 locations sampled at Varanasi showed Cd, Ni and Pb levels above their maximum admissible concentrations. This may lead to serious health implications in long – run since Ganga water is also used for drinking purpose by a large population.

Abstract

Macrobenthos are an important part of sea-bed fauna which include *Polycheata*, *Decapoda* and *Mollusca*. Some species of this group are considered as biological indicators for aquatic ecosystem. Macrobenthos are mostly inhabitants without migration and they can be used as indexes of ecological crises related to water. In the present research, benthic community structure in Ghanam creek and region of Mossa creek, It is located around B.I.P.C sewage outlet were studied, eight station were selected, and water & sediment samples were collected in two season warm (September) and cold (February). Result of research indicated that station of sewage outlet around had least species and higher organic matter, on the contrary, the station far from petrochemical industry (station located in Ghanam creek) activities had higher species diversity. Also, present study showed that Polychaetes, reference of pollution bioindicators had higher aboundance. Cosequently, macrobenthic biodiversity relation with dissolved oxyqen and percentage of organic matter in the sediment.

Key words: Macrobenthos, Ghanam creek, Dissolved oxygen

1. Introduction

Creeks usually considered as most complex and riches ecosystems in aquaticecosystem, and one of as important zones of environmental. Human activity increased in the ecosystems (example industries settlement or entrance of pollutant sewage of urban, industry or agriculture) to cause destroied these ecosystem, because of high production of organic matter and provide a safety place for varied marines.

Mossa creek is a long canal with high depth, it is a tidal marine in Iran. The creek stretches almost 56 km along the North western of the Persian Gulf. It is connected with Mahshahr port and Shadegan watershed (largest watershed in Iran), width of creek on opening mouth is 37-40 km. Water depth on the west is 80m, and on the East decreased (5-18m). Tidal wave in zone cause to water of creek mixed with Persian Gulf. Change of water quantity within seasons is 4m.

It contains numerous sources of organic pollution including sewage outlet industries. The creek is of immense importance to zone for trading, commercial development and increase petrochemical industries.

However industry location in the area to cause huge volume entrance of industry and non-industry pollutans to this aqua ecosystem. In the present research , environmetal condition in Ghanam greek (reference of unpollution creek) and region of Mossa creek, it is located around Bandar Iman Petrochemical Company(B.I.P.C) sewage outlet (reference of pollution Maximum), were studied.

Previous pollution survey in the Ghanam creek, performed Nabavi and Savari(2002), Mahdi soltani(2007) showed that, this area had moderate pollution load.

The objective of this study is to analyse the relationship between Macrobenthos with physicochemical parameter, percentage of organic matter and gerain sediment analyse (GSA) for determine pollution load.

2. Material and methods

2.1. Site selection

Mossa creek is situated in North western Persian gulf ($30^\circ\ 21'$ until $30^\circ\ 31'$, $48^\circ\ 52'$ until $49^\circ\ 15'$). Bandar Iman Petrochemical located in North of Mossa creek, it is largest petrochemical company in Iran, this area is 450 ha . For the purpose of this study, the eight stations along Mossa creek were selected. Stations 1,2&5 were siuated in the earlier sewage outlet of B.I.P.C, Stations 3&4 located in distance 500m from sewage outlet, and Stations 6,7&8 located in Ghanam creek (Figure.1). The creek was sampled on the 8th September 2007, and 8th February 2008.

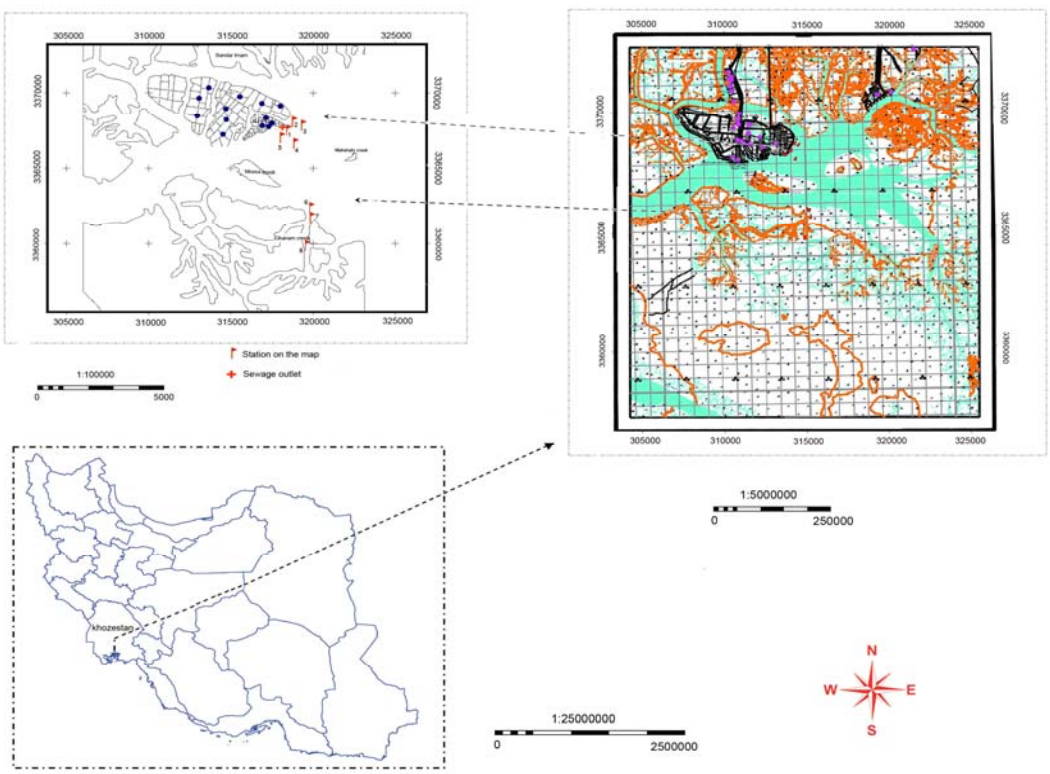

Figure 1. Location of the Mossa creek and B.I.P.C. The sampling stations are indicated.

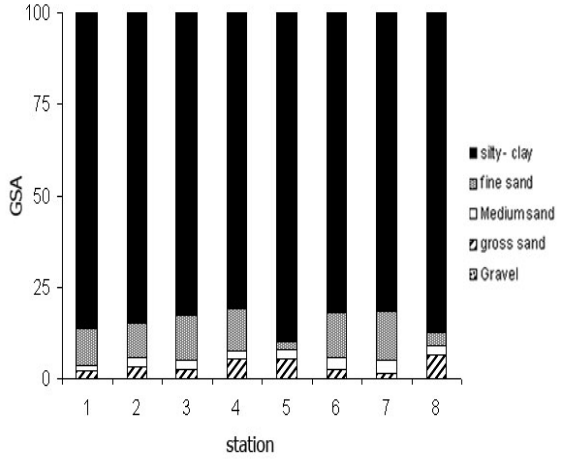
2.2. Water sampling

Water samples were taken in 3 bottles from each station. Point samples in each satation were determined with GPS. Samples were taken from water near the bottom of the creek with Nansen. The dissolved oxygen (DO) and temperature were measured "insitu" by portable do-meter. pH and Salinity were measured in laboratory.

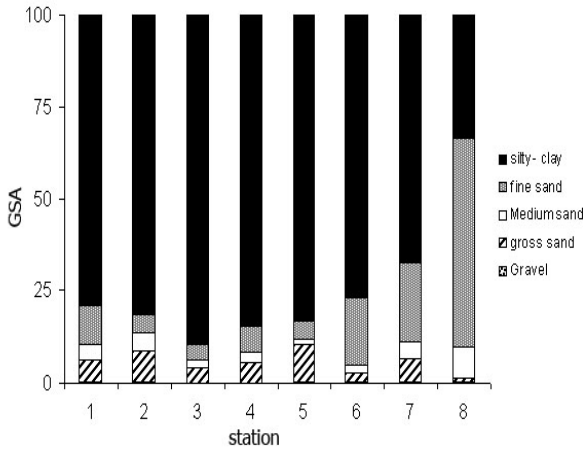
2.3. Macrobenthos sampling

Four grab amples were collected at eight stations with Van Veen grab of $0.025\,m^2$. Three of the samples were allocated to study the macrobenthic and fourth was used for sediment analysis. Samples for macrobenthos were processed through a sieve with a mesh size of $0.5\,mm$ and the retained fraction was fixed 5% formalin stained with Rose Bengal. Granulometry of the sediment was determined using Buchanan and Kain's method (Bunchanan 8 kain, 1984). The organic content was analysed using Elwakeel riley method.



2.4. Statistical Analysis

The total number of species, the shannon- weaver diversity index(Shannonand Weaver 1963) was calculated for each station by using MVSP (Multiple Variate Statistical Package, 2007) software.Differences between stations were tested with one-way ANOVA and differences between seasons were tested with t-test after verifying normality using the Kolmogorov- Smirnov test (Zar, 1999). Correlation between diversity index and physicochemical parameters were calculated by Spearman test. Compersion between stations, season was performed by Duncan's post hoc test. The affinities among stations, based on the macrofona species, were established trough cluster analysis,using UPGMA(unweighted pair group method using arithmetic averages),(Estacio et al, 1997; Garcia & Gomez, 2005).



3. Results

3.1. Physicochemical parameters

Results of ANOVA showed that no difference between stations for purpose of temperature (p=0.985), PH (p=0.425) and percentage of organic mater (p=0.16); also t-test analysis showed that no difference between seasons based on DO(p=0.435) and percentage of organic matter variables (p=0.378). The statistical analysis indicat that the oxygen dissolved and salinity was different between station ($p \leq 0.05$).The different between pH, temperature and salinity was significant ($p \leq 0.05$). All stations for cold and warm season were dominated by silty-clay (Figure.2 and Figure.3). The cluster analysis approach between stations indicat that the physicochemicaly variables was different near and far from sewage outlet (Figure.4).

Figureure 2. warm season

Figureure 3. cold season

Figureure 2. and Figureure 3. Sediment granulometry measured in the eight stations sampled in the warm and cold season.

Spearman analysis gives a correlation of -0.50 between oxygen concentration and organic matter (Figure.5& Figure.6). Also the correlation of 0.55 between changes in the total organic matter and percentages of silty-clay (Figure 7, Figure 8).

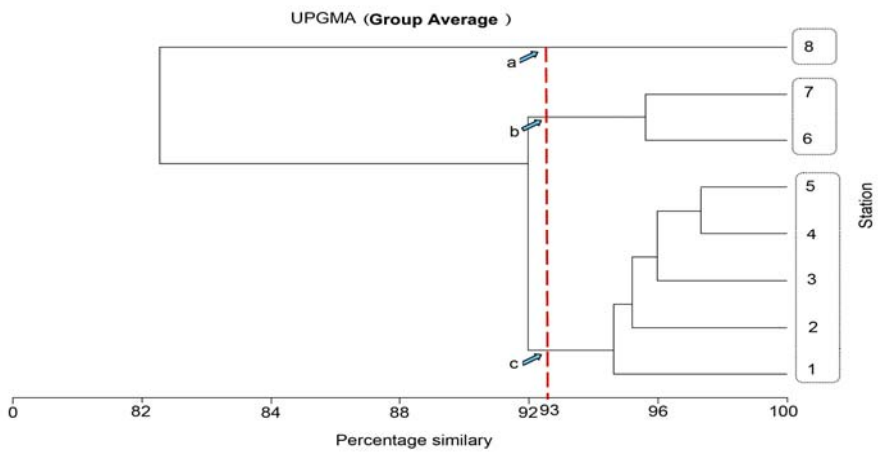


Figure 4. Cluster analysis elaborated using the value of the physicochemical parameters measured in stations.

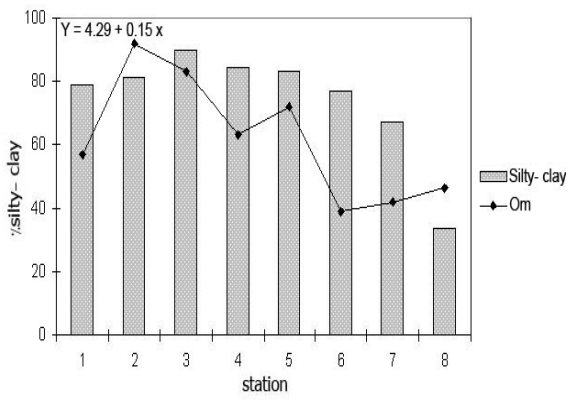

Figure.8. cold season

Figure 7and Figure 8. Comparision between the total organic matter(OM) in sediment (%) and Silty-Clay grains (%) measured in the stations for seasons.

3.2. Macrobenthos

Figure.9 show condition of shanon's index between station. According to statistical analysis , difference between stations was significant($p \leq 0.05$). Cluster analysis based on shanon's index were able to discriminate between stations of near and far from sewage outlet (Figure.10). The polychaetes community was discriminating in the particular conditions (Figure.11, Figure.12).

A sperman analysis give a correlation of0.93 between of shanon's index and combination DO (Figure 13 and Figure 14).

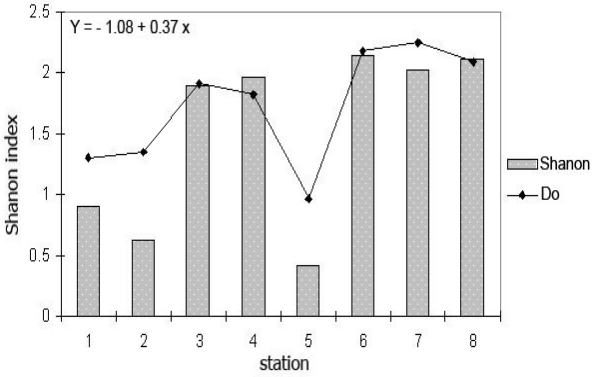

Figure 13 and Figure 14. Relationship between the shanon index and Do(mg^{-1}) showed in the warm and cold season.

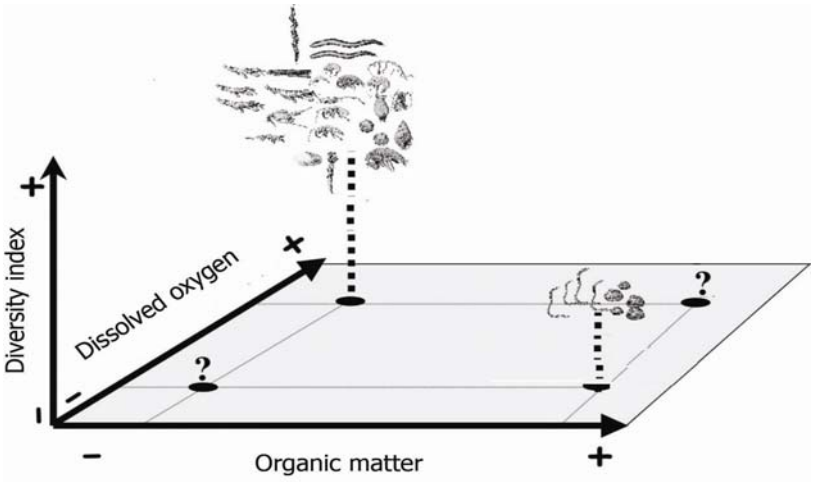
4. Discussion

BIPC located near the Mossa creek and enterance sewage outlet in to this aqua ecosystem.Sewage outlet to cause decrease dissolved oxygen, species diversity and increase percentage of organic matter in the neighbouring stations of sewage outlet. Also according to Welch index, near stations sewage outlet to settle in class of high load pollution.

Table 1. Welch index (1992)



Welch index	Class of water quality
3-5	High pollution
1-3	Moderate pollution
<1	Unpollution water

Table 2. Condition of stations acording to Welch index

Class of water quality	Stations
High pollution	**1,2& 5**
Moderate pollution	**3,4,6,7& 8**

The results of this study show that organic pollution value increase in fine grain of sediment. Our results seem to support the review by Susana carvalho etal (2006);(Figure.2 and Figure.3). In the Mossa creek, polychaetes turned out to be the best group to discriminate between all station. In most of the studies, the polychates were refere to marine pollution, especially to the lack of oxygen and usually discriminate among station better than other groups of Macrobenthos (Carvalho etal. 2006, Garcia and Gomes.2005). The results of this research indicated that macrobenthos diversity relate with dissolved oxygen end percentage of organic matter, the present study highlighted zones of high and low pollution impact on the macrobenthic fauna. Generally, Macrobenthos assemblage decrease from the near seawage outlet, with the opposite pattern for dissolved oxygen, which has led to an increase of macrobenthos in the Ghanam creek.

Abu-hilal(1994), Hassan etal(1995) and EL-sammak(2001) established that high level of organic pollution in Dubai creek to cause decrease dissolved oxygen and macrobenthos diversity.Johansson (1997), Flemer(1999) and Wu(2002) to explained that, in response to decreasing oxygen concentration, species richness and diversity both decrease, and the species composition is largely determined by the tolerance to oxygen deficiency. The adverse biological effects on soft bottom communities are mainly due to reduced oxygen content of the water (Saiz-Salinaz, 1997). However, the interpretation of stress due to low dissolved oxygen is difficult because there is a lack of information about oxygen tolerances for most macrobenthic species (Dauer etal, 1993). Consequently, the importance of oxygen in water column and percentage of organic matter in sediment as key factors for macrofaunal assemblage in sediment is well known. Figure.15 summarises possible outcomes under different levels of organic matter and dissolved oxygen.

Figureure 15. Schematic model indicating the diversity index under different level of organic matter and dissolved oxygen.

Enzymatic Treatment of a Modified Food Processing Wastewater

Dr. Anastasia E. M. Chirnside

Anastasia E. M. Chirnside, Assistant Professor, Department of Bioresources Engineering, University of Delaware. 531 South College Ave., Newark, DE 19716-2140. Tel: 302-831-8871, Fax: 302-831-2469, aemc@udel.edu.

Abstract

The wastewater resulting from soy-processing is found to have extremely high amounts of Total Kjeldahl Nitrogen (TKN), Chemical Oxygen Demand (COD) and a high pH. We have developed an attached growth, packed-bed bioreactor (PBR) containing the white rot fungus (WRF), *Phanerochaete chrysosporium*. This fungus secretes enzymes that catalyze oxidation reactions resulting in degradation of recalcitrant compounds. Previous studies utilizing the fungus in the bioreactor found that the high pH of the wastewater caused inhibition of TKN and COD degradation. Adjustment of the wastewater pH before introduction into the bioreactor resulted in a greater reduction of TKN and COD. However, complete degradation did not occur and pH adjustment was required continuously. Thus, we investigated the effectiveness of treating the wastewater with the enzyme culture solution obtained from the reactor instead of utilizing the fungal reactor itself in order to overcome the inhibitory effect of high pH on fungal activity within the reactor.

The inorganic forms of nitrogen found in the pH adjusted wastewater were removed by treatment with both anion and cation exchange columns. Diluted wastewater (10% and 20%) was treated with enzyme solution (5% and 10%) and monitored for changes in TKN and COD for 24 hours. There was little change in pH over time for any of the treatments. The COD dropped 50 – 67% for all treatments over 24 hours. Removal of the inorganic nitrogen within the wastewater before treatment with the enzymes resulted in a greater reduction in COD. There was little change in TKN over time for any of the treatments.

Treating the wastewater with fungal enzymes successfully reduced the COD concentration by approximately 60%. The results indicate that the use of the ligninolytic enzymes of the white rot fungi to degrade soy-processing wastewater could be a viable treatment technology.

Introduction

Soybean hulls are processed into soy flour in a method similar to paper mill production. The wastewater (SHW) resulting from the soy-processing is found to have

extremely high amounts of Total Kjeldahl Nitrogen (TKN), Chemical Oxygen Demand (COD) and a high pH. After conventional aerobic and anaerobic treatment, the SHW still has extremely high concentrations of TKN (300-350 mg/l), COD (4,000-5,000 mg/l) and pH (>8.0) [Cabe, 2002]. The soy flour processing plant has a NPDES permit to discharge wastewater despite its high levels of TKN. The reasoning for this decision is that the nitrogen is in a complex form that is unavailable to the degrading organisms and therefore will not add to the degradation of the surface water quality. However, this assumption may not include consideration of photo-degradation processes that would, in fact, result in nitrogen availability. Developing a BAT that can treat and remove this nitrogen before the wastewater is discharged would be an environmentally safer approach. The overall objective of this project is to investigate possible alternative treatment technologies.

In recent years white rot fungi, specifically *Phanerochaete chrysosporium*, have been found to have the ability to degrade an extremely diverse range of very persistent or toxic environmental pollutants. Studies have shown that the white rot fungus is able to degrade pesticides, polyaromatic hydrocarbons, polychlorinated biphenyls (PCBs), and most halogenated aromatics (Hammel, 1995; Reddy and Mathew, 2001; and Wu and Yumiko, 1996). We have developed an attached growth, packed-bed bioreactor (PBR) containing the white rot fungus (WRF), *Phanerochaete chrysosporium.* This fungus secretes enzymes that catalyze oxidation reactions resulting in degradation of recalcitrant compounds. Previous studies utilizing the fungus in the bioreactor found that the high pH of the wastewater caused inhibition of TKN and COD degradation (Hetrick and Chirnside, 2001). Adjustment of the wastewater pH before introduction into the bioreactor resulted in a greater reduction of TKN and COD. However, complete degradation did not occur and pH adjustment was required continuously.

The objective of this study was to investigate the effectiveness of treating the wastewater with the enzyme culture solution obtained from the reactor instead of utilizing the fungal reactor itself in order to overcome the inhibitory effect of high pH on fungal activity within the reactor. Initially, the inorganic forms of nitrogen found in the wastewater will be removed by treatment with both anion and cation exchange columns. Therefore, there will be no chance that the enzymes will react with the inorganic nitrogen.

Material and Methods

The WRF was grown and placed in the PBR according to methods described by Chirnside (2008). The fungus was fed growth solution in the PBR for 2 months. Then 4 liters of carbon-limited media was fed to the WRF to initiate peroxidase enzyme production. The pH of the wastewater was adjusted to 7.52 utilizing concentrated H_2SO_4.

The lignin peroxidase enzyme (LiP) extracted from the PBR was used for the experiments. The enzyme solution was tested for activity following the procedure outlined in Chirnside (2008). The enzyme assay resulted in a LiP activity of 871.2 U l^{-1} and a manganese peroxidase activity of 849.0 U l^{-1}. Inorganic nitrogen was removed from half of the wastewater using cation and anion exchange columns. The pH was readjusted

to below 7. Two wastewater dilutions (10% and 20%) and 2 enzyme concentrations (5% and 10%) were examined. The diluted wastewater was treated with the enzyme solutions and monitored for changes in TKN, pH, and COD for 24 hours. Sampled times were at 0 hours, 2 hours, 4 hours, 8 hours, and 24 hours. The experiment was done in triplicate.

Results and Discussion

There was little change in pH over time for any of the treatments. The pH of the "no removal" treatments ranged 6.0 and 7.0 and did not change significantly over 24 hours. For the "removal" treatments, the pH ranged between 4.5 and 5.0 with little change over time. When the inorganic nitrogen was removed from the wastewater, addition of the enzyme solution caused a decrease in pH. There was a greater decrease in the treatments receiving the higher enzyme concentration (Figure 1).

Chemical oxygen demand (COD) dropped 50 – 67% for all treatments over 24 hours (Figure 2). The COD for all treatments began between 4750 and 5800 mgL^{-1} and all dropped below 3250 mgL^{-1} over 24 hours. There was a greater reduction in COD in the wastewater that was diluted 20% than that diluted to 10%. Removal of the inorganic nitrogen within the wastewater before treatment with the enzyme solution had little effect on the degradation of COD. For the treatments receiving higher enzyme concentrations, there was a slight increase in COD degradation.

There was little change in Total Kjeldahl Nitrogen (TKN) over time for any of the treatments (Figure 3). There was an increase in TKN for all treatments during the 24-hour incubation period. It was possible that the degradation of COD resulted in the release of NH_3-N, which would have resulted in higher TKN values. There was a greater decrease in TKN for treatments containing the treated wastewater (inorganic N removal). The greatest change was seen in the higher wastewater dilution containing the 10% enzyme solution.

Conclusions

Continuous recycling of pH-adjusted wastewater was an effective treatment for reducing both the TKN and the COD concentration of the soy processing wastewater. The success of the experiment indicates that further research would be advisable. The physical properties of the PBR need to be optimized in order to design a continuous treatment operation that would require little maintenance. Another option that could be investigated is the utilization of a series of bioreactors in which the effluent is pH-adjusted before introduction into the next bioreactor.

Treatment of the wastewater directly with the fungal enzymes had variable success in decreasing the TKN. When the inorganic nitrogen was removed from the wastewater, the solution pH remained equivalent to the pH of the enzyme solution. This would be advantageous to the ligninase enzyme system of the WRF. The presence of inorganic nitrogen and Total Kjeldahl Nitrogen caused the pH of the enzyme treated wastewater to rise slightly but the pH remained at a neutral value.

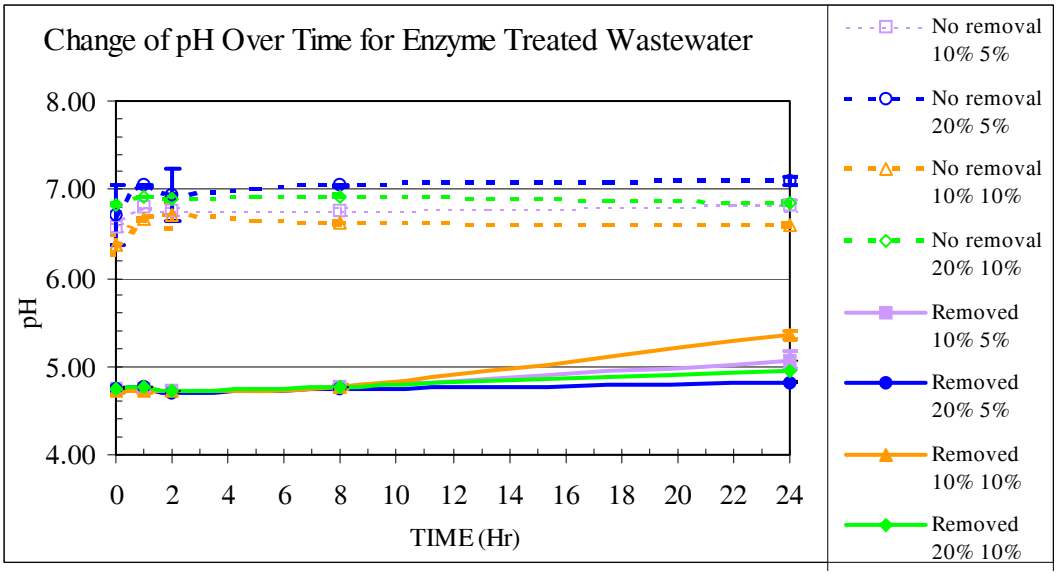

Figure 1. The change in pH over time for the enzyme treated wastewater. The solid curves represent the wastewater that had the inorganic N removed. The first percentage represents the wastewater dilution factor (20 or 10%), while the second percentage represents the enzyme concentration (10 or 5%).

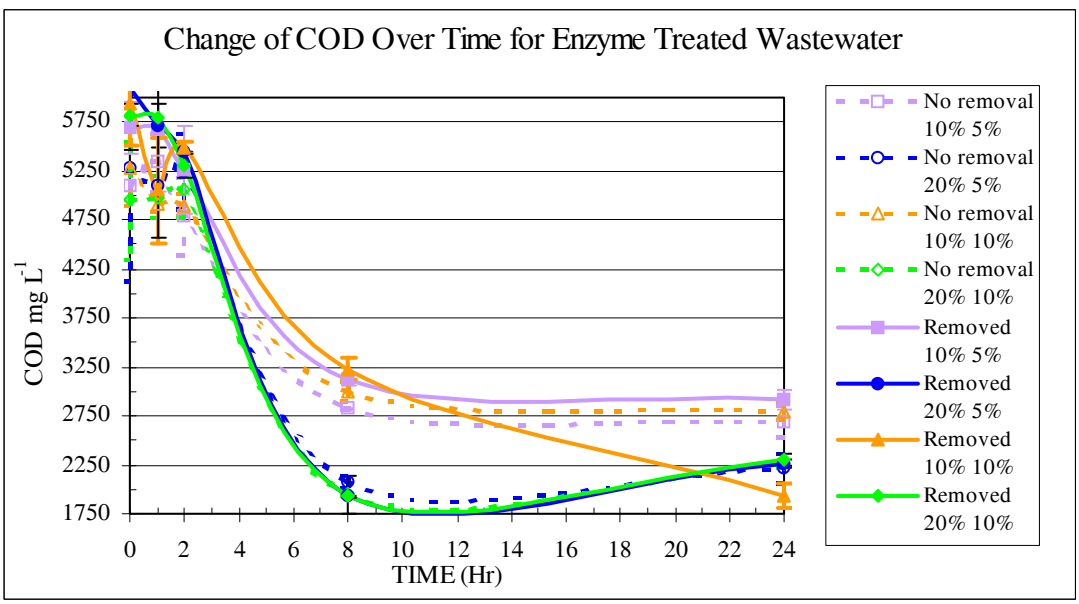

Figure 2. Change in COD over time of wastewater treated with fungal enzymes.

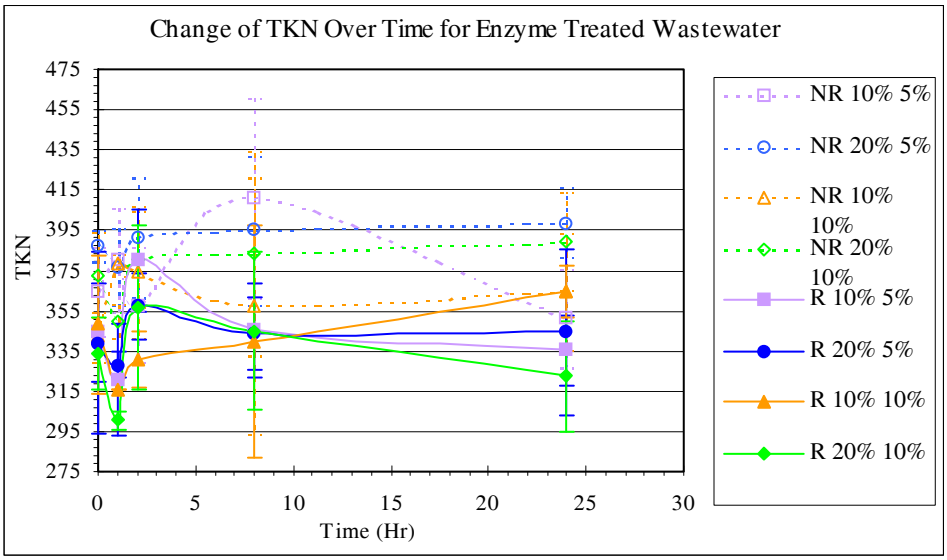

Figure 3. The change in TKN over time of wastewater treated with fungal enzymes.

There was little change in the TKN over time when the wastewater was treated directly with the fungal enzyme solution. However, TKN concentration increased and then decreased during the experiment indicating that chemical reactions were occurring. There was great variability in the TKN concentration during the first few hours of the experiment. Changing the sampling times of the experiment to assess changes during the first 2 to 3 hours may help to explain the decreases and increases in TKN concentration that occurred. The rates of TKN degradation differed among treatments especially during the first few hours. However, it was difficult to assess the trends of the different treatments due to the lack of observations during the first hour or two. Design changes in the experimental set up would provide better data to answer the objectives of this research.

Treating the wastewater with fungal enzymes successfully reduced the COD concentration by approximately 60%. The results indicate that the use of the ligninolytic enzymes of the white rot fungi to degrade soy-processing wastewater could be a viable treatment technology. However, the results also present more questions about the interrelationship between COD degradation and TKN concentration. In order to successfully remove both COD and TKN from the wastewater, a better understanding of the reaction chemistry is needed. Further research in this area would help design a treatment system that could effectively degrade both of these recalcitrant pollutants. Optimization of the PBR to increase both fungal growth and ligninolytic enzyme production is needed in order for this treatment method to become a “best available technology” in the National Pollutant Discharge Elimination System for wastewater discharge control under the Clean Water Act.

Abstract

Federal and state regulations prescribe design requirements for low permeability clay landfill liners based on saturated hydraulic conductivity. The assumption that clay liners are saturated for the duration of their life is a simplification of the true processes at work. The fact that clay liners are compacted to optimum, or just wet of optimum, proves that they are initially subject to unsaturated conditions, and it is well known that liners can remain variably saturated for the duration of their life. While this is appropriate for landfill cover liners, leaching affects may drastically change pore fluid chemistry as water moves through the landfill to the bottom liner. In this study the goal is to determine the affect of modeling two different pore fluids—leachate and water. This research uses an approach that critically assesses how leachate will move through a landfill bottom liner differently than water.

The result of this study is the affect of leachate on the soil-water characteristic curve and a quantitative comparison of how a liner would be expected to perform when permeated with leachate versus water. Samples prepared with leachate resulted in lower water content than samples prepared with water. Both the Van Genuchten and Cory-Brook models fit the data (leachate and water) very well. At higher (400 cm of water) the difference between the leachate samples and water sample became obvious.

Background

Historically solid waste landfills have included natural attenuation and containment landfills. Natural attenuation landfills focused on non-hazardous waste from municipal sources and typically leached into groundwater due to poorly constructed or no liners (Bagachi, 1994). Containment Landfills were developed in the latter half of the twentieth century to accepted wastes from industrial sources in addition to municipal wastes. These landfills used low permeability liners to restrict seepage of leachate to groundwater. As water percolates through the solid wastes, biological materials and chemical constituents are leached into solution as the waste undergoes simultaneous and interrelated biological, chemical, and physical changes (Bagachi, 1994). This solution is referred to as Leachate.

Current practice of sanitary landfill engineering came into play in 1984 with an amendment to the 1976 Resource Conservation and Recovery Act that gave the EPA jurisdiction over landfills (Hickman and Richard, 2000). The EPA responded with the prescriptive Subtitle D that is still referred to today for design specifications. In California landfills are classifies into three categories:

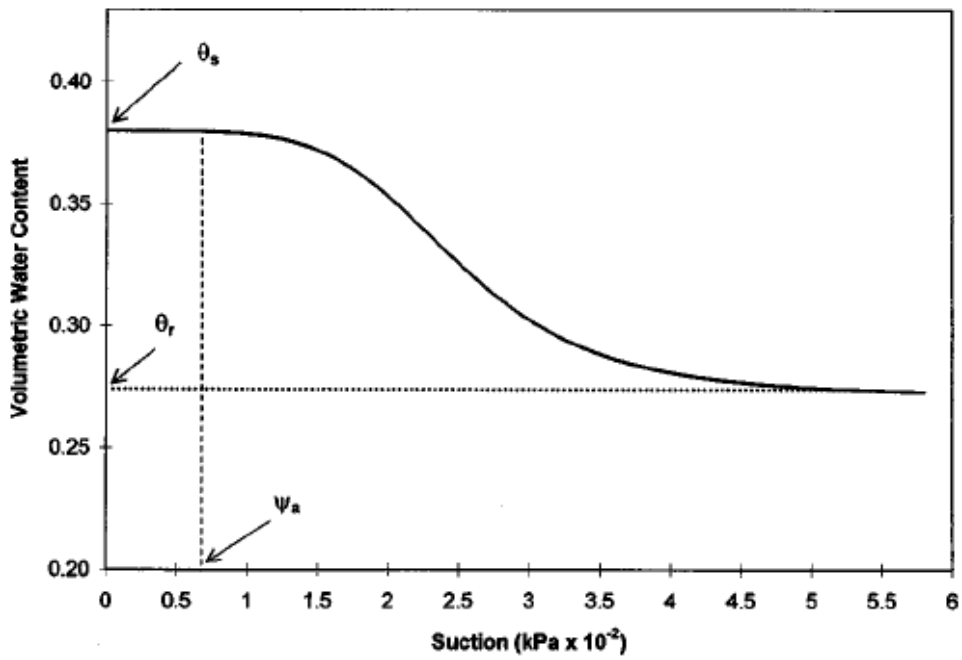
- Class I. Hazardous Waste
- Class II. Designated Waste
- Class III. Municipal Waste

Liners are materials which line the bottom and below grade-sides of a landfill and act as a final barrier to the underlying hydrogeology. Their primary function is to control leachate. Liners collect the landfill infiltration and divert it into leachate collection systems so standing water forms above the liner, forming a hydraulic head. Liners are the final defense for underlying aquifers. Because liners are subject to leachate infiltration, they are the focus of this study.

Covers and liners are multilayered systems with the focus around a low permeability layer. They are made up of three general materials: Geomembrane, geosynthetic clay liner, and compacted clay liners. Often a composite liner is used which utilizes a combination of these materials. Still today clay continues to be an important material in landfill liner design. When clay is used as a hydraulic barrier, field compaction usually occurs at a moisture content wet of optimum. This tends to yield a more oriented or dispersed structure which exhibits a lower hydraulic conductivity. Moisture contents ranging from 2% to 4% above optimum are common (Bagachi, 1994).

Both Federal and California law mandate cover and bottom liner systems for Class I, II, and III. Final Covers are closure and post closure measures which mostly serve to minimize infiltration into the landfill, mitigate erosion, and control gas emissions. Interim covers are spread over the active landfill face in order to control vectors, fire, water infiltration, erosion, and to prevent unsightliness (Dunn and Singh, 1995). Although cover liners are not naturally subjected to leachate seepage, facilities that use leachate recirculation systems will pump leachate from above the bottom liner and redirect it to above the waste layer or to a treatment system where it is removed from the landfill.

Minimum requirements for cover and liner systems are outlined in Titles 40, Part 258 of the Code of Federal Regulations and in Title 27, Chapter 3 of California Code of Regulations. Liners are required to meet minimum standards outlined in Subtitle D of these documents. Liner thickness is usually specified between five to twelve feet of clay, with two feet as the minimum, and hydraulic conductivities are specified in terms of saturated conductivity assuming water as the permeating fluid.



Federal and state regulations prescribe design requirements for low permeability layers based on intrinsic hydraulic conductivity using water as pore fluid. Research has shown that many of the mechanical properties of clay soils are closely related to the water-retention characteristics of the soil mass; and since the latter is a function of the mineralogy, pore fluid chemistry, fabric and structure of the soil mass; any change of the pore fluid chemistry may lead to a removal of the existing bonds and therefore an alteration of the internal equilibrium stability of the soil mass (Raymond et al., 1984).

The current approach to landfill liner design also bypasses an accurate prediction of the rate of water movement through the liner under unsaturated conditions and the assumption that clay liners are saturated for the duration of their life is a simplification of the true process at work. The fact that clay liners are compacted to optimum moisture content, or just wet of optimum, shows that they are initially subject to unsaturated conditions and it is well known that liners can remain variably saturated for the duration of their lives (Bigachi, 1994).

This study seeks to produce a more accurate account of the difference in complex fluid movement processes occurring in municipal landfill liners by accounting for clay-chemical

interactions via the soil-water characteristic relationship (see Figure 1). The purpose is to produce a quantitative one-dimensional comparison of the difference in how leachate and water will be expected to flow through a clay liner. Some of the defining parameters of the SWCC are the saturation water content (θs), irreducible water content (θr), and the air-entry pressure head (Ψ_a).

Figure 1. Soil-water Characteristic Curve (SWCC)

Material and Methodology

Clay

The clay used for this research was sampled from a stockpile currently supplying low permeability clay for the construction of two landfill liners for the Chicago Grade Landfill in the Atascadero-Templeton area of Northern San Luis Obispo County, California. Leachate was sampled from the City of Paso Robles Landfill located just outside of Paso Robles, CA in San Luis Obispo County. This is a Class III waste management facility permitted by the Regional Water Quality Control Board to dispose non-hazardous municipal solid waste.

An initial geotechnical analysis (see Tables 1 & 2) was performed in accordance with ASTM D698, D4318, C127, D70, and D854s on the clay samples to determine their basic properties. This analysis also verified that the samples were representative of the clay used for liner construction by comparing the results with previous geotechnical investigations. Like the one conducted by Hoover and Associates in 2002. In their results showed that the that the hydraulic conductivity measurements in the $1x10^{-8}$ to $1x10^{-7}$ cm/sec range when compacted to 90% relative compaction on the wet side of optimum. The geotechnical report by Hoover & Associates also revealed that the atterberg limits were (LL=40 and PI=14).

Table 1. USCS Classification and Grain Size Distribution

Soil Type	USCS Classification	Grain Size Distribution			
		Gravel	Sand	Silt	Clay
Brown Clay Sample	Sandy-Lean Clay (CL)	8%	28%	13%	51%

Table 2. Standard Compaction Results

Soil Property Index	Value
Standard Proctor Maximum Dry Density	96.6 PCF
Optimum Moisture Content	25.5 %
Liquid Limits	39
Plasticity Index	14
Specific Gravity	2.68

Leachate

Leachate was sampled from the City of Paso Robles Landfill located outside of Paso Robles, CA in San Luis Obispo County. This is a class III waste management facility permitted by the Regional Water Quality Control Board to dispose non-hazardous municipal solid waste. Typical waste types received for disposal are summarized in Table

Table 3: Waste Constituents of Landfill where Leachate was Sampled

Waste Constituent	Percent
Residential Curbside Collection Wastes	21.5%
Commercial Bin Service Discards	40.0%
Roll-Off Box Debris	5.9%
Self-Hauled Wastes	14.9%
City of Paso Robles Waste Debris	2.7%
Sewage Treatment Plant Grit Screenings	0.4%
Mattresses and Sofa's	0.2%

Just less than 5.0 gallons of leachate was sampled from the leachate system that provided recirculation to a closed portion of the landfill. The sample was collected in a 5.0 Gallon HDPE container and was immediately sealed with an air-tight lid. The sample was kept at room temperature (approximately 60°F) and sheltered from any direct natural or artificial light for the duration of laboratory testing. It was beyond the scope of this study to provide analysis of leachate constituents (see table 4); however the March 2003 Detection Monitoring report submitted to the California Regional Water Quality Control Board revealed the following leachate characteristics:

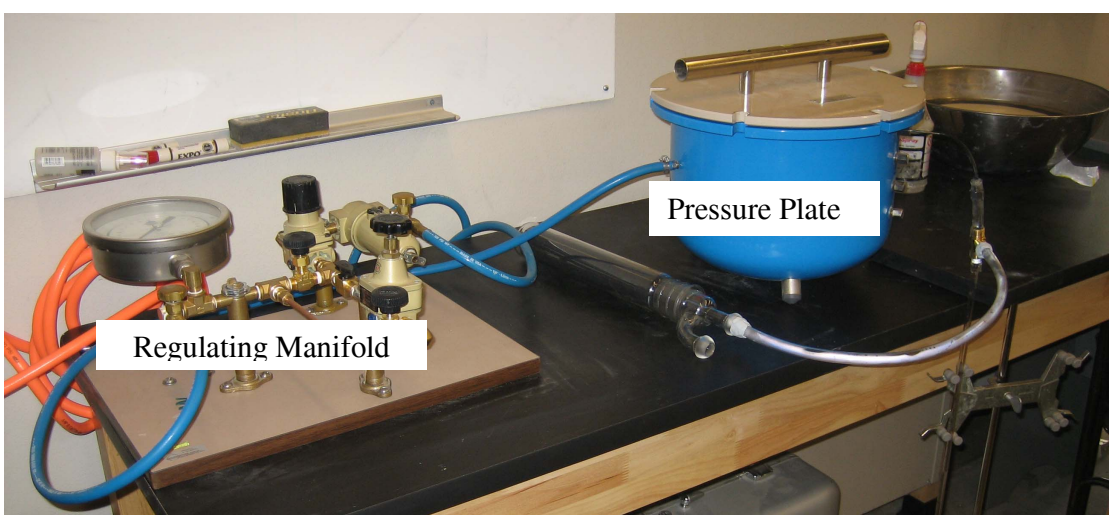
Table 4: March 2003 Leachate Constituents

Analyte	Result (mg/L)
Total Dissolved solids	1240
Chloride	294
Sulfate	91.9
Sodium	246
Barium	0.204
Copper	0.014
Lead	0.026

No volatile organic compounds (VOCs) were detected in the 2003 analysis; however, past reports (January, 1995) have indicated the presence of organic compounds (see table 5):

Table 5: March 2003 VOC Constituents

Analyte	Result (µg/L)
Chloroethane	42
1,1-Dichloroethane	64
Methylene Chloride	350
Tertachloroethane	29
Toluene	23
1,1,1-Trichloroethane	41
Trichlorofloromethane	24
Xylenes	14



Pressure Plate Extractor

For this study the axis translation method was used. This is a simple and effective way to measure soil water characteristic curves.

Hillel (1956) [as discussed in Miller et al., 2002] demonstrated that the pore-water pressure is increased by an amount equal to the increase in the ambient chamber air-pressure. In other words, the soil matric suction remained constant when measured at various ambient pressures.

A Pressure Plate Extractor (PPE) is used to provide ambient pressures above atmospheric. The pressure tank, valves, gages, and ceramic plates were all obtained from Soil Moisture Corporation, in Santa Barbara, a picture of which is provided in Figure 2.

Figure 2. Pressure Plate Extractor and Pressure Regulating Manifold

The PPE is capable of imposing matric suctions up to 5.0 Bars. Four ceramic plates, capable of withstanding air-entry values up to 0.5, 1.0, 3.0, and 5.0 Bars are used in this study. The ceramic plates are manufactured with microscopic pores to allow the passage of water. As long as the pressure in the extractor does not exceed the air entry value of the plate, air will not flow through

the pores because of surface tension forces at the gas-liquid interface. The air-entry value is a function of the pore diameter (Soil Moisture Corp 2006).

When the soil is placed on the ceramic plates, and the extractor is pressurized, water will begin to flow from around each of the soil particles and out through the ceramic plate. Equilibrium occurs when the effective curvature of the water films throughout the soil are the same as the pores in the plate (Soil Moisture Corp 2006).

Pressure is supplied to the PPE through an available 120 psi supply line which is controlled with one standard regulator in series with a nullmatic regulator. Together, the two regulators can control a stable pressure supply within 0.5 psi (0.02 Bar) accuracy. The nullmatic regulator has a maximum capacity of 4.0 Bars and must be bypassed beyond this range. The main difference in using this bypass was an increased difficulty in setting the target pressure. Once the target pressure was set, no fluctuations were visible.

In order to determine the affects of leachate on unsaturated fluid movement two samples are prepared—a control utilizing water as the pore fluid and another utilizing leachate. A pressure plate extractor (PPE) is used to indirectly measure changes in matric suction and corresponding water contents to determine the soil-water characteristic relationship. Samples are compacted at 3 to 4% wet of optimum using a standard compaction effort. For each test, twelve samples are carefully cut from the compaction mold, placed into confining rings and then positioned on a ceramic plate in the PPE. The resulting water contents are measured at four imposed matric suctions—0.5, 1.0, 3.0, and 5.0 BARs.

SWCC Functions

Soil water characteristic functions provide mathematical representations of the soil water characteristic curve based on empirical parameters. These functions vary in their ability to describe the curves and their applicability may change depending on the soil properties. This study considered two different characteristic functions.

The Brooks Corey Model [(1964) as discussed in Merayyan, 2001]:

$$\theta(h) = \theta r + \frac{\theta s - \theta r}{\left[(h/\Psi_a)\right]^{\lambda}} \tag{1}$$

where λ is the pore-size distribution index.

The Van Genuchten Model [(1980) as discussed in Merayyan 2001]:

$$\theta(h) = \theta r + \frac{\theta s - \theta r}{\left[1 + (-\alpha h)^n\right]^m} \tag{2}$$

where α is an optimized parameter and is inversely related to the air-entry suction.

Both of these models require parameter optimization in order to uniquely describe a soil. Brooks Corey requires optimization of θ_r, ψ_a, and λ. The Brooks Corey is heavily dependent on λ. Through Kelvin's capillary law, the pore-size distribution index is assumed to be analogous with the slope of the soil-water characteristic curve (Leong and Rahardjo, 1997).

The Van Genuchten model is defined by three parameters, α, n, and m. Each of these parameters is described by Leong and Rahardjo (1997). The parameter α is the pivot point of the

curve; as α increases, the air-entry suction decreases [(Tinjum et. Al, 1997) as discussed in Miller et al., 2002]. The parameter n controls the slope of the SWCC about the pivot point, which occurs at a normalized volumetric water content (Θ) of 0.5, where: $\Theta = (\theta_w-\theta_r)/(\theta_s-\theta_r)$. As n increases, the sloping portion of the curve between ψ_a and the knee (the point of inflection at the lower portion of the curve as it approaches a horizontal position) of the SWCC becomes steeper (Merayyan, 2001). The parameter m rotates the sloping portion of the curve. As m increases, the range of the curve between ψ_a and the knee of the SWCC decreases. The stability of the curve-fitting process is improved by equating the parameter m to 1-(1/n) [(Van Genuchten et al., 1997) as discussed in Merayyan, 2001]. This relationship was adopted for this study.

Excel Solver

Soil Water Characteristic parameter optimization was conducted using Microsoft Excel's Solver routine. Solver is part of a suite of commands which operated within Excel's programming structure. Solver allows the user to find an optimal value for a single cell, called the target cell, by changing the value of other user-specified cells, called adjustable cells. The target cells and the adjustable cells are directly or indirectly related via formulas. Once the constraints relating to iterations, precision, and convergence are inputted, the program will change the values in the adjustable cells to achieve the desired kind of optimization in the target cell, i.e. maximum, minimum, or target value. In this case a SSR method is computed as the desired minimized target. The residuals are computed as the difference between the measured and theoretical volumetric water contents and summed over all equilibrium pressures (i.e. 0.5 Bar, 1 Bar, 3 Bar, 5 Bar). The sum of the square residuals can be calculated as the following:

$$SSR = \sum_{i=1}^{n} w_i \left(\theta_{mi} - \theta_{ci}\right)^2 \quad (3)$$

Solver Setup

All options are selected in a fashion which allows for the best possible precision. The largest values allowed by Solver for iterations and computation time are chosen and the smallest values for precision and tolerance are selected. The default values for all other options are accepted. Table describes the necessary Solver inputs relating to iterations, precision, and convergence.

Table 6: Excel Solver Configuration

User Input	Value
Maximum Computation time	10,000 sec
Iterations	10,000 sec
Precision	0.0000001
Tolerance	0.0000001 %
Convergence	0.0000001
Other Constraints	None

Results

The results of this study are presented in this section. A statistical significance was performed on the experimental data. Further more, the effects of leachate on the Soil Water Characteristic Curve using the Van Genuchten and Brooks Corey Models are presented. This result is discussed in terms of how parameters have affected common properties of the soil water characteristic curve including air-entry suction head.

Statistical Significance

There is an apparent decline in measured equilibrium water contents for samples permeated with leachate. In order to determine if this decline is significant or the result of experimental variability, a two-tailed T-test is conducted on the difference in means for the final measured gravimetric water contents (see table 7). The null hypothesis is no difference exists between the mean water contents for leachate and water at a given equilibrium moisture content. The outcome is that experimental results are significant at the 2.5% level, meaning the probability of measuring a difference similar to what was measured in this study if leachate had no affect on equilibrium water contents is less than 2.5%. The T-test results are summarized in Table .

Table 7: Experimental Data Results

Optimization Results

The Parameter Optimization process resulted in the soil-water characteristic function parameters given in

Table .

Table 9: Parameter Optimization Results

Soil-Water Characteristic Model	Parameter	Physical Interpretation	Parameter Optimization Results	
Van Genuchten	α (1/cm)	Empirical constant	Water	1.103105
			Leachate	1.129887
	n	Empirical constant	Water	m=1-(1/n)
			Leachate	
Brooks Corey	h_b (cm)	Air-entry value	Water	149.1409
			Leachate	158.9680
	λ	Empirical constant	Water	0.091387
			Leachate	0.109697

Soil Water Characteristic Curve

The following figures present the SWCC for leachate and water based on the results of the parameter optimization process. Figure 3 through Figure **6** show the Van Genuchten and Brooks Corey SWCCs for water and leachate. Both models showed a relatively good fit of the data and a close fit to one another.

Figure 3: Van Genuchten SWCC for Water

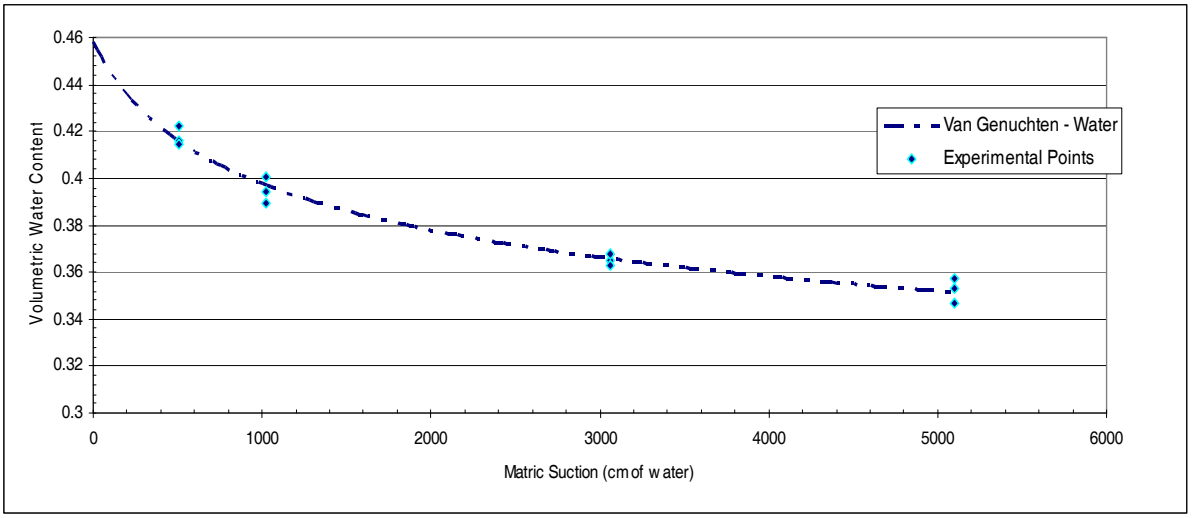

Figure 4: Van Genuchten SWCC for Leachate

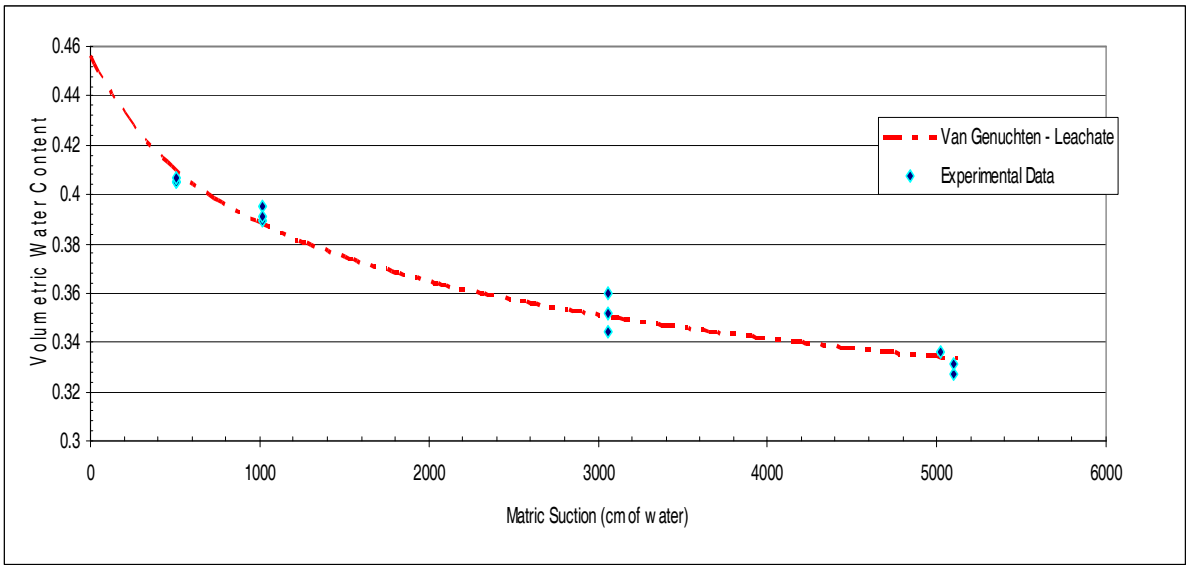

Figure 5: Brooks Corey SWCC for Water

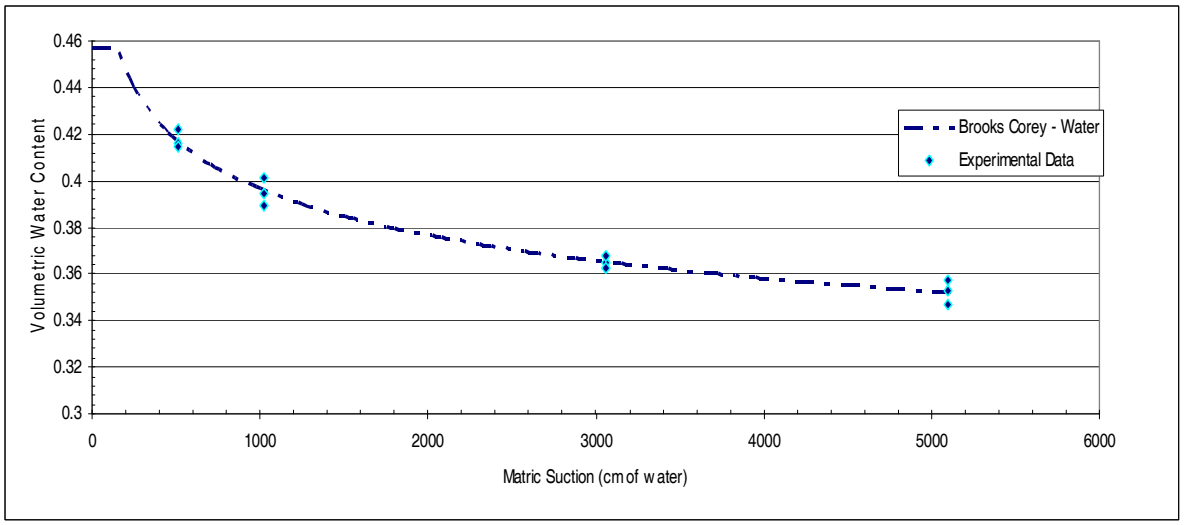

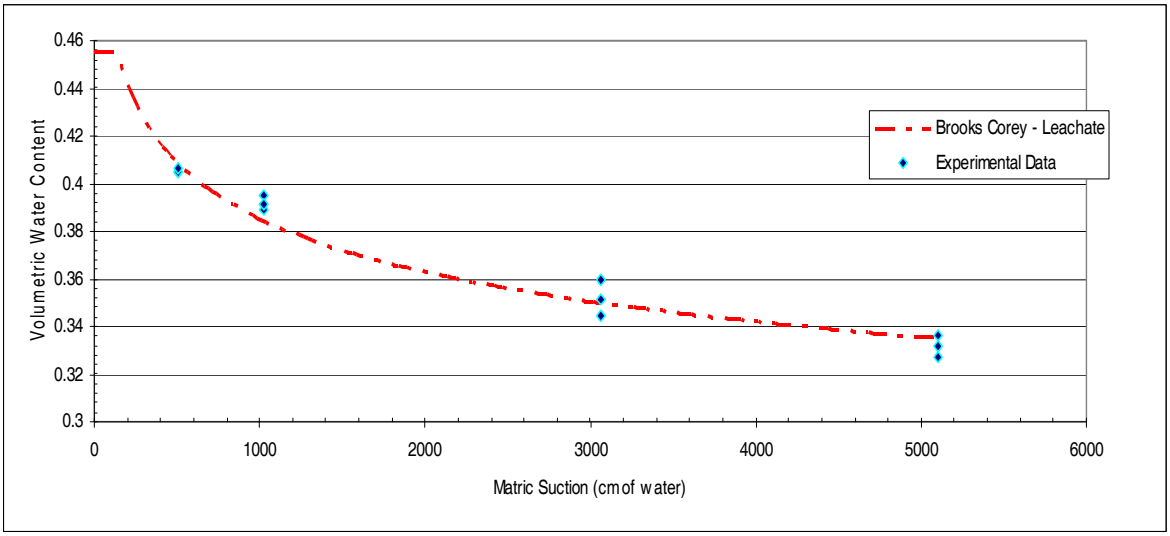

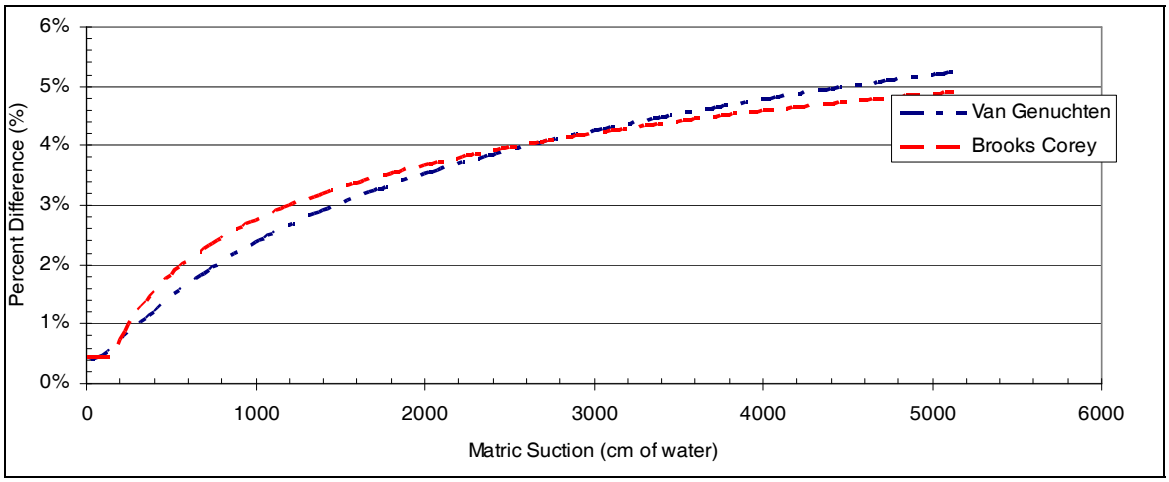

Figure 6: Brooks Corey SWCC for Leachate

Affects on the SWCC

Leachate has a discernable impact on the soil-water-characteristic curves. For both Van Genuchten (VG) and Brooks Corey (BC) models, the leachate curve fell bellow the water curve. The percent difference between the leachate and water SWCCs is provided in Figure .

Figure 7: Percent Difference between Leachate and Water Volumetric Fluid Contents

Higher values of matric suction exhibit greater percent differences in computed or theoretical volumetric water contents. The range which is applicable for this study and for

landfill liners in general lies below 2000 cm of suction—this range corresponds to moisture contents at or above optimum which are appropriate for clay liners. For purposes relative to landfill liners, it appears leachate caused as much as a 25% difference in the SWCC.

The affects of leachate on individual characteristics such as air-entry value, steepness, inflection, and rotation are a bit more subtle. The most significant difference between models is how they handle the air-entry portion of the curve (ψ_a), also called the bubbling pressure. Along a drying path, the SWCCs normally remain horizontal at saturated volumetric water content until ψ_a is reached at which point the curve begins to dip downward. While this point is not clearly defined on the Van Genuchten curve, ψ_a is distinctly represented on the BC SWCCs. The VG model depicts the curve as immediately dropping away from saturation as matric suction increases. Although the VG model does not specifically define a variable for ψ_a, the parameter α is commonly associated with the inverse of air-entry portion of the curve. Work by Merayyan et al (2002) has found similar differences in the way the BC and VG models predict the air entry-portion of the curve.

Comparison of the results from the parameter optimization indicates that α decreased by 4.0% when the soil was permeated with leachate, suggesting the air-entry increased. This is consistent to the BC model which indicates leachate increased the air-entry value from 149.1 to 158.0 cm, a 6.4 % increase. The affect on other SWCC parameters are provided in

Table 10.

Table 10: Leachate's Affect on BC and VG Parameters

Model	Parameter	Parameter Optimization Results		% Difference
Van Genuchten	α (1/cm)	Water	0.003901	-4.0%
		Leachate	0.003747	
	n	Water	1.103105	2.4%
		Leachate	1.129887	
Brooks Corey	h_b (cm)	Water	149.1409	6.4%
		Leachate	158.968	
	λ	Water	0.091387	18.2%
		Leachate	0.109697	

The other parameter in the Brooks Corey model is the pore-size distribution index, λ, which showed an 18.2 % decrease indicating a steeper slope about the pivot point. A decrease in the slope controlling parameter in the VG model, *n*, also indicates a steeper slope about the pivot point for the leachate SWCC.

Summary and Conclusions

Municipal landfill leachate and clay which was used in construction of a low permeability liner were used to assess the impacts which leachate could have on the soil-

water-characteristic curve and subsequent flow characteristics. A pressure plate extractor was used in conjunction with the axis-translation technique to produce matric suction vs. water content data. The SWCC's were developed based on PPE data and curve fit to the Van Genuchten and Brooks Corey models using Excel Solver routine for parameter optimization. A numerical analysis was conducted with CHEMFLO-2000 using a finite differences approach to solving Richards Equation for the change in matric suction, unsaturated conductivity, and cumulative flux with respect to time. Because the purpose of this study is to discuss the impacts leachate might have on the SWCC and consequent flow conditions through unsaturated clay as it pertains to landfill liners, every effort was made to model the soil in terms of realistic landfill conditions where feasible. Decisions about modeling inputs such as initial conditions, boundary conditions, and soil column properties are managed to match field conditions.

The study indicates leachate causes a decrease in matric suction for given moisture content and consequently an increase in hydraulic conductivity and cumulative flux through a common landfill clay for both Van Genuchten and Brooks Corey models. The largest difference in predicted matric potentials for water contents between saturation and those appropriate for landfill liner design vary depending on the modeling scenario utilized. On average these differences ranged from zero to 209 cm at saturation (20.5 kPa) for Brooks Corey and 368 cm (36.1 kPa) at saturation for Van Genuchten. Hydraulic conductivities also increased when permeated with leachate. Increases in cumulative flux are mostly dependent on the time lag between when leachate and water begin saturation.

The Brooks Corey and Van Genuchten models handle the air-entry portion of the SWC quite differently and this had a substantial impact of the outcome of hydraulic conductivity versus matric suction relationships. Consequently any predictions of flow conditions which depended on this portion of the curve, below a matric potential of about 200 cm (19.6 kPa) was heavily dependent upon the choice of model. Because the numerical modeling appropriate for landfills depended on this the air-entry portion of the curve, the change in hydraulic conductivity from water to leachate depended on the model. Even though there was a discernable difference in both models, the largest difference was not more than 2.4×10^{-7} cm/hour.

These findings are consistent with historical research detailing how pore fluid chemistry has a definite affect on flow characteristics. The most recent study, published by Ichola & Gaidi (2006) at the same time this study was being conducted, concluded leachate causes an increase in hydraulic conductivity when measured with methods similar to those in this study. Ichola & Gaidi found that even though permeability was influenced by leachate, the increase was not more than 4.32×10^{-5} cm/hour.

A significant original contribution of this study is the use of finite difference model in conjunction with the soil water characteristic curve to determine possible chemical effects leachate may have on landfill performance. Previous studies have used geotechnical methods such as flexible and rigid wall-permeameter tests to analyze these affects. These methods are very different from the soil-water characteristic approach used in this thesis.

Engineering Implications

Current regulations and common landfill liner design practices use a water-saturated permeability approach for specifying liner materials. While this approach utilizes a specification which can be easily tested in the laboratory, it does not represent true conditions in the field. This study has attempted to more closely model field conditions for the time between liner construction and saturation. A complete analysis of how leachate might flow through a landfill liner while also considering the chemical affects by leachate on flow characteristics is a significant contribution of this study. Most previous analysis of chemical pore-fluid interactions and its affects on the soil water characteristic curve or flow characteristics have been in some part different from the unsteady-state approach used in this study (with the exception of the 2006 study by Ichola & Gaidi).

While it has been determined that leachate increases unsaturated permeability, although not more than $1x10^{-7}$ cm/hour, it cannot be concluded that current regulations for liner designs are deficient. From an environmental perspective, specifying intrinsic permeability may be a more conservative approach in specifying permeability characteristics; unsaturated permeability tends to be lower than intrinsic values for clay soils. Better understanding of desiccation cracking, wilting point, and field capacity of materials used for landfill liners and covers might stand to gain from understanding how design criteria might be impacted by changes in pore fluid chemistry. The bottom-line is pore fluid chemistry has a real affect on properties of clayey soils. Engineers should be aware of the limitations invoked by neglecting pore fluid chemistry.

Abstract

A landfill is considered functionally stable when it no longer presents an unacceptable threat to human health and the environment. Landfill stability depends on factors which include variables that relate to operations both before and after the closure of a landfill cell. Therefore, post closure period (PCC) decisions should be based on operational factors, design factors and post-closure performance data. The question of appropriate PCC period for landfills requires in-depth case studies focusing on the analysis of the performance data from closed landfills. In this study the performance data from a closed case study landfill was evaluated to forecast the level of stability of a landfill in terms of leachate and gas generation rates and quality .The data was analyzed by time series decomposition technique since seasonality in graphs was identified by regularly spaced peaks and troughs. The data clearly showed the general trend and provided a clear forecast for future planning purposes. Decreasing trends were seen for leachate quantity, landfill gas and methane , chloride, sodium , total dissolved solids, vinyl chloride,1,4-dichlorobenzene, chlorobenzene, xylenes, ethylbenzene, toluene, total BTEX and cis-1,2-dichloroethylene. Increasing trends were seen for iron and bicarbonate. Steady trends were seen for pH, ammonia and benzene. Based on these results, PCC monitoring needs identified for closed case study landfill.

Introduction

Post closure care (PCC) begins when the landfill is closed. PCC duration prescribed by Resource Conservation and Recovery Act (RCRA), Subtitle D is 30 years. The 30-year period can be shortened or extended depending on whether the landfill presents potential threats to human health or the environment or not (Tansel et al., 2007). A landfill is considered functionally stable (once Municipal Solid Waste inside the landfill reaches a functionally stable state) when it no longer presents an unacceptable threat. Currently, there are no specific metrics which can be used for systematic evaluation of relative stability of closed landfills; which, at the same time, allow an objective determination of the adequacy of the 30-year post closure period (Tansel et al., 2008). To forecast PCC monitoring needs include leachate monitoring, groundwater and gas monitoring, final cover maintenance and risk analysis (Vesilind et al., 2001; Reinhart et al., 1997; Tansel et al., 2008). Leachate monitoring should be based on evaluation of leachate quantity and quality trends, and projection of future

trends for parameters of concern. Evaluations of these parameters give the present levels and projection of future concentrations and trends for the parameters of concern overtime. Based on the evaluations, decisions can be made to continue or discontinue the monitoring for determined parameters (Tansel et al., 2008). The purpose of the Landfill Gas (LFG) monitoring is to evaluate whether LFG monitoring can be changed, optimized, reduced or discontinued in terms of the landfill gas production trend overtime.

Prediction of the changes in leachate quantity and quality and landfill gas quantity require quantitative tool. Thus, the monitoring of these parameters with the suitable trend analysis method can make long-term predictions of landfill stability easier. The trend analysis for the landfill components gives an idea to predict the future generation rates. Time series decomposition approach is a quick and easy method of generation a range of parameters to forecast (Worrall et al., 1998). Decomposition has been widely regarded as a successful strategy for the extrapolation of time series in the traditional approach of using mean, seasonality, trend, and error (Armstrong et al., 2004). MacGregor, 2001 showed that decomposition to be beneficial for judgmental forecasting. The purpose of this study is evaluation to forecast the level of stability of a landfill in terms of leachate and landfill gas generation rates.

Materials

In this study the performance data from a closed case study landfill was evaluated to forecast the level of stability of a landfill in terms of leachate and gas generation rates and quality. The case study landfill is located in south Florida, USA which has a subtropical climate. The landfill has been closed since 1987. The case study landfill is partially lined and has vegetative cover. Landfill gas data are available from 2004 to 2008 and are recorded on a monthly basis. Generated Landfill gas is collected by the landfill gas management system and eliminated through an enclosed flare approximately 1 to 1.5 hours per day. The landfill gas composition is shown in Table 1. Leachate quantity data is available from 1989 to 2008 and leachate quantity is monitored on monthly basis. Leachate quality is monitored twice a year (April and September). The monitoring data were available from 2001 to 2006. After 2006, leachate quality was sampled once a year. A total of 46 parameters was monitored. Among these parameters, 28 parameters were non-detected parameters (i.e., always below the detection limit), eight parameters were always above the maximum contaminant limit (MCL) and ten parameters were below the MCL. Table 2 presents the parameters detected in leachate.

Table 1. Landfil gas composition.

Constituent	Percentage in gas
Methane	45%
Oxygen	1.36%
Carbon dioxide	30%

Table 2. The parameters of interest in leachate.

Below MCL	Above MCL
1,4-Dichlorobenzene	Chloride
Chlorobenzene	Bicarbonate
cis-1,2-Dichloroethylene	Sodium
Dichlorodifluoromethane	Ammonium as N
Ethylbenzene	Iron
Methyl-tert-butyl ether (MTBE)	Benzene
Tetrachloroethene	Vinyl Chloride
Toluene	Total Dissolved Solids
Xylenes	
Total BTEX	

Methods

Available leachate quantity and quality data and landfill gas data were plotted as a function of time to identify changes in these parameters to forecast the stability of landfill. At the beginning, data were plotted as a function of time with fitted line regression analysis. But the graphs did not show a clear trend (i.e., decreasing or increasing). The classical regression analysis approach could not be used for most of the data since there were significant seasonal variations in the data. Seasonal effects on the data were identified by regularly spaced peaks and troughs which had a consistent cycle with approximately similar magnitude. Therefore, the data were analyzed by Minitab 15 The time series decomposition method which separates the data into linear and seasonal components, as well as error, and forecasts future trends (Minitab 15, 2005). Time series decomposition approach is a quick and easy method of generation a range of parameters forecast (Worrall et al., 1998). It can be used by either selecting an additive or multiplicative model.

For the additive model, forecasts can be made by the following model:

$$y_t = T_t + S_t + e_t \qquad t = 1, \ldots, n$$

For the multiplicative model, forecasts can be made by the following model:

$$y_t = T_t \times S_t \times e_t \qquad t = 1, \ldots, n$$

where, t : time, y_t : observed data, T_t : trend component, S_t : seasonal component, and e_t : error term.

The additive model assumes that amplitude of both the seasonal and irregular variations in data do not change as the level of the trend rises or falls. The multiplicative model assumes that the amplitude of both the seasonal and irregular variations increase as the level of the trend rises. The data from the case study landfill showed more adequate fit with the multiplicative model with a linear parametric component (T_t). Therefore, time series decomposition with multiplicative model was used for the trend

analyses. The accuracy of the time series analysis can be expressed by mean absolute percentage error (MAPE), mean absolute deviation (MAD), and mean squared deviation (MSD) as shown in Table 3 (Minitab15 StatGuide). Smaller values generally indicate a better fitting model (Armstrong et al., 2004).

Table 3. Methods for determining the accuracy of the time series analysis.

Mean Absolute Percentage Error (MAPE)	Mean Absolute Deviation (MAD)	Mean Squared Deviation (MSD)
Measures the accuracy of fitted time series values as a percentage.	Measures the accuracy of fitted time series values in the same units as the data.	More sensitive measure of an unusually large forecast error than MAD.
$MAPE = \frac{\sum \left\| (y_t - y_t^1)/y_t \right\|}{n} x100$	$MAD = \frac{\sum_{t=1}^{n} \left\| y_t - y_t^1 \right\|}{n}$	$MSD = \frac{\sum_{t=1}^{n} \left\| y_t - y_t^1 \right\|^2}{n}$

* y_t : actual value , y_t^1 : fitted value, n : number of observations, $y_t \neq 0$

Results

Figure 1 shows the leachate generation rate for the 80 months. Leachate quantity data were used from January 2001 to December 2005 (60 month). Leachate quantity samples collected each month showed that leachate quantity has increased during the rainy season and decreased during the dry season. The generated leachate has a decreasing trend. However, when forecasting values were compared the real values, it was seen that forecasting values were significantly smaller than the real values. Leachate generation rates are greatly affected by the type and condition of the in placed cover system and waste materials at the landfill (Akesson et al., 1997).

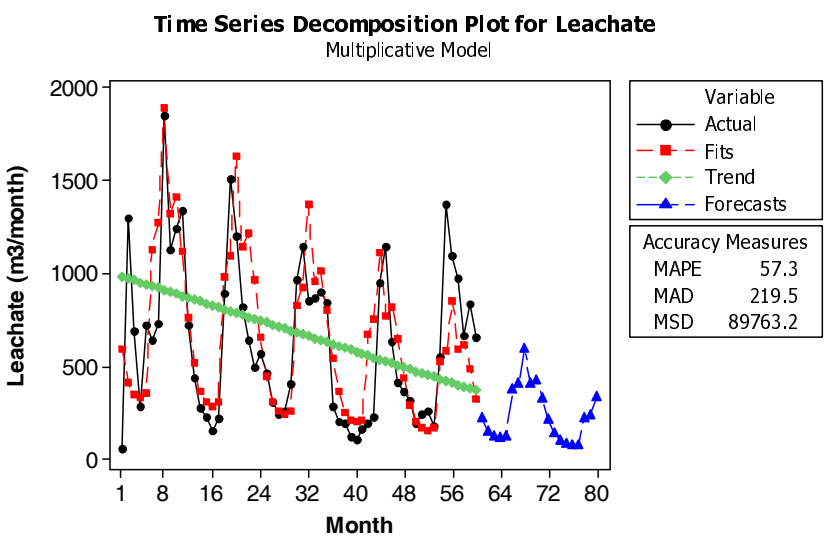

Figure 1. Time series projections leachate generation

Since the case study landfill has vegetative cover, leachate quantity mostly depend on the volume of the infiltrating rainfall and the other weather related event (e.g., hurricanes). Figure 2 presents the predicted monthly gas generation rate for 80 months period. Landfill gas data were used from January 2004 to June 2008 (54 months). The graph did not give the clear correlation but showed that Landfill gas has decreasing trend and in the 80th month LFG generation will be minimum value.

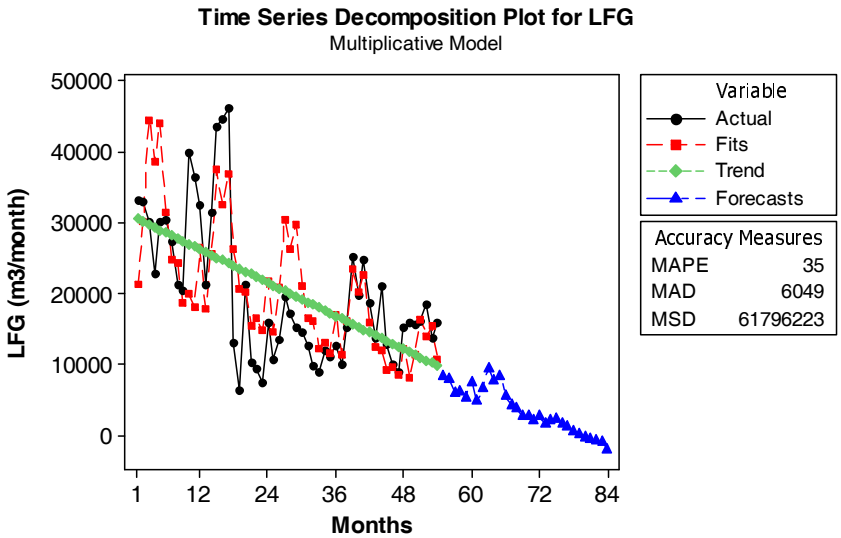

Figure 2. Time series projections of gas generation

Figure 3 presents the methane generation rate for 80 months period. Landfill methane data were used from January 2004 to June 2008 (54 months). The graph shows that methane generation is decreasing overtime.

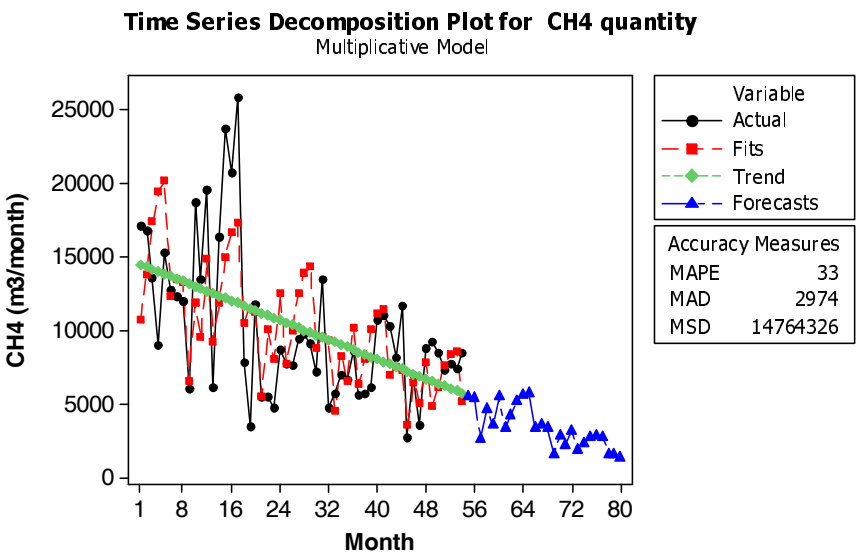

Figure 3. Time series projections of CH_4 generation

Available leachate quality data were plotted as a function of time showed that samples collected at the end of the dry season (April) had high contamination levels; and the samples collected at the end of the rainy season (August) had lower levels due to dilution by infiltrating rain water. Figure 4 presents the chloride levels in leachate. The available data from April 2001 to April 2006 were used. The data after 2006 were not used due to changes in the sampling period. (Leachate samples were collected biannually until 2006. After 2006 the management decided to collect the leachate samples once a year) The graph shows a clear trend that the decomposition model fits adequately except part of the second annual cycle is under predicted. Based on the time series analysis, the chloride concentration would be below the MCL by the year 2023. The major sources of chlorine in MSW are paper and plastics. (U.S. Congress, Office of Technology Assessment. (1989).
