A variety of commercially available technologies for reducing residential irrigation water use are available to homeowners. These technologies include soil moisture sensors, rain sensors and evapotranspiration (ET) based controllers. The purpose of this research was to evaluate the effectiveness of these various technologies comparing the adequacy and efficiency of the irrigation schedules for each control device with an irrigation schedule developed using a theoretical soil water balance. Testing was performed on a soil moisture sensor (SMS, LawnLogic) at a low and a medium soil moisture threshold setting. Mini-Clik rain sensors (RS) comprised four treatments, with one treatment pre-set for 3 mm of rainfall and an irrigation frequency of 7 d/wk. The other three RS treatments had sensors pre-set to bypass irrigation for 6 mm of rainfall and irrigation schedules of either 1 or 2 d/wk. An ET controller was also tested, the Toro Intelli-Sense controller (TORO). A time-based treatment with irrigation 2 d/wk and no rain sensor (WOS) was established as a comparison. In general the irrigation schedule for all treatments was more adequate during the fall months of testing than the spring months. Efficiency decreased for most treatments in the fall months of testing. Adequacy values calculated for 30-day running totals tended to vary greatly during a testing period. During the spring months of testing the average range in 30-day adequacy ratings was 24% and during the fall months the average range was 21%. The range in adequacy was as high as 63% during testing for one treatment. Looking at only one 30-day testing period may not fully capture the adequacy of an irrigation control device.

Key Words Theoretical irrigation requirement, soil moisture sensor, rain sensor, ET controller, turfgrass

Introduction

Residential irrigation systems that are automated have been shown to use 47% more water on average than sprinkler systems that are not automated (Mayer et al., 1999). High water use with automated irrigation systems can be attributed to several factors, including the tendency to not adjust irrigation systems in response to

changing weather conditions. Another factor may be that the irrigation system is not uniform and/or the system irrigates all zones similarly regardless of soil and slope conditions. In an attempt to reduce the amount of water used for irrigation purposes, landscape irrigation has been regulated in most, if not all, areas in Florida. In the St. Johns River Water Management District (SJRWMD) irrigation is restricted to a maximum of two days/week between 4 pm and 10 am (SJRWMD, 2008).

Various irrigation control technologies are commercially available to optimize landscape irrigation. These technologies include; soil moisture sensor controllers, ET (evapotranspiration) controllers and rain sensors.

In a soil moisture based irrigation controller, data from the sensor is used to allow or bypass timed irrigation events. The sensor has an adjustable threshold setting and if the soil moisture content exceeds that setting the event is bypassed (Dukes, 2005). A single sensor can be used to control the irrigation for many zones or more than one sensor can be used to irrigate multiple zones. In the case of one sensor for several zones, the zone that is normally the driest, or most in need of irrigation, is selected for placement of the sensor in order to ensure adequate irrigation in all zones.

Evapotranspiration (ET)-based irrigation controllers ideally allow irrigation according to ET needs of the plant. ET is the water lost from the soil and plant surfaces by evaporation and from the plant by transpiration. Since the two processes occur simultaneously and are very difficult to separate, they are combined into one process (Allen et al., 1998). ET controllers can generally be programmed for various site specific conditions such as soil type, plant type, root depth, sun exposure, etc. ET controllers can be purchased as an addition to an existing irrigation timer or as a single component to replace the standard timer.

Rain sensors are devices designed to collect rainfall and after a certain depth of rainfall is collected the devices will interrupt scheduled irrigation events. These devices open the circuit between the irrigation timer and the irrigation valves (bypassing timed irrigation events) after a specific amount of rainfall has occurred. Rain sensors are attached to existing irrigation timers. An initial program is programmed into the timer and this program includes timing and depth of irrigation. The rain sensor then either bypasses or allows the programmed irrigation events based on local rainfall (Dukes and Haman, 2002a).

A soil water balance can be used to calculate the theoretical irrigation requirement. This approach sums inputs and outputs of water to the soil water profile based on a specified time step (Allen et al., 1998).

It was assumed that RO was equal to zero due to the high infiltration rate of sandy soils, which are present at the research site and capillary rise was neglected due to water table depth exceeding 10 m. The maximum amount of water that can be stored effectively in the root zone is equal to field capacity (FC), which is the soil water content 2 to 3 days after wetting event has occurred and the downward movement of water due to gravity is negligible (Soil Science Society of America SSSA, 2008). Any water that is applied in excess of FC is considered to contribute to deep percolation. Precipitation that does not lead to DP or RO is considered effective or counted in the soil water balance.

Reference ET (ET_o) is the transpiration and evaporation from a uniform surface of actively growing vegetation with a specified growing height and that is well-watered. Crop evapotranspiration was calculated by multiplying ET_o with the crop coefficient (Allen et al., 2005) as follows:

When scheduling irrigation, the availability of water in the soil profile has to be considered. The maximum amount of water that can be held in the soil profile is related to the soil type and root zone depth. The amount of water in the soil that is available for plant use is called available water (AW) and is the difference between field capacity and permanent wilting point over the plant root zone (Cassel and Nielsen, 1986). Irrigation should be applied before the soil water content is equal to the PWP, since permanent damage occurs to many plants before the soil water status reaches PWP. The portion of AW that is allowed to be depleted before irrigation occurs is known as the readily available water (RAW). Typically RAW is between 40 and 60% of AW for turfgrass irrigation purposes. The theoretical depth of irrigation required is the amount of water that needs to be applied to maintain the soil water content within the RAW moisture status.

As a soil dries, the potential energy of the water in the soil decreases. In dry soil, the water is more strongly bound to soil particles through capillary and absorptive forces. The increase in these forces make plant uptake of the water more difficult. Below a soil moisture level equal to RAW the crop is considered water stressed due to the decrease in water extractability from the soil. The effects of the water stress lead to a decrease in crop transpiration which is calculated using a water stress coefficient (K_s) as described in Allen et al (1998). When the soil water level is above RAW, the value of K_s is 1. As soil water depletion increases to a depth greater than RAW the value of K_s decreases linearly as described by the Allen et al. (1998).

The irrigation depth required to replace the water lost through ET_c that has not been replaced by rainfall is the net irrigation requirement. The actual application of water by the irrigation system is not perfectly uniform so the net irrigation requirement has to be increased to account for the inefficiency of the irrigation system. Gross irrigation is the total amount of water to be applied including the water which is required by the plant and the water which is lost during distribution of the water (Irrigation Association, 2005). Gross irrigation, therefore, accounts for water which is applied unevenly due to less than perfect distribution uniformity (DU). The efficiency factor ensures that all landscaped areas get the necessary amount of water. For irrigation scheduling purposes, the low half distribution uniformity (DU_{lh}) has been recommended (Irrigation Association, 2005). The gross irrigation depth is then calculated by multiplying the net irrigation requirement by the efficiency factor.

The objectives of this experiment were to evaluate the irrigation water applied using soil moisture sensors, ET controllers and rain sensors compared to the theoretical irrigation requirement.

Materials and Methods

This study was performed at the Plant Science Research and Education Unit in Citra, Florida. There were four treatment periods during April 22 2006 to June 30, 2006 (S06), September 23, 2006 to December 15, 2006 (F06) and May 1, 2007 to

August 31, 2007 (S07) and September 1, 2007 to November 30, 2007 (F07). The experimental area consists of 72 plots of 'Floratam' St. Augustinegrass (*Stenotaphrum secundatum*). Soil particle size analysis showed that the soil present at the field site consisted of 1.7% clay, 1.1% silt and 97.3% sand (Shedd, 2008). Treatments were established in a randomized block design due to increasing values of FC and PWP across the field. Both field capacity and permanent wilting point values varied across the experimental blocks; however, only the block with a soil moisture sensor controlling irrigation, where appropriate, was used in theoretical analysis. Based on the average DU_{lh} the calculated adjustment factor for the irrigation system was 0.8 (Shedd, 2008).

Irrigation applied by the various irrigation control technologies was compared to theoretical depth required to determine how adequate and efficient the irrigation applied was. The actual water applied was placed in a daily soil water balance along with ET_c and rainfall to determine the daily soil water level (mm). Adequacy (%) refers to whether or not the irrigation applied was sufficient for plant needs (SWAT, 2006) and was calculated as follows:

$$Adequacy = \left(\frac{ET_c - Deficit}{ET_c} \right) \times 100 \qquad [1]$$

where *Deficit* was calculated as the water that was needed by the plant, according to the calculated ET_c, that was not readily available. There were two scenarios that were considered when calculating the deficit. The first was when soil water at the beginning of the day was above the depth for RAW, but at the end of the day was below. The equation for this scenario was as follows:

$$IF\left[SW_{i-1} > (FC - RAW)\ and\ SW_i < (FC - RAW)\right]$$
$$then\ Deficit = (FC - RAW) - SW_i \qquad [2]$$

where SW_{i-1} is the soil water level (mm) at the start of the day and SW_i is the soil water level at the end of the day. The second scenario considered was when the soil water level at the beginning and end of the day were below the depth for RAW. If the soil water level at the beginning and end of the day were both below RAW often the soil water fell as low as PWP. Even though the soil water balance does not allow the soil water to fall below the PWP, there is still water that is needed by the plant that is not available. For these instances the *Deficit* had to be calculated using:

$$IF\left[SW_{i-1} < (FC - RAW)\ and\ SW_i < (FC - RAW)\right]$$
$$then\ Deficit = ET_c - I_{net} - P_e \qquad [3]$$

where I_{net} is the depth of water applied (mm) that actually reaches the root zone of the plant and P_e is the depth of rainfall that reaches the root zone.

Efficiency is a measure of how well irrigation depths were applied, preventing runoff and drainage as follows (SWAT, 2006):

$$Efficiency = \left(\frac{Net\ Irrigation - Scheduled\ Losses}{Net\ Irrigation} \right) \times 100 \qquad [4]$$

where *Scheduled Losses* (mm) is the amount of water applied that exceeded the FC of the soil, leading to drainage (deep percolation) or direct runoff. Due to the high infiltration rates at the test site runoff was assumed to be zero, meaning any over

irrigation lead to drainage below the root zone. Using the efficiency, the irrigation excess (%) was calculated as:

$$Irrigation\ Excess = 100 - Efficiency \quad [5]$$

where irrigation excess represents the water applied over the actual depth theoretically required for plant needs.

All three of these parameters were calculated as an average for the entire treatment period and as 30-day running totals. The value was only calculated for the 30 day period if rainfall totaled at least 10.2 mm and the ET_o was at least 63.5 mm based on SWAT (2006) methodology. The theoretical irrigation requirement was calculated using values of FC and PWP found during soil testing (Table 1). A summary of the various inputs used in the soil water balance is provided in Table 1.

Water use was monitored using pulse-type displacement flow meters, specifically AMCO PSMT 20 mm x 190 mm flow meters (Elster AMCO Water, Inc., Ocala, FL). Weather data was collected using an automated weather station (Campbell Scientific, Logan, UT) within 900 m of the experimental site. Rainfall data at the weather station was collected with both a tipping bucket rain gauge and with a manual rain gauge located at the research plots. Monthly values of K_c were calculated using warm season turfgrass (Jia et al., 2007).

Turfgrass quality was rated at least once every two weeks during S06 and F06 and at least once a month during S07 and F07 using National Turfgrass Evaluation Program (NTEP) procedures (Shearman and Morris, 1998). Ratings were on a 1 to 9 scale, with 1 representing dead or dormant grass and 9 representing grass with good color and density, and without weeds (Shearman and Morris, 1998). A quality rating of 5 was considered minimally acceptable for a homeowner lawn.

Table 2 gives a summary of experimental treatments reported here. The LawnLogic LL1004 (Alpine Automation, Inc., Aurora, CO.) was used for the SMS treatments. The LawnLogic, which uses site specific calibration methods, comprised two treatments, with low and medium levels of soil moisture threshold settings (LL Low and LL Med; Shedd, 2008). The thresholds of the LL controller are on a scale of 1 (dry) to 9 (wet). The settings used in this experiment were initially 2 (LL Low) and 5 (LL Med). In S06 turf quality was damaged in the LL Low plots so the setting was modified to 4 for the remaining testing periods (Table 3). The SMS treatments utilized one sensor buried in one of four experimental blocks to control the irrigation for all plots in the treatment. SMS-based treatments were restricted to irrigation two days per week. The Toro Intelli-sense (The Toro Company, Bloomington, MN) ET controller was installed at the test site in F06. The Toro Intelli-sense controller (TORO) calculates irrigation runtime and frequency of irrigation events. Rain sensor (RS) treatments, using the Mini-Clik rain sensor (Hunter Industries Inc., San Marcos, CA.), comprised three treatments. There were three irrigation frequencies 1, 2, and 7 d/wk (RS1, RS2, RS7) with a rainfall setting of 6 mm for the RS1 and RS2 treatments and a rainfall setting of 3 mm for the RS7 treatment.

Two comparison treatments were used; time-based treatment without a rain sensor (WOS) and a time based treatment with a rain sensor set at 6 mm and a schedule that was set to apply 60% of the possible depth scheduled for WOS and the other RS treatments (DWRS). The control was a non-irrigated treatment (NON).

The same total application depth per week was divided over the possible number of days of irrigation per week. Every treatment except for the TORO, DWRS and the NON treatments had the same possible total depth of irrigation application. The monthly irrigation schedule was based on recommendations by Dukes and Haman (2002b).

Results

Compared to the theoretical irrigation requirement calculated using the soil water balance (SWB) most of the treatments tended to over water during the F06 and F07 testing periods. In S06 none of the treatments applied more water than the cumulative theoretical irrigation requirement. In S07 only the DWRS treatment had a cumulative depth of water applied (383 mm) that was less than the SWB cumulative depth (456 mm).

The LL Low treatment was ended early in F06 and S07 due to poor turf quality (Shedd, 2008). In S06, the LL Low treatment applied less water cumulatively (111 mm) than the SWB requirement (290 mm) and produced less than acceptable turf quality (4.2). The 30-day adequacy ratings for the treatment were below 62% throughout the testing period and as low as 24% (Figure 1). The average adequacy rating for the LL Low treatment during S06 was 47.9%, while 69% of the 30-day adequacy ratings were below this value (Table 3).

The turf quality ratings for the LL Med treatment were higher than the LL Low treatment. In S06, the LL Med treatment had a turf quality rating of 6.5 (acceptable) and applied more water cumulatively (237 mm) than LL Low (Table 4). The depth applied for the LL med treatment was 53 mm less than the depth for the SWB in S06. The average adequacy rating for the LL med treatment in S06 was 72% and the 30-day adequacies ranged from 64% to 84% (Table 3 and Figure 1). The 30-day efficiency ratings of the treatment varied between 66% and 100% (Figure 1). The depth of water applied for the LL Med treatment was sufficient to promote good turf quality.

During S06 and S07, as adequacy increased, efficiency decreased. This trend can be seen in the adequacy and efficiency figures for the LL and the RS treatments (Figure 1 and Figure 2). Both testing periods were relatively dry, compared to typical Florida conditions. Due to the shallow depth of rainfall and the high values of ET_o during the two testing periods, irrigation was vital for turfgrass quality. According to the soil water balance, deficit occurred quickly in the root zone of the turfgrass (30 cm) due to the low water holding capacity of the soil. This meant that with one or two day-per-week water restrictions, the adequacy ratings were lower due to deficit occurring between irrigation events. This was especially true for the RS1 treatment, which only received irrigation a maximum of once per week (Figure 3). Deficit occurred as soon as the soil water content dropped below the RAW level, which happened between all of the irrigation events during the S06 testing period (Figure 3).

The RS 1 treatment had the lowest turf quality rating (5.3) in S06 compared to the RS 2 (6.1) and the RS 7 (6.2) treatments. The average adequacy rating of the RS 1 treatment was 63% with 30-day values ranging from 53% to 68% (Table 3). The lowest 30-day efficiency rating for the RS 1 treatment was 30%, compared to the RS 2 and RS 7 treatments with 63% and 88% (Figure 2). The RS 1 treatment had the

lowest average efficiency and adequacy ratings of the RS treatments during all testing periods (Table 3). During all of the testing periods the RS1 treatment had the largest range in 30-day adequacy values, with the exception of S06. The RS2 treatment received 30-day adequacy ratings ranging from 37% to 100% during S06, while RS1 received ratings ranging from 53% to 68%. The average adequacy rating for the RS2 (69%) was slightly higher than RS1 (63%). During the 30-day period where the RS2 treatment received a 37% adequacy rating only one irrigation event was bypassed and eight were allowed. During the same 30-day period the RS 1 treatment did not bypass any irrigation events. Between the irrigation events, during the months of April and May, the soil water content remained below the RAW level part of the time. The irrigation depth per event for the month of April was used for May in 2006 for all of the treatments. When irrigation was applied it was not deep enough to bring the soil water content up to FC (Figure 4). May 2006 was very dry compared to historical rainfall averages in the area. The depth of rainfall for May 2006 was only 16 mm which is much lower than the historical average for the area (102 mm). The depth of rainfall during June 2006 (142 mm) was much larger than May and closer to the historical average of 180 mm (NOAA, 2006). The irrigation schedule was calculated based on the historical net irrigation requirement, which takes into account historical rainfall. During June 2006 the soil water content never dropped below RAW. In S07 the proper irrigation schedule for the RS2 treatment was used and the water content never dropped below RAW. The treatment was less efficient during S07 (75%) than S06 (82%) due to drainage occurring from most of the irrigation events.

The RS7 treatment consistently had higher adequacy and efficiency ratings than the RS1 and RS2 treatments (Table 3). This treatment irrigated more frequently with shallower depths than RS1 and RS2. This meant that irrigation rarely caused deep percolation leading to higher efficiency scores. In S06, the RS7 treatment had only 4.6 mm of irrigation water lost to deep percolation compared to 32 mm for RS1 and 18 mm for RS2 (Figure 5). According to the soil water balance, the water content of the soil for the RS7 treatment dropped below the RAW level for an extended period of time in S06. The average adjusted ET_c for the S06 testing period was 3.5 which was the same depth as the average depth of water applied per irrigation event of 3.5 mm for the RS7 treatment. Without rainfall, irrigation applied only accounted for the depth that was generally lost during one day of ET_c. If an irrigation day was bypassed and no rainfall occurred than the soil water content dropped, and the irrigation the next day was only sufficient to maintain the soil water content for the previous day (Figure 5). Turf quality for the RS7 treatment in S06 was acceptable (6.2) even though the soil water content was below the level of RAW for almost an entire month (Figure 5). Some level of deficit irrigation was acceptable for maintaining adequate turf quality.

During F06 and F07 (cooler months) the average adequacy ratings increased for all treatments, except LL Low in F06, compared to S06 and S07 (Table 3). The LL Low treatment was ended early in F06 due to poor turf quality. In F06, there were seven 30-day periods which were not analyzed because the minimum weather parameters, cumulative rainfall depth of at least 10.2 mm and ET_o depth of at least 63.5 mm, were not met. Adequacy ratings increased in F06 compared to S06, due to lower values of ET_c during the F06 months and more rain during the 30-day periods.

For April and May cumulative rainfall during the running 30-day periods never exceeded 30 mm, while in F06 30-day rainfall always exceeded 30 mm after 10/28. Non-irrigated plots had average turf quality ratings that were acceptable in F07 (5.0; Table 4).

The TORO treatment had the lowest average adequacy rating for F06 (80%) and the highest efficiency rating (97%; Table 3). Turf quality for the TORO treatment was above minimally acceptable (6.5; Table 4). An adequacy rating of 100% proved unnecessary during all testing periods for producing good turf quality. Optimally, the irrigation schedule should provide adequacy and efficiency. In S07, the TORO controller received an adequacy rating of 91% which was less than the ratings for the LL Med (92%), RS2 (96%) and RS7 (100%) treatments. The TORO treatment applied between 35 mm (RS7) and 106 mm (RS2) less than these other treatments. The controller for the TORO treatment can reduce depth of irrigation applied based on a theoretical soil water balance performed in the controller. Only two treatments received higher efficiency scores in S07 than the TORO treatment (85%); DWRS (98%) and RS7 (87%; Table 3). Both DWRS and RS7 applied less water per irrigation event than the SMS or other RS based treatments and the controller for the TORO treatment generally irrigated a shallower depth than that of the RS and SMS based treatments (Figure 5, 6 and 7). The DWRS, RS7 and TORO treatments had acceptable turf quality ratings in S07 (ranging from 6.1 to 6.9; Table 4). Based on the soil water balance irrigating less per irrigation event can increase irrigation efficiency and provide good adequacy when scheduled correctly.

Summary and Conclusions

In general, adequacy of irrigation for all treatments improved in the fall months compared to the spring months of testing. This may be due to both a decrease in ET_c and in the case of F07 an increase in rainfall. Also, low adequacy ratings, based on the SWB were not always an indicator of damage to plant quality. This was seen in the DWRS treatment which received 30-day adequacy ratings during S06 and S07 as low as 34% (S06) and 58% (S07) however turf quality during these testing periods was always acceptable for the treatment (6.5 and 6.9 respectively; Shedd, 2008). In some instances, such as LL Low in S06 (adequacy rating of 48% and average turf quality of 4.2) the adequacy ratings were a good indicator of the need for a greater depth of irrigation application. According to the results, an average adequacy rating greater than 70% always ensured minimally acceptable turf quality ratings on St. Augustinegrass. A low adequacy rating; however, did not necessarily mean a low turf quality rating. The DWRS treatment had an adequacy rating of 60% in S06 and received a turf quality rating of 6.5.

Efficiency and adequacy ratings varied substantially for most treatments during spring testing periods compared the fall testing periods. Based on 30-day values, a range in adequacy of up to 63% was seen. An average range inadequacy including all treatments of 24% occurred during the four testing periods. The ranges in adequacy between 30-day values show that using an adequacy for just one 30-day time period or averaged over the entire time period may not give an accurate representation of the change in adequacy over time. For example, in F07 the LL Low treatment had an adequacy rating for the entire testing period of 95%, but during the testing period the

treatment had 30-day adequacy values as low as 58% and as high as 100%. The reported adequacy of the irrigation schedule would depend heavily on which 30-day period was used when testing occurred. Simply using adequacy alone or efficiency alone was not a good indicator of the accuracy of an irrigation schedule. Efficiency of irrigation may be high due to little drainage occurring, but this may be due to a decrease in irrigation applied. Some treatments received high efficiency scores but very low adequacy scores because irrigation was not sufficient for plant needs. For example, treatment LL Low produced an efficiency rating of 100% for all of the 30-day testing periods during S06. The adequacy ratings for the LL Low treatment however fell as low as 24% during S06 and average turf quality for the treatment was a 4.2 (Shedd, 2008). An efficiency rating of 100% can be achieved by simply not irrigating at all.

There were some limitations for the experimental treatments compared to the SWB. The SWB was allowed to irrigate whenever soil moisture dropped to RAW and it only irrigated to FC. The experimental treatments were scheduled for irrigation on specific days of the week (1, 2 or 7 d/wk) and irrigation depth was programmed into the timer, with the exception of TORO.

Table 1. Summary of input parameters used for calculating the theoretical irrigation requirement and evaluating the adequacy and efficiency of the actual irrigation applied by treatments.

Soil Water Balance Input	
Management Allowed Depletion, MAD	50%
Root Depth, RD	30 cm
Field Capacity, FC	8%
Permanent Wilting Point, PWP	3%
Readily Available Water, RAW	8 mm

Table 2. Summary of treatment codes and descriptions along with the frequency of the irrigation schedule.

Treatment code	Irrigation Frequency (d/wk)	Treatment description
LL Low	2	LawnLogic soil moisture sensor set at low setting[1]
LL Med	2	LawnLogic soil moisture sensor set at medium setting (#5)
TORO	2	Toro Intelli-Sense ET Controller
RS1	1	Rain sensor with 6mm rainfall threshold
RS2	2	Rain sensor with 6mm rainfall threshold
RS7	7	Rain sensor with 3mm rainfall threshold
WOS	2	Without sensor
NON	0	Non-irrigated
DWRS	2	Rain sensor with 6mm rainfall threshold Irrigation schedule 60% of WOS

[1]LL Low setting was #2 for S06 and then changed to #4 for F06, S07 and F07.

Table 3. Summary of average adequacy and efficiency ratings during the four testing periods.

	Average Adequacy (%)				Average Efficiency (%)			
Treatment	S06	F06	S07	F07	S06	F06	S07	F07
LL Low	48[2]	--[1]	--[1]	95	100[2]	--[1]	--[1]	60

ABSTRACT

In recent years, an increasing number of municipalities throughout the country have implemented mandates, rebates and/or cost-saving programs for the use of rain sensors (RSs). The objectives of this research were to evaluate two expanding disk RS types, Mini-Click (MC) and Wireless Rain-Click (WL), with respect to: a) the accuracy of their set point with respect to rainfall depth, b) the number of times in irrigation bypass mode, and c) the duration in irrigation bypass mode. For the MC treatments, rainfall set points of 3, 6, and 13 mm were established. Rain sensor models were monitored from 1 January 2006 to 31 July 2007, except for MC set at 6 mm which was monitored starting on 13 September 2006. The 576-day experimental period had rainfall frequency and cumulative amount below a historical year. The number of times that replicate units within a treatment switched to bypass mode tended to behave the same through time, for treatments WL and 3-MC, which ranged from 64 to 78 events and from 57 to 68 events, respectively. Treatment 6-MC was the most consistent between replicates, where three units switched to bypass mode on 39 occasions, and one unit did it on 34 times. Replicates from treatment 13-MC showed the most variable behavior, shutting off between 50 to 29 times. On average, treatment WL shut off after 2.8 mm of rain. Because this model does not have a specific set point, accuracy could not be calculated. Accuracies for the other treatments resulted in 73% for 3-MC, 30% for 6-MC, and 58% for 13-MC. Treatments WL, 3-MC, 6-MC, and 13-MC, remained in bypass mode 82, 80, 64, and 83% of the time, respectively, for less than 24 h.

INTRODUCTION

Rain sensors (RSs), are designed to interrupt a scheduled irrigation cycle on an automatic irrigation controller (i.e. time-clock or timer) when a specific amount of rainfall has occurred (Dukes and Haman 2002). During recent years, an increasing number of municipalities in seven states throughout the country have implemented mandates, rebates and/or cost-saving programs for the use of RSs because they appear to be a useful tool for irrigation water conservation, at a relatively low cost (Dewey 2008). Since 1991 Florida has had an overall RS statute, which requires an automatic

rain sensor shut-off device that is properly installed and functioning on all automatic irrigation systems (Florida Statutes, 2008).

The most common type of RSs employs hygroscopic disks to absorb water and expand proportionally to the rainfall amount. Then, a mechanical switch interrupts the system common wire, disabling the solenoid valves, until the sensor hygroscopic disks dry out. To adjust the drying rate of the disks, these sensors have an adjustable vent ring.

A version of these devices (also with hygroscopic disks inside) is a wireless RS, which has a sensor/transmitter installed in an area subject to rainfall and a receiver unit connected to the timer. According to the manufacturer, these RSs have a quick shut down of the irrigation system after it starts to rain (without preset adjustments for a certain precipitation amount). The wireless RSs can also be adjusted to keep the irrigation system off after the rain stops by setting the adjustable ventilation windows that control the dry-out time (Hunter Industries, Inc. 2006).

This research was based on the original work by Cardenas-Lailhacar and Dukes (2008), who studied the performance and reliability of some expanding disk RSs. The objectives of this experiment were to evaluate the reliability of two commercially available expanding disk RS-types with respect to: a) the accuracy of their set point with respect to rainfall depth, b) the number of times in irrigation bypass mode, and c) the duration in irrigation bypass mode.

MATERIALS AND METHODS

Twelve Mini-Click (MC) and four Wireless Rain-Click (WL) rain sensor models (Hunter Industries, Inc., San Marcos, CA) were placed at the University of Florida Agricultural and Biological Engineering Department turfgrass research facility in Gainesville. This experiment took place from 1 January 2006 to 31 July 2007. Four treatments with four replications each were established. For the MCs, three set points were established: 3, 6, and 13 mm thresholds (treatment codes 3-MC, 6-MC, and 13-MC, respectively). The dry-out ventilation windows of the MCs and WLs were kept completely open. All RSs in this study were 9 months old having been set up originally for the study reported by Cardenas-Lailhacar and Dukes (2008).

Each time an RS unit changed status (from allowing irrigation, to bypass mode, or vice versa), the date and time were automatically recorded, at a one-second sampling interval, by means of two AM16/32 multiplexers connected to a CR 10X model datalogger (Campbell Scientific, Logan, UT). Weather conditions were recorded by an automated weather station containing a CR 10X model data logger, located within 15 m of the experimental site. Rainfall was measured by means of a tipping bucket rain gauge, which was routinely checked against a manual rain gauge located nearby. Rainfall data were recorded at intervals of 0.25 mm (day of year, hour, minute, and second were logged). Until 13 September 2006, treatment 6-MC was not connected to the datalogger, so it was not considered for the calculations previous to that date. The total time that each RS remained in the irrigation bypass mode after the rain has stopped was computed (dry out period). Total rainfall before each RS switched to bypass mode was calculated, in order to evaluate the accuracy of

the rainfall thresholds. According to Figliola and Beasley (2000), the accuracy of an instrument refers to its ability to indicate a true value exactly. Accuracy is related to absolute error, ε, which is defined as the difference between the true value of a measurement and the indicated value of the instrument:

$$\varepsilon = \text{true value} - \text{indicated value} \quad [1]$$

from which the percent accuracy, A, is found by:

$$A = \left(1 - \frac{|\varepsilon|}{true\ value}\right) \times 100 \quad [2]$$

RESULTS AND DISCUSSION

Weather Conditions

Overall, the experimental period was drier than normal. During the 576-day experiment, 138 days exhibited rainfall (24%), including 28 days with more than 15 mm (3% of the days). These numbers could be considered below a historical year (1970 to 2000), which for the same period had 31% rainy days and 5% of rainfall events above 15 mm. The cumulative precipitation was 1,723 mm compared to a historical of 2,094 mm, or an 18% of deficit for the study period. Over the entire monitoring period, the tipping bucket rain gauge was very accurate (R^2= 0.99) compared to the manual rain gauge across a range of rainfall events from less than 1 mm up to 60 mm.

Number of Times in Bypass Mode

Figures 1 to 4 show the cumulative number of times in bypass mode of the replicates within treatments. It can be seen that this parameter was variable between the different replicates, with 13-MC the most variable treatment. Replicates at a particular set point sometimes responded properly according to their settings, sometimes did not detect rainfall events five or more times their set points, and sometimes they even shut off several hours after the rain had stopped (data not shown). This explains the range of variation in the number of times that individual RS units switched to bypass mode.

The four replications of the WL treatment (Figure 1) followed a similar pattern, with 64 to 78 events in bypass mode. However, these units were much more consistent when they were newer, varying between 78 and 83 bypassed events over a 282 day experimental period (Cardenas-Lailhacar and Dukes, 2008). Analogous to the WL units, all four 3-MC sensors (Figure 2) behaved similarly, with 57 to 68 times in bypass mode. In the case of the 6-MC treatment (Figure 3), the units were not set up until 13 September 2006. Therefore, the number of times in bypass mode were

smaller than the other treatments. However, these replicates were very consistent, where three of them switched to bypass mode on 39 occasions, and one unit did it on 34 times. The different replicates of treatment 13-MC showed an irregular performance (Figure 4). All replicates tended to behave similarly until 23 July 2006. After that date, one replicate switched to bypass mode more times (50) than the other units. Two other replicates operated similarly until 13 May 2007 (with 34 and 33 time in bypass mode), but afterwards they followed a different pattern and ended the testing period with 42 and 36 times in bypass mode. Finally, the last replication of treatment 13-MC shut off a fewer number of times than the other units after 23 July 2006, and ended with a total of only 29 times on bypass mode. No recorded weather data or physical evidence was found to explain the different performances between the 13-MC units after 23 July 2006.

Depth of Rainfall before Shut Off

The average depth of rainfall before the rain sensors switched to bypass mode, accuracy, and standard deviation for the different treatments is shown in Table 1. Treatment WL shut off after 2.8 mm of rain on average, with a standard deviation of 1.1. Because this model does not have a specific set point, accuracy could not be calculated. However, when these replicates were new they triggered the switch at an average of 1.4 mm of rainfall (Cardenas-Lailhacar and Dukes, 2008). Treatment 3-MC switched to bypass mode after an average of 2.2 mm of rainfall, resulting in an accuracy of 73%, with a standard deviation of 1.9. Unexpectedly, treatment 6-MC shut off on average after 1.8 mm of rainfall (even less rainfall than 3-MC), with a standard deviation of 1.2, and a resultant accuracy of just 30%. It should be noted that the different units were very consistent in their behavior (Figure 3). These sensors were previously set at 25 mm for almost two years, but no physical evidence was observed of any alteration on their expanding disks neither on their mechanism that could be related to this behavior. Treatment 13-MC switched to bypass mode after an average of 7.5 mm of rain, which corresponds to an accuracy of 58%, and resulted in the highest standard deviation (2.7). These average accuracies show that only 3-MC responded close to its set point and that all MC sensors became more sensitive to rainfall; whereas, WL sensors became less sensitive to rainfall compared to previous results (Cardenas-Lailhacar and Dukes, 2008).

Duration in Irrigation Bypass Mode (Dry-Out Period)

The time that it takes the RSs to reset for normal sprinkler operation after the rain has stopped is determined by weather conditions (temperature, wind, sunlight, relative humidity, etc.), which will determine how fast the hygroscopic disks dry out.

Figures 5 to 8 show histograms and frequency distribution for 6 h intervals in bypass mode for treatments WL, 3-MC, 6-MC, and 13-MC, respectively. Results showed that WL sensors remained in bypass mode 82% of the time for less than 24 h, and 23% of the time for less than 12 h (Figure 5). This result does not agree with manufacturer claims that the WL sensors will remain on that status shortly after the

rain stops (Hunter Industries, Inc. 2006). In previous work, WL sensors dried out 50% of the time before 12 hours (Cardenas-Lailhacar and Dukes, 2008). Similar to WL, the dry out period of treatment 3-MC (Figure 6) was 80% of the time less than 24 h, a higher frequency than the 51% found previously (Cardenas-Lailhacar and Dukes, 2008). Treatment 6-MC (Figure 7) also remained most of the time (64%) in bypass mode for less than 24 h, and 86% of the time for less than 36 h. Similar to the other treatments, the dry out period for 13-MC (Figure 8) was most of the time less than 24 h (83%). It is remarkable that the dry out period for all treatments occurred almost always in less than 48 h. Thus, it appears the MC sensors dried out faster with age, but the WL sensors dried out slower.

SUMMARY AND CONCLUSIONS

A study to evaluate and quantify the performance of RSs was carried out from 1 January 2006 to 31 July 2007. This testing period recorded a lower frequency and a lower amount of cumulative rainfall compared to historical records. Accuracy tests results suggested that the 3-MC responded close to its set point (73%), but 6-MC and 13-MC resulted in lower accuracies (30 and 58%). Replicates at a particular set point were variable, sometimes responding properly according to their settings, sometimes not detecting rainfall events five or more times their set points, and sometimes even shutting off several hours after the rain had stopped. This explains the accuracies and the range of variation in the number of times that individual RS units switched to bypass mode. Most of the time, treatments remained in bypass mode for less than 24 h, and almost all treatments dried out in less than 48 h during this testing period. Generally, MC sensors became more sensitive to rainfall and dried out quicker than when they were new; whereas, the WL sensors became less sensitive and dried out slower. In any case, after more than two years of continuous operation these devices still have the ability to bypass irrigation cycles during rainy weather; however, their accuracy appears to be degrading with time.

ABSTRACT

The Irrigation Association has developed a smart water application technologies (SWAT) testing protocol for ET controllers that describes a procedure for testing the efficacy of ET controllers. The test requirements include a minimum of thirty consecutive days with 63.5 mm of reference evapotranspiration (ET_O) and 10.2 mm of rainfall. The objectives of this study are to duplicate the soil water balance calculations specified by the SWAT test and recreate the SWAT bench test in a humid region using ET controllers previously tested under the SWAT protocol in an arid climate. Three brands of ET controllers previously tested under the SWAT protocol by CIT were installed at the Agricultural and Biological Engineering campus research facility (Gainesville, FL). The controllers are as follows: Weathermatic SL1600 with SLW20 weather monitor, Toro Intelli-sense duplicates utilizing the WeatherTRAK ET Everywhere Service, and ETwater Smart Controller 100 duplicates. Duplicate controllers were distinguished by whether they utilized an additional Mini-clik rain sensor denoted with a rain sensor (WRS) or without a rain sensor (WORS). The study period for each controller received less ET_O and rainfall compared to historical averages by 40% and 56%, respectively. The results found during the 2008 SWAT test showed that the ET controllers generally scored well in SWAT performance scores of scheduling efficiency and irrigation adequacy. However, the controllers resulted in lower scheduling efficiency scores than the original published results: 2.5% for the ETwater controllers, 14% by the Toro controllers, and 5.6% by the Weathermatic. It is likely that manufacturers would have opted to not publish these results as a SWAT score and restarted the test with minor adjustments. The SWAT test determines whether the controllers have accurate irrigation scheduling capabilities and does not rate the potential for a controller to conserve water. The SWAT testing protocol should be clearly outlined and detailed enough for results to be reproducible if it will continue to be used as an industry standard.

INTRODUCTION

Water resources are limited in many areas of the United States. A recent study by Mayer et al. (1999) showed that 58% of total household water use was used for landscape irrigation. Of that outdoor water use, 40% was wasted by over-watering plant material (Mayer et al. 1999).

The increased demand for conservative irrigation practices has opened a market for technologies to aid in scheduling irrigation for the homeowner. One such technology, termed a smart controller, is defined by the Irrigation Association ([IA] 2008) as "…controllers [that] estimate or measure depletion of available plant soil moisture in order to operate an irrigation system, replenishing water as needed while minimizing excess water use...requires initial site specific set-up and will make irrigation schedule adjustments, including run times and required cycles throughout the irrigation season without human intervention." Smart controllers can come in many forms; one such controller is a climatologically-based controller, also known as an ET controller.

The Irrigation Association developed a smart water application technologies (SWAT) testing protocol for ET controllers (IA 2008). This testing protocol, currently under its 8th draft, describes a procedure for testing the efficacy of ET controllers and is performed solely by the Center for Irrigation Technology (CIT) at California State University (Fresno, CA). The test requirements include a minimum of thirty consecutive days with 63.5 mm of reference evapotranspiration (ET_O) and 10.2 mm of rainfall. Many of the tests performed to date required longer than 30 days to achieve 10.2 mm of rain. It is questionable whether these test limits are reasonable. For example, in humid climates the 10.2 mm rainfall limit is only a fraction of what might occur in a given growing season where amounts of 500 mm or more are common. Also, thirty days is a relatively short time period when testing an ET controller's ability to adjust irrigation over time.

As the industry progresses and new water conservation programs require ways to test smart technologies, the need for a formal, industry accepted procedure exists. The protocol is vague in various areas and the testing procedures cannot be fully duplicated as they are written. The objectives of this study are to duplicate the soil water balance calculations used by CIT as the SWAT test and recreate the SWAT bench test in a humid region using ET controllers previously tested under the SWAT protocol in California.

MATERIALS AND METHODS

SWAT Protocol. The SWAT test, as defined in the SWAT protocol document, uses a daily moisture balance to simulate the water dynamics of a landscape plant system. Six landscape scenarios are specified so that the controllers can be evaluated on their ability to schedule irrigation under different environmental conditions (Table 1). These landscape scenarios or "virtual irrigation zones" range from turfgrass to trees, drip to spray head irrigation, shady to sunny areas, loamy sand to clay soils, and 2% to 20% slopes. The daily balance is calculated by the following equation:

$$MB_i=MB_{i-1}-ET_C+R_E+I_E$$

where MB is the soil water content (mm) on day i or i-1, ET_C is the plant specific ET (mm) on day i, R_E is effective rainfall (mm) on day i, and I_E is effective irrigation (mm) on day i.

MB represents the water storage level in the soil profile on any given day. This level fluctuates from 0, or no readily available water in the soil profile, to a maximum value specified by the protocol for each zone termed root zone working water storage (RZWWS). A moisture balance level of 0 does not equate to the absence of water in the soil column. Therefore, MB does not represent the actual water level in the soil profile, but the level under which the plant material will no longer be considered well-watered.

Plant-specific evapotranspiration (ET_C) is calculated for any given plant material by applying a crop coefficient (K_C) using the following equation (Allen et al. 1998):

$$ET_C=K_C*ET_O$$

K_C values are specified by plant type and exposure expressed in the SWAT protocol (IA 2008).

Net rainfall is defined as the depth of total rainfall that enters the soil profile and is considered available for plant use. The protocol specifies that daily net rainfall is 80% of total daily rainfall. Effective rainfall is calculated from net rainfall and is the depth that causes the MB to reach RZWWS. Excess rainfall (that which exceeds soil storage capacity) is lost due to surface runoff or deep percolation.

ET controllers schedule irrigation by calculating the depth of irrigation required to reach RZWWS, termed net irrigation (I_{NET}). These controllers apply more irrigation than is scheduled to take into account system application inefficiencies (Table 1). The depth actually applied by the controllers, including efficiency adjustments, is considered gross irrigation. Effective irrigation is the portion of net irrigation that can be used by the plant. Effective irrigation can be less than net irrigation due to any combination of surplus and direct runoff. Surplus (S) is the depth of daily net irrigation exceeding RZWWS and is calculated as:

$$S=MB_{i-1}-ET_C+R_E+I_{NET}-RO_{DIR}-RO_{SOAK}-RZWWS$$

where RO_{DIR} is direct runoff (mm) for day i and RO_{SOAK} is soak runoff (mm) for day i. If the value of S is calculated as a negative value, then surplus is zero. Direct runoff is the depth of any one irrigation event exceeding the maximum runtime. It is calculated as:

$$RO_{DIR}=\left(I_{EVENT}-Rt_{MAX}\right)*E_{APP}*PR/60$$

where I_{EVENT} (min) is the irrigation occurring per event cycle, Rt_{MAX} (min) is the maximum runtime according to allowable surface accumulation and infiltration rate restrictions, E_{APP} is the application efficiency (Table 1), and PR (mm/hr) is the

precipitation rate (Table 1). Direct runoff is calculated for each event cycle and summed for a daily total. If I_{EVENT} does not exceed Rt_{MAX} , then RO_{DIR} is zero. Soak runoff is the depth of the next irrigation event during a cycle/soak irrigation schedule that occurs before the minimum soak time is complete. It is calculated as:

$$RO_{SOAK}=\left[\frac{I_{EVENT_a}*E_{APP}*PR}{IR*60}-Rt_{SOAK}\right]*\frac{PR}{60}$$

where I_{EVENTa} (min) is the event cycle runtime prior to Rt_{SOAK}, IR (mm/hr) is the infiltration rate defined by the soil type, and Rt_{SOAK} (min) is the soak cycle runtime between event cycles for a cycle/soak schedule. The RO_{SOAK} calculation is valid assuming $0<RO_{SOAK}<I_{EVENT_b}$, where I_{EVENTb} (min) is the event cycle runtime following the soak time. When RO_{SOAK} is calculated to be greater than I_{EVENTb}, then RO_{SOAK} equals I_{EVENTb}. Also, RO_{SOAK} is a positive value and is zero if found to be negative.

The SWAT protocol process "scores" the performance of the irrigation controllers with respect to over-irrigation and under-irrigation. As a result, scores of scheduling efficiency and irrigation adequacy are computed to represent measures of over-irrigation and under-irrigation, respectively. Scheduling efficiency is defined as the ability of a controller to schedule irrigation without applying excess irrigation that results in drainage or runoff (IA 2008). It is calculated in thirty day running totals or greater depending on the length of the test for any given controller with the following equation:

$$E=\frac{(I_{NET}-SL)}{I_{NET}}*100$$

where I_{NET} refers to the sum of net irrigation applied and SL refers to the scheduling losses summed over the time period. Scheduling losses include summed values of surplus, RO_{DIR}, and RO_{SOAK}. Irrigation adequacy quantifies the ability of the controller to supply sufficient irrigation to meet the plant water demand (IA 2008). It was also calculated in thirty day running totals using the following equation:

$$A=\frac{(ET_C-D)}{ET_C}*100$$

where D represents the deficit or the sum of the depth of water below the maximum allowable depletion over the time period (i.e. below RZWWS). Because the testing occurs for a virtual landscape, it is assumed that high irrigation adequacy results translate to acceptable landscape quality. Acceptable levels of irrigation adequacy and scheduling efficiency have not been specified by the protocol. Some discussion has indicated that respectively levels of 80% and 95% would be acceptable limits; however, evidence has not been made available to date to show that any particular level is an acceptable balance to meet plant water needs and to limit excessive watering.

Florida Test. Five ET controllers previously tested under the SWAT protocol by the Center for Irrigation Technology (CIT) in Fresno, California, were installed at the Agricultural and Biological Engineering campus research facility (Gainesville, FL). The controllers are as follows: Weathermatic SL1600 with SLW20 weather monitor (Weathermatic, Inc., Dallas, TX), Toro Intelli-sense duplicates (Toro Company, Inc., Riverside, CA) utilizing the WeatherTRAK ET Everywhere Service (Hydropoint Datasystems, Inc., Petaluma, CA), and ETwater Smart Controller 100 duplicates (ETwater Systems LLC, Corte Madera, CA). Duplicate controllers consisted of one with an additional Mini-clik rain sensor (Hunter Industries, Inc., San Marcos, CA) set at a 6.3 mm threshold, denoted with a rain sensor (WRS) or without a rain sensor (WORS). The Weathermatic gathers weather data from the on-site weather monitor and uses Hargreaves equation to calculate ET_O. The Weathermatic controller has an integrated expanding disk rain sensor similar to the devices used on the other controllers. The Toro and ETwater controllers are signal-based controllers that receive daily ET_O, calculated using the ASCE standardized ET_O equation (Allen et al. 2005), through remote signals.

Each controller was connected to a CR-10X datalogger (Campbell Scientific, Logan, UT) to record time and date at the beginning and end of each irrigation event for all active zones. Each controller was programmed by the manufacturer, or with the manufacturer's supervision, with settings identical to the original SWAT test performed by CIT. The official test began when the manufacturer determined that the controller(s) were programmed correctly.

Weather data were collected from two weather stations for this test. The first weather station was located on-site and managed by research personel. Values for reference evapotranspiration were calculated using the ASCE standardized reference evapotranspiration equation (Allen et al. 2005) as specified in the SWAT protocol (IA 2008) and used for the soil water balance model in association with the on-site controller. The second weather station was part of the Florida Automated Weather Network (FAWN) located in Citra, FL, approximately 20 miles from the study location. This station data were available via the internet. The ET_O and rainfall data were downloaded directly from the website and ET_O was calculated by FAWN using the IFAS Penman method. This weather data was used in the soil water balance model for the signal-based ET controllers.

The SWAT protocol specified that testing should occur over a minimum of thirty consecutive days (IA 2008). This test was performed for each ET controller for a minimum of ninety days to obtain multiple thirty day periods of results per controller. Thirty day results were reported only if they met the minimum requirements of 63.5 mm of ET_O and 10.2 mm of rainfall (IA 2008). Final results from the entire testing period were also calculated for each controller by averaging results from each zone. Preliminary results were given to the manufacturers periodically so they may update their settings if necessary. Updates made by the manufacturers to the program settings throughout the test did not affect results of the controllers.

RESULTS

The study period for each controller began in the fall season and continued through winter months. Historical ET_O and rainfall were reported from data collected at the Gainesville Regional Airport weather station operated by the National Oceanic and Atmospheric Administration using six years of data (Table 2). Cumulative ET_O was much less than historical totals for every controller in respective time periods by: 29% for the ETwater, 31% for the Toro, and 60% less for the Weathermatic. Rainfall was also less than historical totals by: 59% for the ETwater, 61% for the Toro, and 48% less than the Weathermatic.

Irrigation adequacy quantifies water deficit due to under-irrigation. The Weathermatic controller and both ETwater controllers always kept the moisture balance above zero for all zones, resulting in 100% average, maximum, and minimum irrigation adequacy scores (Tables 3 & 5). The Toro controllers both received slightly lower irrigation adequacy results with an average score of 98% and 97% for the WORS and WRS treatments, respectively (Table 3). Minimum scores for these controllers were 94% and some zones resulted in no under-irrigation due to the maximum irrigation adequacy result being 100%. Adding a rain sensor did not result in differences of irrigation adequacy. Also, there were no differences in irrigation adequacy results due to differences between methods of obtaining ET, whether calculated on-site or received by signal.

Scheduling efficiency is used to quantify over-irrigation. The ETwater WORS had results ranging from 80% to 100% with an average of 94% for the six zones (Table 3). The ETwater WRS performed better with results ranging from 92% to 100% with an average of 98%. In this case, the addition of a rain sensor to the controller caused irrigation scheduling to be more efficient. The Toro WORS and Toro WRS resulted in 86% and 85% averages for scheduling efficiency, respectively. These controllers had some zones that did not perform as well, with minimum scores reaching 67% and 62%, respectively, dropping the average results below the other controllers. In contrast to the ETwater controllers, scheduling efficiency results were reduced for the Toro controllers by using a rain sensor. The Weathermatic performed similarly to the ETwater WRS controller with results ranging from 92% to 100% and averaging 94% from the six zones. These results also show that there were no differences in results between controllers that use different methods for obtaining weather data.

The ETwater controllers, both with and without a rain sensor, began the SWAT test on 14 September 2008 with manufacturer permission and testing ended on 11 January 2009. Running totals for thirty, forty-five, and sixty day periods from the start date were calculated when totals for ET_O and rainfall were above the minimums specified by the protocol. The ETwater WORS and ETwater WRS consistently resulted in 100% irrigation adequacy for all thirty, sixty, and ninety day periods (Table 4). The ETwater controllers generally maintained scheduling efficiency results throughout the different time periods with average and maximum results slightly decreasing and minimum results slightly increasing over longer periods (Table 5). Results for these controllers differed by less than 2% between time periods.

The Weathermatic controller began the SWAT test on 23 September 2008. This controller consistently averaged 100% in irrigation adequacy for all zones and

over all time periods (Table 4). However, scheduling efficiency decreased as test length increased (Table 5). Minimum scheduling efficiency scores decreased by less than 2% indicating that lower averages occurred due to cumulative over-irrigation by individual zones when performing the SWAT test over time.

The Toro WORS and Toro WRS controllers began testing on 23 October 2008. The minimum requirements set by the SWAT testing protocol for ET_O were not met during the thirty day testing periods; results cannot be reported for thirty day running totals. Results from longer time periods indicate that irrigation adequacy was not affected by length of time period (Table 4). However, scheduling efficiency decreased for the Toro controllers, by 7-10% on average, by increasing the running time period by fifteen days (Table 5).

DISCUSSION

Irrigation scheduling by ET controllers occurs based on past weather information and do not have forecasting abilities. Therefore, the ET controllers schedule irrigation on the current day based on information from the previous day. Since it is not addressed in the testing protocol, it would be appropriate to assume that the SWAT program would also calculate the moisture balance in this way if the goal of the test is to verify the controller's ability to schedule irrigation. However, the SWAT program uses ET_O, rainfall, and irrigation on the same day to calculate the moisture balance. For optimum results, the ET controllers should be programmed to apply irrigation late in the day when running the SWAT test so that the controllers have the opportunity to gather weather information about the current day prior to the first irrigation cycle. However, in the "real world", typically irrigation is scheduled early in the day.

Priority of inputs and outputs to the daily moisture balance level were not specified prior to the current version of the protocol. It was unknown during the original testing of whether effective rainfall was calculated before or after irrigation. It was determined after working with the SWAT program that ET is removed prior to the calculation of effective rainfall and irrigation is applied after the effective rainfall calculation. By putting these inputs and outputs in this order, it assumes that rainfall occurs later in the day after most of the ET has left the soil profile. This allows for more rainfall, and consequently less irrigation, to be considered effective.

The SWAT protocol specifies in the newest version that a weather station must be on-site to perform the SWAT evaluation. However, irretrievable or inappropriate weather data is possible and can occur at any time. For the test performed in 2008, weather data was missing on 26 September 2008 to 28 September 2008. When using the data collected in the SWAT program, the missing data were replaced with zeros. However, the ET controllers would likely use the last ET_O value calculated or received by the controller until a signal was reestablished; this is what was done for the 2008 evaluation. It is likely that an official SWAT test would be restarted when this happens; however, the protocol does not specify a course of action.

The results presented for different time period lengths were averages of multiple periods within the study period. However, only one time period, or one data

point for irrigation adequacy and one data point for scheduling efficiency, is reported using the SWAT protocol. The manufacturer can continue to test their product until they decide to publish their scores. This can bias the validity of the test if the controller, over one short time period, can achieve one set of good scores by appropriate irrigation scheduling compared to a controller that consistently produces good scores.

Controller programming is the key to receiving good SWAT results. Controllers for the Florida test were programmed with settings that do not necessarily describe the landscape specified in the protocol. Typically, the changes create a smaller RZWWS than specified for the zone. This can be done by using a small root zone depth, increasing slopes, and using seasonal adjustments. Most settings were similar to the protocol for the ETwater controller with only minor adjustments. The Toro controllers were generally programmed with denser soil types, larger slopes, and smaller root zone depths than default values. The Weathermatic cannot adjust the root zone depth. As a result, precipitation rates were lowered to get the same effect. Also, denser soil types, larger slopes, and different landscape coefficients were sometimes used.

Inputting slightly different program settings can significantly impact SWAT scores. For example, the difference of a minute in gross irrigation can affect the scores by 5% to 10%. Events are scheduled so that they are short and frequent to ensure the soil profile receives enough water, but will not create direct or soak runoff. Short and frequent irrigation events will also minimize the penalty failing to properly predict rainfall. However, scheduling irrigation in this way is not consistent with standard irrigation practices, watering restrictions, or horticultural recommendations for healthy plant material. Small, frequent irrigation events occurring in the evening could increase the possibility of disease or fungi and may discourage deep root growth (Doss et al. 1960).

Since controller programming is extremely important to obtaining good SWAT results, manufacturers program the controllers based on how to get a good score rather than using the landscapes described in the protocol. The virtual landscape descriptions were provided so that manufacturers could program their controllers based on the landscape as would occur at a residential site. However, settings used for each zone do not necessarily coincide with the landscape descriptions. Also, there is a lack of standards for determining designations for each setting. Each controller may use a different reference for determining setting descriptions when designing the controller. It is misleading for presented results for a certain landscape when settings were incompatible to the landscape description.

PRELIMINARY CONCLUSIONS

The SWAT test determines whether the controllers have accurate irrigation scheduling capabilities and, despite some misconception, this test does not rate the potential for a controller to conserve water. The test does not include other areas of the controller's performance that could greatly hinder the success of implementation. These areas could include its ability to properly receive or calculate ET, ease of installation, ease of programming, and homeowner educational opportunities.

Cumulative totals for rainfall and ET_O over the study period were lower than the historical average, averaging 56% and 40%, respectively. The combination of low ET and rainfall suggests that irrigation wouldn't generally be required and plant material would be dormant during most of the time period.

The results found during the 2008 SWAT test showed that the ET controllers generally scored well in SWAT performance scores of scheduling efficiency and irrigation adequacy. However, the controllers resulted in slightly lower scores, mainly concerning scheduling efficiency, than what was published from the original SWAT test. Scheduling efficiency results were lower than the original published results by 2.5% for the ETwater controllers, 14% by the Toro controllers, and 5.6% by the Weathermatic. It is likely that manufacturers would have opted to not publish these results as a SWAT score and restarted the test with minor adjustments. The results also showed that there were no differences in results between controllers that use different methods for obtaining weather data.

The SWAT testing protocol should be clearly outlined and detailed enough for results to be reproducible if it will continue to be used as an industry standard. However, the testing procedures are not reproducible based on the current form of the protocol document.

Abstract

Soil-Water sensor controllers have been used since the mid-1990s to manage turf irrigation. While evapotranspriation (ET) based controllers have been more widely adopted for turf and landscape irrigation, soil-water-sensor based systems hold some distinct advantages, particularly in humid regions where rainfall contributes significantly to turf water requirements and is highly spatially variable. Some perceived disadvantages of soil-water-sensor based systems are representativeness of whole landscapes when only one sensor is used; sensor accuracy and repeatability, and proper setting of soil-water setpoints. Several studies involving soil-moisture sensors have been done in Florida, and one study in North Carolina is near completion. These studies have looked at soil-water sensor based systems of various manufacturers in similar settings; have compared results between different moisture setting thresholds; have contrasted water usage with ET based controller systems; and have monitored root zone soil-water status in plots irrigated by soil-water based systems. Soil-water data has also been collected for replicates of sensor-based treatments in an effort to address the question of repeatability and sensor placement representativeness. Preliminary data from these studies have shown that there is wide variability between different sensor systems with respect to both applied water and turf quality. The data has also shown that soil water sensor based systems may in some cases apply less water than ET controllers. Consistent relationships between soil-water-content and controller settings has been found to be problematic. Analysis of soil-water data indicates that while there are differences in soil-water between replications of soil-water-based sensor treatments, soil-water trends are generally consistent between replications and turf quality is generally not substantially different between replications.

Introduction

Soil-water based controllers govern irrigation events using soil-water information. The concept is that all components of a water balance can be integrated into soil-water content. In essence, soil-water based controller systems measure soil-water while ET controller systems predict it. Most sensor-based systems require setting of one threshold (setpoint) moisture content, above which previously programmed irrigations are overridden. Some operate using two thresholds; one to initiate an irrigation event and the other to terminate the event. These thresholds are set to soil-water contents reflective of what is commonly termed an allowable depletion level (single setpoint for one-setpoint systems and lower setpoint for two setpoint systems) and field capacity (upper setpoint for two setpoint systems). While some products adjust baseline run times based on soil-water content, most do not adjust run time but simply allow or disallow a previously programmed irrigation. Some systems interrupt an irrigation cycle immediately when the soil-water content is above the threshold setting, while others allow completion of the irrigation event. Most systems are ‘‘add-on’’ systems meant to be added to an existing controller, while other are ‘‘stand alone’’ complete systems including a controller specifically designed for the system. The ‘‘add-on’’ systems are designed to operate with one sensor while some stand alone systems can accommodate multiple sensors corresponding to multiple irrigation zones. The soil-water sensors that come with these systems include tensiometric-based, conductivity-based and dielectric-based sensors. Setpoints vary from relative settings such as ‘‘wet’’ to ‘‘dry’’ to volumetric soil-water content.

Sensor based control of irrigation in turf began in the mid 1990s. Numerous systems have entered and left the market since then. In a recent review, eight soil-water sensor controllers design for turf and landscape irrigation were described (USBR, 2007). While the preponderance of research and testing has been done for ET controllers, research on these sensor-based systems dates back to the late 1990s. Most of these studies have compared water savings from soil-water sensor controllers versus ‘‘standard’’ timer based controllers with or without a rain shutoff device. In a study conducted in Utah, Allen (1997) found that the use of a simple automated device for overriding a standard electronic irrigation clock by monitoring soil-water can result in an average of 10% savings in water use and can still maintain healthy green lawns compared to a system without a rain sensor. In Florida Dukes et al. (2008) found that most SMS systems saved significant amounts of water when compared to time-based irrigation schedules typically used by homeowners. They recorded ‘‘wet weather’’ savings of 69% to 92% for three of the four systems tested and ‘‘dry weather’’ savings of 28% to 83% while maintaining turfgrass quality at acceptable levels (Cardenas-Lailhacar, et al., 2005).

Grabow, et al. (2008) found that soil-water sensor based systems saved from 12% to 50% of a timer treatment in a dry year when the sensor system was added to a controller programmed exactly as the timer treatment. Preliminary results from the subsequent year that had timely rain show a 24% to 58% savings for the same comparison. Turfgrass quality for both the timer-based and SMF systems suffered in

the first year of the study as the base controller for both was programmed for normal, rather than the dry conditions experienced that year.

Recently studies have been taken from controlled research facilities at universities and moved into residential settings. Haley et al., (2007) evaluated sensor based controller systems in a study conducted in Florida. Fifty-nine homes were included in the study that was divided into four groups, one of which had sensor based add-on systems and a standard timer controller. The residences with the sensor based technology saved 51% when compared to water use of the group using only standard controllers with no intentional guidance. This savings were more than those attained with a standard clock controller and rain sensor that saved 19% compared to the same group. Results of several studies done in Florida have led to the publication of a field guide on the use of soil-water based controller systems in Florida (Philpot et al., 2008).

Soil-Water sensor controller Performance Between Manufacturers

As soil-water sensor based controller systems vary with sensor type, threshold setting interfaces, and modes of operation, it follows that these systems do not all perform identically even when used on similar landscapes, soils and subjected to the same weather patterns. Cardenas-Lailhacar et al (2005) compared four sensor-based systems in irrigation of bermudagrass in Florida. The manufacturers and systems were: Acclima RS500 (Acclima,Inc., Meridian, ID), Watermark 200SS-5 (Irrometer Company, Inc., Glendora, CA), Rain Bird MS-100 (Rain Bird International, Inc., Glendora, CA), and Water Watcher DPS-100 (WaterWatcher, Inc., Logan, UT). The Rain Bird product is no longer on the market, and WaterWatcher is no longer in business. The study also looked at the effect of three irrigation frequencies; weekly, bi-weekly, and daily. While on average, the SMS systems saved 57% in terms of applied water compared to a timer based system set to replace 100% of historical evaportranspiration, individual systems varied widely in the amount of water applied. For the period 20 July to 14 December 2004, the average depth applied over all frequencies ranged from 100 mm to 420 mm. In the case of the system that applied 420 mm, only the weekly treatment resulted in a water savings when compared to the historical ET treatment (Cardena Lailhacar, et al., 2005). After two years of study at the same site, overall savings from 20% to 72% were reported by Dukes, et al,(2008).

Comparison with ET-based Systems

So-called “SMART” controllers can be placed into two broad categories; those that use weather data and site information to irrigate based on the evapotranspiration (ET) of the landscape and those that use soil-water sensors to control irrigation. More studies have been done with ET controllers, however some comparisons between the two types of systems have been made. Some relative comparisons can be made from studies in which the two types are not compared “side-by-side” but compared to a similar standard. Davis, et. al, (2007) in a study that evaluated three commercially available ET controllers, found water savings as much as 40% compared to the theoretical gross irrigation requirement, and water wastage by as

much as 63% depending upon the season. Much of the variation in the results in ET controllers is probably due not only to their ET estimation methods, but also to their ability (or lack thereof) to account for on-site rainfall. This is where the soil-water sensor based systems hold an advantage.

Vasanth et. al, (2007) and Grabow et al. (2008) found that two soil-water sensor systems applied less water than an ET controller in a study conducted in Raleigh, NC. As in the study done by Cardenas Lailhacar et. al. (2005) weekly, bi-weekly and daily irrigation frequencies were part of the experimental design. The two sensor based systems were manufactured by the same company, but one was a single setpoint "add-on" system, and the other was a two-setpoint or "on-demand" system. The on-demand sensor system was allowed to irrigate daily, but only did so when the soil-water level was below the lower setpoint. In the first year of the study, the single setpoint sensor system applied 46 - 48% less than the ET controller while the two-setpoint system applied from 31% less to 8% more depending upon irrigation frequency. Preliminary analysis of the second year's data show even more relative savings from the sensor based system, likely due to the increased rainfall and the system's ability to account for on-site rainfall. It should be noted that while the soil-water sensor systems afforded water savings in the first year of the study, turf quality suffered for the add-on systems. The on-demand sensor system has offered the best combination of water savings and turf quality in this study to date.

Representativeness and Repeatability

One argument against the soil-water based systems has been the perceived problems with representativeness of sensor location and repeatability of the sensor systems. Dukes and Miller (2005) evaluated the same four soil-water sensor systems as tested by Cardenas-Lailhacar et al (2005). They found that only one of the four sensors tested was highly predictable (repeatable) in its relationship between soil-water content and controller settings. Despite the lack of repeatability in three of the four systems, all but one system reduced applied water by 60-80% compared to a twice–a-week time based system. They noted that the slopes of the regression lines of controller setting vs. volumetric soil content varied by the irrigation frequency settings of the same controller. This was attributed to possible manufacturer variability or localized soil differences.

Studies in both North Carolina and Florida have looked at the difference in soil-water content over time in turf plots that are replications of one soil-water sensor treatment. This goes to addressing concern with sensor placement. In both of these studies, a sensor buried in one plot served as the "master" to "slaved" plots that served as replications. Figure 1 shows soil-water data over time in a study done in Florida. Three plots are slaves to the control plot (E04), i.e, plot EO4 has the control sensor and the other three have monitoring sensors. Note that while there are differences in the volumetric water content at any one time, soil-water trends the same in all plots. The differences are likely due to soil heterogeneity.

Figure 2 shows a similar plot that contains soil-water data from three soil-water-sensor controller systems and an ET controller and standard timer-based systems. These plots are in a clay soil located in Raleigh, North Carolina. Volumetric water

content was measured at four depths with a down-hole capacitance probe and an access tube. While not as in concert as the plots shown in Figure 1, soil water content of the replications for the soil-water sensor systems generally trend the same. The other treatments are shown for comparison. Variability is also evident in these other treatments, illustrating the fact the ET controllers are subject to the same variability as a soil-water sensor system. In this study done in North Carolina, differences in turf quality were noted in some of the soil-water sensor based replications in the first year (2007) but not in the second year.

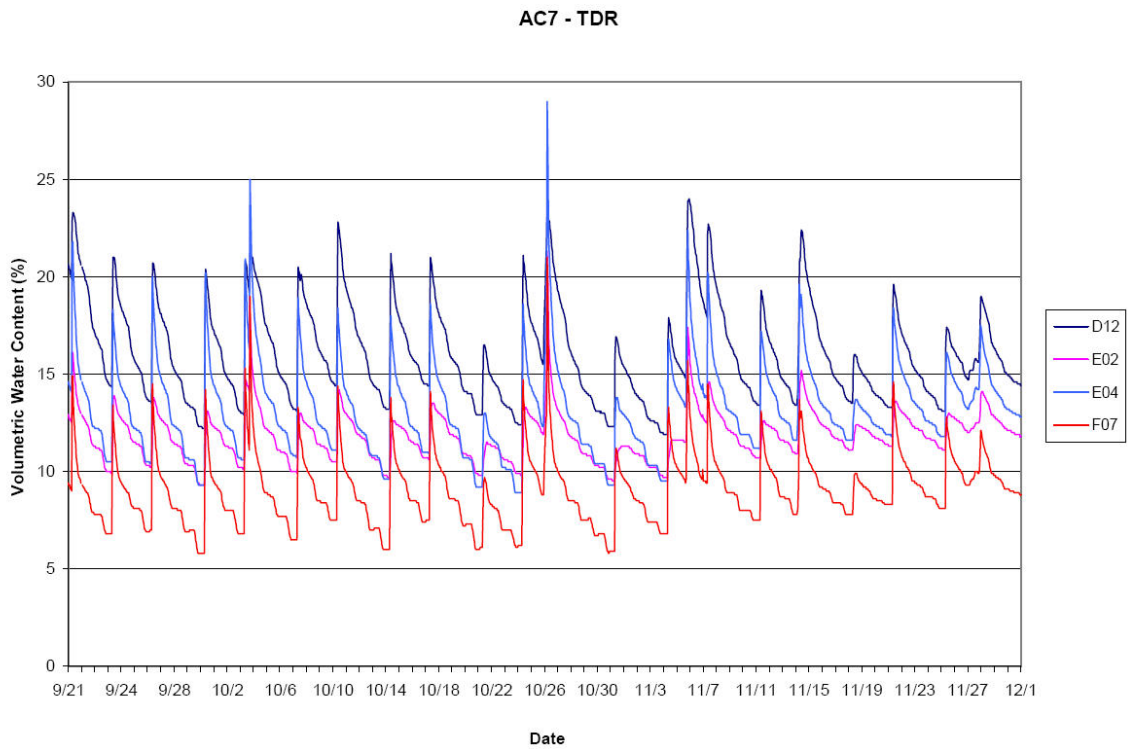

Figure 1. Volumetric Soil-Water Content for Four Replications of a Soil-Moisure Sensor Controller Treatment in Florida (2006). EO4 is the plot with the control sensor and the other three are slaves.

Summary And Conclusions

Soil-water sensor controller systems have conceptual advantages in irrigation control since they integrate all elements of a soil-water budget into the soil. Studies have shown the these systems consistently reduce water use when compared to standard controller systems set to irrigation on historical ET or historical gross irrigation requirement. They have also to been shown to apply less water than ET controllers in some instances while maintaining turf quality. The relative advantage of soil-water sensor systems to ET controllers may be enhanced in humid regions, as these systems can account for local effective precipitation. Sensor placement and representativeness may not be as problematic as first thought, and in fact spatial variability in soil, microclimate, plant and turf characteristics leads to spatial variability in soil-water content for ET systems as well. Sensor-bases systems that

allow for multiple sensors (e.g. one for each irrigation zone) would further address this concern.

As with any "SMART" irrigation system, proper installation and setup is critical. Guidance for this systems has been formulated in Florida and continuing research in other locations will aid in local guidance. It is imperative that for soil-water sensor based systems that run times be adequate to guard against periods of drought, yet not be longer than required to fill the root zone to field capacity. This is especially important for those systems that allow a complete irrigation rather than immediate termination of a cycle once the soil-water level has increased to above the threshold setting.

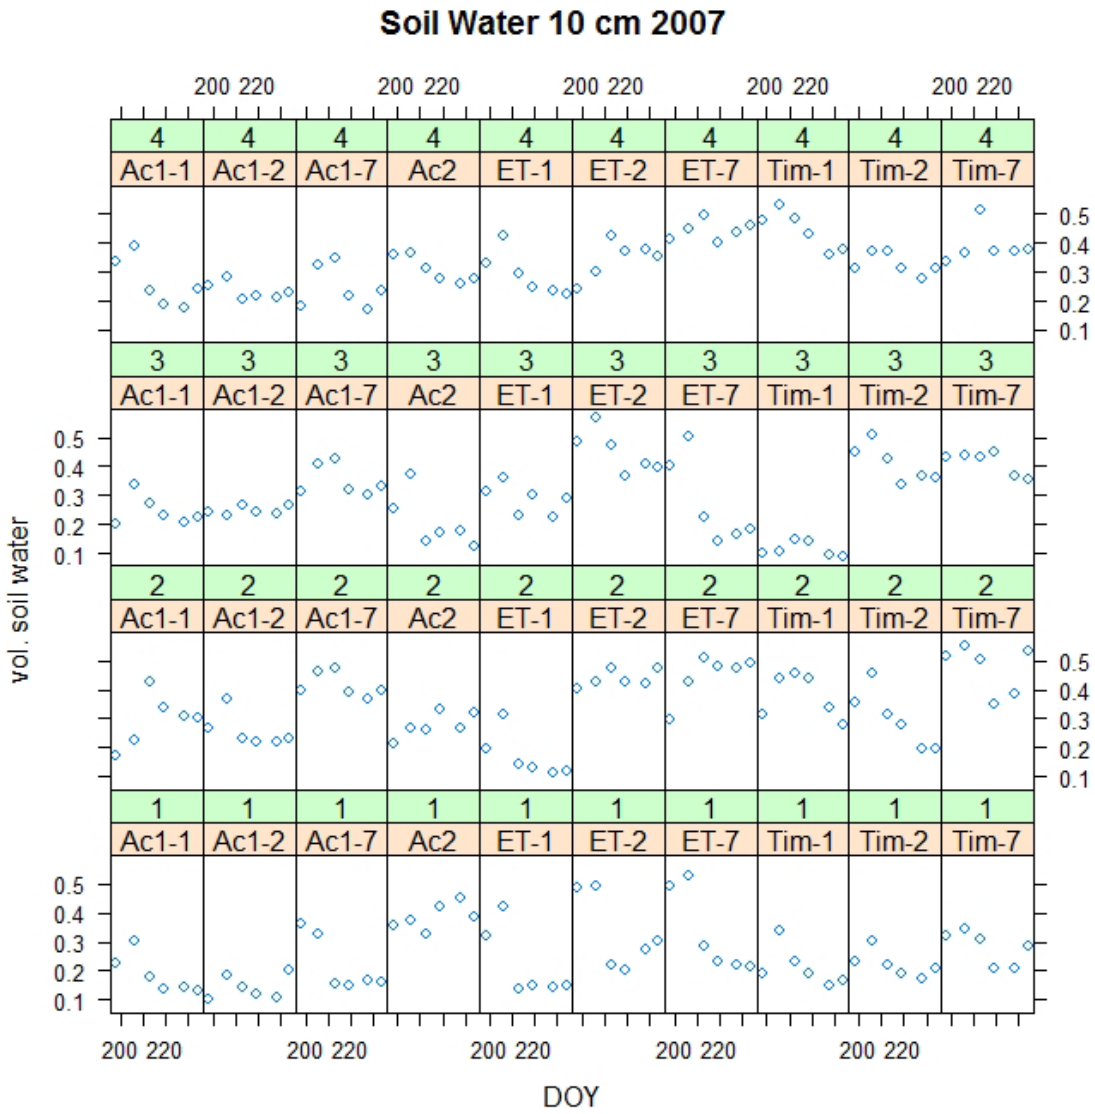

Figure 2. Volumetric Soil Water Content at 10 cm depth for 4 replications of four technology (Ac1, Ac2, ET, and Tim) and three irrigation frequencies (1-weekly, 2-bi-weekly, and 7-daily). The green band indicates rep (1,2, 3, and 4) and the brown band is treatment (technology x

frequency). DOY is day of year 2007. The Ac treatments are the sensor treatments and their control sensors are located in rep 2.

Application of SVMs Algorithms for Prediction of Evaporation in Reservoirs

Arun Goel[1]
[1]Assistant Professor, Civil Engineering Department, National Institute of Technology (Deemed University) Kurukshetra.136119. Haryana. INDIA. E mail: drarun_goel @yahoo. co. in., Fax: 91-1744-238050.

ABSTRACT

Assessment of water resource requires effective procedures for evaporation estimation involving measurable meteorological parameters and such approaches are rarely available in the literature. In the present work, the data of daily evaporation, temperature, solar radiation, relative humidity, wind speed are used to assess the potential and usefulness of SVM based modeling. The performance of the SVM algorithms (Rbf & Polynomial) is compared with the linear regression on the basis of performance parameters having different combinations of input parameters. The comparison of results showed that there is better agreement when more input parameters are considered for model building as compared to a single parameter. The outcome of study suggests that the SVM based modeling can be applied as an alternative approach for estimation of daily evaporation from the reservoirs.

Keywords: SVM, modeling, error, linear regression, evaporation, reservoir.

INTRODUCTION

Accurate estimation of evaporation influences water balance studies undertaken for efficient planning, design, construction, operation and management of water resources. The evaporation is considered to be most difficult to estimate in the hydrologic cycle due to complex interaction between components of land-plant-atmosphere system (Singh & Xu 1997). In the hydrological practice, the evaporation can be estimated by conventional approaches like direct or indirect methods involving use of empirical equations. The sole direct method is the U S weather Bureau Class A pan measurement. The indirect methods use meteorological data to estimate evaporation by the empirical based methods or statistical and stochastic approaches. The indirect methods are temperature based formula, radiation method, humidity based relation, Penman formula, energy balance approach etc. (Abtew 2001; Choudhury 1999; Vallet-Coulomb et al. 2001; Terz and Keskn 2005). All these approaches are although based on Penman formula but they are sensitive to site-specific evaporation parameters, which can vary form one place to other. Further it is not

possible to consider all the parameters affecting the evaporation estimation by any of the above approaches due to many assumptions and phenomenal constraints.
The literature review showed that these equations vary greatly in their ability to define the magnitude and variability of the evaporation from the reservoirs and the lakes. It is therefore necessary to develop alternate approaches to estimate the evaporation rates based on metrology variables, which are comparatively easier for measurements and estimation. One of the recent alternate approaches is to use of soft computing modelling techniques, which have better modelling flexibility & capability rather than previous empirical approaches where in each of the metrological parameter takes it share proportionally.
The ANN models have been applied to estimate the Pan evaporation by Terzi et al. 2006, Eskin and Terzi 2006) recently. Some studies by (Pal and Goel 2006, Pal 2006) have shown the SVM regression are working well in civil engineering applications in comparison to the neural network approach. However, very few studies have applied SVM modelling approach in this area of evaporation from reservoirs. Murthy and Gawande (2006) have applied linear regression approach for prediction of evaporation by using individual parameters form an Indian reservoir. They have used field data of air temperature (T), wind speed (U), sunshine hours (Sh) and relative humidity (Rh) to predict the evaporation loss (E) as individual parameters. This study has a major limitation that they have not considered the combined effect of all the input parameters in determining the evaporation losses. The average weekly evaporation and meteorological data of Manasgaon (from 1990 to 2004) are collected from a reservoir in Anand Sagar, Shegaon, India (Murthy and Gawande, 2006). Measured meteorological variables include daily observations of evaporation, mean air temperature, sunshine hours, mean relative humidity, and wind speed have been use in the present study.
The present study is aimed to check the potential and application of SVM modelling in predicting the evaporation loss along with linear regression models.

SUPPORT VECTOR MACHINES

Support vector machines (SVMs) are classification and regression methods, which have been derived from statistical learning theory (Vapnik, 1995, 1998). The SVMs classification methods are based on the principle of optimal separation of classes. If the two classes are separable - this method selects, from among the infinite number of linear classifiers, the one that minimize the generalization error, or at least an upper bound on this error, derived from structural risk minimization. Thus, the selected hyper plane will be one that leaves the maximum margin between the two classes, where margin is defined as the sum of the distances of the hyper plane from the closest point of the two classes (Vapnik 1995). The modelling techniques like support vector machines have the capability to reproduce the unknown relationship present between a set of input variables and the output of the system. Support vector machines performance was found to be better due to its use of the structural risk minimization principle in formulating cost functions and of quadratic programming during model optimization. These advantages lead to a unique optimal and global solution as compared to conventional neural network models.
If the two classes are non-separable, the SVMs tries to find the hyper plane that maximizes the margin and that, at the same time, minimizes a quantity proportional to the number of misclassification errors. The trade off between margin and misclassification error is

controlled by a positive constant that has to be chosen beforehand. This technique of designing SVMs can be extended to allow for non-linear decision surfaces. This can be achieved by projecting the original set of variables into a higher dimensional feature space and formulating a linear classification problem in the feature space (Vapnik, 1998). Support vector machines can be applied to regression problems and can be formulated as below:

Vapnik (1995) proposed ε-support vector regression (SVR) by introducing an alternative ε-insensitive loss function. The purpose of the SVR is to find a function having at most ε deviation from the actual target vectors (y_i) for all given training data and have to be as flat as possible (Smola, 1996). This can be put in other words as the error on any training data has to less than ε. For a given training data with k number of samples, represented by $(\mathrm{x}_1, y_1),.....,(\mathrm{x}_k, y_k)$ and a linear function $f(\mathrm{x}) = \langle \mathrm{w}, \mathrm{x} \rangle + d$ (1)

where $w \in \mathrm{R}^N$ and d $\in$ R. $\langle \mathrm{w}, \mathrm{x} \rangle$ represents the dot product in space R^N and N is the dimension of input space. A smaller value of w indicates the flatness of Equation 1, which can be achieved by minimizing the Euclidean norm as defined by $\|\mathrm{w}\|^2$ (Smola, 1996). Thus, an optimization problem for this can be written as: minimize $\frac{1}{2}\|\mathrm{w}\|^2$

$$\text{subject to } \begin{cases} y_i - \langle \mathrm{w}, \mathrm{x}_i \rangle - d \le \varepsilon \\ \langle \mathrm{w}, \mathrm{x}_i \rangle + d - y_i \le \varepsilon \end{cases} \quad (2)$$

The optimization problem in Equation 2 is based on the assumption that there exists a function that provides an error on all training pairs which is less than ε. In real life problems, there may be a situation like one defined for classification by Cortes and Vapnik (1995). So, to allow some more error slack variables ξ, ξ' can be introduced and the optimization problem defined in Equation 1 can be written as:

$$\text{minimize } \frac{1}{2}\|\mathrm{w}\|^2 + C\sum_{i=1}^{k}\left(\xi_i + \xi_i'\right)$$

$$\text{Subject to } y_i - \langle \mathrm{w}, \mathrm{x}_i \rangle - d \le \varepsilon + \xi_i$$

$$\langle \mathrm{w}, \mathrm{x}_i \rangle + d - y_i \le \varepsilon + \xi_i'$$

$$\text{and } \xi_i, \xi_i' \ge 0 \text{ for all } \mathrm{i} = 1, 2, \ldots\ldots, \mathrm{k}. \quad (3)$$

The parameter C is determined by the user and it determines the trade-off between the flatness of the function and the amount by which the deviations to the error more than ε can be tolerated. The optimization problem in Equation 3 can be solved by replacing the inequalities with a simpler form determined by transforming the problem to a dual space representation using Lagrange multipliers λ_i, λ_i', η_i, η_i' i = 1,….,k (Leunberger, 1984). The prediction problem can finally be written as:

$$f(\mathrm{x}, \alpha) = \sum_{i=1}^{k}\left(\lambda_i' - \lambda_i\right)\langle \mathrm{x}_i, \mathrm{x} \rangle + d \quad (4)$$

This technique can be extended to allow for non-linear support vector regression by introducing the concept of the kernel function (Vapnik, 1995). This is achieved by mapping the data into a higher dimensional feature space, thus performing linear regression in feature space. The regression problem in feature space can be written by replacing $x_i \cdot x_j$ with $\Phi(x_i) \cdot \Phi(x_j)$.

Where $K(x_i, x_j) \equiv \Phi(x_i) \cdot \Phi(x_j)$

The regression function for this can be written as:

$$f(x, \alpha) = \sum_{i=1}^{k} (\lambda_i^{'} - \lambda_i) K(x_i, x) + d \quad (5)$$

PERFORMANCE COMPARISON CRITERIA

Much success has already been achieved using neural network algorithms in lake water prediction (Eskin 2006), while the use of support vector machines is comparatively new to the field of hydraulics and water resource engineering (Khan and Coulibaly, 2006; Pao-shan et al., 2006, Pal 2006, Pal & Goel 2006). The SVMs, in addition to the choice of kernel require setting up of kernel specific parameters. The optimum values of the regularization parameter C and the size of the error-insensitive zone ε need to be determined. To select user-defined parameters i.e. (C, γ and d^*) a large number of trials were carried out by using different combination of these parameters on each of the data sets. Similarly, a number of trials were also carried out to find a suitable value of ε (error-insensitive zone) with a fixed value of C and kernel specific parameters. To reach at a suitable choice of these parameters, the correlation coefficients (CC), Root relative square error (RRSE), mean absolute error (MAE), relative absolute error (RAE) and Root Mean Square Error (RMSE) were compared and a combination of parameters providing smallest value of RMSE, MAE, RAE, RRSE and the highest value of correlation coefficient (CC) were selected for the final results. A number of trials were carried out with different data set to select a suitable value of regularization parameter C. Variation in the error-insensitive zone ε have no effect on the predicted scour so a value of 0.0010 was chosen for all experiments.

The data sets from Gawande and Murthy (2006) was used in the present study for model building and validation to assess the potential linear regression based modelling and RBF & Poly based kernels support vector machines in predicting the evaporation loss from the reservoir. Further, measured evaporation values were plotted against the computed values obtained with linear and SVMs algorithms. To study the scatter around the line of perfect agreement (i.e. a line at 45 degrees) was also plotted for the data set. Due to the availability of small data sets, a cross validation was used to train and test the performance of the SVMs. The cross-validation is a method of estimating the accuracy of a classification or regression model. The input data set is divided into several parts (a number defined by the user), with each part in turn used to test a model fitted to the remaining parts. In this study, the field data were used for both creating and testing the models. The choice of input parameters used in modeling the evaporation may influence the predicting capabilities of support vector machines. Graphs have been plotted for difference in actual and predicted values of the evaporation loss along with errors in results as shown in Figures 1-5.

ANALYSIS OF RESULTS

Scatter diagrams as well as error differences between actual and predicted daily pan evaporation values are plotted considering different input combinations of meteorological parameters. The results of the different methods obtained by using RBF & Polynomial kernels of SVM, and linear regression models, are compared with the actual pan evaporation values of the reservoir based on correlation coefficient, RMSE, MAE, RAE, and RASE. The examination of plotted figures 1 to 5 shows that there is better agreement of predicted results based on rbf kernel of SVM rather than for other modelling techniques like polynomial kernel of SVM and the linear regression.

The first set of analysis was carried out by using SVMs and linear regression with input as temperature and output as evaporation loss and the results are plotted as shown in Fig.1 (a). The SVMs determine a relationship (i.e. create a model) between the input and the output of the available data set of any system. These models are than used to predict the output from the known input values of the same system, thus requiring sufficient number of data to create and test the models. A 10 fold cross validation was used to create and test the models. A number of trials were carried out to reach at the various user-defined parameters required for The SVMs using both polynomial and RBF kernels and linear regression based algorithms using WEKA software. The Table 1 provides the value different user defined parameters and the (Table 2) shows the values of correlation coefficients, RMSE, MAE, RAE, RASE for the data set.

Similarly wind velocity, sun shine hours and relative humidity were taken as input parameters separately and evaporation loss were predicted and the results obtained are plotted as shown in Fig. 2 (a), 3(a) and 4(a) respectively. A graph shown as Fig.5 (a) is plotted when all four parameters were taken for model building and evaporation loss was predicted. Further, it is evident from Figure 1(a) to Figure 5(a) that more number of points are lying on the 45^{o} line when the rbf kernel was used to predict the evaporation in comparison to polynomial kernel and linear regression based algorithm for any combination of input parameters. The error obtained between actual and predicted values of evaporation loss has been plotted in Fig. 1(b) to Fig. 5 (b). The figures indicate that there is larger variation of error in case of polynomial based kernel and linear regression approach as compared to radial basis function approach in the present study. It is evident from Fig 1(a) to 5(a) that the maximum value of correlation coefficient was obtained for air temperature followed by wind speed and relative humidity while, minimum values were obtained for sun shine hours (Table 2). Similarly minimum values of RMSE, MAE, RAE, RASE, were obtained for air temperature followed by wind speed and relative humidity and sunshine hours as shown in Table 2. However, all the factors influence concurrently, so it is pertinent to consider the combine influence of all the parameters in the evaporation loss estimation.

CONCLUSIONS

The study concludes that a combination of all input parameters provides better performance of model in estimating the evaporation loss rather than individual parameters. The study revealed that evaporation loss is best estimated by RBF-based SVM modelling rather than polynomial based SVM modelling and the linear regression techniques.

Further, the critical examination of three figures indicates that the performance of the SVM modeling is data dependent to a great extent. The outcome of the study provided an impetus to the potential use of RBF kernel based SVM approach in predicting the evaporation from the reservoirs.

ACKNOWLEGEMENTS

The author wishes to acknowledge Murthy and Gawande (2006) for their data set used in the present study.

Abstract

Control of water table is one of the management processes in irrigation and drainage networks to reduce nitrogen, other salts and drainage water. Suitable depth of water table is decided upon based on the balance between effective root depth, capillary zone and upward flow. In addition sensitivity to water logging, soil water storage capacity, and electrical conductivity of irrigation water and soil stratification should also be taken into account.

If saline irrigation water is used, as a result of water loss through evaporation a salt stratification will result with the soil surface being more saline because of gradual accumulation of salts. The main effect of soluble salts on plants is osmosis effect because the presence of salts, adequate water absorption would be difficult for plants.

This study was conducted to examine the feasibility of implementing water table control technique (i.e., controlled drainage) in an arid and semi-arid region (e.g., Iran) with particular attention to its salinity management. Two water table control treatments including: free drainage (FD) and controlled drainage (CD) with 40 cm controlled water table and three different irrigation water salinity namely: 0.75, 3.4 and 4.8 dS/m were considered. The experimental setup included 6 treatments and three replications. Treatments were applied in 18 lysimeters (90 cm height, 55 cm diameter). The crop cultivated in lysimeters was sorghum. The results indicated that CD method can be used in arid and semi arid regions. The evidence showed that yield of the CD treatment is 2.5 times higher than FD treatment.

Keywords: Controlled drainage, free drainage, Water table management, Lysimeter, Salinity

1- Introduction

Irrigation and drainage management is a basic factor in soil's surface and subsurface flows in arid and semi arid areas. Since salt replacement occurs due to soil water flows, irrigation and drainage management quality represents salt flow quality in the soil to some extent. For example time of irrigation affects capillary rise in the root zone. Capillary rise causes to salt accumulation and irrigation reduction. With encouraging farmers to benefit from shallow water table to meet plant's water requirement and deficit irrigation, management of shallow water table would be possible. Although in this case, due to capillary rise, salinity risk and accumulation of poisonous elements in upper layer of the soil would be occurred. Root zone salinity increases osmosis pressure, therefore more energy should be spent by the plants to absorb the water in order to meet their evapotranspiration requirement. So in a certain viscosity rate, plant's roots are able to exert adequate force to absorb water from soil layers.

Meyer et al. (1980) showed that wheat extracted up to 28% to 38% of its ET from a water table of 1 meter in a loamy soil. Jia et al. showed the effectiveness of controlled drainage and vegetative buffers on reducing the transport of waste water nutrients from land applications filed in a 3 year field study. Positive effects of compatibility of controlled drainage in arid and semi arid areas through waste water reduction and irrigation water saving are presented in several researches by Abbott et al. (2001). Kahlown et al. (2005) concluded that water table depth of 1.5-2 m is the optimum water table depth for most crops except sugarcane which gave even higher yields with the water table at 2 m depths. Asad (2001) also concluded that high wheat yield could be obtained with 1–2 irrigations of 7.5 cm each when the water table depth was from 1 to 2 m. However, if the groundwater is saline generally more than 4.0 dS/m_1, the water table of 1–2 m or less results in decreased wheat and sugarcane yield.

It is clearly obvious that groundwater contribution as an important factor in water balance which provides ET of plants should be considered. Therefore it would be resulted in water and energy saving and also would be kept water level in a desired depth. At Karaj, Iran 18 lysimeters were constructed to evaluate controlled drainage and shallow water table effects on plants. Main objectives of this research are: (1) crop yield under controlled drainage system (2) groundwater contribution in meeting crop water requirements and (3) root distribution in shallow water table conditions.

2- Materials and methods

2-1- Model construction

In this research 18 lysimeters from PVC were used. To control water table, some pipes from PVC with 3cm diameter and 10cm length were applied. Some holes with the space of 2cm from each other and the diameter of 2mm were made on the pipes. To avoid from the entrance of soil particles to the pipe, a suitable filter like gunny fiber is used around the pipe. In the drainage outlet 5cm above bottom of the lysimeter one valve is installed which connected to the riser pipe beside the lysimeter. It acts as pisometer that made it possible to read the water level every time. In

controlled drainage treatments up to 40 cm of the lysimeter filled with sand and then the lysimeter fulfilled with soil. To avoid from the entrance of soil particles in sandy layer and mixture of soil with sand two layer of gunny fiber were used. In free drainage treatments, lysimeters were filled with sand just above the valve and then fulfilled with soil rest of it.

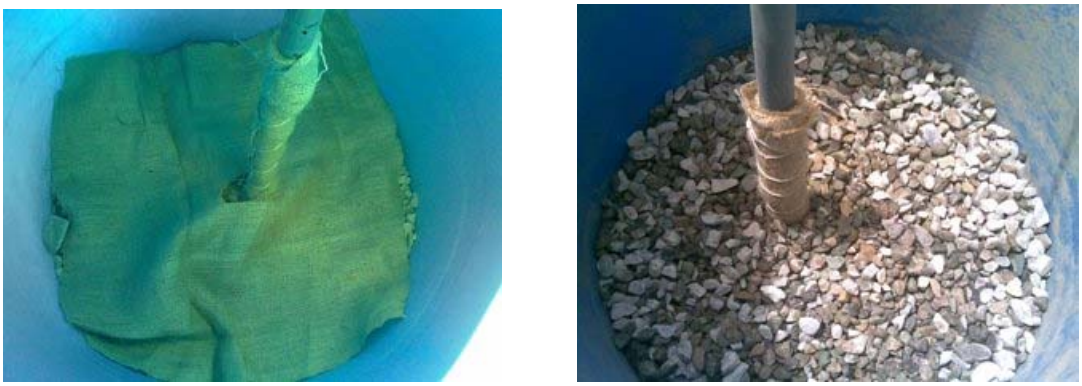

Figure 1- filling the lysimeters

2-2- water table control in the lysimeters

Water table control in controlled drainage treatments in 40 cm from the soil surface was done with the plant of sorghum simultaneously. After first irrigation event, rise and fall of the water table were read before and after irrigation. Hydraulic relation between riser and lysimeter follows the rule in which the water level in the lysimeter is equal to water level in the riser pipe. In other words water level in the riser shows the water level in the lysimeter. In figure 2 the fluctuations of water table for different treatments during the experiment are shown.

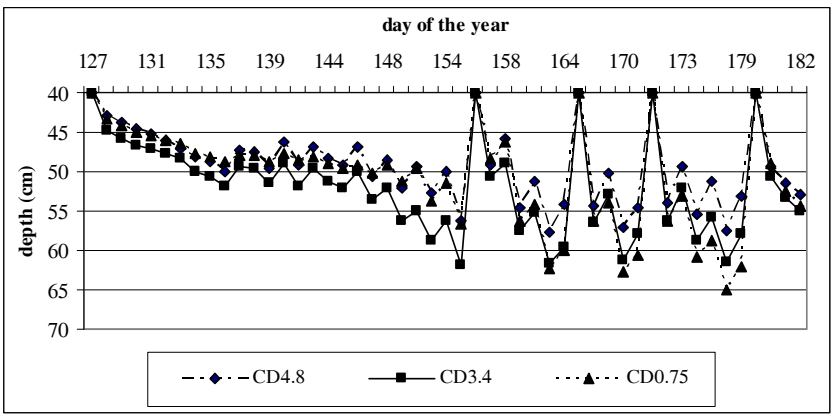

Figure2- water table fluctuations during the experiment period

2-3- Irrigation water

Three different quality of water included: 0.75 dS/m, 3.4 dS/m and 4.8 dS/m were used. In the beginning of the season for the sprouting of the seeds and establishment of roots, all treatments were irrigated with the same amount of

irrigation water. After that irrigation is done according to the NETWAT data for that specific area, considering two days for irrigation time. In controlled drainage treatments, total water volume is calculated through multiplying drop of the water table by area of the lysimetr and porosity. Total irrigation water for both kind of drainage is shown in the table 1 and 2.

2-4- crop yield

2-4-1-Dry matter

Wet weight of the forage is measured and then by determining the dryness index, dry matter of the plant is calculated.

2-4-2-Water Use Efficiency

By considering the total volume of the water, water use efficiency for each treatment is also calculated.

2-4-2- Root weight

The roots were removed by washing the soil of the lysimetrs. Length of the roots were measured and then they were cut and weighted 10 cm by 10 cm. Surface roots based on the 40-30-20-10 rule absorb higher amount of water requirement.

3- Results and discussion

3-1- irrigation water

Although the amount of irrigation water was similar for the free and controlled drainage treatments, water use was found to be higher in controlled drainage. In controlled drainage plants can benefit from the presence of a nearby water table and compensate their ET requirement shortage. Capillary rise contribution and soil surface absorption were shown in table 3.

Table 4 - water use percent from capillary rise and soil surface absorption

treatment	Water use amount	
	Capillary rise	Soil surface absorption
CD0.75	28.21%	71.79%
CD3.4	33.21%	66.79%
CD4.8	27.91%	72.09%

Water use in controlled drainage treatments can be considered as nearly potential ET. Capillary rise has an important role on providing water requirement. Contrary to the case of Free Drainage that irrigation is just equal to compensate soil water depletion. The plant would gradually be faced with difficulty to absorb water after each irrigation and before the next irrigation. The rate of plant water use would then be less than potential in this case.

As the weather warms up and ET requirement is increased, more water is absorbed by the plant from the water table. This is just possible water table is controlled at an optimum depth that plant roots are able to extend to, easily. Higher rates of water extraction from the water table in controlled drainage treatments as the growing period progresses confirm this fact.

3-2- crop yield

Crop growth and development depend on the environmental conditions of root zone, root system depth, and crop sensitivity to salinity and drought. As we see from the figure 3 total dry matter of plant in the controlled drainage and free drainage

treatments indicated that production in CD was higher than in FD treatment. This is due to higher accessibility to moisture that lowered stress for the plants. We can actually propose that plants under the CD treatment, capillary rise of water could decrease the effect of salinity stress to some extent. Thus the yield of controlled drainage treatment with irrigation water of 0.75 dS/m (CD0.75) was higher than controlled drainage treatment with irrigation water of 3.4 dS/m (CD3.4) and higher than controlled drainage treatment with irrigation water of 4.8 dS/m (CD4.8).

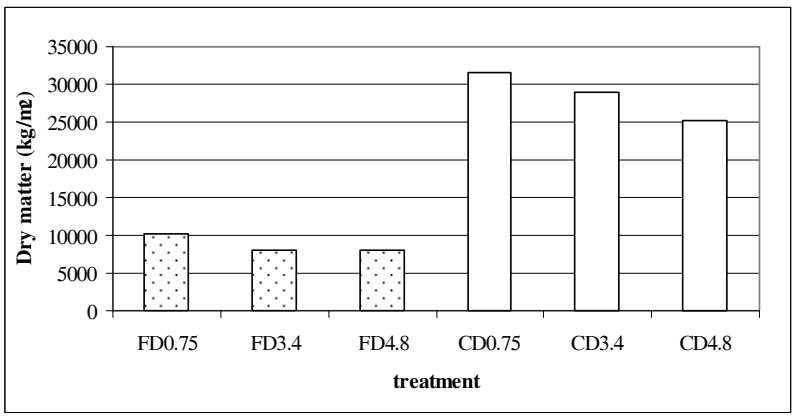

Figure 3 - crop yield of the treatments

3-3- Water use efficiency

The results presented in figure 4 clearly shows that water use efficiency in CD treatment is better than FD's but the more saline irrigation water the lower water use efficiency. Observation showed that salt accumulation in soil in CD treatment is more pronounced than what is in FD which would have a negative effect on the yield. Mutual effect of both saline irrigation water and water level indicated that better moisture condition in CD than in FD has decreased the salt accumulation effect which finally resulted in better yield.

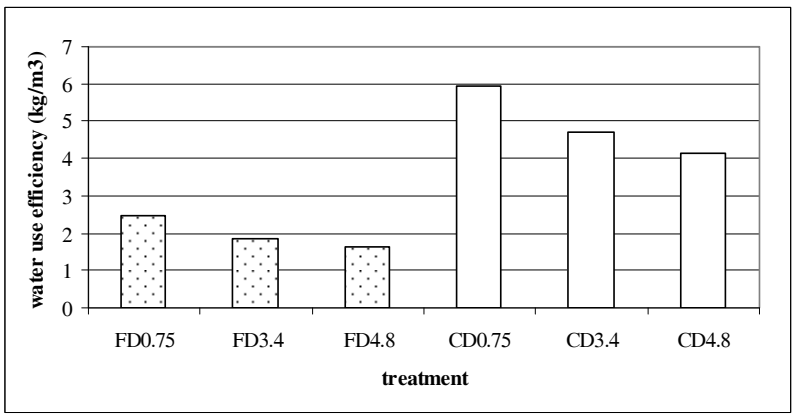

Figure 4 - water use efficiency of the treatments

3-4- Root weight

Root extension and development in the FD treatment is less than what is in CD, it is because access to adequate water in the root zone was limited. The results were shown in figure 5.

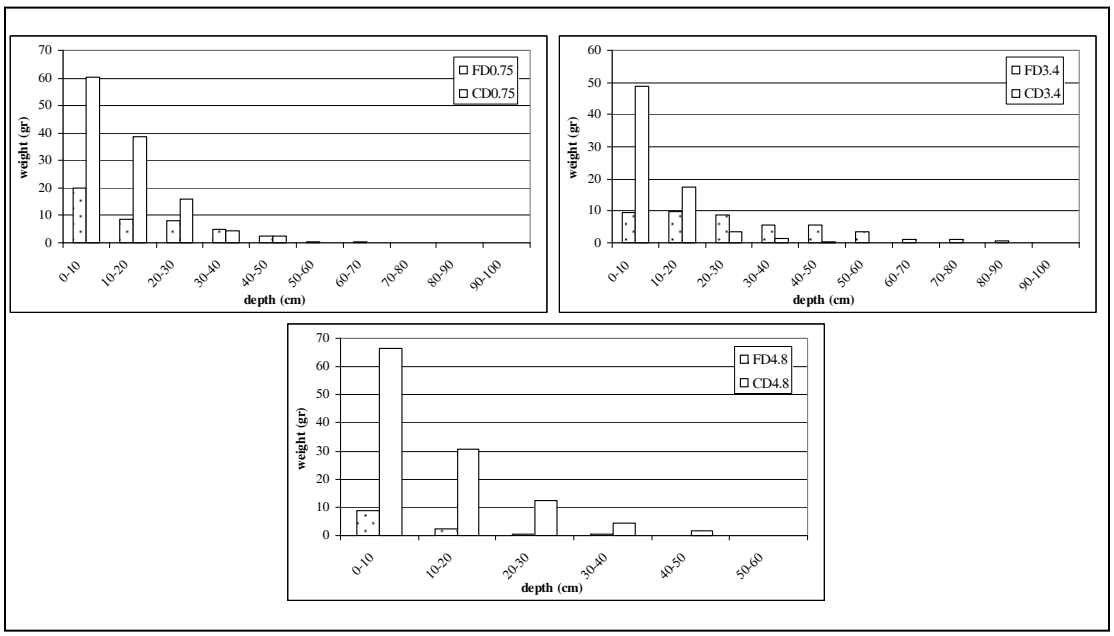

Figure5- root weight in soil profile

Root depth in CD treatment is limited to the level of water table, but in FD it has extended to even 80 cm depth. However the root development, distribution and volume are less than what is in CD treatments. By comparing salinity profile and root weight we can conclud that in lower layer of the soil there were lower salinity and root weight in both free and controlled drainage treatments.

4- Conclusion

Preservation of shallow water table using controlled drainage can provide water requirement from the groundwater in addition to what is applies at the surface. Crop yields can often be enhanced and the amount of irrigation applied can be reduced significantly. Controlled drainage has the potential to reduce drainage volumes and subsequently salt loads. This can help reduce negative downstream effects associated with subsurface drainage. The potential for root zone Salinization will be a major consideration when developing management practices to ensure the sustainability of controlled drainage. Careful monitoring and management will be required when implementing controlled drainage.

Finally the experimental results exhibited the potentials for environmental and economic benefits of the application of controlled drainage in semiarid regions like Iran.

Estimation of regional reference evapotranspiration from land surface temperature and co-kriging method at Tehran province, Iran

Mahdi Shahabifar, Maryam Chaichi and Mahdi Kouchakzadeh

Abstract

Evapotranspiration is the main factor of water cycle in nature and having the information of the amount of that is necessary to soil and water study. Estimation of this amount by using available equations indicates only the amount of evapotranspiration at the stations. Whereas in order to expansion water resources for irrigation and drainage, regional scale studied are required which geostatistical tools are used for achieving that. In this study reference evapotranspiration at 31 meteorology stations in Tehran province with Hargreaves-Samani method in January (wet) and July (dry) were estimated. To supply reference evapotranspiration maps in province that capable to be used at regional study, Co-Kriging was used. Land surface temperature was covariate in this method and has been determined by using image of NOAA14-16 at (1999-2003) and spilit window algorithms. Estimated temperature of images was compared with the temperature of 5cm depth of soil and Mean Absolute Error (MAE) was criterion for algorithms evaluation. Then land surface temperatures were determined from the network with 9200×7500m distance at area and were used for covariate of co-Kriging method and the maps of monthly reference evapotranspiration were drawn.

Keywords: Reference Evapotranspiration, Hargreaves-Samani, Geostatistics, Co-Kriging, Land Surface Temperature, NOAA Satellite.

1. Introduction

Evapotranspiration is the main factor of water cycle in nature, which causes water return from land surface into the atmosphere. In general, evapotranspiratuion is statement of crop water consumption and having information of the amount of that is necessary to soil and water studied. Also minute determination of this quantity and prediction ability of it is a valuable capital for water resources managers. Because the information about evapotranspiration was useful in expansion planting programming, climatology and hydrology studies.

Evapotranspiration is related to climate factors and is determined by using of meteorology data. In order to estimate it, so many methods were expanded. These methods used parameters such as air temperature, relative humidity, wind speed and sunshine. These are spatial data which strongly depend on special studied place. Therefore, evapotranspiration is a spatial variable.

Application of evapotranspiration estimation equations are only limited to meteorology stations and these estimations do not give any information for points without data. In water resources expansion studies which are done in large area, the information of the regional reference evapotranspiration amount is necessary and insufficient data of stations are not enough. Geostatistics is a suitable solution for this question because geostatistics is the collection of statistics methods for spatial variable estimation. Therefore, using of this method is limited in cases that spatial variable has been existed and interpolation is needed. In geostatistics, after estimation of a variable, interpolation methods are used in order to generalize these estimated amounts to a large scale [6]. Then the information of available stations is used to estimate unknown variable in the area and the related maps are provided.

In cases with insufficient data from a variable or the target variable for all the sampling network have not been measured, estimation process meets information shortage. Most of the time, measuring or collection of the target variable is time consuming and needs high cost; therefore, the estimators ,which are able to estimate by using a covariate and reciprocal correlation between target variable and covariate, are used. The covariate in evapotranspiration estimation could be a elevation, sunshine, or air temperature. It is worth using covariate which helps to estimation process; because, the estimation will be better and more precise by using more information. Remote sensing technique and using of satellite images are efficient methods that are provided the information from extensive area. Because of extensive covering of satellite images, these data are efficient in regional studies and research. Although using this method for collecting data seems to be more expensive than land method, in some conditions, which is needed distribution of variable at regional, is only the method for reaching the data. Therefore, covariate for geostatistical methods can be collected by using remote sensing. In this study, land surface temperature determined from noaa image has been applied for covariate.

So many researches have been done for generalization evapotranspiration in the world. For providing reference evapotranspiration map in Clorado, the climate

parameters were collected and meaning relations between climate parameters and elevation have been found by using correlation (Claessens et al (1994)). Reference evapotranspiration was calculated by using the data from 158 stations and Blleny-Kridel model and grnerallized into the all studied area by geostatistical tools (Martinez-cob (1996)). Dalezios et al (2002) were considered spatial variation in reference evapotranspiration in Greece. Reference evapotranspiration was interpolated by kriging method and kriging variance was estimated. Results were showed in the form of daily and yearly contour line maps which can be used for all the agriculture aims.

Remote sensing technique and Geostatistics were used by researchers in soil and water studies frequently. Recently, the determination of evapotranspiration as an effective factor in crop irrigation program by using of these techniques was also considered and it is increasing. But combining these techniques and using remote sensing data as a covariate of geostatistics estimators, has not been considered.

2. Methods and Material

Tehran province, the case study in this paper, with 19000 km^2 area situates in the north of Iran between northern latitude $34^{'}\ 46^{''}$ to $36^{'}\ 18^{''}$ and eastern longitude $50^{'}\ 14^{''}$ to $53^{'}\ 12^{''}$. Climate at north is moderate and hilly and in plains are semiarid. Average of annual rain, average of annual evapotranspiration and average of temperature are 187 mm, 2000 mm and 22.1 ^{o}C respectively. In this province, 31 meteorology stations exist.

For calculation reference evapotranspiration, Hargreaves-Samani method was used that explained with equation (1).

$$ET_o = 0.0023(T + 17.8)(T_{\max} - T_{\min})^{0.5} R_a \qquad (1)$$

Where,

ET_o, Reference evapotranspiration mm/day

T, Average of air temperature ^{o}C

$T_{\max}$, Average of maximum air temperature ^{o}C

$T_{\min}$, Average of minimum air temperature ^{o}C

And R_a, Average extraterrestrial radiation mm/day

In Hargreaves-Samani method, only required data is air temperature which is measured at all of the stations. Therefore, reference evapotranspiration in July and January (1999-2003) with this method were calculated at all the stations. July was selected for warm month that evapotranspiration has maximum amount and January was selected for cold month that evapotranspiration has minimum amount.

In order to determination of reference evapotranspiration in Tehran province, co-kriging method was used. In geostatistics interpolation methods, the estimation of a variable is done in two stages. At first, the semivariogram is drawn and the best model is fitted on it. Then according to model parameters, local structure of variable is considered. In the second stage, the estimation of a variable is done by interpolation methods which depend on parameters of the first model.

In geostatistics, correlation between various variables is estimated via co-kriging method that causes accuracy increasing and economizing on cost. In some cases which there are not enough data from one variable or the purpose is estimation with several variables, this type of kriging is used. In this method, the estimation is done with considering to a covariate in interpolation algorithm and on the basis of spatial relation between target variable and covariate. Target variable is the factor that measured in random points and covariate is the factor that amount of this is existed in most or all of the points. Using of this method is advised in the cases that high correlation coefficient between two variables is existed. Co-kriging equation for estimation of unknown point is stated with equation (2).

$$Z^*(x_i) = \sum_{i=1}^{n} \lambda_i Z(x_i) . \sum_{k=1}^{n} \lambda_k y(x_k) \quad (2)$$

Where,

$Z^*(x_i)$, Estimated amount for point x_i

λ_i , Weight for variable z

λ_k , Weight for covariate

$Z(x_i)$, Observed amount for target variable

And $y(x_k)$, Observed amount for covariate

In this study, covariate was land surface temperature (LST) that was determined by using remote sensing technique.

For determination LST by using noaa image, spilit window algorithm was used. At first, these algorithms were explained for sea surface temperature (SST) because sea surface emissivity was fixed and then used for land surface. SST determination equation is stated with relation (3).

$$SST = A.T_4 + B.(T_4 - T_5) + C \quad (3)$$

Where,

SST , Sea surface temperature ^{o}k

T_4, T_5 , Brightness temperature for channels 4 and 5 of AVHRR ^{o}k

And A, B, C are constants.

Determination of LST is more difficult than sea surface because of variation surface emissivity. The variation land surface emissivity is because of variation in structure, composition and moisture. Also specifications of vegetation and surface topography are effected on surface.

Price (1984) supposed that land surface emissivity was fixed and stated a spilit window equation for determination LST from noaa image that showed with equation (4).

$$LST = T_4 + 3.33(T_4 - T_5) \quad (4)$$

Where,

LST , Land surface temperature ^{o}k

However, other researchers such as Becker and Li (1990), Prata and Platt (1991) and Uliverir et al (1994) believe that variation of surface emissivity must be considered in spilit window algorithms. The effect of land surface emissivity in spilit window equations by using of channels 4 , 5 emissivity, average and these differences are considered. NDVI that showed accumulation of vegetation can be used instead of emissivity. NDVI determined by using of equation (5).

$$NDVI = \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \quad (5)$$

Where,

ρ_2, ρ_1, Channels 1 and 2 reflectance of AVHRR

Cihlar et al (1997) proposed using of empirical equations on the basis of correlation between NDVI and emissivity channels 4 and 5 for considering land surface emissivity. Empirical equations between NDVI and emissivity channels 4 and 5 which is in the form of liner-logarithmic relation are stated equation (6) and (7).

$$\varepsilon_4 = 0.9897 + 0.029 Ln(NDVI) \quad (6)$$

$$\varepsilon_4 - \varepsilon_5 = 0.01019 + 0.01344.Ln(NDVI) \quad (7)$$

Where,

ε_4 , Emissivity for channel 4

And ε_5 , Emissivity for channel 5

On the basis of different options for LST determination and effect of land surface emissivity, many algorithms by researchers have been published. In recent 20 years, more than 17 spilit window algorithms have been published. These algorithms can be divided into four categories based on needed parameters: 1) emissivity-dependent models that set the atmospheric effects as constant and emphasized on LST change with ground emissivity. 2) two-factors models using only two essential parameters, ground emissivity and atmospheric transmittance or water vapor for determination of LST. 3) combined models that set other parameters as constant for the computation and 4) radiance models, directly using the observed radiance for the computation [15].

In this study, 10 algorithms from emissivity-dependent models were used for determination of LST: Price (1984), Mc Clain et al (1985), Becker and Li (1990), Prata and Platt (1991), Vidal (1991), Kerr et al (1992), Sobrino et al (1993), Coll et al (1994), Uliverir et al (1994) and Coll and Caselles (1997).

For evaluation of estimated LST from these algorithms, the temperature of 5 cm depth of soil, which was measured in synoptic stations, was used. At first it is required that

temperature of 5 cm depth of soil change to temperature at time of crossing satellite. Then Mean Absolute Error (MAE) as a criterion evaluation of algorithms is calculated by equation (8).

$$MAE = \frac{\sum_{i=1}^{n} \left| Z(e)_i - Z(m)_i \right|}{n} \quad (8)$$

$Z(e)_i$, Estimated amount by algorithm

$Z(m)_i$, Measured amount

n, Number of observation

The model with minimum amount of MAE was selected as the best algorithm to determine the LST in case study. After LST determination from each image, average of them for two investigated months in 5 years was calculated and the results were used in heads of a 9200×7500 m network in the area to covariate in co-kriging method.

For each of January and July during the investigation period (1999-2003) one images without any clouds was prepared by Noaa 14-16 satellite, so ten images were used to determine the LST.

3. Conclusion

Minimum of MAE in July was at Coll and Caselles algorithm (1997) with amount of $9.924\,^{o}C$ and in January with $7.767\,^{o}C$ at Mc Clain et al algorithm (1985). Therefore Coll & Caselles and Mc Clain et al algorithms were used for LST determination in July and January respectively. Estimated LST were used as covariate in co-kriging method. Table (1) shows results of fitting semivariogram on reference evapotranspiration - LST and also reciprocal semivariogram on LST - reference evapotranspiration in July and January.

TABLE 1- semivariogram and reciprocal semivariogram parameters

factor	model	C_0	$C_0 + C$	A_0	$\frac{C}{C_0 + C}$	R^2
$ET_0(july)$	*spherical*	110.00	7776.00	0.957	0.986	0.841
$LST(july)$	*spherical*	0.60	92.20	0.579	0.993	0.842
ET_0 & $LST(july)$	exp*otential*	31.20	120.10	0.050	0.740	0.001
$ET_0(january)$	*linear*	1.00	710.90	1.537	0.999	0.880
$LST(january)$	*spherical*	6.70	45.50	0.655	0.842	0.671
ET_0 & $LST(january)$	*spherical*	1.39	19.24	0.388	0.928	0.022

Amount of $\frac{C}{C_0 + C}$ represents the existence of suitable local structure. If this amount was more than 0.5 then local structure will be suitable. Results from table (2) showed that investigated variables in this study had a suitable local structure and by increasing distance, amount of semivariogram increased and met a fixed amount. This fixed or sill amount have been shown with $C_0 + C$ and after that by increasing distance,

semivariogram have not a noticeable change. Table (2) gives statistical parameters and RMSE that calculated by cross validation method.

TABLE 2- statistical parameters and RMSE at each month $^{mm}/_{month}$

factor	min	max	mean	Stder	RMSE
ET_0 & $LST(july)$	280.30	626.24	450.62	73.92	
ET_0 & $LSTco-kriging(july)$	355.53	586.15	449.00	53.73	47.99
ET_0 & $LST(january)$	32.66	98.95	79.92	15.77	
ET_0 & $LSTco-kriging(january)$	46.18	92.39	72.64	12.35	13.48

Minimum and maximum of reference evapotranspiration in July were 280.30 and 626.24 in Alodegi Firuzkouh and Zivan stations, respectively. In January, minimum of 32.66 was reported from Alodegi firuzkouh and maximum was in Mamloo station with 98.95. Figure (1) shows the maps of reference evapotranspiration in Tehran province in July and January that designed by co-kriging method. Maximum of reference evapotranspiration were observed in the south of province that had a semiarid climate. High temperature in the southern plains causes dryness of air and whereas reference evapotranspiration depends on temperature, it can be said that temperature is a factor of increasing the reference evapotranspiration.

Results, obtained from this study can be used in crop irrigation programming and local distribution of reference evapotranspiration maps are utilizable in soil and water project as a data layer.

ABSTRACT

Three independent approaches were applied to estimate annual evapotranspiration (ET) for the Imperial Irrigation District of Southern California for the 1998 water year (October 1997 to September 1998). These approaches included remote sensing (Surface Energy Balance Algorithm for Land, SEBAL®), a district-wide water balance with ET as the closure term, and a dual crop coefficient approach based on the procedures of FAO Irrigation and Drainage Paper No. 56 with refinements to account for field-specific irrigation frequency. Differences between annual ET from each independent ET estimation approach are evaluated relative to estimated confidence intervals.

INTRODUCTION

To grow and produce food, plants must release water through the process of transpiration. When the soil surface is wet due to rainfall or irrigation, evaporation also occurs. These two processes together are termed evapotranspiration (ET). In irrigated areas, evapotranspiration is usually the largest consumer of water. Thus, accurate determination of evapotranspiration is important for water resources planning. This paper describes the methodology and compares the results of three independent methods to determine annual evapotranspiration from the Imperial Irrigation District (IID), a large irrigated area in the Southwestern United States.

The three approaches were an energy balance based on remote sensing, a water balance utilizing 15-minute flow measurements and a dual crop coefficient procedure (Allen, 1998 and Allen, et al 2005). The energy balance used was the Surface Energy Balance Algorithm for Land (SEBAL®) utilizing Landsat satellite images and the California Irrigation Management Information System (CIMIS). The water balance utilized 15-minute flow data collected by the Imperial Irrigation District. The dual crop coefficient procedure utilized crop areas and plant and harvest dates collected by the Imperial Irrigation District, reference ET obtained from CIMIS and crop coefficients from the Food and Agricultural Organization (FAO) (Allen, 1998) adjusted for local conditions as appropriate (Allen et al, 2005a).

This paper briefly outlines the physical setting, describes the input data and methodology used for each method, reports the results of each method and concludes with a discussion comparing and contrasting the results.

PHYSICAL AND INSTITUTIONAL SETTING

Established in 1911, IID is the nation's largest irrigation district, providing water to about 475,000 acres of diverse crops. The agricultural area lies in the Imperial Valley with much of the area below sea level. The lowest fields are just above the Salton Sea standing at 230 feet below sea level. The land slopes gradually northward from the Mexican border to the south shore of the Salton Sea. A shallow saline groundwater aquifer underlies the agricultural area. The four months of June through September have average high temperatures above 110 degrees Fahrenheit. Annual reference ET (ET_o) has averaged 74 inches ranging from 64 to 83 inches over the last 22 years. Annual precipitation has averaged 2.75 inches ranging from 0.2 to just over 5 inches over the last hundred years. ET_o was 71 inches and rainfall was 2.13 inches for the water year 1998 studied.

Soils underlying eighty-five percent of the cropped area contain a high percentage of clay with low infiltration rates and high water holding capacities. Annually about 100,000 acres of vegetable crops are grown throughout the area. Carrots, onions and lettuce are the most widely cultivated vegetable crops. The most common field crops include alfalfa, Bermuda grass, wheat, sugar beets and Sudan grass. Most of the vegetable area is double cropped, and roughly 350,000 acres is cropped year-round. In this climate, eight alfalfa cuttings are obtained in a typical year.

ET ESTIMATION METHODOLOGY

Three independent approaches were applied to estimate annual ET for the Imperial Irrigation District of Southern California for the 1998 water year (October 1997 to September 1998). These approaches included the remotely sensed energy balance SEBAL®, a district-wide water balance with ET as the closure term, and a dual crop coefficient approach based on the procedures of FAO Irrigation and Drainage Paper No. 56 with refinements to account for field-specific irrigation frequency. Input data and methods used are described in the following sections.

Remote Sensing Estimate of ET with SEBAL

The sun's net radiation reaching the Earth's surface balances with soil, sensible, and latent heat fluxes to conserve energy at the Earth's surface. Taking into account the latent heat of vaporization and density of water, latent heat flux can be converted into ET flux (volume of water per unit area per unit time). ET flux can be estimated as a closure term from estimates of the remaining fluxes (Equation 1).

$$ET_a = \frac{1}{\lambda \rho_w}\left[R_n - (G + H)\right] \qquad [1]$$

where λ is the latent heat of vaporization of water, ρ_w is the density of water, ET_a is the actual crop ET, R_n is the net radiation flux at the Earth's surface, G is the soil heat flux, and H is the sensible heat flux.

The SEBAL model estimates actual crop ET (ET_a) from the energy balance by applying radiative, aerodynamic, and energy balance physics in 25 computational steps. Multispectral satellite imagery with a thermal band is used to calculate ET_a at the pixel-scale. Required input data include radiances in the visible, near infrared, and thermal infrared regions sensed by earth observing satellites; ground based weather data from agricultural or other weather stations; and land use data describing general vegetation types, when available. Knowledge of specific crop types is not needed to solve the energy balance. SEBAL avoids the need for absolute calibration of the surface temperature of each pixel by utilizing a unique internal calibration for each image to estimate sensible heat flux between the surface and the atmosphere. A detailed explanation of the algorithm is provided by Bastiaanssen et al. (1998). Continuing refinements to the model include the use of digital elevation models for radiation balances in mountains (Allen et al., 2001), an improved albedo function (Tasumi et al., 2005), advection corrections, an improved soil heat flux relation, and an improved relation for surface roughness for momentum transport. Recent validations of SEBAL, summarized by Bastiaanssen et al. (2005), have shown seasonal ET_a results generally fall within five percent of seasonal ET_a determined from reliable ground-based measurements.

Input Data

A combination of satellite, ground based-meteorological, topographic, and land cover classification data are utilized to quantify spatially distributed ET_a. For this study, these datasets were obtained from the U.S. Geological Survey (USGS), CIMIS, and IID. These data are described in greater detail in the following paragraphs.

Satellite Images. Twelve Landsat 5TM multispectral images encompassing the period from October 1997 to September 1998 (Water Year 1998 or "WY 1998") for Path 37/Row 39 were obtained from USGS. Cloud-free images were selected to achieve a temporal frequency of one image per month for the WY 1998 period.

Meteorological Data. Measurements of incoming solar radiation (R_s), relative humidity (RH), air temperature (T_a) and wind speed (WS) were available as hourly averages for the time of image acquisition. Daily (average for the image date), and period (average for the days represented by an individual image) measurements were

also available. Five stations falling within or on the edge of the study area were used during image processing. The stations selected were Salton Sea West (Station 127), Salton Sea East (Station 128), Calipatria/Mulberry (Station 41), Meloland (Station 87), and Seeley (Station 68). Weather data were quality checked according to the guidelines specified in Appendix-D of the ASCE Task Committee Report on the Standardized Reference Evapotranspiration Equation (Allen et al., 2005).

Landuse Data and Digital Elevation Model (DEM). A generalized landuse map from the National Land Cover Dataset (NLCD) for 1992 was obtained from USGS and used to estimate obstacle heights for different surfaces within the study area. The NLCD data has been developed at a 30 meter pixel resolution using a series of Landsat images along with aerial photographs and ground-surveys.

A DEM of 1 arc-second resolution (approximately 30 meter resolution) was obtained from USGS and was used in SEBAL to incorporate the effects of the slope, aspect and elevation into the energy balance.

District-wide Water Balance Estimate of ET

IID's physical and climatic situation results in a unique opportunity to measure inflows and outflows accurately and develop a water balance that closes on ET with high accuracy. IID is unique in that a water balance can be performed based on measured surface flows (Figure 1) that solves for ET of the command area with a high degree of confidence. This is due to the following factors:

1. Location in an extremely arid environment with little annual rainfall,
2. Accurately measured single source of all surface water used for irrigation in the command area,
3. Accurate measurement of all surface water flows out of the command area (about 35 locations) ,
4. Tile drains convey deep percolation from about 95 percent of the command area into surface drains that are tributary to the 35 outflows,
5. Deep percolation not captured by the tile drains, enters the groundwater and is discharged into surface drains,
6. Groundwater is saline and unusable for irrigation (no pumping), and
7. Subsurface natural flows across the area boundaries into and out of groundwater are negligible.

Input Data

A water balance summarizes all the flows entering and leaving a defined area, specified by a closed boundary, within a defined time period. Water balances can be performed at various scales and for various time periods and are defined by equation 2.

$$\sum \text{Inflows} - \sum \text{Outflows} = \Delta \text{Storage} \qquad [2]$$

The next sections describe the boundaries and the flow measurements

Boundaries. The study area chosen for comparison is defined by the water balance boundaries. With the exception of small areas on the east and west, this area

is bounded by the All American Canal (AAC) on the south, the Westside Main Canal (WMC) on the west, the Salton Sea on the north and the East highline Canal on the east (Figure 1). These boundaries can be considered vertical planes and all subsurface and surface flows crossing the planes are considered in the water balance. ET flux and precipitation cross a horizontal plane imagined just above the crops within the vertical planes.

Figure 1. IID Water Balance Boundaries and Boundary Flow Measurements.

Inflows and Outflows. The inflows shown in Figure 2 include the AAC, Alamo and New Rivers from Mexico, rainfall, Mesa storm flows and subsurface inflows. The outflows going to the Salton Sea include the New and Alamo Rivers, drain flows to the Salton Sea (termed Direct to Sea flows) and subsurface outflow. Flows from the AAC and Direct to Sea measurement locations are transmitted to a central location at 15-minute intervals. The 15-minute data is loaded into a large database

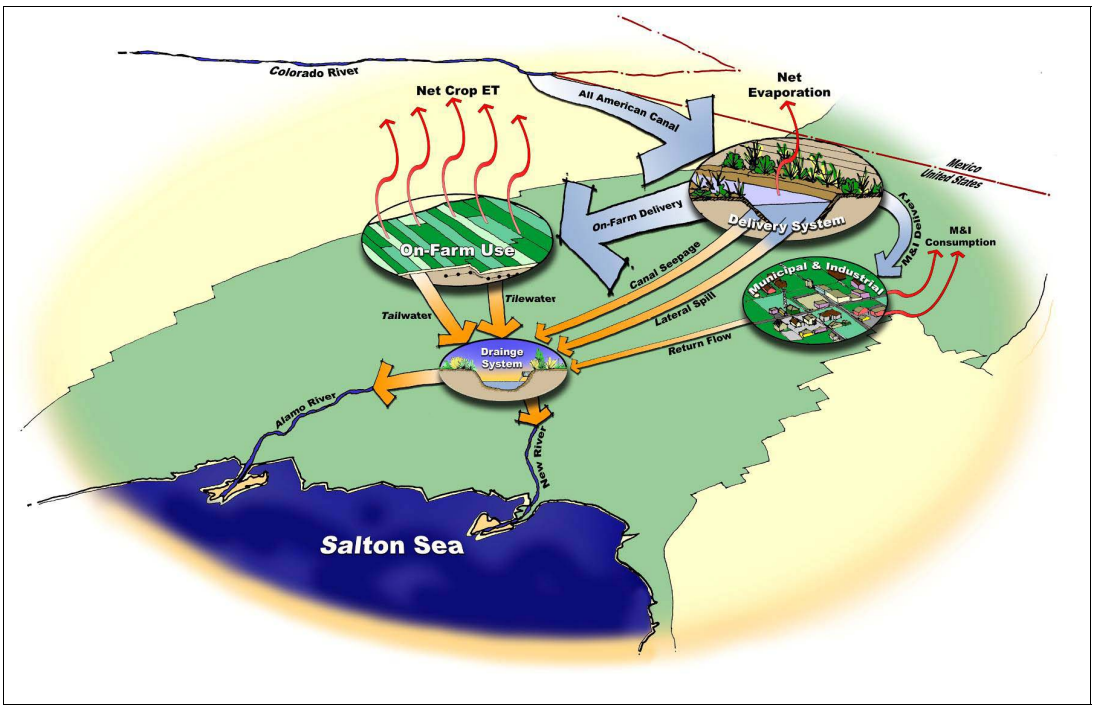

Figure 2. IID Water Balance Components and Flow Paths.

called the IID Water Information System (IID-WIS). In the WIS, the flow data is reviewed on daily, monthly and annual intervals. The 15-minute flows are summarized and reported as daily values. The New and Alamo River inflow and outflow measurements are conducted by the United States Geological Survey (USGS). Daily values from the USGS were used in this study. Rainfall is estimated based on the rainfall measured at three CIMIS stations (Calipatria/Mulberry, Meloland, and Seeley) within the water balance boundaries. Mesa storm inflows are estimated based on rainfall measurements. Small subsurface inflows and outflows estimated by groundwater studies are also included in the water balance.

Water Balance

A water balance was performed to determine total consumptive use (ET_a) within IID. The change in storage component of the water balance was limited to 50% of the available water content of the soils within the study area and estimated as a function of the monthly measured drain outflows relative to farm water deliveries. Given the factors listed above and the measurement accuracy of the surface inflows and outflows, the 95 percent confidence interval on ET_a, as the water balance closure term, was estimated to be 4.4 percent following the methodology of Clemmens and Burt (1997).

Crop Coefficient Estimate of ET

Potential crop evapotranspiration (ET_p) represents the total ET of a crop expected to occur under non-stressed growing conditions. Potential ET was estimated for each field-season by using the standardized dual crop coefficient approach described in FAO56 with planting and harvest dates recorded by IID. Total potential ET was

disaggregated into ET derived from precipitation and from applied irrigation water using a daily root zone water balance model (Allen et al, 2005a).

Input Data

Meteorological Data. The model uses daily weather data (relative humidity, wind speed, reference ET (ET_o), and precipitation) and crop and soil information for each identified field-crop season. Weather data parameters are calculated as a weighted average of quality controlled values from the Calipatria/Mulberry, Meloland, and Seeley CIMIS stations based on the area represented by each station determined using Thiessen polygons.

Crop Planting and Harvest Dates and Areas. IID zanjeros (ditch tenders) deliver water to growers and also record the crop plant and harvest dates and irrigated areas. This data is entered into IID's water order entry database and transferred to the IID-WIS.

Crop Coefficients. The crop coefficients used in the computations were based on FAO 56 and University of California Extension Leaflets 21427 and 21428 (Snyder et al., 1989a, 1989b). These crop coefficients were adjusted for local weather conditions using the FAO 56 recommended adjustment for extreme wind and humidity values.

Crop Water Use Computations

Effective (net) precipitation was estimated using a daily root zone water balance model developed in QuickBasic. Specified field-crop seasons were parameterized based on crop type, planting date, harvest date, and soil type (light or heavy).

The daily root zone water balance model was used to simulate the timing of irrigation applications, with irrigation triggered once the soil moisture depletion reached a crop and soil specific management allowed depletion. The model computes total potential ET (from both applied water and precipitation) by applying the standard dual crop coefficient approach described in FAO 56 (Allen, 1998). Daily values of reference evapotranspiration (ET_o) and precipitation were inputs to the root zone water balance.

The planting time period for many crops can span months due to the mild winters. For example, wheat can be planted anytime between October and January with a few plantings in February. To capture the variability in seasonal ET resulting from highly variable planting dates and resulting season length, root zone model runs were made for unique field-crop season plant and harvest date combinations.

ET ESTIMATION RESULTS

Remotely Sensed Surface Energy Balance Estimate of ET with SEBAL

The ET within the study area was estimated to be 2.010 million acre-feet by the remote sensing approach using SEBAL. The variation of ET across the study area is shown in Figure 3. The average ET for cropped areas within the IID is shown in Figure 4. Peak water consumption for the irrigated areas occurs in June. The average monthly actual ET (ET_a) is always less than the CIMIS reference ET.

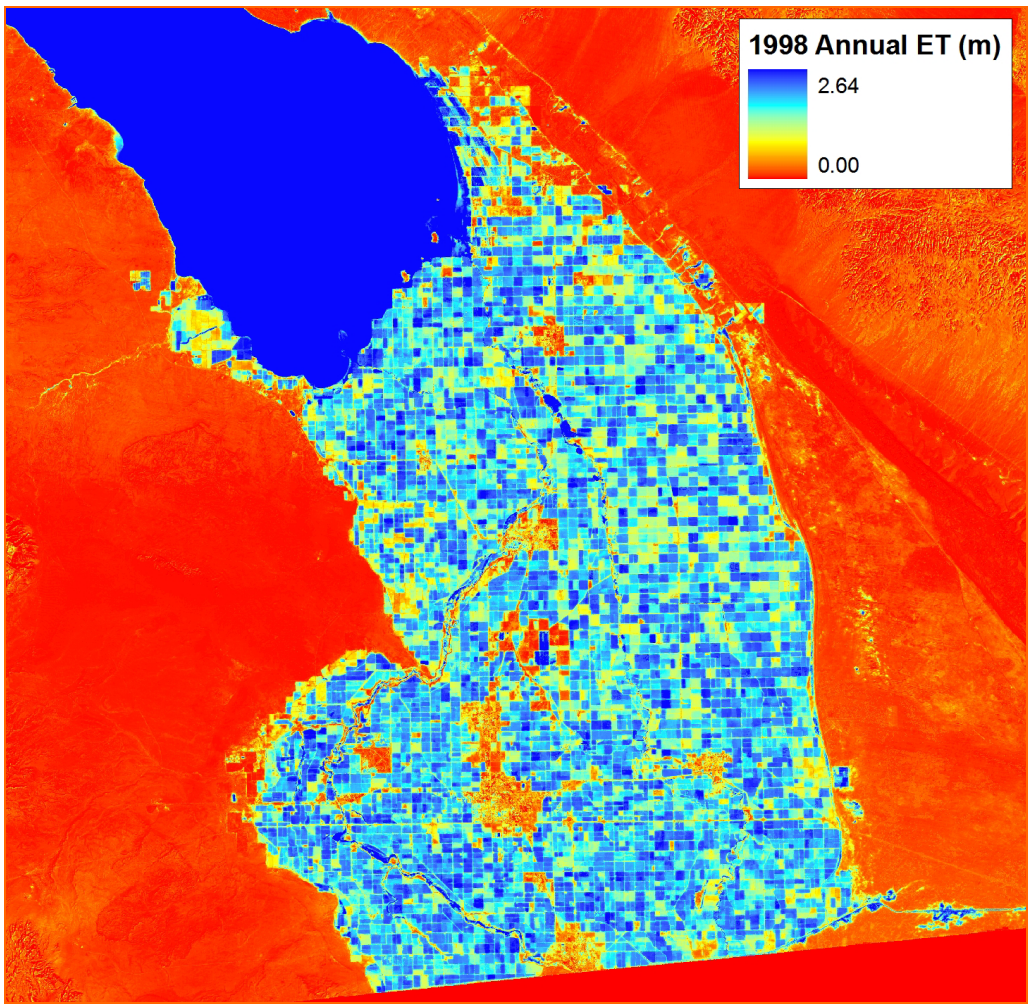

Figure 3. Water Year 1998 Seasonal ET_a Variation across IID Irrigated Area.

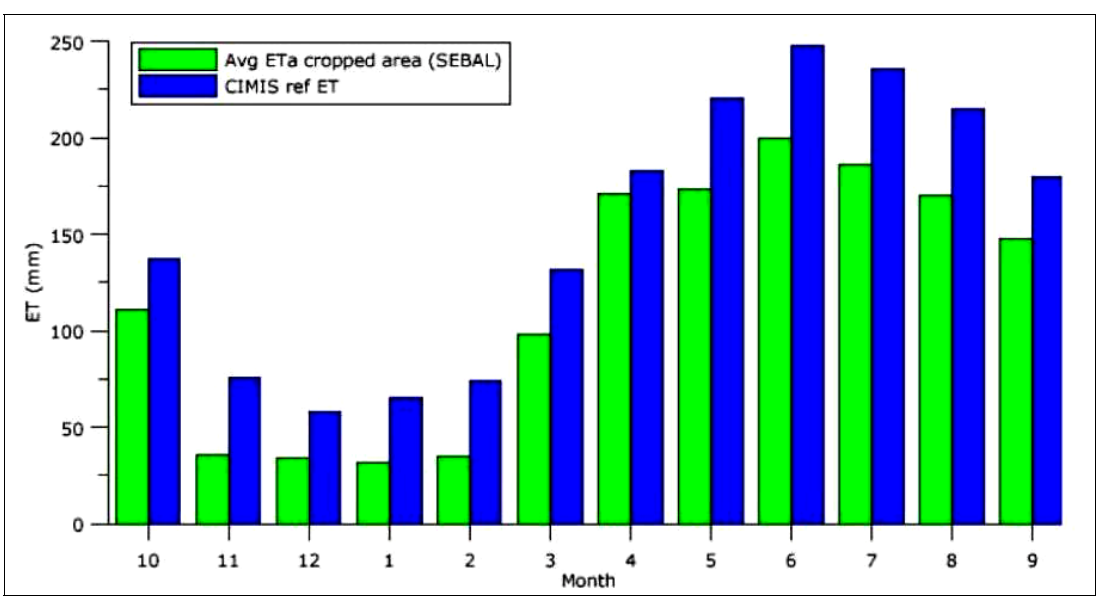

Figure 4. Average ET_a for Cropped Area in IID Compared with Average ET_o.

District-wide Water Balance Estimate of ET

The total inflow to the area from the AAC was 2.9197 million acre-feet. All the other inflows combined totaled 0.3116 million acre-feet. Outflows totaled 1.2327 million acre-feet, including a net depletion in soil water storage over the course of the year of 102 thousand acre-feet. The resulting estimate of ET within the study area is 1.9985 million acre-feet (Table 1).

The water balance quantifies all primary flow paths and associated water volumes within the study area. This improved understanding is important for water resources planning and management. However, the water balance itself provides no information on the variation of ET across the study area.

Table 1. Water Year 1998 IID Study Area Water Balance.

		Volume (1000 ac-ft)	
Location	**Data**	**1998**	**CI**
Total Inflows			
AAC Inflow at Mesa Lat. 5	Input	2,919.7	2.4%
Alamo River from Mexico	Input	1.5	2.0%
New River from Mexico	Input	181.0	2.0%
Total Rainfall	Calc.	103.2	22.4%
Mesa Storm Inflows	Calc.	5.9	100.0%
External Subsurface	Input	20.0	100.0%
Total Inflows	**Calc.**	**3,231.2**	**2.5%**
Total Outflows			
Alamo River to Salton Sea	Input	665.6	2.3%
New River to Salton Sea	Input	564.0	2.0%
Direct to Sea Drains	Input	104.1	20.0%
Subsurface to Sea	Input	1.0	100.0%
Change in Soil Storage	Input	-102.0	50.0%
Total Consumptive Use	Close	1,998.5	4.4%
Total Outflows	**Calc.**	**3,231.2**	**2.9%**

Crop Coefficient Estimate of ET

Computing ET for each field in the study area using a root zone water balance program with inputs of soil type, recorded plant and harvest dates, ET_o, rainfall, crop coefficients and related irrigation management parameters and summing the total across all fields resulted in a total ET of 2.280 million acre-feet. The climate in the study area allows for crops to be produced year-round and results in a wide range of possible plant and harvest dates for crops. For example, wheat can be planted any time from October through January and sometimes even in February and March. This results in a wide variation of seasonal ET totals for wheat as the later plantings extend into warmer weather before maturing (Figure 5).

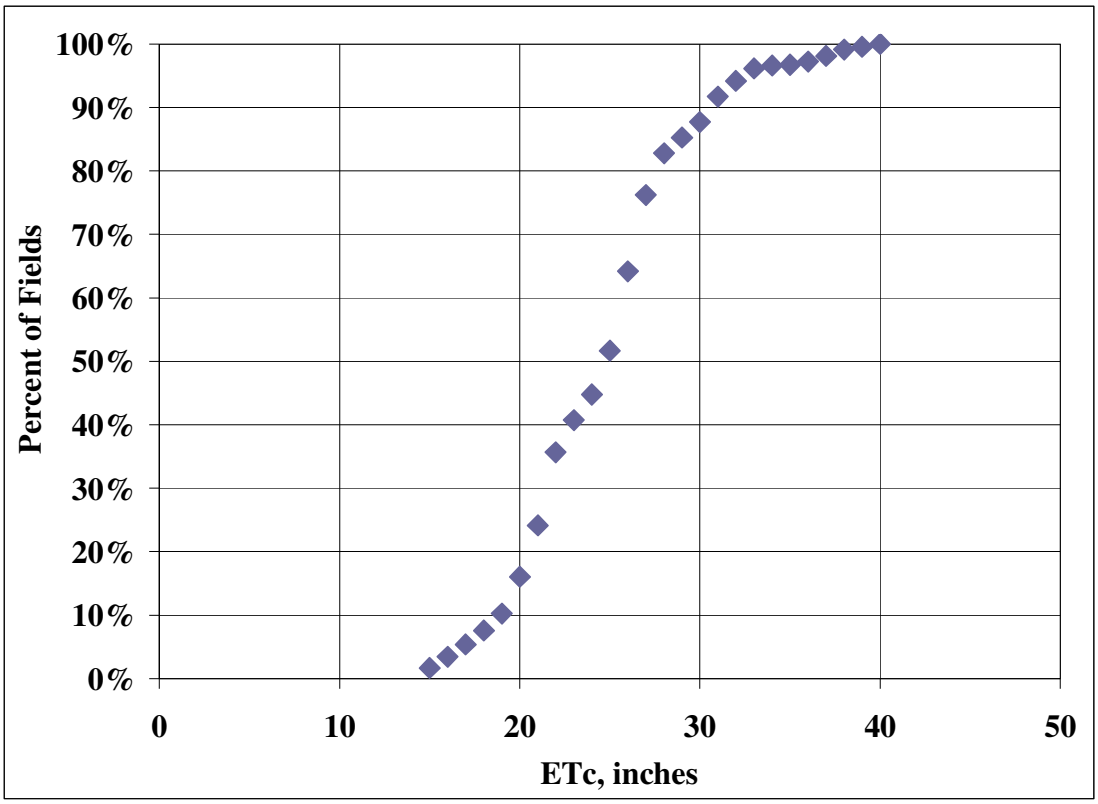

Figure 5. Cumulative Distribution of Wheat ET_c on Heavy Soil Using Reported Plant and Harvest Dates.

DISCUSSION

Annual ET in the study area was estimated using water balance closure, remote sensing energy balance and the FAO 56 crop coefficient approaches. Annual ET estimates varied from 1.999 million acre-feet to 2.280 million acre-feet for the water balance and FAO 56 crop coefficient approaches, respectively. The SEBAL remote sensing ET was very close to the water balance results at 2.010 million acre-feet. For this unique study area, the water balance estimate of ET was estimated to have a confidence interval of 4.4 percent based on the sum of variances method (Clemmens and Burt, 1997). The FAO 56 crop coefficient approach was expected to result in higher ET estimate than the other approaches due to unavoidable ET reducing heat and water stress experienced by crops during the extremely hot summers that is not accounted for in the crop coefficient approach. All estimates agreed within 15 percent (Table 2); however, the water balance and SEBAL approaches were within one percent of each other while the crop coefficient approach estimate was just over 14 percent greater than the water balance results.

Table 2. Comparison of the Three Approaches over the 1998 Water Year.

ET Estimation Approach	Water Year 1998 Total, kaf	Percent Difference (SEBAL-WB)/WB
Water Balance	1998.5	0.0%
SEBAL	2010.4	0.6%
Crop Coefficient	2280.2	14.1%

The monthly percent difference between the water balance and the SEBAL results varied from -2.7 percent to just over 30 percent in one month (Figure 6 and Table 3). Most of the difference is attributed to likely error in estimating the monthly change in soil water storage within the water balance computation. The annual estimate of change in soil water storage error is less error prone. Allen et al. (2005) discusses the month to month storage change and uncertainties in some detail.

The 30-m by 30-m pixel spatial resolution of the SEBAL results allow for a more complete understanding of ET among fields. Only a few alfalfa fields in the study area approach the potential ET computed by the FAO 56 crop coefficient procedures (Figure 7).

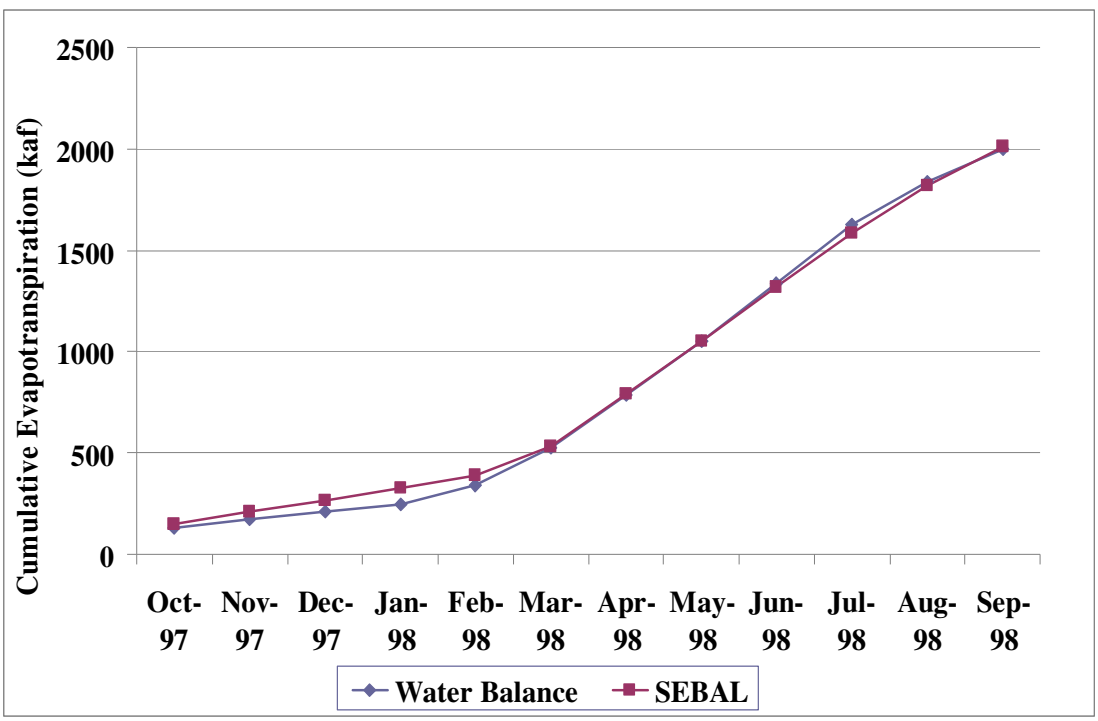

Figure 6. Cumulative ET from Water Balance and SEBAL Results.

Table 3. Comparison of Water Balance and SEBAL Cumulative Monthly Volumes.

Month	Cumulative, kaf		
	Water Balance	SEBAL	Percent Difference (SEBAL-WB)/WB
Oct-97	132.1	147.8	11.9%
Nov-97	173.0	208.6	20.6%
Dec-97	209.2	268.2	28.2%
Jan-98	249.5	326.1	30.7%
Feb-98	339.6	390.6	15.0%
Mar-98	525.8	531.7	1.1%
Apr-98	785.3	790.8	0.7%
May-98	1050.8	1049.4	-0.1%
Jun-98	1337.0	1316.2	-1.6%
Jul-98	1630.5	1585.7	-2.7%
Aug-98	1837.9	1820.9	-0.9%
Sep-98	1998.5	2010.4	0.6%

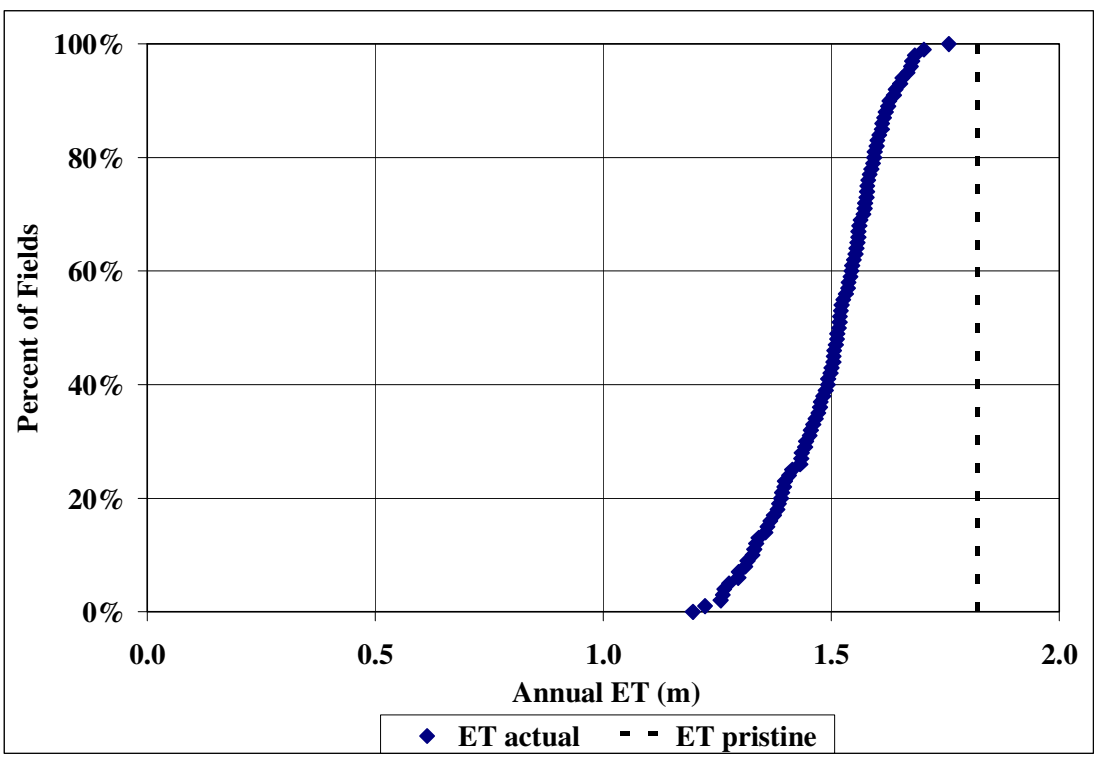

Figure 7. Cumulative Distribution of Water Year 1998 Field Scale ET for Flood Irrigated Alfalfa on Cracking Soils.

The SEBAL results allow for a more complete understanding of ET across time. Although a few fields exceed the monthly pristine ET in some months, the average monthly ET_a from the alfalfa fields in the study area is below the monthly pristine ET computed by the FAO 56 crop coefficient procedures (Figure 8). The low ET in the winter months is likely due to: 1) sheep grazing on some alfalfa fields lowers the averages and 2) 30-60 day periods in the winter when many alfalfa fields are not irrigated, remaining dormant for a couple months in the cooler part of the year.

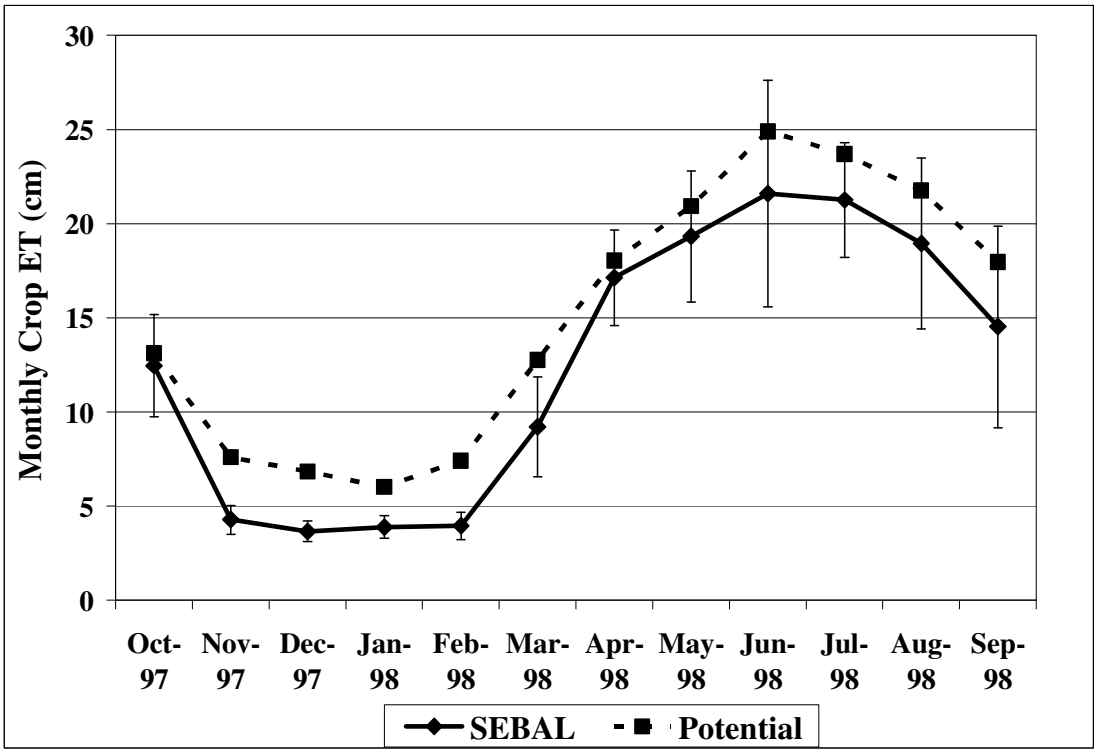

Figure 8. Comparison of Monthly Actual and Pristine ET for Flood Irrigated Alfalfa on Cracking Soils.

The SEBAL results allow for a more complete understanding of ET variation within fields. Six fields with boundaries superimposed on the July 98 SEBAL results are shown illustrating ET variability within fields (Figure 9). The largest field is ½ mile by ½ mile, 160 acres, 65 hectares, 720 pixels. Reduced ET often occurs uniformly and in concentrated areas. Fields with low uniformity may benefit from improved irrigation management to achieve ET (and yield) increases.

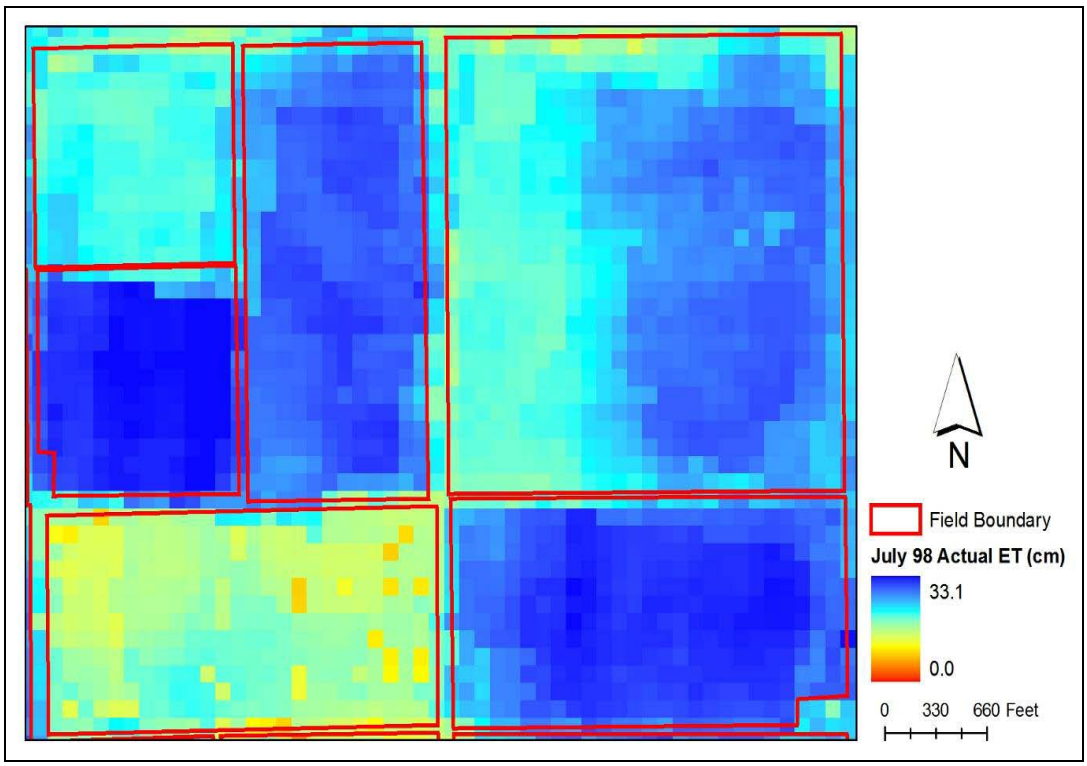

Figure 9. Example of ET Variation between Fields Identified through Remote Sensing.

CONCLUSIONS

Results of the district-wide water balance were compared to corresponding results from the remote sensing approach utilizing SEBAL for the 1998 water year (October 1997 to September 1998), resulting in a difference of less than one percent, providing a strong validation of SEBAL in arid, advective environments. The ET computed from the crop coefficient approach was 14 percent higher than the ET computed by the water balance approach.

The following additional conclusions are evident:

1. The 30-m by 30-m pixel spatial resolution of the remote sensing approach results allow for a more complete understanding of ET within and among fields.
2. The remote sensing approach results allow for a more complete understanding of ET across time.
3. Remote sensing of ET using thermal imagery plays an important role in the IID/SDCWA water transfer and, more broadly, water management in the West.
4. Remote sensing of ET provides opportunities for improved agricultural water management at field, farm, district, basin, state, and regional scales.

ABSTRACT

An accurate estimation of evapotranspiration (ET) is an integral part of the hydrological cycle and is increasingly important in local and regional water resource management in central and western United States. Traditionally, estimation of ET included substantial uncertainties, but with the advent of algorithms applied to high resolution (30 m) satellite imagery, ET estimates from bare soil and vegetation can be obtained with greater accuracy. The METRIC image processing model estimates net radiation, soil heat flux and sensible heat flux through a series of steps before estimating ET as the residual from the energy balance. This paper describes a comparison of the METRIC surface energy balance model outputs produced by two different research groups when using the same two 2007 Landsat 5 images as input. One of the research groups is based at the USDA Conservation and Production Research Laboratory in Bushland, Texas where the images and ground-based data were captured, and the other group is from the Kimberly Research Center, University of Idaho where METRIC was developed.

INTRODUCTION

Considerable uncertainty exists regarding the spatial and temporal variability and distribution of the consumptive water use (CWU), not only for agricultural crops but also for rangeland, riparian zones and other areas with natural vegetation. The variability is caused by local and regional differences in weather, precipitation distribution and quantity, soil, land form and land use, vegetation type, cultivar and cropping system, irrigation application method and land management. Normally the vast majority of CWU is made up by evapotranspiration, ET. A common method to

estimate actual ET (ET_a) from the ground and vegetation include multiplying weather-based reference evapotranspiration (ET_r) with a crop coefficient (K_c) (Allen et al., 1998; ASCE-EWRI, 2005). Allen et al. (2007b) estimated ET with this procedure and is relatively accurate with an error of up to ± 20 %. Errors may arise from actual vegetation and growing conditions deviating from the idealized K_c values or results from undocumented water shortage in the vegetation. In addition, it is difficult to predict the correct crop growth stages for a large population of crops and fields.

Application of remote sensing algorithms solving the energy balance using high resolution satellite imagery has proven useful for establishing estimates of ET_a and K_c for large populations of fields and water users (Bastiaanssen et al., 1998; Tasumi et al., 2005, Allen et al. 2007a). The METRIC model (Mapping Evapotranspiration at high Resolution with Internalized Calibration) is a satellite image processing model which estimates ET as the residual of the energy balance (Tasumi et al., 2005, Allen et al., 2007b), Eq. 1.

$$LE = R_n - G - H \qquad (1)$$

where LE is latent heat flux density, R_n is net radiation, G is soil heat flux density and H is sensible heat flux density. In METRIC, R_n is calculated by solving the radiation balance as described by Allen et al. (2007b). Soil heat flux is the rate of heat being conducted into the soil and vegetation, and is estimated based on R_n, surface temperature and the Normalized Difference Vegetation Index, NDVI.

METRIC utilizes the *CIMEC* (calibration using inverse modeling of extreme conditions) procedure (Bastiaanssen, 1995, Bastiaanssen et al., 1998) procedure to calibrate the dT function based on a regression relationship between the dT and radiometric surface temperature of two "anchor" pixels. The advantage of the SEBAL approach to developing a dT vs. T_S relationship by inverting the energy balance at the two calibration points is that many biases in energy balance components are factored out, including those in T_S itself. In addition, the use of a dT that 'floats' above the surface may eliminate some of the issues with single source models (Allen et al., 2007b). The anchor pixels ideally represent the conditions of an agricultural field with full and actively transpiring vegetation cover and a bare agricultural field with no vegetation cover. The anchor pixel representing full vegetation cover has the characteristics of green vegetation and its dT is low due to evaporative cooling. This condition is often referred to as the "cold" condition. The anchor pixel representing a bare field has the characteristics of bare soil and its dT is high due to radiometric heating of the surface and is generally referred to as the "hot" condition.

METRIC uses alfalfa based ET_r to establish the energy balance at the cold pixel, thus establishing a ground reference for the satellite image based ET_a estimate. ET_r is calculated outside of METRIC using hourly (or shorter) weather data from a weather station preferably located toward the center of the study area. The use of ET_r is generally effective in tying down the energy balance calibration, especially in arid

and semiarid climates having advection. The use of ET_r for calibration and extrapolation of ET to longer time periods makes the METRIC process congruent with traditional ET_r based estimation methods. One of the outputs from METRIC is a map of the ET from each pixel stated as a fraction of ET_r, ET_rF. The ET_rF is synonymous with the well known K_c (for an alfalfa reference basis). Daily ET_a maps are calculated by multiplying the instantaneous ET_rF calculated for each pixel with the 24-h summed ET_r. The resulting high resolution maps of ET cover regions typically up to 150 km in scale. When used properly, METRIC provides a rapid and cost effective method to determine ET for focused regions.

The METRIC model can be set up to be nearly fully automated, but does require rather essential input from the user to define and interpret e.g. vegetation roughness, land use, and anchor pixels, during image calibration, representing fields with dry soil surface and with a vegetated, fully transpiring surface. Additionally, some of the algorithms for atmospheric attenuation and emission of radiation can benefit from further testing to be used with confidence over vide range of climates.

There is therefore merit in doing an inter-comparison of the output from METRIC produced individually by two independent groups. This paper describes a comparison of the preliminary results of METRIC outputs produced by two different research groups when processing the same two Landsat 5 images from 2007. The images were processed without contact between the two groups. Subsequently, following this comparison, the two groups will continue the collaboration and conduct an additional processing run, integrating local knowledge and experience about e.g. cropping patterns and land management, and long-term experience in METRIC application. Additionally, images from other times during the growing season and other years will be processed for inter-comparison purposes.

METHODS

One Landsat 5 scene from 07/10-2007 from path 31 row 36 have been selected. The scenes cover the central portion of the Texas panhandle, but were not geometrically corrected. To avoid errors caused by geometric incongruencies within the Landsat images and for the purpose of the initial comparison of METRIC output four square fields at the USDA-ARS, Conservation and Production Research Laboratory in Bushland was selected for the comparisons. The relative location of the fields in the Landsat image is shown in Fig. 1. The fields are equipped with four high precision weighing lysimeters each located at the center of each field (Howell et al., 1995). Each lysimeter (3 m length × 3 m width × 2.4 m depth) is located in the middle of 4.7-ha fields and all four lysimeters are arranged in a block pattern. Dryland cropping systems are managed on two lysimeter fields in the west and irrigated cropping systems are managed on two lysimeter fields in the east with a 10-span lateral move sprinkler system. The location of the fields and the 2007 crop cover is shown in Fig. 2.

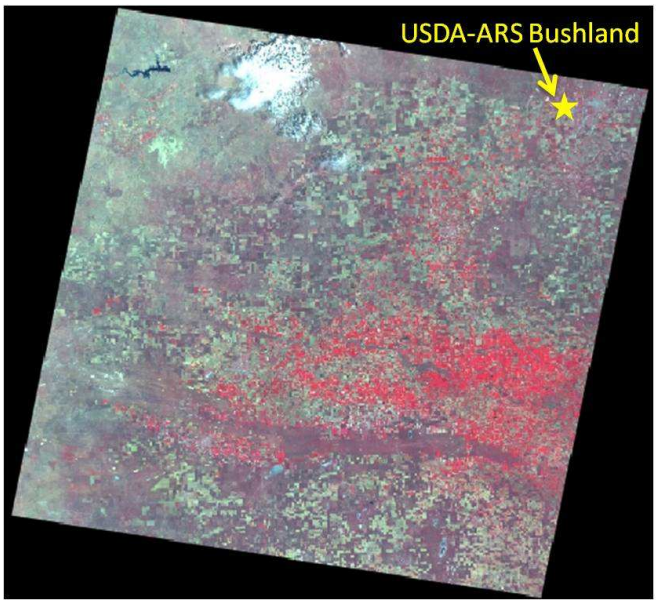

Figure 1. Location of the fields at USDA-ARS in Bushland used for the METRIC output comparison

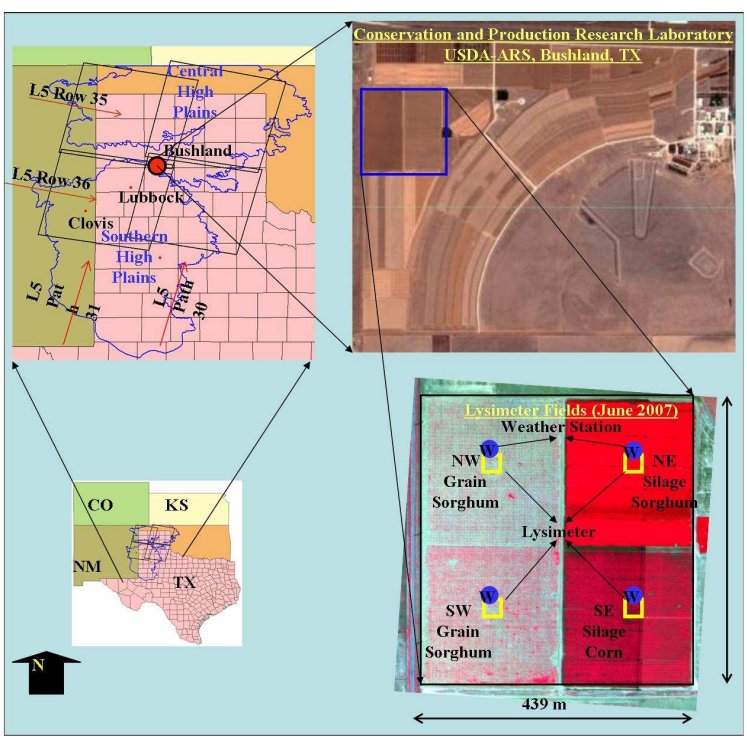

Figure 2. Location of the Bushland weighing lysimeters from. The geographic location of the SE lysimeter is shown in the lower right corner, 35° 11' 09.96'' N 102° 05' 43.35'' W.

The METRIC model was coded and processed using the ERDAS Imagine Spatial Modeler tool independently by each group. Reference ET was calculated using the RefET software (Allen, 2003) using meteorological data as input. Supporting input information, including a water balance to estimate residual evaporation from bare soil (for the hot pixel calibration) and the iterative numerical solution of the dT function equation based on the cold and hot anchor pixels, were carried out using a regular spreadsheet.

Weather data from the weather station located approximately one km from the fields were used during the processing. The station is part of the Texas High Plains Evapotranspiration network, operated by Texas A&M University. The quality of all meteorological data used in the METRIC processing were checked following the recommendations by Allen (1996), Allen et al. (1998) and ASCE-EWRI (2005). As ET_r was also used to establish a soil water balance several months before each image acquisition date, the integrity of the meteorological data for the entire year 2007 were evaluated. Hourly and daily values for solar radiation R_s were compared to computed clear sky solar radiation (R_{s0}). R_{so} was calculated based on atmospheric pressure, sun angle and precipitable water in the atmosphere. Generally a good agreement was found between observed R_s on days with clear sky conditions and the theoretical R_{s0} values, although the observed R_s values does run a few % higher than the R_{s0} curve during the winter period.

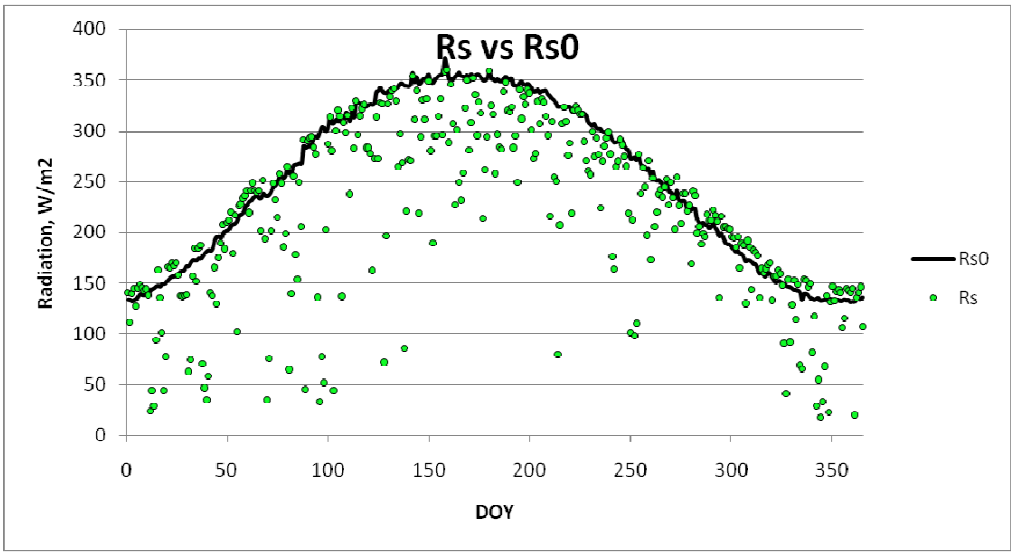

Figure 3. Daily solar radiation observed at the Bushland weather station versus theoretical clear sky solar radiation, R_{s0} during year 2007.

A range test was used to check daily minimum and maximum relative humidity. In addition, daily mean computed dewpoint temperature was compared against daily minimum air temperature following ASCE-EWRI (2005). The air temperature (T_a) was compared to nearby weather stations, and hourly T_a measurements were checked visually for sudden spikes and the expected diurnal

occurrence of minimum and maximum values. Wind speed was checked by calculating the gust factor (ASCE-EWRI, 2005) and comparing average daily wind speed to that of other nearby weather stations.

A daily water balance model based on Allen et al. (1998) was employed to estimate residual evaporation from the hot pixel (Fig. 4). The satellite overpass moment were obtained from the respective image header files and used to estimate the zenith angle of the sun and instantaneous values of wind speed at screen height and 200 m, air humidity and ET_r.

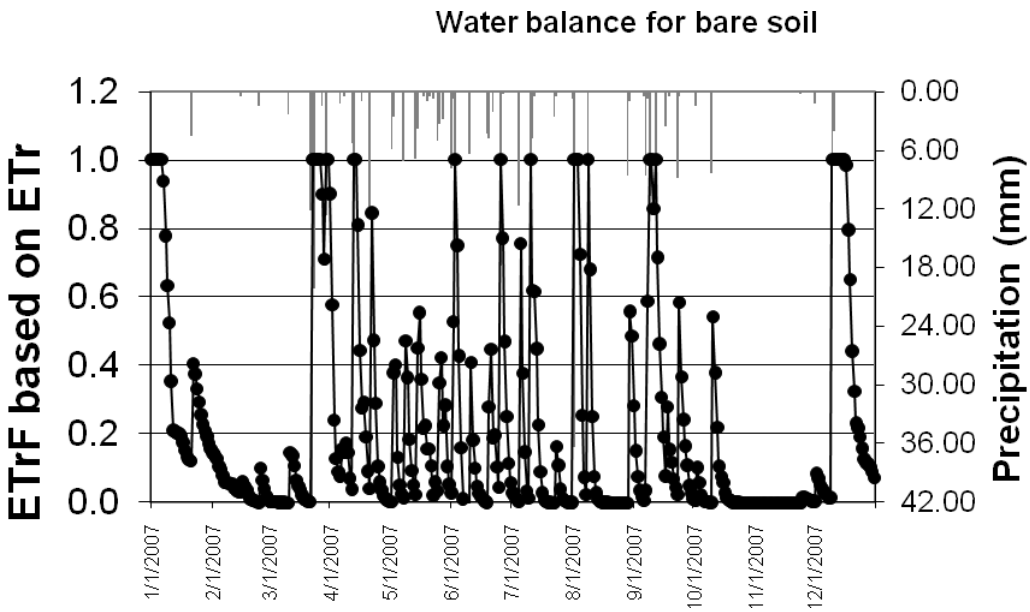

Figure 4. Soil water balance for bare soil calculated using meteorological data from Bushland, Texas 2007 and used to determine ET_rF for the hot pixel calibration.

PRELIMINARY RESULTS AND DISCUSSION

ET estimates from four 30-m pixels located towards the center of each of the four fields are sampled and averaged. Center pixels are generally selected to avoid sampling field edges where the vegetation cover is less due to e.g. traffic, insufficient irrigation and similar. The northwest and southwest fields were grown with grain sorghum under dryland conditions in 2007. Drought damaged the crop and by mid-summer the vegetation cover was relatively sparse. The northeast field was grown with a silage sorghum crop under irrigated conditions, while the southeast field had an irrigated silage corn crop. The crop pattern and the associated ET_rF values are recognized in Fig. 5. The crosshair is at the same geographic location at the four corners of the fields. The ET rates are highest for the corn being at full cover and under relatively good water supply.

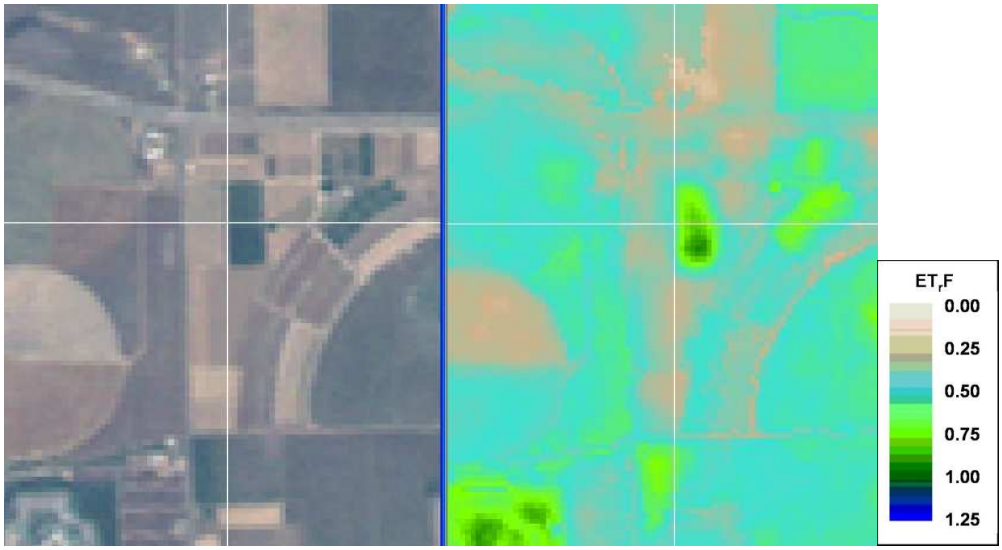

Figure 5. Satellite image in true color (left) and the corresponding resulting ET_rF map on July 10 2007, for the ARS station in Bushland, Tx. The crosshair is at the same geographic location.

A comparison of the instantaneous ET as measured by each of the four lysimeters and as predicted by each of the two research groups producing the estimates using METRIC is shown in Figure 6. The deviation in net radiation estimated by METRIC, Figure 7, is probably caused by differences in the estimation of atmospheric transmissivity and or emissivity of the surface or the atmosphere. For the field grown with silage corn the estimates of ET are close between the lysimeters, while more deviation is found for the two dryland fields. A thin layer of wilted plant material on the soil surface or the presence of senescenced standing crops may cause the differences between the lysimeter and the METRIC estimates. This may increase the "skin" temperature "seen" by the satellite causing H to be overestimated in METRIC and subsequently underestimate ET. A likely cause of the deviation between the estimates of ET between the two groups A and B is that the "hot" pixel selected by one (or both) of the groups does not entirely represent the conditions of a bare, dry field. This causes a deviation in the estimation of H, figure 8, possibly leading to an underestimation of H.

The scale of the fields used for the comparisons between the output produced by the two research groups adds additional uncertainty for the final result. Since each field has a side length of approximately 225 m there will likely only exist one thermal pixel (120 m) within each field. Since the thermal band has been resampled to 30 m resolution using cubic convolution (CC) resampling it is not possible to locate the original thermal pixel. There is therefore a risk that among the four pixels sampled for ET averaging one or more will be from a 120m thermal pixel that is not contained entirely within the field, or is located towards the edge of the field. Such thermal pixels may not be representative for a larger field, and may draw the ET estimates down. Additionally, meteorological sensors mounted on a bench are located near the

lysimeters, which may impact the amount of radiation reflected and emitted from that location.

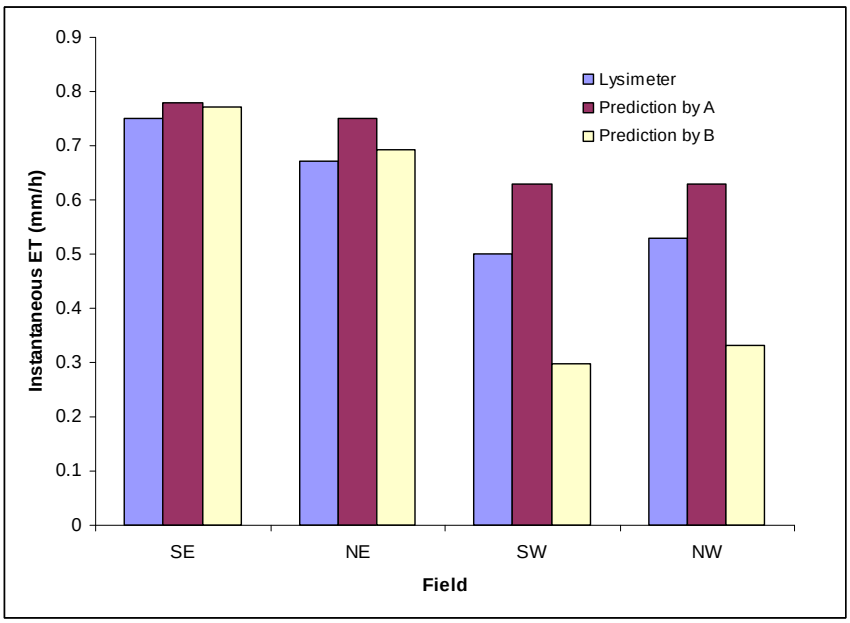

Figure 6. Comparison of instantaneous evapotranspiration (mm/hr) as measured by the four lysimers, and as predicted by user group A and user group B using METRIC.

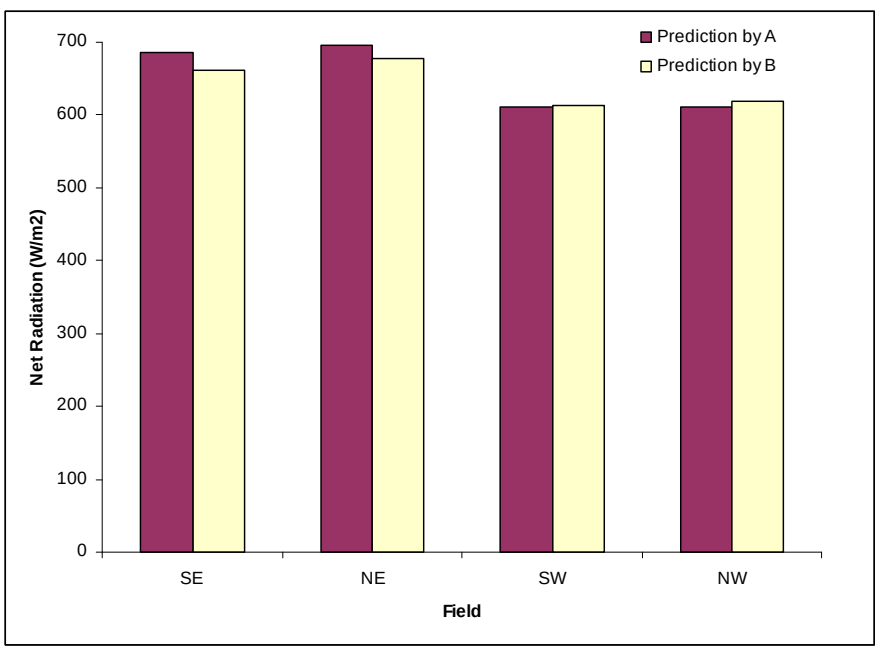

Figure 7. Comparison of net radiation as predicted by user group A and B using METRIC.

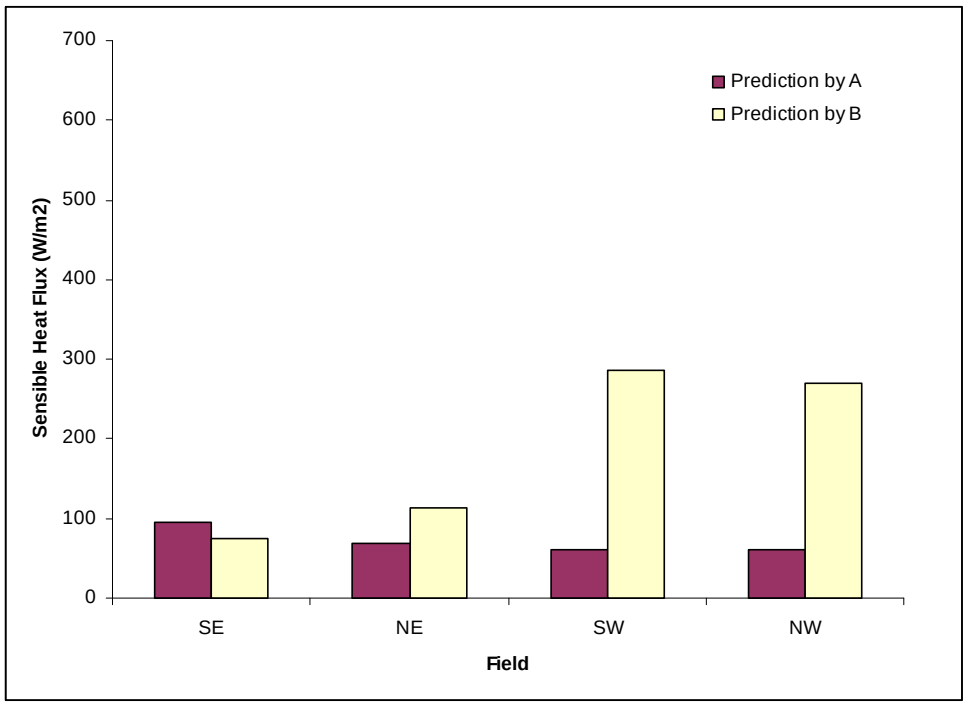

Figure 8. Comparison of sensible heat flux as predicted by user group A and B using METRIC.

Further investigation and comparisons, and through conducting an additional processing run the deviations should be minimized. The results obtained this far underlines the importance of the user being trained in the use of METRIC and having experience with running the model, including selection of hot and cold anchor pixels in order to obtain good and consistent results.

Measuring Soil Moisture in a Heterogeneous Field

Chadi Sayde[1], John Selker[1], and Marshall English[1]

[1]Department of Biological and Ecological Engineering, Oregon State University, 116 Gilmore hall,

Corvallis, OR 97331; PH (541) 737-2041; email: saydec@onid.orst.edu

ABSTRACT

Effective irrigation management commonly relies upon soil moisture measurements to ascertain crop water availability in field soils. But all such measurements are intrinsically uncertain, and even when individual soil moisture measurements are relatively accurate, estimates of crop water availability derived from those measurements may be quite uncertain due to the field scale variability of soil parameters and uneven distribution of applied water.

Replication of soil moisture measurements can reduce that uncertainty. Commonly, measurements at two or more sites in a field are averaged to reduce the variance of the estimate. Alternatively, multiple replications can be used to quantify the uncertainty of any single measurement. That quantitative uncertainty can then be used in a Bayesian decision model that combines soil moisture measurements with model estimates of cumulative ET. The result is an improved estimate of soil moisture.

Either approach depends upon replication of soil moisture measurements. But current measurement technology is such that the most accurate methods are expensive while the more affordable methods are relatively inaccurate and therefore require more replications. Either way replication is expensive.

This paper explores the theoretical basis, preliminary experimental results and potential benefits of using fiber optic technology for distributed measurement of field soil moisture. This technology determines soil moisture content by measurement of soil thermal response to a heat pulse. With a resolution of 1 m along a fiber optic cable this technique is capable of literally hundreds of measurements along a single cable installed at a specific depth. The technology is still under development at the time of this writing, but the indications are that it can quantify soil water variability with relatively high accuracy at moderate cost.

INTRODUCTION

Uncertainty in soil moisture measurements. The fundamental objective of scientific irrigation scheduling is accurate tracking of crop-available water in the soil. A variety of techniques are employed to measure soil water content, which is then used to calculate the amount of available water remaining in the root zone. But measurements of soil water content are inherently uncertain, and because crop water availability is defined in terms of the remaining 'available capacity' in the root zone the uncertainty of measured soil moisture is compounded by the natural variability of soil water holding characteristics and inexact knowledge of crop root zones and water uptake patterns.

The net effect is that estimates of field-wide crop water availability derived from soil moisture measurements are quite uncertain. Some degree of uncertainty is intrinsic to the measurement technique used. Additional uncertainty derives from soil heterogeneity and uneven distribution of applied water.

This paper is primarily concerned with the uncertainty of soil moisture measurements, and in particular, the uncertainty that derives from spatially variable factors illustrated in the following two Figures. Figure 1 shows a soil survey image of a 125 acre circle encompassing two different soil types. Using the indicated soil depths and holding capacities of these two soils, and assuming that local variations of both parameters have a standard deviation of 10%, a statistical simulation of total holding capacities generated the result indicated in the histogram. Figure 2 is a compelling indication of field scale variability that might be encountered under ordinary conditions.

Figure 3 illustrates small scale variations in the amount of irrigation water stored in a soil profile. The observed variability (from Scotter and Clothier, 1986) indicates the disposition of applied water to a depth of 60 cm over a 3.6 m span of a field following irrigations at two different application rates.

These figures confirm what most field managers have observed; that a point measurement of soil water content will often not be representative of average conditions, nor will it provide any information about the variability of soil water content. Additionally, the uncertainty of computed values of crop available water will be compounded by wide variations in total holding capacities.

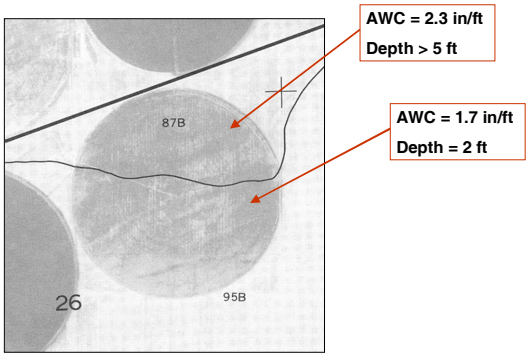

Figure 1: Field Scale Variations in total holding capacity

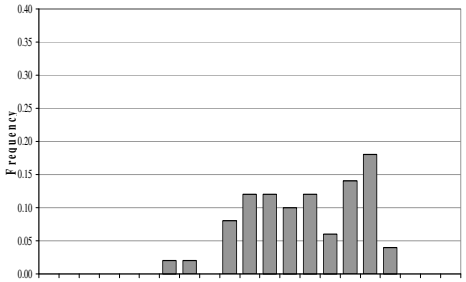

Figure 2: Variability of total available capacity

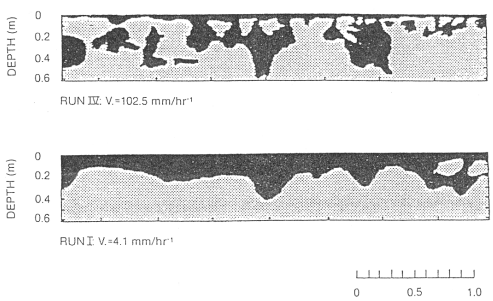

Figure 3: Local redistribution of applied water

Dealing with uncertainty. When water supplies are not limited the problem of measurement uncertainty is often circumvented by maintaining soil moisture at higher than critical levels, relying on point measurements of soil moisture to decide when to irrigate, and maintaining some soil water in reserve as a hedge against uncertainty. But with the accelerating competition for water and resulting increases in opportunity costs of water the practice of holding soil moisture in reserve will become progressively more expensive. That implies a need for more accurate ways of estimating crop water availability in heterogeneous fields.

More accurate determinations can be derived by replication, i.e. by taking measurements at several points in the field. The common assumption is that the variance of measured depletion is reduced inversely with the square of the number of

replicated measurements. However the validity of this assumption is limited by two factors:

- Individual measurements are not always statistically independent. Different soil types encompassed within a single field imply patterned variations in water holding characteristics (Figures 1 and 2).
- Non-uniform applications of irrigation water, compounded by redistribution of surface runoff and preferential subsurface flows may result in systematic variations in soil water distributions (Figure 3). Consequently, soil moisture measurements taken within definable sub-sectors of a field may be highly correlated.
- Uncertainties of crop root zone and uptake patterns are not reduced by replication of soil moisture measurements. The uncertainty of available capacity remains a confounding factor.

A proposed alternative approach to reduce the uncertainty of estimated crop available water would utilize a Bayesian decision model to integrate information embodied in estimates of ET with the information derived from soil moisture measurements (Sayde et al., 2008). Bringing additional information provided by another independent estimator (cumulative ET) into the analysis can reduce the overall uncertainty. The result is a maximum likelihood estimator of cumulative depletion. (The ET model may also compensate to some extent for the uncertainty of available capacity by indicating whether measured depletion is consistent with the assumed available capacity.) However, this Bayesian approach requires that the uncertainties of estimated ET and measured soil moisture must be quantified.

AN ALTERNATIVE APPROACH TO MEASURING SOIL MOISTURE

This paper presents an alternative soil moisture sampling technique that utilizes fiber optic cable and Distributed Temperature Sensing (DTS) technology to monitor soil response to a heat pulse. Though the method is still under development the indications are that this technology may offer two important advantages. One is that the marginal costs of replicated samples should be low. Because soil water content can be sampled at 1.0 meter increments along the length of cable, the number of sample sites increases as the length of cable is increased. Additionally the method can be automated and the results obtained by telemetry without routine human intervention.

Another important advantage is that soil water content can be sampled frequently. That makes it possible to observe peak water content (an indicator of available capacity), and to derive additional information about soil water dynamics by sampling the rates of change of soil moisture over relatively short intervals of time.

Distributed Temperature Sensing (DTS). DTS technology allows the measurement of temperature along a fiber optic cable with a spatial resolution < 1m. The principle behind temperature measurement along a fiber optic cable is based on the thermal sensitivity properties of the cable (Perzlmaier et al., 2006). Parts of a laser pulse injected into the fiber optic cable are reflected back at original energy, or absorbed and re-emitted at longer or shorter wave-length than the injected light. The reflection with a longer wavelength, called Stokes backscatter, is almost completely independent of temperature, while the reflection with a shorter wavelength, called anti-Stokes backscatter, is strongly dependent on the temperature at the point where it was reflected (Selker et al, 2006). By measuring the time of arrival of reflected light, the position along the cable from which the light was reflected can be obtained. Through calibration using sections of cable at known temperatures, temperature can be inferred by frequency analysis From the Stokes/Anti-Stokes ratio everywhere along the cable.

For a given DTS instrument and fiber optic sensing cable, the precision of a single temperature reading depends on two factors: 1) injection/reading cycle duration, and 2) distance from the light source.

In a longer cycle duration a higher number of light pulses are used to derive temperature, thus improving the temperature reading precision but only at the expense of high frequency readings rate.

The injected and reflected lights lose strength with distance, thus the signal-to-noise ratio decreases with distance from the light source.

The ability of fiber optic distributed temperature sensing (DTS) to measure temperature at high temporal frequency each meter along fiber optic cables several kilometers in length has opened many important opportunities in environmental monitoring. Selker et al. (2006) and Tyler et al. (2008) presented the basic methodology, and demonstrated its utility in a wide range of hydrologic applications.

DTS for soil moisture monitoring. Thermal properties of soils are a function of soil moisture content. Thus soil moisture content can be inferred by analysis of thermal responses of specific soils to a heat pulse. Available DTS technology can be used to monitor thermal responses of soil to a heat pulse, along a fiber optic cable with spatial resolution < 1 m. Many available fiber optic cables are composed of one or more optical fibers enclosed in stainless-steel tube and wrapped by stainless steel or other metallic wires. The metallic component of the fiber optic cable can be used as an electric resistance heater to inject heat into the surrounding soil, while the optical fiber is used as a thermal sensor to monitor temperature changes. This method, called the Actively Heated Fiber Optic (AHFO) method has been successfully used for subsurface water movement monitoring (e.g., Perzlmaier et al., 2004; Aufleger et al., 2005; and Perzlmaier et al., 2006). The application of AHFO method to determination of water content was reported to be only adequate to distinguish between dry, wet and saturated soil (Perzlmaier et al., 2006), but inadequate to

distinguish between small changes in volumetric soil moisture content above 6 % (Weiss, 2003). This is mainly due to the fact that the method of heat pulse analysis used in both articles is based on deriving the thermal conductivity (λ) of a soil from its thermal response to the slope and intercept of a line fit to the heat pulse signal with a log transformed time scale, then relating the obtained value of λ to soil moisture content by a data calibration equation. In fact, this method of heat pulses interpretation requires high frequency temperature readings, high signal-to-noise ratio, high energy input to accurately determine soil moisture content, mainly at high soil water content status. These requirements are not satisfied with the temperature and temporal resolutions provided by current DTS technology. Weiss (2003) concluded that only with dramatic improvement of the signal-to-noise ratio could the thermal conductivity be determined by a DTS heat pulse method with sufficient accuracy to quantify water content above 6%. In this context, a new method of data analysis that is suited to the nature of DTS readings is needed to allow better estimation of soil moisture content.

The Thermal Integral method. A new method of analyzing soil thermal responses to heat pulse is being developed at Oregon State University. Details and experimental results of this method can be found in Sayde et al. (2009). In summary, the thermal response of a soil to a heat pulse is quantified in the form of cumulative temperature increase over a certain period of time:

$$T_{cum} = \int_0^{t_0} \Delta T \, dt$$

Where T_{cum} is the integral of temperature increase over time [°C] as measured at the fiber optic cable, t_0 is the total time of integration, ΔT is the DTS reported temperature change from the pre-pulse temperature [°C].

Sayde et al. (2009) showed that T_{cum} monotonically decreases with water content. In fact, higher heat capacity and higher thermal conductivity, both monotonically increase with water content (θ), increase the rate at which heat is conducted away from the probe and reduce the integral (Figure 4).

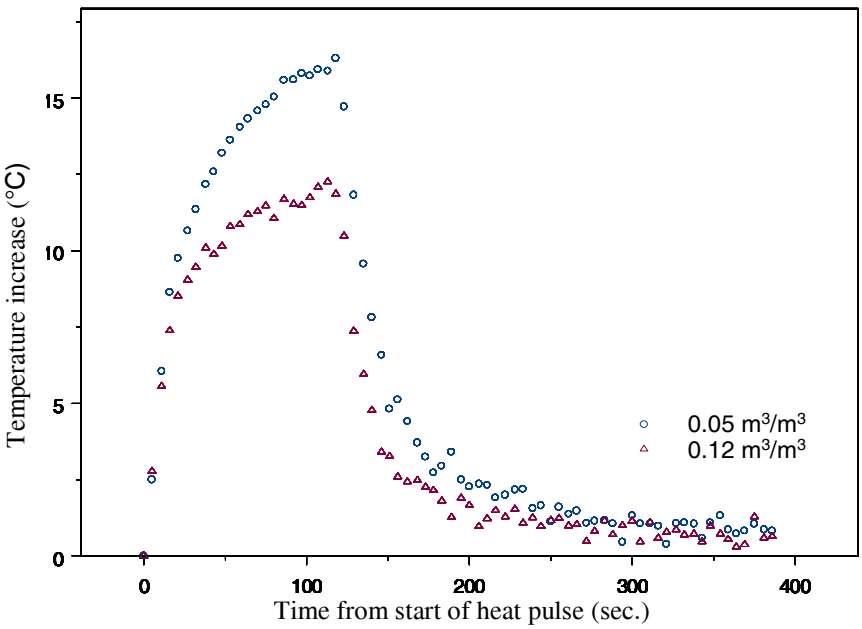

Figure 4: Thermal response of soil at two locations with different moisture content to a heat pulse of "2minutes - 20 W/m". $T_{cum,}$ The integral of temperature increase over the 2 minutes heating duration, was 1562°C and 1250°C for soil moisture contents of 0.05 m^3/m^3 and 0.12 m^3/m^3 respectively.

The use of the thermal integral method for interpretation of the AHFO heat pulses data has been tested under laboratory conditions where a 30 m section of a fiber optic cable was installed in a sand filled column, and several combinations of heat pulse durations and intensities were tested for the sand column under wide range of soil moisture content.

Sayde et al. (2009) demonstrated that for a 2 minute heat pulse at 20 W/m, the thermal integral method was able to distinguish water contents with coefficient of variation of 0.08 across volumetric water contents ranging from 4-41%. The highest error (0.033 m3/m3) is observed at saturation (θ = 0.41 m3/m3). This error can be further reduced by averaging several heat pulses results, or by increasing the heat pulse duration and integration time.

Another advantage of the integral method is that it requires much lower energy input and heating time than the methods described in Perzlmaier et al. (2006) and Weiss (2003), reducing the risk of water displacement from around the heated fiber optic cable and allowing more frequent heat pulses to be conducted. In fact, repeated measurements of soil moisture content under laboratory conditions have not shown any signs of water displacement.

Field application. A field trial of the technique was conducted in an agricultural field located near Hermiston, eastern Oregon. Three fiber optic cables, each of 250 m length, were installed at three different depths (30 cm, 60 cm, and 90 cm) to monitor spatial variability of soil moisture depletion.

A 45° angle, 2.54 cm thick plow designed specifically for this purpose was used to install the 3 fiber optic cables simultaneously at their respective depths with a minimum of soil disturbance (Figure 5). Soil moisture was monitored by the AHFO method with a rate of 1 heat pulse/hr. At this writing the data from this experiment are still under analysis.

(a) (b)

Figure 5. (a) 45-degree "lift-plow" showing cable insertion tubes, (b) in operation.

Challenges and concerns. In decreasing order of significance, the main concerns that can lead to substantial errors when applying the actively heated fiber optic method are: 1) the contact between soil and probe, 2) water displacement due to over-heating of the soil surrounding the cable, 3) spatial variability of soils properties, and 4) temperature dependence of soil thermal properties.

The biggest challenge during field installation is to minimize soil disturbance around the cable, and insure a good contact between the cable and the surrounding soil. A poor contact between the fiber optic cable and the surrounding soil at a particular point, caused by installation or by shrinking–swelling mechanics observed for some particular soils, will increase the thermal resistivity and reduces the thermal conductivity causing erroneous lower soil moisture estimation at this particular point. If those perturbation points are assumed to be randomly distributed along the fiber optic cable, a larger spatial scale for DTS measurement can be used to improve the accuracy of soil moisture estimation.

A large local temperature increase may cause water to evaporate and diffuse from a high temperature area toward a lower temperature area. Farouki (1986) showed that this moisture movement is a function of the interaction between the thermal gradient and the time of existence of this gradient. Therefore, it is crucial to reduce both the

magnitude and duration of the heat pulse.

Like any other heat pulse method, concerns regarding the accuracy of such methods remain related to soil bulk density (Tarara and Ham, 1997), soil mineralogy (Bristow, 1998) and total porosity (Ochsner et al., 2001). In fact, soil thermal properties are dependent on the volumetric fractions of solid, water, and air. (Ochsner et al., 2001). Those fractions vary greatly in space and time, and may substantially affect the thermal responses of soil along the fiber optic cable.

Heat pulse methods were found to be sensitive to ambient temperature due to the changes in the density and specific heat of water and specific heat of soil with respect to temperature (Olmanson et al., 2006). Diurnal cycling of soil thermal properties and moisture content is reported by Heitman et al. (2003), while Bristow et al. (2004) indicated that different initial temperature conditions, ranging from 24.20 °C to 38.53 °C, had negligible effect on measured thermal conductivity using a single probe heat pulse method.

CONCLUSION

The key findings of this work is that AHFO technique has a great potential to monitor soil moisture at temporal resolution under one hour, and spatial resolution of 1 m along cables exceeding several km in extent. Heat pulse method using coaxial heating and DTS sensing, when the results are interpreted using the Thermal Integral method, is feasible for determination of water content of soils across a much broader range of moisture contents than previously thought.

Such measurements are essential to quantify uncertainty and monitor spatial variability of soil water dynamics across m to km scales.

Many questions should be subject to further research efforts, mainly regarding the radius of influence of such measurements, optimal heating strategies, and errors that can be induced by soil disturbance during installation or by spatial variability of soil parameters.

ABSTRACT

Soil heat flux plays an important role in land surface energy dynamics by constraining the amount of available energy for partitioning between latent heat flux and sensible heat flux. Thus accurate quantification of the soil heat flux is of key importance in energy balance studies. In this study, the performances of four different methods have been evaluated for the soil heat flux estimation in maize and soybean fields under irrigated and dryland conditions. Statistical analysis of the model performance has shown a wide variation in the ability of these models from site to site and from year to year. The RMSE for irrigated maize ranged from 15.16 W m^{-2} to 81.25 W m^{-2}, whereas the range for dryland maize was 14.99 W m^{-2} to 55.81 W m^{-2}. The RMSE between predicted and measured soil heat flux for irrigated soybean was between 19.36 W m^{-2} and 50.83 W m^{-2}. Relatively a narrow range (18.45-35.24 W m^{-2}) of RMSE was found for dryland soybean. In view of wide range of RMSE and negative model efficiency, it is recommended that the local calibration of the model should be carried out for remote estimation of soil heat flux.

Keywords: *Soil heat flux; Energy balance; Net radiation; NDVI; Nebraska*

INTRODUCTION

Soil heat flux (G) is a significant component of the daytime surface energy balance in many ecosystems. It can become a significant component in relatively sparse vegetation (Kustas et al., 2000) and predominant during night time (Murray and Verhoef, 2007a). In forest ecosystem, G usually accounts for 5% of net radiation ($R_{n)}$ (Beringer et al., 2005; Chen et al., 2002), while in grasslands, G can account for 25% of R_n (Wilson et al., 2002). In sparse canopy ecosystems in semi-arid or arid regions, G was found to account for up to 40% of R_n, which could be equal to or higher than LE (Verhoef et al., 1996). Shao et al. (2008) found that the spatial variability in G can account for 48 W m^{-2} (13% of R_n) during the day and 15 W m^{-2} (34% of R_n) at night, with an average of 28 W m^{-2} (24% of R_n) across three steppe ecosystems. An accurate quantification of *G* is of key importance in energy balance studies, particularly for energy balance closure assessment (Stannard et al., 1994) and for energy balance-based model output verification (Heusinkveld et al. 2004; Murray and Verhoef 2007a, b).

The remote sensing methods are increasingly used for estimating surface energy balance components including G. Kustas and Daughtry (1990) developed a method for estimating *G* based on measurements of R_n and ground-based reflectance in bare soil, alfalfa, and cotton fields in Arizona. They developed two G/R_n equations based on the ratio of ρ_{NIR}/ρ_R and NDVI. They

reported that the mid-day ratio of G and R_n (G/R_n) was linearly related to the ratio of ρ_{NIR}/ρ_R and NDVI as follows:

$$\frac{G}{R_n} = 0.294 - 0.0164\frac{\rho_{NIR}}{\rho_R} \qquad (r^2=0.74, n=11) \qquad (1)$$

$$\frac{G}{R_n} = 0.325 - 0.208 NDVI \qquad (r^2=0.86, n=11) \qquad (2)$$

Bastiaanssen et al. (1998) pooled together the G/R_n and NDVI data from Clothier et al. (1986), Choudhury (1989), Kustas and Daughtry (1990), and Oevelen (1991) and found the following relationship:

$$\frac{G}{R_n} = 0.30(1 - 0.98 NDVI^4) \qquad (r^2=0.61, n=35) \qquad (3)$$

Melesse and Nangia (2005) compared the measured and the estimated fluxes for local conditions using 10 Landsat Thematic Mapper (TM) and Enhanced Thematic Mapper (ETM) images in Montana and suggested a modified equation (Eq. 4) for estimating G as a function of R_n and NDVI.

$$\frac{G}{R_n} = 0.153(1 - 0.98 NDVI^4) \qquad (4)$$

Singh et al. (2008) found that the relationship used in Surface Energy Balance Algorithm for Land (SEBAL) prediction for soil heat flux (Equation 3) significantly overestimated G in a subsurface drip-irrigated maize field in south-central Nebraska with an r^2 of 0.055 and an RMSE of 79.8 W m^{-2}. Due to poor estimation of G, Singh et al. (2008) used measured G data to develop an exponential relation that utilizes NDVI and R_n as follows:

$$G = [0.3811\exp(-2.3187 NDVI)]R_n \qquad (5)$$

Although these equations have been shown to perform well for the conditions that they have been developed for, their applications to a different soil environments are not well known. Our overall objective is to apply and test aforementioned empirical equations for their ability to estimate G under maize (*Zea mays* L.) and soybean (*Glycine max* L.) cropping systems in the Great Plains environmental settings of the United States.

MATERIALS AND METHODS

Study Site: Mead, Nebraska

We used available data sets collected at three sites during 2003 to 2005 from an ongoing carbon sequestration research program at the University of Nebraska-Lincoln, Agricultural Research and Development Center (ARDC) near Mead, NE. The sites at ARDC represent three major cropping systems: a) irrigated continuous maize, b) irrigated maize-soybean rotation, and c) rainfed maize-soybean rotation. The first site (Site 1) (41° 9' 54.2"N, 96° 28' 35.9"W, 361 m above mean sea level) is irrigated with a center-pivot irrigation system and is about 48.7 ha in size. The second site (Site 2) (41° 9' 53.5"N, 96° 28' 12.3"W, 362 m above mean sea level) is also center-pivot irrigated and is 52.4 ha, while the third site (Site 3) (41° 10' 46.8"N, 96° 26' 22.7"W, 362 m above mean sea level) is rainfed and about 65.4 ha. These three sites are within 1.6 km of each other. The soils at all three sites are deep silty clay loams. The cropping details of the sites are presented in table 1. More details about these sites can be found in Verma et al. (2005) and Suyker et al. (2005).

Table1: Cropping details of the study sites

Site	Year	Crop/cultivar	Plant population (plants per Ha)	Planting date	Harvest date

Clay Center: sub-surface drip irrigated	2005 2006 2007	Maize/Pioneer 33B51 Maize/ Pioneer 33B54 Soybean/ Pioneer 93M11	72,900 75,400 385,500	April 22 May 12 May 21	October 17 October 5-6 October 24

Net radiation was measured at 5.5 m above the ground using a Kipp & Zonen CNR1 net radiometer (Campbell Scientific Inc., Logan, Utah). Soil heat flux was measured at a depth of 0.06 m below the ground using soil heat flux plates (Radiation and Energy Balance Systems Inc., Seattle, WA). The soil heat flux was adjusted for soil moisture variation (Verma et al. 2005). Net radiation and soil heat flux were sampled at 0.1 sec intervals and averaged over 60 minutes using a Model CR10X datalogger and AM416 Relay Multiplexer (Campbell Scientific, Inc., Logan, UT). Spectral reflectance was measured in 2003, 2004, and 2005 with a pair of inter-calibrated SKR 1850 series four-channel light sensors (Model SKR 1850, Skye Instruments Ltd., Powys, UK) mounted at approximately 5 m on a mast located near the eddy covariance flux tower in the center of the fields. The SKYE radiometers measure in four narrow spectral bands: (1) 536-561 nm (green band), (2) 665-676 nm (red band), (3) 700 - 720 nm (red-edge band) and (4) 862-874 nm (near infrared band); all except the 700-720 nm red-edge band are comparable to MODIS bands. In the field, the SKYE instruments measured the same location, obtaining a 10 min average every half-hour between 11:30 am and 1:30 pm (Central Standard Time).

Study Site: Clay Center, Nebraska

A field experiment was conducted at the University of Nebraska-Lincoln, South Central Agricultural Laboratory (SCAL) during the 2005, 2006, and 2007 growing seasons. SCAL is located approximately 160 km west of Lincoln in the south central part of Nebraska near Clay Center, NE, U.S.A. (40°34′ N, 98°08′ W, 552 m above sea level). The soil at the experimental site is Hastings silt loam with a field capacity of 0.34 m^3 m^{-3} and permanent wilting point of 0.14 m^3 m^{-3}. Maize was planted during the 2005 and 2006 growing seasons, and soybean was planted in 2007 (Table 1). The experimental field (13 ha) was irrigated using a subsurface drip irrigation system. Measurements were made using a deluxe version of a Bowen Ratio Energy Balance System (BREBS) (Radiation and Energy Balance Systems, REBS, Inc., Bellevue, WA). Soil heat flux was measured using three REBS HFT-3.1 heat flux plates and three soil thermocouples. Each soil heat flux plate was placed at a depth of approximately 0.06 m below the mean ground

level. The REBS STP-1 soil thermocouple probes were installed in close proximity to each soil heat flux plate at depths of 0.02, 0.04, 0.06, 0.08, and 0.10 m below the soil surface. Measured soil heat flux values were adjusted to soil temperatures and soil water content as measured using three REBS SMP1R soil moisture probes. Net radiation was measured using a REBS Q*7.1 net radiometer that was installed approximately 4.5 m above the soil surface. All variables were sampled at a 30 sec interval and averaged and recorded on a hourly basis using a Model CR10X datalogger and AM416 Relay Multiplexer (Campbell Scientific, Inc., Logan, UT). More details about the measurements can be obtained from Irmak and Irmak 2008. The NDVI at the Clay Center site was calculated using cloud free Landsat5 and Landsat7 satellite images (Path 29, Row 32). The acquisition dates for Landsat5 and Landsat7 images are shown in table 2.

Table 2: Details of Landsat images (Path 29 Row 32) used for the study.

RESULTS AND DISCUSSION

Comparison of empirical models for predicting G for irrigated and dryland maize cropping systems

Several models are available to estimate G from R_n and NDVI, and we compared some of those models to assess their performance at our study sites. We selected the Kustas and Daughtry (1990) (M1), Bastiaanssen et al. (1998) (M2), Melesse and Nangia (2005) (M3), and Singh et al. (2008) (M4) models for comparisons. Results are presented in the table 3.

Comparisons of measured and estimated G from the four models (M1-M4) for irrigated maize showed a wide variation from site to site and year to year (Fig. 1). At Mead site 1, M2 resulted in the highest mean absolute error (MAE) (44.14 W m^{-2}) and root mean square error (RMSE) (48.56 W m^{-2}) in 2005 (Table 3). The lowest values of MAE and RMSE at site 1 were 16.97 W m^{-2} and 24.43 W m^{-2}, respectively, using M3 during the 2004 cropping season. It is interesting to note that both M2 and M3 resulted in the same r^2 value as both equations have similar structures. However, M3 had a better model efficiency as compared with M2 during 2004 (0.51 vs. -0.75) and 2005 (0.43 vs. -0.74). The negative efficiencies of M2 indicated that the observed mean of G is a better predictor than the model.

Comparisons at Mead site 2 for irrigated maize showed that the M2 and M3 equations yielded the highest (46.65 W m^{-2}) and the lowest (13.51 W m^{-2}) values of MAE, respectively, in 2003. The maximum RMSE was 50.68 W m^{-2} (M2), and the minimum RMSE was 24.71 W m^{-2} for M3. Using the M1 model, G was overestimated by 38% in 2003 and 17% in 2005 at Mead site 2 (Fig. 1d-e). For the same site, M2 resulted in overestimation of G by 50% (2003) and 22% (2005). When compared with Mead site 1, the overestimation at Mead site 2 increased in 2003

but decreased in 2005. This decrease in 2005 may be due to less crop residue in 2005 as a result of the soybean crop in 2004.

Table 3: Statistical analysis results of the model validations using Kustas and Daughtry (1990) (M1), Bastiaanssen et al. (1998) (M2), Melesse and Nangia (2005) (M3), and Singh et al. (2008) (M4) equations.

Measure	Method	Mead Site 1			Mead Site 2			Mead Site 3			Clay center		
		2003	2004	2005	2003	2004	2005	2003	2004	2005	2005	2006	2007

	M4	0.22	0.21	0.12	0.45	0.43	0.03	0.14	0.75	0.54	0.82	-1.41	0.38

The best performance at the Clay Center site for irrigated maize was obtained by using M4, because this model was calibrated at this site using data from the 2005 growing season. We excluded this model from our discussion here. The next best MAE and RMSE were obtained by using M3, whose minimum values were 28.62 W m^{-2} and 32.06 W m^{-2}, respectively. The corresponding r^2 and E values were 0.57 and 0.19, respectively. M1 had the highest r^2 (0.94), but its model efficiency was poor in both 2005 (-1.59) and 2006 (-3.68). The overall variation in G estimation during 2005 (Fig. 1f) ranged from -8% (M3) to 81% (M2). However during 2006 (Fig. 1g), all the models overestimated G at the Clay Center site, with M3 having the lowest (5%) and M2 having the highest (106%) values.

Dryland maize was grown at Mead site 3 during 2003 and 2005. The comparison of measured and estimated G for this cropping system showed similar distributions for 2003 and 2005 (Fig. 2). The M3 equation resulted in the lowest MAE during 2003 (10.41 W m^{-2}) and 2005 (9.13 W m^{-2}). In fact, these values were the best MAE achieved from among all the cropping systems in our analyses. The highest MAE was 49.45 W m^{-2} and 52.99 W m^{-2} during 2003 and 2005, respectively. These values were obtained from using M2. In 2003, the maximum RMSE was 52.89 W m^{-2} (M2), and the minimum RMSE was 14.99 W m^{-2} (M3). There was a slight increase in the minimum (17.74 W m^{-2}) and the maximum (55.81 W m^{-2}) RMSE in 2005. Though M1 had the highest correlation during 2003 (r^2 =0.91) and 2005 (r^2 =0.93), the model efficiency was negative during these two years (-1.24 in 2003 and -0.27 in 2005). Only M3 and M4 had positive model efficiency values for dryland maize. As similar to Mead sites 1 and 2, G

was overestimated at Mead site 3 using M1 and M2 and underestimated by M3 and M4 in 2003 (Fig. 2a) and 2005 (Fig.2b).

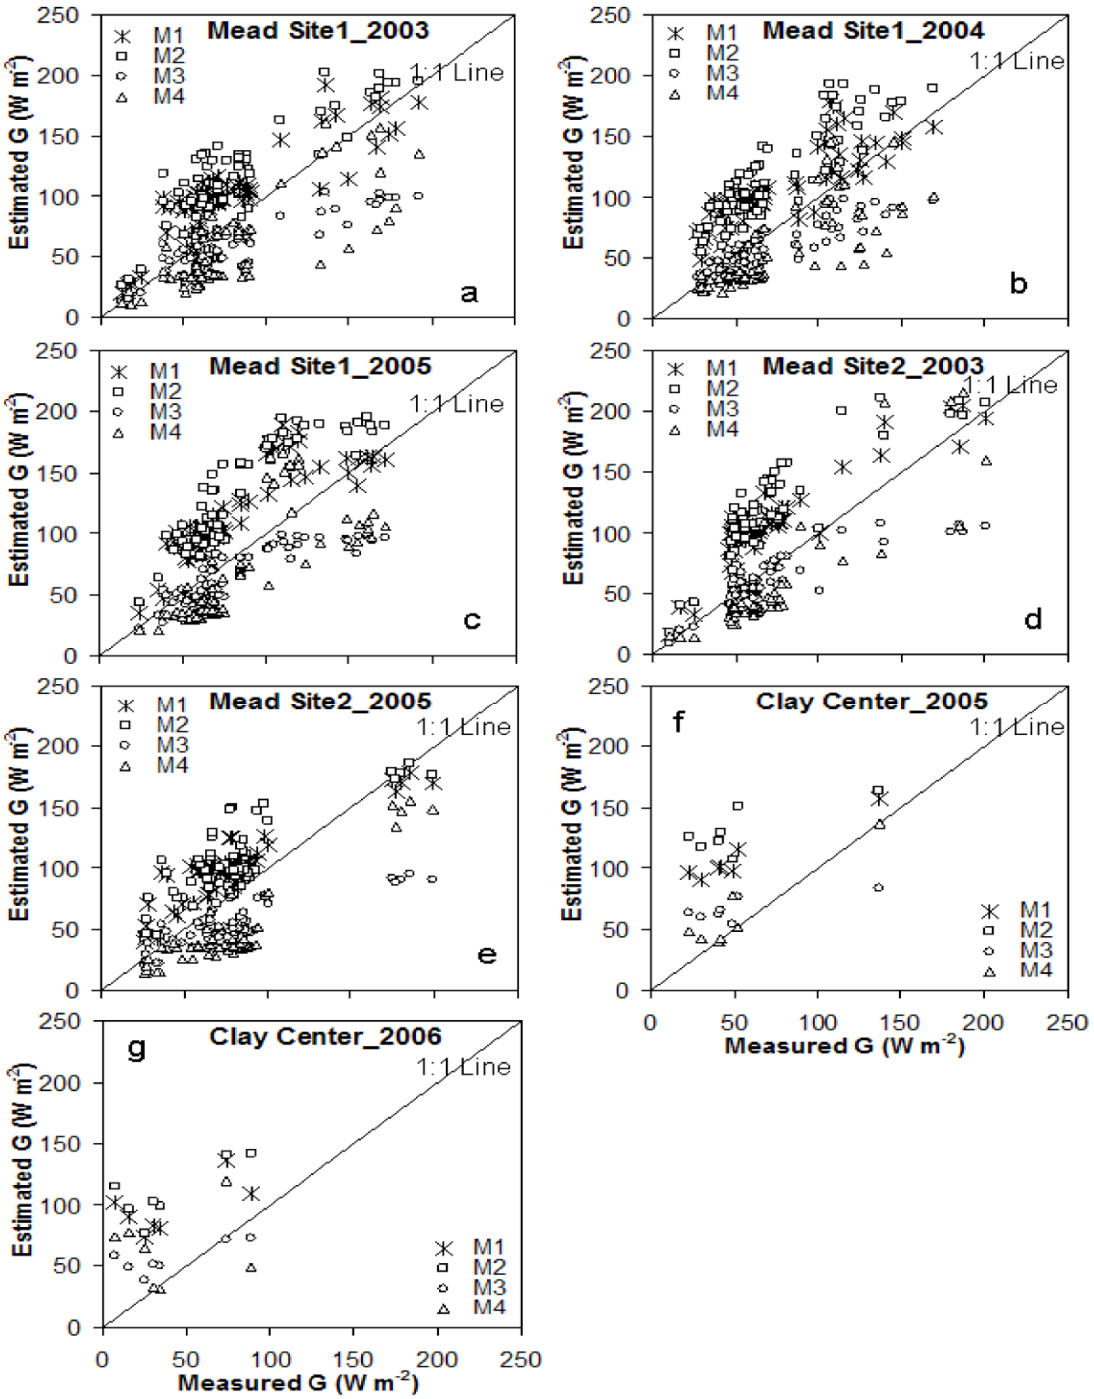

Figure 1. Model comparison for irrigated maize at Mead site 1 during (a) 2003, (b) 2004, (c) 2005, at Mead site 2 during (d) 2003 and (e) 2005 and at Clay Center site during (f) 2005 and (g) 2006 for estimation of G using the Kustas and Daughtry (1990) (M1), Bastiaanssen et al. (1998) (M2), Melesse and Nangia (2005) (M3), and Singh et al. (2008) (M4) equations.

Comparison of empirical* models *for predicting G for irrigated and dryland soybean cropping systems

The comparison of measured and estimated G for the irrigated soybean cropping systems is shown in figure 3. While M1 and M2 overestimated G, the other two equations (M3 and M4) underestimated G at Mead site 2 during 2004 (Fig. 3a). The overestimation was about 48% and 46% by M1 and M2, respectively. In contrast, M3 and M4 resulted in underestimation of G by 25% and 13%, respectively. The lowest MAE at Mead site 2 was 16.69 W m^{-2} using the M3 equation followed by M4 (19.37 W m^{-2}). The highest MAE obtained by M1 (34.03 W m^{-2}) was more than double that of the lowest MAE at Mead site 2. A very good correlation (r^2 =0.83-0.90) was obtained at this site for all four compared methods. However, only M3 (0.58) and M4 (0.43) had positive model efficiencies, indicating good model performance. Model efficacy for G estimation in subsurface drip-irrigated soybean at Clay Center site is shown in figure 3b. Comparison for irrigated soybean at Clay Center during the 2007 cropping season showed that, in general, the MAE and RMSE were higher at this site as compared with Mead site 2 (Table 3). We found that overall, the Kustas and Daughtry (1990) equation underestimated G by about 6%. The comparison of measured and estimated G for the dryland soybean cropping system is presented in figure 4.

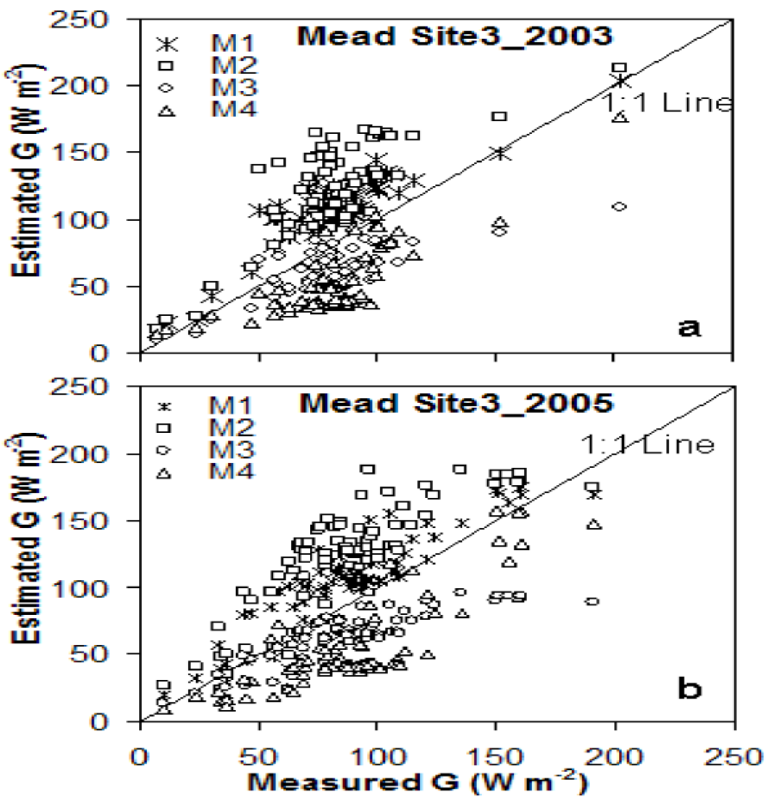

Figure 2. Model comparison for dryland maize at Mead site 3 during (a) 2003 and (b) 2005 for estimation of G using the Kustas and Daughtry (1990) (M1), Bastiaanssen et al. (1998) (M2), Melesse and Nangia (2005) (M3), and Singh et al. (2008) (M4) equations.

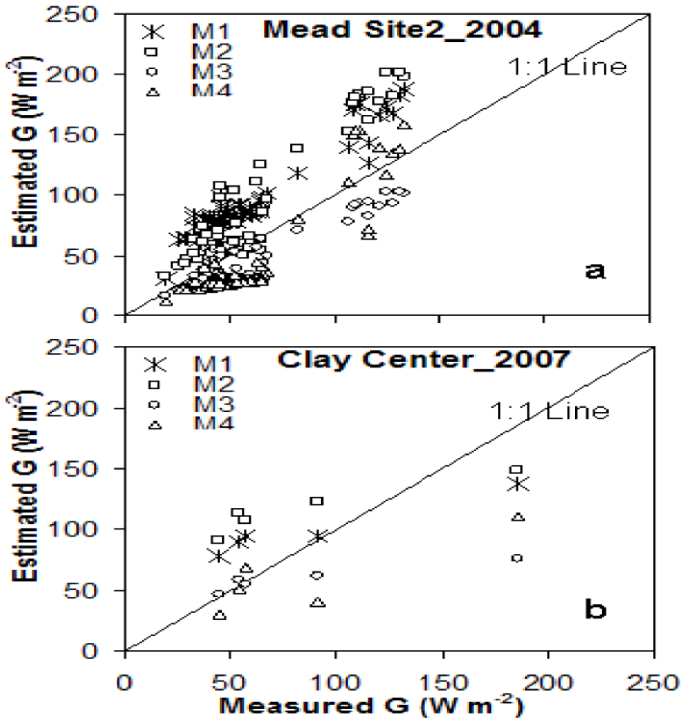

Figure 3. Model comparison for irrigated soybean at (a) Mead site 2 during 2004 and (b) Clay Center site during 2007 for estimation of G using the Kustas and Daughtry (1990) (M1), Bastiaanssen et al. (1998) (M2), Melesse and Nangia (2005) (M3), and Singh et al. (2008) (M4) equations.

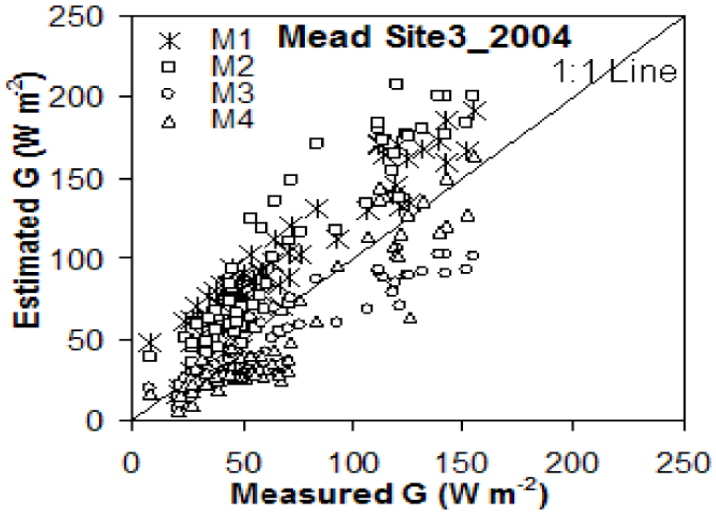

Figure 4. Model comparison for dryland soybean at Mead site 3 during 2004 for estimation of G using the Kustas and Daughtry (1990) (M1), Bastiaanssen et al. (1998) (M2), Melesse and Nangia (2005) (M3), and Singh et al. (2008) (M4) equations.

We observed considerable variations in model performance depending upon site, crop, and irrigation conditions. The differences in the performance of the models (M1-M5) may be attributed to various factors such as soil properties, measurement of G and R_n, band width for NDVI, NDVI measurement, model calibration procedures, and tillage and residue management

conditions. For example, in the case of Kustas and Daughtry (1990), the soil heat flux plate was buried at a depth of 5 cm. In the study reported in Singh et al. (2008), the soil heat flux plate was placed at a depth of 6 cm. Hence it is possible that the extra storage of the heat flux in the soil above the soil heat flux plate can cause differences in model performance. Meyers and Hollinger (2004) have discussed the impact of storage terms in the surface energy balance of maize and soybean. They showed that these components, taken together, can be about 14% for maize and 8% for soybean cropping systems. The NDVI for M1-M4 was calculated based on band widths similar to the Landsat satellite. In the present study, NDVI was calculated at the Mead sites based on band widths similar to MODIS and at Clay Center using Landsat data. Further, M3 and M4 were calibrated with NDVI calculated at the top of the atmosphere. However, in the present study, NDVI was calculated at the top of the surface at the Mead sites. Different methods of tillage and crop residue management can have an impact on G as well. All these differences may be a source for variations in the performance of the models used in this study.

CONCLUSIONS

Soil heat flux estimation is important in energy balance studies. The data collected from maize and soybean fields under irrigated and dryland conditions were used for models performance using different statistical measures. On an average, the soil heat flux was lower in soybean field as compared to heat flux in maize field due to higher NDVI of soybean. Overall, among the four evaluated models, the Melesse and Nangia (2005) model resulted in the best performance. However, in some cases this model also resulted in high RMSE (50.83 W m^{-2} at Clay Center in 2007) and low r^2 (0.57 at Clay Center in 2005). Based on the statistical analysis of the models performance, it can be concluded that local calibrations of soil heat flux models are essential for accurate and reliable soil heat flux estimation.

ABSTRACT

Tillage practices directly impact runoff processes, erosion and water quality in agricultural watersheds. Consequently, environment models require tillage information for water quality modeling but often this information is not available at required spatial and temporal scales. Remote sensing approach facilitates tillage mapping at a larger scale than the conventional surveying methods. Models based on remote sensing can classify contrasting tillage practices with accuracy of 80% to 92%. The objectives of this study were to use reflectance based logistic regression models to classify contrasting tillage practices in agricultural watersheds using Landsat imagery. This study is conducted in the Upper White River Basin (7,000 km^2) located in central Indiana, an agricultural watershed with corn-soybean rotation. A single tillage practice can have different level of impact at different slope classes within the watershed therefore; the tillage system information is coupled with the slope classes within a watershed using geographic information system (GIS). This can identify the optimum slope class for a tillage system for minimum sediment loss. The tillage data derived are input in the Soil and Water Assessment Tool (SWAT) model to evaluate the distribution of tillage practices and their impacts on runoff, sediment, and pollutant losses.

INTRODUCTION

Tillage information is crucial in environmental and watershed modeling as it has a direct impact on soil and water quality but often this information are not available at required spatial and temporal scales. Remote sensing approach facilitates tillage mapping at a larger scale than the conventional surveying methods. The conventional method of crop residue cover and tillage practices assessment is done from roadside surveys in selected counties of the U.S. The survey is not done every year for each county and therefore leads into data inconsistency. Also, manual data collection from roadside surveys is often time-consuming, labor-intensive and costly. There is no program that can objectively monitor tillage over broad areas. Remote sensing can be an effective tool in differentiating contrasting tillage practices over a large spatial area in a time- and cost-effective manner.

Models based on remote sensing can classify contrasting tillage practices with an accuracy of 80% to 92%. Different tillage practices have different level of impact on runoff processes, erosion and water quality in agricultural watersheds. Sediment erosion from agricultural watershed is major pollutant for stream and river impairment. The U.S. Environmental Protection Agency and state agencies working on implementing Total Maximum Daily Loads (TMDLs) to address agricultural non-point source pollution require specific knowledge of prevailing tillage patterns as well as their location for adoption of conservation practices to reduce non-point source pollution. Watershed studies have shown that the adoption of conservation tillage (CT) methods can substantially reduce soil and phosphorus (P) losses compared with conventional tillage methods as they retain at least 30% of the soil surface covered with crop residue after a crop is planted. Conservation tillage includes no till, ridge till, strip till, mulch till and reduced till. The Conservation Technology Information Center (CTIC) has defined CT as any tillage and planting system that has >30% residue cover after planting, reduced tillage (RT) as 15 to 30% residue cover, and intensive tillage as <15% residue cover (CTIC, 2000). Conservation tillage system, or crop residual management, is recognized as a cost-effective means of significantly reducing soil erosion and maintaining productivity.

Logan and Adams (1981) found that conservation tillage practices were effective in reducing sediment and sediment-bound P losses by 89%. Similar results were observed by Angle et al. (1984) in their study on a Manor loam soil in Howard County, Maryland, where total P losses were 8 and 161 g/ha from corn plots with conservation and conventional tillage systems, respectively.

In recent years, numerous spectral models have been developed to measure crop residue cover or identify contrasting tillage practices. They exploit the characteristic shape of the green vegetation spectrum by combining the low reflectance of the visible with the high reflectance of the near infrared to identify and quantify green vegetation (Daughtry, 2004). Many spectral indices had been used to enhance the Landsat Thematic Mapper (TM) signal from crop residues which include Normalized Difference Tillage Index, Simple Vegetation Index (NDTI; STI; van Deventer et al., 1997) and Normalized Difference Index (NDI; McNairn and Protz, 1993). These indices utilize the relative difference in reflectance from soil and vegetative reflectance.

Daughtry et al. (2005) evaluated several spectral indices for crop residue cover using satellite multispectral and hyperspectral data and to categorize soil tillage intensity in agricultural fields. They found weak relationships between Landsat TM indices and crop residue cover. Similar results were reported in Minnesota (Thoma et al. 2004). However, these studies reported higher prediction accuracy when crop residue cover was classified into two categories (>30% and <30%), indicating that Landsat TM indices are useful in identifying contrasting tillage practices.

Van Deventer et al. (1997) developed a set of Landsat TM based probability models for discriminating conservation tillage from conventional tilled fields in Seneca County, northern Ohio. In their study, models using the ratio and the normalized

differences of TM bands 5 and 7 classified 93% of the tillage attributes correctly evaluated with independent data from 15 fields. The objective of this study was to evaluate a set of Landsat TM-based logistic regression models proposed by van Deventer et al. (1997) for their ability to identify tillage management practices.

STUDY AREA

This study is conducted in the Upper White River Basin (UWRB; 7,000 km^2) located in central Indiana, an agricultural watershed with corn-soybean rotation (Table 2). It extends across sixteen (16) counties including significant portions of Hancock, Marion, Hendricks, Johnson, Hamilton, Morgan, Boone, Tipton, Madison, Henry, Delaware, and Randolph Counties, as well as smaller portions of Owen, Monroe, Brown, and Clinton Counties. The city of Indianapolis is located in Marion County. Typical planting dates for major crops (Corn and Soybean) in the Indiana vary from May5 – May 20 for Corn to May 15 – June 5 for Soybean (NASS, 1997).

Annual average precipitation is about 1040.13 mm and 942 mm for Marion and Hamilton counties, respectively in UWRB. The dominant soil in UWRB is mainly Crosby-Treaty-Miami (headwaters areas) and Miami-Crosby-Treaty (downstream areas). These two soil type cover about 78% of the UWRB soil type. The most common conventional tillage system in Indiana for Corn crop is moldboard plowing.

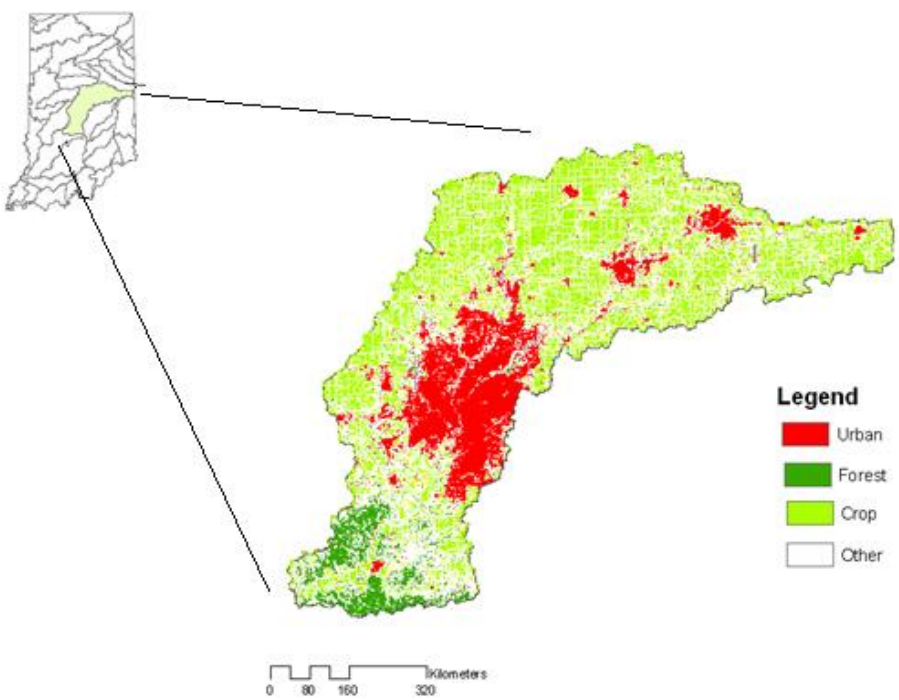

Figure 1 : Upper White River Basin (UWRB) in central Indiana with major land use classes.

MATERIALS AND METHODS

Table 1: Land use classification for Upper White River Basin

Land Use	Area
Agricultural Land	57.1%
Urban	23.9%
forest	14.4%
Water	0.4%
Other	4.1%

Developing and evaluating the tillage models consisted of four steps: (1) groundtruth data collection, (2) remote sensing data acquisition, (3) development of models using the linear logistic regression modeling technique, and (4) evaluation of models. Two Landsat TM scenes were acquired, one on 8th May 2003 for UWRB area (Path 21/Row 31-32) and the other on 25th July 2003 (Path 21/Row 31-32), for developing and evaluating Landsat TM-based tillage models. First image 8th May 2003 is during the time 70% of tillage was been done at central Indiana to prepare tillage classification maps (NASS, 2003) and the second image 25th July 2003 is during the crop growing season to classify land use (agricultural and non-agricultural land) in UWRB. Six TM based logistic regression models proposed by van Deventer et al. (1997) were used to identify contrasting tillage practices (Table 2). The Landsat TM-based logistic regression models (SAS, 1990) used in this study has the form:

$$\text{Logit}(\text{p}) = \ln\left(\frac{\text{p}}{1-\text{p}}\right) = \alpha + \beta\text{X} \quad (1)$$

$$p = \frac{e^{logit(p)}}{1+e^{logit(p)}} \quad (2)$$

Tillage practices were assigned a class value of 0 for conventional tillage and 1 for conservation tillage. In this study, the p in equation (1) is the conservation tillage probability. Therefore, the ideal p values for 100% conventional and 100% conservation tillage are 0 and 1, respectively. Logistic regression models require users to specify a cut-off response probability to classify the outcome of an event occurring. The p values below the cut-off value were classed as conservational tillage whereas values above cut-off value were classed as conservational tillage. Tillage classification was based on the percentage of the soil surface covered with crop residue. We defined conservation tillage systems as those that retained at least 30% of the soil surface covered with crop residue after a crop is planted.

Table 2 : Landsat TM-based logistic regression models proposed by van Deventer et al. (1997).

Model	Band	Intercept	Slope	Cut-off Tillage Probability
I	TM5	10.215	-0.072	0.62
II	R15	-19.404	29.949	0.56
III	M15	8.785	40.947	0.56
IV	D35	10.931	0.135	0.44
V	STI	45.218	-23.998	0.64
VI	NDTI	30.464	-99.483	0.62

Six logistic regression models were used with different values for abscissa in Eq. (1). Model I was derived from TM band 5. Model II was based on the ratio of TM bands 1 and 5 (R15). Model III was based on the normalized difference between TM bands 3 and 5 (M15). Model IV was based on the difference between TM bands 3 and 5 (D35). Model V was based on the ratio of TM bands 5 and 7 (Simple Tillage Index - STI). Model VI was based on the normalized difference between TM bands 5 and 7 (Normalized Difference Tillage Index - NDTI).

Tillage probability values (p) for each pixel in the TM image was calculated using model-builder module in ERDAS imagine, image processing software for 8th May 2003 image. The second image acquired on 25th July 2003 was used to classify land use class into agricultural and non- agricultural using ArcGIS software.

RESULTS AND DISCUSSION

Table 3 shows percentage of agricultural land in UWRB (county-wise) under conventional and conservational tillage practices (ISDA, 2004). This data was based on tillage survey conducted by the Indiana State Department of Agriculture (ISDA). Based on this survey data, about 56% of the fields surveyed adopted conventional tillage in the UWRB. The model results for percentage of conservational and conservational tillage in UWRB is shown in Figure 2. The Table 4 shows that model R15 and M15 has closer classification result than other models. The model STI and NDTI did not perform well in present study. This is consistent with results presented in Gowda et al. (2006) to Ochiltree County in the Texas Panhandle where they found that STI and NDTI models performed poor than other models which may be due to fact that TM Bands 5 and 7 are sensitive to organic matter content and soil water conditions. Also, in the same study, they found R15 and M15 models performed better than other models in classifying conservational and conservational tillage practices.

Table 3: Percentage area of Conventional tillage and Conservational tillage in UWRB counties (ISDA, 2004).

Counties UWRB	Conservational Tillage (%)	Conventional Tillage (%)
Randolph	74	26
Delaware	78	22
Hendricks	60	41
Hamilton	40	61
Morgan	33	68
Madison	19	81
Johnson	49	51
Henry	52	48
Tipton	4	95
Hancock	30	70
Average	**43.9**	**56.3**

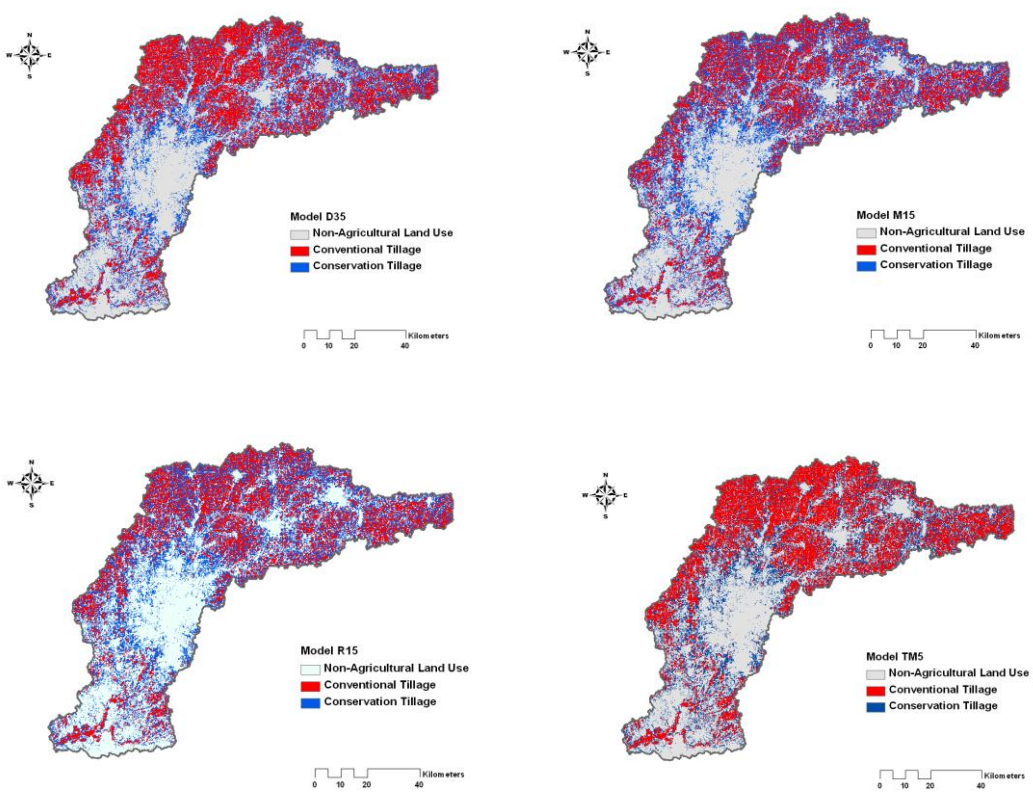

Figure 2 : Conventional tillage and Conservational tillage classification in UWRB obtained from logistic regression models D35 = Band 3 - Band 5, M15 = (Band 1 - Band 5) / (Band 1 + Band 5), R15 = (Band 1 / Band 5) and TM5.

Table 4: Percentage area of Conventional tillage and Conservational tillage in UWRB obtained from logistic regression models.

Model	Conservational Tillage (%)	Conventional Tillage (%)	Error Conventional Tillage (%)
TM5	59.5	40.4	15.8
R15	46.4	53.6	2.7
M15	45.8	54.2	2.1
D35	53.8	46.2	10.1

CONCLUSIONS

Tillage information is crucial in environmental and watershed modeling as it has a direct impact on soil erosion. A remote sensing approach is promising for the rapid collection of tillage information on individual fields over large areas. In this study, six Thematic Mapper (TM) - based logistic regression models proposed by van Deventer et al (1997) were used to distinguish conventional and conservation tillage practices in the UWRB located in central Indiana. Logistic regression models were easy to use, cost and time effective, and produced reasonably accurate tillage maps. The results were compared with county level data available from Indian State Department of Agriculture. This approach is useful in locating contrasting tillage information over large basin which can be applied to water quality models Soil and water Assessment Tool (SWAT) for more precise study for nonpoint source pollution from agricultural watersheds.

ABSTRACT

When managing local and regional water resources, the estimation of evapotranspiration is important and has generally been one of the components of the hydrological cycle that has the greatest uncertainty. With the development of suitable models and algorithms applied to high resolution (30 m) satellite imagery, evapotranspiration may be estimated with greater accuracy, and in a cost effective and time efficient manner. The METRIC image processing procedure calculates net radiation, soil heat flux and sensible heat flux through a number of steps before estimating evapotranspiration as the residual from the energy balance.
Sensible heat flux is calibrated using the so-called “cold” and “hot” anchor pixels. These pixels are selected by the user, which may introduce some operator dependency or human errors on the estimation of sensible heat flux and subsequently error in the final map of evapotranspiration. A procedure for automated selection of the anchor pixels is presented. The automated pixel selection procedure will reduce the user dependency of the estimations of sensible heat flux. Additionally, it may allow more novice users to obtain good results when applying METRIC.

INTRODUCTION

Application of remote sensing algorithms solving the energy balance using high resolution satellite imagery has proven useful for establishing estimates of actual evapotranspiration, ET_a and crop coefficients, K_c for large populations of fields and water users (Allen et al., 2007a). The METRIC model was developed for application with Landsat imagery to achieve high ET product resolution (30 m). This

resolution allows calculation of populations of ET within individual fields and along relatively narrow riparian systems along streams for the entire approximately 185 by 185 km Landsat scene.

The METRIC model (Mapping Evapotranspiration at high Resolution with Internalized Calibration) is a satellite image processing model which estimates ET as the residual of the energy balance (Tasumi et al., 2005, Allen et al., 2007b), Eq. 1,

$$LE = R_n - G - H \qquad (1)$$

where LE is latent heat flux density, R_n is net radiation, G is soil heat flux density and H is sensible heat flux density. In METRIC, R_n is calculated by solving the radiation balance as described by Allen et al. (2007b). Soil heat flux is estimated based on R_n, surface temperature and the Normalized Difference Vegetation Index ((NDVI).

Sensible heat flux is the rate of heat loss from the surface to the air due to a temperature difference. H is estimated in METRIC using a one-dimensional, aerodynamic, temperature gradient based equation for heat transport, Eq. 2,

$$H = \frac{\rho c_p dT}{r_{ah}} \qquad (2)$$

where ρ is air density (kg/m^3), c_p is air specific heat (J/kg/K), dT (K) is the temperature difference between two heights (z_1 and z_2) floating above the surface, and r_{ah} is the aerodynamic resistance to heat transport (s/m) between z_1 and z_2. METRIC utilizes the *CIMEC* (calibration using inverse modeling of extreme conditions) procedure (Bastiaanssen, 1995, Bastiaanssen et al., 1998) to calibrate the dT function. The *CIMEC* process is applied by inverting Eq. 2 for dT after solving Eq. 1 for H for two extreme conditions representing nearly full LE and nearly zero LE within the image. LE for the full LE condition is estimated using the ASCE-EWRI standardized alfalfa-based reference ET, ET_r, method (ASCE-EWRI, 2005) calculated using quality controlled hourly weather data (Allen, 1996, ASCE-EWRI, 2005). The weather station providing the weather data should preferably be located towards the center of the image or study area. LE for the low LE condition is estimated using a daily soil water balance evaporation model accounting for residual evaporation from antecedent precipitation events. Simulation results from the soil water balance model can be found in e.g. Kjaersgaard et al. (2008) and Allen et al. (2008). The dT for each remaining pixel in the Landsat scene is estimated as an indexed value based on a regression relationship between dT and the radiometric surface temperature from the satellite, T_s at two extreme conditions within the scene, Eq. 3,

$$dT = aT_{s_dem} + b \qquad (3)$$

where a and b are calibration coefficients. T_s is lapse corrected to a common arbitrary elevation datum using a specified lapse rate. This correction adjusts for change in T_s caused by warming or cooling of air masses with elevation rather than change in evaporation and surface energy balance. The linearity of the dT vs T_s function is a major assumption of METRIC. Research by Bastiaanssen (1995) and comparisons of final ET estimates over a range of dT values (Tasumi et al., 2005, Allen et al., 2007b), indicate that this assumption fits a wide range of conditions.

Agricultural areas are generally selected for the extreme condition calibration because of their importance in water consumption and management. Also, the vegetation in intensively managed agricultural systems is normally more uniform at the 30 m scale compared to natural systems. For each satellite image the extremes are identified by the user through selection of two "anchor" pixels. The anchor pixels ideally represent the conditions of an agricultural field with full and actively transpiring vegetation, and a bare agricultural field with no vegetation cover and with little or no residual evaporation from the soil. The anchor pixel representing full vegetation cover has the characteristics of green vegetation and its dT is low due to evaporative cooling. This condition is often referred to as the "cold" condition. The anchor pixel representing a bare field has the characteristics of a bare soil and its dT is high due to radiometric heating of the surface. This condition is often referred to as the "hot" condition.

The use of ET_r in the estimation of LE at the cold anchor pixel is generally effective in "tying down" the energy balance calibration, especially in arid and semiarid climates having advection. Going through the extra efforts in selecting representative anchor pixels in METRIC may improve the accuracy of the resulting ET maps compared to other single source satellite based ET estimation methods (Allen et al., 2007b). It comes at a cost, however, as selecting representative anchor pixels is a time consuming and usually iterative process which requires an experienced operator. The anchor pixel selection process may also introduce some operator dependency or human errors on the estimation of sensible heat flux and subsequently the final map of evapotranspiration. An automated selection of the anchor pixels will greatly reduce the user dependency of the estimations of sensible heat flux, and allow more novice users to obtain good results when applying METRIC.

In this paper a procedure based on simple statistical procedures for automated selection of cold and hot anchor pixels to aid the user is presented. The set-up of the method in ERDAS Imagine Spatial Modeler is described as the procedure may be integrated with the METRIC model code. The procedure identifies a number of anchor pixel candidates from which the user can select which ones to use. A color coding directs the user towards more preferred pixels. Results from applications in Montana at different times during the growing season show the method identifies anchor pixels that compare relatively well to pixels selected independently by an experienced user.

METHODS

A statistical procedure to select the cold and hot anchor pixels was developed by Allen and Kelly (2004, unpublished). The method was tested by Burnett (2007) and Trezza (unpublished). The approach has been further refined in the current application. A summary of the statistical procedures is shown in Table 1.

Table 1. Summary of the statistical procedure for automated cold and hot anchor pixel selection

Anchor pixel	Step no	Procedure
Cold	1	Select the top 5 % NDVI pixels within a predefined and filtered Area of Interest (AOI).
	2	From the group in (1), calculate the average temperature among the coldest 20 % of T_s.
	3	Cold pixel candidates are pixels that have a T_s within ± 0.2 K of the average T_s from (2) and an albedo within ± 0.02 of Eq. 4.
	4	One pixel is selected from the group in 3) based on the homogeneity among its neighboring pixels.
Hot	1	Select the lowest 10 % NDVI pixels within a predefined and filtered Area of Interest (AOI).
	2	From the group in (1) calculate the average temperature among the hottest 20 % T_s. The average temperature is adjusted using Eq. 5.
	3	One pixel is selected from the group in (2) that has a T_s ± 0.2 K of the average T_s and has high homogeneity among neighboring pixels.

In addition to the criteria listed in Table 1, the anchor pixels should generally be:

- Located within 20 – 30 km of the weather station
- Located towards the center portion of an agricultural field with a homogenous surface
- Located on non-sloping terrain

The procedure to isolate reasonable cold and hot anchor pixel candidates is described below. From the resulting population of suitable cold and hot anchor pixel candidates, one cold and one hot pixel is selected by the user, and all attributes of the selected pixels are used during calibration of H.

Preprocessing. The first step is to delineate a cloud free Area of Interest (AOI) that lies completely within an irrigated agricultural project area. The hot and cold anchor pixels are found within this AOI and its outline should be relatively close to the weather station (generally, the cold and hot anchor pixels should be located within 20 – 30 km from the weather station). The AOI should be large enough to include a wide distribution of bare and vegetated fields (e.g. 10 by 10 km), and exclude significant areas of non-agricultural areas such as desert, forest, lakes, steep slopes or cities. In

desert areas it is important not to include large inclusions of non-irrigated land as this will bias the estimates. The AOI is a contiguous area that does include roads, farmsteads, etc. An example of an AOI is shown in Figure 1. Burnett (2007) discussed the relative importance of the outline of the AOI.

Step A: Identify homogenous fields. The 30 m pixels are grouped into clumps based on the DNs in band 6. The size of the clumps is defined by the user. Clumps are groups of contiguous pixels with the same value and are also called patches or raster polygons. The Coefficient of Variation (CV) within each clump is calculated by dividing the standard deviation by the mean of NDVI for each clump.The CV is used to determine whether the surface contained within the clump is relatively homogenous, and therefore, are pixel candidates from where the cold or hot anchor pixel can be selected.

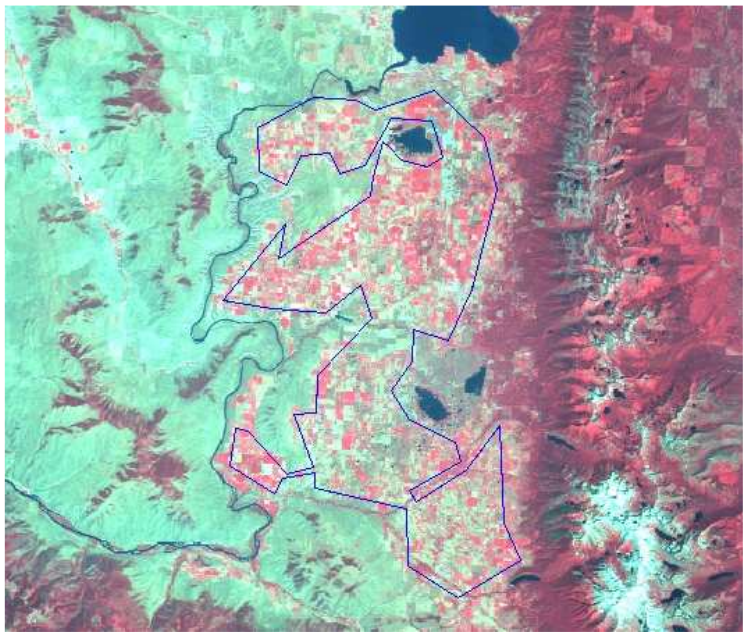

Figure 1. Example of the outline of an Area of Interest (blue line) delineating the area used for locating possible cold and hot pixel candidates.

If the CV of a particular clump is greater than a threshold value, it can be assumed that there is too much variation in NDVI within the clump and those pixels are rejected. A high CV may be due to the clump being located near e.g. a field edge, along a road, on top of a farmstead or in an area with a large spatial variation in the surface cover. In this application 240 m clumps and a CV threshold of 15 % were used to select clumps for sampling in steps B and C.

Step B: Cold pixel identification. From the subsample of homogenous pixels from Step A, the population of 30 m pixels having the top 5 % of NDVI is identified. From this 5 % subpopulation, the pixels that have a T_s in the bottom 20 % of the T_s are selected. This selection results in a pixel population of 1 % of the original sampled

and filtered (for homogeneity) population. This 1 % will have nearly the highest NDVI and the coolest T_s. From this 1 % population, the average T_s is calculated. Cold pixel candidates are selected among the pixels that meet all the following requirements:

- Lie in the interior of a homogenous field,
- Have a value of T_s that is within ± 0.2 K of the statistically identified average T_s
- Have an albedo that is within ± 0.02 of the albedo threshold calculated using Eq. 4,

$$\alpha = 0.001343\beta + 0.3281\exp(-0.0188\beta) \qquad (4)$$

where α is the albedo threshold, and β is the sun angle (°) above the horizon. Eq. 4 was developed by Dong at al. (1992) and parameterized by Trezza (2007) for Southern Idaho. The purpose of Eq. 4 is to compensate for effects of sun angle on albedo at the time of the image for full cover vegetation.

Step C: Hot pixel identification. From the subsample of homogenous pixels from step A, the population of 30 m pixels having the bottom 10 % of all NDVI is identified. From this 10 % subpopulation, the pixels that have a T_s in the top 20 % of the T_s are selected. This selection results in a pixel population of 2 % of the original sampled and filtered (for homogeneity) population. This 2 % will have nearly the lowest NDVI and nearly the warmest T_s. From this 2 % population, the average T_s is calculated. Burnett (2007) found that this average T_s required a modification for the "relative dryness" of bare soils late in the season. The T_s is modified by adding additional temperature computed as a function of the ratio of precipitation to reference ET the 60 days prior the image date, Eq. 5,

$$T_{fac} = 2.6 - 13\frac{precipitation_{60}}{referenceET_{60}} \qquad (5)$$

where T_{fac} is the adjustment factor and the ratio precipitation/reference ET is calculated for the 60 days prior to the image date. The ratio is limited to ≥ 0. When the ratio precipitation/reference ET is greater than about 0.2, no addition is needed. Eq. 5 was developed by Allen (unpublished) and tested by Burnett (2007) for Southern Idaho.

Hot pixel candidates are selected among the pixels that meet all the following requirements:

- Lie in the interior of a homogenous field and one that has bare soil, i.e. having no mulch or vegetation residue cover that may impact "skin" temperature
- Have a value of T_s that are within ± 0.2 K of the statistically identified average $T_s + T_{fac}$

Step D: Application of a colorization routine. A colorization routine can be implemented to indicate the relative appropriateness of pixels to select as cold and as hot anchor pixel. An example is shown in Fig. 2, where possible anchor pixels

identified by the statistical procedure are shown in non-black, while rejected pixels are black. Green indicates good/preferred pixels, while red indicates pixels that are unusable or pixels that need to be scrutinized before they are selected.

From the resulting population of suitable cold and hot anchor pixel candidates, a single cold and a single hot pixel is selected by the user, and all attributes of the selected pixels are used during calibration of H. Before selecting the anchor pixels, the user needs to review a possible candidate carefully by e.g. locating the pixel on the Landsat scene for a visual check of the pixel and its surroundings. This visual check is done to avoid selecting pixels located in near field edges, roads feedlots, construction areas, forests and similar non-agricultural settings.

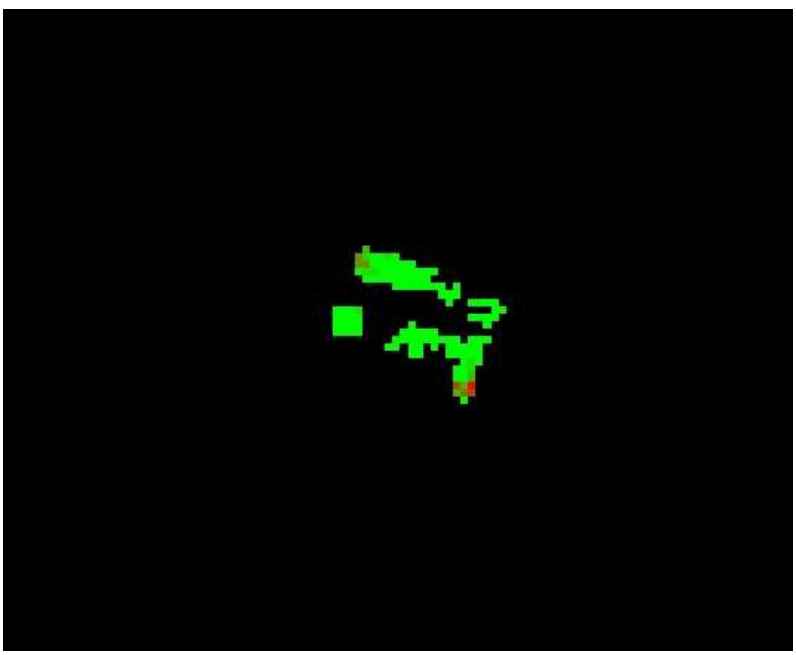

Figure 2. Example of the color scheme used to identify possible anchor pixels. Green indicates good/preferred pixels, while red indicates pixels that are unusable or pixels that need to be scrutinized before they are selected.

The procedures in steps A - D have been implemented into ERDAS Imagine Spatial Modeler as five separate sub-models. The models are summarized in Table 2.

STUDY AREA

The applicability of the automated anchor pixel selection routine was tested using seven Landsat 5 scenes from path 41, row 27, located in NW Montana. The Mission Valley, a basin about 20 km wide and 35 km long dominated by irrigated agriculture and surrounded by mountains, Fig. 1, are located in the center of the image. Weather data quality control and trends for weather data recorded in the basin were described by Kjaersgaard and Allen (2008).

Table 2. Procedures from steps A – D as implemented into ERDAS Imagine Spatial Modeler code.

Model	Input	Output	Description
1	Band 6 from Landsat	Four identical raster maps: Mean, SD, CV and CV15	In model 1 the pixels of the identified AOI are grouped into clumps. Each clump is assigned a unique number, starting from the upper left corner. Before running the model the model window must be set; select Model->Set Window from the menu bar of Spatial Modeler. The subsequent models may abort if the model window is not defined. The dimensions of the "Set Window" can be defined using an inquire box. The area defined in the Window is a rectangle that may include non-agricultural areas and must completely contain the AOI.
2	Maps of NDVI, Mean and SD	Attributes to Mean, SD, CV and CV15	In model 2 the mean, standard deviation and coefficient of variation of NDVI for each clump is calculated and attributed to the rasters created in model 1. A binary map indicating whether the CV in NDVI within each clump is above or below a threshold of 15% is created as the end product.
3	Maps of CV15, NDVI, T_s and albedo. Sun angle is input as scalar	Map of cold pixel candidates (no color)	Candidates for cold anchor pixels are calculated in model 3. The albedo threshold value is calculated using Eq. 4. Prior to processing the window must be set (same as when running model 1) and the AOI created in the preprocessing step invoked.
4	Maps of CV15, NDVI and Ts. T_{fac} is input as scalar	Map of hot pixel candidates (no color)	Candidates for hot anchor pixels are calculated in model 4. The T_{fac} adjustment calculated using Eq. 5 is included in the model. Prior to processing the window must be set (same as when running model 1) and the AOI created in the preprocessing step invoked.
5	Maps of cold and hot pixel candidates (no color)	Maps of cold and hot pixel candidates (in color)	A colorization routine is applied to indicate more or less representative anchor pixel candidates. The user must review these possible candidates and select a pixel located in the interior of a field with relatively homogeneous vegetation.

RESULTS

The typical T_s of the cold anchor pixel suggested by the statistical automated pixel selection system are compared to the T_s of the anchor pixels selected by an experienced METRIC user in Fig. 3. The absolute average deviation is 0.6 K which is slightly lower than the average deviation 0.8 K Burnett (2007) found for 11 images in Southern Idaho. Burnett (2007) estimated the deviation of 0.8 K would result in an error of 1.7 % in the average ET flux for the cold pixel. The good correlation on the first image date, April 13, is promising as there are very few fields at full vegetation cover at this early date.

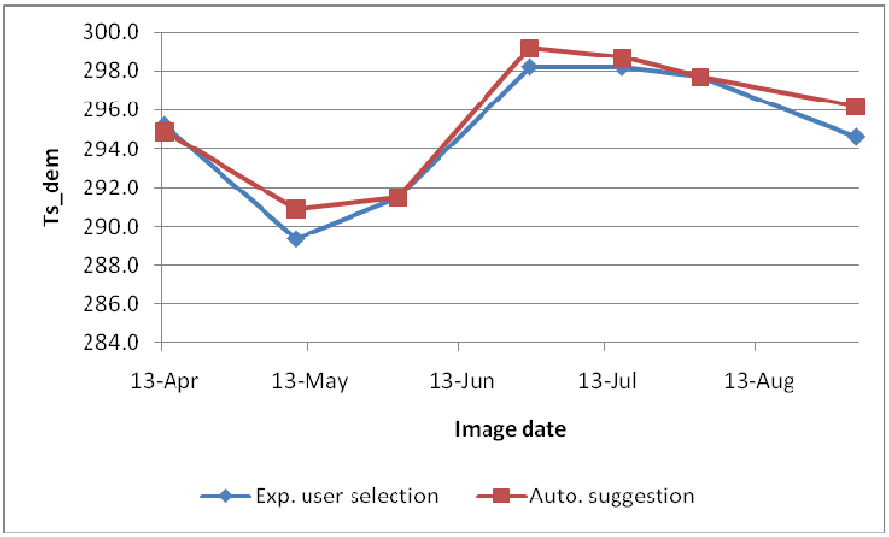

Figure 3. Surface temperature, $T_{s\ dem}$, of the cold anchor pixel selected by an experienced user and that of typical cold pixels candidates selected by the statistical routine.

The typical T_s of the hot anchor pixel suggested by the statistical automated pixel selection system are compared to the T_s of the anchor pixels selected by an experienced METRIC user in Fig. 4. The absolute average deviation is 1.0 K which is lower than the deviation of 2.0 K Burnett (2007) found for 11 images in Southern Idaho. Burnett (2007) estimated the 2.0 K deviation would produce an average error in H around 33 W/m^2 or 7 % of the average ET_r. The ratio of precipitation/reference ET for the 60 days before the image dates was well above 0.2 for all image dates where there is a bias in T_s, so that the $T_{fac} = 0$.

The biggest deviation in T_s between the pixels selected by an experienced user and the automated selection is found for two consecutive image dates in late June and late July. This may, in part, be caused by relatively few fields with no vegetation cover during the middle portion of the growing season. This causes the statistical procedure to include fields that with some vegetation cover, which is relatively colder than bare soil due to evaporative cooling thus biasing the average T_s downward. Further testing will show whether this phenomena is a random error, a systematic error that can be corrected, or is an artifact of an inadequate delineated AOI.

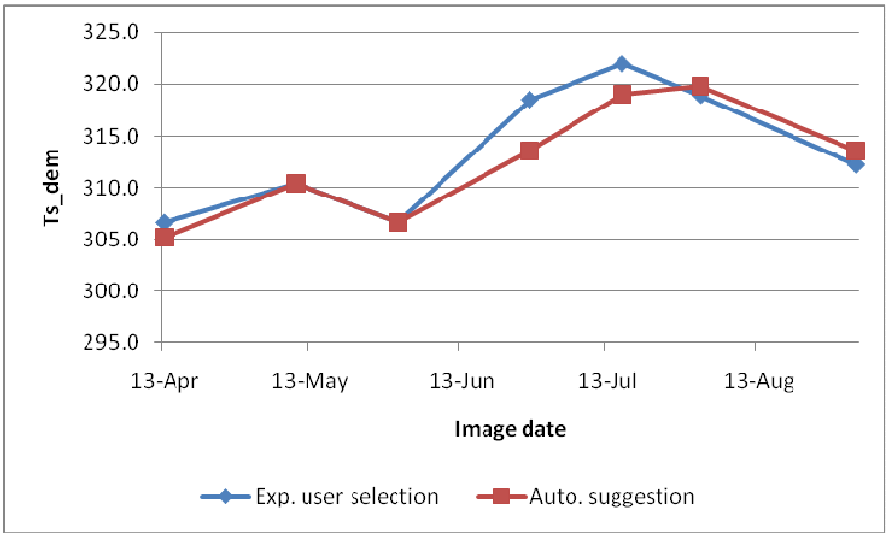

Figure 4. Surface temperature, $T_{s\ dem}$, of the hot anchor pixel selected by an experienced user and that of typical hot pixels candidates selected by the statistical routine.

Abstract

Periodic and accurate estimates of spatially distributed evapotranspiration (ET) are essential for managing water in irrigated regions and in hydrologic modeling. In this study, METRIC (Mapping ET at high Resolutions with Internal Calibration), an energy balance algorithm originally developed for application with Landsat imagery at a regional scale, was applied to very high resolution aircraft imagery (0.5-2 m pixels) in the Texas High Plains. ET predictions were evaluated using data from four large precision weighing lysimeters located in the USDA-ARS Conservation and Production Research Laboratory, Bushland, Texas. Statistical results indicated that METRIC worked better for crops with leaf area index greater than 2.5 m^2 m^{-2}. Potential limitations may have been the areal extent of the imagery, the surface roughness for the momentum transfer sub-model, and the lack of a cold pixel with characteristics similar to the reference crop, i.e. alfalfa.

Introduction

Remote sensing (RS) derived ET maps can potentially be used in the monitoring of spatially distributed crop water use, to schedule irrigations, and as input for hydrologic models. Also, spatially distributed seasonal ET may be used to assess the water use efficiency of irrigation projects. Spatially distributed ET has been estimated using land surface energy balance (EB) models using RS multispectral imagery and ground-based micro-meteorological data. Gowda et al. (2008) and Gowda et al. (2007) present a description and discussion on most of the RS-based EB models available in the literature. Most of these EB models are single source models, e.g. SEBI (Menenti and Choudhury, 1993), SEBAL (Bastiaanssen et al., 1998), SEBS (Su, 2002), METRIC (Allen et al., 2007a), ReSET (Elhaddad and Garcia, 2008).

Of all these algorithms, METRIC may have an advantage under advective conditions. METRIC's ET estimation errors were reported to be approximately 10 to 20% for

daily estimates and as low as 1 to 4% for seasonal ET estimates (Trezza, 2002; Allen et al., 2007b; Chávez et al., 2009) for a semi-arid environment. Therefore, the attributes presented by METRIC make it very attractive for mapping ET in the Southern High Plains (SHP) where advective conditions are regularly encountered. The SHP is a semi-arid region with heterogeneous landscapes in which irrigated fields are surrounded by dryland crops, fallow land, and/or rangeland. Therefore, the advection of hot air from dry surfaces is a significant source of energy that has a major impact on ET from irrigated areas. For example, Tolk et al. (2006) reported an average ET rate of 11.3 mm d^{-1}, measured with a large weighing lysimeter, for irrigated alfalfa in Bushland, Texas, with ET for some days exceeding 15 mm d^{-1} due to regional advection. However, METRIC has not been applied using very high resolution (0.5-2 m pixel) airborne imagery. METRIC was adapted from SEBAL (Surface Energy Balance Algorithm for Land) and was used with satellite imagery, Landsat 5/7, with pixel spatial resolutions in the order of 30-120 m.

In this study, the objectives were: a) to apply METRIC to the advective semi-arid SHP environment, using very high spatial resolution (0.5-2 m pixel) airborne RS imagery and ground-based meteorological data, and b) to evaluate METRIC estimated daily ET values using large precision weighing lysimeters.

Material and Methods

Study Area

This study was conducted at the USDA-ARS Conservation and Production Research Laboratory (CPRL) located in Bushland, Texas. The geographic coordinates of the CPRL are [35º 11' N, 102º 06' W], and its elevation is 1,170 m above mean sea level. Soils in and around Bushland are classified as slowly permeable Pullman clay loam. The major crops in the region are corn, sorghum, winter wheat, and cotton.

Remote Sensing System and Data

The RS system used in this study was the Utah State University (USU) airborne digital multispectral system. The USU RS system acquired high resolution imagery in the visible, near-infrared, and thermal-infrared portions of the electromagnetic spectrum. The USU multispectral system was comprised of three Kodak[1] Megaplus digital frame cameras (Eastman Kodak Company, Rochester, New York) with interference filters centered in the green (Gn) (0.545-0.560 μm), red (R) (0.665-0.680 μm), and near-infrared (NIR) (0.795-0.809 μm) portions of the electromagnetic spectrum. The fourth camera was an Inframetrics 760 (Inframetrics, N. Billerica, MA) thermal-infrared scanner radiometer (8-12 μm) that provides thermal-infrared (TIR) imagery, used to obtain surface radiometric temperature images. The USU airborne digital multispectral system flew at an altitude of about 1,000 m (above

[1] The mention of trade names of commercial products in this article is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the U.S. Department of Agriculture or Colorado State University.

ground level), which resulted in a 0.5 m pixel resolution for the visible and NIR bands and 1.8 m for the TIR band.

Six airborne RS images acquired over the CPRL during the 2007 cropping season, on June 25 (DOY 176), July 3 (DOY 184), July 10 (DOY 191), July 11 (DOY 192), July 26 (DOY 207), and August 11 (233), were used in this study (e.g., Fig. 1). All images were acquired close to 11:30 AM CST, except on DOY 184 in which the image was acquired close to 9:00 AM CST. These images were calibrated and transformed into surface reflectance and temperature images for estimating reflected outgoing shortwave and longwave radiation, respectively, with both components required in the estimation of spatially distributed net radiation.

Radiometric and Atmospheric Calibration of Aircraft Data

The shortwave images were corrected for lens vignetting effects and geometric distortions using procedures similar to those described by Neale and Crowther (1994) and Sundararaman and Neale (1997). The individual R, Gn, and NIR images were registered into three band images and rectified to a digital orthophotoquad base map.

The digital numbers of the rectified multispectral image were converted to radiance using the system calibration method described in Neale and Crowther (1994). These radiances were divided by the incoming solar irradiance to obtain surface spectral reflectance. Solar irradiance in each spectral band was obtained from radiance measurements made concurrently to the flights with an Exotech radiometer placed over a barium sulfate standard reflectance panel with known bidirectional properties (Jackson et al., 1992).

The TIR imagery was rectified to the high-resolution three-band images described above. The digital numbers were transformed into apparent (at sensor or brightness) temperature values using the Inframetrics 760 thermal scanner system calibration bar at the bottom of each image. The surface brightness temperature images were corrected for atmospheric effects considering surface thermal emissivity and using the atmospheric radiative transfer model MODTRAN4 v3 (Berk et al., 2003). These corrections resulted in at-surface radiometric temperatures (T_s).

METRIC Model-based Remote Sensing ET

In METRIC, ET is computed as a residual from the surface EB equation as an instantaneous ET or latent heat flux (LE; Brown and Rosenberg, 1973; and Stone and Horton, 1974), Equation (1).

$$R_n = G + H + LE \tag{1}$$

where R_n is net radiation (W m^{-2}) calculated using T_s, near surface vapor pressure from a near-by weather station (WS), and R_s as explained below. G is soil heat flux (W m^{-2}), and H is sensible heat flux (W m^{-2}). R_n was computed using the following equation:

$$R_n = R_s \downarrow - \alpha R_s \downarrow + R_L \downarrow - R_L \uparrow - (1 - \varepsilon_o) R_L \downarrow \tag{2}$$

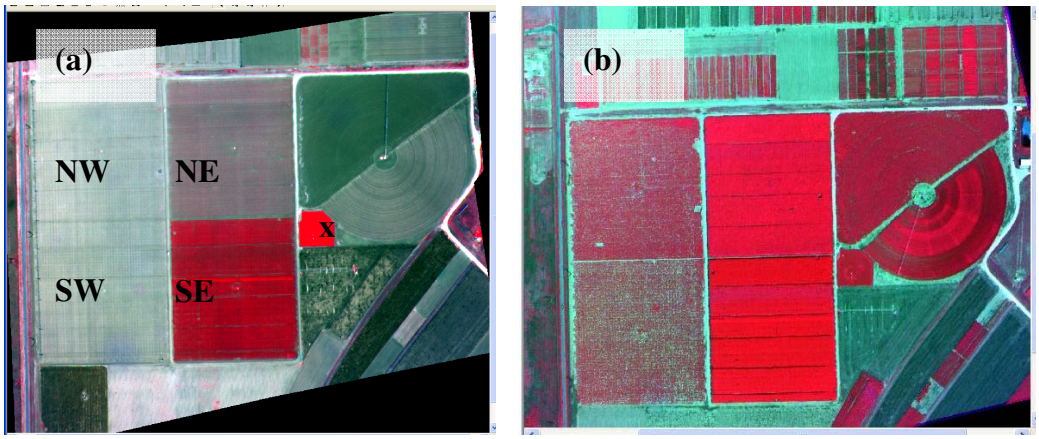

Figure 1. False color (NIR, R, Gn) composite reflectance images for (a) DOY 176 and (b) DOY 223. Lysimeter fields NW, NE, SE, and SW plus the weather station location (x) are shown in image (a) for DOY 176.

where $R_s\downarrow$ is incoming shortwave radiation (W m^{-2}). In this study, $R_s\downarrow$ was not estimated as indicated in Allen et al. (2002, 2007a) but rather measured with a pyranometer (model CMP 6, Kipp and Zonen, Bohemia, NY) installed at the USDA-ARS-CPRL weather station (TXHPET, 2006). Surface albedo, α, was estimated following Brest and Goward (1987). $R_L\downarrow$ is incoming long wave radiation (W m^{-2}) or downward thermal radiation flux originated from the atmosphere, which was estimated using the Stefan-Boltzmann equation and near surface air temperature as well as vapor pressure and sky emissivity. Sky/air/atmospheric thermal emissivity was estimated according to Brutsaert (1975). $R_L\uparrow$ is outgoing long wave radiation (W m^{-2}), a function of T_s and surface thermal emissivity (ε_o, dimensionless). The ε_o term was estimated according to Brunsell and Gillies (2002).

Soil heat flux (G) is a function of R_n, a vegetation index, T_s, and α (Bastiaanssen, 2000):

$$G = ((T_s - 273.15)\,(0.0038+0.0074\,\alpha)\,(1-0.98\,NDVI^4))\,R_n \qquad (3)$$

where NDVI is the Normalized Difference Vegetation Index [(R-NIR)/(R+NIR)], R is reflectance in the red band and NIR is reflectance in the near infrared band.

Sensible heat flux (H) is defined by the bulk aerodynamic resistance equation.

$$H = \rho_a Cp_a \frac{dT}{r_{ah}} \qquad (4)$$

where ρ_a is air density (kg m^{-3}), Cp_a is specific heat of dry air (1004 J kg^{-1} K^{-1}), dT (K) is a function of T_s, ($dT = a + b\,T_s$; Bastiaanssen, 1995) representing a near surface temperature difference between z_1 and z_2, and r_{ah} is aerodynamic resistance (s m^{-1}),

calculated between two near surface heights, z_1 and z_2 (0.1 and 2.0 m) using a wind speed extrapolated from a blending height above the ground surface (200 m) and an iterative stability correction scheme for atmospheric heat transfer based on the Monin-Obhukov stability length scale ($L_{_MO}$, similarity theory; Foken, 2006).

The determination of *a* and *b* (in dT) involves locating a hot (dry) pixel in a fallow agricultural field with large T_s and a cold (wet) pixel with a small T_s (irrigated field) in the RS image. Then, the EB of Equation (1) can be solved for H_{cold} and H_{hot} as $\boldsymbol{H_{cold} = (R_n - G)_{cold} - LE_{cold}}$, and as $\boldsymbol{H_{hot} = (R_n - G)_{hot} - LE_{hot}}$, respectively. H_{hot} and H_{cold} are the sensible heat fluxes for the hot and cold pixels, respectively. The hot pixel is defined as having $LE_{hot} = 0$, which means that all available energy is partitioned to H. In METRIC, the cold pixel is assumed to have an LE value equal to 1.05 times that expected for a tall reference crop (i.e., alfalfa), thus LE_{cold} is set equal to 1.05 ET_r λ_{LE}, where ET_r is the hourly tall reference ET calculated using the standardized ASCE Penman-Monteith equation (ASCE-EWRI, 2005).

The hot pixel was chosen in a fallow agricultural field displaying high temperatures, high albedo and low biomass (low LAI). Thus, with the calculation of H_{hot} and $H_{cold,}$ Equation (4) was inverted to compute dT_{hot} and dT_{cold}. The *a* and *b* coefficients were then determined by fitting a line through the two pairs of values for dT and T_s from the hot and cold pixels. These *a* and *b* values were initial estimates that were used in an iterative stability correction scheme programmed in a Microsoft Excel™ spreadsheet, which after some iterations shows numerical convergence. The *a* and *b* coefficients for each iteration were then exported to a model in ERDAS IMAGINE® (ERDAS, Inc., Norcross, GA) to obtain the final stability corrected H image.

Instantaneous LE image values were obtained using Equation (1) and were converted to hourly ET (ET_i) in mm h^{-1} by dividing LE by λ_{LE} and ρ_w, as follows:

$$ET_i = 3600\ LE\ /\ \{[2.501 - 0.00236\ (T_s - 273.15)]\ (10^6)\ (1.0)\} \quad (5)$$

Reference ET fraction (ET_rF) is the ratio of ET_i to the alfalfa reference ET (ET_r) that is computed from WS data at overpass time (hourly average). Finally, the computation of daily or 24-h ET (ET_d), for each pixel, was performed as:

$$ET_d = ET_rF \times ET_r24 \quad (6)$$

where ET_r24 is the cumulative 24-h ET_r for the day (mm d^{-1}).

Verification of estimated daily ET values

Estimated daily ET values were verified by comparison with measured ET with four large monolithic weighing lysimeters located at the CPRL. The lysimeters (3×3×2.4 m) were situated in the middle of 4.7-ha fields. In 2007, the lysimeter fields, northeast (NE, Fig. 1) was planted to forage sorghum (planted on May 30), the southeast (SE, Fig. 1) was planted to corn (planted on May 17) both for silage production, the

northwest (NW, Fig. 1) was planted to grain sorghum in rows (planted on June 6), while the southwest (SW, Fig. 1) lysimeter field was planted to grain sorghum (planted on June 6) in clumps as part of another ongoing research project. Furthermore, the NE and SE lysimeter fields were irrigated while the NW and SW lysimeter fields were managed under dryland conditions. Each lysimeter field was equipped with one net radiometer [Q*7.1, Radiation and Energy Balance Systems (REBS), Bellevue, WA] and one infra-red thermometer, (Exergen, Watertown, MA) for measuring R_n and surface temperature, respectively.

Errors between estimated and observed ET values were reported as mean bias errors (MBE) and root mean square errors (RMSE). Besides ET, predicted instantaneous net radiation (R_n) was verified with measured data and differences were reported as MBE and RMSE.

Results and Discussion

Net Radiation Estimation

Remote sensing based R_n compared well with observed R_n as shown in Fig. 2. Net radiation was estimated with a small average under prediction error/bias of -17 W m^{-2} (-2.8%) and a RMSE of 48 W m^{-2} (7.9% of the observed mean); which shows a small error spread. Larger under estimation occurred when observed R_n values were larger than 700 W m^{-2} (Fig. 2). The error perhaps was due, in part, by error in the estimation of surface albedo for large biomass (LAI), closed canopy conditions. Nevertheless, it is an overall small error.

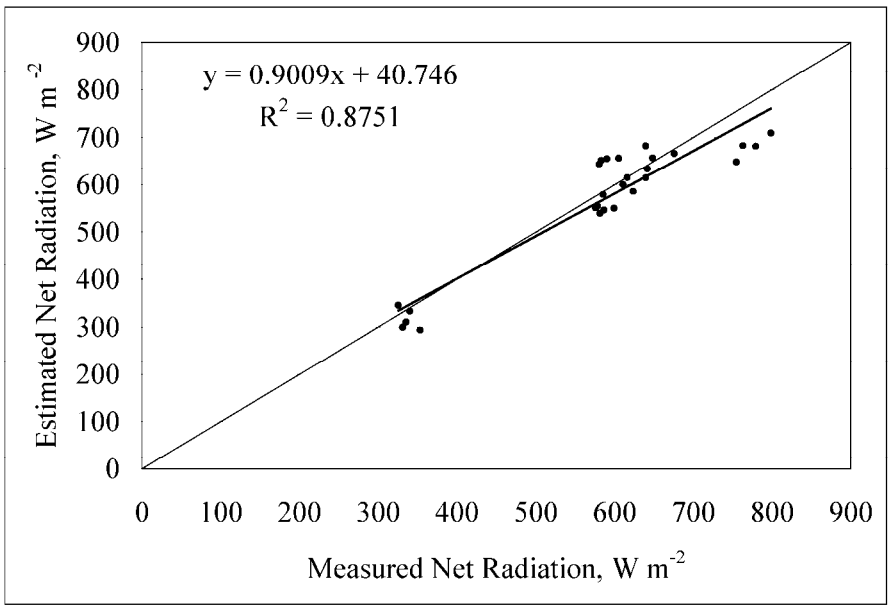

Figure 2. Estimated vs. observed instantaneous net radiation comparison.

Daily ET Estimation

METRIC underestimated daily ET with a MBE of -0.2 mm d^{-1} (-6.9%) and a RMSE of 1.9 mm d^{-1} (-40.1%). Although, Fig. (3) shows that the underestimation occurred on ET values ranging from 2 to 6 mm d^{-1} while an overestimation occurred for measured ET values larger than 6 mm d^{-1}. In part, errors in estimating ET may have been due to errors in locating true hot and cold pixels, i.e. true hot and cold pixels (extreme temperature pixels) may fall outside of the area covered by the aircraft overpasses. The areal extent of the airborne imagery used in this study was approximately 800 m (E-W direction) by 650 m (N-S direction) while a Landsat 5 Thematic Mapper (TM) scene covers an area of 170 km (N-S) by 183 km (E-W).

Errors associated with the selection of the cold pixel in the irrigated grass field of the ARS weather station location could have been another potential source of error. The grass height was kept at about 0.12 m; however, METRIC indicates selecting the cold pixel on a field with crop characteristics (height and LAI) similar to the alfalfa reference crop. This selection was not possible on DOY 176 and 184 because, all other fields covered in the airborne imagery were drier/warmer than the reference WS grass field.

The absolute differences (in %) between estimated and measured ET were plotted versus LAI in Fig. (4). As shown in Fig. (4), most large errors in ET (larger than 40%) occurred at LAI values smaller than 2.5 m^2 m^{-2}. Coincidently, most of these low LAI values showed the largest surface temperature. See Fig. (5). Although, there were some data points showing much cooler temperatures (circle) at low LAI values in Fig. (5). This latter fact may be attributed to an irrigation event (approx. 18 mm, to keep the sorghum alive) on DOY 184 on the NW and SW dryland lysimeter fields, and to a rainfall event on DOY 192 (approx. 15.5 mm) that lowered the temperature of these fields.

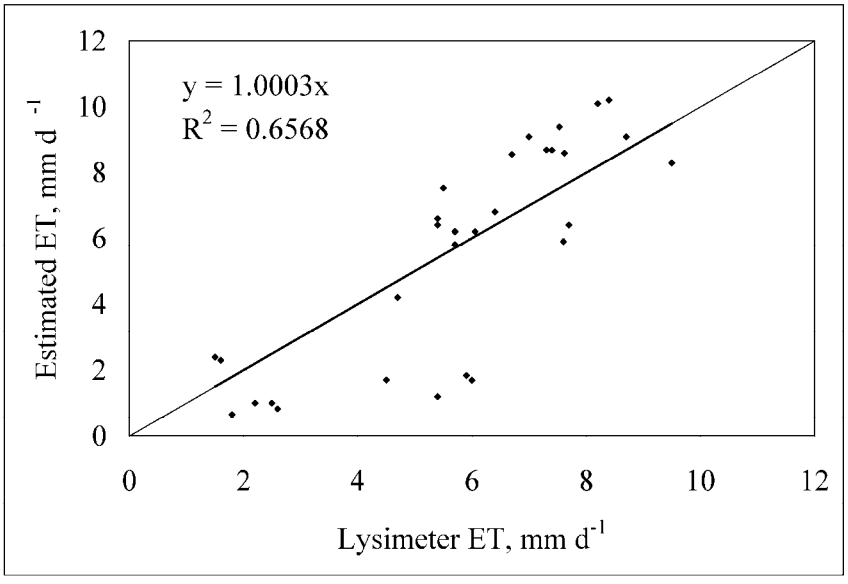

Figure 3. METRIC estimated ET vs. Lysimeter measured ET.

Therefore, the larger ET underestimation (circle in Fig. 4) occurred for LAI values smaller than 2.5 m^2 m^{-2} on DOY 184 and 192 when the sparse sorghum fields were wet. Under these conditions, the estimation of the roughness length for momentum transfer (Z_{om}), friction velocity (u_*), and aerodynamic resistance (r_{ah}) may have been compromised, resulting in errors in the estimation of H_{hot} and hence in ET.

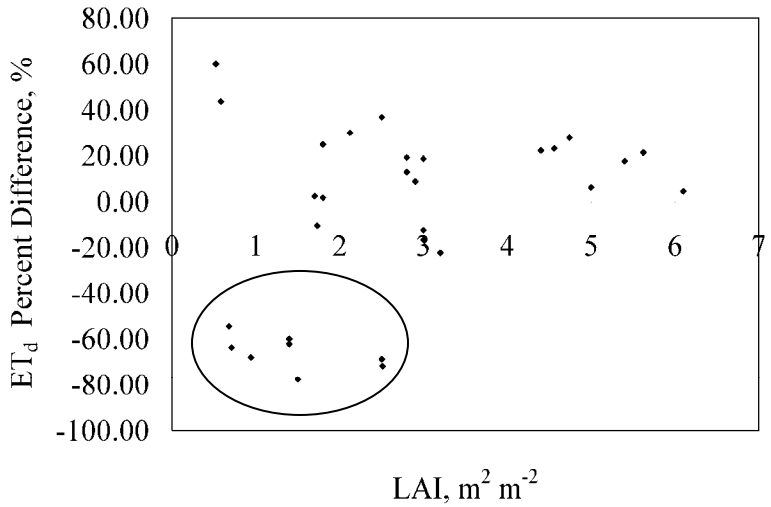

Figure 4. Percent ET error vs. LAI.

METRIC estimated ET with a MBE of 0.6 mm d^{-1} (10.8%) and a RMSE of 1.2 mm d^{-1} (16.5%) when estimated ET values from those fields/crops with LAI smaller than 2.5 m^2 m^{-2} were excluded from the analysis.

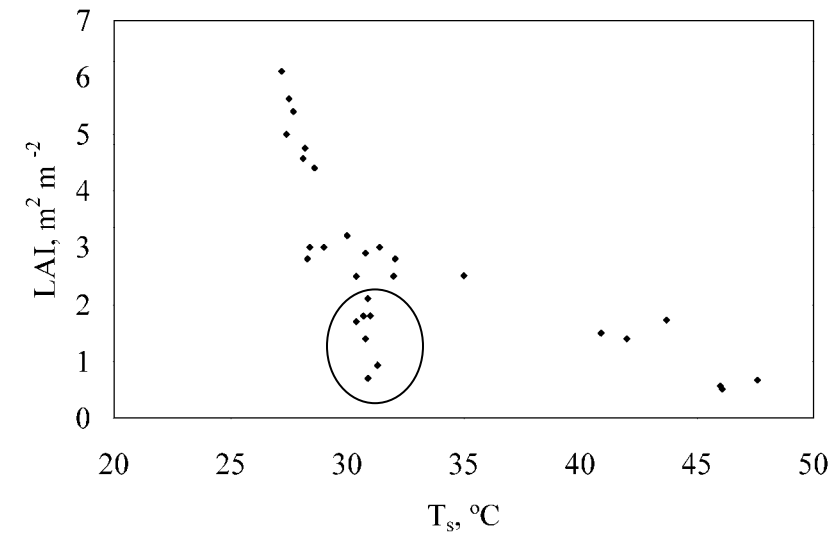

Figure 5. LAI vs. surface temperature (T_s).

Conclusions

METRIC was applied on six airborne RS images acquired over the CPRL during the 2007 cropping season over the semi-arid region of the Southern High Plains. There were large ET underestimation errors for crops with LAI values smaller than 2.5 m^2 m^{-2} under wet surface conditions. Removing ET values under those conditions reduced the error to 10.8±16.5% (an overestimation). It is hypothesized that the roughness length for momentum transfer (Z_{om}), friction velocity (u_*), and aerodynamic resistance (r_{ah}) may have not been well estimated under the conditions described above, resulting in errors in the estimation of H_{hot} and hence in ET. In addition, the areal extent covered by the airborne system may have prevented selecting true extreme cold and hot pixels. Moreover, selecting a cold pixel on a field with crop characteristics different from the alfalfa reference crop may result in a bias scaling of surface temperature in the dT function. Nonetheless, this result is encouraging. It is believed that by improving the Z_{om} sub-model and by enlarging the areal coverage of the airborne RS system, using multiple stitched images (mosaic), it may be possible to further improve the accuracy of ET estimates.

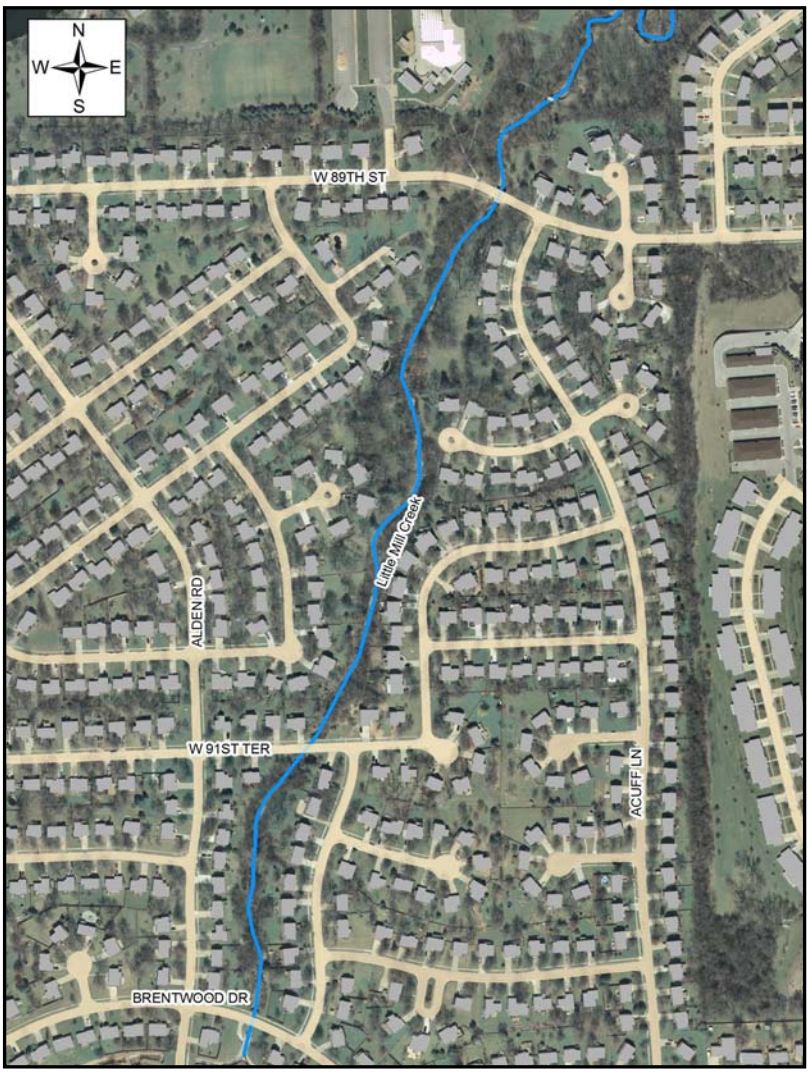
Introduction

The City of Lenexa, Kansas (City) is a growing suburban community located in the Kansas City Metropolitan area. As with many growing communities, the City is regularly faced with various stormwater management challenges, including flooding, erosion, water quality impacts, regulatory requirements, and the ability to finance infrastructure improvements and new programs. To address these challenging issues, the City formed the Rain-to-Recreation Program.



The Rain to Recreation program is a proactive, integrated, watershed based approach to address stormwater quantity and quality. The goals of the program are to reduce flooding, protect water quality and natural habitat, and provide recreational and education opportunities. With the implementation of new development regulations, the City has created greenways and trails while protecting the environment and preserving wildlife. The long-term success of the program relies upon the support of individuals and businesses throughout the community. As such, the City builds community support through environmental education, and working together with local residents. Working together with the community, the program enhances the quality of the natural and built environments, ultimately conserving and even restoring our natural resources.

One of the recent challenges addressed by the City involves the flooding and severe erosion problems along the Brentwood stream, which is located in a fully urbanized residential watershed. The following paragraphs describe the project background and challenges associated with this stream reach.

Project Background

The Brentwood stream reach of Little Mill Creek, like many urban streams, has been a constant source of frustration over the past 20 years with severe bank erosion as well as home and street flooding. The stream reach extends from Brentwood to 87th Street, which migrates between the backyards of approximately 60 residential property owners. As development occurred in the watershed, the stream changed dramatically due to increased stormwater runoff volumes and velocities. This in turn caused street and home flooding along the stream, as well as streambank stability problems that adversely impacted the existing retaining walls, public utilities, and residential property.

The channel is bordered by mature trees, homeowner fences, and landscape features, located along the edge of the streambank. And this lack of open space along the channel for improvements and the desire to minimize property owner impacts was a major challenge during the design process. In addition, a limited number of existing easements exist along the channel, which required easement negotiations with nearly all of the local residents that live along the channel.

Project Location

The City's Rain to Recreation program partnered with the Johnson County Stormwater Management Program to correct the problems along the stream. The agencies retained Camp Dresser & McKee Inc. (CDM) to lead the design team and serve as the prime contractor using a design-build approach. CDM was responsible for the overall technical direction of the project, channel design, roadway improvements, and utility relocation components. Other design partners included Intuition & Logic which provided geomorphology technical support, and Patti Banks Associates, who assisted with the landscape plan and stakeholder involvement activities.

Project Goals and Objectives

The goals of the project were to improve safety, protect citizen's homes and property from flooding, reduce street flooding impacts, protect public utilities and property from damage due to erosion, and restore the stream as a neighborhood amenity. To achieve these goals, the following objectives were considered key components of the project:

- Select durable streambank protection materials to provide a long-term solution to the erosion problems
- Integrate natural features to enhance the aquatic and terrestrial habitat along the stream corridor
- Implement a comprehensive stakeholder involvement process to provide regular communication throughout the entire project

- Restore the stream back to neighborhood amenity

Major Design Elements

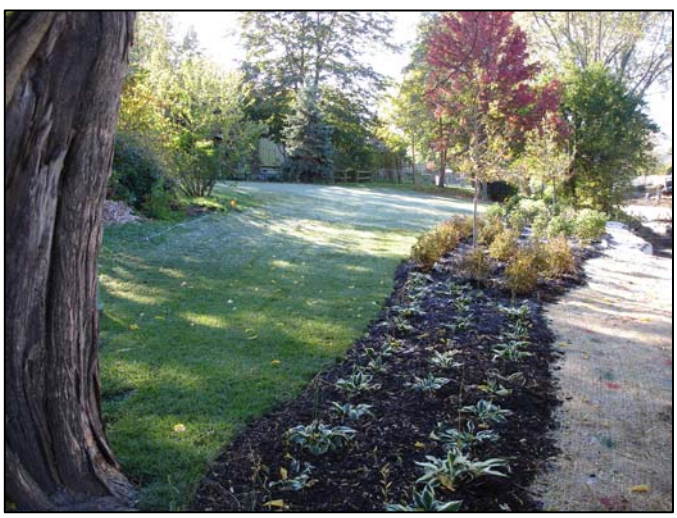
The following is brief discussion on the three major design elements of the project, including the streambank protection, in-stream grade controls, and the stream roadway crossings.

Streambank Protection

As result of the urbanization process, severe bank erosion existed along the majority of the channel. Using the HEC-RAS open channel hydraulic model, the Brentwood stream was evaluated in detail to determine the shear stress and velocity for this stream reach under various flow conditions. The results of this evaluation found that this stream segment is a high energy stream, with average velocities of over 5 feet per second (fps) and local peaks of over 10 fps. In addition, shear stress values average over 2 pounds per square foot (lbs/sq-ft) with localized areas of over 4 lbs/sq-ft. Shear stress is a measure of the erosive forces acting on the channel bed and banks and is a function of velocity and depth in the stream.

Examples of Channel Bank

To solve the erosion problem, the design team evaluated a wide range of armoring systems, including both natural and hard material options. The goal was to select a streambank protection system that would provide long-term stream stability, while providing an environmental benefits and aesthetically pleasing. The design team originally evaluated several options for armoring the lower and upper banks of the stream. Each of the armoring options was evaluated based on their shear stress resistance, and allowable stream velocity.



Bank Armoring Systemes Evaluated

- Coir Toe
- Turf Reinforced Mat (TRM)
- Vegetated Rip-Rap
- Composite Revetment
- Rock Gabions

Due to the high velocities and shear stress values, the lower part of the channel (below the 2-year design flow elevation), was designed with a retaining wall system. As part of the design process, several wall systems were considered, including Keystone™, Redi-Rock™, gabion baskets, and stacked limestone. All of the hard solutions were capable of meeting the design criteria, but each had a different appearance and cost. The Keystone™ wall system was eliminated because of the potential for movement during high stream flows without costly soil reinforcement. Upon the completion of an alternative analysis for the remaining options, the project team selected the Redi-rock wall system for the following reasons:

- Minimal long-term maintenance is required because of the size, mass, and durability of the Redi-Rock™ blocks.
- This system is well suited for steep embankments, which was required at a few specific locations
- Given the wide range of options available for face textures and color treatments, the Redi-Rock™ system provided a wall that is visually pleasing.

Retaining wall, TRM, and landscape transition

In areas where the shear stresses were not as severe, a TRM application with native plantings was installed.

The upper banks were treated with more green solutions. The upper banks had a landscaping TRM fabric with a dense plant cover that blended into the surrounding landscape. The purpose of the fabric and plant zones was to protect the upper banks from erosion, replace plant material that was removed during construction, and to reintroduce native plants to the stream corridor that have deeper roots to help support the streambank. In addition, the upper bank included a landscape transition zone between the stream corridor and the backyards.

In-stream Grade Controls

Another key component of the design was the integration of in-stream grade controls to properly manage the energy of the stream. With the selection of Redi-Rock™ material as the wall system, the project team utilized this same material to design customized in-stream drop structures. The in-stream drop structures reduce the slope along the stream reach which provides a stable bed slope and dissipates hydraulic energy. In addition, the drop structures are shaped to deflect scouring flows away from the streambank, which allows the channel bed and banks to become more stable over time. Prior to the construction effort the bed slopes ranged from 0.8 to 1.2 percent.

Culvert Improvements

This project also included the replacement of box culverts at three stream road crossings, due to insufficient capacity. The new box culverts were enlarged and redesigned to be a "two stage" culvert, also known as conservation culverts. This culvert configuration matches more closely the stream cross-section; with a low flow channel and higher overbank flow. The lower box is utilized to carry the more frequent storm events, while the box culvert placed at the higher elevation is only utilized during larger storm events.

Grade controls and culvert improvements

One of the benefits of this arrangement is that it reduces the amount of sediment and debris accumulation at the crossing. Each of the three street crossings have a rip-rap "stilling basin" downstream to help reduce energy as water exits the culverts.

Delivery Approach

As the design process was nearing completion, the City decided to utilize a design-build approach to expedite the schedule to complete the project. The Design/CM-at-Risk method was used, which provided the City with multiple additional benefits, including:

- An integrated design/construction team which streamlined coordination efforts between all parties.
- Provided an efficient vehicle for risk management
- Single point of responsibility reduced the City's administrative burden

- Discrete work packages maximized competition and provided lower subcontractor bid pricing
- Subcontractors were selected on both qualifications and price to deliver the best value to the City

By using the Design/CM-at-Risk approach, the overall schedule was reduced by 5 months. The time savings were realized by overlapping initial construction phases with final design, and by eliminating the traditional advertising and bidding process that follows the completion of a traditional design-bid-build approach. In addition, the construction professionals were involved early in the process to identify critical path portions of the project. Also, the constructability reviews focused on ease of construction and sequencing, which further accelerated the schedule and reduced the potential for delays.

Environmental Protection Measures

One of the main drivers for this project was to stabilize the existing channel by reducing the streambank erosion. However, to improve the channel it was necessary to remove existing vegetation and excavate in and around the stream. Therefore, steps were taking during the construction to limit impacts to the environment. Environmental considerations included special steps taken to preserve and protect the environment, wildlife, and habitat during the construction phase.

The biggest environmental challenge was sediment control. Sediment control measures included phasing the construction, maintaining "rock checks" that were inspected and maintained on a nearly daily basis. As areas were completed, the checks were removed or relocated. Streets were also swept in the evening after work activities. The other environmental issue was migratory bird habitat. Construction along the stream required the removal of several trees which had the potential for disturbing the nests of migratory birds. Removal of trees was completed prior to bird migration season which in Kansas was April 1.

Stakeholder Involvement

A comprehensive stakeholder involvement process was used to provide a forum for residents to voice their concerns about the project, and to be actively involved during the study, design and construction process. This required a fully integrated stakeholder involvement process which began during the study phase, and was intertwined throughout the design and construction process, through to the final ribbon cutting ceremony. Other community relation activities that were very important to this project and intertwined with the project are described below.

Neighborhood Meetings

The stakeholder involvement process began with local residents coming together for a series of three public meetings during the study phase. The first meeting was held to listen to the residents concerns and issues, which included:

- Regular flooding of homes, yards, and streets
- Streambank erosion that was impacting private property
- A strong desire for the corridor to remain as natural as possible
- The desire to protect the mature trees, landscape plantings and back yard amenities

The second and third meetings where held to obtain feedback on the proposed design concepts and anticipated project schedule. The messages consistently voiced by residents included the concern over losing their privacy and uniqueness of their backyards, and the preference to use materials that blended with the neighborhood to provide a natural appearance. The results of these three project meetings helped the CDM team understand the neighborhood issues which helped get the design phase off to a fast start.

During the design phase, two additional neighborhoods meetings were held to present the design details and to obtain the required easements necessary to construct the project. With nearly 60 property owners impacted by the project, securing the necessary easements in a timely manner was a major concern of the project team. To overcome this obstacle, easement specialists were present at the neighborhood meetings, to provide one-on-one consultation with the property owners to answer questions, and to review the necessary legal documents. This process proved to be very successful, which resulted in securing the majority of the easements, thus allowing the project to remain on schedule.

Results

The Brentwood Stream Restoration Project resulted in a final product that reduced flooding problems, addressed the severe erosion, integrated natural features to provide environmental benefits, and achieved stakeholder acceptance. As such, the project produced a sustainable solution that met the triple bottom line concept of economics, environmental, and social benefits.

Economics

This channel improvement project needed to meet the City's available budget and schedule. Therefore, the construction materials and delivery methods were evaluated to provide cost effective solutions that could be efficiently delivered. Using a Design/CM-at-Risk delivery method, the construction schedule was reduced by 5-months, while the selected materials matched the design requirements; which resulted in a project that completed under budget.

Environmental

One of the critical goals of this project was to improve the stream, by reducing the erosion of the banks and channel bottom, which would result in significantly improving improve water quality downstream. Using both engineered hard materials combined with green features, the

constructed solution provides a sustainable stream that meets the goals and objectives of the project.

Social

Streams tie neighborhoods together. The City is committed to the Rain to Recreation Program which uses stormwater challenges as an opportunity to enhance neighborhoods. For this project, the Brentwood stream corridor was transformed into a neighborhood amenity, and was fully embraced by the neighborhood. Throughout the project, the community was actively involved which resulted in project ownership. In essence, this was the biggest success of this project. As demonstrated by the enthusiasm during ribbon-cutting ceremony (insert graphic), the entire neighborhood community embraced the success of the project, which demonstrates the power of public and private partnerships working together for a common good.

ABSTRACT

The Kickapoo Water Intake Structure on the Delaware River is located on the Kickapoo Reservation in southern Brown County, Kansas, approximately 6 miles west of Horton, Kansas, and ½ mile south of Kansas 20. It is in section 32 of Township 4 South, Range 16 East. This paper addresses bank instability problems in the vicinity of a water intake structure owned/operated/maintained by the Kickapoo Tribe of Kansas. Eroding left and right banks around the concrete weir structure have undergone previous attempts at stabilization. Previous repairs have not performed successfully. Erosion has continued, both in the area that had been protected by previous revetments immediately downstream of the weir, and along both banks for approximately 200 feet farther downstream. Bank erosion continues to threaten the stability of the structure, water supply lines, and the access road to the site. The purpose of this paper is to assess the instability problems, provide and compare conceptual alternatives with respect to feasibility, and make a recommendation as to the preferred alternative to accomplish the repairs.

BACKGROUND INFORMATION

Intake Structure. The construction of the intake structure and weir dates to 1978; they were built as part of a water system construction project that included water lines, treatment facilities, a pump station, and the weir structure. The weir is located approximately in the middle of the straight channel reach. The construction plans showed the following elements:

- A concrete lined trapezoidal channel section 130-ft wide and 20-ft long, including 5-ft wide horizontal concrete slabs at the top of banks, concrete side slopes with a ratio of 2 horizontal to 1 vertical, and a concrete invert varying from 36 to 32-ft wide. The top portion of the slopes, and the adjacent slabs, are 12-in thick concrete; the lower portion of the slopes, and the invert, are 18-in thick. The tops of the slopes are shown at elevation 1005; the weir elevation is 990; the flowline at the upstream end of the invert is 984.
- A 6-ft high concrete weir located at the upstream face of the concrete channel section, with two 4-ft wide stop log slots in the center. The stop log slots are buttressed with triangular concrete supports.
- A continuous sheet pile cut-off wall located along the full width of the upstream face of the structure, plus an additional 20-ft to each side. The portions of the

sheet pile cut-off wall outside the limits of the paved channel section have a 4-ft high concrete cap wall. The sheet pile is shown extending a minimum of 30-ft below the sides of the paved channel section, and approximately 3-ft into shale, to elevation 958.

- A concrete cut-off wall along the downstream edge and top sides of the structure, extending 4-ft below the paved slopes, adjacent top slabs, and invert. The center portion of the concrete cutoff wall is shown as supported by timber or H-piles on 7-ft centers. The piles were to extend to elevation 953 or refusal.
- Two 8-in cast iron pipe intakes, on the upstream face of the weir, at elevations 985.33 and 987.66.
- A 2-ft layer of riprap, on a 6-in layer of bedding, extending 20-ft downstream of the channel paving and 25-ft past the top of banks (the entire width of the sheet pile cutoff wall). The riprap was to be placed flush with the surface of the structure; the downstream edge is shown as vertical, flush with the adjacent ground surface.

The plans did not show riprap or any other slope protection along the upstream face of the structure. The plans showed areas of grading disturbance adjacent to the structure significantly greater in extent than the coverage of the riprap. No information on riprap gradation was found in the plans; presumably it was defined by construction specifications. The plans showed a boring log for the structure site: it indicated a top layer consisting of 4½-ft of loose clayey silt, underlain by approximately 38-ft of silty clays and clayey silts, then by shale. The top of shale was shown at elevation 961.8.

Aerial Photographs. The Delaware River in the project reach appears to be a relatively recent, manmade channel. The 1954 aerial photo from the 1960 Brown County Soil Survey Report appeared to show the river channel not at the current location; rather it followed a meander to the north. The 1957 United States Geological Survey (USGS) map showed a new channel cut through the southern extent of the meander and running west to east generally straight for some 1000-ft.

Subsequent aerial photos dated 1981 and 1991 showed the river channel in the current location with the intake structure and weir in place. Both photos depicted the straight channel having some vegetation and trees on and adjacent to the bank. The 1981 aerial appeared to show the riprap indicated on the original plans; on the right bank and toe, that riprap seemed to be missing in the 1991 aerial photo. It was indeterminate whether riprap remained on the left bank in that picture. Two sandbars appeared on the 1991 aerial photo that were not evident on the 1981 image. The 1991 aerial photo showed a large bar deposit in the middle of the channel downstream of the structure. There also appeared to be a deposit of material along the left toe, just downstream of the original riprap location.

Site Inspection Photographs. The Corps of Engineers (COE) provided inspection photographs from several dates: June 24, 1987; June 30, 1993; November 9, 1993; and June 21, 1995. There was little or no rock protection remaining on the right bank slope downstream of the structure in the 1987, 1993 and 1995 photographs. It appeared that the rock was washed away leaving a near vertical, bare soil slope. There was a visible

washout beneath the right bank concrete sill/cutoff wall on the downstream side, which progressively worsened throughout the period covered by the 1987 to 1995 photographs.

Immediately upstream of the structure on the left side there was visible bank erosion in photographs prior to the 1996-1997 construction. For a few hundred feet upstream of the erosion adjacent to the weir structure, the photographs showed that the banks were generally vegetated down to the low flow channel. The photographs (1987 through 1999) consistently showed a steep, bare soil bank on the right bank at the outside of the first channel bend upstream of the structure. The appearance and apparent extent of that steep soil bank did not change much through the period covered by the pictures.

The progression of photographs did not as thoroughly cover the left bank downstream of the structure, but it generally appears that there was some rock slope protection covering the majority of the slope, with exposed soil areas visible near the structure. The pre-project (1996-1997 construction) rock protection appeared loose and not interlocked, had an irregular surface, and consisted of many long, flat rocks. Scattered tall weeds throughout the surface indicated the rock protection was probably thin. A June 1995 picture showed four square concrete slabs with manhole rings in the middle on the left slope downstream from the weir. Approximately 200-ft downstream of the structure, the succession of photographs showed a large sand/gravel bar situated in the middle of the channel. It appeared to be progressing downstream over time.

Previous Repairs. Repairs had been reportedly performed more than once, prior to the original (1996-1997) construction of the bank revetments. This is evidenced by 1987 photographs showing riprap on slopes downstream of what was included in original construction plans, and by some riprap that appeared on 1995 photographs of the right bank just downstream of the structure, where bare soil existed in 1993 photographs. The original streambank stabilization construction plans and documents were prepared in 1994-1995 and construction occurred in late 1996 and early 1997.

The stabilization efforts attempted to restore protection to the eroded downstream side slopes and channel bottom and add slope protection to the upstream slopes near the structure by placing a 3-ft minimum depth of rock stone revetment on 2:1 slopes with thickened toes. The stone protection extended for some 45-ft upstream to approximately 75-ft downstream of the structure, with 25-ft long transitions to existing at both ends. The irregular bank surface below the 3-ft revetment depth was to be filled with stone or concrete rubble. A 2-ft thickness of stone was placed on the bottom of the channel for a distance of 25-ft downstream of the intake. A washed-out area under the concrete sill/cut-off wall along the right side of the downstream edge of the structure was filled with gravel. Subsequent high flows in the channel, since the repairs, have caused damage to the rock slope protection.

Weir Raise. To remedy water supply shortages experienced during dry weather, the Kickapoo Tribe constructed a 2-ft temporary weir raise in July of 2000, but it collapsed within a month of construction. The supplementary structure was constructed of steel channels anchored to the existing concrete weir and removable wooden stoplogs.

In May of 2001 another 2-ft temporary weir raise constructed, this time designed and funded by the Bureau of Reclamation. The supplementary structure was constructed of welded steel channels and plates anchored to the existing concrete weir and removable wooden stoplogs. Plans for this raise stated that the stoplogs are to be removed during expected high flows and over winter months. Also, this weir raise was expected to be temporary, lasting only until an alternate water source could be implemented. During subsequent flood events (notably the May 2007 event), this raise suffered significant damaged and is no longer functional. The Federal Emergency Management Agency (FEMA) is currently in the process of replacing the structure.

ANALYSIS OF THE STREAMBANK EROSION PROBLEM

Flow Conditions. The erosion, bank instabilities, and riprap displacement that have occurred since the construction of the intake structure are mainly the result of the impact of the structure on flow conditions in that river reach. Velocity fluctuations that occur at the weir and paved channel section result in flow turbulence. The observed downstream erosion patterns, both in the riprap that was installed in 1996-1997 and in the left and right bank erosion areas, are likely the result of the flow turbulence. Prior experience with turbulent flow conditions at other sites has been that larger riprap than normally required is necessary for calculated velocities. A type of stilling basin has formed immediately downstream of the structure, consisting of a hole in the channel bottom and deposits of stone formerly located in riprap revetments on the channel sideslopes. For some discharges, there are probably secondary hydraulic impacts downstream of this stilling basin. Hydraulic analysis indicates the potential for a hydraulic jump occurring in the channel downstream of the structure; if this actually occurs, the resulting forces and turbulence may be beyond what any reasonable riprap gradation can withstand. The turbulent flow conditions and the stilling basin formation suggested that analysis should be performed using the COE Waterways Experimental Station (WES) Hydraulic Design Criteria 712-1.

Materials. It had been reported that much of the stone in the three-foot thick riprap layer installed in the previous stabilization project had been 6 to 8-inch stone. At the site investigations for this study, most of the stone remaining in place was estimated to be 4 inches to 6 inches in largest dimension. The specifications for the previous project apparently allowed shot rock, and the stone delivered and installed at the site was apparently too small to be stable for the velocities and turbulence that can occur.

The riprap installed upstream of the weir in the prior stabiliztion project is adequate in size, according to preliminary hydraulic analysis and preliminary Riprap15 results.

Photographs and observations of remnants of previous repairs were inconclusive. The material appeared to have been larger, but gradations may not have provided enough range of size to allow fully effective interlocking. The riprap installed with the original construction of the structure did not extend upstream of the structure, therefore providing

no protection for the acceleration of flow towards the weir. The original riprap also only extended 20 feet downstream of the weir, an inadequate distance for the increased velocities and turbulence resulting from the structure.

Geotechnical. Based on a review of available boring logs, the shale bedrock encountered at about elevation 960 is covered by a thick alluvial deposit of clay and silt with a few sand seams. The near-surface soils (those above about elevation 1000) are described on the National Resource Conservation Service (NRCS) soil survey as Kennebec silt loam, a moderately well drained material formed in the floodplain. These soils are considered susceptible to erosion, particularly the silty portions.

During the site visits described in this report, no scarps or other indicators of deep-seated slope instability were observed along the river banks upstream and downstream of the weir structure. Some of the remaining riprap from previous repairs was found to be highly friable, likely as a result of weathering. Downstream of the weir, bank instability is apparent with the observed vertical slopes and sloughing that is actively widening the channel on both sides. On the other hand, a vertical slope on the right bank upstream of the weir has not significantly sloughed for several years.

During site visits, the team did not observe any evidence of near surface slides on riprap covered 2(h):1(v) slopes, but this could be because subsequent or concurrent erosion removed slumped materials and other evidence.

Conclusions. It appears that energy dissipation downstream of the intake structure was not addressed by the original design. The original design also apparently did not consider the upstream effects of the acceleration of flow towards the weir. The riprap stone installed downstream of the structure in the initial stabilization work was too small for the velocities and turbulence that occur downstream of the intake structure. Stone installed previous to 1996 may have been of poor gradation that did not allow adequate interlocking of stones. The riprap stone installed upstream of the structure in the initial stabilization work appears to be adequate.

A hydraulic jump may occur in the channel downstream of the structure for a limited range of discharges. Occurrence of a hydraulic jump would have heavily damaged any of the previous revetments.

SITE HYDROLOGY AND HYDRAULICS

Discharges. The Delaware River has a drainage area of approximately 135 square miles at the project site. A USGS recording stream gage is located 14 miles downstream, near Muscotah, Kansas. The gage has been in operation since 1970. The drainage area at the gage is 431 square miles. The COE computer program HEC-FFA was used to determine expected probability discharges at the gage. Those discharges were then adjusted for the drainage area at the project site. Regression equations as developed for the state of Kansas by the USGS were also used to estimate discharges for various frequencies.

The table below shows the results of the hydrologic calculations for discharges at the project site.

Exceedance Probability	Return Frequency	Gage Analysis	USGS Regression
50%	2-Year	5,330 cfs	5,980 cfs
20%	5-Year	7,980 cfs	10,400 cfs
10%	10-Year	9,830 cfs	15,700 cfs
2%	50-Year	14,100 cfs	28,200 cfs

Normally, the results of gage analyses match regression results more closely. The procedure followed to adjust for the difference in drainage areas between the USGS gage site and the project location may have caused underestimation of the discharges at the intake structure. For expected discharges at the study site, the results of the regression analysis are assumed to be more accurate. Also, it was reported in 2001 by Bill Allen of the Kickapoo Environmental Office that a 2-in rain would cause the channel to flow half to two thirds full, and that bank-full conditions would result from 4 to 5-in of rain. This, in conjunction with the channel capacity calculations described in the following paragraph, supports the higher discharge results (by indicating that bank-full events are not extremely rare).

Hydraulic Modeling. To assess the flow conditions at the intake structure for a wide range of flow conditions, a HEC-RAS model was developed from the geometric information available from surveys. The model extended from about 4,400-ft downstream of the structure to 400-ft upstream. A wide range of discharges was analyzed (100 cfs to 16,000 cfs), and the model was run for mixed flow conditions, starting at both ends from an average channel slope determined from the USGS map. The hydraulics of the river was analyzed for different scenarios, as well as for sensitivity to varied conditions. The n-values were originally assigned relatively low values, for conservatism in hydraulic conditions, because higher downstream velocities would lessen the tailwater depth and increase the possibility for the occurrence of a hydraulic jump. As a result of photographs and field observations of significant flow events, a calibration exercise was performed that increased the n-values.

Results of the Hydraulic Analysis. The weir raise conditions should not have a significant effect on the proposed protection, although the plunge pool design was based on the long term existing plunge pool configuration. HNTB's analysis of the weir raise indicates that the proposed streambank stabilization design (designed for the pre-weir raise condition) will also provide adequate protection for the 2-ft raise as shown in the Bureau of Reclamation plans (RFQ NO. 01SQ600089). This analysis is based on all stoplogs in-place at an equal elevation across the structure. Weir raise effects become unpredictable if weir raise stoplogs are out of place, debris

accumulates on the weir, or other undesirable situations (such as an ice jam) arise that cause non-uniform flow patterns across the weir raise. Sustained non-uniform flow has the capability to jeopardize the function and integrity of the proposed stabilization protection. For this reason, proper flow conditions across the weir raise need to be monitored and maintained by water plant personnel as part of ongoing plant operations.

The true size of the existing plunge pool is likely heavily dependent on the major and abrupt drop from the end of the concrete section to the adjacent downstream channel, once the channel slopes have eroded. This has been the predominant condition for many years at the site, except for brief periods subsequent to previous repairs. This abrupt drop will not exist after construction of the proposed bank stabilization project. The impact of the weir raise on the size of the plunge pool is expected to be more than counter-balanced by the elimination of the abrupt drop at the end of the structure.

CONCEPT DESIGN ALTERNATIVES

In order to meet the goals of an emergency streambank stabilization project at this site, five (5) alternatives were considered. Exhibits showing a schematic drawing for each alternative can be found in the Golden Eagle Feasibility Analysis dated May 29, 2008. Typical sections for the various improvements discussed can also be found in Exhibit 9 of the Feasibility Assessment.

Alternative 1 Riprap Stilling Basin, LPSTP (Longitudinal Peaked Stone Toe Protection), and Slope Revetment (Page 11)

The first 60-ft downstream of the weir would be protected by a 54-in thick large diameter rock blanket. It would match the geometry of the downstream section of the concrete drop structure, with a top elevation of 1004.00 and 2:1 sloping sides. On the left bank, a 90-ft slope revetment transitioning from full bank height (elevation 1004.00) upstream to half bank height (elevation 995.00) downstream would be installed. It would have a thickness of 24-in on the 2:1 side slope. The first 40-ft of slope revetment would be supported at the bottom with a toe blanket and the remaining 50-ft would be supported with an incised section of toe rock. This incised toe would be an inverted trapezoidal section, 36-in thick with a 10-ft flat bottom. The 48-in thick toe blanket would provide toe support for the left bank slope revetment and protect the channel bottom from the transition out of the large riprap blanket plunge pool.

LPSTP would be placed along both the left and right banks. The left bank protection would match the end of the slope revetment on the upstream end with a top elevation of 995.00 and a 2:1 riverward side slope and will have a 1.5:1 landward side slope. It would transition for the first 60-ft in length, down to top elevation 992.00 and a 1.5:1 riverward side slope. The LPSTP would continue downstream for 120-ft on a linear alignment, where it would tie into the existing bank. The right bank would have a combination of slope revetment and LPSTP protection. It would match the end of the

large riprap blanket on the upstream end with a top elevation of 995.00 and a 2:1 riverward side slope and would have a 1.5:1 landward side slope. It would transition for the first 40-ft in length, down to top elevation 992.00 and a 1.5:1 riverward side slope. The LPSTP would continue downstream for 195-ft with a linear alignment, where it would tie into the existing bank. Overall, the left bank protection would extend 30-ft further downstream than the right bank protection.

Within the protective works area, the channel would be graded to a flat flowline elevation of 985.00, with the exception of the invert within the large riprap blanket plunge pool. Downstream of the proposed protective works for a length of approximately 200-ft, the existing channel has dual thalwegs and an island accretion of rocky material. The excess material in the center of the channel would be moved toward the split channels near the left and right banks, and graded to drain toward the center and downstream in the channel to an elevation of 984.50 at its terminus.

Alternative 2 Concrete Stilling Basin, LPSTP, and Slope Revetment
The stilling basin in this alternative would have the first 45-ft downstream of the weir protected by a concrete stilling basin with 11-foot high walls instead of the riprap stilling basin. The other features of this alternative are identical to Alternative 1.

Alternative 3 Sheet Pile Stilling Basin, LPSTP, and Slope Revetment
The stilling basin in this alternative would have the first 45-ft downstream of the weir protected by an 11-foot high sheet pile stilling basin with a concrete lined bottom instead of the riprap stilling basin. The other features of this alternative are identical to Alternative 1.

Alternative 4 Sheet Pile Wall
Another alternative that was further assessed subsequent to detailed hydraulic analysis was the usage of sheet piling. For this variation, riprap revetments would not be used for armoring the presently unprotected eroding banks. The sheet piling would be driven along the downstream edge of the intake structure (existing sheet pile only provides formwork for grout work and protection for interface between grout and soil) and down the left bank to protect the waterline. There would also be some sheet pile driven for a short distance down the right bank to prevent the existing concrete weir from being flanked. The scour hole would remain as is and the stream would be left to run its natural course. The scour hole would be allowed to expand, to serve as an energy dissipater.

Alternative 5 Riprap Stilling Basin with Stabilized Slopes
The soils behind the large riprap blanket and the slope revetment would be stabilized to provide slopes that satisfy criteria specified in EM 1110-2-1913. Horizontal layers of geogrid reinforcement vertically spaced at 4-ft are proposed. The geogrid would be embedded in 12-in layers of sand (6-in above and 6-in below). The remaining 3-ft of material between sand layers would be soil fill from the site. Filter fabric wrapped around the riverward face of these 3-ft layers would prevent migration of fines into the gravel bedding layer below the riprap. The top elevation of the stabilized slopes

would match the top of the faced rock protection. A rock layer would be placed below the soil, sand and geogrid stabilization. The displaced existing riprap on the site would be recovered for this rock layer. The bottom of this rock layer would be at elevation 980.00 for the large riprap blanket and slope revetment with toe blanket, and elevation 981.00 for the slope revetment with incised toe.

CONCLUSIONS AND RECOMMENDATIONS

Protection of the site is technically and economically feasible. The first priority is to protect the water line and intake structure. The second priority is to stabilize the left bank downstream, to protect the access road. The third priority, while not required by the project, is to stabilize the right bank downstream in order to help control flow conditions at the intake structure. Protection on the right bank would help prevent an asymmetrical scour hole and potential flanking of the weir structure, so it is felt to be important.

A "No Action" alternative would likely result in eventual damage to the structure and require its complete replacement, as it is not believed that the piling at the structure would be adequate for its support if most of the underlying soil washes out. Replacing the structure is a viable alternative, especially if the new structure incorporated an energy dissipater; however, replacement would be far more expensive than stabilizing the downstream channel.

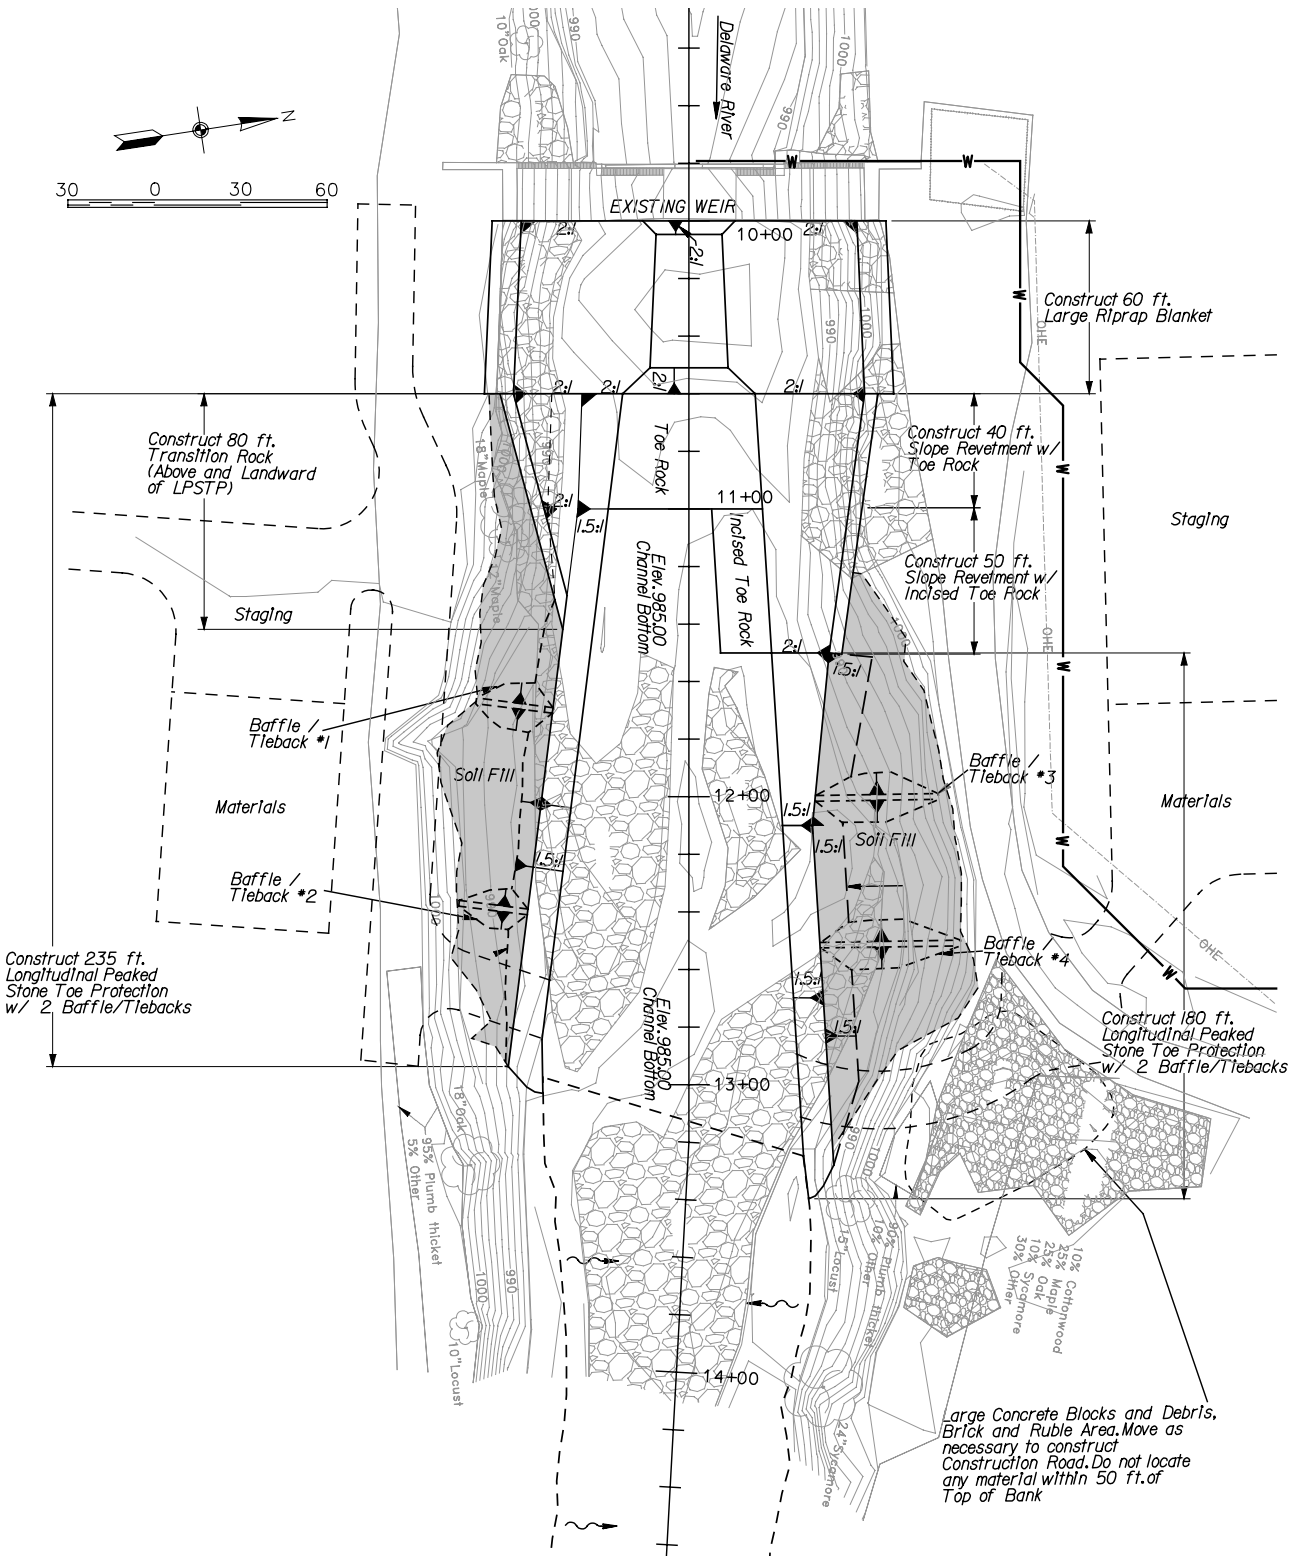
Biostabilization techniques were determined not to be a feasible option for this project based upon the turbulent flow conditions and excessive velocities through the proposed stabilization area. In addition, the scour hole that is already present needs to be addressed by the chosen solution.

The hydraulic analysis shows that unstable conditions (potential hydraulic jump) may exist downstream of the weir due to the abrupt drop from the end of the concrete section to the adjacent downstream channel. All alternatives except Alternative 4 address this issue. The sheet pile wall protects the road and water line, but it does nothing for the existing scour hole or erosion elsewhere. Alternative 4 is also significantly more expensive than the other alternatives.

Alternatives 2 and 3 could have safety issues because the sheetpile or concrete will leave high vertical walls. As people have been known to fish the area, safety measures such as railing and/or barriers would be needed at a minimum. That cost is not currently included in the estimates, which already show higher costs than Alternatives 1 and 5.

The geotechnical investigation performed in 2000 included slope stability analysis. Results indicated that the slope stabilization measures described in Alternative 5 are needed to meet the design criteria specified in EM 1110-2-1913 for levee slopes. Because (1) site observations to date have found no evidence of deep slides and (2) the consequences of a bank failure downstream of the intake weir are not commensurate with failure of a levee, the additional costs associated with Alternative 5 do not appear to be warranted.

Alternative 1 is the recommended solution for the site. This riprap stilling basin, along with the LPSTP and slope revetment meets all of the priorities of the proposed project and is the most economical.



SOURCES OF INFORMATION

Aerial photographs were acquired from the NRCS Brown County Field Office in Hiawatha, Kansas. Plans for the intake structure, previous site inspection photographs, and the 1995 bank stabilization plans were provided by the Kansas City District (KCD) COE.

The following is a list of the information used for this paper:

- USGS Horton NW Quadrangle, 1:24,000 (based on 1957 aerial photography).

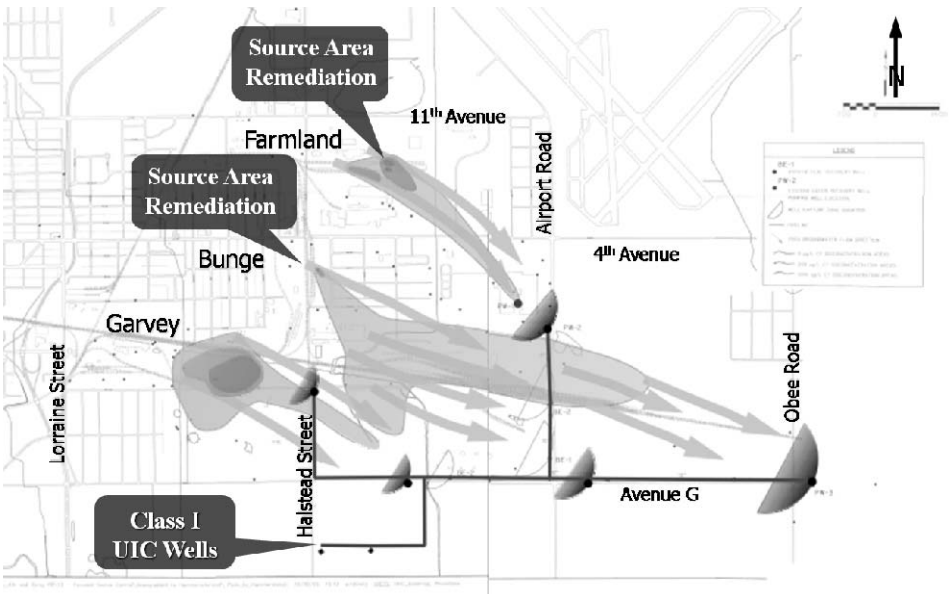
Abstract

In the early 1980s, the 4th and Carey groundwater contamination site was discovered when the U.S. Environmental Protection Agency (EPA) began testing public water supply wells. A city of Hutchinson well located at the intersection of 4th Avenue and Carey Street was found to be contaminated with volatile organic compounds (VOCs). The groundwater contamination findings issued as a result of EPA and Kansas Department of Health and Environment (KDHE) investigations led to the establishment of the 4th and Carey Site. Strong proactive efforts by the city and local industry leaders prevented the site from being placed on EPA's National Priority List (NPL, or Superfund). The city signed a consent agreement with KDHE in 1994, assuming responsibility to clean up the site. At that time, the city contracted with CDM for remedial assistance. Impacts by high chloride levels in groundwater areas to be treated left the city faced with discharge restrictions due to total maximum daily load requirements for chloride in Cow Creek. The city evaluated alternatives that included beneficial reuse of contaminated water, including a regional solution that addressed the site's contamination, the high chloride waters, water appropriation issues, and other industrial groundwater contamination in the area. Implementation of the approved regional plan included the following activities: delineation of soil and groundwater contamination; installation of source area air sparge and soil vapor extraction systems; soil excavation; installation of a groundwater remediation well system for downgradient capture of regional contamination; water appropriations permitting; two Class I non-hazardous underground injection control (UIC) wells; and construction of a fully automated 6-million-gallon-per-day (mgd) reverse osmosis (RO) water treatment facility. The facility blends treated water with 4 mgd of existing municipal water, producing 10 mgd of higher quality water for potable water use. The RO water treatment facility design and construction management was performed by Professional Engineering Consultants, P.A. (PEC).

The source area and downgradient remediation systems, Class I non-hazardous UIC wells, and portions of the buried waterlines are operational and are being monitored under the direction of KDHE. The RO water treatment facility is currently under construction and is anticipated to be fully operational in spring 2009. Funding for the project was obtained utilizing the potential responsible party settlement money, third-party negotiated funds, tax increment financing, KDHE low-interest loans, and water utility capital improvement project funding. The project was estimated to cost approximately $33 to $35 million and has cost approximately $34.5 million to date.



Introduction

The 4th and Carey Site, U.S. Environmental Protection Agency (EPA) Identification Number KSD061608006, is located in Hutchinson, Kansas, in Reno County. The site encompasses approximately 1,240 acres. Groundwater contamination at the site was discovered in the early 1980s, when the EPA and Kansas Department of Health and Environment (KDHE) began testing public water supply wells. A city of Hutchinson well located at the intersection of 4th Avenue and Carey Street was found to be contaminated with volatile organic compounds (VOCs). The groundwater contamination findings issued as a result of EPA and the KDHE investigations led to the establishment of the 4th and

Carey Site in 1994, with the city of Hutchinson assuming the lead role, in order to keep the site from being placed on EPA's National Priority List (NPL, or Superfund). Agreements were reached with potential responsible parties (PRPs) for the contamination. The city of Hutchinson contracted with CDM to provide remedial assistance, including KDHE coordination, investigations, planning, remedial design, and associated construction to address the VOC contamination of the site. Professional Engineering Consultants, P.A. (PEC) was the engineer of record associated with the design and construction for the reuse component of the project.

The site is generally bounded by Lorraine Street to the west, Carey Street to the south, Corey Road to the east, and 11th Avenue to the north, with an extension north to 17th Avenue west of Halstead Street. The general site layout is shown in Figure 1.

Figure 1: Overall Remediation, Containment, and Concentrate Disposal

The 4th and Carey site is named for the location of public water supply (PWS) well #8 at the intersection of Carey Street and East 4th Avenue in Hutchinson. VOCs were detected in groundwater samples collected from this well in 1982. Carbon tetrachloride (CT) was first detected at a concentration of 1.6 micrograms per liter (µg/L) in a sample collected from PWS well #8 on June 7, 1982, and increased in concentration until the city removed PWS #8 from service on April 20, 1985, at KDHE's request.

The site has been subject to a series of investigations beginning in 1984. Following completion of a Listing Site Investigation in 1991, EPA scored the site using the Hazard Ranking System (HRS) for inclusion of the site on the NPL in January 1993. The city and CDM, with the PRP group's assistance, took the lead on the remedial investigation and feasibility study (RI/FS), because of the potential threat to public health and because property values could be adversely affected if the site was in the Superfund Program. This resulted in EPA transferring oversight of the RI/FS to KDHE. KDHE outlined the requirements of the RI/FS and defined the site boundaries in a Consent Agreement and Consent Order (CACO) between the city and KDHE on April 25, 1994.

Remedial Investigation and Source Control Investigation Results

CDM conducted the 4th and Carey RI field activities between August 1994 and January 1997. KDHE approved the resulting RI Report as final on February 12, 1998. Upon completion of the RI, CDM conducted source control investigations (SCIs) at the former Farmland Elevator J, Bunge Elevator, and Garvey Elevator. The SCIs at these elevators were completed and approved by KDHE on October 26, 2001.

Site Characteristics

The site is generally flat with a gentle topographic dip to the south and southeast. The land use within the site is diversified and includes commercial, industrial, recreational, and residential properties. The geology of the study area primarily consists of Arkansas River Valley alluvium, Pleistocene-age glacial outwash, and associated terrace deposits overlying the Permian-aged Ninnescah and Wellington Formation bedrock. Both formations primarily consist of shales with salt deposits present within the Wellington Formation. Depth to bedrock averages approximately 60 feet below ground surface. The aquifer at the site consists of sands and gravels with an average thickness of 43 to 55 feet. In general, the sediments in the water-bearing zone appear to be coarser (more permeable) with depth. The upper 12 to 15 feet consist of interbedded silts and clays, with some minor sand stringers.

Aquifer testing in the area indicates a hydraulic conductivity ranging between 517 to 771 feet per day. Storativity ranges from 0.019 to 0.065. Groundwater flows principally to the southeast, although local flow directions vary considerably with localized aquifer stresses (e.g., pumping wells). The hydraulic gradient also varies locally, ranging from 0.0006 to 0.003 feet/foot with the hydraulic gradient and groundwater velocity increasing near pumping wells.

Contaminant Distribution

Two shallow groundwater CT plumes were identified as emanating from three source areas at the former Farmland Elevator J facility. One shallow groundwater CT plume was identified as emanating from the former Bunge Elevator. A CT plume was also identified as emanating from the former Garvey Elevator. Several additional plumes have been identified in the area and are being managed by KDHE under separate CACOs. Three offsite groundwater plumes (two perchloroethelyene [PCE] and one PCE and trichloroethelyene [TCE]) were observed migrating onto the western portion of the site**.** In addition, chloride contamination was discovered at the site. Three sources of chloride contamination were identified by KDHE. The chloride-impacted areas are generally in the south central portion of the site, as well as south of the site.

At the Farmland and Bunge elevator source areas, the CT contamination is primarily situated in the upper portion of the aquifer and then migrates into the middle and lower portion of the aquifer as it progresses downgradient. VOC contamination in the groundwater at the former Garvey Elevator is present both in the shallow and the deep aquifer; it is characterized by shallow and deep plumes in the alluvial sediments. In general, the shallow plumes originate in the source areas and are of limited horizontal extent and contaminants move from shallow to deeper groundwater away from the source areas, as the deeper sediments appear to be more permeable than the shallow sediments. The downgradient groundwater plumes are more extensive than the shallow source area plumes.

Corrective Action Decision

KDHE issued a final interim corrective action decision (CAD) for source area remediation at the 4th and Carey site in June 2002. The final interim CAD summarized the RI/FS report for the 4th and Carey site and established selected remedial alternatives. The selected remedial alternative specific to the Bunge and Farmland source areas was focused air sparging (AS) and soil vapor extraction (SVE). The final interim CAD revised the plan to include the preferred remedial alternative for downgradient containment in November 2004 and became the final CAD for the site on May 9, 2005. The presence of significant chloride contamination in the area of the downgradient containment systems impacted the choice of the selected remedy for the site. As a result, the downgradient system would need to be

configured in a way that isolated the anticipated high-chloride contaminated groundwater from future reuse through the installation of a reverse osmosis (RO) water treatment facility.

Cleanup goals for groundwater at the 4th and Carey Site follow the federal maximum contaminant levels (MCLs) associated with the Safe Drinking Water Act. Cleanup goals for soil are the Kansas Risk-Based Standards for the residential migration to groundwater pathway. The city of Hutchinson is responsible for the remediation activities at three CT source areas at the former Farmland J Elevator; one CT source area at the former Bunge Elevator; and a fifth CT source area at the former Garvey Elevator. Other VOC source areas are being addressed by other responsible parties.

Several controls have been instituted with the intent to prevent exposure to contaminated groundwater. These controls consist of: (1) groundwater use restrictions; (2) deed restrictions; (3) public education, such as mailings and public meetings; and (4) provision of alternate water supply. The city of Hutchinson monitors and maintains these controls on an annual basis to ensure protection of human health and the environment. Changes of land use in impacted areas are also monitored.

Pre-Design Data Acquisition (PDA)

Data collected by CDM during the PDA field work included AS/SVE pilot testing and groundwater pumping tests. These data provided a basis for sizing the equipment, piping, and wells; for designing the placement of AS, SVE, monitoring, and extraction wells; and for optimizing system cycling needs to minimize the impacts of groundwater mounding associated with air sparge operations at the former Farmland J and Bunge elevators. The PDA established water level and contaminant concentration information to serve as a basis for measurement of remedial effectiveness for the site.

During 2004, the shallow source area at the former Garvey Elevator was remediated by excavating and properly disposing of shallow soils in the vicinity of the former CT tank. The deep groundwater at the former Garvey Elevator is being monitored to ensure that no CT concentrations re-occur, which could trigger the implementation of source control measures.

Source Area Remediation (Farmland J and Bunge Elevators)

The selected remedy for the remediation of the shallow soil and groundwater source areas at the former Farmland J (Farmland NE, Farmland SE, and Farmland SW) and Bunge Elevators was AS/SVE. Several site conditions impacted the CDM design of the AS/SVE systems.

- The PRP properties are currently owned and operated by separate parties. Therefore, work in these areas required access agreements and associated design approvals by the respective party, in addition to the PRPs.
- Facility-owned rail lines located at the north and south sides of Farmland limited the placement of wells and associated piping.
- SVE and AS wells had to be completed below grade to accommodate elevator operations.
- The AS wells were divided into operating zones with each zone operating individually to accommodate a pulsing operation for groundwater mounding and collapse.
- Clayey soils with intermingled silt and sand lenses identified at Bunge, Farmland SW, and Farmland SE required an alternate SVE design to capture as much sparged air as possible. SVE wells operate continuously at all four locations.
- Vapor monitoring points (VMP) were installed to monitor vacuum in the vadose zone created by the system.

Startup for the AS/SVE systems was January 9, 2006, with final acceptance of the system by the city of Hutchinson on October 10, 2007.

Downgradient Remediation

Based on the downgradient modeling results performed by CDM, the settlement agreement with PRPs, and the water-supply needs of the city, a downgradient preferred alternative was developed. It

integrated the hydraulic containment of the contaminant-impacted groundwater with a treatment process that provides a beneficial reuse of the water. The alternative involves hydraulically containing the plumes with extraction wells and piping the contaminated groundwater to a treatment facility that would use RO membranes to treat elevated chloride and VOC levels. An air stripper will be installed as a polishing process for removing VOCs and carbon dioxide from the treated water. Additional inorganic compounds from the groundwater would also be removed through this process. The RO concentrate that contains the rejected organic and inorganic compounds will be disposed of via Class I non-hazardous underground injection control (UIC) wells upon completion of the RO treatment facility discussed later in this paper.

The preferred alternative was developed incorporating two third-party pumping systems in conjunction with the new city-constructed pumping system. In April 2007, five extraction wells in the southern portion of the site began operation as part of chloride plume containment efforts of a third party. Groundwater flow in the southeastern portion of the site is also impacted by groundwater extraction efforts of a separate third-party remedial containment system for a TCE groundwater plume. These regional systems provided additional benefits to the CT remediation, as shown in Figure 1. Therefore, the city of Hutchinson and the two third-party entities entered into agreement for addressing the regional concerns of KDHE. In addition to the third-party systems, the city of Hutchinson installed three downgradient extractions wells to address migration of CT within the central region of the downgradient contamination. Two of the three southeastern downgradient third-party wells provide containment of the eastern most portions of the CT plume, along with other VOCs in the region. These wells will ultimately become the city's responsibility and be pumped directly to the RO treatment facility upon completion of the pipeline and RO treatment facility.

The downgradient containment system designed and installed by the city of Hutchinson and CDM is described in further detail below:

- Piping was installed to accommodate 500 gallons per minute (gpm) of high-chloride water from the neighboring former salt facility property, as agreed upon between the city and the associated third-party owner. Groundwater from one city extraction well, which has a pumping rate of approximately 100 gpm, will also be continually sent to the Class I non-hazardous UIC wells.
- Two additional city extraction wells were installed and completed in March 2006. Both wells are pumped at a design pumping rate of approximately 300 to 400 gpm.
- Connection point and associated valving was installed for ease in transition to the future RO treatment facility.

As a result of water from the wells being injected down the Class I non-hazardous UIC wells (and eventually to the RO treatment facility), the extraction wells were designed and developed such that minimal turbidity and suspended solids were produced.

Extraction wells EW-1 and EW-3 were fully operational on July 24, 2006, while operation of extraction well EW-2 was delayed until April 16, 2007. Operation of EW-2 was delayed until the five extraction wells for the third-party chloride plume containment began operation. Final acceptance of the downgradient system occurred on October 16, 2006.

Water Appropriations

The remediation project required that permits be obtained from the Kansas Department of Agriculture's Division of Water Resources for the five groundwater extraction wells (EW-1, EW-2, EW-3 and two third-party wells). Groundwater appropriations for the remediation wells total approximately 4,188 acre-feet per year (afy) (1,365 million gallons per year [mgy]) resulting in groundwater withdrawals of nearly 3.75 mgd at maximum capacity.

Due to the unique nature of the project and the beneficial use of the treated groundwater in the public water supply, the quantity of water permitted from the remedial wells shall be limited to the quantity of water previously authorized for the city's municipal wellfield—consisting of 20 wells permitted for a

total withdrawal quantity of 11,666 afy (3,801 mgy). Therefore, the additional groundwater appropriations required for the contamination remediation use did not increase the total pre-existing appropriations amount for the area. This is both an important regulatory and environmental element of the project, as aquifer appropriations had previously reached or exceeded maximum development limitations under the state's safe-yield regulation, which seeks to balance groundwater withdrawals with natural aquifer recharge to prevent groundwater mining.

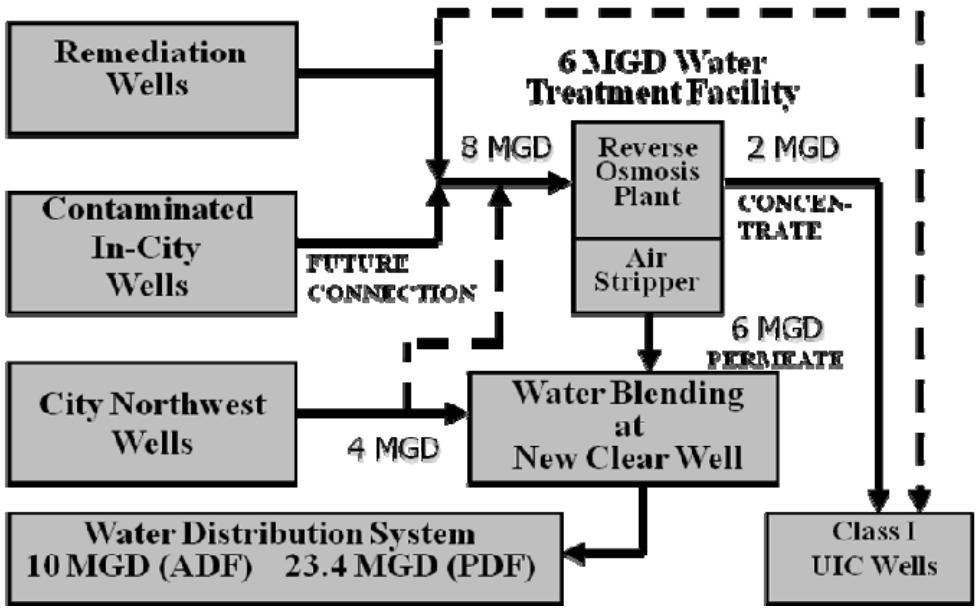
The additional treatment and use of the contaminated groundwater for beneficial purposes allow the city to remediate the aquifer without significantly increasing groundwater usage from the area. The quantity of water withdrawn from the remedial wells will offset or reduce the amount of water pumped from existing municipal wells. As a result, it is the city's intent to apply the annual water use for the remediation project to the city's prior municipal water permits that have not yet been certified by the state of Kansas.

Class I Non-Hazardous Underground Injection Control Wells

Implementing the downgradient containment system in a timely manner is critical to prevent ongoing migration of the contaminant plumes. Therefore, it was determined that the best option was to proceed with construction of the extraction wellfield as soon as possible. This required implementing a disposal option for the high-chloride groundwater and VOCs by using an environmentally acceptable method while the RO water treatment facility is being designed and constructed. To this end, untreated groundwater from the downgradient wellfield is being injected directly into the Class I non-hazardous UIC wells, designed and constructed by CDM (shown in Figure 1), until the RO water treatment facility is operational. Once the facility and all associated transfer piping are constructed, water from the downgradient wellfield will be treated for distribution to the potable water supply system.

Flow to the Class I non-hazardous UIC wells currently consists of the 700 to 900 gpm of groundwater from the proposed extraction wells and an additional 500 gpm from the neighboring chloride remediation efforts. After construction of the RO treatment facility, the Class I non-hazardous UIC wells will accept rejected concentrate water from the RO process, approximately 100 gpm from the city's extraction well, and 500 gpm from the neighboring chloride remediation system. Ultimately, approximately 2 million gallons per day (mgd) of RO membrane concentrate water will require disposal through these wells.

Permitting was performed for the installation of three Class I non-hazardous UIC wells; however, the city proceeded with construction of two wells to meet the demand of the remediation and RO treatment facility. The third well was permitted for additional future capacity, should it be necessary. A siting study was performed to minimize design impacts, permitting delays, and costs by identifying key issues that could affect the project prior to submitting the permit application documents to KDHE-Bureau of Water (BOW) (UIC) and subsequent public notice. The KDHE-BOW Class I UIC permits became effective May 9, 2005. The two constructed injection wells were fully operational on July 24, 2006.



Reverse Osmosis (RO) Water Treatment

Professional Engineering Consultants, P.A. (PEC) designed and provided construction management services associated with the RO water treatment system. The reuse portion of the preferred remedial alternative calls for the blending of RO membrane treated water from the downgradient remediation wellfield with water from the Northwest (NW) wellfield. Because the two wellfields are at opposite sides of the city, the decision was made to pipe the raw water to the RO water treatment facility located near the center of town. The associated raw water piping was constructed primarily during the year 2008.

The water treatment system consists of several key components, including remedial and raw water collection, the RO water treatment facility, concentrate waste piping, Class I non-hazardous UIC well disposal, and the distribution system. The RO product water will be blended with the NW wellfield water for the city of Hutchinson's drinking water supply. The water from the NW wellfield is not

contaminated with VOCs; however, it contains elevated levels of hardness, chlorides, iron, and manganese. By blending this water with RO-treated water, the city will produce a higher quality of water for its citizens. The concentrated brine stream produced by the RO system will be sent to the Class I non-hazardous UIC wells for disposal. A schematic of this system is shown in Figure 2.

Figure 2: Proposed Hutchinson Water Treatment System Schematic

Raw Water and Finished Quality Goals

Currently, the raw water supply for the city of Hutchinson is entirely groundwater from the Equus Beds aquifer, which is primarily composed of saturated sand and silt. The city of Hutchinson's public water supply system consists of 16 active groundwater wells, which are divided into two geographic regions of the city: the NW wellfield and the In-City wellfield (southeast areas). The NW wellfield consists of higher quality groundwater and will be used to blend with the RO-treated water. The In-City wellfield, including several wells in the central portion of the city, consists of poorer quality groundwater. The water from these wells will not be used or treated by the RO treatment facility under the initial design plan; however, these wells may be brought online and treated in the future.

Currently, it is intended for only the NW wellfield and the remediation wellfield to supply water to the RO facility for treatment. The facility is designed for varying raw water blends of the two water sources to accommodate the overall water usage by the city. Current water quality data associated with these blends were obtained through existing and pilot plant programs. The treatment goal for the RO water treatment facility is to produce a finished water quality that meets and exceeds current and foreseeable future regulations. The result will be water with lower naturally occurring chloride, hardness, iron, and manganese levels, which will be more aesthetically pleasing to consumers. Table 1 shows the raw and finished water quality desired by the city of Hutchinson.

TABLE 1.
RAW AND FINISHED WATER QUALITY

Parameter	Unit	Raw Water	Finished Water
Alkalinity	mg/L	234 ~ 350	120 ~ 150
Chloride	mg/L	135 ~1420	80 ~ 120
Hardness	mg/L	315 ~ 517	100 ~ 150
Iron	mg/L	0.23 ~ 5.21	0.05 ~ 0.15
Langelier Index (L.I.)	-	-0.60 ~ +0.44	0.10 ~ 0.55
Manganese	mg/L	0.09 ~ 0.52	0.01 ~ 0.03
Nitrate nitrogen	mg/L	1.34 ~ 6.85	1.00 ~ 3.50
pH	-	6.8 ~ 7.7	7.8 ~ 8.2
Sulfate	mg/L	134 ~ 304	60 ~ 100
Temperature	Deg. C	12.8 ~ 18.3	12.8 ~ 18.3

The finished water quality presented in Table 1 is achieved by blending 60-percent RO-treated water with 40-percent NW wellfield water. Sodium hydroxide and chlorine are added for final water pH stability and for disinfection credits and residuals.

Reverse Osmosis Water Treatment Facility

The RO water treatment facility is currently under construction and scheduled to be operational in spring 2009. The facility has been designed and sized to meet the projected flow demands for the average daily flow projection of 10 mgd in the year 2030 by producing 6 mgd of RO-treated water to be blended with 4 mgd of NW wellfield water. Additionally, the facility is designed to support a peak pumping capacity of 23.4 mgd to meet projected peak-day demands using modified RO-treated water and NW wellfield water blends. The RO water treatment facility will consist of several distinct components used to meet the requirements for treatment, blending, distribution, and wastes. All components will be located at the same treatment site and will be automatically controlled with online water quality instrumentation and a centralized computer and radio telemetry system.

The influent wetwell will consist of two 50,000-gallon concrete reservoirs used to collect and blend raw water for treatment. Four vertical turbine pumps on variable frequency drives (VFDs) are used to pump raw water through the facility for treatment. Six greensand and anthracite pressure filters are provided to remove iron and manganese from the raw water, which include chlorine and potassium permanganate chemical feed systems for oxidation of the iron and manganese and for recharge of the filter media.

The RO treatment system consists of pretreatment, RO membranes, and post stabilization subsystems. The pretreatment system consists of sodium bisulfate feed to eliminate any residual chlorine, antiscalant chemical feed to protect the membranes from particulate formation, cartridge filters to protect the membranes from particulate carryover, and online instrumentation. The RO membrane system includes a manual clean-in-place system for acid and caustic chemical feed and pumping. Following the RO membranes, the permeate water is further treated by a degasification tower to strip any dissolved gases, carbon dioxide, and VOC compounds. This process leaves the water unstable with a low pH. Therefore, caustic soda chemical feed systems are provided to raise the pH to desired levels and to stabilize the water and make it less corrosive.

The RO-treated water is blended with NW wellfield water to meet the desired quantity and quality of water needed. Blending takes place within the piping, and chlorine disinfection is accomplished in a disinfection basin. The disinfection basin leads to two 300,000-gallon clearwells to store the treated water prior to distribution. Six VFD-driven high-service pumps are used to send clearwell water to the city distribution system. Clearwell water is also used by two VFD-driven pressure filter backwash pumps.

Concentrate wastes from the RO membranes are collected onsite and pumped approximately 5 miles to the Class I non-hazardous UIC wells. A wetwell of approximately 150,000 gallons is designed to provide for flexibility in operations and controls between the RO treatment facility pumps and the Class I wells.

Distribution System

With the construction of the RO water treatment facility, several improvements to the distribution system are required, including additions to the distribution system piping and upgrades to the water tower control system to accommodate varying flow directions, pressures, and water chemistry. The distribution piping modifications were completed in 2007 and 2008, during early RO water treatment facility construction and other city capital improvement projects.

Conclusions and Project Status

To date, the source area remediation at the former Farmland J and Bunge Elevators has resulted in significant reduction in the contaminant concentrations at the source areas. CT concentrations at the source areas have been reduced from several hundred µg/L to less than 5 µg/L (MCL), and in several cases less than the laboratory reporting limit of 1 µg/L. The AS/SVE system at the former Bunge Elevator was shut down shortly before the third quarter sampling and remained down during the fourth quarter of 2008 to monitor for possible rebound effects. The Bunge source area monitoring results have shown a minor rebound effect of CT above MCLs. Therefore, the Bunge AS/SVE system was restarted for the first quarter of 2009. All other source area systems remain in operation. The downgradient and Class I non-hazardous UIC wells have been in continuous operation since startup and are anticipating full operation of the RO treatment facility in spring 2009. At that time, the city will work toward taking over the third-party wells associated with downgradient capture and send this water to the RO treatment facility.

A collaborative effort between all parties involved in planning, design, and startup have worked to make this project a success, while remaining within the planned budget of $33 to $35 million. Key project components, costs, and funding are estimated as follows:

Project Components:

- Source remediation components; 4 AS/SVE source area systems, 1 soil source excavation.
- 3 extraction wells and 13,600 linear feet of 6" through 18" collection piping.
- 2 Class I UIC wells and equalization for remedial and RO concentrate disposal.
- 10-mgd average daily flow RO membrane water treatment facility.
- 90,300 linear feet of 12" through 36" raw water, concentrate, and distribution piping.

Project Funding:

Payments from companies responsible for contamination (PRPs)	$10,547,000
TCE and chloride remediation party agreement payments	$ 1,675,000
TIF district tax proceeds and interest earned	$ 1,086,000
Federal grants ($3.5 million less grant admin. costs)	$ 3,372,000
KDHE low interest loans – city funds	$16,650,000
Water utility capital improvement project (CIP) funds – city funds	$ 1,350,000
Total	$34,680,000

Project Cost:

Groundwater contamination source remediation	$ 740,000
RO Concentrate and Class I non-hazardous UIC wells)	$ 4,095,000
Groundwater remediation wells and pipelines	$ 2,610,000
RO water treatment facility	$17,660,000
RO raw water, concentrate and distribution system pipelines	$ 9,340,000
Total	$34,445,000

The city of Hutchinson, CDM, and PEC continue to work toward meeting the goals of remediation of the site, while minimizing design, construction, and operational costs associated with groundwater treatment and the RO water treatment facility.

Hutchinson, KS – 4th and Carey Site
Groundwater and Source Control Measures at Two Grain Elevators

Abstract
The 4th and Carey Site, U.S. Environmental Protection Agency (EPA) Identification Number KSD061608006, is located in Hutchinson, Kansas in Reno County. The site encompasses approximately 1,240 acres. Groundwater contamination at the site was discovered in the early 1980s when the EPA and Kansas Department of Health and Environment (KDHE) began testing public water supply wells. A city of Hutchinson well, located at the intersection of 4th Avenue and Carey Street, was found to be contaminated with volatile organic compounds (VOCs). The groundwater contamination findings conducted by EPA and the KDHE led to the establishment of the 4th and Carey site in 1994 with the city of Hutchinson assuming the lead role in order to keep the site from being placed on EPA's National Priority List (Superfund). Agreements were reached with potential responsible parties (PRPs) for the contamination.

Investigations at the site conducted by CDM for the city resulted in the identification of six carbon tetrachloride (CT) source areas; one trichloroethene (TCE) source area; one tetrachloroethene (PCE) and TCE source area; and two areas impacted by petroleum hydrocarbons. The TCE and PCE/TCE source areas are being addressed by the property owners under KDHE oversight. The areas impacted by petroleum hydrocarbons and one of the CT source areas are being monitored by the city. The remaining CT source areas required the implementation of source control measures for CT and its degradation products, primarily chloroform (CFM).

Source area investigation activities determined that the contaminant distribution at the five remaining CT source areas was predominantly located in the unsaturated soils and the top ten feet of the aquifer. The soils at the source area consist of 10 to 12 feet of silty clays underlain by 45 to 50 feet of sands and gravels. A shale formation serves as the base of the alluvial aquifer at the site. The water table at the CT source areas is generally within a couple feet of the base of the silty clays. The five CT source areas are located adjacent to grain elevators that used a CT-based compound as a fumigant prior to its banning by EPA in 1985.

Contamination at one of the CT source areas was addressed by a limited excavation program in 2004. The selected remedial alternative for the remaining four CT source areas was a combination of air sparging (AS) and soil vapor extraction (SVE). The AS/SVE remedial system was selected because of concerns that excavation efforts could impact the stability of the adjacent grain elevator bins and the operation of the elevators. With the water table at or near the base of the clays, the subsurface conditions were not ideal for an effective SVE collection system. Special construction techniques were required for the installation of SVE collection points to ensure that air sparge vapors could be collected.

The startup date for the AS/SVE systems was January 9, 2006. The AS/SVE systems in groundwater at the source areas have resulted in the reduction of CT concentrations from greater than 1,000 micrograms per liter (µg/L) to less than 5 µg/L without impacting the operations at the grain elevators.

Introduction

The site is located in south central Kansas in the city of Hutchinson, within Reno County and encompasses approximately 1,240 acres. Groundwater contamination at the site was discovered in the early 1980s when the EPA and Kansas Department of Health and Environment (KDHE) began testing public water supply wells. A city of Hutchinson well located at the intersection of 4th Avenue and Carey Street was found to be contaminated with volatile organic compounds (VOCs). The groundwater contamination findings conducted by EPA and the KDHE led to the establishment of the 4th and Carey site in 1994 with the city of Hutchinson assuming the lead role in order to keep the site from being placed on the U.S. Environmental Protection Agency's (EPA) National Priority List (Superfund). The site, EPA Identification Number is KSD061608006, is shown on **Figure 1**.

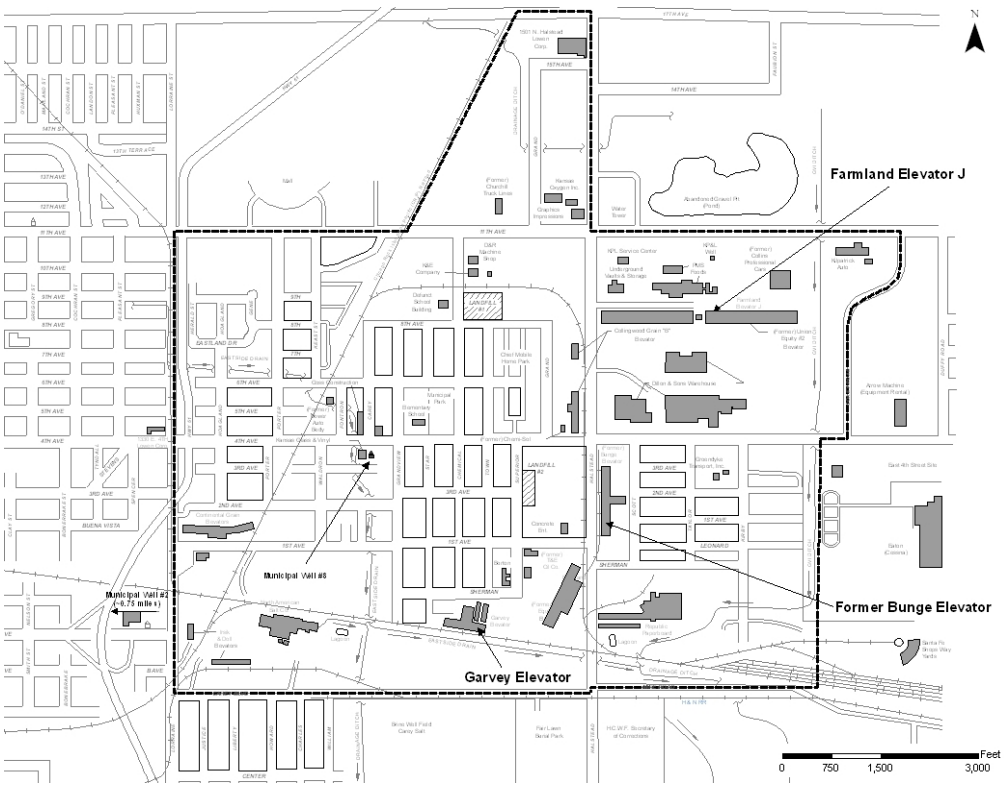

Figure 1 – Site Map – 4th and Carey Site, Hutchinson, Kansas

Carbon tetrachloride was first detected at a concentration of 1.6 µg/L in a sample collected from public water supply well #8 (PWS #8) on June 7, 1982 and increased in concentration until the city removed PWS #8 from service on April 20, 1985 at KDHE's request.

The site has been subject to a series of investigations beginning in 1984. Following completion of a Listing Site Investigation in 1991, EPA scored the site using the Hazard Ranking System (HRS) for inclusion of the site on the National Priorities List (NPL) in January, 1993. The city, with the Potentially Responsible Party (PRP) Group's assistance, took the lead on the Remedial Investigation (RI) and Feasibility Study (RI/FS) because of the potential threat to public health and because property values could be adversely affected if the site were enrolled into the Superfund Program. This resulted in EPA transferring oversight of the RI/FS to KDHE. KDHE outlined the requirements of the RI/FS and defined the site boundaries in a Consent Agreement and Consent Order (CACO) between the city and KDHE on April 25, 1994.

The 4th and Carey remedial investigation (RI) field activities were conducted by CDM for the city between August 1994 and January 1997. The RI report was approved as final by KDHE on February

12, 1998. Upon completion of the RI, source control investigations (SCIs) were conducted at the former Farmland Elevator J, former Bunge Elevator, and former Garvey Elevator. The SCIs at these elevators were completed and approved by KDHE on October 26, 2001.

Site Characteristics

The site is generally flat with a gentle topographic dip to the south and southeast. The land use within the site is diversified and includes commercial, industrial, recreational, and residential properties. The geology of the study area primarily consists of Arkansas River Valley alluvium, Pleistocene-age glacial outwash, and associated terrace deposits overlying the Permian-aged Ninnescah and Wellington Formation bedrock. Both formations primarily consist of shales with salt deposits present within the Wellington Formation. Depth to bedrock averages approximately 60 feet below ground surface. The aquifer at the site consists of sands and gravels with an average thickness of 43 to 55 feet. In general, the sediments in the water bearing zone appear to be coarser (more permeable) with depth. The upper 12 to 15 feet consists of interbedded silts and clays, with some sand stringers.

Aquifer testing in the area indicates a hydraulic conductivity ranging between 517 to 771 feet per day. Storativity ranges from 0.019 to 0.065. Groundwater flows principally to the southeast, though local flow directions vary considerably with localized aquifer stresses (e.g., pumping wells). The hydraulic gradient also varies locally, ranging from 0.0006 to 0.003 feet per foot. Based upon the above information, the groundwater velocity is estimated to range between 0.3 to 2.3 feet per day. The hydraulic gradient and groundwater velocity increase near pumping wells. In April 2007, a private third party (third party #1) began operating five extraction wells with a planned total extraction rate of 500 gallons per minute (gpm) in the south central portion of the site as well as south of the site as part of their chloride plume containment efforts. The extracted groundwater is discharged at two Class I non-hazardous underground injection (UIC) wells installed by the city as part of the final corrective action decision (CAD). Groundwater flow in the southeastern portion of the site is also impacted by groundwater extraction efforts of another third party (third party #2) as part of their remedial containment system for their TCE groundwater plume. Third party #2 operates three groundwater extraction wells with total rate of approximately 1700 gpm. The groundwater extracted by third party #2 is currently treated by air stripping and discharge to a surface water drainage ditch. **Figure 2** shows a potentiometric map as of September 2008.

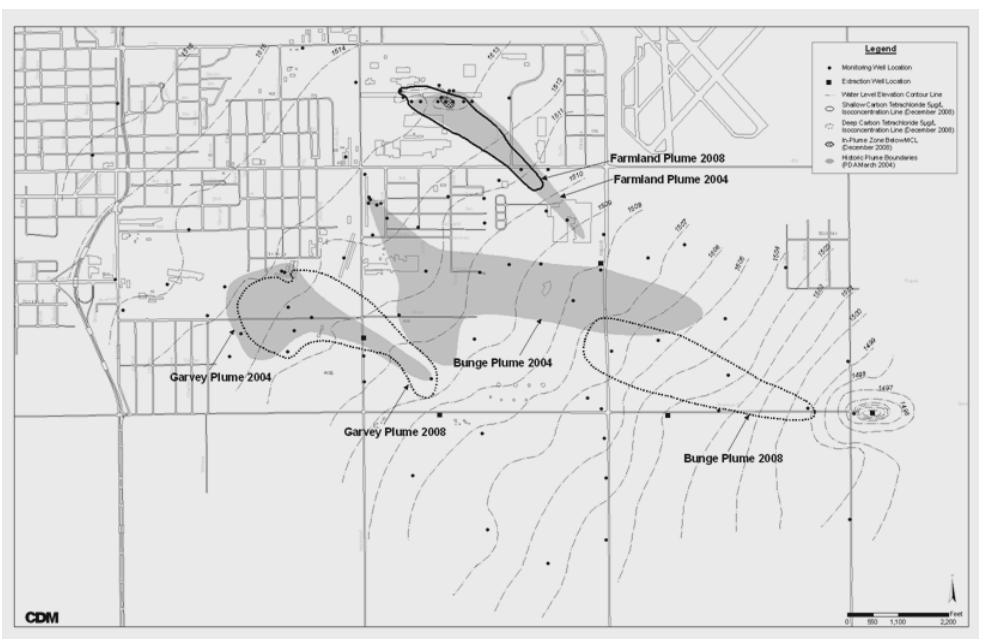

Figure 2 – September 2008 Potentiometric Surface Map and CT Plume Distribution

Contaminant Distribution

Investigations at the site conducted by CDM for the city resulted in the identification of six CT source areas; one TCE source area; one PCE and TCE source area; and two areas impacted by petroleum hydrocarbons. The TCE and PCE/TCE source areas are being addressed by the property owners under separate CACOs with KDHE oversight. The areas impacted by petroleum hydrocarbons and one of the CT source areas are being monitored by the city. The remaining CT source areas required the implementation of source control measures. Three offsite groundwater plumes (two PCE and one PCE and TCE) were observed migrating onto the western portion of the site. These plumes are being addressed by outside parties under KDHE oversight.

Through its own investigations, KDHE identified three areas with chloride impacts within the site. The sources of chloride impacts include a former salt mining and production facility; a former soda ash mining operation; and a former tanning operation. The majority of the chloride impact is in the south central portion of the site, as well as south of the site. The chloride impacts on the groundwater are significant in that extracted and VOC-treated groundwater could not be discharged to surface waters due to the total maximum daily limit (TMDL) restrictions associated with total dissolved solids.

Two shallow groundwater carbon tetrachloride (CT) plumes were identified as emanating from three source areas at the Farmland Elevator J facility. One shallow groundwater CT plume was identified as emanating from the former Bunge Elevator. A CT plume was also identified as emanating from the Garvey Elevator.

VOC contamination at the former Farmland J and former Bunge Elevator is characterized by soil impacts at the release areas, which extend down to the water table interface. CT is a dense non-aqueous phase liquid (DNAPL) and as a pure product can migrate vertically through an aquifer and accumulate as a free phase product at the base of an aquifer. At the former Farmland J and Bunge Elevators, the data indicates that the CT product migrated downward to the water table but appeared to be of insufficient mass or density to overcome the capillary pressure in the sediments at the water table interface. The CT contamination appears to have spread laterally over a relatively small area on top of the water table surface. Groundwater testing at these source areas indicated that the bulk of the CT contamination was confined to the upper few feet of the aquifer. The identified releases at the former Farmland J Elevator are referred to as farmland J southeast (SE), farmland J southwest (SW), and farmland J northeast (NE). Maximum CT concentrations in groundwater at the three Farmland J SE, SW, and NE source areas, collected by direct-push technology (DPT), were 7,700; 2,000; and 5,300 µg/L; respectively. It appears that the monitoring wells installed at the source areas had lower concentrations as a result of dilution effects due to a larger sensing zone compared to the direct-push sensing zones. The maximum CT concentrations observed in groundwater at the Bunge source area, collected by DPT, were 8,000 µg/L. As with the farmland source areas, the monitoring well installed at the Bunge source area was lower than the DPT results. At the Farmland and Bunge elevator source areas, the CT contamination is primarily situated in the upper portion of the aquifer and then migrates down into the middle and lower portions of the aquifer.

VOC contamination at the former Garvey Elevator had two components. The shallow soils at the former CT storage tank pad were impacted by CT. Additionally, the RI investigation identified significant CT groundwater contamination (in the milligrams per liter range) at the base of the aquifer at the former Garvey Elevator. Groundwater testing did not identify significant CT impact in the middle portion of the aquifer and the mechanism of the CT release for the deep groundwater contamination was not identified. Subsequent source control investigation (SCI) work conducted between 1998 and 2002 indicated that the high levels of deep CT contamination at the former Garvey Elevator had apparently migrated downgradient with only minimal CT concentrations remaining in the deep groundwater at the apparent source area. VOC contamination in groundwater associated with the Garvey source areas is characterized by shallow and deep plumes in the alluvial sediments.

In general, the shallow plumes originate in the source areas and are of limited horizontal extent as the contaminants tend to move from shallow to deeper groundwater away from the source areas due to

apparent increased permeability with depth in the shallow sediments. Thus, the downgradient groundwater plumes are more extensive than the shallow source area plumes.

Corrective Action Decision

The KDHE issued a final interim CAD for source area remediation at the 4th and Carey site in June 2002. The final interim CAD summarized the RI/FS report for the 4th and Carey site and established selected remedial alternatives for the site. The selected remedial alternative specific to the Bunge and Farmland J source areas was air sparging (AS) and soil vapor extraction (SVE). Excavation at these four source areas was screened as a remedial action due to concerns over the stability of the adjacent grain bins. The final interim CAD was revised to include the preferred remedial alternative for downgradient containment in November 2004 and became the final CAD for the site on May 9, 2005.

Cleanup goals for groundwater at the 4th and Carey Site are 5 µg/L for CT, 80 µg/L for CFM—the federal maximum contaminant levels (MCLs) associated with the Safe Drinking Water Act. Cleanup goals for soil are the Kansas Risk-Based Standards for the residential migration to groundwater pathway (0.2 milligrams per kilogram (mg/kg) for CT and 0.96 mg/kg for CFM).

The city of Hutchinson is responsible for the remediation activities at three CT source areas at the former Farmland J Elevator; one CT source area at the Bunge Elevator; and a fifth CT source area at the former Garvey Elevator. Other VOC source areas are being addressed by other responsible parties.

Several controls have been instituted with the intent to prevent exposure to contaminated groundwater. These controls consist of: 1) groundwater use restrictions, 2) deed restrictions, 3) public education (such as mailings and public meetings), and 4) provision of alternate water supply. The city monitors and maintains these controls on an annual basis to ensure protection of human health and the environment. Changes of land use in impacted areas are also monitored.

Source Area Remediation

Pre-design data acquisition (PDA) activities were conducted in accordance with the KDHE's Interim CAD for Source Area Remediation established on July 9, 2002 between them and the city. Data collected during the PDA field work provided a basis for sizing the equipment, pipes, and wells, and for designing the placement of AS and SVE systems, as well as the monitoring and extraction wells. Additionally, the PDA provided water-level and contaminant-concentration information to serve as a basis for measurement of remedial effectiveness.

Based on the findings of the PDA, it was concluded that AS can effectively reduce VOC concentrations in groundwater at the source areas. The air sparge zone of influence (ZOI) with a radius of 20 feet was established at a pressure of 14 pound-force per square inch gauge (psig). Pilot testing indicated a 4-hour air sparging interval was sufficient to produce mounding and collapse of the groundwater. The data also indicated that two hours with no air sparging was sufficient time to allow the water table to return to static conditions between AS pulses.

The SVE testing showed no minimal effect in the shallow vadose zone soils at the former Farmland J Elevator. The former Bunge Elevator testing showed one well with no vapor flow while the other well produced vacuum. The SVE ZOI was established to be between 40 and 57 feet at 25 inches of water vacuum based upon the pilot test at Farmland J Northeast. Other design considerations based on PDA data include SVE well designs customized for local lithology (in cases where limited unsaturated sands are present for vapor collection) and related engineering controls to capture as much AS air as possible.

During 2004, the shallow source area at the former Garvey Elevator was remediated by excavating the shallow soils in the vicinity of the former CT tank. The excavated soils were properly disposed at a KDHE-approved landfill. The deep groundwater at the former Garvey Elevator is being monitored to ensure that no CT concentrations re-occur, which could trigger the implementation of source control measures.

Source Area Remediation at the Former Farmland and Bunge Elevators

The selected remedy for the remediation of the shallow soil and groundwater source areas at the former Farmland J (NE, SE, and SW) and Bunge Elevators was AS/SVE. Several site conditions affected the design of the AS/SVE systems.

- The PRP properties are currently owned and operated by separate parties. Therefore, work in these areas required access agreements and associated design approvals by the respective party, in addition to the PRPs.
- Facility-owned rail lines located at the north and south sides of Farmland limited the placement of wells and associated piping.
- SVE and AS wells had to be completed below grade to accommodate elevator operations.
- The AS wells were divided into operating zones with each zone operating individually to accommodate a pulsing operation, groundwater mounding, and collapse.
- The presence of clayey soils with intermingled silt and sand lenses at the Bunge, Farmland SW, and SE source areas at or just above the water table required an alternate SVE design to capture as much AS air as possible.
- SVE wells operate continuously at all four locations.
- Vapor monitoring points (VMP) were installed to monitoring vacuum in the vadose zone created by the system.

Startup for the AS/SVE systems began on January 9, 2006. A description of each AS/SVE system is provided below.

Bunge

The AS/SVE system installed at the former Bunge Elevator consists of four AS wells and two SVE wells. The AS/SVE system is described below.

- Two sets of two, 2-inch diameter AS wells were installed with 35 foot spacing. One set was installed on the north side of the elevator and the second set was installed on the south side of the elevator.
- The four AS wells were divided into two operating zones (two north wells in one zone, two south wells in the second zone) with each zone (two wells) operating individually to accommodate a pulsing operation. A total flow per zone of 30 standard cubic feet per minute (scfm) is provided to each zone in operation.
- Two, 4-inch diameter SVE wells were installed within 6-foot diameter boreholes due to an insufficient thickness of vadose-sand interval above the water table to capture vapor from the AS systems. One well between each AS well set spaced approximately 15 to 20 feet from each AS well. SVE wells operate continuously to capture as much AS air as possible.
- Two vapor monitoring points (VMP) were installed to monitor vacuum in the vadose zone created by the system.

Farmland NE

- Seven, 2-inch diameter AS wells were installed, including two wells north of the railroad tracks spaced 40 feet apart east to west and five wells south of the railroad tracks spaced 40 feet apart, extending 160 feet east to west. One existing AS well, constructed for the pilot test and located between the railroad tracks, was also incorporated into the AS system.
- The eight AS wells were divided into three operating zones (two to three wells in each zone) with one zone (two to three wells) operating at one time translating to a total flow per zone of 30 to 45 scfm.
- Three, four-inch diameter SVE wells were spaced 60 to 70 feet apart over 130 feet, between the two sets of railroad tracks.
- Three vapor monitoring point (VMP) wells were installed to monitor the vacuum in the vadose zone exerted by the SVE system.

Farmland SE

- Five, 2-inch diameter AS wells, including three wells north of the railroad tracks spaced 40 feet apart, extending 80 feet east to west, and two wells are between the railroad tracks spaced 40 feet apart east to west.
- The five AS wells are divided into two operating zones (the three northern wells in the first zone, the two southern wells in the second zone) with one zone (two to three wells) operating at one time translating to a total flow per zone of 30 to 45 scfm.
- Two, 4-inch diameter SVE wells were installed within 6-foot boreholes evenly spaced between the northern AS wells.
- Two VMP well was installed to monitor the vacuum created by the SVE system.

Farmland SW

- Six, 2-inch diameter AS wells are spaced 35 feet apart and extend 175 feet east to west between the railroad tracks and the Farmland J Elevator west wing.
- The six AS wells are divided into three operating zones (two wells in each zone) with one zone (two wells) operating at one time translating to a flow of total flow per zone of 30 scfm.
- Three, 4-inch diameter SVE wells are installed within 6-foot boreholes spaced approximately 70 feet extending 140 feet east to west, approximately five feet south of the AS well line and beginning 17.5 feet east of the westernmost AS well.
- Three VMPs were installed to monitor the vacuum in the vadose zone exerted by the SVE system.

The AS wells were installed using an 8.25-inch outside diameter (OD) hollow stem auger and drill rig. Each well was constructed with two-inch diameter, Schedule 40 PVC with a five-foot, 0.010-inch slotted screen set at the bottom five feet of the well. The wells were completed by placing filter sand from the bottom of the borehole to approximately 2 feet above the screened interval, a two-to-four foot-thick filter pack seal of ¼-inch coated bentonite pellets above the filter pack, and an annular space seal of neat cement grout from the top of the filter pack seal to approximately 5 feet below ground surface (bgs). The total depth of the AS wells was 40 feet bgs (approximately 26 feet below the water table) with five foot of screen at the base of the well.

In order to compensate for the lack of sufficient permeable sand material in the vadose zone above the water table at the Bunge, Farmland SE, and Farmland SW source areas, SVE wells at these source areas were installed using a bucket auger rig to create a six-foot diameter borehole. A temporary 8-inch plastic casing was lowered to the bottom of the borehole and centered within the borehole. A 4-inch diameter PVC well with a 5-foot, 0.010-inch slotted screen was placed inside the temporary casing. The bucket auger borehole was filled to 8 feet bgs with crushed rock material. The annulus between the temporary casing and the 4-inch well was filled with filter sand from the bottom of the borehole to 8 feet bgs (approximately 2 feet above the screened interval). Following placement of the filter pack, the temporary casing was removed. Approximately 2 to 4 feet of 3/8-inch diameter bentonite chips were placed above the crushed rock and filter pack material. The screen interval of these SVE wells is 10 to 15 feet bgs. **Figure 3** shows a generalized cross-section of the AS/SVE system at the former Bunge Elevator.

SVE wells installed at the Farmland NE source area were installed using an 8.25-inch OD hollow stem auger and drill rig. Each well was constructed with 2-inch diameter, Schedule 40 PVC with a 5-foot, 0.010-inch slotted screen set at the bottom 5 feet of the well. The wells were completed by placing filter sand from the bottom of the borehole to approximately 2 feet above the screened interval, placing a 2-to-4-foot-thick filter pack seal of 3/8-inch bentonite chips above the filter pack, and placing an annular space seal of neat cement grout from the top of the filter pack seal to approximately 4 feet bgs. The screen intervals for the Farmland NE SVE wells are 9 to 14 feet bgs.

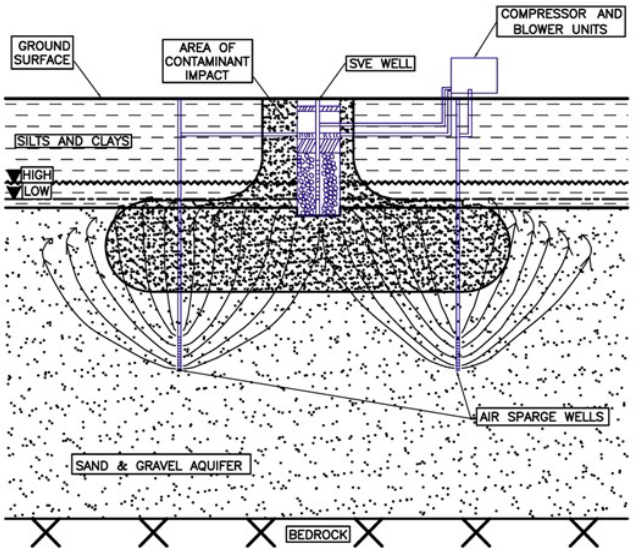

Figure 3 – Generalized Cross-Section of AS/SVE System at the Bunge Source Area

Generally, the AS systems operate at approximately 12 to 15 psi pressure with a typical flow of approximately 12 to 18 scfm per well at the manifold. The AS manifold timers are set to operate on a staggered on/off cycle to reduce the potential of sparge bubbles from setting up preferential pathways and potentially failing to effectively strip VOCs out of the aquifer. The AS wells are connected to the compressors via manifolds with a combination of two or three wells per manifold. The SVE system operates at approximately 10 to 50 inches of water (IOW) vacuum pressure, depending on the system, and a typical flow of 22 to 32 scfm for the individual wells. The SVE wells are connected to the blower via a manifold. The SVE system is in continuous operation and the blowers operate at approximately 150 percent of the AS flow rate. The piping is buried at a minimum of 42 inches for freeze protection and has been slightly sloped towards either the wells or condensate knockouts to minimize condensate collection in pipelines. Buried and trailer mounted condensate knockouts are pumped into a temporary storage tank for off-site disposal, when necessary.

System Operation and Monitoring

Groundwater monitoring for the 4th and Carey Site is required under the Final Corrective Action Decision dated May 17, 2005 and is as follows:

- The site monitoring network was selected from existing monitoring wells for the purposes of monitoring volatile organic compound (VOC) concentrations within the existing plumes and at or in the vicinity of the MCL boundaries, and to monitor contaminant transport from shallow to deep groundwater. Site monitoring network locations were selected to provide data for evaluating changes in site-wide contaminant transport and contaminant mass, as well as monitoring site-wide plume boundaries.

- Source area remediation performance monitoring measures the effectiveness of the air sparge/soil vapor extraction (AS/SVE) systems at the former Bunge and Farmland J elevators and documents contaminant levels at each source area. The startup date for the AS/SVE systems was January 9, 2006 with final acceptance on October 10, 2007. Groundwater monitoring and air monitoring of VOC concentrations are conducted on a quarterly basis for these source areas. The shallow Garvey source area was addressed by limited soil excavation activities in 2004. Currently, remediation activities at the Garvey source area consist of quarterly groundwater monitoring of VOC concentrations to verify continued reduction in contaminant concentrations.

The former Garvey Elevator was demolished and the resulting debris removed in 2008. The other elevators continue to remain operational.

To date, the source area remediation at the former Farmland J and Bunge Elevators has resulted in significant reduction in the groundwater concentrations at the source areas. **Figure 2** shows the plume configuration as of December 2008. CT and CFM concentrations at the source area monitoring wells have been reduced from several hundred µg/L to less than MCLs and in several cases less than the laboratory reporting limit of 1 µg/L. The monitoring wells immediately downgradient of the source areas have also shown significant reductions in CT concentrations. **Figures 5 through 8** show the CT trends at the Farmland and Bunge source areas. There are two charts shown for each source area. The above chart shows the concentrations at the source area monitoring well. The lower chart shows the concentrations at the nearest downgradient monitoring well located outside of the direct influence of the AS/SVE system. The AS/SVE system at the former Bunge Elevator was shut down shortly before the third quarter sampling and remained down during the fourth quarter of 2008 to monitor for possible rebound effects. The Bunge source area monitoring well results do show a minor rebound effect of CT above MCLs. The Bunge AS/SVE system was restarted for the first quarter of 2009. Based upon the available data, CDM anticipates shut down of all four AS/SVE systems by late 2009 or early 2010

Summary and Conclusions

The 4th and Carey Site has been impacted by a number of chlorinated VOCs. Groundwater has also been contaminated by elevated chloride concentrations from three sources. The chloride impacts are significant enough that discharge of groundwater only treated for VOCs to surface waters would not be permitted by KDHE. The city of Hutchinson is responsible for the remediation activities at three CT source areas at the former Farmland J Elevator; one CT source area at the Bunge Elevator; and a fifth CT source area at the former Garvey Elevator. Other VOC source areas are being addressed by other responsible parties. Source area remediation at the former Farmland J Elevator and the former Bunge Elevator is being implemented through AS/SVE systems. The AS/SVE systems have been in operation since January 2006. CT and CFM concentrations in the source area monitoring wells have been reduced from several hundred µg/L to less than MCLs and in several cases less than the laboratory reporting limit of 1 µg/L. The Bunge AS/SVE system was shut down during the fourth quarter of 2008 and did show a minor rebound (CT <20 µg/L). All four systems are currently operating. Shut down of all four AS/SVE systems is anticipated to occur in late 2009 or early 2010.

ABSTRACT

To understand the region-specific effects of biota on function of bioretention cells, a lysimeter study was conducted at Kansas State University to determine how earthworms and native Kansas grasses impact runoff treatment and hydraulic function of a bioretention cell. This study also employed the Comprehensive Bioretention Cell (BRC) model to demonstrate how three seasons of growth could impact bioretention cell function. The model results of the first season of growth were then compared to field data. Results indicate that the interaction of plant roots and soil macrofauna over one growing season improved several aspects of bioretention cell function. The greatest increase in saturated hydraulic conductivity was in the treatment that included both plants and macrofauna. The presence of vegetation reduced ponding effects and increased water storage. Earthworm treatments had a lesser ability to store water. All treatments were effective in reducing the concentration of P in effluent. A large amount of N was released during all events from all treatments probably because of a high initial N content of the bioretention media. No treatment performed significantly better in improving water quality, indicating that macropore flow in the earthworm treatments did not induce a higher rate of pollutant transport.

INTRODUCTION

Urban stormwater management is receiving increased attention as a result of the National Pollutant Discharge Elimination System (NPDES) Permit Program and growing awareness of stormwater runoff impacts on surface and groundwater source quality and quantity. To alleviate stormwater impacts on receiving waters, a number of Stormwater Best Management Practices (BMPs) have been developed. BMPs can be used in conjunction with, or as an alternative to, traditional stormwater practices and facilitate water treatment through natural processes.

A bioretention cell is a recessed area of vegetation designed to accept and treat stormwater runoff through infiltration into layers of plant roots and growing medium, and is just one example of a BMP. The conventional design has been found to significantly

reduce concentrations of heavy metals (copper, lead, and zinc), oils and grease, Total Kjeldahl Nitrogen (TKN), ammonium, and total phosphorus from stormwater runoff (Davis et al., 2001; Davis et al. 2003; Sharkley and Hunt, 2005). However, design limitations arise from the lack of understanding of the influence of ecological factors on the function and longevity of bioretention cells.

Previous bioretention research has focused on engineering the cell for hydraulic properties and has thus neglected the important role that plants and belowground processes play in improving infiltration and pollutant removal. Bioretention cell research has also primarily been conducted on the east and west coasts of North America, leaving few applicable standards for other regions. A functioning bioretention design must mimic a natural, functioning ecosystem. This "ecosystem" must be regionally appropriate and site-specific. By incorporating native vegetation and fauna, a bioretention cell will establish more rapidly and be more stable during changes in runoff volumes and pollutant concentrations.

A lysimeter study was conducted on the Agronomy Research farm at Kansas State University to assess the impacts of vegetation and microfauna, particularly a native Tallgrass Prairie mixture and *Lumbricus terrestris* (Canadian nightcrawlers), on the pollutant removal and hydraulic function in a bioretention cell. The objectives of this lysimeter study were; (1) to quantify overall water quality improvements, (2) to quantify overall changes in runoff quantity, (3) to quantify how earthworms and plants influence infiltration rates, and (4) to employ a model showing impacts of earthworms and soil fauna on soil macroporosity, and compare results to field data.

METHODS AND MATERIALS

Study Site

The study was conducted using twelve lysimeter cells (75 cm wide, 230 cm long, and 230 cm deep) located on the Kansas State University North Agronomy Research farm. The average high temperature range is from 4-32°C and the average low temperature ranges from -10-20°C. The mean annual precipitation is 835 mm (LTER, 2008). Three-fourths of the annual precipitation falls during the growing season from April-June with intense thunderstorms. This is followed by periods of drought during hot summer months (Hayden and Davis, 1998).

Experimental Design

The study consisted of four treatments in a completely randomized design; (1) earthworms only, (2) vegetation only, (3) earthworms and vegetation, and (4) control (see Figure 1). The cells were installed belowground with a 5 cm drainage pipe to allow water to drain from the cell. The lysimeter cells were used for previous water quality studies and were left with a 1 m layer of silt-loam soil. The remaining 100 cm were filled with a similar silt-loam soil (48% sand, 43.5% silt, 8.5% clay).

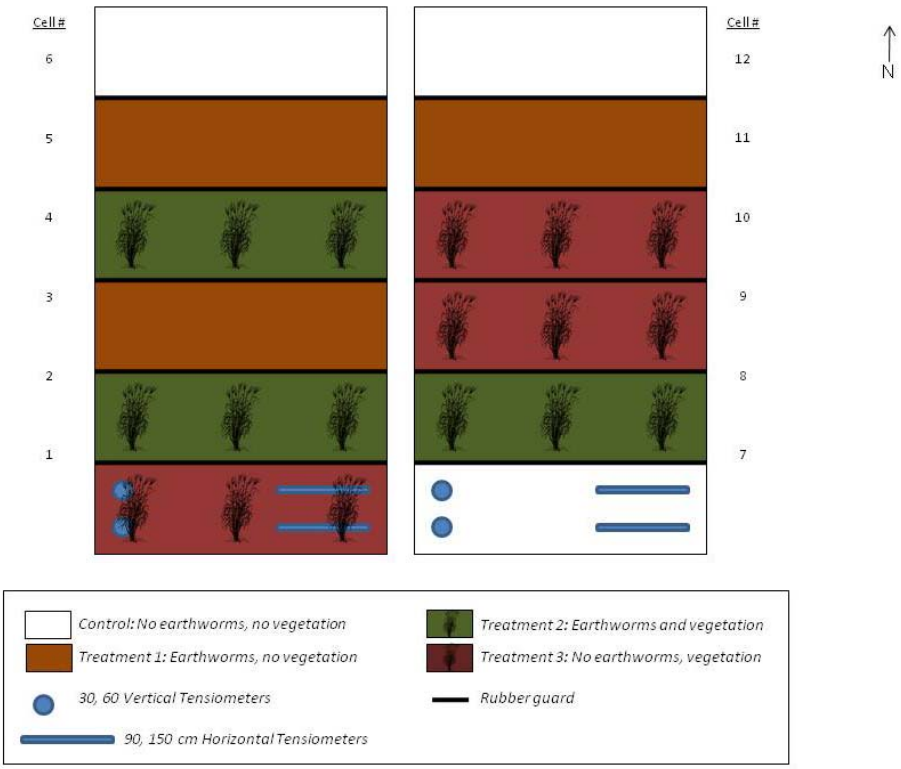

Figure 1. Configuration of lysimeter cells in completely randomized design.

To track changes in nutrient and metal content, five 30 cm (1 ft) deep soil cores were taken after weathering over the winter and after the conclusion of the growing season. Soil samples were analyzed for pH, nutrients, and metals. Synthetic stormwater and irrigation water was applied via a gravity-fed PVC pipe system. The chemicals used for the synthetic stormwater were mixed with potable water from the North Farm in 100 gallon tanks that drained into the PVC pipe system. Outflow was measured to the nearest liter.

On April 15, 2008 lysimeters cells 2, 3, 4, 8, and 10 (see Figure 1) were planted at with *S.* scoparium, Tripsacum *dactyloides*, *Sorghastrum nutans*, and *Bouteloua curtipendula*. These grasses were chosen because of their dense root structure and their ability to withstand the climatic variability. The root formation provides paths for water to flow into the soil, and thus may increase the storage capacity of a bioretention cell. Plant growth was monitored throughout the season and biomass was measured at the conclusion of the season by removing all aboveground biomass 5 cm above ground level. Roughly 10% (by weight) of removed biomass was dried overnight at 105°C and weighed to determine the dry-weight of aboveground biomass.

On April 1, 2008, 72 Canadian Nightcrawlers (*Lumbricus terrestris,* Figure 3.3) from Derick's Bait and Tackle (of unknown origin) in Manhattan, KS were introduced to cells 2, 5, 8, 9, 10, and 11 (see Figure 1). The burrowing activity of earthworms facilitates water movement via macropore flow. *L. terrestris* form vertical burrows that can be up 2.4 m deep (Shipitalo and Butt, 1999) that remain intact in an undisturbed soil system.

Synthetic Stormwater Tests

Each cell received natural precipitation as well as synthetic stormwater treatments. Table 1 shows the components of the synthetic stormwater. Water samples were collected for quality analysis either during synthetic stormwater application or at 48 hours after application, depending on the storm duration. Water pooled at the cell bottom for 48 hours may induce anaerobic conditions, and thus may impact nitrate removal through denitrification.

Table 1. Chemical components of synthetic stormwater

Pollutant Source	Mass (mg $10L^{-1}$)	Pollutant	Conc. (mg L^{-1})
Cupric Sulfate $CuSO_4 \cdot 5H_2O$	0.8	Copper	0.13
Sieved Soil	1	Total Suspended Solids	100
DAP $(NH_4)_2 \cdot HPO_4$	26	Nitrogen	0.47
		Total Phosphorus	1.2
Urea $(NH_2)_2 \cdot CO$	63	Nitrogen	2.83
		Total Nitrogen	3.3

Two different types of synthetic stormwater treatments were applied to the lysimeter cells. The first type of treatment, TREAT1, consisted of the water quality volume (WQv) generated from a representative watershed of 11.7 m^2 (MARC, 2008). Based on this procedure, 0.38 m^3 (100 gal.) of synthetic stormwater was applied to each cell for TREAT1. In the second treatment, TREAT2, 1.5 m^3 (400 gal.) of synthetic stormwater was applied to each cell. Results from the second treatment provided minimum size requirements for a bioretention cell to effectively treat an area.

All stormwater treatments were applied within 48 hours of each significant (> 13 mm) natural rainfall event from August to October 2008. There were no synthetic stormwater applications prior to August 2008 to demonstrate a potential bioretention cell management technique: routing stormwater runoff away from the cell during vegetation establishment.

Infiltration Tests

Cell soil moisture was measured prior to synthetic stormwater applications using vertical tensiometers located at 30 and 60 cm depths to note the impact of soil moisture on infiltration. Cell soil moisture was recorded weekly from August to October 2008 to note fluctuations in moisture. Infiltration rates were measured using a double ring infiltrometer prior to planting in March and again in October at the completion of this study. Infiltration during synthetic stormwater application was measured by noting the difference in time between whole-cell application and complete infiltration of the water front.

Comprehensive Bioretention Cell Model

The Comprehensive Bioretention Cell (BRC) Model was used to predict how a bioretention cell functions under a single storm event. The model allows cell designers to determine appropriate dimensions for bioretention layers based on desired pollutant

trapping efficiency and effluent water quality (Christianson, 2005, Christianson et al., 2004). Three parameter inputs, fractal dimension (Dv), macropore size (MAC), and layer depth, were manipulated to represent earthworm and vegetation impacts on infiltration; all other parameters were held at default values. Estimates for the parameters were based on the rates of macropore formation by earthworms and vegetation and the resulting macropore densities. This information was taken from previous research on earthworm dynamics and soil physical properties (Binet and Curmi, 1992, Butt and Nuutenin, 1998, Edwards et al., 1988, Edwards et al., 1990, Lee and Foster, 1991, Rice et al., 1998, Shipitalo and Butt, 1999, Weaver, 1946, Weaver, 1958, Weaver and Rowland, 1952)

It is very difficult to model the development of a living system over time as many different environmental factors control the progression of growth. The complex process was simplified for use in the BRC model by first compiling information on earthworm burrow and plant root size, population density, depth, and season of activity from ecological literature. Table 3 shows estimates for the D_v, MAC, and layer depth parameters in the BRC model based on ecological data. These values were used to model cell performance over the first three years of growth.

RESULTS AND DISCUSSION

Establishment of Ecological System

The maximum vegetation density (visual) occurred in late August and began to decline near the close of September and into October. The system was very productive compared to the Konza Prairie (Table 3). On average, cells treated with both vegetation and earthworms had higher densities of biomass and roots ($P > 0.6384$), possibly due to the symbiotic interaction between earthworms and plants (Baker *et al.,* 2006 and Kirkham,

1982). The high productivity rates were likely due to the high amount of nutrients available, particularly N, concentrated sunlight, and the lack of competition. The successful establishment of the grasses and earthworms may have been due in part to the management technique of routing the stormwater runoff away from the cell during the first few months of growth.

Table 3 Dry weight (g/m^2) of aboveground biomass

Treatment*	Biomass Density (g/m^2)	Estimated Root Density** (g/m^2)

AVE	*1093.78*	*875.03*

* VEG is vegetation treatment and VEGEW is vegetation + earthworm treatment
** Assumed ratio of roots to tops was 0.8 (Weaver and Zink, 1946)

Infiltration

On a seasonal-basis, the conductive ability of soil was enhanced by the introduction of vegetation and earthworms (Table 4). The effective saturated hydraulic conductivity (K_{eff}) is indicative of the ability of the soil profile to infiltrate water. The seasonal change in K_{eff} was significant in the earthworm only treatment and vegetation and earthworm combination treatment ($P > 0.0281$ and $P > 0.0046$, respectively).

Table 4. K_{eff} (cm/hr) by cell type

Ave.	1.77	35.73	*Ave.*	0.80	11.47			
Std. Dev.	0.90	10.23	*Std. Dev.*	0.92	9.53			

*VEG is vegetation treatment, VEGEW is vegetation + earthworm treatment, EW is earthworm treatment, and CONT is control

It is important to note that the typical K_{eff} for a silt loam is 0.65 cm/hr. In April 2008, the overall average saturated hydraulic conductivity for all cells was close to this K_{eff} value, at 1 cm/hr. The average infiltration rates of all treatment cells in October 2008 were around 20 cm/hr, almost double that of the control. The considerable increase in infiltration rates in all treatment types reflects the degree of establishment of the soil matrix, vegetation, and earthworms over the growing season. The greatest increase in K_{eff}

was in the most biologically diverse treatment (vegetation/earthworm) implying that earthworm and vegetation interactions in the combination treatment enhanced infiltration rates over vegetation or earthworm only treatments.

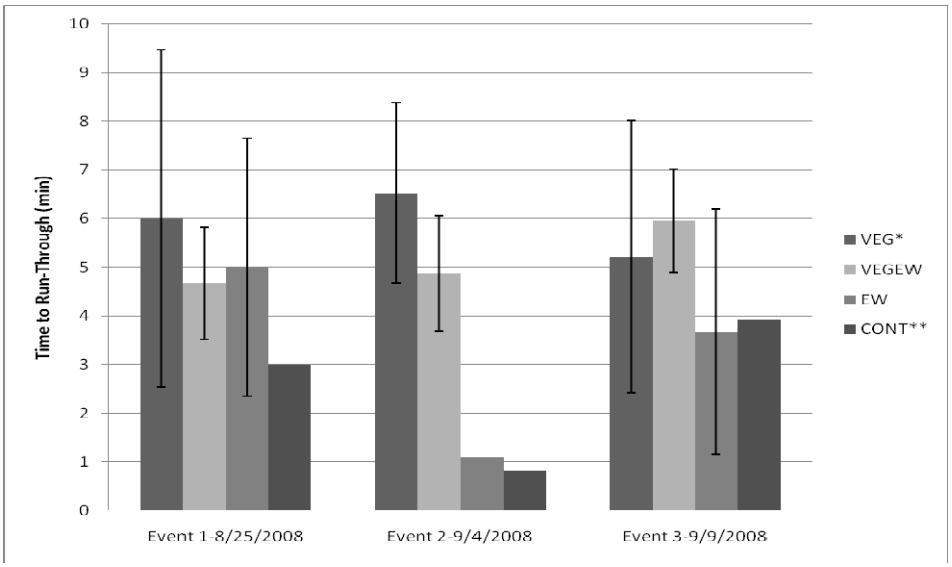

Figure 2. Time to run-through averaged by treatment for each storm event

On an event-basis (Figure 2), the treatments had an interesting impact on infiltration. Vegetation and vegetation/earthworm treatments generally had greater run-through times, while the earthworm and control treatments generally had shorter run through times. This may be explained by the presence of roots and the maintenance of the fine structure of the soil (Hino et al., 1987) which results in fewer macropores and an ability to remove water from the top soil via uptake and evapotranspiration. Detainment of runoff in the soil profile dissipates runoff energy and allows time for filtration and pollutant removal. The control and earthworm treatment do not detain water; water was instead readily conducted through the soil matrix.

Soil Moisture Fluctuations

Soil moisture fluctuations reflected how the presence of vegetation and earthworm impacts on long-term bioretention cell function. During the growing season, vegetation activity utilized water for growth and maintenance. Their influence continued in the off season through the macropores created during the active season that remained intact in the soil profile. The drying effect was evident in the tensiometer data at both 30 and 60 cm depths (Figures 3 a, b) because the tension of the control cell remained lower (wetter) than all other treatments.

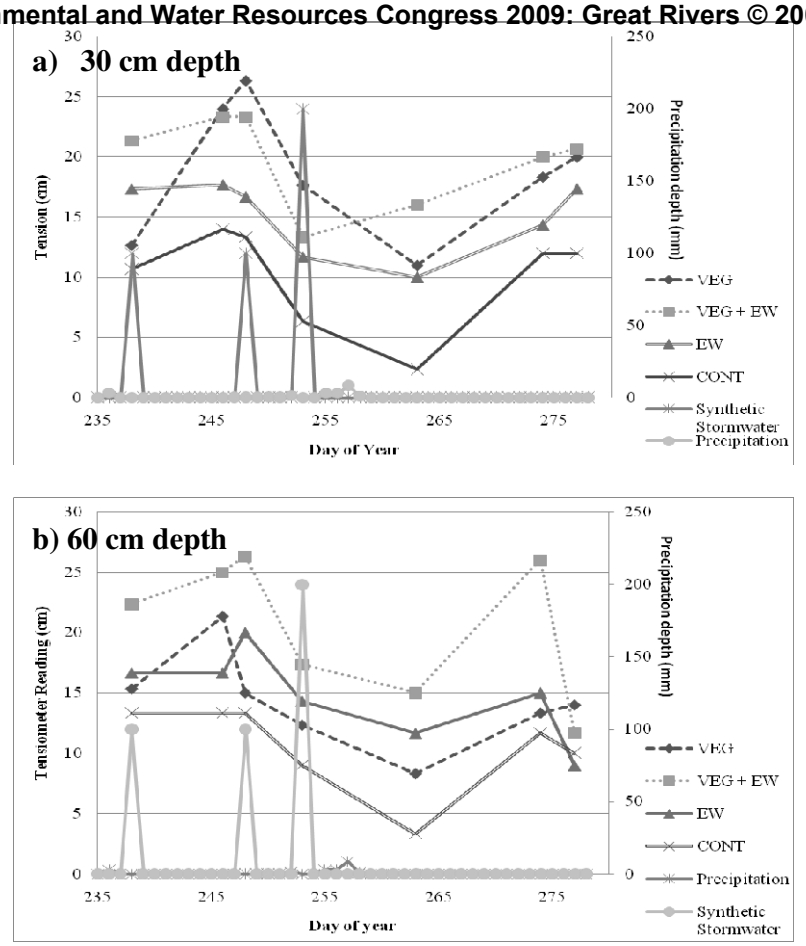

Figure 3. Tensiometer readings taken from August-October 2008 given in cm at a) 30 cm depth and b) 60 cm depth

In the top 30 cm of the soil profile, tension readings taken near the end of the growing season followed predicted trends of cells with more biological activity (VEG + EW > VEG > EW) drying out quicker. This was likely due to evapotranspiration and vegetation utilizing water for growth. However, the effect of the treatments on the soil moisture fluctuation was less pronounced at a 60 cm depth. This may be due to the fact that the roots of the vegetation had not yet reached the 60 cm depth in the first growing season.

Soil Quality

The media composition analysis (Table 4.2) of the cells in November 2007 prior to plant and earthworm inoculation showed high levels of N and P, a relatively neutral pH, and varying levels of chloride (from 0.5-12.5 ppm). The elevated levels of nutrients and chloride was likely a residual from the last experiment conducted in the lysimeter cells (Roberts, 2007).

Table 5. Summary of average percent change in soil quality by treatment type

	Mehlich-3 P	NH4-N	NO3-N	Total N	Total P	Chloride	pH

These large increases in P, N, and chloride indicate that plant uptake of water and nutrients did not sufficiently decrease the concentrations of pollutants in the topsoil. However, trapping pollutants in the top 30 cm of soil prevents pollutants from exiting the cells as effluent. With continued establishment, mature grass should utilize excess N and reduce export over time. These results show that plant processes minimally affected the uptake of nutrients and salts in the top 30 cm of soil. However, retention of the pollutants in the top soil reduced the concentration of pollutants in outflow.

Water Quality

All treatments reduced P by 84-96%. A large amount of N was released during all events from all treatments probably because of a high initial N content and consequent leaching potential of the bioretention media. It was difficult to analyze the results of Cu and TSS; the percent trapping efficiency was highly variable in the VEG, EW, and VEGEW treatments. With continued establishment, the mature grass will use more N and reduce the export of the nutrient with outflow over time.

Table 1. Percent trapping efficiency for each pollutant averaged for storm events

	Total N		Total P		Cu		TSS	
	Ave	Std Dev	Ave	Std Dev	Ave	Std Dev	Ave	Std Dev
VEG	-1205	1143	85	17	-171	452	-94	322
EW	-1541	710	84	4	-124	341	77	20
VEGEW	-2590	2512	85	4	62	53	28	62
CONT	-736	323	96	3	93	9	95	5

It is important to note that there was no significant difference among the treatments in transporting pollutants. Past studies have suggested that macropore flow increases the movement of pollutants, particularly with the transport of herbicides and in tile-drained agricultural fields (Nuutinen and Butt, 2002, Shipitalo et al., 1994). However, results from this study did not support these findings.

Model Results

Functional parameters investigated in this study included hydraulic conductivity, ponding depth, drawdown time, infiltration depth, storage, and volume outflow. The model results validated the hypothesis that the introduction of an ecologically diverse system improves bioretention function during the first two years of establishment by improving

infiltration, increasing infiltration depth, storage capacity, and reducing drawdown time. The model results for Season 1 reflected data collected from the first season of the field study. By the end of the first growing season, the vegetation and earthworm combination treatment exhibited the greatest impact on bioretention cell function. The maximum impact of vegetation on bioretention cell function occurred at the end of the second growing season, reflecting the fact that Tallgrass prairie root systems reach their greatest density after the second year of growth.

As depicted in Table 4.7, the earthworm treatment had an immediate impact on the ponding and storage in April of the first growing season. Without earthworm burrows, soils would likely be dominated by smaller, more uniform pores that would restrict infiltration to saturated flow only. Treatments with earthworms permitted unsaturated water flow via macropores and reduced the ponding drawdown to 24 hours within the first growing season. In the field, treatments with only earthworms actually restricted water movement due to surface sealing effects. Although the model results indicate that the control treatment drawdown time was always greater than 48 hours, the effects of surface sealing in the earthworm treatments were accurately characterized.

CONCLUSIONS

Despite poor initial growing conditions, the tallgrass plants and earthworms became well established over the course of the study and had interesting impacts on bioretention cell function. Perhaps the most notable impact was the considerable increase in infiltration rates in all treatments. As predicted, the greatest increase in saturated hydraulic conductivity was in the treatment with both vegetation and earthworms. It is also apparent from similar improvements in all cell types that ecological succession occurs to a certain extent despite ecological additions made prior to establishment. This was reflected in model results. When operated within the valid bounds of fractal dimension and macropore size, the BRC model can be an informative tool for bioretention cell design providing estimates for desired outcomes.

Other findings illustrate the important balance between biology and function: cells with biological components, such as earthworms and native vegetation, behave more like a natural system. Soil moisture fluctuations determined from tensiometer readings indicate a drying effect in treatments with biological activity. The control treatment (little to no macro-biology) consistently had a lower tension reading over time, indicating that the soil profile remained wetter longer than other treatments. Tensiometer readings taken at the end of the growing season (after day 265) followed the trend that higher levels of biology had a greater impact on soil moisture regimes. The trend was not as pronounced in the 60 cm deep tensiometers. This demonstrated that soil moisture fluctuations reflect the level of ecological establishment not only in the time it takes to dry the soil profile, but also in the depth of activity. With continued development, it is expected that the plant roots will have a greater impact deeper in the soil profile.

The results of this study show that ecological development is improved with diverse inputs. More biologically diverse bioretention cells experienced enhanced grass/root development, a decrease in drawdown time, reduced ponding, and an increase in infiltration rates. Cells with vegetation and earthworms also were more effective in drying out the soil profile, improving the ability of the cell to function in subsequent stormwater events. By conducting research in the Midwest utilizing native plants, fauna, and soil, the results of this study contribute to a growing pool of information which developers can use to guide effective BMP design. It is critical to continue developing our understanding of NPS pollution generation, transport, and mitigation in the urban environment. This will enhance our ability to develop and implement BMPs that have initial and long term viability and sustainability.

ABSTRACT

Kansas City's deliberate location along the Missouri River at the confluence of the Kansas River played a key part in the city's rich history and prosperity. From the city's beginnings, the river was a way to link one part of the country to another through transportation and trade. It provided a means to westward expansion and free enterprise. From early on, though, the river demonstrated its power over those that settled along its banks. That brought rise to federal flood control which originated in the early 1900s as a coordinated attempt to provide flood protection. As flood control evolved, the Flood Control Acts of 1936 and 1944 allowed the construction of the existing protection system in Kansas City. The Kansas City metropolitan system of seven flood protection levee units protect vital infrastructure while the rivers continue to provide an important asset to the area. Major flood events in 1951 and 1993 proved the potential devastation to the areas along the Missouri and Kansas Rivers. The 1951 flood led to improvements on many of the levee units. An ongoing feasibility study as a result of the 1993 flood will determine what beneficial changes can be made for the future. Billions of dollars have been saved over the years through property damage prevention, along with an unknown number of lives. As the river continues to be an important part of Kansas City, so too does the flood protection system that surrounds it.

ESTABLISHMENT OF A RIVER CITY

The Kansa, or Kaw, Native Americans were the first occupants of the area now known as Kansas City. Following the Louisiana Purchase, Meriwether Lewis and William Clark became the first people of European descent to come to the area. Lewis and Clark camped at the confluence of the rivers for three days in 1804 during their expedition. They mapped the area now known as Quality Hill calling it "a fine place for a fort." That declaration drew some interest for the area, but it was not until several years later that a Frenchman from St. Louis named Francois Chouteau settled along the river. He established a depot in 1821 for the American Fur Company about three miles below the large bend in the Missouri River (the current Northeast

Industrial District). Within five years after setting up the depot, however, Chouteau's warehouse was destroyed in a flood. When he decided to rebuild on slightly higher ground, several other French families joined him and the town of Kansas developed.

The appeal of the Missouri River also brought John Calvin McCoy to the Kansas City area in hopes of a successful selling and trading business. He set up a store in 1832 a few miles inland of Chouteau on the Santa Fe Trail. McCoy called this area south of the river Westport, as he considered it a portal to the West. At the same time, McCoy established a rock ledge area on the south shore of the Missouri as a landing area for river boats. Travelers soon found that the water route was faster and easier than shipping by land. Even with the four mile trip overland to Westport, the land travel reduction was substantial because the previous transfer point was about 22 miles farther east in Independence, Missouri. By 1845, Westport had replaced Independence as a source of supplies and point of departure for wagons headed west (see Exhibit 1).

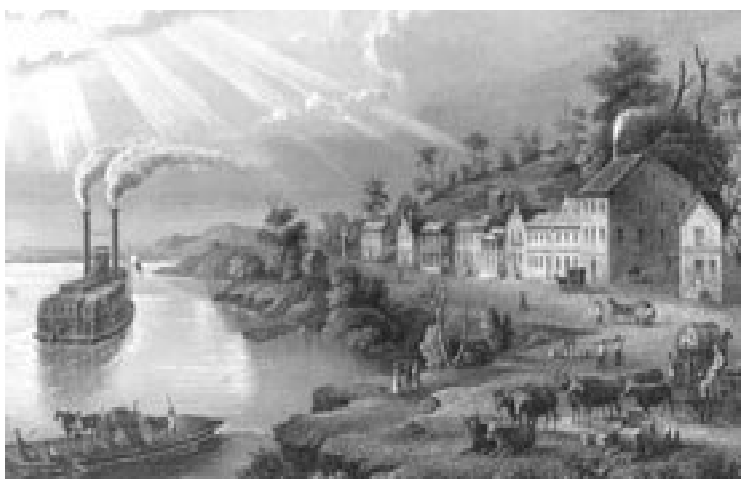

Exhibit 1: Depiction of Kansas City around 1850

Both the town of Kansas and Westport prospered under western migration for several years until a cholera epidemic threatened that in 1849. The epidemic took half of the population and drove business out of town. It took several years for the town of Kansas to recover, but it stayed viable and was incorporated as the City of Kansas in 1853. Westport survived as well and overland trade returned to the area. The settlements began to prosper again just in time for conflicts over slavery and the outbreak of the Civil War to disrupt the trend. Following some years of turmoil, the Missouri River came to the rescue once again for the Kansas City area. The Missouri Pacific Railroad arrived in 1865 and decided that the confluence of the Missouri and Kansas Rivers was the perfect spot for its railroad distribution center. The City of Kansas emerged as a wheat and grain exchange center. This led to the bridging of the Kansas River in 1866 and the construction of the Hannibal Bridge across the Missouri River in 1869. The first stockyards opened in 1870, setting the stage for the area to become known as a "cowtown." Kansas City adopted its current name in 1889 and annexed Westport in 1897.

ORIGINS OF FEDERAL FLOOD PROTECTION

As development and prosperity continued beyond the turn of the century in the Kansas City area, the Missouri River periodically reminded those living along its entire corridor that it remained an untamed force of nature. Major floods occurred along the Missouri River in 1903, 1915, 1926, and 1934. The 1903 flood inundated Kansas City, as seen in Exhibits 2 and 3. It is evident that the Kansas City area already had a vast amount of infrastructure that needed protection from the river.

Exhibit 2: 1903 photo of flooded business area in Kansas City

Exhibit 3: Photo of 1903 flooding at the old Union Station

Levees were constructed by locals in the early 1900s in what are now the Argentine, Armourdale, Central Industrial District, North Kansas City, and

Birmingham units (see Exhibit 4 in next section). Similar local and agricultural levees were being constructed in many parts of the country.

The failures of an uncoordinated levee system throughout the country were recognized in the late 1800s when the Mississippi River Commission was created to undertake flood control planning on the lower Mississippi. Despite this Commission, though, the existing levee-based flood control system was proven to be inadequate. When over 16 million acres in the lower Mississippi River valley were flooded in 1928, Congress passed flood control legislation and gave a role to the Corps of Engineers in its implementation. Congress eventually followed with the 1936 Flood Control Act which created a strong role for the federal government in floodplain management. This act declared flood control to be an acceptable federal government activity and authorized the expenditure of $310 million for more than 200 flood control projects, including several in Kansas City (Government Printing Office, 1940). Expenditure was conditioned on local interest participation and long-term operation and maintenance.

The Flood Control Act of 1944 allowed for expansion of the levee system and construction of multiple-purpose reservoirs for irrigation, navigation, water supply, hydropower, and recreation in the Missouri River basin. The development of the plan passed as part of this Act began as more flooding occurred in the early 1940s. Three floods in 1943 were particularly severe in the Omaha, Nebraska area. As Omaha's airport was vital to the war effort at the time, the flooding brought unprecedented congressional and public attention to the Missouri River basin.

The Corps of Engineers was authorized by the House Committee on Flood Control to produce a plan for the Missouri River basin that would provide flood control and other benefits. Colonel Lewis A. Pick, then division engineer in the Corps' Omaha office, was in charge of preparing the plan. On March 2, 1944, just 90 days after authorization, Pick submitted his plan which included major provisions for dams and levees along the river and its tributaries. It called for five dams on the Missouri River below Fort Peck, Montana, over a dozen reservoirs on tributaries, and 1,500 miles of levees on both sides of the river from Sioux City to the confluence of the Mississippi River (National Park Service, 2009). The plan was heavily focused on flood control and navigation, without much substance for irrigation benefits.

During the same timeframe, the Department of Interior's Bureau of Reclamation had been performing a multi-year study of the basin's water needs with the goal of producing a comprehensive plan by 1945. The impetus behind the Bureau's study was unsustainable agricultural practices, economic depression, and prolonged drought in the basin. Submission of the Pick Plan caught the Bureau by surprise and prompted the rapid completion of their plan. It was submitted to the Senate Committee on Commerce on May 5, 1944 and called for 17 power plants, 90 reservoirs, and the irrigation of nearly five million acres of the Great Plains (National Park Service, 2009). The focus of the Bureau's plan, known as the Sloan Plan, was irrigation and reclamation.

With two differing plans, a debate ensued in Washington. There were strong supporters on both sides, along with a growing idea of creating a Missouri River Authority that would manage efforts in the basin. President Roosevelt requested that the agencies develop a unified plan. Aided by the fact that the Corps and the Bureau

agreed on their dislike of the potential for a Missouri River Authority, they ultimately reached a compromise plan. The resulting Pick-Sloan Plan included the majority of provisions outlined by the individual plans and was ratified by Congress in the Flood Control Act of 1944. President Roosevelt signed the Flood Control Act on December 22, 1944 which also authorized appropriations to each of the two agencies for construction of the initial stages.

KANSAS CITYS FLOOD CONTROL IMPROVEMENTS

The combined 1936 and 1944 Flood Control Acts provided authorization and funding that led to the emergence of a focused protection system for the Kansas City area. The existing system is known as the Kansas Citys Flood Damage Reduction Project, as it provides local flood protection for the metropolitan areas of Kansas City, Missouri and Kansas City, Kansas. The project consists of seven levee units along reaches of the Kansas and Missouri Rivers:

- Argentine Unit
- Armourdale Unit
- Birmingham Unit
- Central Industrial District Unit
- East Bottoms Unit
- Fairfax-Jersey Creek Unit
- North Kansas City Unit

The existing project extends over the lower 10 miles of the Kansas River and, on the Missouri River, from 6.5 miles upstream to 12.5 miles downstream of the mouth of the Kansas River. The seven units of the flood protection system were designed and constructed in conjunction with each other, but are independently operated to some extent. The total protected area covers about 32 square miles and is characterized by dense industrial and commercial development. Some limited residential habitation is also present. Communities (or portions thereof) within the area include Kansas City, North Kansas City, Randolph, and Birmingham all in Missouri; and Kansas City, Kansas.

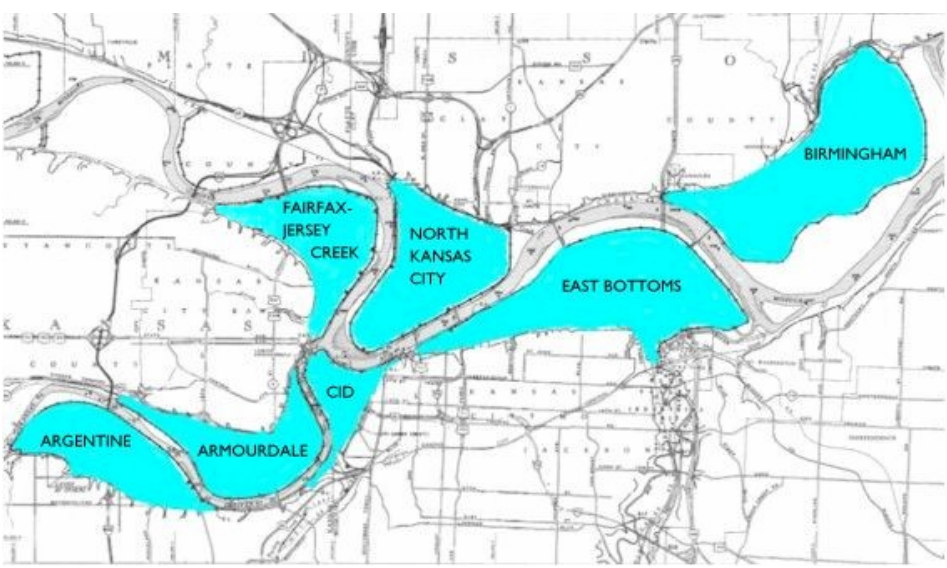

Exhibit 4: Overview map of the Kansas Citys Levee System

The **Argentine Unit** is located in Wyandotte County, Kansas, on the right bank of the Kansas River. The unit begins at the Santa Fe Railroad embankment upstream from the Turner Bridge at a point approximately 4,000 feet east of the mouth of Barber Creek. The beginning portion of the levee unit parallels the Santa Fe Railroad embankment before turning northwesterly toward the Barber Creek mouth. At about Kansas River Mile (RM) 10.1, the unit turns to follow the course of the Kansas River. The levee unit ends on the Kansas River at a point about 2,000 feet downstream of the 18th Street Bridge (Kansas RM 4.7). A floodwall containing two stoplog gaps crosses the train tracks to the south and ties into high ground.

Modification and strengthening of works originally constructed by the Kaw Valley Drainage District began in May, 1951 and were completed in November, 1955 by the Corps of Engineers. More recent improvements, separately authorized as the 1962 Modification, were completed in April, 1978.

The flood protection facilities consist of levees, stability berms, floodwalls, underseepage control, 2 stoplog gaps, 6 pumping plants and 18 drainage structures. The levees total approximately 5.2 miles long. The floodwalls total about 1,350 feet.

The **Armourdale Unit** is located along the left bank of the Kansas River from RM 7.0 to RM 0.3, near the confluence of the Kansas and Missouri River. The original levees and floodwalls were constructed under the jurisdiction of the Kaw Valley Drainage District. The protection is separated into three sections totaling about 5.8 miles in length. The uppermost levee section is a tieback from high ground west of Mattoon Creek, then heads downstream to the Union Pacific Railroad tracks. From the Union Pacific Railroad tracks, the levee extends from the railroad embankment near the mouth of Mattoon Creek downstream along the left bank of the Kansas River to the floodwall. The second portion is a floodwall that begins north of the Chicago, Rock Island, and Pacific Railroad Bridge and extends downstream to connect with the third levee section. The third levee section ties back into high ground at the embankment of the Lewis and Clark Viaduct.

Construction of the Federal project began in May, 1949 and was completed in February, 1951. More recent improvements, separately authorized as the 1962 Modification, were completed in April 1976.

The flood protection unit consists of levees, stability berms, retaining walls, floodwalls, underseepage control including 45 relief wells, 2 sandbag gaps and 2 stoplog gaps, 10 pump plants, and 36 drainage structures. The levees stretch about 5.7 miles through the Armourdale Unit and the floodwalls total approximately 6,600 feet.

The **Birmingham Unit** is located on the left bank of the Missouri River, approximately 12.4 miles downstream from the mouth of the Kansas River. The original construction was done under the jurisdiction of the Birmingham Drainage District allowed by a resolution dated February 18, 1946. The upstream section of the levee was raised and strengthened in 1952 by the Federal Government. The downstream section was strengthened and modified in 1954 and 1955. The levee begins at the bluff southeast of Randolph, Missouri and extends southwest along an abandoned railroad fill. It continues south to the Missouri River and downstream until it turns north and west along the left bank of the old Liberty Bend channel to the

old Wabash Railroad. From there, the levee goes upstream along the right bank of Shoal Creek to high ground at Liberty Road.

The flood protection works include a levee, stability berms, floodwalls, underseepage control, 3 sandbag gaps, 2 stoplog gaps, 2 pump plants, and 4 drainage structures. The levee is about 11.0 miles long and the floodwalls total approximately 430 feet.

The Kansas portion of the **Central Industrial District Unit** is located in Wyandotte County and extends from the Kansas/Missouri state line along the right bank of the Missouri River to the mouth of the Kansas River. It then continues upstream along the right bank of the Kansas River to RM 3.4. The Kaw Valley Drainage District is the local agency responsible for operation and maintenance. The original unit was constructed by the Kaw Valley Drainage District prior to May, 1948, when initial Federal improvements began. The bulk of the improvements were completed by November, 1955. The most recent improvements were completed in December, 1979.

The unit consists of a system of levees and floodwalls, underseepage control including 17 relief wells, a stoplog gap, a sandbag gap, 10 pump plants, and 23 drainage structures. The levee is approximately 1.7 miles long and the floodwalls total about 7,900 feet.

The Missouri portion of the Central Industrial District flood protection unit is located in Kansas City within Jackson County. The unit extends along the right bank of the Missouri River, upstream from the Grand Avenue Viaduct (RM 365.7), to the Kansas/Missouri state line (RM 367.2). The initial construction took place in March, 1946 and was completed in September, 1947. Significant improvements and repair of 1951 flood damage followed the initial construction and were completed in November, 1955.

The unit consists of a system of levees, floodwalls, underseepage control, 1 sandbag and 7 stoplog gaps, 7 pump plants, and 5 conduits. The levees total about 430 feet in length and the floodwalls are about 1.5 miles long.

The **East Bottoms Unit** is located in Kansas City, Missouri within Jackson County. The unit extends downstream along the right bank of the Missouri River from the Armour-Swift-Burlington (A.S.B.) Bridge, RM 365.6 (adjusted 1960) to the mouth of the Blue River, RM 357.7 (adjusted 1960). Then the levee turns and heads west upstream along the left bank of the Blue River to the Union Pacific Railroad embankment.

The initial construction was completed in September, 1950, and the City of Kansas City formally accepted the project on July 30, 1951. The most recent work on the East Bottoms Unit was completed in August, 1974.

The unit consists of a system of levees, floodwalls, stability berms, retaining walls, underseepage control including 28 relief wells, 3 stoplog gaps, 11 pump plants, and 17 drainage structures. The levee portion is about 9.2 miles long. The floodwall portion is approximately 2,190 feet long.

The **Fairfax-Jersey Creek Unit** is located on the left bank of the Kansas River from the Union Pacific Railroad Bridge (Kansas RM 0.3) downstream to the mouth of the Kansas River. It then extends along the right bank of the Missouri River from Missouri RM 367.5 to RM 373.9 (1960 adjusted mileage).

Initial construction occurred in April, 1940 and was completed in May, 1941. Numerous modifications and improvements were constructed in the late 1940s, early 1950s, and 1955, with the most recent completed in June 1955.

The flood protection facilities consist of levees, floodwalls, underseepage control including 113 relief wells, 4 stoplog gaps, 1 sandbag gap, 13 pump plants, and 23 drainage structures. The total length of levees is about 5.3 miles and the floodwalls are approximately 4,040 feet. The Fairfax Drainage District provides operation and maintenance from levee Sta. 31+50 (boundary line with Kaw Valley Drainage District) to Sta. 313+72 (bluff at upstream end of unit).

The Airport Section of the **North Kansas City Unit** is located in Kansas City, Missouri within Clay County. The protection lies along the left bank of the Missouri River from a few feet beyond the city boundary with North Kansas City, Missouri (RM 369.6, 1960 adjusted) to the downstream floodwall at the Hannibal Bridge (RM 366.2, 1960 adjusted).

Construction began in May, 1946 and Kansas City, Missouri accepted the unit in October, 1947. Several improvements have been made since the initial construction, with the most recent work being completed in June, 1955.

The flood protection facilities consist of levees, floodwalls, underseepage control including 48 relief wells, 3 pump plants, and 3 drainage structures. Total lengths of levee and floodwall are approximately 2.5 miles and 530 feet, respectively.

The portions of the North Kansas City Unit maintained by the North Kansas City Levee District are located in both North Kansas City and in Kansas City, Missouri. These portions include a short upper section extending downstream along the left bank of the Missouri River from the bluff just north of the Kansas City, Missouri Waterworks intake to where the Airport section (described above) begins. After the Airport Section ends, the North Kansas City Levee District portion continues in an easterly direction. It follows along the left bank of the Missouri River to a point where the North Kansas City hillside ditch exits to the Missouri River near the Missouri River Chouteau Bridge. At the hillside ditch outlet, a long hillside tieback turns back sharply to the Northwest and runs to a termination point just west of the North Cherry Street Bridge. Construction began in 1946. Several improvements have been made since initial construction, with the most recent work being completed in June, 1955.

The unit consists of a system of levees, floodwalls, underseepage control, 3 stoplog gaps and 1 sandbag gap, 6 pump plants and 6 conduits. The North Kansas City Unit portion maintained by the North Kansas City Levee District has approximately 6.2 miles of levees and about 310 feet of floodwalls.

One can observe from the descriptions above that the protection system for the Kansas City metropolitan area is somewhat complex. It involves two states, two major rivers, and seven levee units operating together with multiple local sponsors. There are over 50 miles of flood protection works including 46 miles of earthen levee (typically over 12 ft. high) and 6 miles of floodwall (heights ranging from 2 ft. to 22 ft.). The estimated fixed investment within the protected area is over $16 billion. It protects about 5,000 structures (business and residential) and about 20,000 residents. About 90,000 people are employed within the protected area, where there are

extensive road and rail systems of regional and national importance. A municipal airport and several vital utilities also exist.

IMPACT OF MAJOR FLOODS

The Missouri River natural valley floodplain is approximately 2 to 2½ miles wide, while the main channel averages about 1,000 feet wide throughout the protected reaches. Bank-full discharge is approximately 140,000 cubic feet per second (cfs) for the reach of the Missouri River upstream of the mouth of the Kansas River. For the reach of the Missouri River downstream of the mouth of the Kansas River, the bank-full discharge is approximately 180,000 cfs. The drainage area of the Missouri River just upstream of the confluence with the Kansas River is 425,100 square miles.

The Kansas River natural valley flood plain is approximately 1¼ miles wide, while the main channel averages about 600 feet wide throughout the protected reaches. Bank-full discharge is approximately 60,000 cfs. The drainage area of the Kansas River basin is 60,060 square miles.

Two major floods stand out in the history of the modern Kansas Citys flood protection system. The Great Flood of 1951 was mainly a Kansas River event, while the Great Flood of 1993 was primarily a Missouri River event. The peak flow on the Missouri River downstream of the confluence of the Kansas was estimated to be about 573,000 cfs for the 1951 event, the highest discharge on record. The 1993 event was slightly lower at about 543,000 cfs and ranks third behind the 1903 event mentioned earlier.

At the time of The Great Flood of 1951, only one reservoir (Kanopolis Lake) of the several that were planned was in operation on the Kansas River. The peak on the Kansas River was estimated to be about 510,000 cfs. The protection system was in its early stages of completion and the flood overtopped all three of the levee units along the Kansas River – Argentine, Armourdale, and the Central Industrial District. An estimated 15,000 people were evacuated from the area and five people lost their lives to the flood. The damages were approximately $870 million in 1951 dollars, which would be almost $10 billion today.

Exhibit 5: Kansas City newspaper photo from The Great Flood of 1951

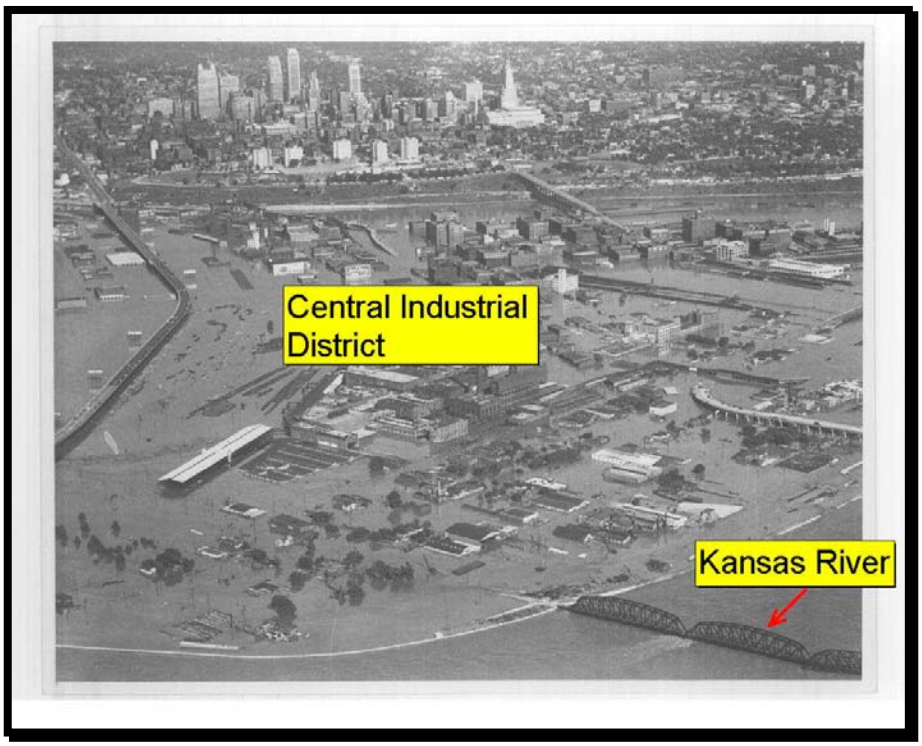

Exhibit 6: Photo of Central Industrial District during 1951 flood

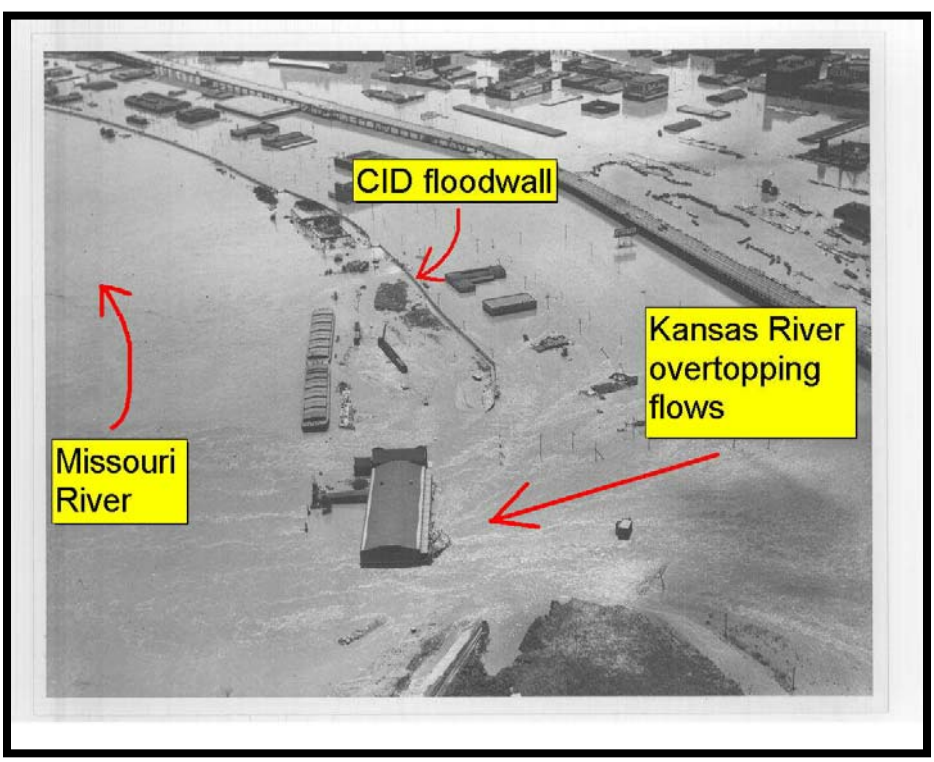

Exhibit 7: 1951 flood photo of overtopping in the Central Industrial District

Examination of the 1951 flood and associated peak discharges led to the 1962 modified design flows and ultimately the "1962 Modification" that raised the Kansas

River levees. It also expanded the control system by authorizing more upstream reservoirs, including Milford, Perry, and eventually Clinton Lake in the Kansas River basin.

Upstream flood control lakes and levee raises in Kansas City were in place in 1993, when the new benchmark flood on the Missouri River occurred. The Great Flood of 1993 was a major test of the Kansas Citys levee system. The Kansas River reservoirs utilized all of their flood control storage volume and greatly reduced the flows down the Kansas River. The Missouri River mainstem dams were operating to greatly reduce flows on the Missouri as well. The entire protection system passed the flood without failing, but the water crested close to the levee tops on the lower Kansas River. The flood peaked about three to five feet below the top of levee on most of the Missouri River units. It is estimated that about $4.5 billion in damages were prevented.

CURRENT CORPS OF ENGINEERS FEASIBILITY STUDY

From a hydraulic overtopping standpoint, each of the Kansas Citys seven levee units passed the 1993 flood event. Some minor repairs to the flood protection system were needed after the waters receded, but that was not unexpected. Based upon observations from the 1993 flood, some questions were raised regarding the system's performance relative to the original design intent, and regarding the geotechnical and structural components. The levee unit owners (also known as "sponsors") requested a reevaluation of the Kansas Citys Levee System. In 1999 the Kansas City District, Corps of Engineers initiated a comprehensive $8 million investigation of the Kansas Citys Levee System, called a "feasibility study".

The feasibility study is authorized by Section 216 of the Flood Control Act of 1970, which provides general authority to review completed projects as follows:

> *The Secretary of the Army, acting through the Chief of Engineers, is authorized to review the operation of projects the construction of which has been completed and which were constructed by the Corps of Engineers in the interest of navigation, flood control, water supply, and related purposes, when found advisable due to the significantly changed physical or economic conditions, and to report thereon to Congress with recommendations on the advisability of modifying the structures or their operation, and for improving the quality of the environment in the overall public interest.*

The City of Kansas City, Missouri, the North Kansas City Levee District, the Fairfax Drainage District, and the Kaw Valley Drainage District are the study sponsors. Their share of the feasibility study costs is 50 percent.

The feasibility study is evaluating modifications to increase the system reliability, reduce flood damages and reduce the flood risks for six of the seven levee units within the existing Kansas Citys Levee System. These include the Argentine Levee Unit, the North Kansas City Levee Unit, the East Bottoms Levee Unit, the Fairfax-Jersey Creek Levee Unit, the Armourdale Unit, and the Central Industrial District Unit. The Argentine, Amourdale, and the Kansas portion of the Central Industrial District levee units are owned by the Kaw Valley Drainage District. The Fairfax-Jersey Creek Unit is owned by the Fairfax Drainage District. The City of Kansas City, Missouri owns the Missouri portion of the Central Industrial District Unit and the East Bottoms Unit. The Birmingham Levee Unit was not deemed to need improvements.

In 2006, an Interim Report was completed and submitted, and subsequently approved by the Headquarters, U.S. Army Corps of Engineers (HQUSACE). The interim or "Phase I" report recommended site specific improvements to structural and foundation features for the units located on the Missouri River, but no Missouri River units were recommended to be raised in height. The report found that the Argentine

Unit on the Kansas River does not provide the nominal 500-year level of protection originally anticipated by the authorization, and the Phase I Report has recommended a levee raise for that unit of 5 feet on average. The feasibility study is continuing, with detailed evaluations of the Armourdale and Central Industrial District units to be published in a final or "Phase II" report in 2010. The recommended plan modifications from Phase I of the report are summarized below:

Argentine Levee Unit: Approximately 5.5 miles of levee would be raised an average of about 5 feet. The levee unit raise includes modifying earthen levee and berms, about 1,340 feet of flood wall, stop log gaps, and other necessary line of protection features. Fourteen utility crossings would be relocated over the levee, including pressure pipelines that currently pass under the levee. Three pump stations would be modified or replaced to retain the reliability of the line of protection.

Fairfax Jersey Creek Levee Unit – Fairfax-Jersey Creek Sheetpile Wall: The modifications would include reconstructing about 870 feet of sheetpile wall to ensure the wall's stability and construction of about 600 feet of new sheetpile wall to reduce the risk of levee failure.

East Bottoms Levee Unit: Modifications would include installing approximately seventeen pressure relief wells to reduce underseepage and reduce the risk of failure and constructing approximately 2,100 linear feet of 30-inch pipe system to transfer collected seepage from the wells to the proximity of the Hawthorne pump plant.

North Kansas City Levee Unit – Harlem Area: Modifications would include constructing a new buried collector system about 2,600-feet long and 18-inches in diameter with seepage collection vaults to enable pumping during flood events. This would control underseepage pressures at the interior toe of the existing levee.

North Kansas City Levee Unit – National Starch Area: Modifications would include installing approximately 20 pressure relief wells, an approximately 2,000-feet long and 30-inch diameter pipeline, and a new pump station to collect, move and remove water in order to control underseepage at the interior toe of the existing levee.

Fairfax Jersey Creek Levee Unit – Fairfax-BPU Floodwall: The modifications would include strengthening about 1,450 feet of floodwall using approximately 50-foot deep; 24-inch diameter piles about seven feet apart**.**

The table on the next page (Exhibit 10) shows the estimated total costs and cost sharing associated with the levee modifications recommended in the Phase I Report. Construction of features recommended in a feasibility report is cost shared 65 percent by Federal, and 35 percent by the local sponsor. Currently, as funding becomes available, design work has been initiated on several of the project features approved in the Phase I Report.

Levee Unit and Site	Price Level Estimate ($1000)		
	Total By Site	Federal (65%)	Sponsor (35%)
Argentine 5 ft levee raise	52,873	34,367	18,506
Fairfax/BPU floodwall modification	7,879	5,121	2,758
Fairfax-Jersey Creek sheetpile wall	4,984	3,240	1,744
NKC-Harlem buried collector	1,549	1,007	542
NKC National Starch area wells & pump	6,621	4,304	2,317
East Bottoms pressure relief wells	1,644	1,069	575
Totals	75,550	49,107	26,443

Exhibit 10: Summary of levee modification costs recommended in the Phase 1 Report

CONCLUSIONS

The history of the Kansas City metropolitan area is tied very closely to the Missouri and Kansas Rivers, and the Kansas Citys Levee System that protects much of the commercial, industrial, and residential development in the very heart of the area. If we had the ability to turn back the clock 200 years, certainly all would agree that development in the floodplain should have been avoided. However, the evolution of history and man's interaction with nature does not often have the full benefit of hindsight. Meanwhile, the areas protected by the levee system provide critical manufacturing, transportation, and other essential services for the region and the entire Nation. Our responsibility now, along with pursuing wise policies in floodplain management and risk communication, is also to reduce the exposure to flood risk whereever justified and affordable. The Army Corps of Engineers, along with its many partners, is now embarking upon the challenge of the next century and the next millennium - striking the proper balance between multiple goals in water resources, effective risk management, and maintaining a viable levee protection system prepared to meet the future challenges of a dynamic and changing river system.

KANSAS CITY, MISSOURI WET WEATHER SOLUTIONS PROGRAM A TWELVE STEP PROGRAM

Erin Ollig and Sheila Shockey

Shockey Consulting Services, LLC, 7611 Park Street, Lenexa, Kansas 66216; PH (913) 248-9585; FAX (913) 248-9581; EMAIL: Erin@shockeyconsulting.com; Sheila@shockeyconsulting.com

ABSTRACT

The measure of a successful public participation effort is not only sharing information, and gathering public input but also in changing behaviors on a larger scale. The Wet Weather Solutions Program was created by the City of Kansas City Missouri to reduce flooding, improve water quality and protect and restore the natural environment. To prepare the long-rang plan, a large scale public participation process was employed. It resulted in an innovative plan but also drove significant changes to the culture of an entire city organization; and introduced and promoted sustainability throughout all aspects of the City. As a result of the public participation process, Kansas City is destined to be one of the greenest cities in the United States over the next 25 years. A unique perspective from inside the public participation process of a $4.0 billion public infrastructure project is outlined from the lead public participation consultants for the Program.

INTRODUCTION & BACKGROUND

In 2001, the Kansas City Missouri Water Services Department began to develop a Combined Sewer Overflow (CSO) Plan as required by state and federal regulators. That effort evolved into a Wet Weather Solutions Program primarily as recommended by stakeholders during a large scale public participation process. The stakeholders further drove significant changes to the culture of an entire city organization, introducing and promoting sustainability, starting with management of water resources and moving throughout all aspects of the city services. As a result of the public participation process, Kansas City is destined to be one of the greenest cities in the United States over the next 25 years.

Born out of the regulatory and financial drivers, the Overflow Control Program (OCP), a division of the Kansas City Missouri Water Services Department, moved beyond the traditional management of wastewater facilities and started to manage wet weather in a more integrated way. The Wet Weather Solutions Program's mission was to manage the City's water resources in a sustainable way. The City's Water Services Department had previously never involved the public until this program demonstrated successful public participation efforts. Now, several citizen committees work on policy issues and participation at the project level.

But things didn't change overnight. Over a span of five years, a variety of methods were used to involve the public. Some methods worked, others didn't. The methods that did succeed were the reasons why the Plan ultimately received broad stakeholder support.

WHO WANTS TO TALK ABOUT SEWERS?

Citizen leadership was very important, however it was not all sunshine and daisies. Many bumps and roadblocks set progress back and moved progress in a different direction. At the end of the day, citizen leadership made the difference. It is not always easy to get people to give up their time to talk about sewers.

Community Panel Chairperson

The heart of the public participation program for the Wet Weather Solutions Program was the Wet Weather Community Panel. A strong chairperson who had a passion for improving Kansas City and a capacity to learn new and complicated information was very important. Carol Grimaldi, President of Brush Creek Community Partners, was the Chairperson of the Panel the entire five years. She never missed one of the forty-five meetings that were held and attended many of the subcommittee meetings as well as meetings with the consultant team and staff. She was able to help the program team understand what was not being said out loud or behind the scenes. Her meeting management style was inclusive but firm. She often let the other Panelists' air their concerns, while making sure the message stayed on task. She became the spokesperson for the program and the Overflow Control Plan.

In 2005, the Panel nearly fell apart because the Panelists felt like they were not allowed to get to the "meat" of the discussion. The staff and project team had not gathered all the data and information needed yet so the meetings were primarily basic education. They were worn out. The turning point was in late 2005 and early 2006 when the Panelists revolted. Finally, the Panelists were allowed to provide important input. They began to develop Guiding Principles and Goals and Objectives that eventually helped to define the Panelists' purpose and the entire Wet Weather Solutions Program. The data was not available to discuss alternatives so the Panel focused on values and a general strategy. They finally had the "meat" that they wanted and felt like their time was being used wisely.

Subcommittees

The subcommittees of the Community Panel were developed to discuss specifics of the recommendations in more detail. These subcommittees were found to be an invaluable method to work on the details of important issues. Some members of the Community Panel were more interested in certain subjects than others. When opportunities arose to discuss some of those subjects in more detail, they were encouraged to participate in the subcommittee meetings. The subcommittees would meet and often make recommendations that would be forwarded on to the entire Community Panel for further discussion. Many complicated discussions took place in the subcommittee meetings, discussions that couldn't have taken place in the time constraint of the two-hour long Community Panel meetings.

Funding Task Force

The Wet Weather Community Panel did not discuss funding for the program as part of their scope. Instead, a separate Mayoral-appointed committee was formed in January 2008. The Water Services Utility Funding Task Force was tasked with helping to integrate community values into forming a funding strategy for the City's water, sewer and stormwater utilities. The Task Force developed guiding principles for the development of user charges and fees that are fair, equitable and sufficient to meet revenue requirements. In addition, the Task Force provided guidance on how to fund the Overflow Control Program. The Task Force provided the Mayor and City Council written recommendations regarding funding issues. A resolution was passed endorsing their recommendations in December 2008.

Council Participation

In May 2007, Councilwoman Jan Marcason was made the point person for sewers for Kansas City. Eventually deemed the "Sewer Queen", Councilwoman Marcason attended most of the Community Panel meetings after she came to office and was the Chairperson for the Funding Task Force. Once the draft Plan was submitted to the City Council for approval in May 2008, Councilwoman took the heat because many didn't think the Plan was "green" enough. She began to educate her fellow council members and worked with staff to educate them. Eventually, in December 2008 when the Plan was approved by the City Council, Councilwoman Marcason was praised by her peers for her on-going commitment and dedication.

Lessons Learned

1. It is important to be able to include people with varying interests in the conversations, particularly those with different perspectives and dissenting views. Getting the right people involved and asking them to discuss the right questions at the right time is key.

2. People talk about what they know. Distribute materials ahead of the meeting is a good idea, but most participants won't read it if there is too much or if the information is highly technical. It's hard to grasp the nuances of the technical details of such a project such as levels of control and the magnitude of the costs. Don't be surprised is someone nontechnical is the one to change the entire conversation because they simplify the topic and say something very profound around their basic values. That type of thinking and conversation is how you build consensus.

3. Don't start too early with advisory groups or citizen committees. Wait to convene stakeholder committees when you have recommendations for them to develop or input that is needed.

IT'S ABOUT THE SEWERS STUPID!

Let's be honest, sewers aren't sexy. It's hard to peak interest in something that is out of sight, out of mind, as they say, but it is after all about the sewers. You need to talk

about pollution, public health and explain the risks and tradeoffs. This was difficult for some team members initially. They didn't want to say what the problem was and that something needed to be done about it because then the regulators may force them to fix it. This created an "elephant in the room" that no one would talk about. This seemed silly because the agency folks were going to make the city do something about overflows and we needed citizens to feel good about paying for it. If people couldn't talk about sewage in streams, how were they going to help to figure out how to address it or feel good about paying to fix it? We needed to help them understand how it all affected them or how they would benefit from solutions and investment. The public was told that there was a problem, yet the details were very vague. The local newspaper even said it wasn't a story.

In 2006, the City began to shift its thinking and began to tell people that fixing the sewers will relieve basement backups, remove diluted sewage from the streams and that the Plan will be very expensive to implement. Interest began to pick up. Consultants were allowed to use different language than before such as "sewage" and "billion" to describe the problems. The program was tagged as the "largest infrastructure improvement in Kansas City's history." Then sewers became the sexy story and people wanted to talk about them.

When funding began to be discussed in detail in early 2008, the newspapers became very interested. Interest peaked in other aspects of the Program as well. One reporter who came to the funding meetings began to write more about water quality too. Sometimes the news was inaccurate or negative, but the City felt that any coverage on the Program would be good coverage- this was a way to get the word out to the larger public. As the media became more and more interested, we developed a good working relationship with reporters and an editor in particular who really began to understand the issue and therefore reported the facts and figures accurately.

Lessons Learned:

4. Tell people why they should care! It is important to be blunt about what the problem is when you are trying to get the public's interest. People don't understand that sewage goes into the streams. People don't understand that dog poop and geese droppings make more of an impact on water quality than they do. Be upfront and forthcoming and the interest and trust will increase.

SPAGHETTI DINNERS AND FISH FRIES

Successful public education is not just about counting the number of cookies that have been eaten at a meeting, but about the number of people that have been educated. Again, sewers aren't sexy, so sometimes innovative methods need to be used to get the word out.

In 2006 and 2007, Basin Coordinating Committees were formed throughout the City. There were a total of 57 meetings and 11 open houses that took place as part of this process. A lot of time and money went in to the preparation of these meetings. After

all is said and done, it may have been more efficient to reach out to existing groups at existing meetings than trying to get people to come to a meeting about sewers.

To increase attendance at one of the open houses in the inner city, spaghetti dinner and fish were served. A couple of pancake breakfasts were held to draw people in and to get them to listen to staff speak about the problem. The turn out at the events was high. We are uncertain whether the people in attendance really learned anything about the issues and there was little input provided. It was, however, a positive event to reach out to the public.

Kansas City is divided up into many small neighborhood associations, block groups, and homes associations. The City decided to reach out to the neighborhood leaders and ask if they could speak at one of their meetings. This was well-received. To date, over 2,300 people with 92 organizations have received a road show presentation. There was great interaction and discussion at the meetings.

Lessons Learned:

5. Serve food, and they will come but not necessarily pay attention and participate.

6. Go to where people already gather to get the best collaboration.

YOU CAN'T SAY IT TOO MANY TIMES OR TOO MANY DIFFERENT WAYS

The average person needs to hear something five (5) times before they internalize the message and act on it. Using multiple communication techniques and methods with the same message really helps build understanding.

One of the most used tools was a short video about the issues and plan. In 2006, a video was created primarily for the Overflow Control Program to visually demonstrate what the sewer system looks like and describe the problem Kansas City faces. In 2008, the video was updated to include elements about stormwater as well as educating people on the way the City will fix the problems and what they can do to help.

Other methods included water bill newsletter inserts that are distributed to over 450,000 persons, television programming on the local access channel, a 10,000 Rain Gardens Campaign that was advertised through television and radio media, two public opinion surveys that were randomly distributed throughout Kansas City, and a Wet Weather Solutions Program website that contains information on what citizens can do as well as information on meeting dates and materials.

A lot of money was spent on public education and participation and that was criticized by the City Council, but many felt there was not enough. At many Community Panel meetings, we heard "we need more public education," "we need to get the word out," and "my neighbor has not heard anything about this problem."

This was really frustrating for us but we feel like we should have communicated better to people what we had been doing to educate and involve the public more and invite them to participate in the education process.

Lessons Learned:

7. Repetition is the key.

8. Use multiple methods and techniques.

9. Try to be efficient in your use of resources.

10. Communicate to stakeholders what you are doing and involve them in the education and outreach as much as possible to build buy in.

DON'T BLAME ME, IT'S GOT TO BE SOMEONE ELSES FAULT

As people became more and more educated about how watersheds work, the neighbor upstream, Johnson County, Kansas became a target. Johnson County is at the top of the Blue River watershed- a watershed that is a central focus of the problem and proposed improvements.

Johnson County officials came to a majority of the Community Panel meetings and twice gave presentations on what their County and municipalities are doing to improve water quality on their part. Despite all of that, some Community Panelists pointed fingers upstream and pressed for ways to get them to pay for it. The result of this conversation was the inclusion of the Blue River Watershed Plan in the Overflow Control Plan. It is a commitment to continue to work with neighbors in the watershed to solve problems jointly.

Lessons Learned:

11. Involve stakeholders beyond city limits to solve watershed issues.

GREEN TAKES ON A LIFE OF ITS OWN

In late 2006 and early 2007, a shift took place. Green solutions became a purposeful and intentional part of discussions, particularly amongst Community Panelists. It is hard to determine how the movement began, but when it did, it took on a life of its own. For various reasons, whether it was a business opportunity, personal interest, interest in finding ways to reduce the cost of the Program, or interest in improving the City as a whole, many people thought green solutions were the answer. The conflict came about when people thought green solutions were the only answer.

Green solutions and technologies for combined sewer overflow control is not the typical strategy. The project team wanted to accommodate stakeholders' desire for green solutions but they wanted to make sure it would be accepted by the agencies and not just be an add-on to the program. Sustainable thinking considers people, prosperity and the planet and there was concern about green solutions costing more

up front. This program was already going to cost billons. A subcommittee of the Community Panel was formed in January 2007 to discuss green solutions as part of the Plan in more detail. This became an impassioned group that produced a Position Paper that eventually was endorsed by the entire City Council and Mayor. This interest peaked interest by other City departments and the regulators. The U.S. Environmental Protection Agency's Deputy Director, Benjamin Grumbles, became a rock star to Community Panelists when he distributed a memorandum touting the benefits of green solutions for combined sewers.

The project team was never against green solutions, although some may disagree. There was a lot of discussion about whether green technologies were the silver bullet, the miracle cure, or simply one tool in the tool box. The project team felt green solutions was an important tool in the tool box. They were working with regulators to accept green in Kansas City but that was perceived by some proponents of green as not having enough support for green. Some community participants and even City Council members didn't think the project team was truly committed to green. It began to feel like two people were in the same room saying the same thing but neither one hears the other. Everyone was talking past each other. Outside forces were feeding the misunderstanding and mistrust. It was frustrating.

Because of the on-going discussions on green solutions, the City was granted a six-month extension on submitting its Plan to determine if more green solutions could be added to the Plan. The City will spend the first ten years on green solutions and committed to some more specific plans for green pilot projects.

Lessons Learned:

12. Public participation can sometimes be messy but in the end, it is completely worth it.

SUMMARY

As a result of the public participation process of the Wet Weather Solutions Program for Kansas City Missouri, a shift has taken place. Not just green solutions, but also about how and when to involve the public. The Water Services Department did not involve the public in developing plans in the past, but as a result of this process, the staff and consultants have developed a new respect for citizens. Ultimately, the City's partnership with citizens resulted in a better plan and that partnership will be vital for the implementation of this long-term plan.

Kansas City, MO Overflow Control Program: Line Creek/Rock Creek Sanitary Sewer Study

Jeffrey W. Davies, P.E.

HNTB Corporation, 715 Kirk Drive, Kansas City, MO 64105; PH (816) 527-2838; FAX (816) 221-9016; email: jwdavies@hntb.com

ABSTRACT

Kansas City's Water Services Department (WSD) prepared a Long Term Control Plan (LTCP) to provide a roadmap to reduce the magnitude, frequency, and duration of combined sewer overflows (CSOs), and for the rehabilitation and improvement of the sanitary sewer system (SSS) to prevent sanitary sewer overflows (SSOs) and basement backups.

The study area for this project includes the sanitary sewer system within the Line Creek, Rock Creek, Buckeye Creek, and Searcy Creek watersheds. The drainage area of these watersheds is approximately 25 square miles north of the Missouri River and contain 8-in to 72-in diameter sanitary sewers.

A hydraulic model was developed using XP-SWMM based on data collected from the City's Geographical Information System. Recommended improvements were evaluated to prevent SSOs, and preliminary cost estimates were developed.

HYDRAULIC MODEL

The collection system hydraulic model was developed based on the Kansas City, MO *Hydrologic and Hydraulic Model Protocol* and included pipelines with a diameter of 24 inches or greater, associated manholes, diversion structures, and pump stations. Inclusion of 24-inch and greater diameter pipelines served the purpose of minimizing model analysis run time while retaining the hydraulic integrity of the collection system. A summary of the modeled pipe diameter and length is provided in Table 1 and can be seen in Figure 1.

Table 1 Summary of Modeled Pipe Diameter & Length

Diameter (in)	Length (ft)		Diameter (in)	Length (ft)
24	41,615		48	8,071
27	9,762		54	6,596
30	16,630		60	2,704
33	4,265		66	3,495
36	26,874		72	3,195
42	2,209		Total	125,416

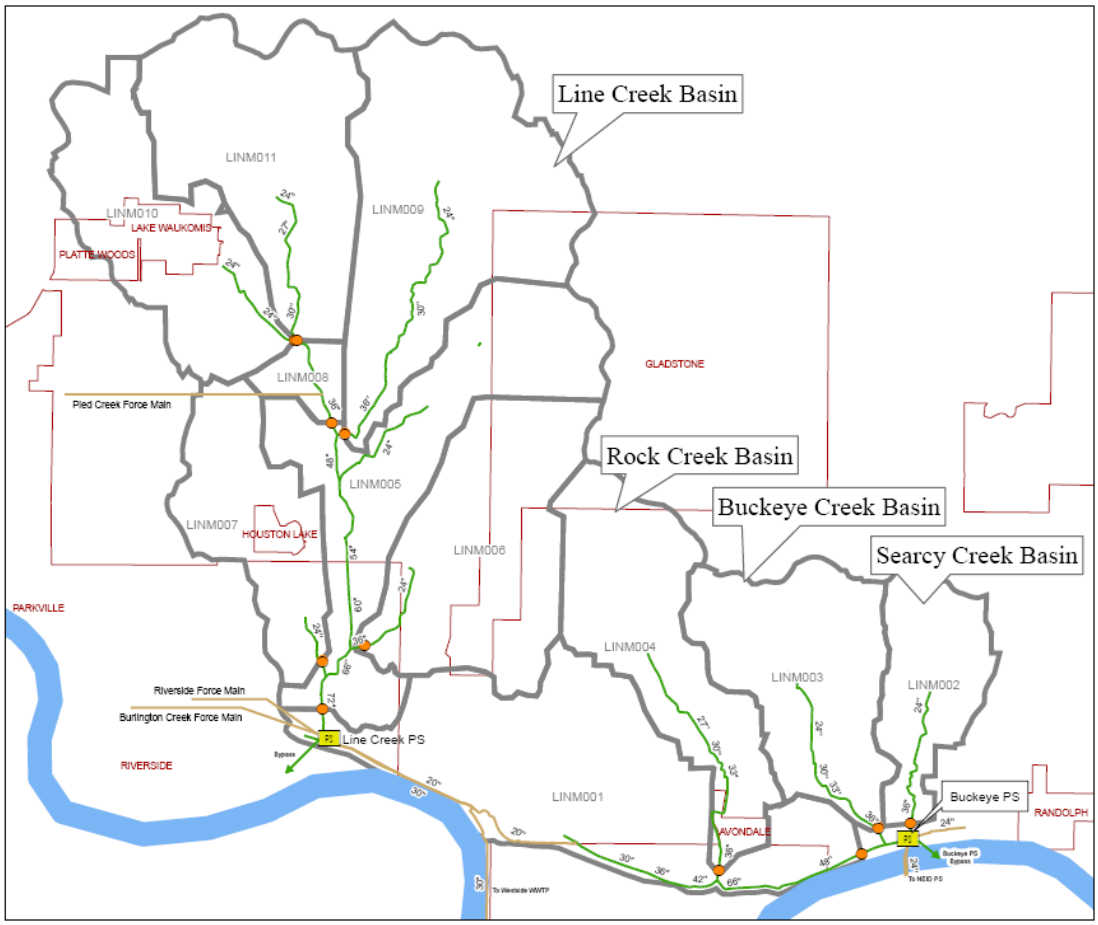

Figure 1 Basin Locations & Modeled System

The development and calibration of the wastewater collection system model proceeded in four phases:

Phase 1 - Data Collection
Phase 2 - Network Development
Phase 3 - Flow Projection
Phase 4 - Dry and Wet Weather Calibration

Data Collection

The data collection phase consisted of gathering the City's best available data on the sewer collection and conveyance system. For the existing sanitary sewer system, information on pump stations, pipes, manholes, and control structures which served as the physical foundation of the sewer model was developed from the City's GIS database and available reports. In addition to the physical data, current and future sewer loads were needed. Data from the pump stations, wastewater treatment plant influent data, and data from the 2005 flow monitoring program were gathered and analyzed to assist in model development and calibration.

Network Development

Pipe network attribute data was verified through quality control procedures in an effort to minimize the amount of erroneous information incorporated into the model. The manhole database was checked for quality control first, by following the procedures below:

- Verified XY coordinates through GIS
- Checked for duplicate manhole IDs
- Checked for manholes with duplicate XY coordinates
- Ensured that rim elevations were greater than manhole invert elevation
- Verified that appropriate manholes were referenced in the pipe database

After verifying the manhole database, the following procedures were used to provide quality control for the information in the pipe database:

- Checked for duplicate pipe IDs
- Verified pipe lengths using a GIS

Once the quality control checks were performed, manholes and pipes with missing data (i.e., IDs, elevations, sizes, lengths, etc.) were documented and provided to the field investigation team. The field investigation included:

- Locate manhole and provide global positioning coordinates (GPS) of the manhole lid (northing, easting, top elevation).
- Open manhole and provide depth to flow lines, pipe diameters, pipe material, manhole size, assessment of manhole condition, etc.
- Complete manhole inspection form.
- Photograph manhole exterior and interior.

Flow Projection

During model development, existing and future land use data was used to generate sanitary base flows at the sewer system manholes. Using the GIS, the sanitary base flows at each manhole were computed by taking the sewer flows for various land uses in the sewer service area and assigning sewer flows to the nearest manhole. The Line Creek GIS sewer layer and hydraulic model network of the sewer system were used to as the basis for delineating the existing sewer service area.

Dry and Wet Weather Calibration

The calibration process consisted of calibrating both dry and wet weather flow events. Dry weather flow calibration ensured an accurate depiction of base flow generated within the study area. The wet weather flow calibration consisted of calibrating the hydraulic model to a specific set of storm events to quantify the peak flow and volume of rainfall dependent inflow and infiltration (RDII) entering the collection system. The amount of RDII allowed to enter the collection system is essentially the difference between the wet weather flow and dry weather flow components.

DESIGN STORM ANALYSIS

The City provided information regarding the storm event used for the design storm event analysis. For this project, the U.S. Soil Conservation Service (SCS) Type II 24-hour distribution was used as the design storm. Analysis of the existing system and future system requirements was based on the 5 year storm event. Table 2 summarizes the rainfall totals for the 5 year storm event.

Table 2 SCS 24-hour Type II Rainfall Distribution

Return Frequency (years)	5
Rainfall Depth (inch)	4.68
Peak Hour (inch)	2.34
Peak 30 Minute (inch)	2.00
Peak 15 Minute (inch)	1.29

Existing wastewater production was based on data acquired during the 2005 City wide flow monitoring program. Wastewater production associated with future development was based on 100 gallons per capita per day. Collection system and facility requirements for existing conditions were determined using the previously calibrated model as a starting point. The City stipulated the operation of the Line Creek pump station during design model simulations. After a detailed investigation into the existing operation of the Line Creek pump station, the dry weather models were configured to send 60-70% of flow up to a maximum of 8 MGD to the Hillside Levee Interceptor and the remaining portion of the flow to the Westside WWTP.

The wet weather flow consists of dry weather wastewater production in addition to infiltration and inflow, also known as rain dependent inflow and infiltration (RDII). The limited capacities of the existing Line Creek and Buckeye Creek pump stations caused extensive backup into the collection system. The pump stations were removed from the design storm models and the inlets to the pump stations were modeled under free outfall conditions.

Results of the analysis show that parts of the system contain bottlenecks that become overloaded during large rain events. To establish the location of these flow restrictions, the results from the model were broken into five (5) separate sections. These sections represent the four (4) major watersheds included in the project area and the Hillside Levee Interceptor. To better understand the existing level of service in each one of the watersheds, the number of manholes and length of pipe which are not currently adequate for the desired level of service was summarized. To develop a better understanding of existing system performance, each line segment included in the model was put into one of five (5) categories of percent utilization. When Q refers to the maximum simulated flow and C refers to the design capacity of each pipe segment, the categories are defined as follows:

1. **<100%** - if Q/C*100<100%
2. **Backup** - if Q/C*100<100% and downstream manhole is surcharged
3. **>100%** - if 150% > Q/C*100 > 100%
4. **>150%** - if 200% > Q/C*100 > 150%
5. **>200%** - if Q/C*100 > 200%

The results from this analysis are summarized in Table 3, Table 4, and Table 5.

Table 3 Summary of Existing Conditions Model Results

Model Segment	Length of Sewer (ft)					
	Included in Model	Percent Utilization				
		<100%	Backup	> 100%	>150%	>200%
Buckeye Creek	10,600	2,800	1,000	6,000	700	0

ALTERNATIVE DEVELOPMENT

The Line Creek Drainage Basin was divided into seven (7) sub-basins for I/I flow monitoring. The Rock Creek/Searcy Creek/Buckeye Creek Drainage Basin was divided into four (4) sub-basins. Refer to Figure 1 for the location of the various sub-basins within the overall Drainage Basins.

Inflow & Infiltration (I/I) Removal Plan

Flow was monitored in each sub-basin and an estimate of the cost required to remove I/I flow was developed for each Sub-Basin. The Unit I/I Removal Costs ($/gpd) ranged from $0.48 to $2.09. Total I/I rehab costs ranged from $0.2M to $6.5M per basin being improved. An I/I reduction program known as the "Nashville Approach" was used to determine if there was a cost-effective point for these improvements. This approach begins with the assumption that I/I improvements will be needed in 20% of the total length of the sewers in each sub-basin and that a reduction of I/I flow of 50% will be achieved by the improvements.

Based on this method, it was determined that it is cost effective to remove I/I flow from every basin. A few basin improvement scenarios were selected that will allow a large percentage of I/I reduction to be achieved without removing I/I flow from every basin. Additional basins could be added to the improvement plan in the future to gain extra capacity for the treatment units.

Relief Sewers

Relief sewer improvement costs were also calculated for the number and size of pipes that were required to be replaced or upgraded after I/I improvements were made to each basin. Relief sewer improvement costs ranged from $33.9M if no I/I improvements were made to $9.5M if all the basins received I/I improvements. A summary of the I/I removal costs and the relief sewer improvement cost for the basin improvements scenarios selected for evaluation is shown in Table 6.

Table 6 I/I Removal and Relief Sewer Improvement Cost Summary

Selected Basins for I/I Improvements	Basins 010, 009, 006, 005, and 004	Basins 010, 009, 006, 005, 004, and 003	All Basins
Expected Reduction in Total Flow	28%	35%	41%
Total I/I Removal Cost ($M)	34.3	44.4	70.9
Total Relief Sewer Improvement Costs ($M)	15.7	12.4	9.5

Wet Weather Solutions

Several types of storage, transport, and treatment technologies were compared and evaluated. The types which were most applicable to this project included lift stations/force mains, tunnels for both storage and transport, above ground storage facilities, a new wastewater treatment facility to be built near the current Line Creek Lift Station, and upgrades to the existing Birmingham wastewater treatment facility to treat the additional flows rerouted there.

Selection of Alternatives for Evaluation

Three (3) alternatives utilizing the various technologies were chosen for evaluation:

1. New wastewater treatment facility near Line Creek Lift Station for the Line Creek Basin flow transport of the wastewater (by tunnel) from the

Buckeye Lift Station (Rock Creek/Searcy Creek/Buckeye Creek Basin Flow) to the Birmingham Wastewater Treatment Facility.
2. New force main from the Line Creek Lift Station to the Buckeye Lift Station to the Birmingham Wastewater Treatment Facility.
3. New tunnel from the Line Creek Lift Station to the Buckeye Lift Station to the Birmingham Wastewater Treatment Facility.

Each Alternative was further analyzed under four (4) options involving how flow was split between new and existing treatment facilities:

A Up to 12 MGD of flow is pumped to the Westside Treatment Plant. Up to 10 MGD is pumped to the Blue River Treatment Plant. All remaining flow is treated north of the river.
B. Up to 12 MGD of flow is pumped to the Westside Treatment Plant. All remaining flow is treated north of the river.
C. Up to 10 MGD is pumped to the Blue River Treatment Plant. All remaining flow is treated north of the river.
D. All flow is treated north of the river.

Each Option was further evaluated under the following Basin I/I Improvement Scenarios:

a. No I/I reduction in any basin. No relief sewer improvements.
b. No I/I reduction in any basin. Relief sewer improvements only.
c. I/I reduction in basins 10, 9, 6, 5, and 4. Relief sewer improvements.
d. I/I reduction in basins 10, 9, 6, 5, 4, and 3. Relief sewer improvements.
e. I/I reduction in all basins. Relief sewer improvements.

Design Criteria

The following design criteria were also used in determining the required equipment sizing:

- Pump Stations were sized to handle the peak flow.
- Storage Facilities, including Tunnels and Evacuation Pumps, were sized to fill during peak flow events and to be emptied over a period of 48 hours.
- Treatment Facilities were sized with a 2.5 peak to average ratio. The required pump rate to empty the Storage Facilities in 48 hours was considered the sustained peak flow that the treatment plant must handle, and the plant size (based on the average flow) was calculated based on the ratio listed above.
- Force Mains were sized for a minimum velocity of 2 ft/sec and a maximum velocity of 5 - 6 ft/sec.
- Gravity Outfall sewers were sized to flow up to 75% full at peak flow at an assumed slope of 0.005 ft/ft.
- A minimum slope of 0.1% is assumed for tunnels. A minimum of 3 ft/sec is needed for proper flushing in the tunnel system.

Cost Analysis

All of the Alternatives/Options were analyzed for costs using the Kansas City, MO *Basis of Cost Manual*. Table 7 (Table ES-1 from that Manual), which summarizes the construction cost and O&M cost equations used in this evaluation.

The following values were used for the variables required in the equations:

- C = calculated value
- A = calculated value
- V = calculated value
- N = 6 uses per year
- N_s = based on one shaft every 3,333'
- D = calculated value
- L = Line Creek Lift Station to Buckeye Lift Station – 29,000 ft; Buckeye Lift Station to Birmingham WWTP – 21,000 ft; Total Length – 50,000 ft
- Q = calculated value
- Hr = calculated value
- Q_{ave} = calculated value

The following cost data was used in addition to the cost formulas given in the Basis of Cost Manual:

- Odor Control costs were included in the pump station, storage tank, and tunnel costs as follows: Pump Stations - $1,000 per MGD pumping capacity; Storage Tanks - $11,000 per MG; Tunnels - $200,000 per access shaft.
- Wastewater Treatment Plant costs were estimated at $5 per MGD treatment capacity (average flow).
- O&M costs for existing facilities remaining in operation were not included in the alternative analysis.
- O&M costs for tunnels in continuous operation were assumed to be the same as wet-weather tunnels (N=6).

Replacement Costs were estimated assuming a 50 year design period. Process equipment associated with treatment facilities was assumed to have a service life of 20 years and have a replacement cost of 35% of the original construction cost. Mechanical and electrical systems associated with pumping facilities were assumed to have a service life of 10 years and have a replacement cost of 35% of the original construction cost.

The Present Worth and Equivalent Uniform Annual Cost for the capital, O & M, and replacement costs of each Alternative/Option were calculated using the formulas given in the *Basis of Cost Manual*. A 50 year life cycle and a discount rate of 5% were used.

Table 7 Summary of Construction and O&M Cost Equations

Control Technology	Construction Cost (million $)	Annual O&M Cost ($1,000)
Storage Tanks[5]	$C = 8.367\ V^{0.5546}$	$A = 1.2\ N + 2.5\ C$
Tunnels		
Hard Rock[6]	$C = 1154.4\ e^{0.0721\ D} \times L/10^6$	$A = 2.24 \times 10^{-4}\ L + 6\ N_s +$
Soft Ground[7]	$C = 981.4\ e^{0.1121\ D} \times L/10^6$	$1.2NxL/10{,}000+2.5C$
Swirl Concentrators	$C = 0.310\ Q^{0.611}$	$A = 0.6\ N + 20\ C$
Screens	$C = 0.1275\ Q^{0.843}$	$A = 0.6\ N + 20\ C$
Sedimentation Basins	$C = 0.398\ Q^{0.688}$	$A = 0.9\ N + 20\ C$
High Rate Treatment[8]	$C = 0.2846\ Q$	$A = 0.350V + 20C$
Chlorination/Dechlorination	$C = 0.228\ Q^{0.464}$	$A = 0.3\ N + 20\ C + 0.251\ V_{avg}$
Ultraviolet Disinfection	$C = 0.536 + 0.072\ Q$	$A = 0.3\ N + 1.062\ Q + 0.00043\ Q*Hr$
Sewer Construction	Use cost estimator	Minimal[3]
Pump Station		
Intermittent Service	$C = 0.3437\ Q$	$A = 0.6\ N + 20\ C + 0.372$ $+ 0.419Q + 0.00069Q*Hr$
Continuous Service	$C = 0.3437\ Q$	$A = 219.4 + 20\ C + 0.477\ Q + 5.93\ Q_{avg}$
Combined Sewer Separation[4]		
Residential	$C = 0.036\ S$	None[3]
Commercial/Mixed Use	$C = 0.085\ S$	
Downtown Area	$C = 0.130\ S$	

1. ENRCCI = 8500
2. Cost variables: C=Construction cost (million $); A=Annual O&M cost ($1000); V= Storage volume (million gallons); N=Average annual number of uses; N_s=Number of access shafts; D=Finished tunnel diameter (feet); L= Tunnel length (feet); Q=Design flow rate (MGD); V= Overflow volume treated per year (MG); V_{avg}=Average annual treatment volume (MG); Hr=Average annual operating hours; Q_{avg}=Average annual discharge rate (MGD); and S=Total sewer basin area (acres). The variable "e" is the base of the natural logarithm.
3. The annual O&M cost for new sewers is assumed to be minimal. O&M consist of video inspection and cleaning once every 10-15 years.
4. Unit costs of sewer separation considered valid for basins less than 250 acres only.
5. The unit cost equation for storage tanks is considered applicable for tanks with volumes ranging from 2 million gallons to 30 million gallons.
6. The unit cost equation for hard rock tunnels is considered applicable for diameters of 10 to 35 feet.
7. The unit cost equation for soft ground tunnels is considered applicable for diameters of 5 to 20 feet.
8. The unit cost equation for high rate treatment facilities is considered applicable to facilities with capacities less than or equal to 100 MGD.

RESULTS

The alternative analysis produced total capital costs ranging from $344.2M to $607.3M, and total present worth values ranging from $391.5M to $751.4M.

Based on the results of this analysis, Alternative 3, Option A, I/I Reduction in All Basins was determined to have the lowest present worth value. Alternative 3, Option A, with I/I Reduction in Basins 010, 009, 006, 005, 004, and 003 produced very comparable numbers, and does not rely on achieving a large I/I reduction from every single basin. A summary of the costs associated with these two alternatives is located in Table 8.

Table 8 Alternative Cost Summary

	Alternative 3, Option A I/I Reduction in All Basins	Alternative 3, Option A I/I Reduction in Basins 10, 9, 6, 5, 4, and 3
Expected Reduction in Total Flow (%)	41	35
Required Equipment Sizing Summary		
-Line Creek Basin		
-Tunnel Diameter (ft)	8	9
-Rock/SearcyBuckeye Creek Basins		
-Tunnel Diameter (ft)	8	9
-Pumping Facilities (MGD)	23	26
-Birmingham WWTP Upgrades		
-Treatment Plant (MGD)	10	11
Total Capital Cost ($M)	345.5	344.2
Present Worth Operation and Maintenance Costs ($M)	32.9	35.2
Present Worth Replacement Cost ($M)	13.1	14.5
Total Present Worth ($M)	391.5	393.9
Equivalent Uniform Annual Equivalent Cost ($M)	21.4	21.6

ACKNOWLEDGEMENT

George Butler & Associates was a sub-consultant to HNTB Corporation for this project and provided flow monitoring, hydraulic modeling, and design storm analysis.

ABSTRACT

The City of Lake Winnebago, Missouri, is a tight-knit community focused on providing residents with water-based recreational opportunities on the existing 244-acre lake. The original master plan for the community involved building two lakes; however, bankruptcy by the developer limited the community to one lake. Residents never lost their desire to complete the original lake plan and have partnered with South Winnebago Partners, LLC to complete the vision for the city.

The project proposes to construct a new earthen filled dam downstream of the existing lake. The proposed dam is 65 feet tall and 1,440 feet long. Relocating the dam will expand the surface area of the lake from 244 acres to approximately 416 acres. The proposed project would result in placing fill material into jurisdictional waters of the United States, causing the unavoidable impact to 15,879 linear feet of stream and 16.57 acres of wetlands. Because this project is one of the largest regulated Corps of Engineers activities within the Kansas City metropolitan area, Olsson Associates was hired to complete Section 404 Permitting and mitigation planning.

Mitigation measures are proposed at two locations within the South Grand River watershed. Mitigation is consistent with the project goals of using a watershed-based approach, providing self-sustaining ecological units, protecting rare and unique habitats, and constructing complementary habitats within the existing landscape. Mitigation activities include preserving and restoring 118 acres of the Middle Big Creek floodplain. Restoration includes planting approximately 5,500 trees to restore 25.4 acres and enhance 11.3 acres of riparian woodland. The plan also includes restoring 8.1 acres of native grass buffer, enhancing 8.1 acres of mesic prairie buffer, enhancing 4.3 acres of prairie buffer, and the enhancing 6.0 acres of wetland prairie. Approximately 750 linear feet of tributary will be created to reconnect historic flows to 2,400 linear feet of tributary. To compensate for wetland impacts, 15.28 acres of emergent wetlands will be restored, and 6.45 acres of existing forested wetlands will be preserved.

PROJECT BACKGROUND AND HISTORY

The Lake Winnebago dam relocation project proposes to increase the size of an existing community-based recreational lake to stimulate new residential and commercial development. However, the full breadth of benefits the proposed project offers the local community must also be recognized. The primary driver for this project is the partnership of the City of Lake Winnebago and a local group of development investors, South Winnebago Partners, LLC, to ensure the long term viability of the city. This community, with approximately 485 homes, has focused on providing residents with recreational lake living. Yet, the financial and social livelihood of the community has continually been challenged since the community's conception and the subsequent bankruptcy by the original development group.

In 1964, Mr. Robert Steinhilber established a development company and a master plan to build two phases of a lake community in northern Cass County. The original master plan included constructing the existing Lake Winnebago and the uncompleted Lake Winnebago South. Constructing both phases would have ultimately included residential development surrounding two separate lakes and a commercial retail component located along Missouri Highway 291. Following construction of the first phase of the community in 1968, in 1970 the development company operated by Mr. Steinhilber filed for bankruptcy, leaving the residents to absorb a large debt resulting from unpaid bonds sold to fund the construction of sewers, waterlines, and other infrastructure.

After filing for bankruptcy in 1970, Mr. Steinhilber once again organized a second development company to sell lots around the proposed south lake. Between 1970 and 1972, Mr. Steinhilber sold approximately 400 lots in the second phase before a receivership was filed against his company. The developer once again defaulted on obligations, and the property was held in receivership for over 27 years. All 400 lots sold before the receivership was filed were never deeded to the original purchasers, and only a partial repayment was made following the legal settlement with Mr. Steinhilber's development group.

The financial burden to the residents from the original bankruptcy in 1970, in addition to necessary repairs to the existing dam over the last 40 years, depleted the available financial resources of the community, prohibiting the purchase of the phase two properties when the receivership ended. The properties were ultimately purchased by the current landowner, whom the city approached to complete the development as originally promised by Mr. Steinhilber in 1964.

The city has needed the proposed lake expansion since 1968 due to insufficient economic resources to support the daily operations of the city, maintain important infrastructure, and manage lake maintenance. This large financial burden has resulted in high taxation and financial assessments to community residents. The cooperation with by the existing land owner and the partnership with South Winnebago Partners, LLC provide an opportunity to change the community's future. The project will increase the number of residential properties to almost 900 homes and will add a

commercial district to generate desperately needed tax revenues. The additional revenue stream will provide available funds for significant improvements to the city's infrastructure including roads, sewer lines, waterlines, and more.

PROJECT DESCRIPTION AND LOCATION

South Winnebago Partners, LLC, in partnership with the City of Lake Winnebago, is planning to construct a new earthen filled dam south of the existing Lake Winnebago Dam. The project would expand the surface area of the lake from 244 acres to approximately 416 acres. The overall project site consists of approximately 450 acres located in Cass County, Missouri, immediately south of the City of Lake Winnebago. The project area incorporates the main stem of Middle Big Creek, which is a tributary to Big Creek, in Cass County, Missouri.

The proposed dam would be 65 feet tall and 1,440 feet long and would have a top width of 38 feet to accommodate a roadway surface. The top of dam would be located at an elevation of 930.00 feet, National Geodetic Vertical Datum (NGVD), while the lake's normal pool elevation would be 918.50 feet, NGVD. The proposed flood elevation is 923.00 feet, NGVD, which is six inches lower than the lake's existing flood elevation. Reducing the flood elevation will provide added protection to homes, the existing civic building, and local streets that currently experience flooding. Additional benefits to the community include relocating 167th Street, which is currently closed due to safety concerns from the deteriorated roadway.

The final component of the project includes concurrently developing residential and commercial lots in the uplands adjacent to the expanded lake. The proposed development plan identifies approximately 400 residential lots, including lakefront lots and second and third tier homes without lakefront property. Areas have been set aside to create open green space, an amenity center for the community, and commercial development along the frontage of Missouri Highway 291.

PERMITTING APPROACH

Olsson Associates (Olsson) began working with South Winnebago Partners, LLC and the City of Lake Winnebago during the summer of 2005. Initial efforts focused on developing a new master plan to identify preliminary dam sizing, dam location, available residential and commercial tracts, and available infrastructure to serve the future project area. Understanding the regulatory complexities and agency coordination required to expand the existing 244-acre lake to approximately 416 acres, Olsson's environmental staff completed a comprehensive environmental inventory of the 450-acre project area. The Jurisdictional Wetland Evaluation and Functional Assessment (Olsson, 2005) classified tributaries within the project area as ephemeral, intermittent, and perennial tributaries and identified wetland areas as open water, emergent wetlands, and forested wetlands. Olsson worked closely with the Kansas City District Corps of Engineers to ensure compliance with newly issued guidance addressing significant nexus and reclassifying tributaries to permanent, relatively permanent, and non-relatively permanent tributaries (U.S. Army Corps of Engineers, 2007).

Olsson also coordinated a review with the U.S. Fish and Wildlife and the Missouri Department of Conservation regarding the potential for threatened and endangered species occurrences in the project area. Olsson's review for species and critical habitat included a field survey for the Indiana bat's (*Myotis sodalis*) suitable habitat (Olsson, 2007). No endangered species were identified during the field survey, and the percent of suitable habitat for the Indiana bat was determined to be insufficient for further investigation. A final step completed as part of the environmental inventory included coordinating cultural resources with the State Historic Preservation Office through the Missouri Department of Natural Resources. A section 106 application was submitted, and a Phase I Cultural Resource Investigation was completed for Olsson (Environmental Research Center of Missouri, Inc., 2006). No archaeological or historic resources were identified within the project area.

Project Purpose and Need

The critical component to the Section 404 application is the ability for the applicant to demonstrate a clear and concise project purpose and need. For the Lake Winnebago dam relocation project, Olsson identified three codependent purposes and needs. The project purpose and need included the following components:

1) Expand the City of Lake Winnebago in general accordance with the master plan commitment made to the community over 40 years ago to create development that helps ensure the future economic viability of the city.

2) Reduce the increasing flood risk to residents of Lake Winnebago.

3) Replace an aging 42-year-old high hazard dam with a new structure designed to meet current dam construction standards.

The opportunity for revenue to be generated by the proposed development provides an economically viable option to resolve current and long-term flooding issues, address long-term dam safety issues, and provide a reasonable assurance of long-term economic viability for the community.

Evaluating Alternatives

Olsson coordinated with the applicant to evaluate alternatives pursuant to [40 CFR 230.10]. The National Environmental Policy Act (NEPA) and implementing regulations at [40 CFR 1502.14] require that a range of reasonable alternatives, including the No-Action alternative, be evaluated. To address the three components of the purpose and need, the following four alternatives were considered for the Lake Winnebago project:

1) No Action Alternative - This alternative would not resolve the uncertain economic viability of the community; the City of Lake Winnebago would continue to experience flooding on local streets, residential homes and the civic center; and the aging dam would need continued maintenance for repairs necessary to maintain the community's primary amenity.

2) Dam Removal Alternative - The dam removal alternative would resolve the concerns associated with dam failure for the aging dam; however, it would not address the city's economic stability. Removing the existing dam would cause significant societal and environmental concerns such as land ownership, property values, and maintaining the exposed mudflat. Removing the dam would also be detrimental to the existing aquatic ecosystem and stream corridor. Completely removing the existing dam is not in the public's best interest and would not meet the need for increased protection from flooding and economic stimulus to the city.

3) Dam Reconditioning and Watershed Planning Alternative - Dam reconditioning and watershed planning alternatives focused on structural improvements to reduce flood elevations and protect the integrity of the dam. This alternative considered lowering the permanent pool elevation to increase flood storage, constructing small impoundments upstream to help attenuate storm events, and reconditioning the existing spillway to manage larger storm events. Due to the difficulties of reconstructing the existing dam, the risk of failure as the structure ages, the lack of increased flood protection this alternative did not meet the purpose and need for the project.

4) Dam Relocation (Preferred) Alternative - Constructing a new dam downstream of the existing dam would increase the lake size while maintaining the same permanent pool elevation of the existing lake. The increased storage area would provide increased flood control, protection of aquatic resources, and protection of the health and safety of residents. Constructing the new dam downstream in a similar location to the original master plan serves both the purpose and the need of the project.

Impacts to Waters of the U.S.

The preferred alternative includes constructing an earthen filled dam south of the existing Lake Winnebago Dam. The surface area of Lake Winnebago will be expanded from 244 acres to approximately 416 acres. The preferred alternative for relocating the Lake Winnebago Dam will result in unavoidable impacts to 15,879 linear feet of tributary, including 4,067 linear feet of perennial tributary, 7,864 linear feet of intermittent tributary, and 3,948 linear feet of ephemeral tributary. Approximately 16.57 acres of wetlands, including 1.29 acres of forested wetlands and 15.28 acres of emergent wetlands, will also be affected by the project.

MITIGATION REQUIREMENTS

To determine the appropriate mitigation requirements, Olsson used guidance from the U.S. Army Corps of Engineers Regulatory Guidance Letter 02-2 (U.S. Army Corps of Engineers, 2008) and the Missouri Department of Natural Resources: State of Missouri Aquatic Resources Mitigation Guidelines (MDNR, 1998). Due to agency requirements, wetlands and tributaries were assessed independently to determine the appropriate mitigation measure required of impacted tributaries and wetlands.

Wetlands

Olsson completed a functional assessment of impacted wetlands to provide the background data needed for the Corps to determine an appropriate mitigation ratio for wetland impacts. Given the condition of existing wetlands, it was determined that a 1:1 ratio (15.28 acres) would be appropriate to mitigate emergent wetlands and a 5:1 ratio (6.45 acres) for forested wetlands, assuming a preservation credit.

Tributaries

The Department of the Army and State of Missouri approved Stream Mitigation Method (Department of Army, 2007) was used as a basis to determine tributary impacts (debits) and mitigation credits. The Adverse Impact Factors for Riverine Systems Worksheet was completed to determine the total mitigation credits required to mitigate project impacts. Based on the worksheet and coordination with the Corps of Engineers, it was determined that a total of 77,020 credits were needed to fully mitigate project impacts.

MITIGATION APPROACH

Olsson's approach to mitigation considered a watershed based approach to mitigating resource impacts. Olsson developed a mitigation plan that would fully replace the ecological functions and values as a result of project impacts. The plan incorporated a concept known as habitat architecture into the design process. Habitat architecture is the process of combining independent wildlife habitats, such as prairie, wetlands, forest, etc., into a self-sustaining ecological unit. Habitat creation, restoration, enhancement, and preservation of natural resources were all included as components to the mitigation plan.

Mitigation Site Selection

The single and most difficult component to successful mitigation is location. Mitigation measures completed outside the context of the existing landscape will undoubtedly fail. Olsson invested considerable time and effort into identifying suitable mitigation sites that would complement existing natural resources and ensure mitigation site success.

A mitigation matrix and alternatives mitigation site map was developed for properties within the watershed that appeared to have the potential to provide mitigation opportunities. The mitigation matrix included such criteria as perceived site conditions based on aerial reviews, length of degraded stream, availability, land cost, etc. Once the in-house review was completed, field site visits to each property were completed to further refine the potential for mitigation and to select the most viable mitigation options.

FINAL MITIGATION SITES

Two mitigation sites were ultimately selected: 1) the Ingles Floodplain and Tributary Mitigation Site, and 2) the Pintail Pastures (Urich, Missouri) Wetland Mitigation Site. Both sites were consistent with the project goals listed below of using a watershed based approach, providing self sustaining ecological units, protecting rare and unique habitats, and constructing complementary habitats within the existing landscape.

Goals of Mitigation

The primary goals for the Lake Winnebago mitigation included the following:

Goal 1: Use a watershed based approach. – Mitigation activities and site selection were considered based on protecting aquatic resources and enhancing the entire watershed. Both mitigation sites are located within the South Grand River Watershed.

Goal 2: Provide a comprehensive and sustainable ecological unit. – Providing a sustainable ecological unit is an important goal of the mitigation plan. The mitigation plan encompasses restoration, enhancement, creation, and preservation that work together to provide a long-term sustainable ecological unit.

Goal 3: Protect rare and unique habitats. – A rare and unique habitat, in the form of an undisturbed wet prairie/fen, exists on the "Ingles Floodplain Restoration and Tributary Mitigation Site." An undocumented occurrence for closed gentian (*Gentiana andrewsii*), a flowering plant, was identified during initial site investigations. A primary goal with any mitigation site is to provide long-term protection to rare and unique habitats when possible. The wet prairie on the site has been incorporated into the mitigation plan as a tributary buffer and is permanently protected by legal restrictions on the property.

Goal 4: Constructing complementary habitats within the existing landscape context. – Mitigation activities will be completed within the context of the existing landscape. Planting plans were developed based on existing vegetative communities, while site grading was based on avoiding over-engineered structures. A landscape context is an essential element to meeting the goal of providing a comprehensive and sustainable ecological unit.

Ingles Floodplain Restoration and Tributary Mitigation Site

The Ingles Floodplain Restoration and Tributary Mitigation Site is an approximately 243-acre site located two miles downstream of Lake Winnebago and three miles west of the Town of Pleasant Hill. The site provided a unique opportunity to restore multiple habitats within the watershed and floodplain of Middle Big Creek. The site had been owned by the same family as a working farm for over 100 years. Most of the site had been heavily affected by grazing cattle. However, in areas restricted to cattle, the site was diverse and provided baseline reference habitats for the results restoration could achieve on the site.

To assess mitigation measures relative to the mitigation credits, the site was divided into net benefit areas. Each net benefit area included its own suite of habitats, mitigation opportunities, and generated mitigation credits (see Table 1).

The unique combination creating, restoring, enhancing, and preserving site resources resulted in a total of 78,465 credits and exceeded the 77,020 required credits. Table 1 summarizes mitigation activities relative to net benefit areas and the total mitigation credits achieved on the Ingles Floodplain and Tributary Mitigation Site.

Table 1: Ingles Floodplain and Tributary Mitigation Site Debits/Credits and Net Benefits

Tributary Impacts		
Tributary Type	**Linear Feet**	**Missouri Stream Mitigation Method (Credits Required)**
Perennial	4,067 linear feet	17,175
Intermittent	7,864 linear feet	42,869
Ephemeral	3,948 linear feet	16,976
Total	**15,879 linear feet**	**77,020 debits**

Tributary Mitigation (Net Benefit Areas)		
Tributary Type	**Mitigation Activities**	**Missouri Stream Mitigation Method (Credits Generated)**
Net Benefit Area 1	• Restore 25.4 acres of riparian corridor. • Enhance 11.3 acres of riparian corridor. • Enhance 4.3 acres of native prairie. • Preserve a 300-foot buffer of Middle Big Creek.	58,746
Net Benefit Area 2	• Create 750 linear feet of tributary, and re-connect 1,150 linear feet of historic channel. • Restore part of 8.1 acres of native prairie. • Enhance part of 8.1 acres of mesic prairie. • Preserve a 300-foot tributary buffer.	4,620
Net Benefit Area 3	• Enhance 2.0 acres of rare and unique existing wetland prairie habitat. • Restore part of 8.1 acres of native prairie. • Enhance part of 8.1 acres of mesic prairie. • Preserve a 300-foot tributary buffer.	9,499
Net Benefit Area 4	• Enhance 4.0 acres of rare and unique existing wetland prairie habitat. • Reconnect 1,250 linear feet of historic channel. • Preserve a 300-foot tributary buffer.	5,600
Total	**118 acres of preserved mitigation activities**	**78,465 credits**

Pintail Pastures Wetland Mitigation Site

The Pintail Pastures Wetland Mitigation Site is an approximately 35-acre site located just east of Urich, Missouri. The site is located in the floodplain of the South Grand River and provided a unique opportunity to restore historic wetland conditions to the site. The site was designated by the Natural Resource Conservation Service as a *Prior Converted* wetland. The designation gives a strong indication that restoring historic conditions to the site would result in successfully restoring the wetland. However, the site was not as straightforward as reconnecting historic hydrology. Years of agricultural use and drainage ditches had greatly influenced site conditions. In addition, the site was located within the Truman Lake flowage easement, which restricted constructing any structures or losing flood storage. Working on the site required a complex combination of multiple disciplines, including survey, hydrology, soils, biology, ecology, and engineering.

The final wetland design included restoring historic hydrologic conditions on the site by removing the man-made drainage ditches. Hydrology was then restricted on the site by installing low berms, which increased the residence time and frequency of hydrology on the site. The restored hydrology and low berms, less than six inches in places, provided the hydrology necessary to restore the wetland to its historic and sustainable condition. In addition, the short berms, coupled with seasonal transpiration and evaporation, limited inundation without recharge to less than thirty days. Design criteria were mandated by the Truman Lake flowage easement on the property.

The Pintail Pastures Wetland Mitigation Site restored approximately 20 acres of wetlands and preserved 6.45 acres of existing forested wetlands. A total of 15.28 acres of the restored wetland and all 6.45 acres of forested wetland have been deed restricted. Table 2 summarizes project impacts and mitigation credits achieved on the Pintail Pastures Wetland Mitigation Site.

Table 2: Pintail Pastures Wetland Impacts and Mitigation

Wetland Impacts	
Wetland Type	**Acreage**
Forested	1.29
Emergent	15.28

Wetland Mitigation		
Mitigation Type	**Acreage**	**Ratio**
Preserving existing forested wetland	6.45	5:1
Restoring prior converted wetlands	15.28	1:1
Total Deed Restricted Area	**21.73**	

Olsson continues to provide maintenance and monitoring services for the project and anticipates compliance certification by the Corps at the end of the five year monitoring period.

ABSTRACT

In 2001, Applied Ecological Services, Inc. (AES) was asked to assist in the design and installation of restored native ecosystems and a restored stream and riparian corridor on the 200-acre property proposed as the Zona Rosa mixed-use development, located in Kansas City, Missouri. Following our analysis of over 1,950 linear feet of Rush Creek, a degraded stream within the property, AES designed restoration and bioengineering strategies for a variety of ecological zones, requiring various treatments.

Design strategies were based on extensive hydrologic modeling and environmental engineering. Ecological restoration treatments along the Rush Creek Conservation Area (RCCA) included: native riparian buffer plantings, restoration of upland prairie, savanna and forest buffers, created in-stream pools and riffles, and a variety of bank stabilization strategies using bioengineering techniques. These included brush layering, installation of live stakes and willow posts, and toe protection using biologs. Parking lot BMPs were selected to reduce runoff into the stream, and stormwater management treatments necessary to success of the project were also designed and constructed upstream of the site. Five-year monitoring programs were developed to document water quality, vegetation success, erosion control, and stability of the stream system.

AES installed and has maintained all aspects of this innovative ecological restoration project. The restored riparian corridor represents a healthy mosaic of native plant communities and aquatic habitats, providing a functional and attractive centerpiece to the Zona Rosa development.

INTRODUCTION

The Zona Rosa development is located along Rush Creek at I-29 and Barry Road in Kansas City, Missouri in Platte County. It is a multi-use development, which includes apartments, a movie theater, restaurants, and retail stores in close proximity. The goals of restoring the Rush Creek Conservation Area (RCCA) included: restoring native ecosystems, restoring stream and riparian corridor, stabilize creek and minimize erosion, detain and control runoff from the upstream areas and the development, and mitigate for wetland impacts.

METHODOLOGY

Ecological Design

Existing site data were gathered, reviewed, ground-truthed, and augmented through fieldwork and data collected by AES ecologists and engineers. Based on our site findings, conceptual plans were developed to stabilize the degraded Rush Creek, restore native ecosystems along the stream, and mitigate impacts proposed to occur as a result of the development. U.S. Army Corps of Engineers, Missouri DNR, and City of Kansas City permits were obtained for construction of the project.

Design strategies were based on extensive hydrologic modeling and environmental engineering. AES investigations suggested that the severe erosion of the creek could not be effectively stabilized unless upstream tributary waters were regulated. To store and control runoff from the upstream areas owned by Missouri DOT, AES successfully proposed the establishment of a depressional wetland with outlet controls within the MODOT property.

Various ecological restoration zones were designed, based largely on hydrologic regime and ecosystem function. Customized native plant species lists were developed for each restoration zone, and local ecotype seed and plant materials were specified to maintain ecological integrity of the project. Deep-rooted native plants were selected to provide diverse native habitats, stable soils, and increased infiltration (to reduce runoff). Ecological restoration treatments on-site included: native riparian woodland and grassland buffer plantings, restoration of upland prairie, created in-stream pools and riffles, wetland detention basin, and bank stabilization strategies such as live stake installation and toe protection using four-inch diameter limestone rock and cross veins (Figures 1 and 2).

An Ecological Management Plan and monitoring program is in place for the RCCA to: guide management efforts (e.g., spot herbiciding and periodic mowing); document native vegetation establishment success; assess overall stream stability, erosion control, and ecosystem health; and develop remedial measures when needed. Short-term management efforts (2009 to 2010) will be focused on newly planted areas in the RCCA, followed by a less intensive, long-term management regime in perpetuity for the entire RCCA.

The end of 2008 marks the completion of a fifth full year of restoration/maintenance activities related to native plant installations along the RCCA. During 2008, AES's Contracting Division focused on repairing/restoring areas along the north side of Rush Creek that were damaged during Phase II site development.

Erosion Control Monitoring

Ongoing development activities in Phase II of the Zona Rosa site necessitated erosion control inspections in this portion of the property. Per the project's Missouri DNR permit and its associated Stormwater Pollution Prevention Plan (SWPPP), site inspections were typically conducted weekly and/or within 48 hours of a 0.25-inch rain event. Special attention was focused on unstabilized areas, stormwater BMPs, outfalls, and areas 50 feet downstream from outfalls. During inspections, personnel from AES or Norman Ecological Consulting documented the presence of erosion, turbidity in surface waters, sedimentation, and other erosion-related issues. They also determined if existing erosion control measures were adequate and whether additional measures were required. Photographs were taken to document conditions during erosion control inspections. Inspection results and recommended corrective actions were summarized in weekly reports and submitted to the developer.

Vegetation Monitoring

The purpose of vegetation monitoring at Zona Rosa is to determine if restoration efforts along the RCCA meet the Missouri DNR's minimum requirement of ≥70% vegetation cover noted in the permit for the project. This criterion applies to the entire riparian corridor disturbed by construction, and is required for the termination of the permit. Vegetation monitoring also addresses the Corps' mitigation monitoring requirements. The Corps permit for the Zona Rosa site states that perpetual stewardship must be conducted along the RCCA.

Vegetation along the RCCA was monitored using a qualitative approach, which consisted of a pedestrian survey of the entire RCCA riparian corridor from the upper reaches of Rush Creek at the MODOT embankment downstream to the outlet structure below the wetland detention basin. During the assessment, several parameters were documented, including the general condition and extent of established native vegetation, number of native species observed, location and extent of non-native/invasive species, and other information pertinent to the restoration effort. 2008 monitoring data were collected during one intensive vegetation monitoring effort (June 25-26) in combination with numerous other efforts conducted during erosion control inspections/water quality monitoring during the 2008 growing season.

Photographs were taken to document field conditions during monitoring activities. In addition, communication with AES maintenance staff and project managers provided regular updates and prompt issue identification and resolution during 2008.

RESULTS

Ecological Design

Construction began in 2002 and continued into Winter 2008. Phase I of the Zona Rosa development was completed in 2006, at which time all of Phase I had been stabilized. In October 2003, ecological restoration began along the 1,950-foot stretch of Rush Creek that bisects the Zona Rosa development (the RCCA). Ecological management tasks (management mowing and spot herbiciding of non-native/invasive plants) has been conducted at the site since installation.

During Phase II construction of the Zona Rosa development, some portions of the RCCA were damaged from construction activities. Restoration of Phase II impacts was conducted from July 15 to September 15, 2008, and included the installation of erosion control mat, straw mulch, live native plants, and native seed. Restoration activities covered approximately 0.67 acre of uplands, on which 21,780 native plants (live plugs) and 110 pounds of native seed were installed.

Erosion Control Monitoring

During 2008, regular erosion control inspections were performed from March through November in the Phase II portion of the site. Erosion control issues were identified quickly by AES and/or Norman Ecological Consulting and then addressed by the developer's contractors. The developer's contractors regularly swept roadways, blocked and cleaned storm drains, and installed and/or repaired damaged silt fence and other best management practices (BMPs) to control erosion. Despite these efforts, turbidity was occasionally observed in site surface waters, underscoring the importance of constant vigilance with regard to erosion and sediment control practices.

As of winter 2008, the majority of the Phase II construction areas were stabilized with either impervious surfaces (e.g., sidewalks, buildings, roads) or dense vegetation (e.g., turf, native plantings, or mulched beds). Only a few areas lacked the ≥70 % vegetative cover criteria required to terminate the Missouri DNR permit. Areas that did not meet this criterion included young restoration areas along the north side of Rush Creek, turf areas planted late in the fall, and bare areas stabilized with erosion control mat and mulch that have experienced limited seed germination and vegetative cover. Monthly erosion control inspections are being performed over the winter, and more frequent inspections will likely resume during Spring 2009.

Vegetation Monitoring at RCCA

Our 2008 monitoring indicates that the RCCA generally consists of healthy, maturing native plant communities. The main exception is the areas recently restored after Phase II construction damage. These areas should be well-vegetated by late Spring 2009; however, the young native plantings will probably not be native-dominated

until 2010. While the entire RCCA will be managed in the coming years, these young restoration areas will be the focus of AES's 2009 and 2010 ecological management activities.

CONCLUSIONS

The restoration design of Zona Rosa's Rush Creek Conservation Area was based on thorough data review, field assessment, and detailed modeling and engineering. The restoration is progressing well, based on the observations that most of the riparian corridor is vegetated by a dense stand of native vegetation approaching or above the 70% cover threshold. Portions of the RCCA impacted by Phase II construction activities were repaired/restored by mid-September 2008. These newly restored areas will likely take several years before a thick cover of native vegetation is established. Construction of Phase II of Zona Rosa was mostly complete as of November 2008, with most of the site being stabilized and vegetated. Only a few places remain in Phase II that require more vegetative cover, which should be accomplished with the onset of warmer temperatures in Spring 2009.

Regular erosion control inspections, prompt reporting, and remedial actions have been essential to protecting the site and Rush Creek from the adverse effects of erosion and sedimentation resulting from site development. Vegetation monitoring has provided a critical feedback loop to not only assess existing conditions, but also to guide subsequent ecological management activities. Pursuant to Corps permit requirements, the entire RCCA will continue to be managed in perpetuity, following the site's Ecological Management Plan and associated ecological monitoring program.

The Zona Rosa and Rush Creek Conservation Area restoration project is a showcase example of how a degraded riparian corridor can be restored and how water resources can be protected through thoughtful ecological design and execution. The restoration was designed to grow, evolve, and adapt to the changing conditions in the environment, providing a natural, sustainable, functional, and attractive riparian corridor through a high-use development. The RCCA (including its design, construction, perpetual management, and monitoring) will help to insure that the valuable water resources in the Rush Creek watershed will be protected for future generations.

1. Abstract

This paper presents a methodology to measure the impact of stormwater controls on the receiving stream using a series of discrete events to represent the long-term hydrologic regime as a simpler alternative to continuous simulation. Hydromodification impacts on channel morphology are best evaluated using flow and shear stress duration curves, which typically require continuous simulation. The methodology proposed herein allows the development of these duration curves using discrete events.

The methodology was tested in a hypothetical development in the City of Columbia, Missouri. Design assumptions were made for a typical residential development and a typical stream. Various stormwater controls were designed for this site, including conventional detention, a water quality volume and channel protection volume basin, and bioretention. The outflow from each design scenario was analyzed to determine the effectiveness of different levels of stormwater controls. The objective was to compare the effect of each scenario using duration curves to measure its ability of mimic the original hydrology. The study indicates that LID most closely replicates the original regime and that detention provides some benefits when water quality and channel protection are included, although its effect does not reproduce the original hydrology. Detention criteria based on extreme events, such as the 100-year storm event, are ineffective for this purpose.

2. Detention Requirement

The City of Columbia, Missouri Stormwater Management and Water Quality Manual currently requires that *"the maximum release rate from any development and redevelopment shall be controlled by limiting the stormwater release rates for the 1%, 10%, 50%, and 100% storms to the predevelopment peak flow rates for the 1%, 10%, 50%, and 100% storms respectively."* This requirement was examined to determine effectiveness at preventing potential channel erosion.

Assumptions were made for a typical residential development in the City of Columbia and a typical stream. Stormwater controls for the development were designed using three different scenarios: a detention pond meeting the Manual requirements for the typical development; ponds meeting water quality volume and channel protection volume requirements; and low impact development (LID) technologies. The outflow from the site was analyzed under these development scenarios to determine the effectiveness of different levels of stormwater control. Conclusions based on general effectiveness and levels of protection were then made.

2.1 Pre- and Post-Development Conditions

Table 1 lists the assumptions for the pre- and post-development scenarios. These assumptions represent a typical headwaters development in the City of Columbia, Missouri.

TABLE 1.
Typical development hydrologic parameter assumptions

	Pre-Development	**Post-Development**
Area (Acres)	25	25
Hydrologic Soil Group	C	D
Land Use	Agricultural (Pasture), 0% Impervious	¼ Acre Lots, 35% Impervious
Curve Number	74	89
Runoff Calculation Method	NRCS Unit Hydrograph Method	NRCS Unit Hydrograph Method
Time of Concentration	20	15

2.2 Typical Detention Pond Designs

Detention ponds meeting the Manual requirements for the typical development were designed as well as ponds meeting water quality volume and channel protection volume requirements. All ponds were designed to have 4:1 side slopes and a 4-foot depth without freeboard.

2.2.1 Detention Pond Design

A detention pond was designed to meet the Manual's requirements, which is to match the pre- and post- development runoff rates for the 1-, 2-, 10-, and 100-year 24-hour design storm events. A stair step weir configuration was used for the four-stage pond outlet.

A pond meeting the requirements of the Manual with a 4:1 side slope would have a footprint of 1.09 Acres, which increases to 1.35 acres of space when freeboard and the required access strip are included.

1-Year Storm Event Summary

Post-Development Peak Inflow:	54	cfs
Post-Development Peak Outflow:	16	cfs
Pre-Development Peak Flow:	22	cfs
Total Volume:	3.9	Ac-ft
Peak Storage:	1.5	Ac-ft

10-Year Storm Event Summary

Post-Development Peak Inflow:	111	cfs
Post-Development Peak Outflow:	54	cfs
Pre-Development Peak Flow:	66	cfs
Total Volume:	8.2	Ac-ft
Peak Storage:	2.8	Ac-ft

2-Year Storm Event Summary

Post-Development Peak Inflow:	67	cfs
Post-Development Peak Outflow:	20	cfs
Pre-Development Peak Flow:	34	cfs
Total Volume:	4.9	Ac-ft
Peak Storage:	1.9	Ac-ft

100-Year Storm Event Summary

Post-Development Peak Inflow:	164	cfs
Post-Development Peak Outflow:	111	cfs
Pre-Development Peak Flow:	113	cfs
Total Volume:	12.5	Ac-ft
Peak Storage:	3.6	Ac-ft

Peak flows for the pond configurations are shown above. The Total Volume represents the total runoff volume generated by the storm event, while the Peak Storage represents the maximum runoff volume in the detention facility.

2.2.2 Water Quality Storm and Channel Protection Pond Design

A second pond was sized based on the water quality volume specified by the Manual and a channel protection volume. Because the City's manual does not contain guidance on incorporating water quality detention into a traditional detention facility, the pond was sized to release the water quality volume over a 40-hour period per the newly updated March 2008 Mid-America Regional Council Manual of Best Management Practices for Stormwater Quality (MARC) manual. The volume required for a 40-hour release of the water quality volume was 0.5 acre-feet.

The channel protection volume is pond storage added to the water quality volume. Because the City does not currently have a channel protection requirement, criteria from the Metropolitan St. Louis Sewer District (MSD) were used. MSD requires the 1-year, 24-hour storm to be released with 24-hour extended detention. The 24-hour detention time is defined as the interval between the center of mass of the inflow hydrograph and the center of mass of the outflow hydrograph. The volume required for detention of the channel protection volume is 2.6 acre-feet.

A pond designed to meet only the water quality and channel protection criteria would have a footprint of 0.85 acres, with a 4:1 side slope, which increases to 1.04 acres of space when freeboard and the required access strip are included.

2.2.3 Low Impact Development Stormwater Controls

The third stormwater control scenario assumed the entire site was developed with LID controls such as bioretention and bioswales. The City's Manual states that 90% of all rainfall is less than or equal to 1.30 inches for storms less than 24 hours. It was assumed that up to the first 1.30 inches of each storm event would be retained on-site in the LID controls and any additional rainfall would become direct runoff from the site. The LID storage volume to meet this requirement is approximately 1.0 acre-

foot. This storage can be achieved with approximately 2 acres of total bioretention area, with a depth of 6 inches. This storage represents about 8 percent of the site area and can be incorporated into landscaping and other green space requirements.

TABLE 2.
Stormwater Controls Summary

	Conventional Detention (1-, 2-, 10- and 100-year Design Storm)	**Water Quality and Channel Protection Volume Detention (No additional design storm detention)**	**Bioretention (First 1.3" of each rain event)**
Depth without freeboard (ft)	4	4	0.5
Side slopes	4:1	4:1	Varies
Bottom length (ft)	443	243	Varies
Bottom width (ft)	68	103	Varies
Top length (ft)	475	275	Varies
Top width (ft)	100	135	Varies
Area (no freeboard)	1.09 Acres	0.85 Acres	2
Maximum area with freeboard	1.41 Acres	1.04 Acres	N/A
Maximum storage volume (ac-ft)	3.6 (100-yr)	2.6 (Channel Protection and Water Quality)	1.0 Ac-ft (1.3")
Storage Volume Destination	Receiving stream	Receiving stream (with 40-hr release)	Baseflow

2.3 Channel Shear Effects

Open channels in the City are subject to severe erosion problems. The shear stress created by the flow acting on the channel bed and bank materials is the parameter often used as a measure of a stream's ability to retain the soil particles in the channel bed and banks. Critical shear stress is the shear stress required to mobilize sediments stored on the channel bed and banks and delivered to the channel from upstream. When the shear stress is greater than the critical shear stress for the bank material, erosion ensues and channel degradation will likely result. Assumptions were made to represent a typical channel in the City of Columbia and the shear stress resulting from a variety of flow conditions was calculated. Typical channel characteristics are shown in Table 3.

TABLE 3
Typical channel physical parameters

Parameter	Value	Description
side slope	2H:1V	channel side slope
bottom width	1.56	feet
slope (ft/ft)	0.040	slope along flow line of channel
Manning's n	0.035	Manning's roughness factor

2.3.1 Precipitation Analysis

Precipitation data that recorded at the Columbia Municipal Airport (1948-1969) and Columbia Regional Airport (1969-2007) were used to determine an average year of rainfall. Approximately 59 years of hourly precipitation data (September 1, 1948 through August 1, 2007) were run through the XP-SWMM rainfall utility to determine individual storm events. A minimum six-hour dry period was used to separate precipitation into discrete storm events. A total of 5,916 storm events ranging from 0.01 inches to 5.97 inches were determined.

The storm event data were sorted into several 'bins' based on the total volume of precipitation in the event. This breakdown provides an annual average summary of the rainfall record in terms of depth, duration, and number of events per year. Table 4 displays the results of this summary.

TABLE 4
Annual storm event summary

Bin ID	Lower Limit (in)	Upper Limit (in)	# Storms	Mean Rainfall Depth (in)	Mean Number storms per year	Percent of Total Rainfall in Bin[1]	Mean Annual Rainfall (in)	Mean Duration (h)
1	0.00	0.25	3655	0.078	60.92	13.3%	4.74	3.6
2	0.25	0.50	957	0.366	15.95	16.4%	5.84	7.8
3	0.50	0.75	441	0.620	7.35	12.8%	4.56	9.6
4	0.75	1.00	282	0.869	4.70	11.5%	4.08	12.0
5	1.00	1.25	184	1.122	3.07	9.7%	3.44	12.5
6	1.25	1.50	128	1.379	2.13	8.3%	2.94	14.7

TABLE 4
Annual storm event summary

Bin ID	Lower Limit (in)	Upper Limit (in)	# Storms	Mean Rainfall Depth (in)	Mean Number storms per year	Percent of Total Rainfall in Bin[1]	Mean Annual Rainfall (in)	Mean Duration (h)
7	1.50	1.75	94	1.623	1.57	7.1%	2.54	15.9
8	1.75	2.00	52	1.871	0.87	4.6%	1.62	17.3
9	2.00	2.25	32	2.137	0.53	3.2%	1.14	15.8
10	2.25	2.50	24	2.402	0.40	2.7%	0.96	14.5
11	2.50	2.75	19	2.587	0.32	2.3%	0.82	20.8
12	2.75	3.00	18	2.879	0.3	2.4%	0.86	23.9
13	3.00	6.00	30	4.044	0.5	5.7%	2.02	28.7

[1]Represents the fraction of the total rainfall depth in this bin that fell over the entire period of record.

The mean rain depth for each bin was then used to determine the runoff that would be produced during each 'typical' event. Because only hourly rainfall data was available for the period of record, the total volume was distributed into 15-minute increments using comparable storm durations and appropriate quartile distributions for Columbia from "*Bulletin 71: Rainfall frequency Atlas of the Midwest*" by Huff and Angel.

2.3.2 Runoff Calculation

A model was created using the HEC-HMS version 3.1.0 software. The model incorporated the average annual rainfall series discussed in Section 2.3.1 as well as several design storm events with the SCS Type II distribution to calculate runoff from the watershed. An exceedence curve for the historical rainfall data against the rainfall amounts for the various design storm events shows that the design storms are much larger than the rain events that occur most often in a typical year.

In addition to the pre- and post-development conditions, three additional scenarios evaluate the post-development conditions including the effect of two different detention ponds: the first designed according to the Manual, and the second designed based only on management of the water quality volume and for channel protection. The third scenario evaluates the effectiveness of bioretention.

The pre-development and post-development scenarios have the runoff flow into the trapezoidal channel described at the beginning of this section downstream of the detention pond. In the bioretention scenario, the captured volume is infiltrated and reaches the receiving stream as baseflow. Excess stormwater overflowing the bioretention facilities reaches the stream as direct runoff.

2.3.3 Shear Stress and Erosion Potential

The maximum shear stress acting on the bottom of a channel is given by

$$\tau_b = \gamma S_e R_h$$

where γ is the specific weight of water, S_e the energy slope, and R_h the hydraulic radius. For a trapezoidal channel, the maximum shear stress acting on the side slopes is approximately 80 percent of the maximum on the bottom.

The flows in the trapezoidal channel calculated with the HEC-HMS model were used to determine the normal depth of flow in the channel. The results of the model simulations were compiled and the shear stress was calculated for each scenario.

To understand the long-term effects of excess shear stress, it is necessary to examine behavior of a continuous record of flows, typically resulting from continuous simulation. However, single-event modeling is more commonly known as a design technique. The analysis depicted in Table 4 can be used as a surrogate of long-term behavior based on the individual storm events and their frequency and characteristics. Therefore, the shear stress was calculated for each of the bin storm events in Table 4 and a shear stress exceedence curve was developed based upon the average number of storm events occurring for each bin per year. A summary of this analysis is presented in Figure 1.

Several critical shear stresses are shown in Figure 1 and are listed below in Table 6. The categories shown represent typical channel conditions that may be encountered for a headwaters development in the City of Columbia. Bed material is typically silt loam, but incised channels typically expose stiff clay material. Typical channel critical shear stress in most cases will be between 0.048 psf and 2.16 psf. In a state of dynamic equilibrium, critical stress is exceeded and material is mobilized some of the time. However, the quantity of interest is the work performed by the stream, which is the area under the shear stress duration curve. If a development scenario results in stream work greater than the original conditions, channel degradation will occur.

TABLE 6
Critical Shear Stress

Description	Critical Shear Stress (psf)
Silt Loam, Noncolloidal (ML), clear water	0.048 psf
Stiff Clay, very colloidal, CL, clear water	0.260 psf
Well-established dense vegetation to the normal low water	2.16 psf

3. Results

From Figure 2, it can be seen that a conventional detention pond does little to improve the shear stress. If the pond were designed for water quality and channel protection as described in Section 2.2.2, the figure shows that the stress is below than the pre-development conditions for a range of low-frequency flows but is above for more frequent flows. If the site is designed with LID controls the shear stress curve best approximates the shape of the pre-development curve. The lower levels of shear stress suggest that the LID design could be optimized to better match the target condition.

It should be noted that even under the pre-development conditions, the critical shear stress is exceeded some of the time, which is consistent with the natural dynamic geomorphic processes taking place in the stream. This is observable throughout the City where bare soil and exposed roots can be seen in channel bottoms. The important criterion to consider is how different the post-development conditions are from the pre-development state. When higher shear stresses are experienced over time in a given channel, sediment is lost and erosion begins to occur. If the shear stresses are not mitigated and continue at higher levels over time or are allowed to increase, more sediment is lost in the channel bed and erosion worsens. Eventually, the channel becomes bare of vegetation and the erosion problem continues to move upstream and worsen.

The threshold shear stress values shown in Figure 1 assume that there is no vegetation or armoring of the stream bed material. This explains why channel erosion is such a large problem in Columbia (where bare channels and exposed tree roots already exist throughout the system) and shows the need for citywide stream assessment and restoration. All scenarios modeled produced annual shear stresses well below the critical shear stress for well-established, densely vegetated channels.

Although the shear stress curve for the channel protection criterion is well below the pre-development conditions, it should be pointed out that a lower target should be selected to mitigate current rates of erosion and channel degradation. The 1-year design storm event was selected for this analysis

because it is commonly used for channel protection design. For example, this is the nearby criteria for MSD in the St. Louis metropolitan area and the State of Maryland. Due to the lack of 15-minute rainfall data, the annual period of record was approximated using Huff rainfall distribution and assumptions were made to represent a typical residential development. While these assumptions produce valuable results and verify that channel protection technology or the use of LID controls are valuable tools for the City, the true channel protection target should be closer to the critical shear stress frequency regime that existed during the original conditions, which do not necessarily coincide with the pre-development state. In practice, it is virtually impossible to return stream channels in urban or urbanizing watersheds to a pristine state; therefore, a sensible target is probably somewhere between the original and pre-development conditions.

A detailed analysis encompassing a more detailed approximation of the rainfall record and multiple land use scenarios is necessary to pinpoint the design event criteria most appropriate to replicate pre-development shear stress conditions. Most jurisdictions in the United States have not performed this detailed analysis, which requires development of allowable shear stress curves for a variety of development scenarios and possible customization for different watersheds. Some jurisdictions in the state of California are moving toward developing these curves, and Western Washington State has completed such an analysis. Western Washington State has developed a stand-alone software application that designers can use to meet shear stress criteria for a wide range of conditions.

Potable Water from a Superfund Site?

Marc Schlebusch, P.E.

CDM, 9200 Ward Parkway, Suite 500, Kansas City, Missouri 64114; PH (816) 444-8270; FAX (816) 444-8232; email: schlebuschm@cdm.com

ABSTRACT

This paper will describe the beneficial use of contaminated groundwater after treatment to supplement a local potable water supply. Contaminated groundwater from Superfund sites is usually treated and discharged to a stream or storm sewer or conveyed to a wastewater treatment plant. Discharge of treated water is seen by many as a waste of resources, particularly in areas affected by drought. Beneficial reuse of this treated water as potable water is an attractive alternative, and can become a considerable asset, provided that community stakeholders are assured of the quality of the treated water and that treatment operations meet or exceed federal, state, and local requirements.

INTRODUCTION

At a Superfund site in Nebraska, tetrachloroethene (PCE) and trichloroethene (TCE) contamination in groundwater exceeded the federal maximum contaminant level (MCL) of 5 µg/L and threatened the local potable water system. As an interim remedy, a series of extraction wells were planned upgradient of the city's southern municipal well field to capture contaminated water before it entered the potable water system. During the early planning of the interim remedy, the reuse of treated groundwater as potable water was identified as a goal by the Environmental Protection Agency (EPA). Although the Nebraska Department of Environmental Quality (NDEQ) and the city supported the idea of reuse, the Nebraska Department of Health and Human Services (NDHHS) expressed skepticism. Reuse of treated water from a Superfund site had never been done in Nebraska.

To help allay NDHHS's concerns, the design process began with careful review of Nebraska regulations concerning potable water treatment plants. Based on this review, the design was developed to address such diverse issues as cross connections, backflow prevention, impacts of materials and chemicals on potable water quality, the ability of the potable water system to accept the volume of treated water, the locations of groundwater extraction wells, well vaults, and piping systems, and post-operation sampling.

BACKGROUND

The Superfund site consists of a volatile organic compound (VOC)-contaminated groundwater plume located beneath commercial and residential properties in the southwest, central, and north central portion of the city.

The Superfund site comprises two operable units (OUs). OU1 includes an area in the southern portion of the city and the southern municipal well field where groundwater contamination was originally identified. The contamination was originally traced to two dry cleaning operations located south of the railroad tracks. Subsequent groundwater sampling events indicated an extended area of contamination existed upgradient of the original site area. Additional investigations conducted between 1998 and 2000 showed the plume extended to a third primary source area, a dry cleaning facility, located over ½ mile north of OU1. This extended site area constitutes OU2. Additional areas of contamination not associated with the Superfund site were also identified: a former manufactured gas plant and a former aboveground oil storage facility. Figure 1 shows the site and the locations of the potential source areas with respect to the southern municipal well field.

The southern well field consists of seven wells located near the city's water treatment plant. VOC contaminants have been detected in five of the seven municipal wells in the southern well field and in the city's water distribution system. The city has two additional areas from which it can draw groundwater: five municipal wells in a northern well field and two other municipal wells used mainly for emergency purposes. The entire water collection and distribution system is controlled by a supervisory control and data acquisition (SCADA) system at the southern municipal water treatment plant. The water treatment processes used by the city include chlorination for disinfection, fluoridation, and the addition of a copper sequestrant.

An interim Record of Decision (ROD) for OU2 was signed in September 2001. The selected remedy for the interim action at the site included extraction of contaminated groundwater at one of the municipal wells in the city's southern well field and plume interception by extraction of contaminated groundwater upgradient of the city's southern well field. The primary objective of the interim remedial action was to reduce PCE- and TCE-contaminated groundwater reaching the city's southern municipal well field.

A design package for the groundwater extraction and treatment (GET) system with a packed column air stripper was prepared between 2001 and 2002. Construction of the GET system began in August 2003 and was completed in April 2004. The GET system initially consisted of three extraction wells and one municipal well for a total design flow rate of 1,250 gallons per minute (gpm) or 1.8 millions gallons per day (mgd). In 2005, a fourth extraction well was added to increase the design flow rate of the GET system to 1,400 gpm (2 mgd).

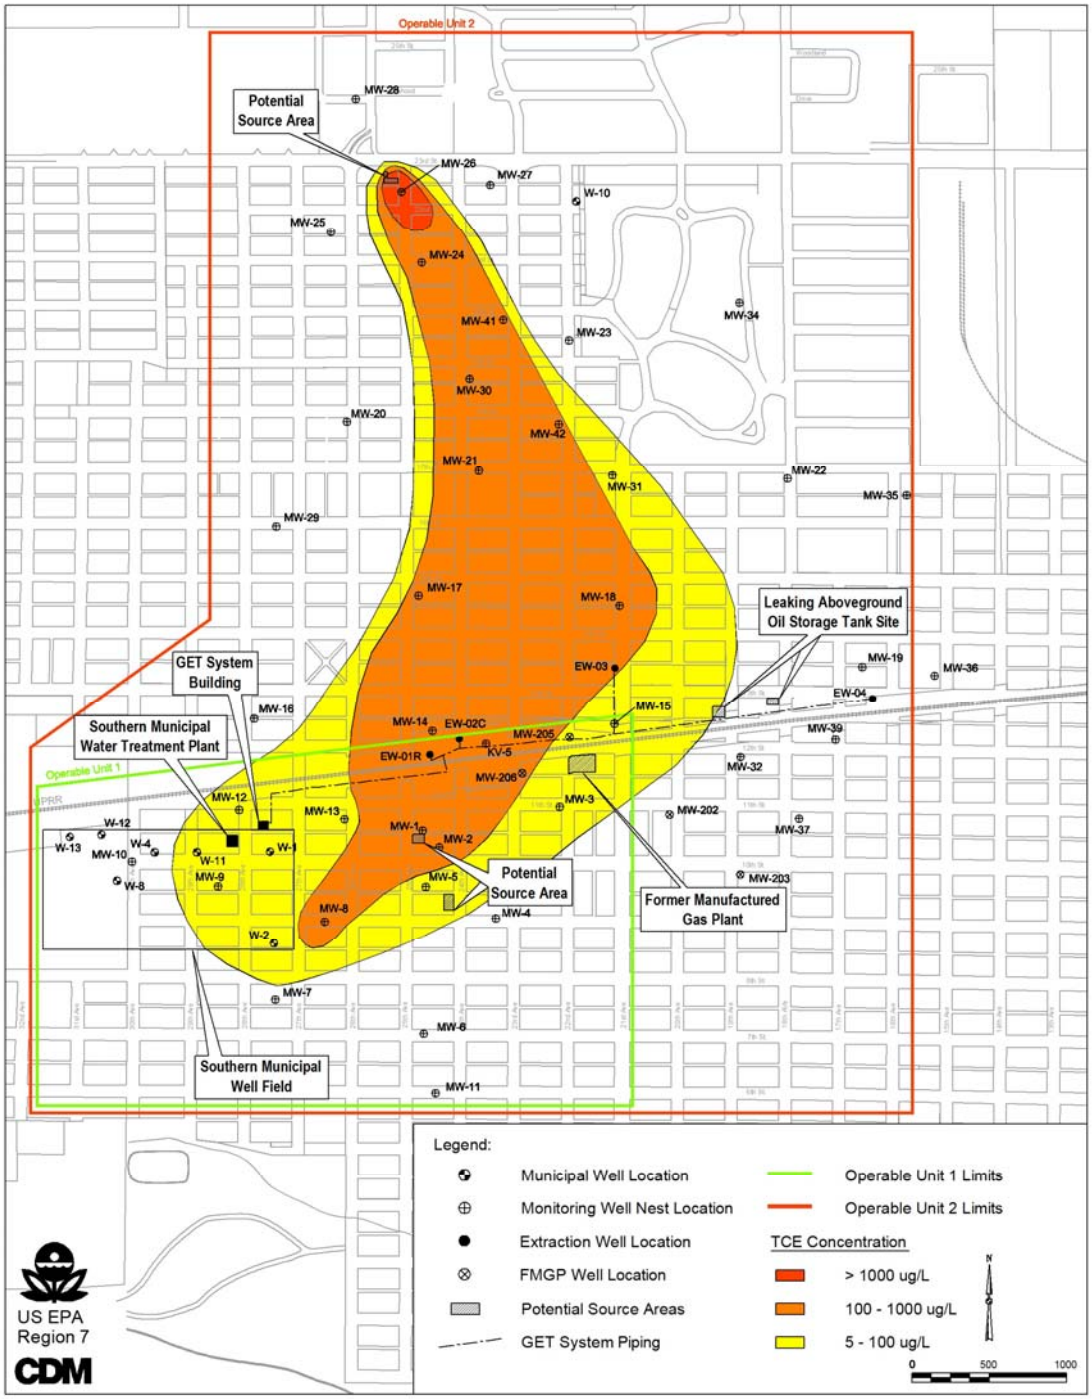

Figure 1. Site Map

DISCHARGE OPTIONS

A discharge system consistent with the interim ROD was developed and approved by the EPA and NDEQ.

The interim ROD for OU2 provided for three discharge options for groundwater:

- Discharge of extracted groundwater to the city's municipal water treatment plant
- Discharge to surface water through the city's storm sewer system
- Reuse options

The option of discharging to the municipal wastewater treatment plant was not selected because the existing wastewater treatment system did not have the capacity to treat the extracted groundwater at the estimated flow rates. Extracted groundwater would first be treated to meet federal MCLs prior to being discharged to the municipal water treatment plant. The municipal water treatment plant would provide chlorination for disinfection and fluoridation. Only during periods of high demand, however, would the municipal plant be able to accept 100 percent of the treated groundwater. In evening hours and winter months, when demand is less, water storage capacity limits would prevent the city from accepting the full volume of treated groundwater. Because the GET system would not run consistently, contaminated groundwater would not be captured at a rate consistent with the ROD.

Discharging to surface water through the city's storm sewer system would allow for consistent operation of the GET system.

The reuse options that were evaluated included a combination of the first two discharge options: potable water reuse and surface water discharge. Reuse would help to conserve water resources. Supplementing reuse with occasional discharge to surface water through the city's storm sewer would allow for consistent operation of the plume interception extraction wells and municipal well W-1 during periods of low demand.

The combination of the two discharge options had the advantage of providing the city with groundwater consistently meeting MCLs without unnecessarily burdening the city's storm sewer system with non-rain event water. The preferred discharge option called for a single treatment facility, which would reduce capital, operation, maintenance, and monitoring costs.

TWO REGULATORY BODIES, ONE GOAL

The solution combining potable water reuse with discharge to the storm sewer required design of a groundwater treatment system that met or exceeded the state requirements of two different agencies. The discharge of treated water to the storm sewer is regulated by the NDEQ and the Nebraska Pollutant Discharge Elimination System (NPDES). The discharge of treated water to the city's southern municipal water treatment plant is regulated by the NDHHS. The design requirements for potable water reuse were the more stringent of the two.

As mentioned above, this project was unique to the state of Nebraska. Officials from NDHHS and NDEQ were consulted early in the design process to ensure that the design met all pertinent design requirements. At first, NDHHS seemed reluctant to perform reviews for designs from EPA and its consultants. Because NDHHS generally works directly with the municipalities that they regulate, they were unaccustomed to providing a high level of review for deliverables from EPA. Eventually, however, NDHHS became a key member of the project team, vital to the overall success.

Design Requirements. Because treated groundwater is discharged to the municipal water treatment plant, the plume interception extraction wells are considered water supply wells and the groundwater treatment system is considered an adjunct potable water treatment plant. Therefore, the following NDHHS-specific requirements (Title 179) pertained to the design and construction of the GET system:

- Wells must be constructed according to the EPA document *Manual of Well Construction Practices*, 1977.
- The groundwater treatment plant must be constructed in accordance with NDHHS Title 179 requirements and the Great Lakes - Upper Mississippi River Board of State and Provincial Public Health and Environmental Managers document *Recommended Standards for Water Works (10 State Standards)*, 2007.
- Each extraction well must be tested for VOCs, semi-volatile organic compounds (SVOCs), pesticides, herbicides, inorganic compounds, dioxin, asbestos in water, radioactive contaminants, general water quality parameters, and total coliform.
- Water supply wells shown to be under the influence of surface water must be screened below 50 feet below ground surface (bgs) and must be further than 50 horizontal feet from any sanitary sewers.
- A Nebraska Class 1 operator must be on call during operation of the groundwater treatment system.

Because treated groundwater is discharged to the storm sewer and ultimately to the river, the following NDEQ-specific requirements pertained:

- Effluent discharge requirements are based on Nebraska MCLs (Title 118, Chapter 4) for potable water, Nebraska National Pollutant Discharge Elimination System (NPDES) limits, and Nebraska surface water discharge limits (Title 117, Chapter 4) for water discharged to the storm sewer/river.
- Applicable standards and requirements of Title 117: Nebraska Surface Water Quality Standards; Title 118: Nebraska Groundwater Quality Standards; Title 119: Rules and Regulations Pertaining to the Issuance of Permits under the National Pollutant Discharge Elimination System; Title 121: Effluent Guidelines and Standards; and Title 129: Nebraska Air Quality Regulations

Installation of Extraction Wells. Groundwater contamination at the Superfund site extends across the upper aquifer from 15 feet bgs to approximately 70 feet bgs. Wells screened above 50 feet bgs are considered under the influence of surface water unless testing proves otherwise. Tests required by the NDHHS in the use of such wells are a microscopic particulate analysis (MPA) for the presence of Giardia and Cryptosporidium and monthly examination of turbidity, pH, and temperature. If the well is determined to be under the influence of surface water, an increased chlorine contact time for disinfection is required by the NDHHS.

The municipal water treatment plant was not designed to provide the required chlorine contact time and modification of the municipal water treatment system was deemed cost prohibitive. All extraction wells were installed with the top of the screen set at 50 feet bgs or greater. Groundwater modeling was conducted to verify the shorter and deeper screened interval would still capture the contaminated groundwater. Modeling results guided the placement of the wells to capture VOCs while avoiding groundwater contamination from a former manufactured gas plant and fuel site.

Materials of Construction and Sequestrant. Materials of construction for a typical Superfund treatment plant are generally selected based on the contamination and the treatment processes used. Because the intent of this treatment plant was to discharge treated water to the city's southern municipal water treatment plant, the materials used in construction needed to be appropriate for contact with a potable water supply.

The *Recommended Standards for Water Works* (also known as the 10 State Standards) are the only standards cited by the state of Nebraska in Title 179, Chapter 2, Attachment 1 for the design and construction of potable water treatment plants. Nebraska regulations do not cite specific National Sanitation Foundation (NSF) and American Water Works Association (AWWA) standards/specifications outside of the 10 State Standards.

According to the 10 State Standards, the two major standards to be followed in the design and construction of potable water treatment plants are from the NSF and AWWA. The 10 State Standards stipulate that "chemicals and water contact materials shall meet ANSI/AWWA quality standards and ANSI/NSF standard 60 or 61 specifications." The 10 State Standards further state that "pipe, fittings, valves, and fire hydrants shall conform to the latest standards issued by the AWWA and/or NSF, if such standards exist, and be acceptable to the reviewing authority. In the absence of such standards, materials meeting applicable Product Standards and acceptable to the reviewing authority may be selected. Special attention shall be given to selecting pipe materials which will protect against both internal and external pipe corrosion."

During the construction of the GET system, the materials used were reviewed for compliance with the appropriate AWWA and NSF requirements. The piping, valve, and gasket materials were reviewed to ensure that they were compatible with the contaminants being treated and complied with the AWWA and NSF requirements.

The influent groundwater was naturally high in calcium, iron and magnesium. These metals precipitate easily in the turbulent environment of an air stripper, creating scale on packing material and the internal works of the air stripper. This precipitation of metals would necessitate frequent acid washing of the packing material, thus increasing operation and maintenance costs and diminishing operating time. A sequestrant was recommended to keep the calcium and magnesium in solution, reducing scale in the air stripper. The sequestrant chosen was a polyphosphate-based material that was NSF-approved. Bench-scale tests were conducted to identify any chemical incompatibility with the copper sequestrant used in the municipal water treatment plant.

Other Design and Construction Issues. Several other design and construction issues developed during construction and subsequent inspections.

Exhaust Vent. To reduce the risk of contamination by birds, NNHSS requested that the air stripper vent not be constructed as a straight vertical shaft, as is typical. A screen had already been designed into the discharge end of the vent. The vent was redesigned to include a 180-degrees turn. Air emissions modeling determined the appropriate height of the air stripper vent to keep below risk levels any vapors discharged toward nearby homes. Air sampling at nearby homes was conducted during startup testing to verify that discharge vapors were below risk levels.

Storm Sewer Discharge. During periods of high potable water demand, the city may accept all the water from the GET system. However, in times of low demand, the GET system discharges by gravity to the storm sewer. One of the main design concerns was ensuring an appropriate air gap between the gravity discharge and potable water transfer components of the GET system to prevent the potential for a backflow in the event of a storm sewer backup. The original design called for the gravity discharge end to flow into a large concrete box with walls extending several feet above grade surface. The water would fall approximately 10 feet from the discharge end to the bottom of the concrete box. The NDHHS insisted that the end of the discharge pipe be cut off to maintain the appropriate air gap between the bottom of the pipe and the top of the walls of the concrete box.

Operating Challenges. During the first six months of operation, the differential pressure across the air stripper increased, necessitating acid cleaning of the packing material. This maintenance requirement was not unexpected as acid cleaning is a routine part of the operation of a packed tower air stripper. However, the acid cleaning was ineffective. Upon inspection, the air stripper packing material was found to be severely coated and clogged with deposits that appeared to be a combination of inorganic precipitates and organic biomass. It was later determined that the packing media was fouled to the extent that it would need to be replaced by new media. The existing fouled media was subsequently removed and disposed.

Prior influent and effluent water sample analyses (pre- and post-stripper) demonstrated that as much as 93 percent of the dissolved iron in the groundwater was

being removed/oxidized in the air stripper. This high percentage was consistent with the high levels of iron oxide and iron phosphate found in the bulk sample from the air stripper deposits. The findings also suggested that the NSF-approved polyphosphate sequestrant was not effective in keeping iron in solution through the air stripper. The high level of phosphate in deposits indicated that the polyphosphate sequestrant was breaking down to orthophosphate. In addition, the orthophosphate appeared to be reacting with iron and calcium in the groundwater to form phosphate precipitates. The presence of phosphate in the deposits (nearly 40 percent by weight) further suggested that the residence time of groundwater in the air stripper was sufficient for polyphosphate degradation. The phosphate contributed by the sequestrant was likely serving as nutrient source for the naturally occurring bacteria in the groundwater.

An NSF-approved, low-molecular weight polymer dispersant (product formulation was based on sodium salts) was identified to replace the polyphosphate sequestrant. The polymer dispersant proved more effective at inhibiting the formation of metal precipitates. Although the polymer dispersant reduced the likelihood of the packing material from becoming fouled to the extent that it needed replacement, the high natural iron levels in the influent groundwater still create iron staining of the packing media. As a precautionary measure, the GET system is shut down every 3 months and the air stripper is acid cleaned.

POST-OPERATION SAMPLING

Representatives of the EPA, NDEQ, and NDHHS participated in pre-final and final inspections of the GET system and provided recommendations for system improvements. Before granting approval to use the treated groundwater in the city's potable water system, NDHHS required proof of the GET system's effectiveness in treating the contaminants of concern. The contaminants of concern and water quality parameters such as pH, turbidity, and metals were monitored. The NDHHS reviewed monitoring results and granted approval for reuse of the treated groundwater in the city's potable water system contingent on additional monitoring.

Initial Startup Testing. Extensive monitoring of the influent and effluent of the GET system has been conducted since the system began operation in February 2004. Samples have also been collected at the system influent, post-chemical addition, and effluent points in the GET system for quantifying the percent loss of metals and hardness across the air stripper. Samples also provided an indicator of how well chemical additives were inhibiting scale formation. A thorough analysis of the GET system was conducted during 14-day and 8-week Operational and Functional (O&F) periods.

Water samples were collected during the 14-day and 8-week O&F periods to confirm GET system performance with regard to contaminant removal and ability to meet effluent discharge limits. In addition, field monitoring using direct reading instruments and HACH test kit analyses was performed onsite by the system operator. Furthermore, the system operator recorded the residual chlorine readings for the

potable water taps at the southern water treatment plant and wastewater treatment plant locations. Samples were collected from the following locations:

- Groundwater influent to the treatment plant
- Treated water effluent from the air stripper
- Within the city distribution system (via taps inside the southern municipal water treatment plant building and city wastewater treatment plant)

Water samples collected during the O&F periods were analyzed for the following parameters:

- VOCs
- Metals
- Total coliform bacteria
- Total organic carbon

Analyses of water samples collected from the GET system effluent and the city distribution system indicated no significant detections of VOCs other than TCE, cis-1,2-dichloroethene (DCE), and low levels of chloroform (periodically detected in the samples from the southern municipal treatment plant). The concentrations for all detected VOCs were well below MCLs. Overall, the air stripper achieved a 97 to 99 percent removal of TCE and 100 percent removal of PCE. Contaminants in the effluent water were consistently below MCLs.

Blending treated water from the GET system with the city's potable water supply had no apparent impact on residual chlorine in the city's distribution system. Residual chlorine values recorded at the city wastewater treatment plant (representing the most remote point in the city's distribution system) were consistently greater than 0.1 mg/L as required. The values were generally higher at the southern municipal water treatment plant.

Quarterly Sampling. The GET system is sampled quarterly at a minimum for compliance with Nebraska Discharge Elimination System (NPDES) permit requirements and to verify that the contaminants in the treated water are either not detected or below the MCLs. Effluent water is also sampled quarterly for VOC analysis at the NDHHS laboratory. This sampling provides an ongoing measure of the treatment system's effectiveness at meeting the MCLs.

PUBLIC MEETINGS AND PUBLIC COMMUNICATION

Before, during, and after construction, EPA and the city held public meetings inform the community of the GET system and the planned reuse of the treated groundwater. Community awareness and acceptance are essential for successful implementation of beneficial water reuse from a Superfund site.

LESSONS LEARNED

The design, construction, and approval of a Superfund site groundwater treatment plant with the intent of potable water reuse led to some valuable lessons learned including:

- Engage the regulator(s) early. Understand the expectations of the regulator and understand who the regulator(s) will engage during design, construction, and operation. In the case of this project, the NDHHS preferred to work through the city who was receiving the treated water and would be the Class 1 operator, and not through the EPA who was constructing the project.
- Understand the drivers of stricter potable treatment standards. The contamination of the shallow aquifer necessitated shallow extraction wells. However, wells with a screened interval of 50 feet bgs or shallower are considered under the influence of surface water unless extensive testing and monitoring show otherwise. A system under the influence of surface water is subject to more rigorous treatment methods than one that is not.
- Understand that the treatment plant will be considered a potable water treatment plant, requiring that all materials and chemicals used must be suitable for a potable water supply. These requirements also apply to the extraction wells, which are considered potable wells.
- Communicate the intentions of the reuse project with the public before design begins, during construction, and before discharging water to the municipal water treatment plant. Water quality and quantity is an important issue with many people. Explaining the beneficial reuse aspects of the project is critical for public acceptance. In the case of this project, there was no public resistance.
- Conduct extensive post-operation sampling to assure the regulatory agencies and the public that the treatment system will consistently exceed state and federal treatment standards.

CONCLUSIONS

Initially, the city only used 26 percent, on average, of the total available treated groundwater. This amount has since increased to more than 70 percent of the treated flow being reused as potable water after the city decreased the amount of water pumped from its other wells. During times of high potable water demand, the city has reused nearly 100 percent of the flow from the GET system. The remainder is discharged to the city's storm sewer system.

Careful planning and extensive communication have been crucial to the success of the project. Between April 2005 and December 2008, the GET system has provided over one billion gallons of treated water that has been reused by the city's potable water system.

RIVERSIDE-QUINDARO BEND LEVEE (L-385) ON THE MISSOURI RIVER: THE ESSENTIAL ROLE OF O&M AND DOCUMENTATION

Gary W. Creason, P.E.

Affinis Corp, 7401 West 129th Street, Overland Park, KS 66213; PH (913) 239-1100; FAX (913) 239-1111; email: gcreason@affinis.us

ABSTRACT

RIVERSIDE-QUINDARO BEND LEVEE (L-385) ON THE MISSOURI RIVER: THE ESSENTIAL ROLE OF O&M AND DOCUMENTATION

The Riverside-Quindaro Bend levee (L-385 in the Missouri River levee system) was originally built as an agricultural levee in the 1920s, was authorized for study by the Flood Control Act of 1944, and drew heightened interest after 1993's major floods in the Midwest. Authorized for final design and construction in September 1997, construction was essentially completed in May 2005. Since then, there has been one high water event, and the levee performed as intended.

The paper provides a brief history of the project, including organizational, legal, and regulatory requirements (including funding, floodplain management plan, operation and maintenance (O&M), flood fight planning, and recertification).

The discussion of L-385 highlights design considerations, key features, and details about levee construction. The discussion emphasizes the basic importance of operation and maintenance and the overwhelming importance of sound documentation for 1) qualifying for federal funds for repairs and rehabilitation after a flood event, and 2) recently mandated levee recertification. Prudently operated and maintained according to existing federal regulations administered by the Corps of Engineers, levees should serve the community and safeguard public investment for many years.

INTRODUCTION

In *Rising Tide*, John Barry's book on the Great Mississippi Flood of 1927, the author observes that major riverine levees designed to absorb phenomenal hydrostatic pressures can fall victim to small flaws:

> "A dozen things can cause a levee to collapse. A single piece of wood, a branch, left in a levee during construction could cause disaster if it rots and creates a cavity. Burrowing animals, even crawfish nests, also create cavities.

> The river will find such flaws and can enlarge them enough to cause a massive levee to collapse…."
>
> "But the biggest danger is simply pressure, constant unrelenting pressure…."
>
> "Each of these dangers could be handled, at least in theory. But men had to do everything right, and they had to do so twenty-four hours a day. As long as a flood lasted, the river could only grow stronger, the levees weaker. Since the river was relentless, men had to be relentless. Since nature missed nothing, made no mistakes, and was perfect, men had to miss nothing, make no mistakes, and be perfect."

To successfully design and construct levees we must first understand and respect the river itself. This requires study and analysis of the floodplain's hydraulics, hydrology, geotechnical, structural, and environmental factors; historic events; and the effects of existing infrastructure on the levee system. Levees can do their work only when engineers and scientists do their work to understand the nature of the river.

To the naked eye, levees look like large, simple, grass-covered embankments built to hold back water. In reality, levee design relies on many engineering disciplines. Beneath that grassy mound, levees are hardworking structures that involve complex engineered systems.

Levees are part of the public infrastructure system. Prudently operated and maintained according to federal regulations administered by the Corps of Engineers, levees should serve the community and safeguard public investment for many years.

This paper uses the L-385 Levee on the Missouri River to illustrate key factors in the life of a levee, most notably operation and maintenance (O&M). It provides a brief historical overview; organization as a political subdivision; general design considerations; construction; O&M; floodplain management plan; flood fight plan; and recertification requirements.

HISTORIC OVERVIEW OF L-385 LEVEE ON THE MISSOURI RIVER

Levee projects typically begin with a singular idea: "We need flood protection." The process from idea to reality can be complex and may take years. Consider L-385: Tired of flooded fields, lost crops, and other damage, the local community organized as a levee district in 1918. Shortly thereafter, they built an agricultural levee. Construction of the levee as it exists today didn't start for another 84 years.

Missouri River Levee System – Unit L-385 was first authorized for study as part of the Missouri River levee system by the Flood Control Act of 1944 (P.L. 534).

The very name of the levee is a good illustration of the impact of the built environment and time: L-385 indicates that the levee is on the left bank of the river (as one faces downstream), 385 miles upstream from the confluence of the Missouri with the Mississippi River in St. Louis. As the result of various federal Missouri River channel projects over the years, the levee is actually located along the river from mile 372 to 376.

Interest in constructing and expanding the levee heightened in the aftermath of major flooding that hit the Midwest in 1993 (see Figure 1). Flooding that approached the 500-year event impacted approximately 1,300 acres of developed and undeveloped land, closing nearly 70 businesses, putting more than 5,000 people out of work for months. Total cost to repair damage to property and infrastructure was approximately $27 million.

Figure 1: Riverside, Missouri, July 1993.

The legal instrument (Project Cooperation Agreement, or PCA) between the U.S. Army Corps of Engineers (USACE) and Riverside-Quindaro Bend Levee District of Platte County, Missouri (referred to as RQBLD) to build the levee was signed in September 1997. Construction began in March 2002. The intent of L-385 is to protect the community located within the city limits of Riverside, Missouri (see Figure 2).

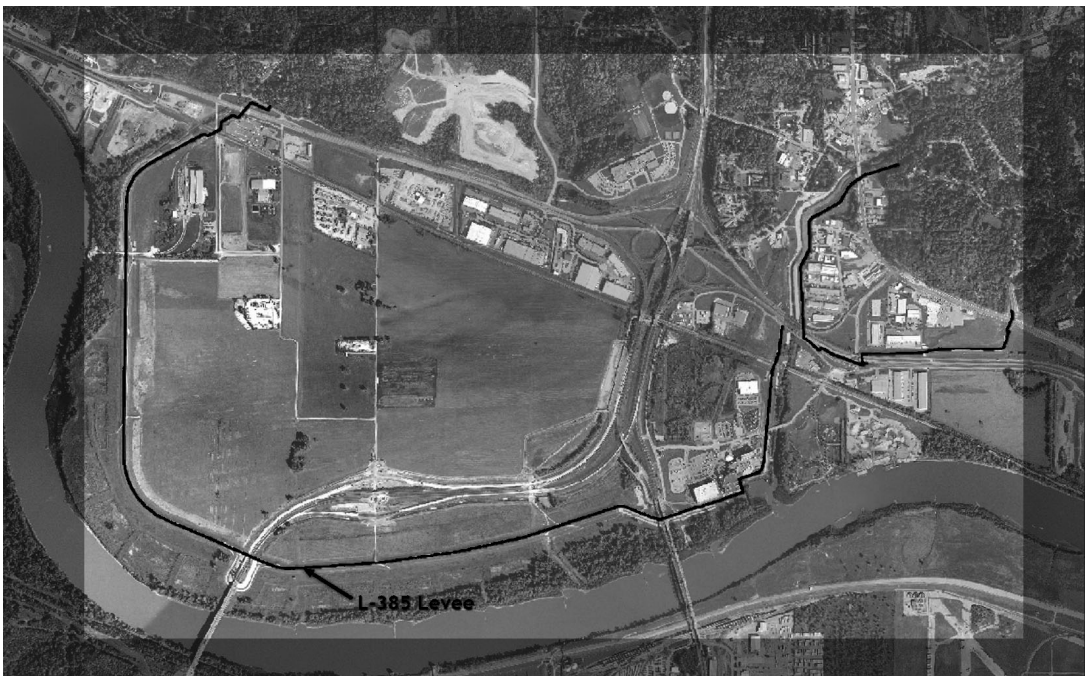

Figure 2. Aerial View of L-385's Location on the Missouri River.

L-385 is the first new Missouri River levee in the U.S. Army Corps of Engineers Kansas City District (KCD) in nearly 30 years. Construction essentially was completed in May 2005. Since then, there has been one high water event, and the levee performed as intended, protecting homes, infrastructure, undeveloped acreage, and business development from floodwaters.

The levee district is actively performing O&M tasks in strict accordance with the *Code of Federal Regulations* Title 33, Pt. 208.10 (33CFR208.10). This document lays out, in detail, the O&M requirements for federally authorized levees.

The technical details of L-385's design are specific to its location on the Missouri River (soils, hydrology, etc.), and its alignment must integrate with existing area roads and utilities. Everything from the organization of the levee district, to a complex engineering design process, to O&M of the system follows the same legal and regulatory process required of any federal levee.

ORGANIZATIONAL, LEGAL AND REGULATORY REQUIREMENTS

Levees as political subdivisions. Levee districts (also known as local sponsors) are political subdivisions, organized under and subject to state statutes, and every state has its own requirements. In the case of L-385, Missouri Statutes Chapter 245 drove the reorganization of two separate districts into the Riverside-Quindaro Bend Levee District in 1988. The statute dictates such things as number of board members, meeting protocol, requirements for attorney-of-record and engineer-of-record, procedures for issuance of bonds for land acquisition and construction, and levying of taxes for O&M, and ultimately adoption of the plan of reclamation.

Funding. Design and construction of federal levees are funded via a cost-sharing agreement between the Corps of Engineers and the local sponsor. Essentially, prior to 1986, the local sponsor's only responsibility was to provide all required lands, easements, and rights-of-way. The Water Resources Development Act of 1986 (P.L. 99-662) (WRDA 1986) also required the local sponsor to provide relocations and disposal of excavated materials. Together, these costs are referred to as LERRDs. For L-385, LERRDs were approximately $25 million.

Rivers exist in political, economic, and public opinion environments. WRDA 1986 marked a significant shift in the cost sharing structure, and local sponsors were required to assume a greater portion of the costs. WRDA 1986 established the cost-sharing split as 75 percent federal/25 percent local sponsor.

> "Congress fundamentally transformed the ground rules for Corps water project planning and funding through WRDA 1986 (33 U.S.C. 2211) by establishing new cost-share formulas, resulting in greater financial and decision-making roles for local stakeholders." (Congressional Research Service 20866, 2006)

In the case of L-385, due to the amount of undeveloped land in the Quindaro Bend portion of the levee district, the final cost-sharing was approximately 50/50 of the total $80 million project cost.

Type of Cost: First costs typically include LERRDs, construction of gatewell structures, closure structures, pump stations, floodwalls, embankment, relief wells, etc. Through a rigorous economic evaluation, the project must demonstrate that the benefits exceed the costs.

Once the levee is built, ongoing costs primarily include both administrative and O&M costs – levees require routine maintenance, whether or not there is a flood. L-385 budgets about $500,000 a year for O&M.

Project Authorization and Contractual Agreements. With the levee district in place, its president signed the PCA with the Corps to formally authorize the plan of reclamation for final design and construction. The PCA establishes the contractual linkages between all players. Under the PCA, the Corps has a contractual linkage with the local sponsor and a contractual relationship with the general contractor. There is no such linkage between the local sponsor and the contractor.

DESIGN CONSIDERATIONS

In general, a levee is a structural system (earthen embankment and other structures) typically on an alluvial fill (materials deposited by the actions of the river over tens of thousands of years). A levee is a significant civil engineering project whose sole purpose is to control and withstand an enormous amount of kinetic energy produced by the swollen river.

Thus, the focus of levee design and (by extension) ultimately O&M is managing the enormous hydrostatic pressure from the river on the levee structure, its foundation soils, and the adjacent ground. The key parameter is the hydraulic grade line (see Figure 3).

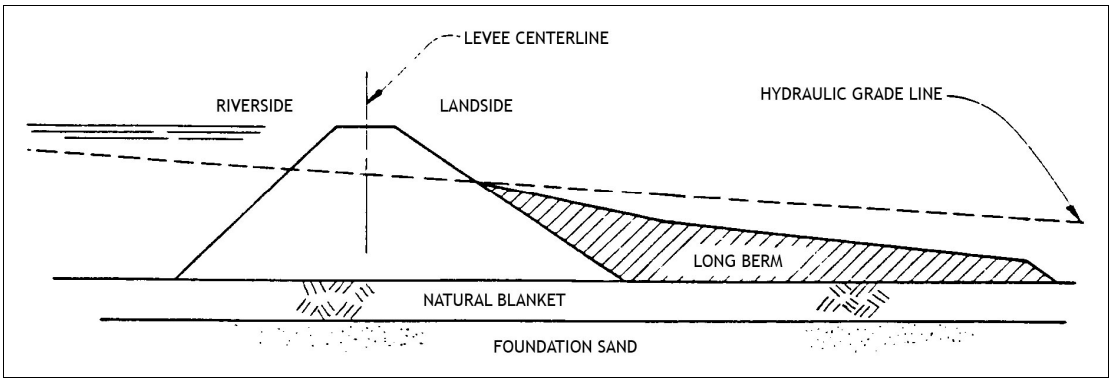

Figure 3. Typical Levee Section.

Suffice it to say that the design process encompasses multiple engineering disciples and involves complex hydraulic, hydrologic, geotechnical, and structural analysis. The process also draws on years of empirical data collected by the Corps for a given river and locale. Each Corps district publishes design standards or guidelines for projects. The standards address such things as slope stability and underseepage.

The output of the design process determines the final alignment and height of the levee, as well as location of stability and underseepage berms, riprap, and other features such as rolling gates, gatewells, stoplog closure structures, pump station, and relief wells (see Figure 4).

- Quindaro Bend levee: 4.1 miles of earthen levee
- Riverside levee: 0.9 miles of earthen levee
- Height: Up to 21 feet
- Concrete floodwall: 1,535 feet
- Two rolling gates
- Four stoplog closure structures
- Pumping station discharge capacity: 75 cfs
- Thirteen gatewells, ranging in diameter from 36 to 108 inches
- Argosy Casino flood door
- Sandbag gaps: 1,043 feet on Quindaro side, 181 feet on Riverside

Figure 4. Features and Structures of L-385 Levee.

In addition to designing the levee to meet the goal of protecting land from flood damage, design considerations also include mitigation of displaced wetlands. In the case of L-385, borrow pits used as a source of material for the levee embankment were designed to address this wetlands mitigation.

As noted in KCD's final environmental assessment for the project, the mitigation provided "appropriate and substantial compensation":

"Establishing functioning wetlands in the remaining 88 acres of borrow area would be a greater than 4-to-1 replacement ratio for wetland mitigation, more than adequate mitigation for the less than 20 acres of wetlands affected by the L-385 levee." (Environmental Assessment: Missouri River Levee System, Levee Unit No. L-385, 2001)

CONSTRUCTION

As agreed to by the PCA, the Corps is responsible not only for design, it also is responsible for levee construction.

There are unique things about the construction of a levee that differentiate this activity from other infrastructure projects. The contractor always has to be aware of the river (its actual and forecasted stage); pipe bedding has to be on direct soil as opposed to granular material; and the contractor must maintain the soil stratigraphy (stratification of materials) during underground excavation and backfill operations.

The newly constructed L-385 levee protects the community from a 500-year Missouri River flood, dwarfing the old 1920s-era agricultural levee by three times the height.

OPERATION & MAINTENANCE

The often tedious process to organize the levee district, request assistance from the federal government, develop a plan of reclamation, secure funding, and complete final design and construction is a huge undertaking. However, it has an endpoint. In contrast, operation and maintenance run for the life of the levee. The integrity of the levee – and thus its ability to perform as intended during a flood – depends on rigorous O&M practices. Poorly operated and maintained, the levee and its many features, may not function well and could lose the battle with the river during a flood.

Whether self-performed by the local sponsor or contracted out to others, effective O&M is similar to setting up and running a small business. For example, the district must hire good people; purchase equipment; develop an accounting system; establish an inspection protocol (another example of the value of the Corps' empirical knowledge base); and conscientiously perform inspections and maintenance on a defined, periodic basis.

As with design standards, the Corps' requirements for O&M, Title 33 (33CFR208.10) contains the standards for federal levees. The Corps develops a unique operation, maintenance, repair, replacement and rehabilitation (OMRR&R) manual for each levee unit. This manual becomes the basic "how to" document for each particular levee unit.

RQBLD employees perform routine maintenance tasks for the Riverside-Quindaro Bend Levee year round. Some tasks occur seasonally, some on a calendar basis, others as needed. The list includes mowing, fertilizing, burrowing animal control, weed control, erosion repair; levee crown rock blading and rolling; and equipment maintenance (gatewells, rolling gates, fences, etc.). For RQBLD these tasks have been itemized and scheduled resulting in a list of 79 items. The documentation to verify that these tasks have been performed is an important piece of levee O&M process.

The Corps defines an important area adjacent to the levee called the levee critical area (LCA). It is defined as that area from 300 feet riverward of the levee center line to 500 feet landward of the levee center line. RQBLD's responsibilities also include coordination and communication with other entities, such as utilities, located in the LCA. Some of the coordination is simply good practice. Maintaining an up-to-date contact list, for example, is one of those activities. Other activity, however, requires RQBLD's engineer-of-record and the Corps to be involved. For example, if Kansas City Power & Light wants to work on buried power lines within the LCA, the

levee district must approve the work (the Corps provides technical guidance) and be able to certify that it was done in accordance with the approved plans.

Conscientious, well-documented O&M is not only a good idea for the levee to provide protection, it is legally required by the Corps, through Title 33 (33CFR208.10). Also, as discussed later, this documentation is important in complying with the new recertification mandate issued by the Federal Emergency Management Agency (FEMA).

FLOODPLAIN MANAGEMENT PLAN

Since October 12, 1996, the Corps has required a local sponsor of a project to develop a floodplain management plan. This condition was a part of the Water Resources Development Act of 1996 (P.L. 104-303) (WRDA 1996). Among other things the plan calls for the local sponsor to implement measures, practices, and policies to reduce loss of life, injuries, and damages to property and facilities brought about by residual flooding. Clearly the development and implementation of the plan requires close coordination with the local community. An example is a reverse 911 call to warn all entities located in the protected area of the need for evacuation in the event the flood is forecasted to exceed the designed capacity of the levee.

FIGHTING THE FLOOD

L-385 was essentially completed in May 2005. Since then there has been one flood event, in May 2007. During what was considered a 15-year event, the levee performed as designed.

Obviously, successful flood fighting will demonstrate the value of the levee. To be successful, flood fighting depends on a detailed flood fight plan. This plan is part of the OMRR&R manual. L-385's plan has 82 specific items. The backbone of its plan is a series of four action levels (see Table 1). These action levels are linked to actual or forecasted river elevations. Each action level dictates procedures to commence at progressively higher river stage.

Table 1. Action Levels in L-385's Flood Fight Plan.

Action Level	Description
1 – Normal operations	Routine duties to be performed regardless of river stage.
2 – Flood season	April 1–July 31, as defined by KCD.
3 – Hannibal gauge of 15	River is capable of reaching appreciable flooding at L-385 within a day-and-a-half from this stage.
4 – Hannibal gauge forecasted gauge of 35 or higher	The river stage that represents the start of appreciable flooding at L-385.

Those responsible for the levee can never turn their backs on the river. These action levels enable RQBLD board members and maintenance staff to be aware of the condition of the river and react appropriately when conditions warrant.

Major flooding will likely take its toll on a levee, no matter how well maintained. After the waters have receded, major repairs or rehabilitation of the levee system may be required. Congress recognizes this and provides for it in the Flood Control and Coastal Emergency Act (P.L. 84-99). This law essentially says that the federal government will pay 100 percent of these costs, provided that the levee unit has been maintained in accordance with the Corps' established procedures (33CFR208.10). This is yet another example of why continual documentation of maintenance is so important.

FEMA RECERTIFICATION

The basic policy governing levee certification for the National Flood Insurance Program (NFIP) was issued by FEMA in 1986 as Part 65.10 of *Code of Federal Regulations* Title 44 (44CFR65.10).

Subsequently, on August 22, 2005, FEMA issued "Procedural Memorandum 34 – Interim Guidance for Studies Including Levees." On June 23, 2006, the Corps responded with the following statement: "[I]f local governments wish areas behind levees to be shown on FEMA's new Digital Flood Insurance Maps (DFIRMs) as protected to at least the one percent change of flood using FEMA's guidance on certification, they must arrange for certification documentation to be provided to FEMA." (USACE, 2006) Furthermore, FEMA requires this recertification to be performed every 10 years.

Although FEMA requires recertification it does not perform recertification. In anticipation of being tasked to do so, the Corps is establishing guidelines for performing levee recertification. Circular EC-1110-2-6067, *Certification of Levee Systems for the National Flood Insurance Program (NFIP)* contains the guidelines (USACE, 2008). (At the time of this writing, the circular is in draft review form.)

This engineering circular makes it clear that documentation is key to this recertification process. This documentation includes both the original design as well as documentation of the design of any repair, rehabilitation, or work performed by others in the LCA. Once again, documentation of O&M and implementation of the floodplain management plan are integral to this recertification process.

The L-385 levee district maintains extensive documentation, which will be one of the most critical activities related to recertification requirements so that when directed to recertify it should be able to do so in a straightforward way.

CONCLUSIONS

Rivers behave according to the laws of physics. We can calculate hydraulic pressures and water velocities. We can study historical weather patterns and analyze the current season's weather, although we can't predict when a flood will come and how hard it will hit. Therefore, we must be ready at all times to react to nature's forces.

As this paper illustrates with the example of the Riverside-Quindaro Bend levee on the Missouri River (L-385), there are myriad state and federal policies and regulations that cover a levee project from the initial awareness of a need for flood protection to the inevitable requirement to successfully fight a flood. Although some of these requirements (such as FEMA's requirement for levee recertification) are relatively new, most of these regulations have existed for many years. They don't need to be changed or added to, they just need to be complied with. Awareness and understanding of these regulations will serve a local sponsor well, to paraphrase John Barry in doing everything right, 24 hours a day:

> "Since nature missed nothing, made no mistakes, and was perfect, men had to miss nothing, make no mistakes, and be perfect." (Barry, 1997)

ABSTRACT

The Emergency Streambank Stabilization program has been a vital part of protecting local infrastructure, including bridges and other utilities, from the dynamic rivers and streams in Missouri. The U.S. Army Corps of Engineers, Kansas City District has a long-established emergency streambank stabilization program, carried out under Section 14 of the 1946 Flood Control Act. The program is cost shared 65 percent Federal, 35 percent local, and after construction, projects are turned over to the local partners, or "sponsors" for ownership and maintenance. In the region surrounding Kansas City, the program has consistently provided for projects which protect critical infrastructure such as roadways, bridges, and utilities, from severely eroding stream banks. Sponsors include counties, cities, Indian Tribes, and state departments of transportation. This paper presents two of ten projects built in the last ten years that have served two sponsors very well: the City of Parkville, Missouri and the Missouri Department of Transportation. Section 14 projects are developed and constructed in a multi-stage process. This process includes evaluation of multiple stabilization techniques, including longitudinal peak stone toe protection (LPSTP), bank armoring, bendway weirs, dikes, jetties, sheet piling, bioengineering, and windrow revetments. The Section 14 program plays a key role in protecting rural and urban transportation and water infrastructure. It assists states and local governments in diligently monitoring and maintaining their infrastructure, supports economic health and development, and contributes to sustainable water resources in the community. Finally, Section 14 program is an example of a highly beneficial partnership between a Federal agency and state and local governments.

INTRODUCTION

The U.S. Army Corps of Engineers (USACE) has a long-established emergency streambank stabilization program, initially implemented under specific Congressional authorities, but since 1947 carried out under Section 14 of the 1946 Flood Control Act. Many districts of the USACE participate in this program, but the Kansas City District is one of the most active and effective practitioners. The District has designed many Section 14 projects. In recent years, due to staff being prioritized to levee, dam safety and Missouri River work, the District has found it very effective to contract with HNTB, taking advantage of their expertise in streambank stabilization projects.

In the past ten years, ten Section 14 emergency bank stabilization projects have been constructed in eastern Kansas and central, western and northwestern Missouri. Five additional projects are in various phases of design and are expected to be constructed by 2011. Another five are planning phase and could be built within the next 2 to 5 years. These projects typically protect infrastructure such as roadways, bridges, utility lines, water intakes, and recreation facilities from rapidly eroding streambanks and degrading stream beds. Five of these completed projects have been constructed with the Missouri Department of Transportation (MoDOT) as the sponsor, including four with MoDOT District 1.

SECTION 14 PROGRAM BACKGROUND

Kansas City District Section 14 projects are generally conducted in a five step process:

- The potential sponsor submits a request and supporting data to the Kansas City District.

- The Kansas City District contracts a task order with HNTB. HNTB visits the project location with their experienced Section 14 team, consisting of a Project Manager, Civil Engineer, Geotechnical Engineer and a Water Resources Engineer. The team reports their observations and conclusions from this site visit with a Site Reconnaissance Report, with a recommendation of whether to proceed to the next step. The site visit generally includes a visit to the local offices of the Nation Resources Conservation Service (NRCS) and Farm Service Agency (FSA), who typically have historic photos available that can be used to track the progress of the problem over a span of anywhere from 10 to 70 years.

- Based upon the recommendations of the Site Reconnaissance Report, an alternatives analysis is conducted, assessing up to four possible solutions. Preliminary field surveys are used to estimate construction quantities and costs, and a matrix is developed comparing potential maintenance and

anticipated performance of the alternatives. The resulting Concept Design Alternatives Report is submitted, with a recommendation for proceeding further.

- Final design is then performed for the recommended solution from the Concept Design Alternatives Report, with preparation of construction plans and specifications. When necessary, additional field surveys are performed for more accurate plans and quantities, and to provide a basis for right of way and easement acquisition. Environmental permitting, easement acquisition and right of way acquisition are also accomplished during this step.

- A contractor is then selected, either through some form of competitive bidding or a negotiation process, and then construction is initiated. The ideal construction season is either January through March, or mid-July through September, which tend to be drier, with less risk of significant flow events. Depending upon the size of the project and weather, construction can take less than one month or up to 3 to 6 months on larger projects.

The majority of the completed Section 14 projects use a stabilization method known as Longitudinal Peak Stone Toe Protection (LPSTP). Other methods used include flow directing stone jetties, stone and sheet pile grade control weirs, and stone slope revetment. Other techniques considered during the alternatives analysis steps include sheet pile revetments, bendway weirs, bioengineered vegetative banks, and windrow revetments (both surface and buried). All constructed projects include a planting component. Due to the rural nature of the majority of projects, and the need to provide rapidly installed and highly reliable projects, measures relying solely or heavily on vegetation have been avoided. The reliance on riprap stone solutions allows a significant design life, and provides better assurance of success under extreme conditions such as droughts or frequent floods, and through extended periods of inundation that could heavily damage a project relying largely on vegetative methods.

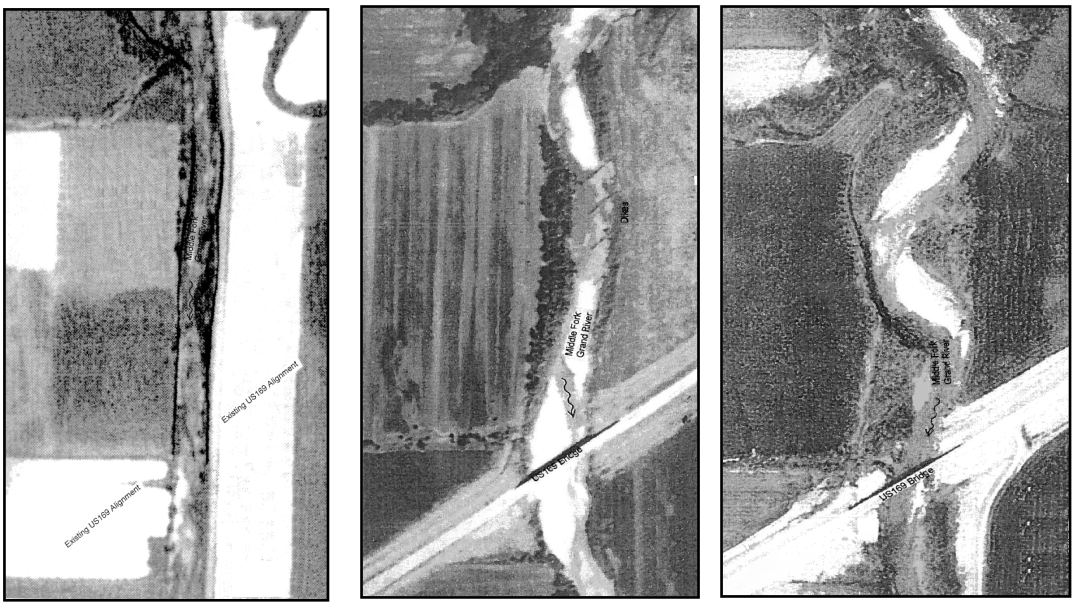
The LPSTP solution in particular is very flexible in its installed condition. LPSTPs are generally used where banks are subject to collapse after flow events. Often, sandy banks are present that collapse under their own weight when water levels drop after the flow peak. The LPSTP is placed either at the toe of the bank, or along a smooth alignment out from the bank and linked back to the bank with baffles/tiebacks. It works by forcing the thalweg of the stream out away from the bank, and by reducing the velocity of the flow adjacent to the bank. Therefore, when banks collapse, the slumping soil no longer falls into the deepest, fastest flowing portion of the stream to wash downstream; instead the slumped soil stays in place, buttressing the bank and helping the bank reach an equilibrium slope that will no longer collapse when wetted. The slope is then further reinforced as natural vegetation is established. The overall area between the LPSTP and the bank eventually fills with sediment and also vegetates.

The top of the LPSTP is generally set at a third to a half of the bank height. Because many of the projects have been on streams that were channelized and oversized many years ago, that height of LPSTP generally equates to an annual or slightly greater high water event. The LPSTP is constructed by dumping a specified weight of rock per unit length (tons per foot) along its centerline. The riprap stone ends up at its angle of repose. If the stream thalweg deepens adjacent to the LPSTP, then the stone launches and the mass of the LPSTP shifts. However, if the initial height of the LPSTP is adequate, then the revetment is essentially self-healing, with the mass of rock providing long term protection and stability. Adjacent banks, if left undisturbed during construction, will continue to collapse until a stable slope develops. Often, the banks are flattened during construction so that they can be included in the project vegetation planting step.

The following two sections describe examples that demonstrate the range of recent Section 14 projects in the Kansas City area. One is a rural project with a simple cause and one specific protection objective, and the other is an urban project, with multiple contributing factors for the instability and numerous potential impacted features.

Middle Fork Grand River

Rush Creek



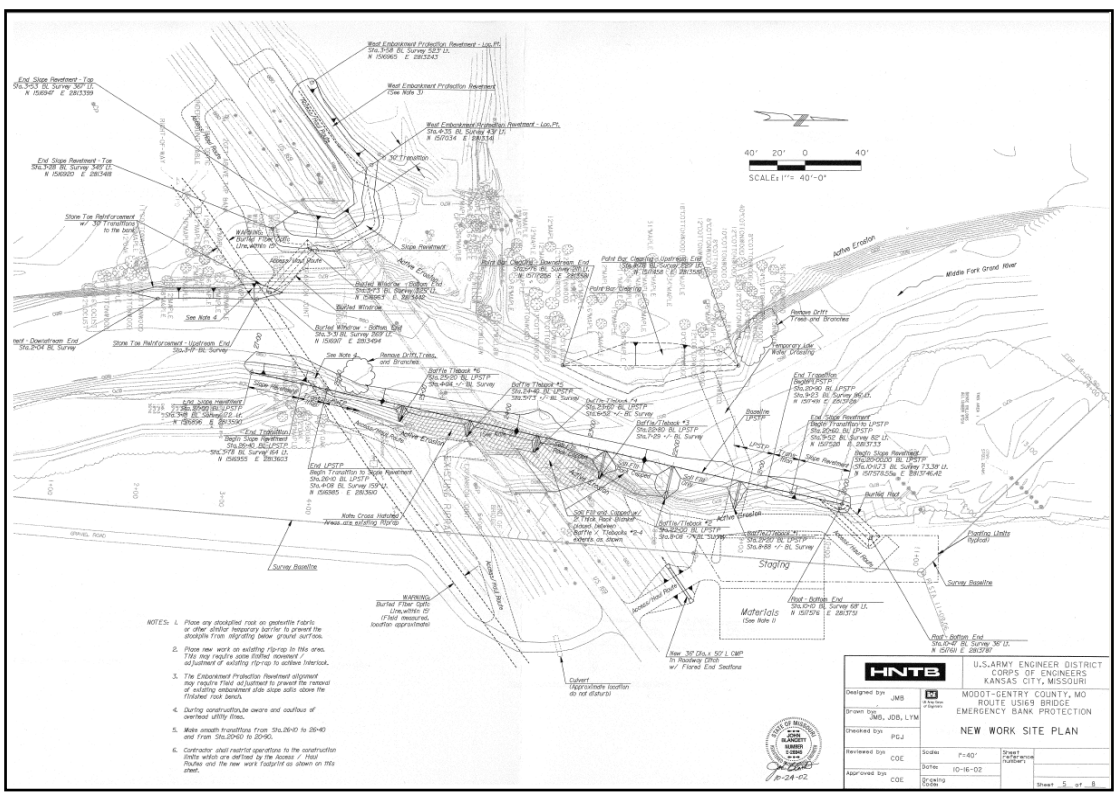
MIDDLE FORK GRAND RIVER AT US 169

This project is located in Gentry County, Missouri. The project sponsor was the Missouri Department of Transportation (MoDOT), District 1. The initial site visit occurred in March 2001, and the project was constructed in the summer of 2003.

Like many rivers in northwest Missouri, the Middle Fork Grand River was reportedly straightened and channelized around 1920 to reduce flooding impacts on agriculture. Over time, a series of meanders has formed and begun progressing downstream. One of these meanders was threatening the east abutment and roadway approach on US Highway 169, near Gentry, Missouri. The existing bridge was constructed in 1961 as part of a new highway project; there was no bridge at the location prior to its construction.

The Middle Fork Grand River floodplain is nearly one mile (1.6 km) wide at the project site. The river's drainage basin at that location is 162 square miles (39,400 hectares). There is minimal urbanization in the watershed, with the predominant land use being agricultural. The channel top width at the bridge is approximately 150 feet (46 m). The bridge has five spans and a total length of 428 feet (130 m). The bridge and its substructure were configured at a 35 degree angle to the channel when it was constructed; that angle had increased to 56 degrees by 2001. The active channel was nearing the east abutment of the bridge, which is constructed on a relatively shallow pile foundation. MoDOT had dumped riprap under and adjacent to the bridge within their right of way, but the eroding bank upstream of the bridge was pushing eastward, resulting in the concern that the meander might threaten the roadway embankment if unchecked. Photo 1 shows the eroding bank and MoDOT's riprap. MoDOT requested that the Kansas City District initiate a Section 14 project, and in February 2001, they contracted the site visit step to HNTB Corporation located in Kansas City, Missouri. HNTB sent their design team with experience from several previous Corps of Engineers Section 14 projects to the site.

Aerial photos from 1940, 1965, 1981, 1990, 1993 and 1996 were acquired at the time of the site visit. The 1940 photo (north at the top, typical) shows a low water channel gently meandering within the limits of what was likely the original channel excavation; sands bars were small and few in number. The 1965 photo depicts a regular series of meanders pushing slightly outside the limits of the original straightened channel, with much larger sand bars. Several hundred feet upstream of the highway crossing, four jetties had been constructed on the left side of the river. The 1981 photo showed significant meanders had formed upstream and directly across from the jetties. The 1990s photos showed these meanders pushing progressively farther out from the original channel alignment, and showed the approach flow angle into the bridge worsening as a meander formed between the jetty area and the highway.



Middle Fork Grand River Erosion Progression, 1940, 1965 & 1996

After receiving their Site Visit and Preliminary Assessment Report, the Kansas City District asked HNTB to conduct an alternatives analysis study and then to perform final design and preparation of construction plans and documents. HNTB subcontracted site surveys to Torres Consulting Engineers, Inc. The Concept Design and Alternatives Report presented four alternatives: bank aligned LPSTP; out-from-bank LPSTP; bank aligned sheet piling; and three rock jetties. After meetings with the Kansas City District and MoDOT, the out-from-bank LPSTP alternative was selected for final design. It was anticipated to be the most cost effective method of halting the bank movement and also improve the angle of flow into the bridge opening.

In final design, it was decided to remove some material from the point bar on the inside of the bend, across from the LPSTP. The LPSTP itself was aligned in virtually a straight line, from 400 feet (122 m) upstream of the bridge to 250 feet (76 m) downstream of the bridge. A total of six baffles, up to 40 feet (12 m) in length, were used to tie the LPSTP into the bank.

Stone toe revetment was included along the right bank, a short distance downstream of the bridge, to protect a portion of a slightly bending outside bank where the proposed LPSTP could conceivably increase the chance of new bank movement. This downstream right bank revetment was connected to new riprap on the west abutment slope of the bridge by use of a buried windrow. This buried windrow consisted of a mass of riprap with four feet (1.3 m) of soil cover. The intent of the windrow was to provide a mass of rock that would launch and create a barrier to further bank movement, if heavy erosion were to eventually occur on the west side of the bridge opening.

In addition to installing new riprap on the west abutment slope of the bridge, a west embankment protection revetment was included for 120 feet (37 m) westward of the abutment riprap on the upstream side of the bridge. The riprap was installed as protection against the possibility of eventual movement of an upstream right bank meander all the way to the bridge. The project budget could not justify LPSTP protection at the location of the meander; it was believed that it would take many years before this meander could progress downstream through a 400 foot (122 m) long wooded area. The west embankment protection revetment was designed to consist of a large mass of riprap stone placed as a wide, thick toe along the existing roadway embank. In the event that the right bank meander eventually progressed downstream through the wooded area to the roadway, this revetment would be expected to launch and provide at least short term protection to the roadway.

Middle Fork Grand River at US 169 Construction Plan

Construction was completed in September, 2003. Photo 1 shows the severity of the erosion and threat to the road and bridge abutment. (MoDOT dumped rock is seen in the photo, intended only as a stopgap measure.) Photos 2 and 3 show the upstream left bank LPSTP during and immediately after construction. Tree plantings in the buffer area are visible in Photo 3. Photo 4 shows the project a few years subsequent to construction.

Photo 1: March 13, 2001

Photo 2: September 8, 2003

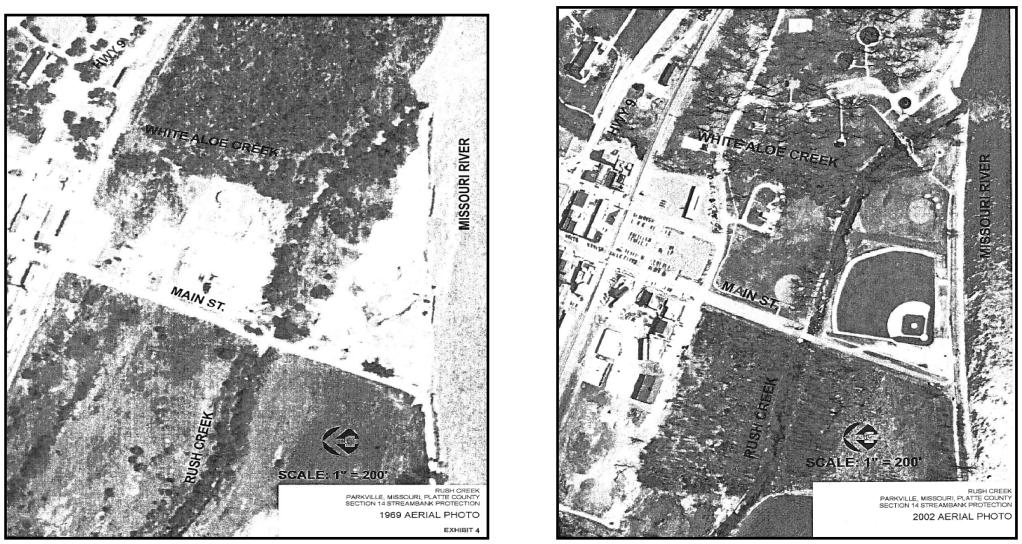
Photo 3: September 24, 2003

Photo 4: March 6, 2006

The construction contractor was Pangea Group, and the construction cost was approximately $225,000. The Middle Fork Grand River at US 169 is representative of the typical rural Section 14 project, providing important transportation infrastructure reliable and cost-effective protection from stream bank movements.

RUSH CREEK AT ENGLISH LANDING

This project is located in the City of Parkville, in Platte County, Missouri. The City was the project sponsor. The initial site reconnaissance occurred in February 2003, and the project was constructed starting in February 2007. The delay from initiation of the project to construction was due in large part to funding for Corps civil works projects being constrained after 2003 due to the war. However, this particular project was also much larger and more complicated than the typical Section 14 project.



Rush Creek at English Landing Park is located immediately south of downtown Parkville, Missouri. The City's wastewater treatment plant is located near the creek, and main sanitary and water lines cross under the streambed. This urban park, a major regional destination, is heavily used, with ball fields, pavilions, boat ramps and a city market nearby.

Rush Creek has a drainage area of 18 square miles (4700 hectares), most of which is steeply sloped land along the north bluff line of the Missouri River. There are two major lakes in the basin: Weatherby Lake is on the main branch of Rush Creek, over five miles (8.0 km) upstream of the project site; and Riss Lake, approximately one mile (1.6 km) upstream on White Aloe Branch, a tributary that joins Rush Creek about half way through the project reach. There is a roadway/pedestrian bridge (Main Street) at the upstream end of the project reach, which is used mainly for public and equipment access to the southern portion of the park.

There is a notable pedestrian bridge in the downstream portion of the project reach (see photos 7 and 8); this structure is a historic relocated railroad bridge that is one of the last two remaining examples of an A-Frame truss as designed by J.A.L. Waddell. The bridge was originally constructed in 1898 in Trimble, Missouri. It was removed in 1984 by the USACE to prevent it being permanently inundated by Smithville Lake on the Platte River, and was installed in English Landing Park in the late 1980s. HNTB contributed some of the design expertise in re-assembling the bridge on Rush Creek.

At the time that the Waddell Bridge was relocated in the park, plans for its installation showed a channel less than 10 feet (3 m) deep at the new location. By early 2003, when the Site Visit and Preliminary Assessment Report were prepared, the channel depth at the bridge had approximately doubled. Most of the banks between the outlet to the Missouri River and the Main Street bridge were showing signs of movement, with numerous trees either having collapsed into the channel or having been undercut by erosion and threatening collapse. An unsightly broken concrete rubble revetment provided some stability to the right (south) bank of the channel adjacent. Adjacent to the channel on this bank was Grigsby Field, a very new and valuable baseball field. On the opposite side of the channel, a bank failure had caused a fence and a portion of a grandstand to collapse into the creek. There was an exposed pipe that had undermined just upstream of the confluence with White Aloe Branch, and an eroding, nearly vertical left bank was getting close to the north abutment of the Waddell Bridge. Very rapid channel erosion and degradation were threatening the City's critical infrastructure and the bridges.

After agreeing to include Rush Creek in the Section 14 program with the City of Parkville as the Sponsor, the Kansas City District contracted with HNTB in 2003 to perform the site visit and prepare a preliminary assessment report.

Rush Creek Aerial Photos, 1969 & 2002

During the Site Visit step, numerous constraints along the creek in the project reach were identified. Primary of those were the two bridges, three ball fields (including Grigsby Field), utility line crossings, a boat landing, a vehicular turn-around area, the sewage treatment plant, the park trail system, benches, parking areas, and numerous large trees. White Aloe Branch was also identified as a concern, although it was not part of the project scope. It was obvious that the headcutting that had already occurred on Rush Creek would very like soon progress upwards on White Aloe Branch. Aesthetics and environmental compatibility of the project were also identified as important issues by the City.

After the site reconnaissance and considerable coordination with the Kansas City District, Parkville and others, HNTB submitted the Site Visit and Preliminary Assessment Report in November 2003. Due to the high visibility of the project because of its location, more numerous and more detailed alternatives were evaluated for the initial report. Five were considered and presented in the report: an LPSTP alternative, a full channel lining/sideslope revetment alternative with sheetpile cut-off walls, a structural planting wall alternative, and two bioengineering alternatives, one with large rock or gabion slope protection, and one with reinforced earth slopes. At a subsequent meeting with the KCD and the sponsor, the full channel lining alternative was eliminated, mainly due to its anticipated impact on adjacent trees.

On proceeding into the Concept Design Alternatives step, considerable effort was spent assessing the causes of the instability including hydrology, geotechnical, and geomorphology. Several factors were found to be significant contributors.

- There is significant recent and ongoing development in the rapidly urbanizing watershed. This results in larger runoff peaks and volumes. A limited number of upstream detention ponds, plus the two large (non-flood control) lakes in the watershed, also impact the hydrology, by increasing the length of

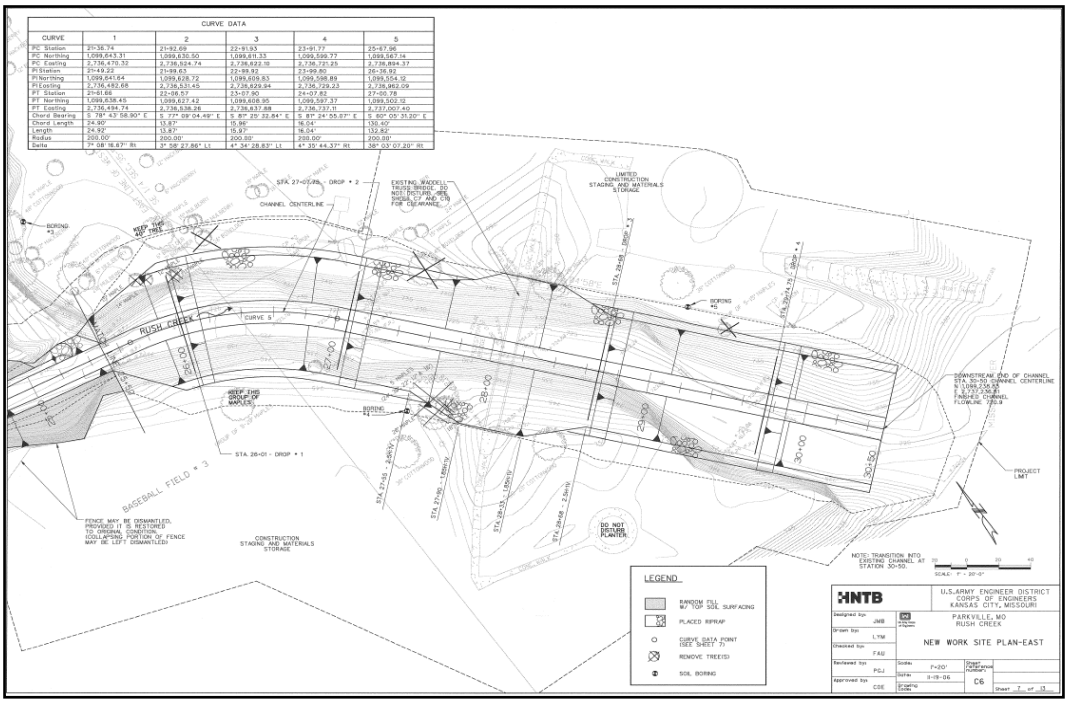
time that bankfull discharges occur. The net result is that flow peaks are larger and of significantly greater durations than would have occurred from the same rainfalls historically. These larger and longer flows impact the stream geomorphology, in essence changing the magnitude of the channel forming event.

- The two major lakes in the watershed, particularly the nearer Riss Lake on White Aloe Branch, probably impact the sediment loading of the stream by discharging relatively sediment starved water.

- The existing channel in the study reach passes through an old land fill area. This suggests that the channel may not be in its natural location. A prior relocation may not have replicated the slopes and meanders of the original stream.

- The Missouri River flow line has reportedly dropped approximately 10 feet (3 m) in the Kansas City reach. This has resulted in headcutting on the lower end of many local streams, including Rush Creek.

- Geotechnical information and investigations identified that the surface material at the project site consisted of clays, silts and loams. Including top soil, the silt-clay layer tended to be 13.5 feet to 15.5 feet (4.1 to 4.7 m) deep in the project reach. This cohesive layer is underlain by sandy material. One result of the lowering of the Missouri River bed is that the downstream end of Rush Creek subsequently penetrated through the silt-clay material into the sand. The sandy material is highly erodible and has led to relatively rapid deepening and widening of the channel throughout the project reach.



The geotechnical factor, related to the presence of the sand layer along the new channel thalweg, adversely impacted the feasibility of several of the alternatives presented in the Site Visit and Preliminary Assessment Report. Therefore, burying and isolating the sand layer from active flows became a major emphasis of the design. This eliminated the bio-engineering solutions from further consideration, because those alternatives did not provide for filling the lower portion of the existing streambed that had degraded into the sand layer. Also, cost estimates developed in the alternatives analysis step indicated that most of the bio-engineering alternatives assessed in the site visit phase were prohibitively expensive.

After additional meetings with the Kansas City District and the City of Parkville, a new alternative was developed and scoped for final design. This new alternative incorporated a grade control structure downstream of the Waddell Bridge, with the intent of restoring the flowline at the bridge and at the upstream confluence with White Aloe Branch back to near its elevation prior to the headcut and degradation of the channel bottom into the sand layer. The design included filling the channel bottom upstream of the grade control, and included use of LPSTP along the new channel toes, extending along both sides of the channel to the Main Street bridge. Work on the upper sideslopes of the channel, in the silt-clay material, was specifically

excluded, with the intent that the city would eventually provide selected vegetation. Virtually all constraints would be avoided, and many of the larger trees along the channel bank would be left in place, albeit with steep adjacent slopes between them and the project's reconstruction of the lower portion of the channel. This design was completed and bid in late 2006. At the time of the potential letting, market pressures from the aftermath of Hurricane Katrina had heavily impacted the costs of steel and concrete, and therefore the proposed grade control structure. In addition, due to heavy area-wide construction activity, only one responsive bid was received. As a result, the one bid significantly exceeded the project cost estimate and the available funds. Having only received one responsive bid, the Kansas City District and the City were able to enter into intensive negotiations with the contractor to value engineer the project to meet the established goals within the project budget.

The Kansas City District, HNTB and Parkville reevaluated the design function, conducted a series of meetings with the contractor who had submitted the responsive bid, and discussed various methods of accomplishing the project goals of stabilizing the stream without impact the numerous adjacent facilities. Ultimately, the decision was made to return to a design concept that had been screened out earlier. It was decided to use a series of four grade control structures, each with sheet piling driven to a minimum depth of 12 feet (4m) below ground, projecting above grade 3 feet (1 m) high or less, to raise the channel flowline above the sand layer. This necessitated compromises on the desired channel elevation and sideslopes at the Waddell Bridge, because it was only possible to construct two of the drops between the bridge and the Missouri River. However, the desired channel bottom raise was achieved slightly downstream of the confluence with White Aloe Branch. The new design also included rock armoring of the banks and bed of the stream at various levels throughout the channel reach. Once consensus was reached with all parties regarding the new approach, HNTB quickly revised the design and plans, and an affordable price was negotiated with the contractor.

The project was constructed in early 2007, by ESI Contracting of Kansas City. Photos 6 and 8 depict the constructed project in direct comparison to the pre-construction conditions in Photos 5 and 7. To this date, periodic monitoring indicates that the project is performing as expected. The City's infrastructure and the English Landing Park have been protected from extremely rapid and destructive erosion. The City and community have generally indicated great satisfaction with the project. The new design required the removal of a few trees that were not initially expected to be removed, which caused concern among some Park visitors. However, left without a project, all of the trees that were removed by construction, and many that were saved by the project, would have fallen victim to the erosion in a very short time.

LONG TERM PERFORMANCE

Another Section 14 project with MoDOT was the bridge over the Grand River at Route A. This project was constructed in March-April, 2001. It has withstood numerous bank full events, including one that occurred during construction, and has proven to be quite stable. It arrested a rapidly moving bank, and has accumulated significant sediments both in the voids of the riprap, and in the open cells between the bank, the LPSTP, and the baffles. These sediments support vegetation that traps more sediment, enhancing both the protective function of the project, and providing natural cover that helps reduce the potential negative impacts of riprap. Photos 9 through 14 show a progression over time, looking upstream from the Route A bridge.

Photo 9: January 20, 1999

Photo 10: April 18, 2001

Photo 11: March 29, 2002

Photo 12: September 5, 2002

Photo 13: March 6, 2006

Photo 14: May 23, 2007

A large flood in 2006 removed some the vegetation that had covered over the silted baffles, and over time it is expected to be restored. Also of note in the photographs is the successful use of a vegetative buffer along the field adjacent to the bank stabilization project. This feature, included in all similar Section 14 projects, involves attaining a permanent easement, combined with selective plantings. The Route A project is typical of the Section 14 projects where the stabilized project fills in with sediment, and then natural vegetation eventually covers the project features, tying in with the riparian zone on the original bank.

CONCLUSION

The Section 14 program in the Kansas City District of the U.S. Army Corps of Engineers has been an excellent example of a Federal agency, local and state agencies, consulting firms, and private contractors coming together in partnership to provide much needed protection to an important segment of the Nation's infrastructure. Dozens of projects have been constructed over the decades, especially on the dynamic and active rivers of Northwest Missouri. Periodic site visits indicate that all of the projects constructed in this region have performed as designed, not only in protecting infrastructure, but also serving to repair scarred streams. Using established construction techniques applied with sound engineering principles, along with the combined experience of the Kansas City District and HNTB Corporation, the Section 14 program is truly a tool that will continue to be highly relevant and valuable in the 21st century in addressing our daunting infrastructure challenges.

Abstract

In the early 1990s, the City of Lenexa, Kansas (City) adopted a flood control standard which required new developments to limit post-construction 1-percent-annual-chance flow rates to 2.79 cubic feet per second (cfs) per acre. In 2003, the City adopted new standards (American Public Works Association Specification 5600) that removed the 1-percent-annual-chance requirement but included matching the 100-percent-annual-chance and 10-percent-annual-chance post-development flow rates to pre-development flow rates (Lenexa City Code, January 2008). As a result of these requirements, many detention basins have been constructed in the past two decades have not been included as part of a city-wide flood hazard analysis. To remedy this omission, the City initiated the East Lenexa Detention Study (ELDS) to quantify the effect of the small detention basins on peak flow rates and water surface elevations.

The purpose of this study was to evaluate the impacts of the smaller detention basins on flood hazard areas in Lenexa using HEC-HMS and HEC-RAS models. For the hydrologic analysis, HEC-HMS models were used to simulate peak runoff from the 50 percent, 10 percent, and 1 percent annual chance storms. For the hydraulic analysis, HEC-RAS models were used to estimate water surface elevations using the peak flow rates estimated by the HEC-HMS model.

The 1-percent-annual-chance peak flows within the Study Area increased as much as 57 percent in one location (Mill Creek) and decreased as much as 32 percent at another location (Indian Creek) to the existing FEMA models as a result of identified detention basins and updated landuse characteristics. The 1-percent-annual-chance peak water surface elevation decreased as much as 6.1 feet in one location and increased as much as 10.9 feet in another location due to refinement of HEC-RAS model input. As a result, 11 buildings within the ELDS Area were removed from the floodplain limits.

Background

Detailed floodplain mapping efforts within the City of Lenexa, Kansas (City), were recently completed by the Johnson County Stormwater Management Program, and the updated Flood Insurance Rate Maps (FIRMs) are currently adopted by the Federal Emergency Management Agency (FEMA). The hydrologic modeling for the mapping effort was accomplished using the U. S. Army Corps of Engineers (USACE) Hydrologic Engineering Center's (HEC) Flood Hydrograph Package (HEC-1). As part of the analysis, large stormwater detention basins that receive significant drainage were included in the evaluation. However, smaller basins that were often designed specifically to detain flood flows from smaller areas were not included in the hydrologic modeling effort. This level of detail was beyond the requirements for the FIRM updates.

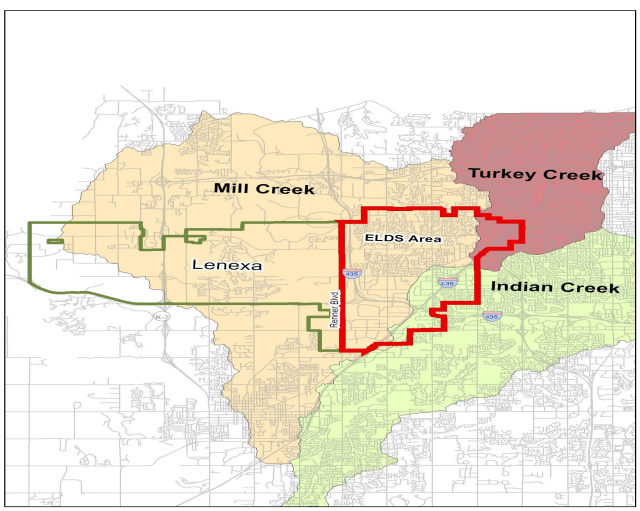

Figure 1. East Lenexa Detention Study Area

In the early 1990s, the City adopted the Kansas City Metropolitan Chapter of the American Public Works Association (APWA) standards for flood control, which required developments to limit post-construction 1-percent-annual-chance unit flow rates to 2.79 cubic feet per second (cfs) per acre. In 2003, the City worked in parallel with the Kansas City Metropolitan Chapter of APWA and adopted new requirements that are more specific to the region. The new standards replace the 1-percent-annual-chance requirement with matching the 100- and 10-percent-annual-chance post- to pre-development flow rates. In addition, the new standard requires implementing best management practices (BMPs) to control the smaller rainfall events (Lenexa City Code, January 2008). As a result of these requirements, many detention basins have been constructed in the past two decades that are specifically designed to detain low probability flows in local drainage ways, but have not been included as part of a city-wide flood hazard analysis. To remedy this omission, the City initiated the East Lenexa Detention Study (ELDS) to quantify the effect of the small detention basins on peak flow rates and water surface elevations.

The ELDS Area includes the area in eastern Lenexa east of Renner Boulevard to the City limits, encompassing approximately 15 square miles (Figure 1). The Study Area land use is mostly residential, commercial, and open space and includes 148 detention basins (Figure 2) distributed throughout three major watersheds: Mill Creek, Indian Creek and Turkey Creek.

Methods

Hydrologic Evaluation

Quantifying the effects of these smaller basins on peak flow rates and water surface elevations required the creation of a hydrologic model (HEC-HMS 3.1.0) with sufficient detail to evaluate the impacts of detention basins. A refined hydraulic model (HEC-RAS 3.1.3) to evaluate the impacts of detention basins on peak water surface elevations was also needed. This section provides a detailed description of the methodology used to estimate the hydrologic effects of incorporating the 148 detention basins.

Following are the steps used to create a refined hydrologic model:

1. Obtaining the FEMA Preliminary Effective Models (HEC-1 Version 4.0)
2. Converting the FEMA Preliminary Effective Models from HEC-1 version 4.0 to the Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS) version 3.1.0, creating the FEMA Converted Model
3. Refining the FEMA Converted Model to include subarea and routing refinements to create the Converted Refined Model
4. Modifying the Converted Refined Model to include storage nodes for all identified detention basins to create the Existing with Detention Model

Each step is summarized in the following paragraphs.

FEMA Preliminary Effective Models

The updated FIRMs are identified as FEMA's "preliminary effective FIRMs" until they become effective in 2009. The hydrologic models (HEC-1) used to create the preliminary effective FIRMs (using HEC-RAS 3.1.1) were used as the starting point for the hydrologic model.

The results from three watershed studies (HEC-1 models) were obtained for the ELDS project. The watershed studies included:

- Mill Creek Watershed Study (Mill Creek Watershed Study, 2006)
- Indian Creek Watershed Study (Indian Creek Watershed Study, 2006)
- Northeast Johnson County Watershed Study (Northeast Watershed Study, 2006)

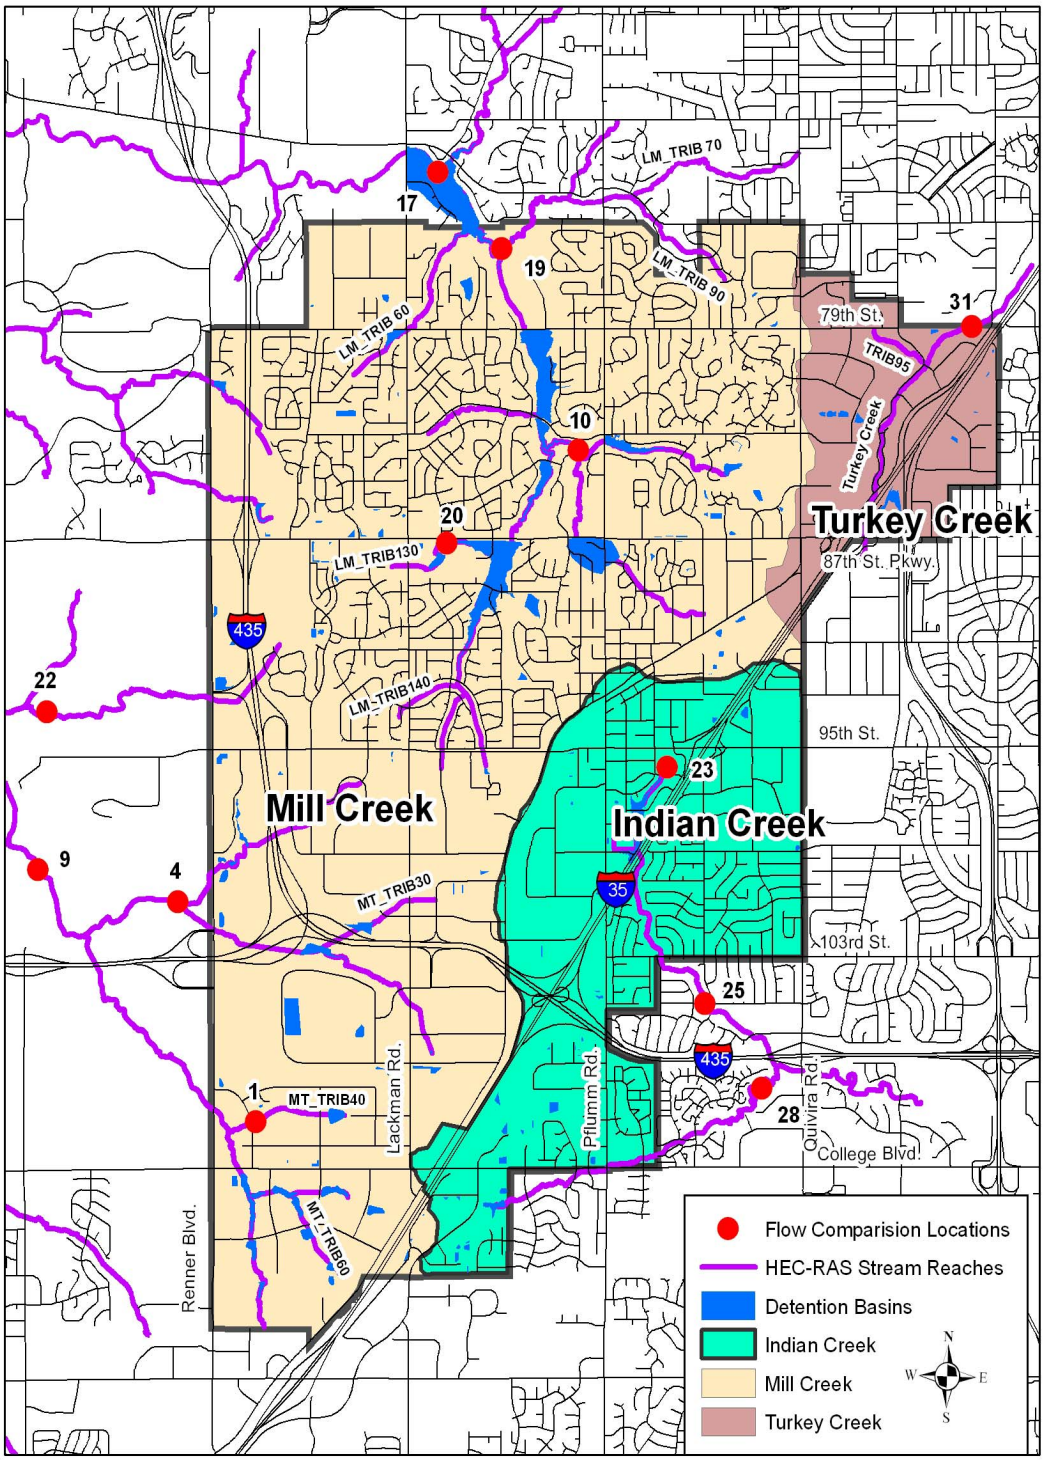

Figure 2. ELDS Area

FEMA Converted Model

The FEMA Converted Model was created by converting the FEMA Preliminary Effective HEC-1 models to HEC-HMS version 3.1.0. HEC-HMS version 3.1.0 was used for this study because it is the currently HEC-supported software and the hydrologic models produced as part of this study are intended to be tools that the City will use in future analyses. The primary purpose of creating the FEMA Converted Model is to isolate the effects of the refined models from changes in the model results associated with software version differences.

Table 1 includes a comparison of the FEMA Preliminary Effective Model to the FEMA Converted Model for 1-, 10-, and 50-percent-annual-chance peak flows along the study reaches at select locations (shown on Figure 2).

Table 1: FEMA Converted Model Flow Comparisons

Mill Creek Watershed

Reach Name	Location ID	FEMA Preliminary Effective			FEMA Converted Model			Percent Difference

Converting the HEC-1 model to HEC-HMS caused the 1-percent-annual-chance peak flows to increase by a maximum of 6 percent at certain locations. The conversion to HEC-HMS generally increased flow rates compared to HEC-1 for the 1-percent-annual-chance event. However, for the 50-percent-annual-chance event, the peak flow rates generally decreased with the HEC-HMS conversion. The 10-percent-annual-chance peak flow rates tended to increase or decrease depending upon the location, within a maximum increase of 11 percent and maximum decrease of 9 percent. This

increase or decrease in flows was due to different computation routines between the HEC-1 and HEC-HMS models (HEC, February, 2001).

Converted Refined Model

The inclusion of the detention basins in the hydrologic model required refining the subbasin boundaries, calculating new hydrologic characteristics, and incorporating new routing reaches. To quantify the impacts of these model refinements on peak flow values, a Converted Refined Model was created. The Converted Refined Model includes all subbasin refinements necessary with the exception of the 148 detention basins. Comparing the results of the Converted Refined Model to those of the FEMA Converted Model identified changes in flow rates due solely to subarea refinement.

Existing with Detention Model

The Converted Refined Model was modified to include information relating to 148 detention basins surveyed within the ELDS Area to create the Existing with Detention Model. Table 2 shows flow comparison between FEMA preliminary effective model and Existing with Detention Model. The difference in peak outflow between these models is discussed in results section.

Hydraulic Evaluation

This section provides a detailed description of the methodology used to estimate the floodplain elevations within the ELDS Area using the refined peak flow rates from the Existing with Detention Hydrologic Model.

As with the hydrologic model refinement, hydraulic models used to create the preliminary effective FIRMs were used as the starting point for the hydraulic model refinements. These models will be referred to as the FEMA Preliminary Effective Models.

The following steps used to create a refined hydraulic model:

1. Obtaining the FEMA Preliminary Effective Models (HEC-RAS version 3.1.1)
2. Running the FEMA Preliminary Effective Models in HEC-RAS version 3.1.3, to create the FEMA Duplicate Effective Model
3. Revising the FEMA Duplicate Effective Model to create the Existing with Detention Model

The FEMA Duplicate Effective Models resulting water surface elevations were compared with the FEMA Preliminary Effective Models, which showed a negligible (plus or minus 0.50 feet) change in water surface elevations at all but four cross sections. All four cross sections are located along Mill Creek Tributary 60.

Existing with Detention Model

The Existing with Detention Model was created from the Duplicate Effective Model. Peak flow rates from Existing with Detention Hydrologic Model were input into the HEC-RAS model

Results and Discussions

Hydrologic Results

The results of the hydrologic model refinements showed an increase in 1-percent-annual-chance peak flows at some locations (with the maximum of 57%) within the ELDS Area. The reasons for the peak flow increase are:

- The FEMA Preliminary Effective Models were run using a 5-minute computation time step. When the models were converted to HEC-HMS, a 1-minute computation time step was used. Use of the 1-minute time step in the computer model resulted in increased flow rates at locations where the 5-minute time step did not capture the hydrograph time to peak.
- Percentage imperviousness was increased throughout the ELDS Area, with the Mill Creek Watershed increasing an average from 22 percent to 38 percent by the largest percentage.

- Refinement of the hydrologic models included refining the drainage area delineations using more detailed storm sewer and drainage information than was available at the time the FEMA Preliminary Effective Models were developed. Slight increases in drainage areas to downstream locations result in increases in peak flow rates.

- Refinement of the rating curves for storage areas modeled in the FEMA Preliminary Effective Model resulted in increased peak flows at the location of the basin and for some distance downstream.

The results of the hydrologic model refinements showed decreases in 1-percent-annual-chance peak flows at many of the locations (with the maximum of 32%) within the ELDS Area. The reasons for the peak flow decrease include the following:

- The detention basin performance in Mill Creek and Indian Creek averaged 25 and 23 percent reduction respectively in the 1-percent-annual chance peak flow rates, and detention basins in Turkey Creek averaged 34 percent reduction. Many areas with reduction in peak flow rates can be attributed to the inclusion of upstream detention.

- Refinement of the hydrologic models included refining the drainage area delineations using more detailed storm sewer and drainage information than was available at the time the FEMA Preliminary Effective Models were developed. Slight decreases in drainage areas to downstream locations show decreases in peak flow rates.

- Refinement of the rating curves for storage areas modeled in the FEMA Preliminary Effective Model resulted in decreased peak flows at the location of the basin and for some distance downstream.

Some of the detention basins analyzed showed zero reduction in the 1-percent annual chance peak flow rates. Closer inspection of these basins indicated that although the basins were identified as detention basins for the purpose of this study, most appear to be drainage features that were not specifically designed for stormwater detention.

Hydraulic Results

The following paragraphs summarize the results for the Mill Creek, Indian Creek, and Turkey Creek Watersheds.

Mill Creek Watershed

The results show a reduction in the 1-percent-annual-chance peak water surface elevation at 193 of the 489 cross sections modeled within the Mill Creek Watershed as part of this study. Increases in peak water surface elevations were observed at 286 of the cross sections. Peak water surface elevations at 10 of the cross sections matched the peak water surface elevation in the FEMA Duplicate Effective Model.

The maximum reduction in 1-percent-annual-chance peak water surface elevation was approximately 6.1 feet. This reduction appears to be a result of the decrease in peak flow rates due to upstream detention.

The maximum increase in the 1-percent-annual-chance peak water surface elevation was approximately 10.9 feet. This increase in water surface elevation resulted from adding the rating curve to define discharge from the in-line detention basin.

As part of the Mill Creek Watershed Study, the lowest adjacent grade (LAG) elevation for 33 buildings located adjacent to the floodplain boundary and within the ELDS Area were surveyed and compared to the 1-percent-annual-chance water surface calculated as part of the study. The LAG is defined by FEMA as the lowest ground elevation touching the building. Of the 33 buildings surveyed, 12 were found to be outside the floodplain (i.e., the LAG was at or above the water surface elevation calculated during the study).

The LAG for the existing 31 buildings was compared to the Existing with Detention 1-percent-annual-chance water surface elevation. Comparing the LAG with Existing with Detention water surface elevations resulted in an additional nine buildings found to be outside the floodplain.

Indian Creek Watershed

Comparison of the FEMA Duplicate Effective Model with the Existing with Detention Model shows a reduction in the 1-percent-annual-chance peak water surface elevation at 70 of the 100 cross sections modeled within the Indian Creek Watershed. Increases in peak water surface elevations were observed at 28 of the cross sections. Peak water surface elevations at two of the cross sections matched the peak water surface elevation in the Duplicate Effective Model.

The maximum reduction in 1-percent-annual-chance peak water surface elevation was approximately 1.7 feet. This reduction appears to be a result of the reduction in peak flow rates due to upstream detention.

The maximum increase in the 1-percent-annual-chance peak water surface elevation was approximately 0.2 feet. This small increase in water surface elevation at this location appears to be the result of adding the rating curve for in-line detention basin.

During the Indian Creek Watershed Study, the LAG elevation for 32 buildings located adjacent to the floodplain boundary and within the ELDS Area were surveyed and compared to the 1-percent-annual-chance water surface calculated as part of the watershed study. Of the 32 buildings surveyed, 17 were found to be outside the floodplain.

The LAG elevations for the 32 buildings were compared to the Existing with Detention 1-percent-annual-chance water surface elevation resulting in one additional building found to be outside the floodplain.

Turkey Creek Watershed

The results from the Existing with Detention Model shows a reduction in the 1-percent-annual-chance peak water surface elevation at 36 of the cross sections modeled. Increases in 1-percent-annual-chance peak water surface elevations were observed at 25 of the cross sections. Peak water surface elevations at one of the cross sections matched the peak water surface elevation in the Duplicate Effective Model. The maximum reduction in 1-percent-annual-chance peak water surface elevation was approximately 1.9 feet. This reduction appears to be a result of the reduction in peak flow rates due to upstream detention.

The maximum increase in the 1-percent-annual-chance peak water surface elevation was approximately 2.8 feet. This increase in water surface elevation appears to be a result of increases in peak flows at this location.

During the Turkey Creek Watershed Study, the LAG elevations for four buildings located adjacent to the floodplain boundary and within the ELDS Area were surveyed and compared to the 1-percent-annual-chance water surface calculated as part of the watershed study. Of the four buildings surveyed, all were found to be within the floodplain.

The LAG elevations for the four buildings were compared to the Existing with Detention 1-percent-annual-chance water surface elevation. Even though the water surface elevations at each of the buildings decreased, the decrease was not enough to change the status of the buildings.

Conclusions

The model refinements that were made to account for existing detention facilities in the study area reduced the estimated 1-percent-annual-chance floodplain elevations in some locations. As a result, 11 buildings within the ELDS Area were removed from the 1-percent-annual-chance floodplain limits.

ABSTRACT

Water quality of streams in Johnson County, Kansas was evaluated from October 2002 through December 2007 in a cooperative study between the U.S. Geological Survey and the Johnson County Stormwater Management Program. Water quality at 42 stream sites, representing urban and rural basins, was characterized by evaluating benthic macroinvertebrates, water (discrete and continuous data), and/or streambed sediment. Point and nonpoint sources and transport were described for water-quality constituents including suspended sediment, dissolved solids and major ions, nutrients (nitrogen and phosphorus), indicator bacteria, pesticides, and organic wastewater and pharmaceutical compounds. The information obtained from this study is being used by city and county officials to develop effective management plans for protecting and improving stream quality. This fact sheet summarizes important results from three comprehensive reports published as part of the study and available on the World Wide Web at http://ks.water.usgs.gov/Kansas/studies/qw/joco/.

INTRODUCTION

Rapid population growth and urbanization in Johnson County in northeast Kansas has affected stream quality. Urbanization results in more residential, commercial, and industrial developments, and generally affects streams by altering hydrology, geomorphology, chemistry, and biology (Paul and Meyer, 2001). Consequently, these changes affect aquatic communities. Contamination entering streams in rural and urban areas can originate from point sources (such as wastewater treatment discharges) and nonpoint sources (such as stormwater runoff, leaking sewer lines, septic tanks, and atmospheric deposition). Water quality in Johnson County streams affects communities in the Kansas City metropolitan area because basins covering about one-third of the county flow northeast into Missouri. Water quality and the effects of combined sewer overflows in Kansas City, Missouri, have been the subject of previous studies (Wilkison and others, 2006).

Streams in Johnson County are important for human and environmental health, water supply, recreation, and aesthetic value. The information obtained during this study is useful for defining current water-quality conditions, understanding

variability in conditions, evaluating effects of urbanization, developing effective water-quality management plans, documenting changes in water quality, and evaluating conditions relative to total maximum daily loads (TMDLs), National Pollutant Discharge Elimination System (NPDES) requirements, and water-quality standards.

Stream quality was evaluated from October 2002 through December 2007 using benthic macroinvertebrate, discrete water and streambed sediment samples, and continuous water-quality monitoring. Macroinvertebrate samples were collected to assess biological conditions, an indication of how well water bodies support aquatic life and, therefore, a measure of overall stream quality. Macroinvertebrates were collected from 15 stream sites in Johnson County and evaluated along with data from seven additional sites collected as part of a separate study with similar objectives in Missouri (Wilkison and others, 2006). Various aspects of macroinvertebrate communities, including organism diversity (number and variety of species), composition, tolerance, and feeding characteristics also were used to evaluate and compare stream quality. Water samples were collected from 42 stream sites representing all of the major basins in the County (Figure 1, some sites represent multiple sampling locations). Water samples were analyzed for suspended sediment, dissolved solids and major ions, nutrients (nitrogen and phosphorus species), indicator bacteria, pesticides, and organic wastewater and pharmaceutical compounds. Samples were collected during base-flow (unaffected by storm runoff, when streamflow is sustained by ground-water inflow, springs, and, in some locations, wastewater discharge) and storm-flow conditions. Constituent concentrations, loads (amount of constituent transported in a stream during a specified period of time), and yields (load divided by drainage area for comparing basins) were determined for five major basins of Johnson County using continuous monitoring (hourly in-stream measurements) and statistical regression models. Streambed-sediment samples were collected from 15 sites and analyzed for major ions, nutrients, trace elements, bacteria, pesticides, and organic wastewater compounds. Unless otherwise referenced, the information summarized here is included in publications by Lee and others (2005), Poulton and others (2007), and Rasmussen and others (2008); additional explanation and results can be found in those reports.

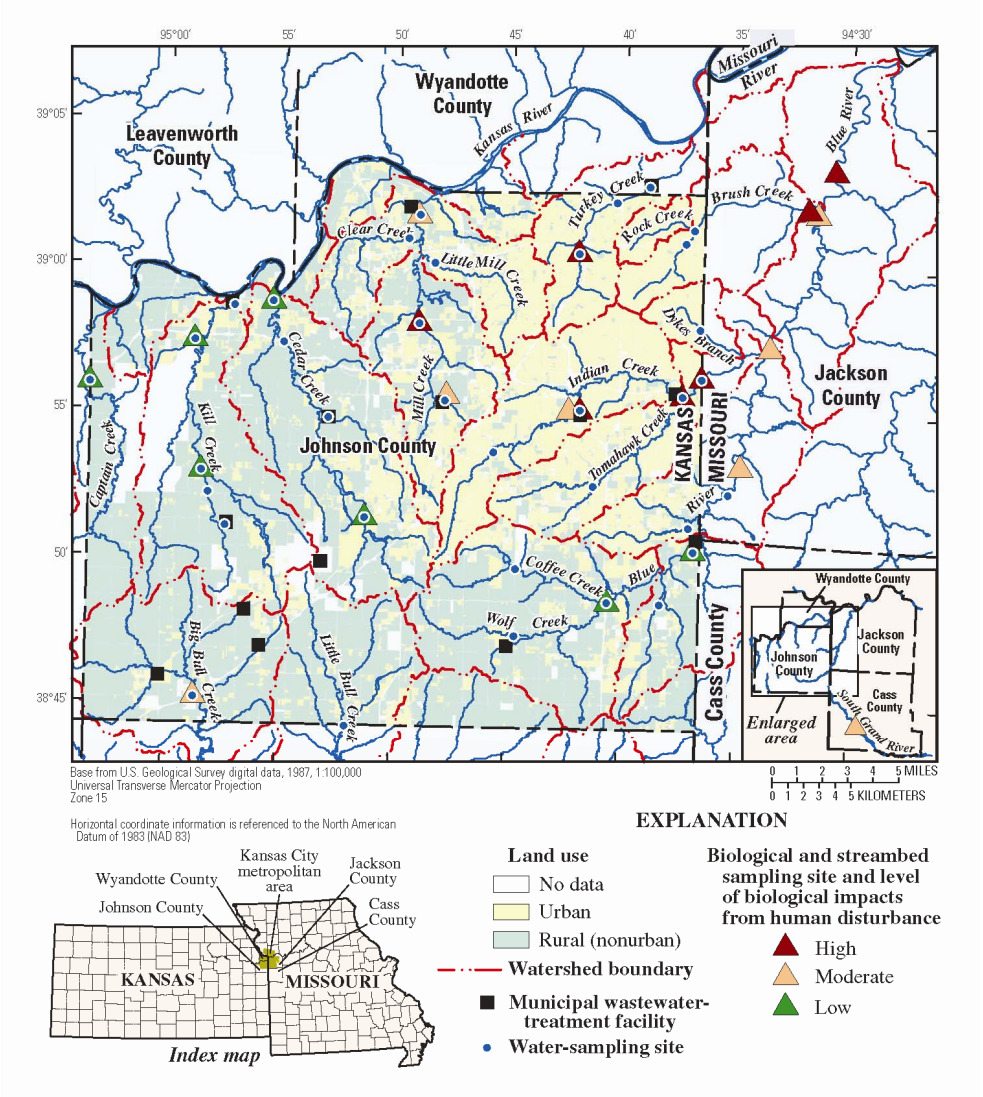

Figure 1. Location of stream sampling sites, urban and rural land use, and relative biological impacts (negative responses associated with human-induced disturbance or stress) in Johnson County, Kansas.

BIOLOGICAL CONDITIONS – AN OVERVIEW OF STREAM QUALITY

- During 2003 and 2004 when biological samples were collected, no sites, including the reference site on Captain Creek, met State criteria (Kansas Department of Health and Environment, 2006) for full support of aquatic life. Reference streams are streams designated by the State as being minimally disturbed by human activity, and generally serve as a basis for comparison in stream evaluations.
- The least impacted stream sites predominantly were in rural areas. As impervious surface area (a general indication of urbanization) increased, biological quality generally decreased.

- Sites in Johnson County that were least impacted by human disturbance included upstream Blue River (Figure 2), Cedar, Kill, and Captain Creek sites (Figure 1). Indian, Tomahawk, and Turkey Creek sites in Johnson County, and downstream Blue River and Brush Creek sites in Missouri were most impacted by human disturbance.

Figure 2. Example of a stream site in Johnson County, Kansas, showing minimal impacts from human disturbance and some macroinvertebrates generally associated with healthy streams (macroinvertebrate photographs from http://www.epa.gov/bioindicators/html/photos_invertebrates.html).

- In the Blue River basin where biological conditions were least impacted, biological quality was strongly correlated with upstream land cover consisting of forests and grasslands. Biological quality declined with increases in impervious land cover, nutrient enrichment, and prevalence of organic wastewater compounds and pharmaceuticals (Wilkison and others, 2006).

SUSPENDED SEDIMENT

- Of the total suspended-sediment load transported in 2005-06, 90 percent or more occurred during less than 2 percent of the time (the equivalent of about 7 days per year), generally during large streamflows, at all five monitoring sites. Therefore, management practices designed to control sediment during large streamflows can substantially reduce annual loads.
- About 35 percent larger average annual precipitation in 2005 compared to 2006 resulted in an average of four times the suspended sediment load.
- Annual sediment yields in the urban basins (Indian and Mill Creeks) were 50 percent larger than in rural basins (Cedar and Kill Creeks, Blue River) in 2005.

- About 70 percent of the time (generally when there was little or no storm runoff), suspended-sediment concentrations in Indian Creek were smaller than in other basins partly because of the large contribution of treated water discharged from upstream wastewater-treatment facilities. However, total annual sediment load and yield in Indian Creek were larger than other basins because of disproportional loading that occurred during large streamflow at that site.
- Sediment transport in Johnson County streams and, therefore, management practices implemented to control sediment are especially important because other contaminants such as nutrients and bacteria frequently are associated with sediment particles.

NUTRIENTS AND DISSOLVED OXYGEN

- In Johnson County stream reaches during 2005 and 2007, about two-thirds of the Indian Creek total nitrogen load and one-third of the Blue River total nitrogen load originated from wastewater treatment facilities (WWTFs) (Figure 3). Nitrogen from WWTFs primarily occurred in the form of nitrate. In 2006, when total annual rainfall was about 65 percent of the total rainfall that occurred in 2005 or 2007 (resulting in less nonpoint-source nutrient load), total nitrogen originating from WWTFs accounted for a larger percentage (about three-fourths) of the total load in Johnson County reaches of both Indian Creek and the Blue River. Wilkison and others (2006) determined that during 2002-04, about 60 percent of the total nitrogen and total phosphorus loads in the lower Blue River in Missouri originated from Indian Creek.

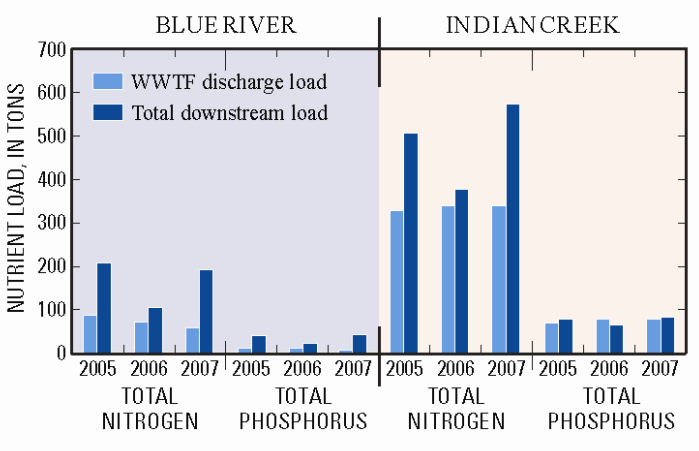

Figure 3. Annual estimated total nitrogen and total phosphorus loads and loads originating from wastewater treatment facility (WWTF) discharges in the Blue River and Indian Creek, Johnson County, Kansas, 2005-07. WWTF discharges were a primary contributor to downstream nutrient loads.

- From March 2004 through December 2007, dissolved oxygen (important to sustain aquatic life) was less than the minimum state criterion of 5 mg/L (Kansas Department of Health and Environment, 2005) less than 5 percent of the time at the 5 continuous monitoring sites except Blue River (8 percent) and Indian Creek (15 percent) (Figure 4). Low dissolved oxygen concentrations primarily occurred during the summer.

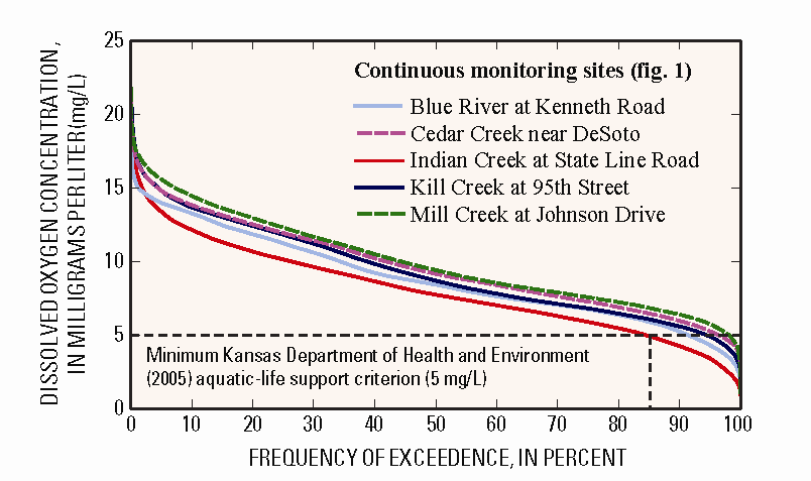

Figure 4. Measured dissolved oxygen (DO) and frequency of exceedence (percentage of time a given value is equaled or exceeded) at five continuous monitoring sites in Johnson County, Kansas, March 2004-December 2007. DO was less than the state criterion about 15 percent of the time at the Indian Creek site.

INDICATOR BACTERIA

- *Escherichia coli (E. coli)* bacteria density at the Indian Creek site, located in the most urban basin, was nearly always largest with a median density more than double that of any other site. *E. coli* is used as an indicator of pathogens in streams that may cause illness in humans who come into contact with the water.
- During base flow, the largest bacteria densities occurred upstream from WWTFs indicating that wastewater discharges generally do not contribute substantially to bacteria densities in streams.
- During 2005-07, less than 3 percent of the total annual fecal coliform bacteria load in Indian Creek and the Blue River originated from WWTFs. Wilkison and others (2006) also reported that bacteria in streams originated primarily from nonpoint sources during storm runoff.
- Water-quality conditions in streams often change rapidly during storm runoff. For example, *E. coli* bacteria density in Kill Creek during May 2007 increased

from about 180 colonies per 100 milliliters of water (col/100mL) to about 100,000 col/100mL during a 12-hour period (Figure 5).

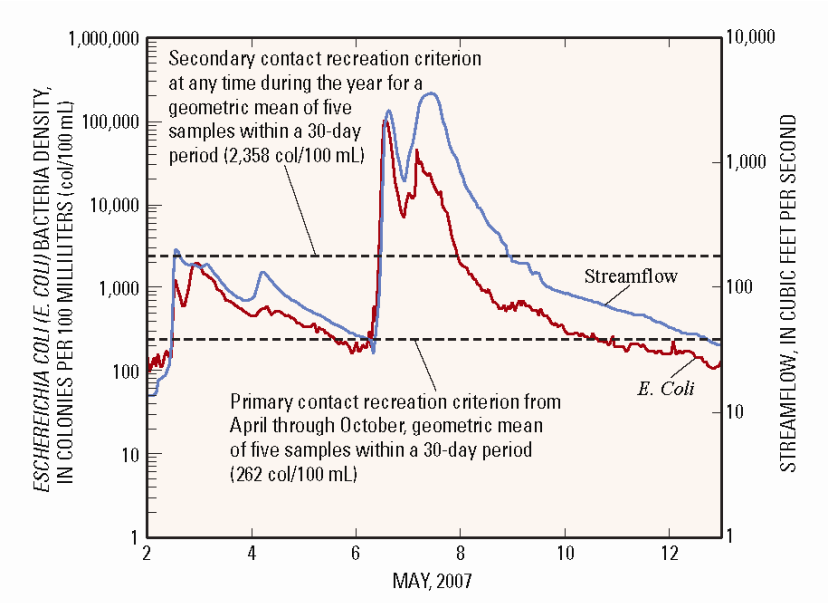

Figure 5. Streamflow and estimated *E. coli* bacteria density at the Kill Creek monitoring site, Johnson County, Kansas, in May 2007. Bacteria density increased from about 180 col/100 mL to about 100,000 col/100 mL during a 12-hour period.

ORGANIC COMPOUNDS

- Atrazine was detected in nearly all water samples, including base flow samples, and had the largest concentrations of all pesticides sampled. Atrazine concentrations, however, did not exceed the state chronic aquatic-life criterion of 3.0 micrograms per liter (µg/L) as an annual average (Kansas Department of Health and Environment, 2005).
- During base flow, water samples from urban stream sites had the largest number of pesticide compounds detected, and water samples from rural sites had the largest total concentration of pesticides.
- The largest total concentrations of organic wastewater compounds occurred in base-flow samples from sites at or immediately downstream from WWTFs. The most common compounds were AHTN (acetyl-hexamethyl-tetrahydro-napthalene, a musk fragrance), caffeine, DEET (mosquito repellant), a detergent surfactant (nonylphenol-diethoxylate), and a flame retardant and plasticizer (tris(2-butoxyethyl) phosphate), which together comprised more than one-half of the total organic wastewater compound concentrations in 80 percent of the base flow samples.

- In streambed sediment samples, the largest organic compound concentrations included chlordane (an insecticide banned in 1988), dichloro-diphenyl-trichloroethane (DDT, a pesticide banned in 1972), and polyaromatic hydrocarbons (PAHs, likely carcinogens that originate from combustion of fossil fuels and are used as an ingredient in asphalt), and were present in urban basins but were not closely linked to WWTF discharges.

ADDITIONAL FACTORS AFFECTING WATER QUALITY

- Water contaminants including sediment, total nitrogen and phosphorus, bacteria, and pesticides (particularly during spring) at urban and rural sites originated primarily from nonpoint sources during storm runoff. As a consequence, climate (precipitation and resulting runoff) had a substantial effect on water quality, and larger amounts of rainfall resulted in larger amounts of contaminants. In addition, the probability that water-quality criteria are exceeded is substantially larger during storm runoff.
- Wastewater discharges were the primary source of streamflow at sites downstream from WWTFs during base-flow conditions. This is true not just immediately downstream, but many miles downstream, from the WWTF.
- About 10 percent of the time chloride concentrations in Indian and Mill Creeks were elevated as a result of runoff from road salt application; however, the acute aquatic life criterion of 860 milligrams per liter (mg/L) (Kansas Department of Health and Environment, 2005) was exceeded less than 1 percent of the time.

CONCLUSION

Water quality of streams in Johnson County, Kansas, varied according to climate (precipitation and resulting runoff conditions), degree of urbanization, and contribution from and proximity to wastewater discharges. Results from the Johnson County water-quality studies generally were consistent with results on Blue River water quality reported by Wilkison and others (2006). Information from these studies is being used by municipal and county officials to address water-quality concerns, particularly those related to expected increases in population and urban land use leading to additional demands on streams. For example, wastewater treatment facilities on Indian Creek and the Blue River are undergoing major upgrades to increase capacity and reduce nutrients in discharges to streams. In addition, the information is being used for public education about stormwater runoff and water quality. It also is being used to enhance and monitor programs to protect streams, such as construction runoff controls and stream setback programs. Ongoing monitoring of water quality and stream health will provide information about trends with time and effectiveness of management plans.

ABSTRACT

From 1998 through 2007, over 750 surface-water or bed-sediment samples in the Blue River Basin – a largely urban basin in metropolitan Kansas City - were analyzed for more than 100 anthropogenic compounds. Compounds analyzed included nutrients, fecal-indicator bacteria, suspended sediment, pharmaceuticals and personal care products.

Non-point source runoff, hydrologic alterations, and numerous waste-water discharge points resulted in the routine detection of complex mixtures of anthropogenic compounds in samples from basin stream sites. Temporal and spatial variations in concentrations and loads of nutrients, pharmaceuticals, and organic wastewater compounds were observed, primarily related to a site's proximity to point-source discharges and stream-flow dynamics.

Total nitrogen concentrations were frequently greater than 10 milligrams per liter in surface-water samples and total phosphorous concentrations were routinely greater than 1 milligram per liter. Non-point source runoff accounted for the majority of bacteria in basin streams. Pharmaceutical and personal-care compound concentrations in water samples typically were less than 1 microgram per liter but mixture concentrations were frequently 30 to 50 times greater. More than 75 percent of samples analyzed had detections of the antimicrobial compound triclosan, the insect repellent DEET (n, n-diethyl-meta-toluamide), metabolites of detergent surfactants, caffeine, and the nicotine metabolite cotinine. More than one-half of stream samples had detections of pharmaceutical compounds; however, over-the-counter drugs accounted for more than 90 percent of the total mass of pharmaceuticals measured.

In effluent-dominated reaches, increased caffeine and cholesterol plus coprostanol contributions to streams occurred during the winter when colder temperatures may have reduced wastewater removal rates; constituent contribution declines coincided with increased summer temperatures. For stream reaches that received only combined sewer overflows, seasonal load patterns more closely followed seasonal precipitation patterns because overflows were controlled by rainfall events. One exception was DEET, for which June to August accounted for the largest percentage of seasonal contributions at all sites.

Biogeochemical processes in bottom sediments reduced some constituent concentrations by approximately two-thirds during a 6 to 8-month period. Bioassessments, indicated substantial declines in macroinvertebrate communities along an urbanization gradient. Declines correlated with increased upstream urban land-use and increased concentrations of anthropogenic compounds at stream sites.

Introduction

Stream-water quality in the Blue River Basin is influenced by a variety of factors including urbanization, point and non-point source pollution, physical stream conditions, and complex water-quality processes. The Blue River Basin encompasses 280 square miles and roughly one-half of the Kansas City metropolitan area. Fifty-four percent of the basin is located in Kansas and 46 percent is located in Missouri. The U.S. Geological Survey (USGS), in cooperation with the City of Kansas City, Missouri, Water Services Department collected water-quality data from 1998 through 2007 to provide an assessment of the chemical, bacteriological, and biological conditions of basin streams, identify sources of selected constituents, and provide an understanding of factors affecting water quality.

Kansas City, Missouri, is 1 of approximately 750 municipalities in the United States with a combined sewer system. Such systems carry sanitary wastewater and stormwater runoff and function differently during dry and wet weather conditions. In dry weather, combined systems convey sewage from homes, businesses, and industry to a wastewater-treatment plant (WWTP). After treatment, the water is discharged to a receiving stream in accordance with applicable water-quality standards. During wet weather, runoff from streets, rooftops, parking lots, and lawns enters the combined system and is delivered to the WWTP for treatment and discharge. However, if runoff and sewage volumes exceed the pipe or treatment plant capacity then excess flow (a mixture of stormwater and untreated sewage) is diverted and discharged to receiving streams, events referred to as combined sewer overflows (CSOs). Roughly ninety percent of the CSO outfall points in Kansas City, Missouri, are located within the Blue River Basin.

Communities with combined sewer systems are required under federal and state regulations to develop a plan to control overflows and to monitor their impacts on receiving waters. Control plans include analysis of current water-quality conditions based on a watershed perspective and characterization of other pollutant sources that might inhibit the attainment of applicable water-quality standards (U.S. Environmental Protection Agency, 1999). To support development of a control plan and to understand the effects of wastewater on urban receiving streams, laboratory and hydrologic analysis of stream samples from the Blue River Basin collected during base flow (defined as streamflow unaffected by storm runoff) and stormflow events included physical properties, nutrients, selected organic wastewater compounds (OWCs), selected prescription and over-the-counter pharmaceutical compounds, *Escherichia coli* (*E. coli)* and fecal coliform bacteria, and benthic macroinvertebrates (fig. 1). Selected base-flow *E. coli* samples were analyzed for host-source using genotypic, geographic-specific, library-based methods (Dombek and others, 2000; Carson and others, 2003). Vertical water-quality profiles were determined for selected impounded reaches of Brush Creek.

Sample locations were determined based on a variety of factors including proximity to tributaries, the combined sewer system area, and WWTPs (fig. 1). Six sites on the main stem of the Blue River (sites 1, 2, 7, 8, 13, and 14), four sites on the tributary Brush Creek (sites 9 to 12), and three sites on the tributary Indian Creek (sites 3, 4, and 6) were sampled. Two stream sites, one in the basin (site 5, Tomahawk Creek) and one

outside of the basin (site 19, South Grand River) were sampled as controls for aquatic-biota measurements. Data from three WWTPs (sites 15 to 17) that discharge in the basin also were analyzed.

Major Factors Affecting Stream-Water Quality

The combination of numerous over-lapping, urban-related factors has adversely affected on water quality and the ecological condition of several stream reaches in the Blue River Basin. Urbanization and flood-control projects have resulted in substantial loss of riparian vegetation, degraded stream habitat through stream channelization and stream-bank armoring, and resulted in extensive loss of native pool and riffle sequences, and altered flow regimes. Urban nonpoint-source runoff contributed a substantial part of the contaminant load in the basin. In areas served by a combined sewer system and WWTPs, discharges of treated and untreated wastewater additionally contributed nutrients, OWCs, and pharmaceuticals to streams. Nutrient enrichment was common at many stream sites with concentrations greater than expected background, non-urban concentrations (Smith and others, 2003). Deleterious water-quality effects were most pronounced in lower Indian Creek (below site 4), the lower and middle reaches of the Blue River (below site 7), and lower Brush Creek (below site 11).

Although there was some daily and seasonal variability, WWTPs provided the dominant source of streamflow, nutrients, and OWCs and pharmaceutical compounds to the middle and lower Indian Creek and the Blue River during base flow. Downstream of WWTPs, effluent can comprise greater than 95 percent of base flow. Only a small part of effluent nutrients were removed by in-stream nutrient assimilation and transformation processes an indication that such contributions frequently exceed the ecological assimilation capacity of many reaches. During storms, the predominant source of nutrients shifted from point sources to non-point sources. Examples of nonpoint sources that may contribute nutrients to streams include runoff from fields, parks, golf courses, lawns, impervious surfaces, storm sewers, compromised sewer lines, and ground- and surface-water interactions with these sources. As flows increased, the concentration of dissolved nutrients declined (figs. 2a and 2b) while concentrations of suspended nutrients, sediment and fecal-indicator bacteria increased (fig. 2c-2f). Suspended sediment and fecal-indicator bacteria loads (concentration times flow) increased substantially over those measured in base-flow samples at all stream sites.

In Brush Creek, wet weather events provided the dominant source of nutrients. Storm-event nutrient loads, a combination of non-point and CSO sources, were 200 to 300 times greater than base flow loads. Because of hydrologic alterations to Brush Creek, particulate nutrients were trapped in impounded reaches - a process that facilitated algal growth and eutrophication in these reaches.

Nutrients

Total nitrogen and total phosphorus loads and yields (load divided by drainage area) were estimated at four basin sites to allow comparison between sites and to those estimated at sites outside of the basin (fig. 3). Approximately 60 percent of the total nitrogen and total phosphorus in the middle and lower Blue River originated from Indian Creek, smaller amounts from the upper Blue River (from 16 to 28 percent), and less than 5 percent from Brush Creek. Nutrient yields from the lower Indian Creek (site 6) and the middle Blue River (site 7) were significantly greater than yields from the upper Blue River (site 2), lower Brush Creek (site 11) and sites outside the basin (fig. 4). Total

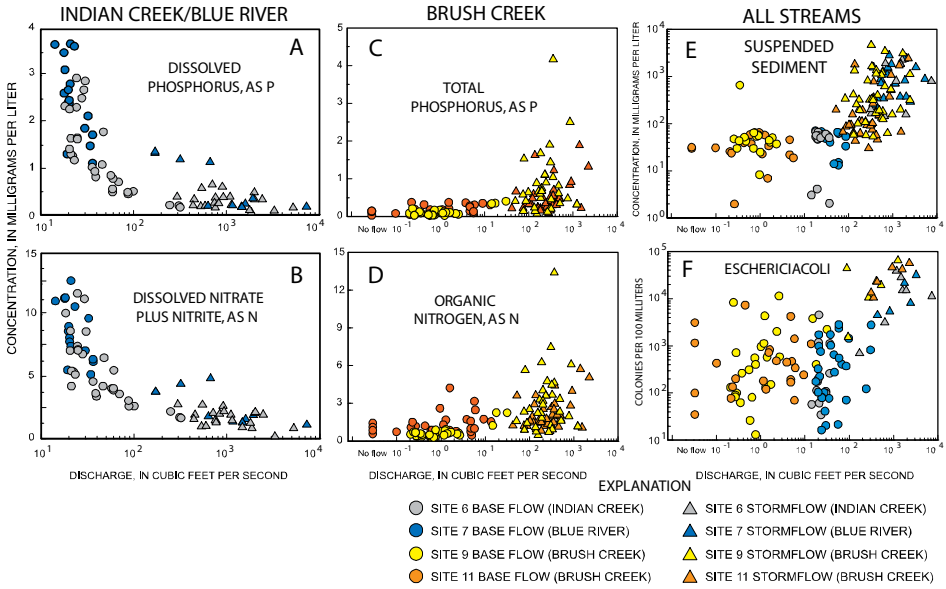

Figure 2. Concentrations of selected water-quality constituents in relation to discharge.

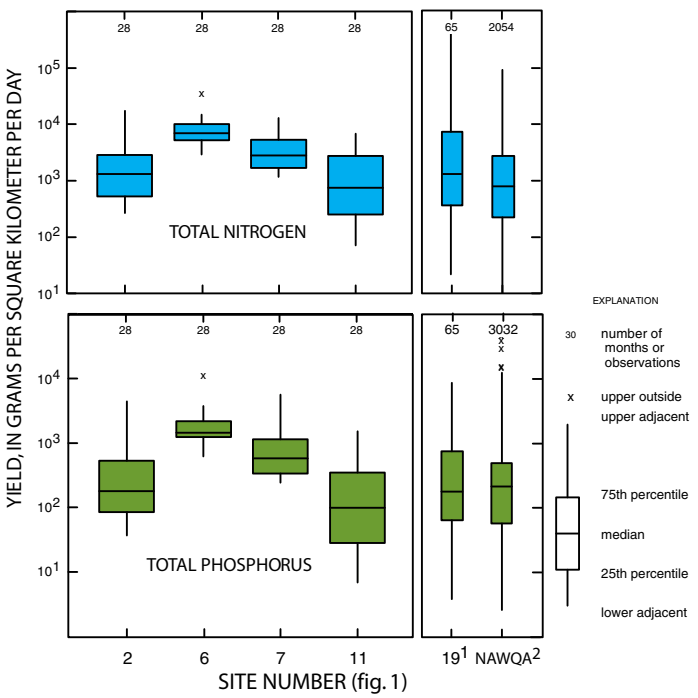

Figure 3. Estimated total nitrogen and total phosphorus yields at sites in the Blue River Basin for the period July 2002 through September 2004, left panels, and yields estimated at sites outside the basin, right panels. [NAWQA, data from 13 urban National Water-Quality Assessment sites (U. S. Geological Survey, 2005]. [1]Upper detached values not plotted. [2]Upper detached, lower outside, and lower detached values not plotted.

nitrogen and total phosphorus yields from the upper Blue River and lower Brush Creek were not significantly different from one another.

Organic wastewater and pharmaceutical compounds

Organic wastewater compounds analyzed included a suite of organic chemicals common to household, industrial, and personal care products, including, but not limited to, detergent by-products, disinfectants, antimicrobials, plasticizers, musk, and fragrance compounds. Pharmaceutical compounds included analgesics (acetaminophen and ibuprofen), an anti-convulsant (carbemazepine), antibiotics (sulfamethoxazole and trimethoprim), cardiac and anti-clotting medications (dehydronifedipine, diltiazem, and warfarin), a cholesterol-regulator (gemfibrozil), a narcotic (codeine), and stimulants (caffeine and cotinine, a metabolite of nicotine).

At sites on Indian Creek and the Blue River, organic wastewater and pharmaceutical compounds were largely attributable to WWTP discharges during base flow (figs. 4 and 5). Two classes of OWCs, defined operationally as detergents (consisting of surfactants and by-products) and sterols (consisting of plant and animal sources such as cholesterol and coprostanol) comprised the majority of OWCs. Over-the-counter medications constituted the bulk of the pharmaceuticals. Concentrations of most OWCs and pharmaceuticals declined in stormflow samples except for two classes of OWCs—pesticides and residues from hydrocarbon combustion and petroleum products — which increased during storms indicating significant non-point source contributions of these compounds during runoff events.

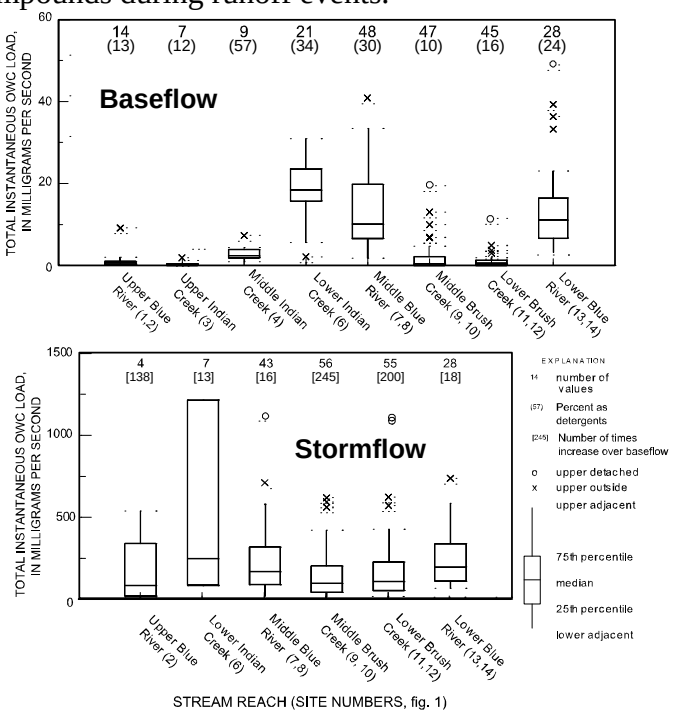

Figure 4. Total instantaneous organic wastewater compound (OWC) load by stream reach in samples collected between August 1998 and September 2004.

On Brush Creek, sources of OWCs and pharmaceuticals were largely attributable to a combination of wet-weather nonpoint and CSO sources as evidenced by general increases in contaminant concentrations with flow. Increased OWC concentrations and streamflow resulted in OWC storm loads several orders of magnitude greater than in base flows (fig. 4). Frequent detections of wastewater compounds at site 9 (upstream from most CSOs) during base flow and stormflows indicated that other factors may be as important as CSOs in the occurrence of these compounds in Brush Creek.

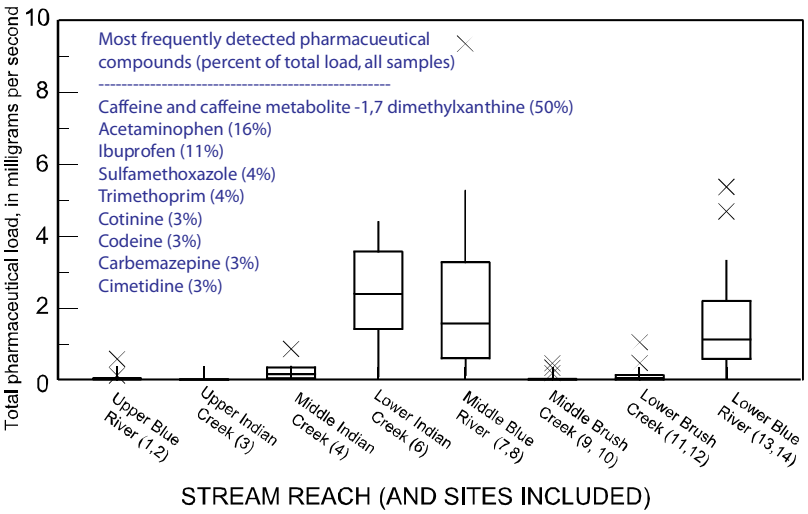

Figure 5. Total pharmaceutical load in baseflow stream samples collected between May 1999 and June 2004, most frequently detected compounds, and percent of total load.

Organic wastewater and pharmaceutical compounds

Organic wastewater compounds analyzed included a suite of organic chemicals common to household, industrial, and personal care products, including, but not limited to, detergent by-products, disinfectants, antimicrobials, plasticizers, musk, and fragrance compounds. Pharmaceutical compounds included analgesics (acetaminophen and ibuprofen), an anti-convulsant (carbemazepine), antibiotics (sulfamethoxazole and trimethoprim), cardiac and anti-clotting medications (dehydronifedipine, diltiazem, and warfarin), a cholesterol-regulator (gemfibrozil), a narcotic (codeine), and stimulants (caffeine and cotinine, a metabolite of nicotine).

Two classes of OWCs, defined operationally as detergents (consisting of surfactants and by-products) and sterols (consisting of plant and animal sources such as cholesterol and coprostanol) comprised the majority of OWCs. Over-the-counter medications constituted the bulk of the pharmaceuticals. Concentrations of most OWCs and pharmaceuticals declined in stormflow samples except for two classes of

OWCs—pesticides and residues from hydrocarbon combustion and petroleum products — which increased during storms indicating significant non-point source contributions of these compounds during runoff events.

On Brush Creek, sources of OWCs and pharmaceuticals were largely attributable to a combination of wet-weather nonpoint and CSO sources as evidenced by general increases in contaminant concentrations with flow. Increased OWC concentrations and streamflow resulted in OWC storm loads several orders of magnitude greater than in base flows (fig. 4). Frequent detections of wastewater compounds at site 9 (upstream from most CSOs) during base flow and stormflows indicated that other factors may be as important as CSOs in the occurrence of these compounds in Brush Creek.

Macroinvertebrate Community Assessment

The diversity and abundance of stream fauna measured at upper Blue River sites (sites 1 and 2) consistently scored at, or above, the control site (site 19) indicating that stream-water quality was sufficient to support a diverse biological component in the upper Blue River (fig. 6). Aquatic community integrity declined downstream in the basin in response to increases in several inter-related urbanization factors including declines in vegetative cover, increases in percent impervious cover, increased nutrient enrichment, and increased wastewater inputs.

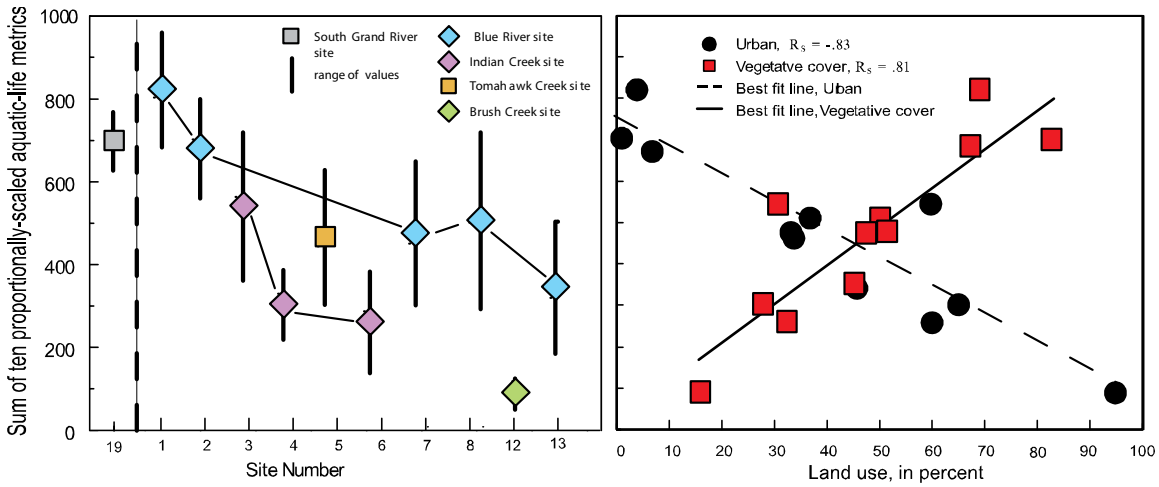

Figure 6. Sum of ten proportionally-scaled aquatic-life metrics by site (left panel) and relation between proportional metric score and the percent of vegetative cover and urban land use at sites (right panel) [Rs, Spearman's correlation coefficient].

Abstract

Water quality impairments remain a pressing concern in the United States. Selecting appropriate management actions (i.e., best management practices) to improve water quality involves tradeoffs between cost and effectiveness, both of which are prone to uncertainty. In addition, significant uncertainties exist in the scientific understanding of the natural system. To address these concerns, we have developed a framework to identify the optimal set of actions to reduce turbidity and sedimentation in the Minnesota River Basin, while explicitly incorporating uncertainty. The framework combines Bayesian inference with multiobjective programming models to select the optimal combination of research actions, which improve our understanding of the natural system, and management actions, which reduce sediment contributions to the river basin. We also evaluate the value of information of each research action, to identify where further study is warranted. Our results communicate the general nature of the tradeoffs and complex interactions among sediment loadings, best management practices, and the possible research projects. More important, our results indicate that explicit consideration of uncertainty can lead to improved selection of management actions that most accurately address the complexity of the problem.

Problem Background

Despite the passage of the Clean Water Act amendments to the Federal Water Pollution Control Act in 1977, many river basins throughout the United States are still impaired, meaning that they do not meet state or federal water quality standards. According to the Environmental Protection Agency, as of the year 2000, "39% of assessed stream miles, 45% of assessed lake acres, and 51% of assessed estuary acres are impaired (US Environmental Protection Agency 2003)". Impairments are due to primarily to nonpoint source pollution, with nearly 48% of the impacts on impaired rivers and streams due to agricultural activities (US Environmental Protection Agency 2003).

The Minnesota River frequently violates federal or state water quality standards for a variety of pollutants including nutrients and turbidity (Mallawatantri 1999). In 2001, the Minnesota Pollution Control Agency published the Minnesota River Basin Plan (Minnesota Pollution Control Agency 2001), which described the state of the river basin and identified priorities for addressing water quality impairments. The plan described a basin management approach that addressed water pollutants by aiming to achieve environmental objectives using an integrated management approach to address both point and non-point sources of pollution while encouraging the involvement of stakeholders.

One focus of the Minnesota River Basin Plan is to reduce sediment loading from nonpoint sources to the Minnesota River, its tributaries, and Lake Pepin. Runoff from

agricultural lands is likely to be a major cause of sediment and water quality impairments. Additionally, stream bank and bed erosion may contribute significantly. The sedimentation of waterways in the Minnesota Basin causes significant problems. Turbidity limits light penetration, causing changes in primary production. Conditions for primary producers can shift from nutrient-limited to light-limited, ultimately affecting dissolved oxygen and stream metabolism. Excess sediment can lead to habitat loss, changes in predation success, and alteration of food web dynamics. Additionally, the amount of sediment originating from each source is highly uncertain.

Sediment reduction in the Minnesota River Basin is addressed here using an efficient framework that considers uncertainty in the system and the benefits of information acquisition. A potentially useful way to address the sedimentation problems in the Minnesota River is to use a systems approach. The uncertainty-based methodology developed here combines a Bayesian approach with a multiobjective programming to select the optimal suite of information acquisition and management actions.

Previous research regarding sediment reduction began with deterministic optimization approaches to nonpoint source pollution reduction dating back to the 1970s. That research aimed to determine the effects of different soil erosion control policies on the agricultural industry. Seitz et al (1979) summarized several studies that maximize social welfare subject to constraints on resources, consumer demand, soil loss, sediment transport and environmental standards. The decision variables described the crop rotation, tillage, and conservation practices needed to meet different policy requirements. The problems were modeled as deterministic linear programs. Sediment transport was described by fixed transport coefficients with constant sediment delivery ratios describing the amount of sediment reaching a targeted area. No uncertainties were considered.

Kramer et al. (1984)also developed a linear program (LP) to evaluate agricultural policies for reducing nonpoint pollution. Their model, like the one I propose, included BMPs not tied to specific agricultural activities, such as grass waterways. Braden et al. (1989)improved on the models described by Seitz et al. (1979)by incorporating spatial sediment movement functions that allow variable sediment delivery ratios. The problem was solved using a dynamic programming nonlinear model. Bouzaher et al. (1990)also developed a dynamic programming model. Their model minimized the cost of achieving a sediment standard by identifying the best set of management alternatives for each sediment delivery path.

Schleich and White (1997) developed an LP that minimizes total phosphorus reduction costs such that a target total phosphorus standard is met. Veith et al. (2003)developed a deterministic integer-programming model for locating BMPs at the watershed level. A genetic algorithm was combined with a geographic information system to determine the most cost effective placement of BMPs. Gitau et al. (2004)built upon the work by Veith et al. (2003)and also determined optimal BMP placement using a genetic algorithm.

Deterministic models described above assume that loadings and control effectiveness are known with certainty. However, the actual values are highly uncertain and even

controversial, as in the Minnesota basin. To address these uncertainties, several stochastic programming models have been developed to address sediment reduction. Chance constrained programming models were developed by several authors. Milon (1987) and Zhu et al. (1994)maximized net economic returns to landowners subject to constraints requiring environmental standards be met with certain user specified frequencies. The loadings of pollutants (Milon 1987) or soil loss (Zhu et al. 1994) to receiving waters were assumed to be uncertain due to variability in precipitation. Kampas and White (2003) and Lacroix et al.(2005) combined chance constrained programming models with simulation models to addressing nonpoint source pollution. Instead of chance constrained programming, Luo et al. (2006) developed an interval two-stage stochastic program that minimized total system costs by choosing cropland to retire.

Yulianti et al.(1999), on the other hand, considered the effects of uncertainty in input parameters to a simulation/optimization model for selecting agricultural management actions to control sediment transported to surface waters. The authors considered two uncertain inputs – uncertainty in soil and land characteristics due to insufficient data, and uncertainty in meteorological and cost data that is inherently variable. Monte Carlo simulation, generalized sensitivity analysis and regret analysis were used to determine management practices that were most and least sensitive to uncertainties considered. Nicklow and Muleta (2001) addressed sediment reduction using a discrete-time optimal control framework. The research determined farm management decisions over a three-year period. Uncertain sediment yield over the time period was simulated and a genetic algorithm was used to determine the set of land cover and tillage practices that result in the minimum sediment yield from the watershed.

Both Farzin and Kaplin (1998) and Borisova et al. (2005)considered the value of information with regards to sediment loading. Farzin and Kaplin (1998) developed a method for addressing uncertainty in site-specific characteristics of pollution sources. A nonlinear model was developed to minimize the cost of environmental damages subject to a budget constraint. The manager must determine the frequency with which to collect data on sediment loading and stream flow, as well as the abatement effort at each source. The data is used to update the manager's prior probability of sediment loading using a Bayesian approach. The authors also consider the expected value of perfect information (EVPI). The value of perfect information is defined as the difference in environmental damages incurred if the manager knows the future stream flows with certainty and if the manager is uniformed.

Similarly, Borisova et al. (2005) calculated the EVPI of various types of information for reducing nitrogen loads from agricultural land to the Chesapeake Bay. The objective was to maximize net benefits of pollution control subject to a variety of policy constraints. A simulation model, composed of an economic agricultural production submodel and a physical submodel, considered three sources of uncertainty: 1) uncertainty about economic costs of changes in agricultural production to reduce nitrogen loads; 2) uncertainties in nitrogen loads due to changes in agricultural practices; and 3) uncertainty in economic benefits from nitrogen load reductions. Both quantity and price control policies were examined.

The research proposed here is most closely related to the research by Farzin and Kaplin (1998)and Borisova et al.(2005). The impacts of uncertainty in sediment load are explicitly considered and the benefits from considering this uncertainty are calculated. However, the research here considers different types of actions for reducing uncertainty regarding sediment loads and combines this information with an optimization program to choose among management actions to reduce sediment loadings. In contrast to previous work, the management actions considered here include actions aimed at stream restoration, not only agricultural BMPs.

Methodology

To determine the optimal set of information acquisition and management actions for controlling sediment loadings in the Minnesota River Basin, we develop a framework combining Bayesian analysis with multiobjective programming. Sediment loadings from each source in each watershed are highly uncertain. To improve our understanding of these loadings, information acquisition or research actions can be performed. Each action has an associated likelihood function that describes the probability of observing a particular research outcome given the true, though unknown, sediment loadings. Starting with a prior joint probability of the sediment loadings from each sediment source in each watershed, Bayes' law is used to combine this prior information with the likelihood function to determine the information acquired from each research action. The application of Bayes' law produces a posterior distribution of sediment loadings. The mean values from the posterior distribution are then input into a multiobjective linear program that determines the optimal set of BMPs that minimizes the expected cost and expected sediment remaining. The framework produces a tradeoff curve describing the non-inferior set of research and management actions that achieve the cost and sediment reduction objectives.

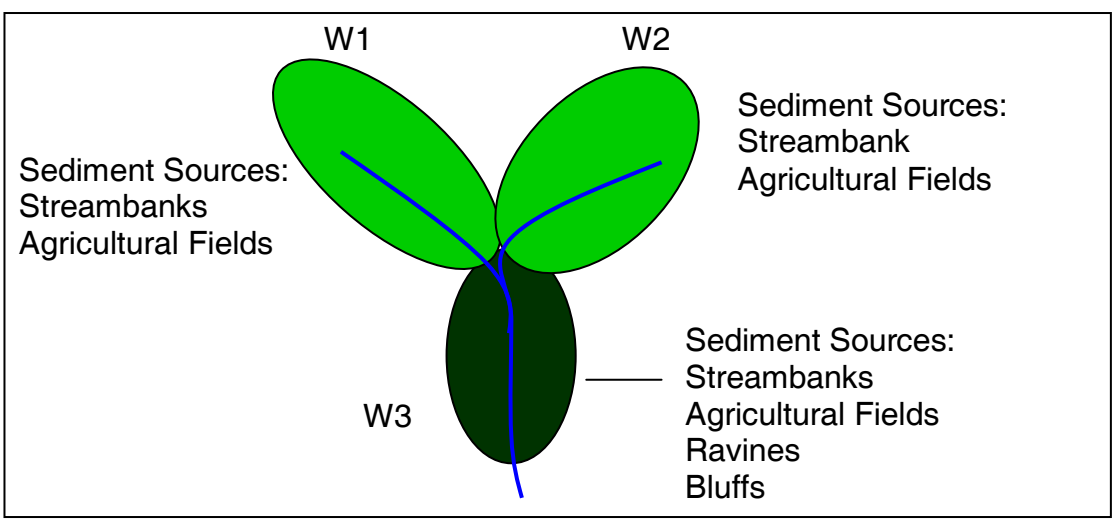

Figure 1: Three watershed model. Watersheds W1 & W2 are upstream of watershed W3

The framework is applied to a three watershed model, representative of the Maple River watershed within the Minnesota River Basin (Figure 1). Watersheds W1 and W2 drain into watershed W3. The upper two watersheds have two major sources of sediment:

streambank and agricultural fields, and the lower watershed has four sources: streambanks, fields, ravines and bluffs.

The framework for selecting information acquisition and management actions is summarized in Figure 2. Before any information acquisition action is chosen, a prior joint probability of the sediment loadings from each source in each watershed is determined by conversations with experts. The eight sediment loadings displayed in Figure 1 are assumed to follow a joint log-normal prior distribution.

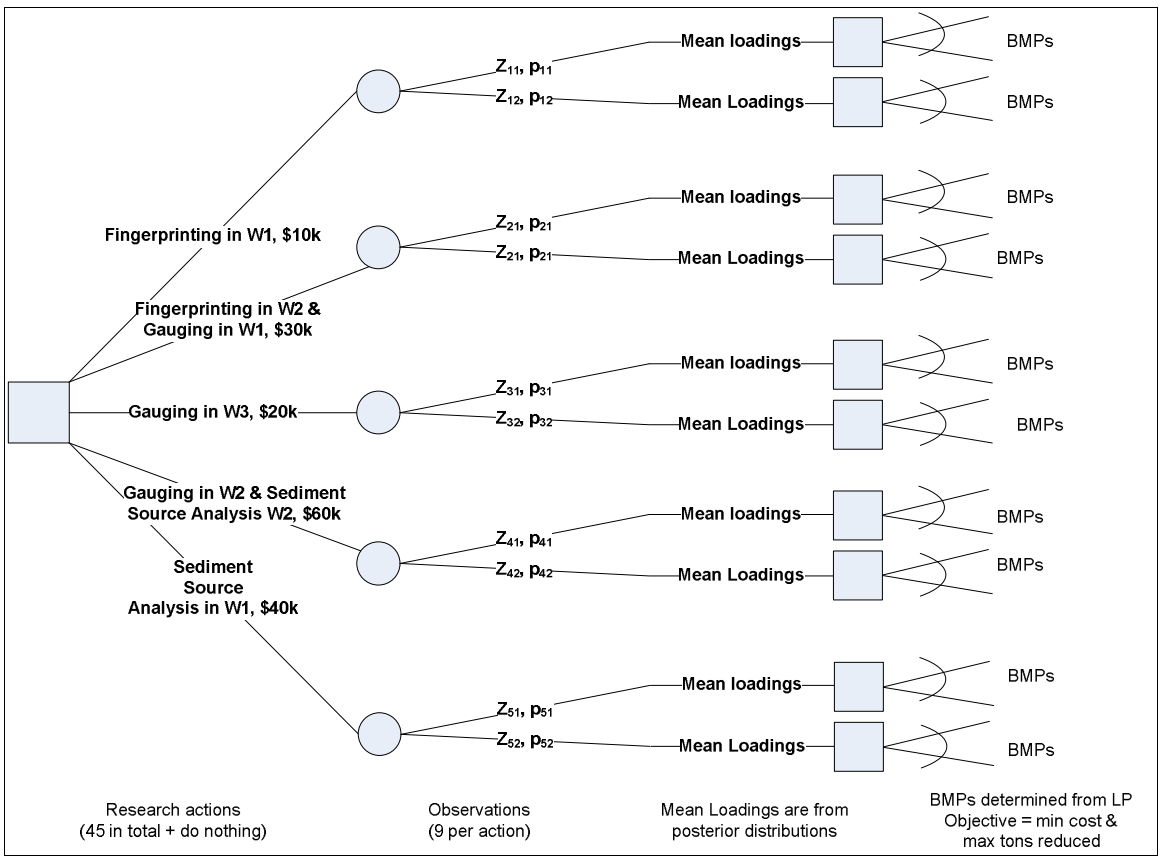

Figure 2: Decision Framework

For each watershed, three information acquisition actions can be performed: gauging, sediment fingerprinting or a sediment source analysis. Gauging involves using stream gauges to determine the total annual average sediment loading at the outlet of the watershed. Sediment fingerprinting involves using atmospherically deposited radionuclides as tracers for sediment sources. The approach determines the annual average ratio of sediment from agricultural fields to all other sediment sources. The sediment source analysis action is similar to a full sediment budget, but excludes the use of gauging data. This action produces estimates of the loading from each source in each watershed. In total, 46 actions are considered, with a limit of at most two concurrent actions. This limit was chosen to allow for a manageable number of information acquisition actions to illustrate the framework. Figure 2 shows a sampling of only five of the 46 possible actions, in order to keep the figure readable.

For each information acquisition action, nine possible observations are considered. Figure 2 displays a sampling of two of the nine observations for each action, to allow for readability. Each observation is written as Z_{ij}, where i is the action number (i = 1, 2,…,46) and j is the observation number (j=1,2,…,9). The probability associated with each of the observations is written as p_{ij}. The likelihood function for each research action is assumed to be log-normal.

For each of the 45 research actions and nine observations, a posterior distribution was generated using WinBUGS (Lunn et al. 2000) with two Markov chains. The results of this Bayesian analysis will then used to choose among management actions using a linear multiobjective program for each of the resulting posterior distributions. The linear program seeks the set of management actions that minimize cost and maximize sediment reduction. The set of selected actions are subject to the constraint that the area placed under each management action cannot exceed the area available for that action. The linear multiobjective program is run multiple times using different objective function weights, producing a tradeoff curve.

The management actions under consideration address all sources of sediment. In particular, for each sediment source (fields, streambanks, ravines and bluffs), three different BMPs will be considered. Field BMPs under consideration are critical area planting, filter strips and conservation tillage. Critical area planting addresses areas of high erosion and involves establishing permanent vegetation, such as perennial grasses, perennial legumes, trees, shrubs, vines or mixture on these sites (USDA NRCS 2009). Filter strips are areas of "herbaceous vegetation situated between cropland, grazing land, or disturbed land (including forestland) and environmentally sensitive areas (USDA NRCS 2006a)." Conservation tillage is an agricultural practice that manages the "the amount, orientation, and distribution of crop and other plant residue on the soil surface year round while limiting soil-disturbing activities to only those necessary to place nutrients, condition residue, and plant crops (USDA NRCS 2006b)."

The three BMPs being considered for stream restoration include streambank and Shoreline protection, stream barbs and rock riprap. Streambank and shoreline protection involves stabilizing and protecting stream banks or shorelines using treatments such as redirecting stream flows, reshaping slopes, and vegetation of streambanks (USDA NRCS 2009). Stream barbs are used to redirect streamflow away from an eroding bank and are defined by NRCS as "low rock sills which project out from a streambank and across the stream's thalweg (USDA NRCS 1999)." Rock riprap involves installing a blanket of graded rocks on a streambank in order to protect the slope by reducing erosion (USDA NRCS 2009).

To reduce erosion from ravines, three BMPs are under consideration: water and sediment control basins, grade stabilization structures, and tile drainage pipes. Water and sediment control structures are earthen embankments that are installed to form a sediment trap (USDA NRCS 2009). A grade stabilization structure is used to grade back the slope of a ravine and often involves the placement of a retaining wall and drainage pipes. Tile

drainage pipes are laid along the bottom of the ravine to direct the flow from the ravine to the stream channel, thus reducing erosion along the bottom of the ravine.

Lastly, the three BMPs under consideration for address soil loss from bluffs are stream barbs, rock riprap and complete stabilization of the bluff.

Preliminary Results and Future Work

At this time, the Bayesian analysis component of the framework has been completed. Figure 3 shows the prior marginal distributions and posterior marginal distributions for one observation from a sediment source analysis in watershed W3, as an example. The prior distribution is shown in blue and the posterior distribution is shown in red and green, one of each chain.

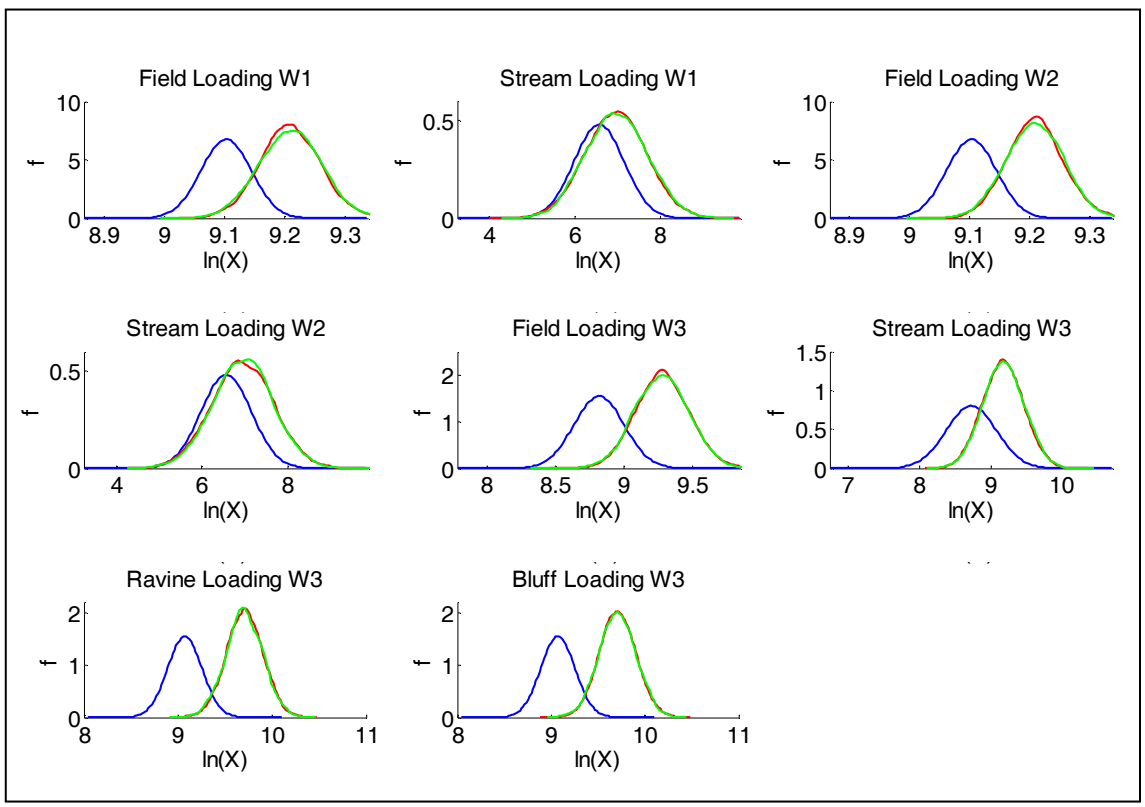

Figure 3: Prior (Blue) and Posterior (Red & Green) Marginal Distributions

The remaining work involves running multiobjective linear programs using the mean posterior loadings as inputs. The results of the linear programs will indicate the non-inferior set of management actions that simultaneously minimize cost and maximize sediment reduction. These results will then be weighted based on the probability of the research observation leading to the posterior sediment loading. Thus, an overall tradeoff curve will be created relating expect cost minimization to expected sediment reduction. In addition, a value of information analysis will also be completed to determine the value of each research action.

Abstract

A watershed can be considered a multi-agent system (MAS) composed of water users (agents) spatially distributed in a distinct manner within a common defined environment from which they can all access a particular resource. The watershed system is characterized by distributed decision processes at the agent level and a coordination mechanism organizing the interactions among individual decision processes. This paper presents a decentralized optimization method known as constraint-based reasoning, which allows individual agents in a multi-agent system to optimize their behaviors. The method incorporates the optimization of all agents' objectives through a bargaining scheme, in which the i^{th} agent optimizes its objective with a selected priority for collaboration and sends the solution back to all agents that interact with it. This methodology allows agents to determine how important their own objectives are in comparison to the constraints, using a *local interest factor* (β_i). A large β_i value indicates a selfish agent who puts high priority on its own local benefit and ignores constraints. This analysis is applied to a hypothetical watershed with three offstream human agents (city and farms), one instream human agent (reservoir) and two ecological agents (fish habitat in the river). The proposed approach takes the objectives of individual agents into account and balances them through interactions among the agents. This bottom-up problem-solving approach mimics real-world watershed management problems better than conventional "top-down" optimization methods in which it is assumed that individual agents will completely comply with any recommendations that the coordinator makes.

Keywords: Multi-agent systems, watershed management, ecohydrology, penalty-based methods, decentralized optimization

Introduction

Watershed systems consist of many interdependent water users (Loucks, 2003) and each one of them will have their own decision process. Traditional water resources management practice usually fragmented by production sectors without holistic resource allocation procedures and divided among land and water management. These practices tend to focus on human needs without sufficient consideration of ecosystem requirements. Sustainable watershed management needs a comprehensive approach and treats watersheds as coupled human-nature systems (Liu et al., 2007). Specific concerns for watershed management should include the balance of human needs which are offstream, with instream environmental needs. Moreover, management of the coupled human-nature system requires the participation of local stakeholders. Therefore, facilitating the transfer of modeling technology to provide information to stakeholders and managers is requested by government agencies (EPA, 1996; NRC, 1999). The stakeholders' participation can transition the traditional top-down management of water resources to bottom-up management (Parker and Tsur, 1997; NRC, 1999).

Conventional watershed management models use a centralized approach to explore the system-wide optimal solution, assuming that (1) there is a top-down management process in

which all watershed stakeholders completely obey a "super brain," such as watershed management coordinator, (2) complete information exchange exists among the stakeholders in different locations and production sectors and (3) perfect economic efficiency is realized, i.e., the marginal welfare of water use is identical for all agents. These assumptions are usually unrealistic in real-world watershed management situations. This paper presents a decentralized modeling approach, which is at least partially free of those assumptions.

New modeling techniques for watershed management have been postulated (Wolf, 2007). The theory of MAS has emerged from the field of distributed artificial intelligence (Sycara, 1998). Under the definition of MAS, an agent is an object that interacts with others and its environment, and the interactions are characterized by behavioral rules of individual agents. Several characteristics define agents: They are autonomous, (i.e., they have control over their actions), they have different and possibly conflicting goals, they share a common environment, and they each make decisions that impact the common environment (Dooley and Corman, 2002).

In this study, we examine the application of a MAS model to a watershed, which can be naturally described as an MAS. Agents in a watershed MAS include offstream land and water user and instream or in-situ water "users," such as riparian aquatic ecosystems. The environment of the MAS is composed of static geomorphologic features (e.g., the natural drainage network) and temporally dynamic attributes such as flow regimes and water quality. Advances in water-related disciplines, including hydrology, ecology, biology and economics have paved the way for modeling the environment of watersheds. In the MAS framework, agents are defined as autonomous computational units. Stakeholder participation associates the computational units with human agents (Drougoul et al. 2003), including land owners and representatives for land and water use agents. Reservoir managers are considered as instream human agents, and government or citizen organizations as ecosystem agents. In this context, a watershed is characterized by disaggregated but interactive decision processes at the agent level, and with a coordination mechanism among individual decision processes.

MAS are increasingly used in the field of environmental and natural resource management issues (Barreteau et al, 2004; Chen et al., 2008), such as ecological modeling (Bousquet and Le Page, 2004), basin land use management (Parker et al., 2003; Jaziri and Paquet, 2006), and urban catchment problems (Pahl-Wostl, 2005). Some researchers have recently begun to use MAS on water resource planning and management issues. It is widely accepted that water resource management demands an integrated assessment of resource use options, including local and regional impacts on the environment and stakeholders (Loucks et al., 2005**;** Croke et al, 2007). MAS can be a suitable approach to dealing the water resource planning and management issue.

However, despite the existing applications of MAS models, mathematical formulation of the framework and development of solution algorithms remain a great challenge for specific MAS problems, including watershed management. This paper adapts a MAS model from decentralized control theory to analyze the water allocation among various water users. Offstream human agents, instream human agents, and ecosystem agents are defined in the spatial domain of a watershed. The behavior of each agent is assumed to be driven by an economic benefit objective. The focus of this paper is to model the interactions among agents and illustrate how the behaviors of individual agents affect the overall performance of the system. Indicators of system performance will be derived from agents' decisions and their consequences. In the rest

of this paper, the description of the methodology is first given, followed by the description and discussion of results and then, finally, conclusions.

Methodology

Penalty-based optimization methods (Luenberger, 1984) provide a convenient way to solve a decentralized problem such as MAS. A modified penalty-based decentralized method (İnalhan et al., 2002) is used in this study. Each agent has its own decision framework that captures only the local dynamics and the interconnecting constraints associated with these dynamics. The method achieves optimization among agents with a bargaining scheme, by which the i^{th} agent optimizes its objective with a selected priority for collaboration and sends the solution back to all other agents with which it interacts. All agents do this simultaneously, and their solutions are evaluated together by a "central processor," from which information, such as system cost and the degree of constraint violation, is sent back to agents for the next round of bargaining. The method is based on a formula that allows agents to deal with infeasible constraints that different subsystems impose. The idea of this method is not to directly seek the optimal solution of a formulated problem, but to use a two-step approach – first finding out a solution based on the choices of all individual agents, allowing the violation of some constraints defined with the optimization models for individual agents, and then trying to reduce the constraint violation at the system level. This follows the bottom-up problem-solving procedures, in which individual agents make decisions and interact with other agents and then the coordinator resolves conflicts by balancing the decisions of different agents.

The mathematical formulation of typical optimization problem is given as follows:

$$\max_{x_i} f_i(x_i) \tag{1}$$

$$subject\ \ to\ \ g_i(x_i|\{x_j\}_i)\begin{cases} g_{li}(x_i) \le 0 \\ g_{gi}(x_i|\{x_j\}_i) \le 0 \end{cases} \tag{2}$$

This optimization procedure has both local constraints $g_{li}(x_i)$ and interconnected constraints $g_{gi}(x_i|\{x_j\}_i)$. An interconnected constraint specifies that agent i receives the value of $\{x_j\}_i$ from agent j and needs to accept the value. Following İnalhan et al. (2002), the penalty-based objective function for agent i is:

$$\max F_i(x_i, \beta_i|\{x_j\}_i) = \max\{\beta_i \cdot f_i(x_i) - P_i(x_i|\{x_j\}_i)\}, \text{ for } \beta_i > 0 \tag{3}$$

where $\beta_i>0$ is a *local interest factor,* f_i is the original objective function, and P_i is the penalty function that penalizes any violation of the constraints in the formulation of equation (3). A larger β_i will result in a larger f_i. According to the proof by İnalhan et al. (2002), a larger β_i will also lead to a larger penalty item, P_i. This scheme allows each agent to use local β_i selection as a tool to search for a solution which increases local benefit (f_i) as much as possible while violating fewer constraints.

The first and second order conditions are used to solve this penalty-based mathematical problem as described in equation (3). The final differential equation for each agent is

$$\frac{\partial F_i}{\partial x_i} = \beta_i \frac{\partial f_i(x_i)}{\partial x_i} - \sum_{k=1}^{k_i} \frac{\partial g_{i,k}}{\partial x_i} \max(0, g_{i,k}(x_i|\{x_j\}_i)^{\gamma-1} \cdot \gamma = 0 \tag{4}$$

where $\gamma \geq 2$ is assumed to ensure the second order differentiability. The number of constraints corresponding to the i^{th} agent is k_i. The most important advantage of this solving process is that it allows each agent to use local β_i selection as a tool to search for a solution which violates fewer constraints while not resulting in the decrease of F_i.

This scheme allows the i^{th} agent to optimize equation (4) by using a local search for β_i. The result of i^{th} agent will then be sent to neighboring agents. The global performance of the entire system is treated as public information that is accessible to all agents. İnalhan et al. (2002) suggested that the sum of the objective function (F_{total}) and the total violation (P_{total}) could serve as a global performance metric since the selection of β_i gives each agent a tool with which to "bargain." With a large value of β_i, the solution ends with a better objective function [$f_i(x_i)$] but a larger constraint violation than it would with a small β_i.

Results

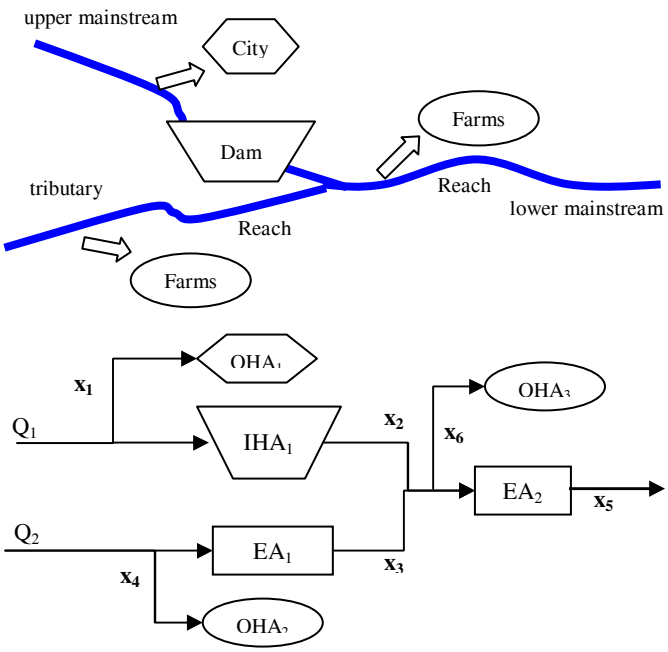

Fig 1. Hypothetical watershed for MAS framework

The MAS framework was applied to solve a hypothetical watershed as in Fig 1. Six agents are identified in this watershed. There are three offstream human agents, OHA_1 as the city, and OHA_2 and OHA_3 as the farms. The objectives of offstream human agents are consuming water to maximize their economic profits. The dam on the upper mainstream is defined as an instream human agent (IHA_1) with the objective to release water for hydropower generation. The general objective functions for OHAs and IHAs were obtained from the literature (Cai et al., 2003 and Loucks et al., 2005). The fish habitats located at the tributary and the lower mainstream are identified as ecosystem agents, EA_1 and EA_2, respectively. The objective functions of EAs can use the results Yang et al. (2008). An assumption is made here that the unit of EAs' objectives is the same with human agents which is the economic benefit. This assumption can make the following analysis easier and provides clearer demonstration of the emergence pattern due to agents' behaviors.

The quadratic objective function, the constraints and the parameters for OHA_1 are provided in Table 1 as an example. The decision models of all agents are inter-connected by the

Table 1. The objective function and constraints of OHA_1

$\max_{x1} f_1(x_1) = a_1 x_1^2 + b_1 x_1 + c_1$ st. $\begin{cases} \alpha_1 - x_1 \leq 0 \\ \alpha_2 - Q_1 + x_1 \leq 0 \end{cases}$	$f(x) = a_1 x^2 + b_1 x + c_1$: the benefit from municipal and industrial water use x_1: water withdraw for municipal water use Q_1: the monthly inflow of mainstream α_1: the minimum water demand for the city α_2: the minimum flow requirement for the dam

water sharing or the upstream – downstream relationships. When one agent seeks its optimal solution, it might violate the constraints with others. Both analytical and numerical results are presented for this hypothetical watershed management problem in the following section.

Penalty-based method is applied to solving the formulated MAS problem. The formulation of a penalty-based objective function and the effect of the local interest parameter (β_i) on the decisions of various agents are demonstrated by equation (5) and Fig 2. Equation (5) shows the penalty-based format of this individual agent's objection function and the value of β_1 indicates "how far" the agent can explore its solutions within the infeasible region (Fig 2).

$$F_1(x_1) = \max_{x_1} \left[\beta_1 \cdot f_1(x_1) - P_1(x_1)\right]$$
$$= \max_{x_1}\left\{\beta_1 \cdot (a_1 x_1^2 + b_1 x_1 + c_1) - [\max(\alpha_1 - x_1, 0)]^2 - [\max(\alpha_2 - Q_1 + x_1, 0)]^2\right\} \quad (5)$$

With a given value of β_1, OHA_1 will search local optimal solutions (x_1) result in maximum benefit ($f_1(x_1)$) inside and outside of the feasible region (gray area in Fig 2, which represent the solutions are $\alpha_1 \le x_1 \le Q_1-\alpha_2$) of the solution space (the entire x-axis). When β_1 is set at zero, all possible solutions (agent's decisions) will locate within the feasible region, if it exists. Under this situation, the violation of the constraints will be minimal (violation will be zero if the feasible region exists). When β_1 is greater than zero, agents may explore solutions in the infeasible region. The value of β_1 indicates how far the exploration can go in the whole solution space. When β_1 approaching infinity, OHA_1 can search the entire space and find the optimum solution without considering any interconnection constraints. In other words, the benefit of OHA_1 changes from point ***I*** to point ***II*** in Fig 2. However, since the optimum solution (point ***III*** in Fig 2) is in the infeasible region, the violation of the constraints caused by the solution may be large.

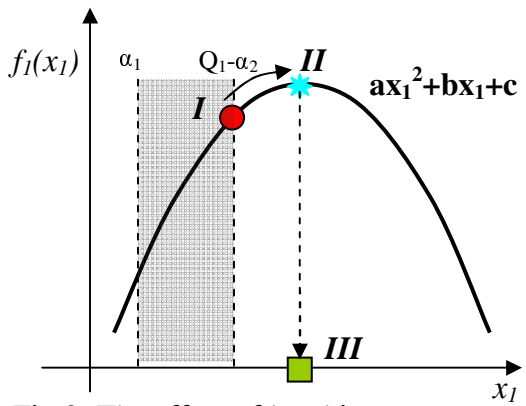

Fig 2. The effect of local interest parameter: β_i

The numerical results of agents' benefit at a given inflow condition are shown in Fig 3(a) for all active agent scenario and in Fig 3(b) for reactive ecosystem agent scenario. The β_i for all agents are set at the same value to simply the problem. In Fig 3(a), since all agents are active which means they all have the power to make their own decision, their benefit will all increase with increasing β_i. When β_i larger than "10" in this case, OHA_2 and OHA_3's benefit will become constant which means that they already achieve their local optimum just like point ***II*** in Fig 2. Fig 3 (b) shows the reactive ecosystem agent scenario, which means that ecosystem agents have no power to make any decision and they can only use the water after human agents' decision. This scenario is similar to the traditional watershed management. The results show that when β_i increases, the benefits for human agent will still increase. The benefits will increase to optimum value when β_i are larger than "10", which is consistent with all active agent scenario. Consequently, the benefits for the ecosystem agents (EA_1 and EA_2) decrease when OHAs withdraw more water from the river. Note that changing β_i has no effect on EAs since the benefits of EAs fully depend on the connected OHAs. These figures illustrate the decentralized results at agent level and also effect of β_i at a given fix flow condition.

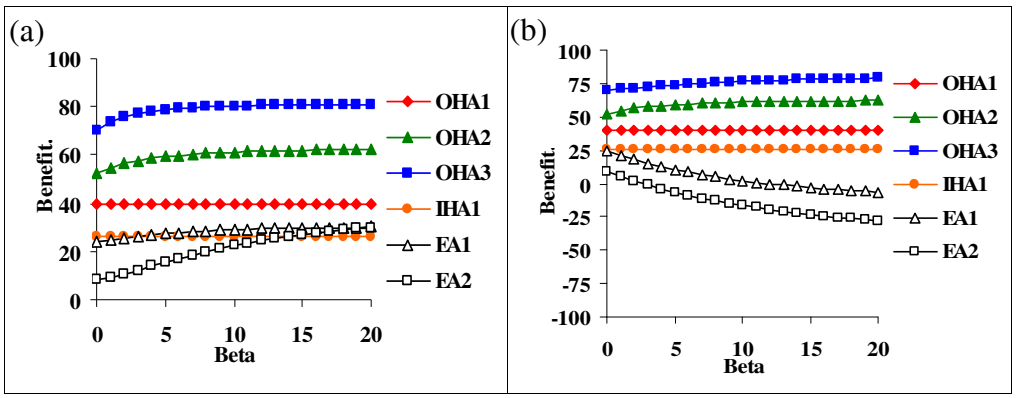

Fig 3. The numerical results of all agent s' benefit change with β_i

The results of Fig 3 can be summed together for the system benefit and we can also compute the system violation by aggregate agents' violation. Meanwhile, the results from different inflow conditions can be evaluated. The inflows are treated as available resource and the agent's behavior is represented by β_i. The concept of β_i can extend the conventional water management issue from a 2D (inflow and benefit) to a 3D (inflow, benefit and agents' behavior) problem. A 3-dimensional figure is given in Fig 4 shows the (a) system benefit (sum of all agents' benefits) and (b) system constraints violation (sum of all agents' violation) due to different agents' behavior (β_i) and available resources (inflow). Notice that the axis orders are different in Fig 4(a) and (b) to clearly show the shapes of two surfaces. The change of benefit with inflow is affected by the value of β_i (Fig 4a). When β_i=0 (the square-symbol line), the benefit increases with inflow, while the violation is zero when inflow is greater than 45 and increases when inflow decreases beyond 45 (Fig 4b). It can also be seen that when inflow is greater than 110 the change of β_i does not affect the benefit and violation, since all agents can achieve their local optimums.

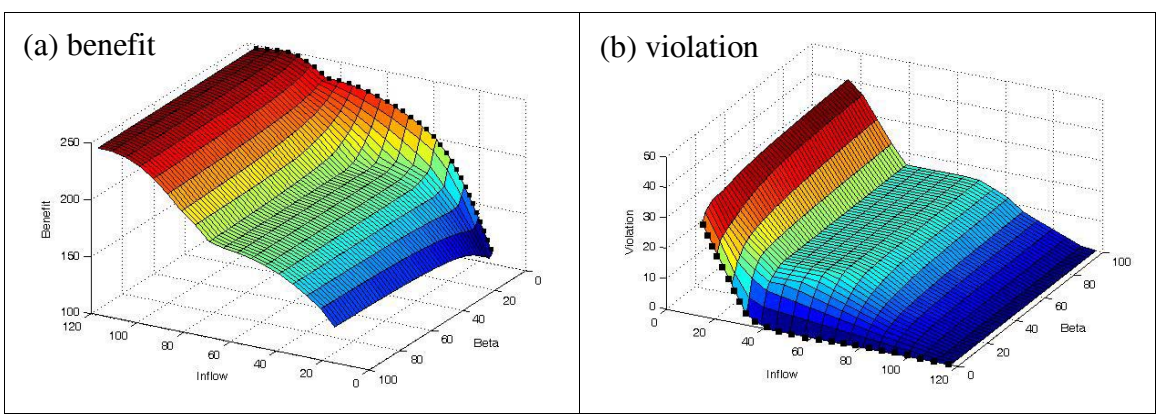

Fig 4. The crossover effect of local interest parameter: β_i and inflow.

Discussion and Conclusion

This study applied a penalty-based decentralized optimization algorithm to solving a watershed MAS problem. The demonstration on a hypothetical case study indicated that the concept of local interest parameter (β_i) can explicitly represent the water user's behavior in the management practice. The value of β_i and associated system violation can be useful in two aspects. First, water users can adjust their behavior (by changing β_i values) to achieve a minimum system violation while maintaining the optimum for system benefit. An ideal situation

is that different values of β_i are identified for different agents so that the system violation is reduced to minimum while all agents are satisfied with their own behavior. Second, for the planning purposes, the violation of constraints, particularly caused by the violation of physical constraints, can be explained as the necessary amount of water imported into the system, or how much supply capacity increase is needed to sustain a certain level of benefit.

Abstract

Alaska's North Slope hosts a phenomenal wealth of natural, cultural, and economic resources. It represents a complex system, not only in terms of the biophysical system and its global importance but also from the standpoint of its social dynamic. A major challenge at the forefront of domestic energy development on the North Slope is the need for best management practices that will ensure benefits for all stakeholders. To do so requires stakeholder cooperation that enables cost-effective development strategies that fit within a broader context of long term cultural, economic, and environmental sustainability.

Ice roads and ice pads provide a cost-effective means of oil and gas exploration with minimal impact to the sensitive underlying tundra. Consequently, these ice structures have become integral to oil and gas exploration activities on the North Slope. Their widespread use represents a challenge to water resource managers, however, due to the large volume of water required to construct and maintain them. Crucial questions on water balance and ecosystem impact must be considered in the state regulatory process that permits construction of these ice structures.

The North Slope Decision Support System (DSS) is currently under development as a technology in support of oil and gas exploration and development that explicitly considers optimal water use, direct and cumulative environmental impacts, and multiple objectives and values among stakeholders. Major modules of the DSS include information systems, natural system models, planning and management functions, and regulation workflow. Development of the DSS is a collaborative effort of academic and industry personnel with significant stakeholder involvement from multiple agencies of local, state, and federal government, private energy companies, and non-governmental organizations.

Fig. 1. North Slope of Alaska (Geographic Information Network of Alaska [GINA] SwathViewer).

Introduction

The North Slope of Alaska lies between the Brooks mountain range and the Arctic Ocean (see Fig. 1). Water is an essential component of the North Slope environment. Local communities use lakes and rivers for access to subsistence resources and to sustain those same resources and requisite habitat. As well, energy development in the region is inextricably tied to water resources. Oil and gas exploration and development require a great deal of freshwater to support ice road and ice pad construction, for drilling muds, domestic water supply, and to implement emerging enhanced oil recovery (EOR) methods.

Due to the fundamental role of water in natural and human systems, successful management of this resource is indeed essential to the broader issue of environmental protection and responsible energy development on the North Slope. The challenges of developing best management practices for water resources include the following: resource planning and management for efficient and sustainable water use; understanding and explicitly considering environmental impacts and protection; and developing and implementing effective participatory management strategies with representative stakeholder participation from all sectors.

Ice roads and ice pads provide a cost-effective means of oil and gas exploration with minimal impact to the sensitive underlying tundra. Consequently, such ice structures have become integral to oil and gas exploration activities on the North Slope. Their widespread use represents a challenge to water resource managers, however, due to the large volume of water required to construct and maintain them. As the proximity of

available water sources has a significant impact on the planned location of ice roads and ice pads, changes in water resource management strategies could significantly impact oil and gas exploration activities. At present, water withdrawals require lake-specific permits that specify the maximum volume of water that may be pumped from each lake. Withdrawal limits are set by the Alaska Department of Natural Resources (ADNR) and depend on the presence and species of fish, total lake storage, and under-ice volume at the time of maximum ice thickness.

Additional water withdrawal considerations include the potential for water withdrawals to impact the annual and interannual lake water balance. Such changes could in turn impact local and regional wildlife habitat, permafrost thermal balance, or other biophysical systems.

How can we identify exploration scenarios that maximize water access and minimize exploration costs, environmental impact, and economic/environmental risk? On the North Slope, limited data is generally understood to be the greatest impediment to tackling problems such as this. Indeed, there are relatively few observational data available for the North Slope to support resource planning and management. This is due to the vast area of the region as well as the extreme, logistically-challenging climate. The majority of data that does exist has evolved over decades of individual and disjointed research efforts undertaken by various agencies, researchers, and private companies. The overwhelming effort required to locate, let alone retrieve, these data is prohibitive to its use and has greatly diminished its effective value. Moreover, drawing conclusions from and basing decisions on only a small fraction of the available data fundamentally increases uncertainty and risk. Therefore, the problem of best management practices inherently includes the problem of locating as much existing data as possible and making it readily accessible. This is also a necessary first step to prioritizing future data investment.

The institutional challenges to participatory resource management are just as important as the physical system analysis. There are many stakeholders of North Slope oil and gas resources. Here and throughout this document, the term stakeholders refers to groups and representatives from local, state, and federal government, North Slope residents, and oil and gas companies. The stakeholder group encompasses a broad range of values with respect to economic development and environmental resources. Furthermore, water uses and management objectives, as with other resources, are not the same for all stakeholders. Traditional approaches to resource development have generally not been inclusive of all stakeholders and, consequently, have not promoted a real sense of shared resource ownership and responsibility. This often leads to mistrust in regulatory and development processes and frequently results in adversarial relationships among stakeholders.

The overarching challenge being addressed in this project relates to North Slope water resource management. ***Specifically, are developing a water resources management solution in support of oil and gas exploration that explicitly considers optimal water use, direct and cumulative environmental impacts, and multiple objectives and values among stakeholders.*** The solution will consist of an information system, software tools for decision support, and methodologies for facilitating stakeholder involvement in the decision making process. The tools developed in this work will not only be applicable to the water management issues considered here, but will also be applicable to broader environmental management issues and industry development applications.

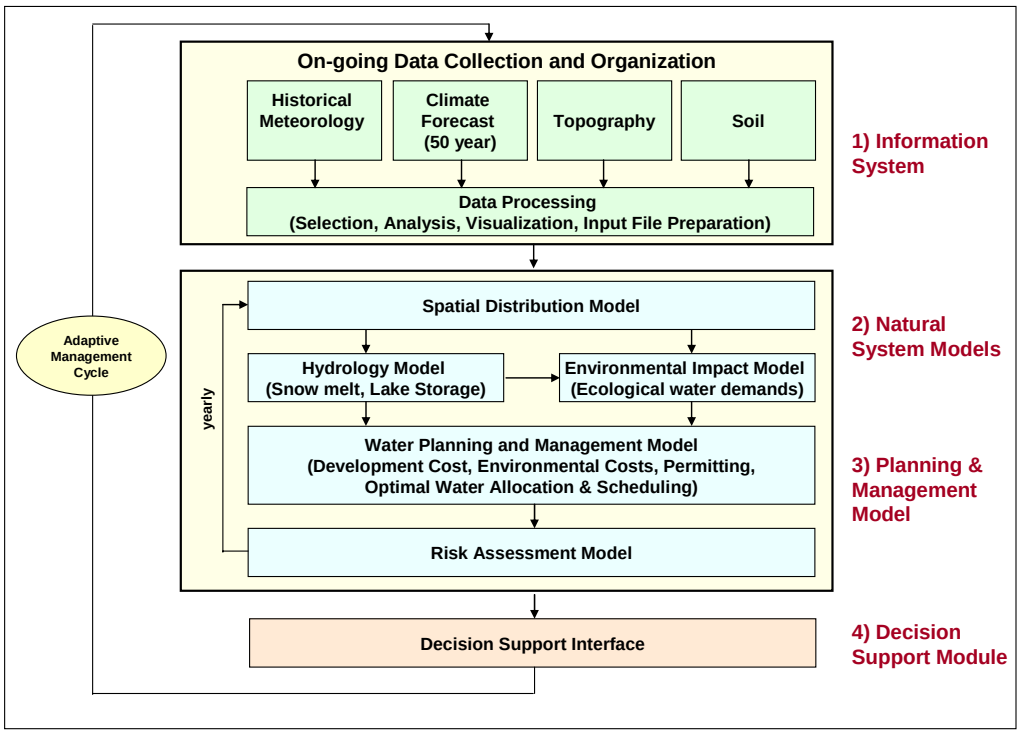

Fig. 2. Conceptual design of the NSDSS.

Design of the NSDSS

Conceptual design of the North Slope DSS structure and its major components is presented in Fig. 2. The DSS will be built on a state-of-the-art GIS-based information system that fully integrates both geospatial and time series data into a comprehensive database. The information system will serve as a workbench for importing, exporting, and quality controlling data. It will also control data flow between DSS modules. The information system will accept ongoing updates to the database as more data become available through field stations, remote sensing, stakeholder workshops, continuing research, etc.

Natural system models will accept user-specified input and simulate hydrologic and environmental responses to meteorological and anthropogenic forcing. The water resources planning and management model will interact with the natural system model to evaluate the costs and benefits associated with potential management scenarios. The interaction can be in the form of scenario exploration (i.e. define a water use scenario and evaluate the impact to a project) or as part of an optimization algorithm that suggests a set of favorable water use scenarios to meet user-defined objectives (e.g., minimize costs and maintain environmental compliance). Uncertainty in the natural and management model results will also be quantified and presented in the form of risk assessment.

The user interacts with the planning and management model through the decision support module. This feature will allow the user to look at operational scale analyses (e.g., water schedules over days, weeks, or months), seasonal planning and management (e.g., ice road planning, source lake selection, permitting support), or long term planning (e.g., multi-year exploration planning and climate change impact assessments.) At the operational scale, the decision support module will allow adaptive management of water resources by reengaging models with newly entered data. This data will be ingested through the information system and

may include updated weather forecasts, observed lake ice, lake depths, or changes in water demand for ice road construction and/or maintenance.

One of the innovations of the NSDSS will be its operational integration of a distributed cyber-infrastructure as part of its information system (Fig. 3). A central, enterprise, geographic database will be installed at the University of Alaska-Fairbanks. The structure of this database will be designed to ensure the database can act as a common foundation for all required data, findings, and management scenarios. The data collection process will add existing data stores – from both Alaskan and national data sources – to the central database. Ongoing data collection from field stations and remote sources will be continually fed into the central database.

The DSS workbench will be developed as a GIS-based application that connects to the central database, downloads user-selected data for analysis, and uploads assessment results. Probable locations for workbench installation include: UAF for research, on the North Slope for stakeholder involvement and outreach, at field sites for adaptive management, and at oil company headquarters in Anchorage for planning.

The central database will house the entire North Slope data inventory collected as part of this specific project. Some of the data types that will be accepted include traditional GIS data layers, such as shape files; point-based station data, such as precipitation and temperature from meteorological stations; remotely sensed data; and gridded data, such as reanalysis data from international climate centers, GCM data, or spatially distributed observational fields (e.g., gridded surface temperature). An important part of the information system design process will be to organize the existing data into a formal geographic database design that captures the spatial relationships from one dataset to another, thereby creating a digital depiction of the physical world.

While the complete central database will be publicly available through an online ArcGIS server, users may select subsets of data for download and off-line access on their individual workbenches. Data will be directly accessible through a GIS interface. The information system will also be designed to communicate with efforts such as the GIS database being developed and maintained by the Geographic Information Network of Alaska (GINA) as contracted by the North Slope Science Initiative. In this way, both systems will have access to data and functionality from the other, and efforts will be neither duplicated nor disregarded. Private data sets will also be accommodated within individual users' desktop environments.

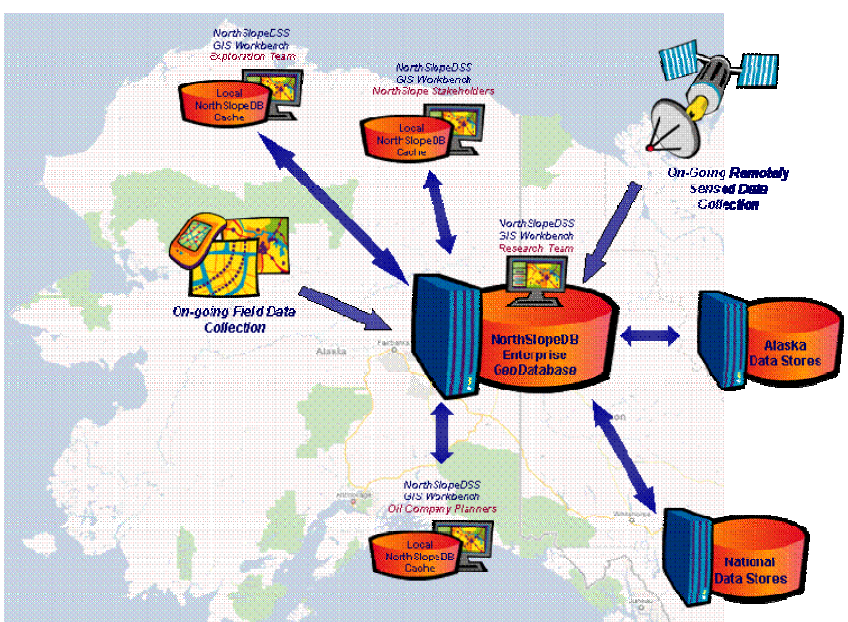

Fig. 3. The physical architecture of North Slope DSS information solution.

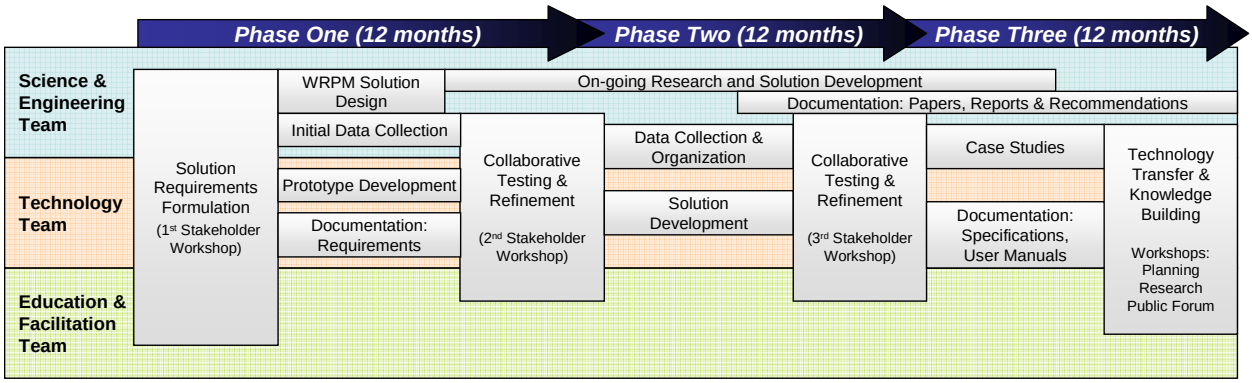

Fig. 4. Project phases and solution development.

Stakeholder Participation and Solution Development

The success of the North Slope DSS depends on its ability to meet existing and future needs of North Slope stakeholders as well as effective technology transfer to promote its use. Therefore, the proposed solution also includes significant stakeholder input during the design, testing, and application (case studies) of the DSS. A series of stakeholder workshops will be held (1) at the beginning of the project to solicit design recommendations from stakeholders; (2) at the end of year one to distribute a prototype DSS for stakeholder testing and feedback; (3) at the end of year two to distribute, test, and refine the full scale DSS; and (4) during year three for hands-on workshops focused on planning/management, research, and public DSS applications. These workshops bound the three major project phases, each one year in length (Fig. 4).

Phase I (October 2008 – September 2009) is focused on DSS prototype development. An initial stakeholder workshop was held in January 2009 to introduce stakeholders to the state-of-the-science in decision support technology and shared vision resource management and to solicit input on workbench design to meet stakeholder needs. This workshop included 28 attendees representing 4 state government agencies, 4 federal agencies, 1 local government, 3 private companies, 1 non-governmental organization, and 4 academic partners (project team excluded from this listing). The workshop involved discussion of multiple "usage scenarios" for the NSDSS that were used to develop functional, non-function, and institutional requirements for the system. The project team is now using these requirements to drive rapid development of a prototype workbench. The prototype will be a focused on a pilot area of the North Slope and will employ simple versions of the suite of models necessary for water resources management.

The prototype system will be delivered to stakeholders during a second workshop at the end of Phase I. This forum will provide an opportunity to present and discuss prototype capabilities in a hands-on fashion, whereby cooperators may test the system and provide feedback for improvements and outstanding needs. The benefits of this approach are two fold. First, the open and engaging format develops trust among scientists, stakeholders, and regulators. Second, the approach ensures that the system is truly designed to meet the North Slope community needs.

Phase II (October 2009 – September 2010) encompasses full scale DSS development. The workbench and information system will be extended to the complete North Slope region and will be upgraded with more comprehensive versions of the natural system and management models. Natural system and planning models will be refined, calibrated, and verified. This phase of work will also address climate change scenarios as well as develop an adaptive management methodology. Phase II will conclude with a third stakeholder workshop where the full-scale system will be presented to stakeholders and regulators for final testing and refining. At this time, case studies will be selected for applying the North Slope DSS to pressing stakeholder water management problems.

Phase III (October 2010 – September 2011) will focus on technology transfer and knowledge building. Case studies will be conducted for North Slope DSS applications, such as water planning and scheduling to support oil exploration and water management for enhanced oil recovery. Technology transfer during this phase will include a series of workshops aimed at various user groups. A planning workshop will be held for stakeholders and regulators and will focus on water planning and management scenario exploration. A second workshop will be held with a focus towards using the North Slope DSS in research applications by university and agency scientists. Participants will be able to formulate questions and explore solutions and scenarios with the tool during these workshops. Finally, a public forum will be held in Barrow to introduce the North Slope community to the tool, research results, and how the system can also be used to explore the existing and future North Slope environment.

A Framework for determining the Possible Impacts of a Changing Climate on Water Supply

MARK SUMMERTON[1] AND ROLAND SCHULZE[2]

ABSTRACT

For effective water resources management, all "stressors" that may impact on balancing future water supply and demand must be assessed. Hydrologists have recently begun making headway towards assessing a previously ignored "stressor", *viz*. the impact of a changing climate. At Umgeni Water, a bulk water utility in South Africa, a process has been initiated to quantify potential impacts, initially on strategic catchments using daily physical-conceptual hydrological modelling. Preliminary results indicate that streamflow could increase by up to 2.6 and 5.3 fold by the year 2065 and 2100 respectively, mostly in the currently dry winter months. Furthermore, inter-annual variability could decrease. This could increase risks of flooding and compromise dam safety. Should additional streamflow improve water yields, climate change could potentially benefit cash flows by delaying capital expenditure on projects to improve assurance of supply. Regardless, it is imperative that the hydrological consequences of a changing climate be included in water development, disaster risk and system operating plans.

Keywords: *Climate Change, Water Resources Management and Planning, sustainable economic development, ACRU Agro-hydrological model, adaptation, Mgeni catchment in KwaZulu-Natal.*

1. INTRODUCTION

A water utility must provide a sustainable bulk supply of potable water to maintain livelihoods and sustain economic development in its region of supply. Sustainability implies that the risks associated with not being able to supply water are managed to maintain an acceptable assurance of supply. Numerous "stressors" that impact on the ability to supply water are considered when balancing water supply and demand. These stressors include, most importantly, the demand for water in the future. However, it has only recently become apparent in South Africa and elsewhere that many water resource managers have yet to include the impacts of climate change on water availability in their future scenario planning, this despite having being sensitised to the potential impacts since *ca*. 1988, as indicated by Schulze *et al*. (2005). The dire reality is that most water resource managers still rely on historic, sometimes vastly outdated hydrology on which to base decisions about future water resources in their development plans and risk management initiatives.

Clear evidence exists to support the notion that the climate is changing globally and that this will have an impact on water resources. Furthermore, contemporary assessments using General Circulation Models (GCMs) which provide an indication of possible future climates are starting to show a degree of consensus in their regional predictions. Changes in climate will be amplified in the water environment, where a relatively small change in precipitation will see average river flows and water availability increasing by 10-40% in some areas, while in others they will decrease by 10 – 30% (Muller, 2007). Africa is seen as one of several regions that will be most severely impacted where, according to the Intergovernmental Panel on Climate Change (IPCC) in its Fourth Assessment Report (IPCC, 2007), between 75 and 250 million people are projected to be exposed to increased water stress due to climate change by 2020. Climate change is projected to alter the magnitude and timing of rainfall and consequently runoff, thereby impacting on the reliability of current water management systems and water related infrastructure. This should be of primary concern to water utilities, along with possible secondary, although no less severe, risks which could include those related to disaster risk management such as droughts and floods.

In response to this, Umgeni Water in the province of KwaZulu-Natal in South Africa, the second largest water utility in that country, has developed a modelling framework to determine the possible impacts of a changing climate on water resources (Figure 1). An initial workshop (Umgeni Water, 2006a) was held to introduce the water utility to climate change and the potential effects on, *inter alia*, water resources. Several recommendations, including the need to model the impact of climate change on water resources emanated from this workshop. The potential risks associated with climate change also began to feature prominently at a corporate level and have been officially included in the top 3 risks facing the utility in its corporate business plan for 2008/9 – 2012/13.

This paper provides a preliminary assessment of the impacts of a changing climate on the water resources of the main water supply catchment, *viz.* the Mgeni catchment, thereby addressing steps 1 to 3 of the framework in Figure 1. This involved setting up a daily hydrological model to simulate the impact of current and future climate scenarios on the water resources of the Mgeni catchment. To enable this, data describing rainfall patterns, land cover and its different water use patterns, other water uses such as irrigation, reservoir abstractions, wetlands, soils, and evaporation were configured as a base scenario in the *ACRU* Agrohydrological model. Simulated streamflows from this base scenario are compared with observed streamflows at 4 weirs in the upper catchments to verify the model's accuracy. Three rainfall simulations from a GCM, and increased evaporation rates have been added to the base scenario to simulate future water resource scenarios. These findings are summarised and discussed in light of contemporary research. Based on these findings, some options for adaptation in order to minimise the consequences are introduced. The paper follows work by Summerton and Gillham (2007) and is largely based on an internal report (Summerton, 2008) by the water utility.

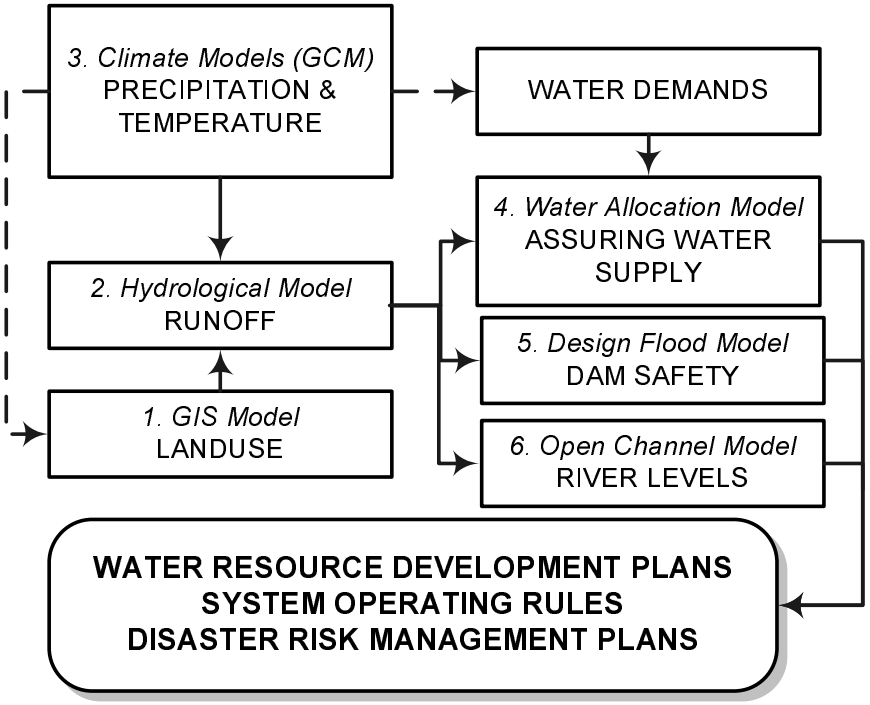

Figure 1. Modelling framework to determine the impacts of a changing climate on water resources.

2. THE MGENI CATCHMENT AND ITS WATER RESOURCES

The 4400km^2 Mgeni catchment provides water resources to the economic hub of Pietermaritzburg and Durban in KwaZulu-Natal, South Africa (Figure 2). Although the Mgeni catchment constitutes only 0.33% of South Africa, it supplies water to nearly 15% of South Africa's population and produces *ca*. 20% of the gross domestic product (Schulze *et al*., 2004). The area can be described as having a warm, sub-tropical climate. Summer (December – March) is generally hot and humid with daily maximum temperatures averaging 28˚C, and currently experiences the majority of the highly variable annual rainfall, while winter, with average daily maxima of 23˚C, is generally dry. Mean Annual Precipitation (MAP) ranges from more than 1200 mm in the upper parts of the Drakensberg mountains in the west, to around 700 mm towards the Indian ocean in the east.

During the 2006/07 financial year ending in June 2007, a total of 363.63 million m^3 of water was treated and supplied to some 5 million people in this area by Umgeni Water. The risks associated with the supply of water are currently based on a 99% level of assurance; however in recent years this has periodically not been achievable due to several "stressors" on the water resource. The main stressor has been an increasing demand for water since 2002 due mainly to development in the area. Indications are that this demand will continue to increase at between 2 - 5% per annum until 2011. These forecasts however do not include the impacts of a changing climate and consequential rainfall patterns which have started becoming anecdotally evident. Sound management of this catchment's water resource is therefore critical to the sustainability of the utility's operations, hence the need to build sound hydrological modelling systems to determine the likely impacts of stressors such as climate change on the water resources of the future.

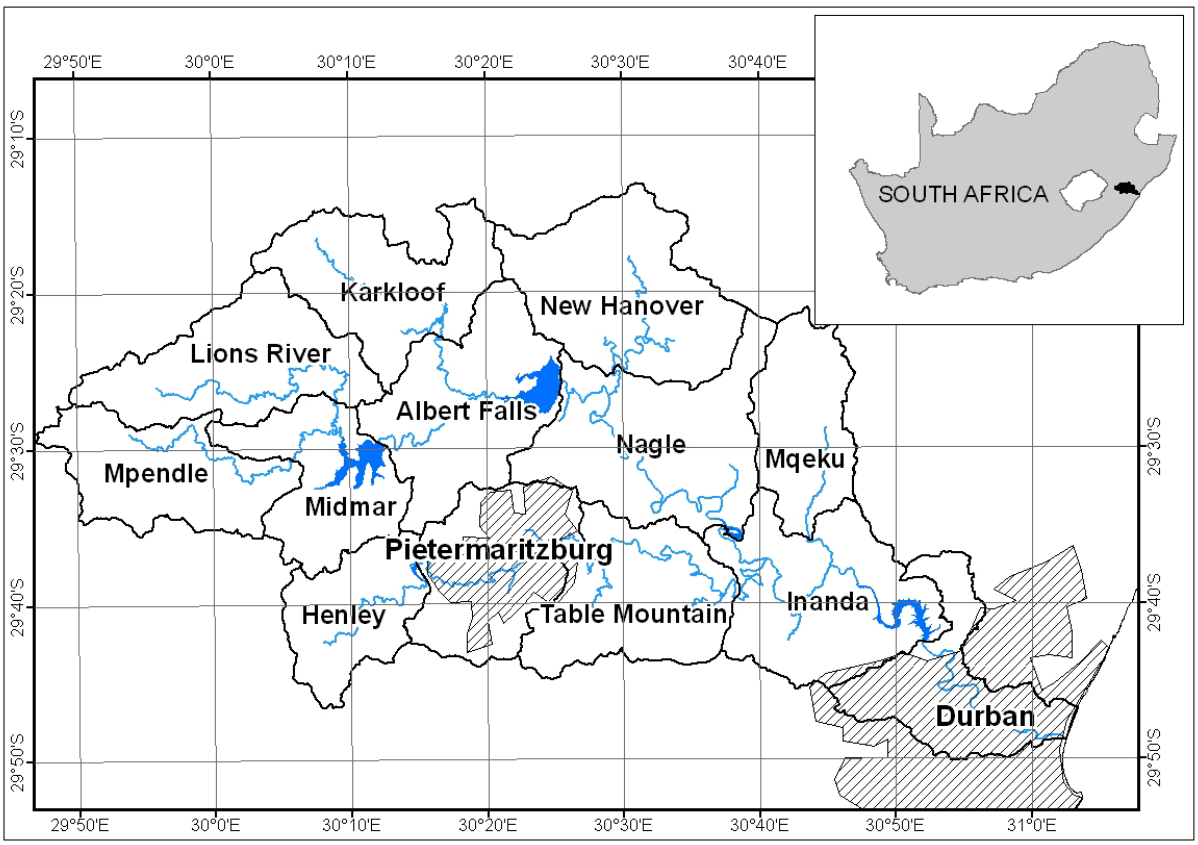

Figure 2. The Mgeni catchment, KwaZulu-Natal, including its 13 management catchments.

3. CONFIGURATION OF THE HYDROLOGICAL MODELLING SYSTEM

Assumptions

Owing to the complexities associated with hydrological modelling, several assumptions were necessary to obtain a model that would realistically simulate natural conditions but not be too cumbersome to apply. These include:

(a) Water demands are not dynamically changed, and 2007 levels are used for all future scenarios,
(b) Water use by land cover remains static for the entire simulation period since the accurate prediction of future land covers is almost impossible, and consequently, and
(c) Any feed-backs or –forwards that would be associated with land cover changes due to a changing climate have not been modelled.

Model Selection

Because of the strategic importance of the Mgeni catchment it was deemed necessary to invest in a model that could not only fulfil the requirements of this project, but of future hydrological studies as well. Furthermore, when modelling the impacts of climate change on hydrological responses, the model should, according to Schulze (2005):

(a) explicitly model the dynamics of the runoff generating mechanisms,
(b) distinguish between channel-based and landscape-based processes,
(c) be verified for a range of climatic regimes, land use practices and spatial scales, and
(d) simulate at a daily time step.

Consequently, based on a high degree of confidence in its ability to successfully model impacts of climate change on water resources in other simulations, the more complex *ACRU* Agrohydrological Modelling System (AAHMS) (Schulze, 1995 and updates) was selected for this study. The Amalgamation of Agro-Hydrological Modelling Groups (AAMG) application (Pott *et al*, 2007), was invaluable in the initial setup and configuration, particularly when data were available in a GIS format, as with all data sourced from Schulze (1997).

Base Data

Using base data such as daily rainfall from Lynch (2004), a detailed land cover map (Summerton, 2008) and associated water use parameters, irrigation and reservoir data based largely on the Department of Water Affairs and Forestry's (DWAF) Water Act Resources Management Service (WARMS) database, evaporation and soils information from the South African Atlas of Agrohydrology and – Climatology (Schulze, 1997) and abstraction and return flows from Umgeni Water's Water Resources Management (WRM) database as input, the base configuration was constructed by delineating the 13 management catchments into 1450 modelling subcatchments for the years 1960 – 2000 in order to run with the daily time step *ACRU* model.

Verification of Streamflow

Simulated streamflows were verified against observed data at the 4 management catchments with streamflow records. Criteria of R^2 values of at least 0.75 and an average error in daily flow of less than 0.2 mm equivalent were met at all 4 subcatchments. At these gauging weirs, highly acceptable simulations were achieved with R^2 values between 0.75 and 0.90 and average errors in flows of between -0.07 and 0.13 mm/day.

4. RAINFALL AND EVAPORATION AS DRIVERS OF CLIMATE CHANGE

For the purposes of predicting future water resources scenarios, future rainfall and temperature patterns are derived from GCMs and are used in hydrological modelling. For the purposes of this project, the Geophysical Fluid Dynamics Laboratory (GFDL) GCM was selected based on the premise that of the six GCMs from the IPCC's Fourth Assessment Report (IPCC, 2007) assessed for southern Africa by Lumsden and Schulze (2007), the GFDL was considered the "middle of the road" scenario. The GFDL GCM is based on the SRES A2 emissions scenario defined by the IPCC (2001), where efforts to reduce global emissions this century are assumed to be relatively ineffective. The Climate Systems Analysis Group (CSAG) at the University of Cape Town used empirical downscaling techniques to downscale the GCM data to a quarter of a degree (*ca*. 25 km^2) resolution. In order to represent the regional climate scenarios at a Quaternary Catchment scale, pixels were selected by Lumsden and Schulze (2007) from regional scenario grids to represent each of the 1946 Quaternary Catchments covering southern Africa. These same pixels and their associated rainfall time series were assigned to each of the 1450 modelling catchments in the Mgeni. For temperature and evaporation changes, plausible estimates were derived from discussions with Schulze (2008). Subsequently, simulations on three climate scenarios were performed, *viz*:

(a) Current Climate Scenario (1960 – 1990) - Based on model configuration with rainfall input from the GFDL GCM replacing *de facto* rainfall data,
(b) Intermediate Future Climate Scenario (2046 – 2065) - Based on Scenario (a), but for an intermediate climate by using GFDL rainfall, and a plausible increase in reference potential evaporation of 6% to mimic a temperature increase of 1.5˚C, and
(c) Distant Future Climate Scenario (2081 – 2100) - Based on Scenario (b), but for a future climate by using GFDL rainfall, a temperature increase of 2.7˚C and a potential evaporation increase of 11%.

Although the GFDL GCM was used for this preliminary study, discussions with Tadross (2008) confirmed that it is imperative that the remaining GCM models be assessed before reaching a conclusive decision on future impacts. Future work should also include advances in the downscaling process to individual station level (as opposed to pixels) available at some 2600 rainfall and 409 daily minimum and maximum temperature stations throughout the country.

5. STREAMFLOW AS A RESPONSE TO CLIMATE CHANGE

For this preliminary assessment, the focus is on accumulated streamflows as the main response to a changing climate. The magnitudes of accumulated streamflows are assessed by means of ratios between intermediate future and current, and distant future and current streamflows. The use of ratios is considered prudent until such time as convergence is shown between several different GCMs, and confidence is built up in the ability of GCMs to predict magnitudes of changes more accurately. In a similar manner the coefficient of variation (CV %) has been used to depict variations about the mean as an indicator of climatic and hydrological risk. Furthermore, to obtain an indication of whether any shifts in accumulated streamflows patterns occurred, monthly patterns were analysed at 4 key locations in the catchment *viz.* the Midmar, Albert Falls, Nagle and Inanda dams.

Magnitude of streamflow change

Figures 3 and 4 contain mapped ratios of mean annual streamflows for intermediate future to present climates and distant future to present climates, respectively. Using the GFDL GCM, indications are that it is likely that streamflows will increase between 1.3 and 2.6 fold by 2065, and 1.7 and 5.3 fold by 2100. Higher increases are observed in catchments on main rivers and major tributaries due to accumulation of water throughout the catchment, particularly the Nagle management catchment. The lowest increase is *ca.* 1.35 and 1.7 fold by 2065 and 2100 respectively for those catchments not on the main channel where accumulation of streamflow is less. These results add overwhelming support to contemporary indications of a wetter eastern South Africa in future climates, although the magnitudes may be excessive and require further investigation.

Inter-annual variability

Figures 5 and 6, displaying ratios for intermediate and distant future to the present climate's annual coefficient of variation, indicate that generally there will be less year-on-year variation in flows under future GFDL climate scenarios. This suggests that in future climates, streamflows are projected to become less variable, and therefore more predictable, especially in the key Nagle management catchment. This projected decline in variability could be partly attributable to lower variability in intra-annual streamflows as a result of increases in streamflows in the low flow winter months. The exceptions are the Lions and Mpendle management catchments where in the intermediate climate, variability could increase.

Distribution of monthly streamflows

Figures 7 and 8 contain ratios of intermediate future to present as well as distant future to present mean streamflows into the 4 key dams for each of the 12 months. Streamflows are predicted to be generally greater in all months of the year. This is especially true during the winter period with ratios of around 3 and 6 for 2065 and 2100 respectively, but above 10 for Nagle Dam. Winter is generally the period of low flows and consequently these results allude to a possible reduction in intra-annual variability. In some respects this is a beneficial result since the increased streamflow could be distributed better over the year rather than occurring during the already wet summer periods with increased possibility of flooding. Figures 9 and 10 contain ratios of intermediate future to present and distant future to present streamflows (95^{th} percentile) for the 12 months of the year. Peak flows are predicted to increase during the winter months, especially into Nagle dam which, depending on actual streamflow volumes, may present issues concerning dam safety. During the summer months, some peak flows may even be lower than under current climatic conditions.

6. CONCLUSIONS

A daily hydrological modelling system for the Mgeni catchment in KwaZulu-Natal, South Africa has been configured at a finer resolution than ever before. The potential applications of this system are vast. However, this initial application has focused on a preliminary assessment of the impacts of a changing climate on streamflows using the GFDL GCM. Notwithstanding the acknowledgement that several aspects of the modelling process are still rudimentary and need improvement, the results do indicate several trends.

Indications are that streamflow will generally increase in the currently relatively drier, low flow winter months by up to 2.6 and even 5.3 fold by 2065 and 2100 respectively, thereby resulting in a smooth supply of streamflow all year round. Inter-annual variability could decrease. Generally, the potential impacts that require further attention would be that of flooding and dam safety. Furthermore, although it would seem that additional streamflow should be beneficial to the supply of water at particular assurance of supply levels, the current capacity of the dams may not be appropriate to harness this extra capacity. If sizing is adequate, there may be benefits in terms of delayed capital expenditure on future water resource supply projects. It is this seasonal shift that could also impact on water quality both in the rivers and in dams due to decreased variability.

In addition to the generalised potential impacts presented above, there are several hotspot catchments within the Mgeni catchment that will require closer attention. Most critical is the Nagle catchment where future mean and peak streamflows have the potential to increase the most. In addition, the Lions and Mpendle catchment where in the intermediate future climate, variability could increase, may require closer observation and management.

7. THE WAY FORWARD

It is imperative that the integrity of the configuration, and therefore the confidence in these results be improved. Key to this requirement is the inclusion of other readily available GCM scenarios that output daily rainfall and temperature values at a climate station (rather than averaged pixel) level. These only became available recently, after the end of this study. Other improvements to the configuration could include using physically based reference potential evaporation calculations, modelling land cover in a dynamic manner with feedback loops from hydrological modelling, and making dynamic changes to the water demands.

Secondly, the hydrological scenarios presented here should be included in the utility's water yield and assurance of supply assessments to identify whether the existing system is capable of harnessing the additional water resources, were these to materialise. Key to this process will be the use of GCM output for the period up to 2040, i.e. the horizon which is influenced by current planning, Should additional streamflow result in additional yield and assurance of supply, the potential benefit of climate change is that capital projects could be delayed.

Additional streamflow could well increase the risks associated with flooding and compromise dam safety, particularly in catchments already prone to flooding. Areas with higher risk include the Nagle management catchment where future mean and peak streamflows have the potential to increase the most, as well as the Lions and Mpendle management catchments where in the intermediate future climate, variability could increase. These areas may require closer observation and management and possibly even a need to consider real time water management systems.

Lastly, in order for the results of this study to be effective, it is imperative that climate change be included water resource development plans, operating rules and disaster risk management plans. These should include adaptation strategies and risk management practices to maximise resilience

against the impacts of climate change on water resources. A framework for this approach is readily available in Umgeni Water (2006b). Mitigation measures, including revision of antecedent precipitation indices to enhance forecasts of flood impacts, reviewing of engineering design criteria and dam safety issues, should be addressed.

Advances in geospatial analysis technology have resulted in new data-gathering techniques for environmental justice (EJ) assessments. Frequently investigated metrics relate to race and income due to relatively easy availability of census data. Geographic information systems (GIS) offer the ability to embed these data in maps in order to better recognize patterns that may designate discriminatory practices. Many other indicators of disproportionate negative effects exist and can be assessed using GIS. Map-based analysis results can also provide data on proximity for various phenomena. However, expert human analysis is required to interpret images which may lead to arbitrary or subjective conclusions. Researchers at the University of Missouri have developed a GIS methodology to overcome the limitations of image-based analyses for evaluating spatial relationships in community infrastructure by employing metrics such as travel time and distance to jobs, education, healthcare, and food markets in order to move beyond identification of those affected to quantification of the impacts on their lives. That is, to quantify the answers to the questions: How does daily life change as a result of infrastructure improvements? How do the impacts on these parameters compare to the impacts of alternative projects? Manifestations of these impacts have been transformed into quantifiable data that will offer planners greater decision-making confidence. Mathematical representations in the form of indices have been developed to offer a consistent approach to infrastructure problems as they relate to EJ.

INTRODUCTION

The Bill Emerson Memorial Bridge project, linking southeast Missouri with southern Illinois across the Mississippi River, was analyzed as a demonstration of the methodology used to study community impacts resulting from transportation infrastructure. The bridge's western approach, located in Cape Girardeau, Missouri, has bisected the immediate community, altering mobility and access to various elements of the neighborhood (Perry 2003). A GIS was used to create quantifiable parameters describing changes in inhabitants' daily life in terms of access to transportation, education, healthcare and food that result from the impacts of this

transportation infrastructure project. Quantification of impacts has not been widely integrated into planning processes (Perry 2003). Identification of these impacts within their spatial context and expression through a numerical representation provides a framework for robust EJ impact analysis and the ability to incorporate this system for other community infrastructure projects.

BACKGROUND

The methodology for evaluating EJ impacts was adapted from a GIS-based analysis of nuclear materials transportation conducted by University of Missouri Researchers. The following steps were identified in the existing methodology: (1) identification of potential parameters for analysis (2) collection and analysis of spatial information (3) assessment of the utility of the spatial information for decision-making (4) assessment of the completeness of the set of parameters (and the subsequent identification, collection, and analysis of additional data, as appropriate), (5) data standardization, (6) weighting of parameters, and (7) aggregation of parameters (Divate et al. 2007a, b). This framework was applied to aid in identifying parameters and quantifying social impact analyses to aid in decision-making for infrastructure planners.

METHODS

The area of interest includes the low-income and minority demographics described in Executive Order 12898 (Clinton 1994). The lowest income and highest minority population percentages coincide in the neighborhood where the bridge approach has been constructed (Figure 1, 2). These census block groups were selected to evaluate possible changes in pedestrian travel as a result of the highway improvements.

One goal of this decision-making tool is to quantify impacts so that individuals can attempt to avoid locales susceptible to disproportionate adverse affects in route planning. Therefore, the parameters selected must be measurable and be expressible in a non-subjective numerical format. As a demonstration of one set of parameters, travel distance and time were selected. The parameters are actually two representations of one metric. Pedestrian travel time simply represents travel distance as a rate per unit time. Thus, the ratio of each parameter change, before and after infrastructure improvements, is identical. Travel time is calculated as:

$$T = (D / S) * (60 \text{ min} / 1 \text{ hr})$$

where T = travel time (min)
D = travel distance (mi)
S = travel rate (mph)

The pedestrian travel rate, S was approximated at 3 mph which is a value between that of average foot travel for men and women (Noland 1996).

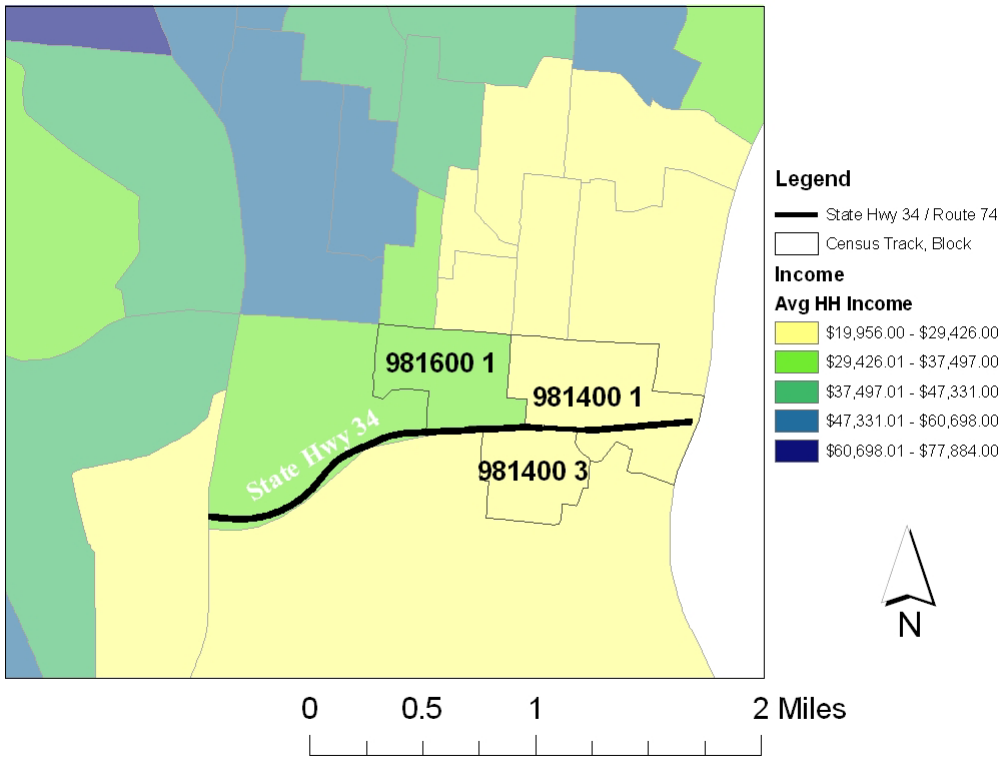

Figure 1. Map of Cape Girardeau income distribution.

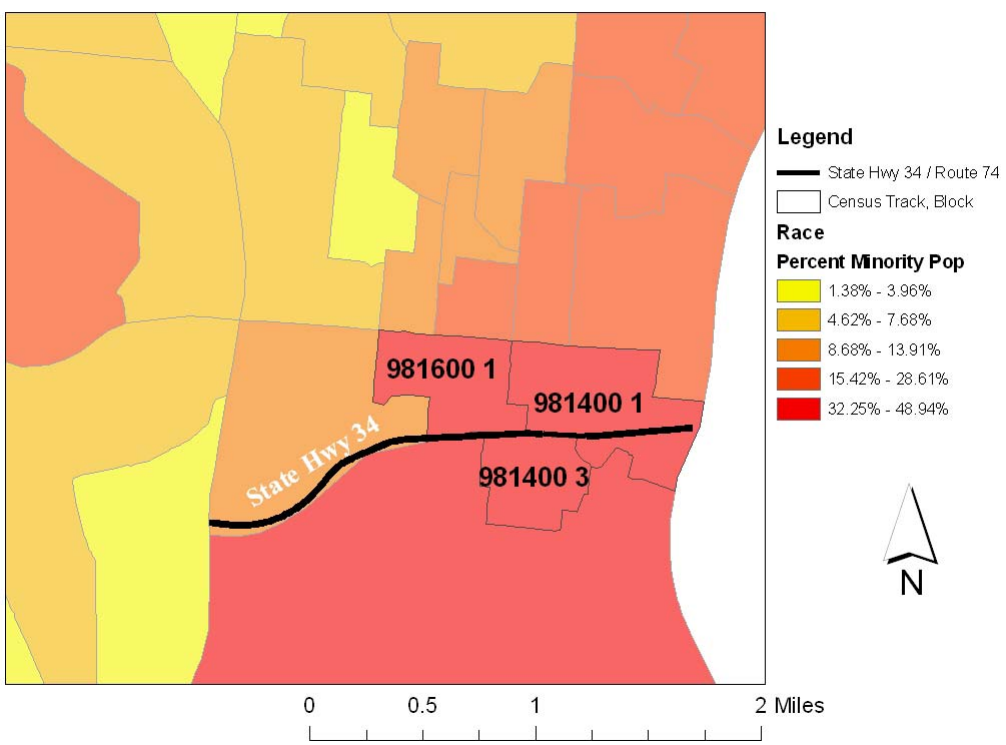

Figure 2. Map of Cape Girardeau minority population distribution.

Spatial information was collected online from the Center for Applied Research and Environmental Systems at the University of Missouri (CARES 2008). Data collected includes aerial images, maps, transportation routes, administrative and political boundaries, socioeconomic and census data (US Census 2000), and site spatial locations. GIS software was used to analyze distance measurements (ESRI 2006). Pedestrian travel was determined by measuring the straight-line distance on the centerline of street travel routes. Measurements begin at the centroid of census blocks and proceed to a destination by either the shortest previously available street path or the shortest path available after completion of the highway project. An alternative approach involves reducing the block group to quadrants to further identify areas most vulnerable to modified mobility. Aerial maps of the selected areas show the census blocks, the highway route and example site locations (Figure 3, 4).

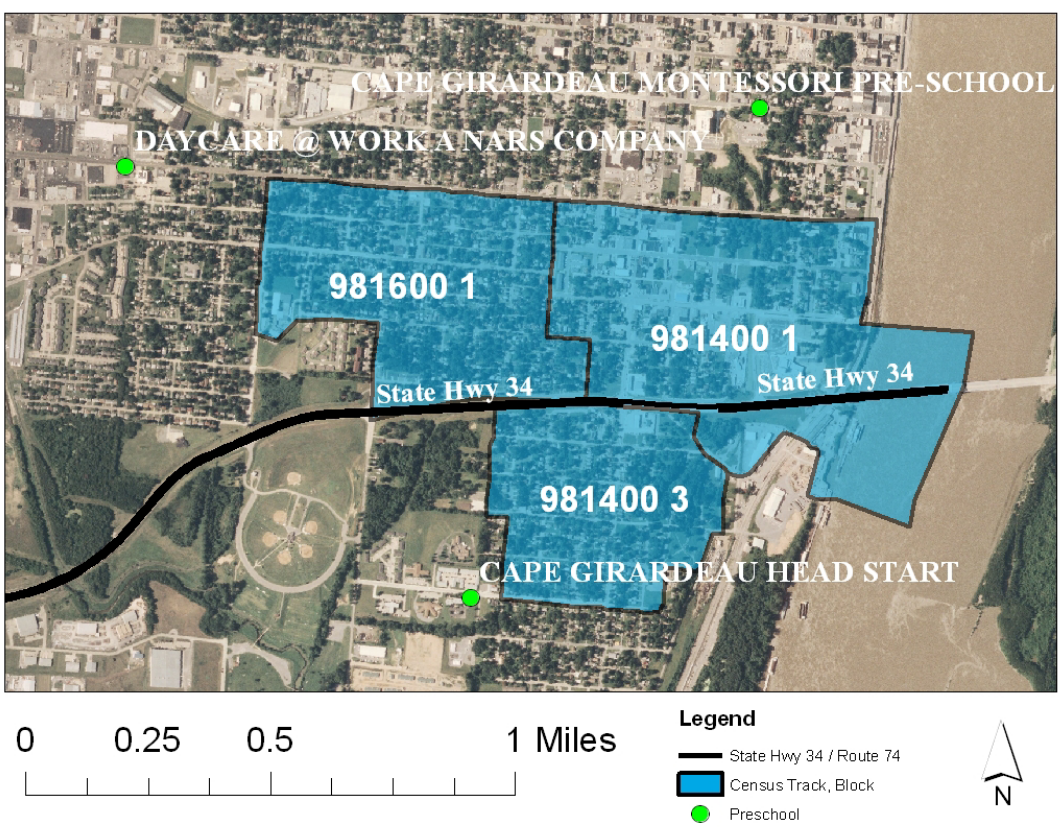

Figure 3. Aerial map of Cape Girardeau and area of interest.

This analysis may fit well within the social impact assessment portion of the design process particularly if it is not addressed along with motorized traffic engineering. Pedestrian traffic patterns have traditionally played a minor role in transportation infrastructure planning and adding this approach may help to eliminate some human impacts during the planning process (Noland 1996).

Figure 4. Close up aerial image of the highway and neighborhood.

Values are normalized using an index ranging from 0 to 1. Pedestrian Travel Index Value, N is calculated as:

$$N = (X_i - X_{min}) / (X_{min} - X_{max})$$

where N = Pedestrian travel index
X_i = the original travel value
X_{min} = the lowest travel change percentage for destination in a category (e.g. healthcare) for all block groups.
X_{max} = the greatest travel change percentage for destination in a category (e.g. healthcare) for all block groups.

These index scores can be compared for various alternative projects in a large array of categories to evaluate impacts and assist in selecting a proposal with the smallest overall impact. Alternatively, the process of comparison could be used to guide the formulation and evaluation of alternative proposals that address the specific impacts identified.

Results

Trip distance, D, travel time, T, percent difference, and the pedestrian travel impact index value, N, for Block Group 9814003 are shown in Table 1. Index results for all three block groups are displayed in Table 2.

The healthcare destinations selected include the three nearest hospitals and the county health clinic. Pedestrian routes to these locations remained unchanged with the highway construction, so travel was not impacted because the shortest pedestrian travel path did not change for any of the block groups.

However, access to some education sites was impacted. The nearest elementary, middle and high schools were selected along with the neighborhood Head Start preschool. The elementary and middle schools travel routes were modestly impacted for one block group. The schools are located northwest of Block Group 9814003 and previously the shortest route to the schools occurred along side streets that are no longer contiguous. Instead, pedestrians must now first travel due north from the center of the block group in order to cross Highway 34 before heading west.

Two large chain food stores and two smaller local groceries were selected to evaluate access to food. Again, only Block Group 9814003 appeared to be impacted by changes in pedestrian travel. Perhaps because nearly all food stores in the area are located northwest of the area of interest. In an online Yellow Pages search, 16 out of 17 grocery outlets listed in the zip code were located northeast of the block group and all were positioned outside of it. One grocer, Cauble & Fields, was located on a side street in Block Group 9814001, north of the highway. Access to this store was only impacted for Block Group 9814003 by a small distance (approximately 0.11 miles). However, its proximity relative to other stores (on average 2 miles away) may indicate that any changes in access to this store could prove significant, particularly to elderly or disabled pedestrians.

Because possible impacts on Block Group 9814003 were identified during a first analysis, a second investigation was conducted on this block group. It was divided into quadrants and distance measurements were performed starting from the street intersection nearest the centroid of each quadrant. Index values were developed using only minimum and maximum values from block group 9814003 quadrants. This moved the distance measurement start point from Sprigg St, the only path for highway crossing in 9814003, to various smaller neighborhood streets (Figure 4).

Each block group quadrant was impacted differently. The greatest impacts occurred at the NW and SW quadrants. Figures 3 and 4 show that the western portion of the block group is bound by the highway on the north and parkland and an undeveloped area on the west. Access to food and educational destinations to the northwest is significantly impacted. For instance, the schools are located northwest of Block Group 9814003 but pedestrians are now required to first travel east in order to cross Highway 34 before traveling back to the west towards the elementary and middle school.

CONCLUSION

This methodology offers the potential for enhanced evaluation of EJ impacts. Determining sites for travel distance measurements are particularly important. In block group 9814003, the centroid aligned with the major street that crosses the highway, allowing for access to the education and grocery outlets in the northeast area of the neighborhood and revealing little, if any, change in travel time. However, those most likely to be adversely affected by the highway project, live in the western two quadrants of the block group. When measurements are taken from the centroids of the northwestern and southwestern quadrants, impact index values increase dramatically. These areas and those in the adjacent block group 9816001 that have seen their previously linked streets severed by the highway expansion experienced the largest changes in travel time (Figure 4).

Greater impacts may exist on smaller streets or more remote parts of neighborhoods. Hospitals and other large amenities may presumable exist on major thoroughfares, while neighborhood grocers, individual healthcare offices, other small businesses or schools may be more likely to be located on smaller streets. Block groups that demonstrated no impacts when travel paths were measured from the block group's center, may indeed reveal potential pedestrians impacts when population density and distribution, existing pedestrian travel patterns, street layout, neighborhood geometry and arrangement relative to other spatial factors are included in the determination of a point of origin for measurement and analysis.

Future work in data collection and analysis methods for enhancing social impact assessments may include greater public involvement. An identified shortfall of the social impact assessment process is the lack of primary data collection (direct public involvement) while secondary data (e.g., census data) is relied upon greatly (Perry 2003). One means of increasing community involvement may be to survey or interview potentially impacted individuals in order to prioritize the importance of access to various elements in a neighborhood. Parameters could be weighted and used to guide planning alternatives and estimate potential impacts during a project design phase.

ABSTRACT

Organizations focused on managing water resources are recognizing the need to have tools for literature review, data integration, modeling, and decision support. Decision support systems (DSS) can help to meet these needs because they are aimed at integrating data and knowledge, evaluating management options in terms of organizational objectives and risk, and facilitating multiple-stakeholder decision making where competing objectives and risk preferences must be reconciled. Using the internet, organizations can share the costs and benefits of existing and newly developed information, theories, and technologies among a broad, diverse user group.

This paper discusses an approach, based on experience, to developing DSSs through a larger, iterative cycle of ongoing, collaborative environmental research and development. Multiple stakeholders with multiple conflicting objectives need insightful, often novel, models of environmental systems. The answers developed to new research questions contribute to requirements and specifications for new tools and technology, and the technology is then built to facilitate the collaborative management process. Information added at any point can influence the collaborative management–research–technology cycle in both directions.

Stakeholder workshops to specify the DSS requirements, formulate its design, and review its use are critical. The DSS must be built progressively, first focusing on pilot areas and tractable research problems and eventually moving to a national scope. To motivate continued development, rapid prototyping is an ideal tool for achieving early success. The DSS—and the entire cycle—must also be self-maintaining. Two case studies illustrate these concepts.

INTRODUCTION

Organizations focused on managing water resources are recognizing the need to have tools for literature review, data integration, modeling, and decision support. Decision support systems (DSS) can help to meet these needs because they are aimed at integrating data and knowledge, evaluating management options in terms of

organizational objectives and risk, and facilitating multiple-stakeholder decision making where competing objectives and risk preferences must be reconciled.

Using the internet, geographically separated organizations with similar objectives can benefit from sharing experiences, data, and models. The development of enterprise- and nationwide DSSs enables organizations to share the costs and benefits of existing and newly developed information, theories, and technologies among a broad, diverse user group.

While DSSs are desirable, it is not very clear how to go about building them. This paper discusses an approach to developing DSSs by focusing on a larger cycle of ongoing environmental research that starts with the need to manage natural environments collaboratively. Environments, such as estuaries, are the focus of multiple stakeholders, each with multiple objectives that are often opposed; thus there is a need for insightful, and often novel, models of these systems. As more insight is sought, new research questions are continually raised. The answers developed to new research questions contribute to requirements and specifications for new tools and technology, which is then built to facilitate the collaborative management process. New information added at any point can influence the collaborative management–research–technology cycle in both directions, as illustrated in Figure 1.

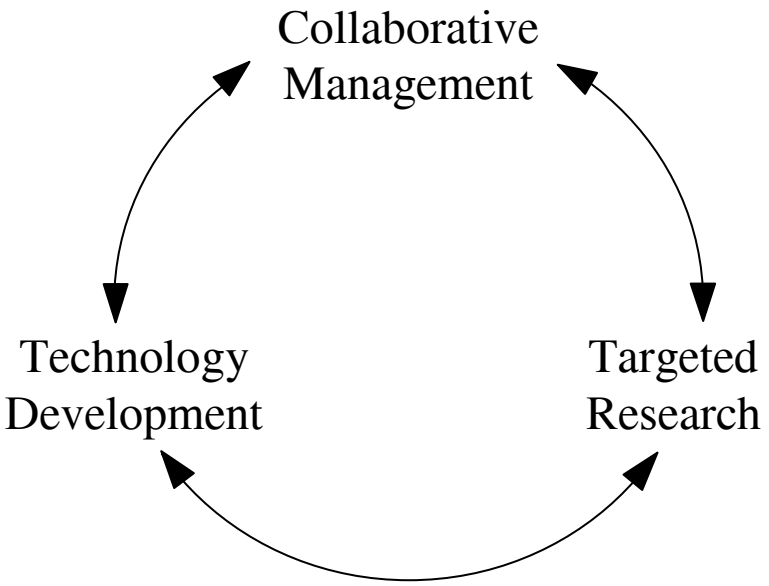

Figure 1. Collaborative management–research–technology cycle.

Establishing the cycle requires a pragmatic approach. First, the community must build the DSS to ensure community adoption. Stakeholder workshops to specify the DSS requirements, formulate its design, and review its use are critical. Second, the DSS must be built progressively—first focusing on pilot areas and tractable research problems and eventually moving to a national scope. Third, the DSS must be built with early success in mind to motivate continued development. Rapid prototyping is an ideal tool for achieving such success. Finally, the DSS—and

the entire cycle—must be self-maintaining. These concepts are illustrated in two case studies, the Northslope DSS, a tool in development for collaborative management of the North Slope in Alaska under proposed oil exploration, and a proposed DSS for management and research of the National Estuarine Research Reserve (NERR) System, under the National Coastal and Estuarine Research Technology (NCERT) Program. The proposed NCERT DSS provides a large-scale, practical example of how the collaborative management-research-technology cycle would be applied to a real-world problem.

NATIONAL COASTAL ESTUARINE RESEARCH AND TECHNOLOGY PROGRAM DSS

In establishing the NCERT Program in partnership with the NERR System, NOAA is seeking to stimulate research and scientific collaboration between the NERRs and their state agency, local governmental, and university partners to develop and implement new and innovative tools, in order to help coastal managers detect, prevent, and reverse the impacts of coastal pollution and habitat degradation. The primary focus of the effort is to address land use, habitat, contamination, and stormwater issues related to coastal development.

The challenge of establishing the NCERT Program, in partnership with the NERR System, to fund collaborative research to assist coastal managers in detecting, preventing, and reversing coastal pollution and habitat degradation, is extraordinarily complex but necessary. The program, therefore, must serve as a catalyst for a diverse array of activities that range from collecting, analyzing, interpreting, and using data to identify significant empirical and mechanistic relationships and develop new and innovative tools for resource protection and management. Developing appropriate management approaches and actions that affect public policy and influence human behavior is possible through stakeholder interactions linked to database analyses.

The skills required to do this work cut across many disciplines and areas of specialization, including biologists (marine, estuarine, riverine, coastal wetland, and upland biologists); geologists; hydrologists; hydrogeologists; geophysicists; statisticians; geographers; climatologists; modelers; coastal engineers; drinking water, stormwater, and wastewater engineers and regulators; highway and land use planners and engineers; and local and regional planning commissions. The coastal watersheds are just as diverse, ranging from very small watersheds (first-order streams) encompassing less than 50 acres (small neighborhoods), to enormous watersheds (tenth-order streams) that encompass more than a million square miles and cover more than half of the country (Mississippi River).

It is hard, then, to identify, let alone choose, a research program or suite of assessment tools that will meet the needs of a single estuarine system, let alone serve the needs of a network of estuaries such as the NERR System. This will not simply happen by creating a program, bringing people together, or sponsoring collaborative research. The approach must connect the *stakeholders* to the *science* and the

technology that they need and thus enable individual stakeholders to help themselves and each other. Each NERR watershed has both unique and generic problems and solutions. The proposed NCERT Program DSS will share knowledge, experience, and expertise and build a base of knowledge and a set of tools that will serve NERR sites individually and collectively.

Each part of the program is highly dependent on the other parts, *i.e.*, each part affects and is affected by the other parts in a highly interactive and adaptive management process, as illustrated in Figure 2. This approach will achieve the desired NCERT Program objectives by actively involving stakeholders in the development of an information system to facilitate and target future research through a collaborative decision-making and management process among NERR stakeholders.

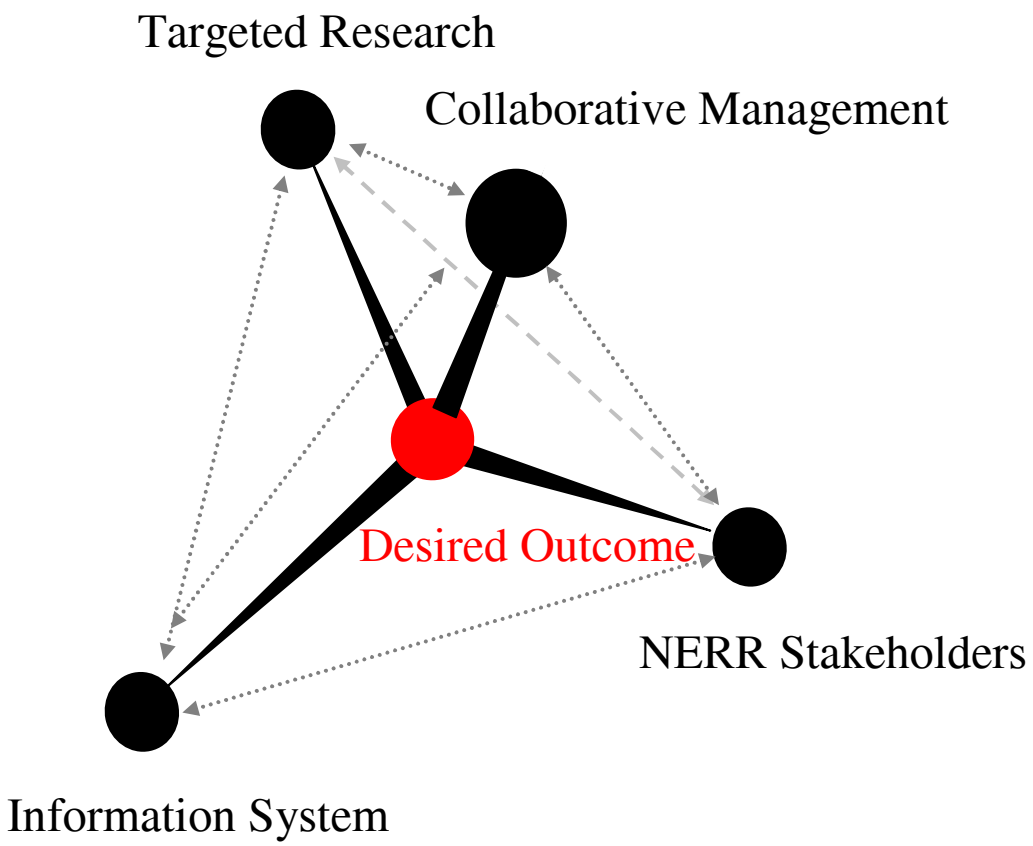

Figure 2. A model for achieving the NCERT Program objectives.

Collaborative Decision-Making Process

Conflict is a natural part of human relationships and reaching consensus is not always possible; however, when properly managed, conflict can be a positive force that leads to new ideas and new ways of doing things. It can also be a catalyst for strengthening stakeholders' relationships and developing better, longer-lasting outcomes.

The project team will coordinate and direct a collaborative process with the NERRs and their state agency, local governmental, and university partners to (a) gain

consensus on critical data needs and research tools for enhancing estuarine assessment and (b) identify appropriate management approaches and actions for restoring and protecting estuarine health. This collaborative process will be implemented using a tiered approach that will facilitate information sharing between the project team and the individual NERRs and their associated stakeholders on a local, regional, and national level.

The results of these interactions will be used to develop an information system, through existing technologies and databases, to link researchers and stakeholders participating in the NCERT Program through a central, online, federated database system via web-based and desktop applications, including NCERT.org. The proposed collaborative process and information system will support estuarine data collection and analysis, and strengthen land and water resource decision making. The end product of this effort will be a data-driven research and technology program that will allow management to incorporate trade-offs that support NERRs into the decision-making process.

A working prototype of this information system, the Analytical Framework for Coastal and Estuarine Study (ACES), has been developed and fully documented by the St. Johns River Water Management District (SJRWMD) and PBS&J. It uses a geographic information system (GIS)–based database of spatial and temporal data to describe the environment and a suite of modeling tools, based on first principles, to evaluate different management scenarios. With ACES, estuarine bulk parameters related to shape, residence time, and flushing potential can be derived, and the influence of tide and terrestrial drainage on estuarine water quality can be assessed using regression and other approaches. ACES was created through a collaborative and rapid-prototype development process involving national estuarine experts that was similar to the process proposed for the NCERT Program DSS.

Annual national NCERT Summits will be held to promote collaboration between NERR stakeholders. These meetings, used as part of a tiered approach—including local "listen-and-learn" meetings with individual NERRs and their governmental and university partners, as well as regional workshops—will engage stakeholders at all levels in the process of developing the information system and building consensus on data needs, assessment tools, and research priorities. Research priorities identified through this process will be funded through targeted grants to participating NERRs, universities, and state and local governments.

Technology Development

As the collaborative management process is implemented, stakeholders will need information to define problems, clarify objectives, and assess the effectiveness of management activities and strategies. The specific information that stakeholders require for planning and management decisions should drive which information is collected. The major challenge to stakeholders will not be collecting information—for there will be an overwhelming amount even if they gather only the specific information needed—but processing data to obtain exactly the required information.

Furthermore, the quality of the information collected is most important, rather than the quantity. Obviously, good information results in better management decisions.

Effective and sustainable management requires an estuary-by-estuary study approach. On the other hand, the NCERT goals of collaboration and efficiency through data-, model-, technology-, and idea-sharing necessitate a communal approach in which a single technological framework is used by all.

These two requirements—estuary-specific study and a single technological framework—are not mutually exclusive. The national, community-based solution proposed will enrich the understanding gained through estuary-specific studies by identifying and focusing on similarities in the research and decision-making processes. That is, while two estuaries may be largely different in their geomorphology, water chemistry, hydrodynamics, etc., the processes undertaken to identify how to model the estuary, collect the data, develop the management alternatives, and ensure stakeholder approval are largely similar. Building a nationally applicable information solution that facilitates these processes is therefore not only possible, but will bring a whole new level of data access, research finding access, and collaboration to the fore.

The project team will develop a comprehensive information system. Existing databases containing data, models, research findings, and management policy documents for all 27 NERRs will be linked to form a national cyberinfrastructure network. This network will form the foundation for storing and communicating the results of the on-going research program. Access to the network will be provided via two methods. First, a GIS-based website called NCERT.org will be created that provides a broadly accessible view of all data, models, and scientific findings. Second, a GIS-based software workbench for analyzing estuaries will be built. This workbench will form the means of conducting new research, and will be stocked with a growing set of models created as the research process continues. As new results and models are created, the user will be able to publish them directly to the national network for review by the NERR community. The research will be driven by the process of building decision support systems for estuarine management, which in turn will drive the development of natural systems models to assess the effect of management plans. The modular design of the software workbench allows researchers to submit their newly developed natural systems and decision support models to the national network so that the entire community can use them.

The NCERT DSS is an ambitious information solution that will serve the needs of a growing and diverse estuarine science community. Certainly, to build the solution from the ground up would be a large effort and would exceed the time and funding available. Fortunately, several national emerging role models and technologies can be leveraged to quickly arrive at an operational NCERT DSS Framework. The proposed framework is based on the following building blocks, as illustrated in Figure 3 on the next page:

- *A national cyber-infrastructure that enables real-time, communitywide communication.*
- *A national standard for storing estuarine information, including GIS-based data, observations data, models, and research findings.*
- *A means of including existing databases, models, and research findings in the national cyber-infrastructure and ensuring they can optionally remain in their current format, or be converted to the national standard, or some hybrid of the two.*
- *A workbench tool that works with data from the national cyber-infrastructure and enables a range of estuary analysis—from first principles to complex, systemwide modeling.*
- *A modular tool framework that allows for the development and incorporation of new tools for estuarine analysis into the national toolset—an openly available suite of tools for all NERRs to use.*
- *A broadly accessible, web and virtual globe–based tool that focuses on serving the estuarine community with user-friendly, ergonomically driven methods for learning about, analyzing, and documenting findings about estuaries.*

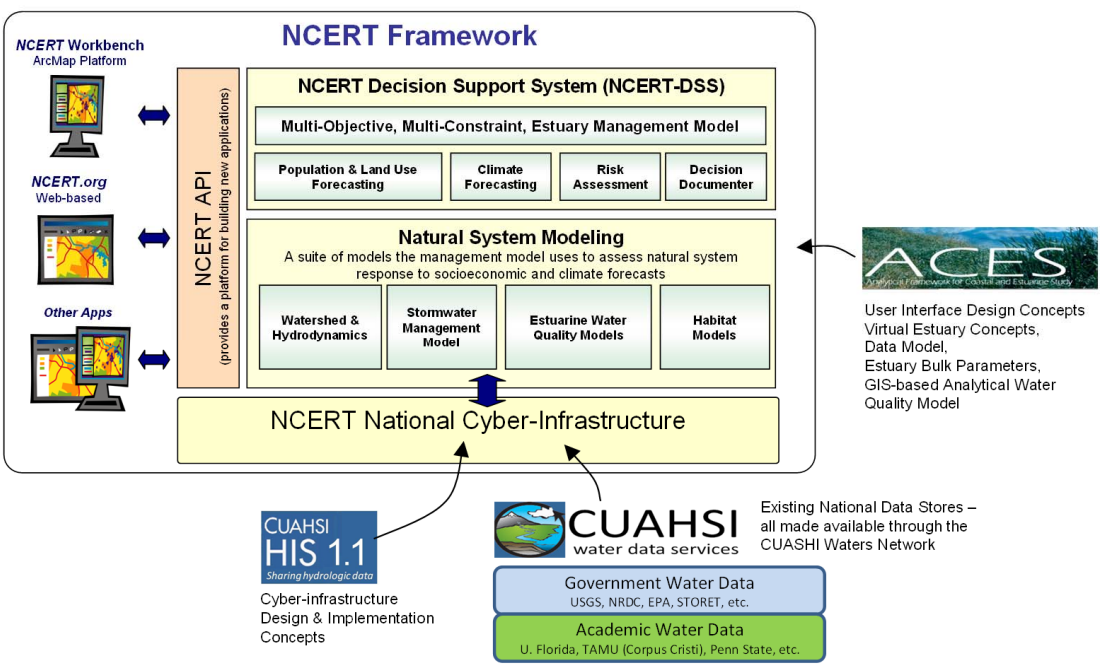

Figure 3. Proposed NCERT DSS framework.

These building blocks are each being developed in some form for efforts similar to NCERT. For example, the water resources and hydrology world is currently experiencing a leap forward in technological innovation with the continued development of the Hydrologic Information System (HIS) concept, a cyber-infrastructure based approach to making available the nation's water data (Maidment 2008). Another example is map-based web technologies, which have exploded in

recent years with the introduction of virtual globe browsers such as Google Earth. These technologies have focused heavily on making the experience the user has with a tool an intuitive one that ensures the user reaches the desired information quickly, without being required to adopt new technology concept models along the way.

Having identified the building blocks for the NCERT information solution and the emerging technologies that will be used to quickly build the solution, it is important to consider the way in which the solution will be built. A strong pragmatism is required in the process of solution development to ensure that adequate proof-of-concept is established early in the process and that sufficient developmental momentum is maintained. Sequencing of tasks and goals is paramount.

The technology developmental approach centers on the following:

- *Starting small and expanding to quickly identify challenges and ensure early success,*
- *Driving the development of technology with a realistic problem, and*

Targeted Research on Impacts of Climate Change and Population Growth

Given their wide geographic distribution across the U.S., the size, geomorphology, hydrology, and ecology of the 27 NERRs vary significantly. In addition, the degree of anthropogenic alteration and watershed development (e.g., dredge and fill, point sources, stormwater runoff) also varies widely among the NERRs. Despite this inherent variability, there are two common stressors that threaten the integrity of all the NERRs: climate change (and associated sea-level rise) and population growth (and associated impacts such as increased pollutant loading).

While each of the NERRs may have unique local and site-specific research priorities, we propose that, as part of the development of the NCERT Program, targeted research be implemented with the common focus of assessing the existing and potential future impacts of these stressors on the estuarine system integrity of each of the NERRs. Assessing and mitigating their effects are clear national priorities, and the implementation of a common thematic research platform will complement the collaborative process proposed for developing a comprehensive information system linking researchers and stakeholders participating in the NCERT Program. The targeted research results will be significantly leveraged, both through collaborative efforts and the dissemination of scientific findings nationally.

Existing data, and data collection needs, will vary widely among the NERRs. Therefore, the first step in the targeted research will be to conduct a complete inventory of available data. Data gaps will then be identified, thus establishing the first tier of research priorities. Furthermore, appropriate spatial and temporal analytical scales will need to be determined for each of the NERRs in accordance with the availability of existing data as well as locally specific management issues.

NORTH SLOPE DSS

The collaborative decision-making and management process for building a DSS described in the NCERT proposal is being implemented in the Northslope DSS, a tool for collaborative management of the North Slope in Alaska under proposed oil exploration. The Northslope DSS will support the construction of ice roads and ice pads to provide a cost-effective means of oil and gas exploration on Alaska's North Slope with minimal impact to the sensitive underlying tundra. Such ice structures have become integral to oil and gas exploration. Their widespread use represents a challenge to water resource managers, however, due to the large volume of water necessary to construct and maintain them. As the proximity of available fresh water sources has a significant impact on the planned location of ice roads and ice pads, changes in water resource management strategies could significantly impact oil and gas exploration activities.

Due to the fundamental role of water in natural and human systems, successful management of this resource is indeed essential to the broader issue of environmental protection and responsible energy development on the North Slope. The challenges of developing best management practices for water resources include the following: resource planning and management for efficient and sustainable water use; understanding and explicitly considering environmental impacts and protection; and developing and implementing effective participatory management strategies with representative stakeholder participation from all sectors.

This project is developing a water resources management solution in support of oil and gas exploration that explicitly considers optimal water use, direct and cumulative environmental impacts, and multiple objectives and values among stakeholders. The solution consists of an information system, software tools for decisions support, and methodologies for facilitating stakeholder involvement in the decision making process. The tools developed in this work will not only apply to the water management issues considered here, but will also be applicable to broader environmental management issues and industry development applications.

CONCLUSION

The challenge in building a DSS is to apply the needed resources for determining the appropriate types of research, without forcing a "one size fits all" product onto the System as a whole. **For this reason, an adaptive management process for identifying data and information needs and a mechanism for targeting and funding the necessary research are major elements of the DSS Program solution.**

Water resources management crosses many boundaries, including political, institutional, and natural. The complexity involved in the management of resources that includes inputs from all participants can be overwhelming. **Thus the proposed DSS solution provides for an inclusive, collaborative management process to**

assist in the understanding of these complexities and to arrive at better, scientifically sound management decisions.

Information management issues lie at the heart of many difficulties in making land and water resource decisions. Resolving certain information management problems—including too much information, a lack of information, data of uncertain quality, and difficulty connecting information from different sources and disciplines—can be addressed with existing technology. Other information management issues, however, must also be addressed, including a lack of standardized technology, resolving multiple data formats, easily accessing available information, and accessing data used to produce published literature and scientific reports.

The challenges of sharing data, models, and research findings must be overcome for stakeholders to fully benefit from their collaborative research efforts. In resolving these challenges, new tools must also be developed to enhance the interpretation of data and information and promote further collaboration between researchers. **For this reason, the development of a comprehensive solution for managing, sharing, and using information is a major element of a DSS solution.**

ABSTRACT

Droughts are prolonged abnormalities of moisture deficits that vary widely across temporal and spatial scales. Many hydrometeorologic variables are used to monitor the status of a drought. However, because of the dependence structure between all affecting variables under various temporal windows, an integrated spatio-temporal analysis of droughts cannot be easily achieved. In this study, a copula-based drought analysis was performed by using long-term monthly precipitation dataset for the upper Midwest United States. The spatio-temporal dependence relationships between various drought variables were investigated, and their joint probability distribution was constructed by combining drought marginals and the dependence structure. A copula-based joint deficit index (JDI) was adopted for an objective (probability-based) description of the overall drought status and compared to the Palmer drought severity index results. Results from the copula-based JDI provide information for drought identification, and further allow a month-by-month assessment for future drought recovery.

KEY WORDS: Copulas, Drought, Standardized Precipitation Index, Palmer Drought Severity Index

INTRODUCTION

Drought has been a challenging topic in water resources management. It is perceived as one of the most expensive and least understood natural disasters. Drought impacts tend to be more severe in areas such as the mid-western United States, where agriculture is the major economic driver. Droughts are categorized based on their impacts and duration. For example, meteorological droughts consider deficits in precipitation, agricultural droughts primarily consider deficits in soil moisture, and hydrologic droughts respond to streamflow deficits (Dracup *et al.*, 1980). Though these different types of deficits are generally positively correlated and are likely responding to the same trigger, they exhibit diverse temporal and spatial scales. An integrated drought indicator, that covers multiple types of deficits over different temporal scales, is therefore difficult to develop owing to the complicated dependencies in the variables that are used to characterize droughts.

Given their somewhat nebulous nature, the status of droughts is often assessed by various indices that are derived from hydrometorologic variables. Palmer (1965) proposed a moisture index (Palmer Drought Severity Index, PDSI) based on water budget accounting using precipitation and temperature data. PDSI soon became a popular choice for drought assessment and is widely used even today (Dalezios *et al.*, 2000; Kim *et al.*, 2003). Another popular index - Standardized Precipitation Index (SPI) was introduced by McKee *et al.* (1993). Based on a given window size, the rainfall depth is transformed to its corresponding cumulative probability, and then mapped onto the standard normal scale. The probabilistic nature of SPI allows it to be comparable among various locations and variables, and it can be further interpreted in terms of recurrence intervals (return periods). Nevertheless, to judge an overall drought status, different SPIs with multiple temporal scales (e.g. 3-, 6-, 9-, 12-month) need to be examined.

Despite the availability of different drought indices, no single index is ideal for characterizing droughts. The drought status that is assessed from one indicator often does not correspond well with that obtained from another. Therefore, to successfully assess the various drought characteristics, information from various sources need to be examined simultaneously. This is currently successfully managed by the US Drought Monitor where the severity of a drought (D0 ~ D4) is determined based on various indicators (PDSI, CPC Soil Moisture, USGS weekly, Percent of normal, SPI, and VCI), and from human input as described by Svoboda *et al.* (2002). Nevertheless, though an Objective Blend of Drought Indicators (OBDI, a linear weighted average of several indicators) is adopted as a measure of the overall severity, the decision of final drought status relies heavily on the subjective judgment of many people, instead of invariant objective standards. Because of the subjective intervention in specification of drought status, a rigorous analysis of the physical and probabilistic characterization of droughts is challenging.

There is a need to develop objective standards for analyzing records and specifying drought status based on multiple variables. So far, one of the major stumbling blocks to such an approach has been our inability to describe the complicated dependent relationships between various drought-related variables. To accomplish this goal, this study employed copulas to identify and construct the dependence structure of droughts. Building on the analysis, we propose a new copula-based drought indicator that enables the computation of a probability-based overall water deficit index from multiple drought-related quantities (or indices). By invoking copulas, we construct joint distributions of droughts so that marginal distributions of relevant variables and their dependence structures can be fully preserved. The joint distribution affords an objective description of the overall deficit, and assists the computation of probabilistic quantities such as return period and associated risk of a drought.

COPULAS

Over the last decade, copulas have emerged as a powerful approach in simplifying multivariate stochastic analysis. Sklar (1959) showed that for *d*-dimensional continuous random variables $\{X_1,...,X_d\}$ with marginal cumulative distribution functions (CDFs) $u_j = F_{X_j}(x_j)$, $j = 1,...,d$, there exists one unique

d-copula $C_{U_1,...,U_d}$ such that:

$$H_{X_1,...,X_d}(x_1,...,x_d) = C_{U_1,...,U_d}(u_1,...,u_d) \quad (1)$$

where u_j is the j^{th} marginal and $H_{X_1,...,X_d}$ is the joint-CDF of $\{X_1,...,X_d\}$. Copulas $C_{U_1,...,U_d}$ can be regarded as a transformation of $H_{X_1,...,X_d}$ from $[-\infty,\infty]^d$ to $[0,1]^d$, in which the marginal distributions are segregated from $H_{X_1,...,X_d}$. Hence, $C_{U_1,...,U_d}$ becomes only relevant to the association between variables, and it gives a complete description of the entire dependence structure. This approach is available for all existing joint distributions, and it further provides a general method for constructing suitable joint distributions. Kao and Govindaraju (2007) showed that copulas allow for easier computation of probabilistic quantities such as means and standard deviations of rainfall excess. The detailed theoretical background and descriptions for the use of copulas can be found in Nelsen (2006). Specific properties that are central to the implementation of study are described below.

Choices of Copulas for Higher Dimensional Joint Distributions

Previous studies have indicated that copulas perform well for bivariate problems, and in particular Archimedean copulas have been a popular choice. However, the direct extension of Archimedean copulas to higher orders (>2) is very limited because they impose severe restrictions on the pair-wise mutual dependencies that can be accommodated, and compatibility conditions are far more difficult to satisfy in higher dimensional problems (Kao and Govindaraju, 2008). Only few parametric copula families with general applicability such as meta-elliptical copulas are available at higher dimensions (Genest *et al.*, 2007). Nevertheless, the computational burden associated with meta-elliptical copulas increases rapidly with increasing dimensions since explicit expressions exist only for the copula densities and not for the copulas themselves. The dimension of drought dependence structure is expected to be quite large to capture the temporal behavior, and consequently nonparametric empirical copulas are chosen in this study.

Similar to the concept of plotting position formula used in univariate statistical analysis (e.g. Weibull formula), empirical copulas are rank-based empirical joint cumulative probability measures (Nelsen, 2006). For sample size *n*, the *d*-dimensional empirical copula C_n is:

$$C_n\left(k_1/n, k_2/n, ..., k_d/n\right) = a/n \quad (2)$$

where a is the number of samples $\{x_1,...,x_d\}$ with $x_1 \le x_{1(k_1)}$, …, $x_d \le x_{d(k_d)}$, and $x_{1(k_1)}$, …, $x_{d(k_d)}$ with $1 \le k_1,...,k_d \le n$ are the order statistics from the sample. Empirical copulas are mostly used for model verification and are treated as the observed (real) dependence structure. When a sufficiently large sample size is available, empirical copulas can be used to construct non-parametric joint empirical probability distributions, which tend to be more computationally efficient. This is a

desirable feature for drought analysis.

Distribution Function of Copulas - K_C

For given *d*-variate sample marginals $\{u_{1x},...,u_{dx}\}$, a copula $C_{U_1,...,U_d}(u_{1x},...,u_{dx})$ is the cumulative probability measure $P[U_1 \le u_{1x},...,U_d \le u_{dx}] = q$. One can expect that there exist other sample marginals $\{u_{1y},...,u_{dy}\}$ with the same value of cumulative probability $C_{U_1,...,U_d}(u_{1y},...,u_{dy}) = q$. If this cumulative probability q is treated as an indicator, i.e. events with same value q are assumed to cause similar impact (e.g. in drought analysis it can be defined as joint deficit status, a smaller q implying overall drier conditions), then it will be of interest to know what the probability of random event $\{U_1,...,U_d\}$ with $C_{U_1,...,U_d}(U_1,...,U_d) = q$, or $C_{U_1,...,U_d}(U_1,...,U_d) \le q$. In this context, the distribution function K_C of copulas can be defined as the probability measure of the set $\{(U_1,...,U_d) \in [0,1]^d \mid C_{U_1,...,U_d}(U_1, ...,U_d) \le q\}$:

$$K_C(q) = P[C_{U_1,...,U_d}(U_1,...,U_d) \le q] \quad (3)$$

Salvadori and De Michele (2004) adopted K_C for defining a secondary return period for bivariate Archimedean copulas. The most appealing feature of K_C is that it can help project multivariate information onto a single axis. Though an analytical expression of K_C might not exist for non-Archimedean copulas, it can be numerically constructed from Monte Carlo simulations, and then the empirical distribution function K_C may be constructed as (example shown in Kao and Govindaraju, 2008):

$$K_{C_n}(l/n) = b/n \quad (4)$$

where b is the number of samples $\{x_1,...,x_d\}$ with $C_n(k_1/n,...,k_d/n) \le l/n$. K_C allows us to compute the probabilistic measure of the joint deficit status, which can be further translated to a joint drought index.

DATA USED IN THIS STUDY

To construct reliable multivariate statistical models, sufficiently long observations are desirable. In the proposed study, the Time Bias Corrected Divisional Dataset (TD-9640, http://www7.ncdc.noaa.gov/CDO/CDODivisionalSelect.jsp#) is adopted for the mid-western US (including states of IL, IN, IA, KS, MI, MN, MO, NE, ND, OH, SD, and WI). The data consists of monthly average temperature, precipitation, SPI and PDSI of each climate division within US from January 1895 to present (see Karl (1986) and Karl *et al.* (1986) for more details), and also provides an areal averaged value of the drought status. To investigate the droughts on a finer scale, the precipitation records over Indiana were obtained from the daily surface dataset (TD 3200) of cooperative stations (COOP) from National Climate Data Center (NCDC). After data processing (such as quality assuring with neighboring stations), a

total number of 73 stations with record lengths greater than 80 years were used in the analysis discussed ahead. Monthly precipitation was computed based on aggregated daily values. In cases where data was missing for the entire month (around 1.22% of the entire precipitation dataset), it was replaced by the historic mean of that specific month (assuming normal moisture status for that unknown month). We adopted copulas for conducting at-site analyses to capture temporal evolution of droughts, and used spatial interpolation for assessing the behavior over the regional scale.

COPULA-BASED JOINT DROUGHT DEFICIT INDEX

In this study, the standardized precipitation index (SPI) introduced by McKee *et al.* (1993) was adopted for developing a copula-based joint drought deficit index. There are several reasons for adopting SPI: (1) it can be applied to precipitation, streamflow, and other variables as well, (2) it does not incur model assumptions that are typical for other indices such as PDSI, and (3) it is a probability measure of cumulative precipitation by definition. Therefore, drought severity (dryness) is normalized in terms of probabilities that can be compared between various temporal scales, locations and variables. Since the current SPI approach cannot account for seasonal variability, an amendment proposed by Kao and Govindaraju (2009) was adopted in order to obtain a more statistically sound SPI. For a *w*-month SPI, the corresponding *w*-month marginal u_w can be expressed as

$$u_w = \phi(\mathrm{SPI}_w) \tag{5}$$

in which ϕ is the standard Gaussian CDF. Referring to the definition of drought categories used in US Drought Monitor (Svoboda *et al.*, 2002), Table 1 shows the range of SPI values along with their probabilities of occurrence and corresponding drought conditions.

Table 1. The categories used in US Drought Monitor along with the corresponding SPI values.

SPI Values	Prob. of Occurrence (%)	Drought Condition	Drought Monitor Category
-0.84 ~ -0.52	20 ~ 30	Abnormally dry	D0
-1.28 ~ -0.84	10 ~ 20	Drought - moderate	D1
-1.64 ~ -1.28	5 ~ 10	Drought - severe	D2
-2.05 ~ -1.64	2 ~ 5	Drought - extreme	D3
< -2.05	< 2	Drought - exceptional	D4

Droughts have varying durations and a single SPI cannot capture the overall status. By invoking copulas, the dependence structure of selected SPIs was constructed, and the overall deficit status was expressed as joint cumulative probability (a lower probability measure corresponds to overall dry conditions) thus allowing for a more comprehensive assessment of droughts. To capture the short- as well a the long-term droughts, window sizes from 1-, 2- to 12-month ($w = 1, 2, \ldots, 12$) were selected. Empirical copulas (Eq. 2) were adopted to construct the dependence structure for precipitation marginals $\{u_1, u_2, ..., u_{12}\}$. Since the record lengths are quite large (>1000 data points for most of stations and climate divisions), empirical copulas were assumed to provide reliable results. The choice of $\{u_1, u_2, ..., u_{12}\}$ in forming

high dimensional copulas increases the complexity of the dependence model. Nevertheless, it was needed because drought durations exhibit wide temporal variations, and only by encompassing various durations (e.g., from 1- to 12-month) the drought characteristics can be analyzed. An annual cycle also accounts for seasonal effects naturally. Moreover, this construct allows for a month-by-month assessment for future conditions, as will be shown later.

After a copula has been constructed, it yields the cumulative probability $P[U_1 \le u_1,...,U_{12} \le u_{12}] = q$. Clearly, when a drought occurs, most of the marginals u_w will be small and result in a small value of *q*. Therefore, the cumulative probability *q* can be viewed as the *joint deficit status* with a smaller *q* implying overall drought conditions while a higher *q* would imply overall wet conditions. We note that the joint deficit status *q* is linked to the given set of marginals and is only comparable to other *q* with the same set of marginals. For instance, q_1 for $\{u_1, u_2,..., u_{12}\}$ and q_2 for $\{u_1, u_2,..., u_{11}\}$ are not comparable. Therefore, a more general index derived from *q* is desirable. By assuming that events with the same value of *q* will have similar joint drought severity, it will be of interest to know the cumulative probability for events with joint deficit status less than or equal to a given threshold *q* (i.e., $P[C_{U_1,...,U_{12}}(U_1,...,U_{12}) \le q]$). The distribution function of copulas K_C (Eq. 3) provides this probability. Therefore, a *joint deficit index* (JDI) can be defined analogously to SPI:

$$\text{JDI} = \phi^{-1}(K_C(q)) = \phi^{-1}(P[C_{U_1,...,U_{12}}(U_1,...,U_{12}) \le q]) \quad (6)$$

where positive JDI ($0.5 < K_C < 1$) implies overall wet conditions, negative JDI ($0 < K_C < 0.5$) indicates overall dry conditions, and JDI zero ($K_C = 0$) indicates normal conditions. In other words, JDI is based on the cumulative probability of joint deficit status *q*. An extreme drought will result in a small *q*, and the JDI will correspondingly yield a low probability. Since JDI is on an inverse normal scale (same as SPI), the classifications listed in Table 1 can be adopted for JDI as well.

An illustration of the JDI using precipitation marginals of station Alpine 2 NE in Indiana (COOPID: 120132) is shown in Figure 1. JDI, SPI_w, $w = 1, 2, \ldots, 12$ and the corresponding 12-month precipitation values are presented for four select cases. In Fig. 1(a), SPI_w values observed in all window sizes for June 1988 report large precipitation deficits indicating a severe drought, which is also noted in the JDI. Nevertheless, only by invoking JDI can the overall deficit status be expressed as a probability-based index. Fig. 1(b) shows an opposite case, in which JDI and SPI_w observed in all window sizes for August 1985 report sufficient precipitation. One can notice that JDI is slightly higher than all other SPI_w in this instance. Since JDI is based on the joint probability of all SPI_w, it suggests that the joint behavior of a drought cannot be assessed by a simple weighted average of SPI_w due to the effect of dependence structure. Fig. 1(c) shows a case of emerging drought in February 1978, in which SPI_w is quite small due to the large precipitation deficit in February while

other SPI_w are above normal. This case is difficult to interpret since most of the indices do not capture droughts in a timely manner. The JDI reflects a drought condition based on the entire dependence structure. Fig. 1(d) shows a prolonged drought in Oct. 1988, in which SPI_1 and SPI_2 report sufficient precipitation in September and October while other SPI_w report precipitation deficit due to the preceding drought. Therefore, an important feature of JDI is that the overall deficit status is based on the dependence structure of deficit indices with various temporal windows. When the deficit indices are found to be uniformly low, the resulting joint drought index will be extremized due to its rareness.

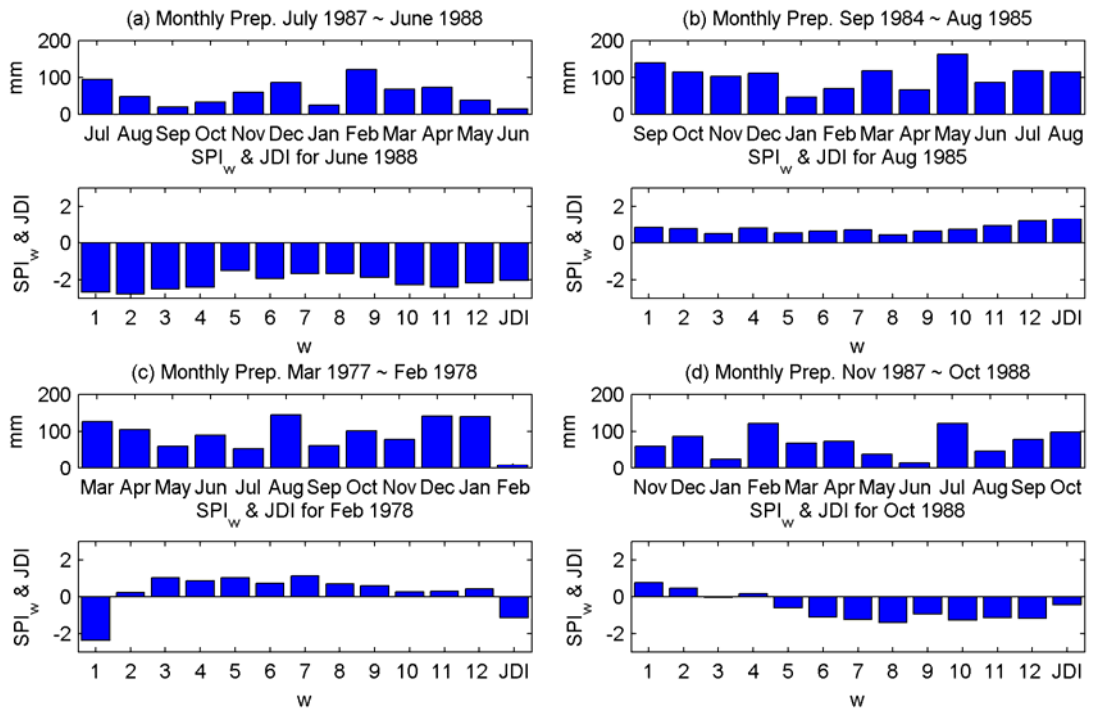

Figure 1. Illustration of JDI and SPI_w, w = 1, 2,…, 12 of precipitation station Alpine 2 NE, Indiana (COOPID: 120132) for four selected cases.

COMPARISON BETWEEN VARIOUS DROUGHT INDICES

To gain more insights into the proposed drought index, a comparison between JDI, SPI_1, SPI_3, SPI_6, SPI_9, SPI_{12} and PDSI was performed using the TD-9640 dataset for the Midwest. Since PDSI has been included in TD-9640, only JDI and modified SPIs were computed for each climate division. Spearman's rank correlation coefficients between different indices were constructed and are shown in Table 2.

Table 2. Average Spearman's rank correlation coefficient between various drought indices of the entire Midwest

	SPI_1	SPI_3	SPI_6	SPI_9	SPI_{12}	JDI
JDI	0.72	0.80	0.79	0.76	0.70	
PDSI	0.45	0.66	0.75	0.77	0.76	0.79

The comparison indicates that the correlation between JDI and SPIs are

generally high (0.7 ~ 0.8). This is anticipated since JDI is built on SPIs with various window sizes. In other words, JDI represents the overall drought status with respect to different temporal scales. We then compare both JDI and SPI to the commonly used PDSI, which is based on a somewhat different water accounting approach. While the correlation between PDSI and SPIs increases with window sizes, it is of interest to note that the JDI shows good similarity to PDSI, especially for the eastern part of Midwestern US as illustrated in Figure 2. Though a more in-depth analysis should be conducted to see why these two different approaches can independently produce similar results, it indicates that JDI can effectively combine SPIs to form an overall drought index. The JDI approach can also be applied to other mixtures of indices, and is worthy for further investigation.

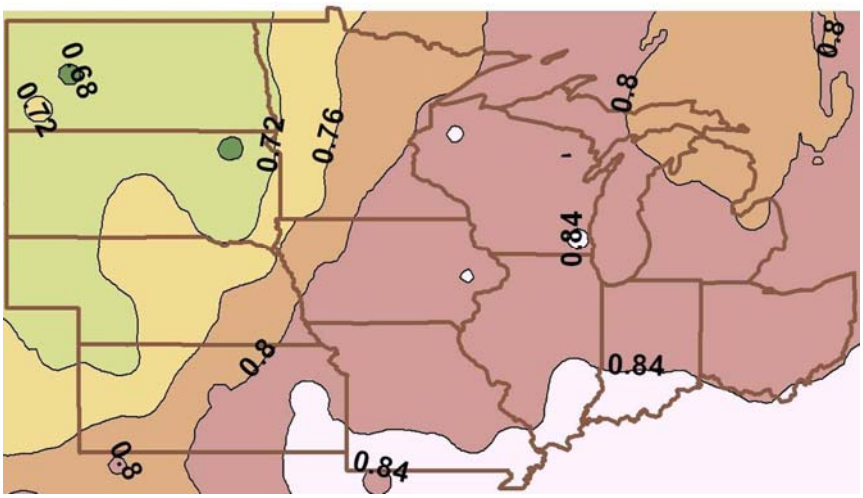

Figure 2. Spearman's rank correlation between JDI and PDSI of the Midwest

USING JDI TO ASSESS THE POTENTIAL OF FUTURE DROUGHTS

The adoption of high dimensional marginals facilitates a month-by-month future drought potential assessment since JDI is based on temporal dependence structure of deficits. Therefore, it will be of interest to know under given current conditions, what amount of precipitation is required in the following months to bring the joint deficit status to normal (JDI = 0 or $K_C = 0.5$). In other words, how much precipitation is required in a future time horizon to recover from an existing drought? This can be achieved via an iterative procedure described in Kao and Govindaraju (2009). A regional illustration of the required precipitation for July 1988 to achieve normality based on the observations made from August 1987 to June 1988 and the corresponding probability of exceedance is shown in Figure 3. As indicated in Fig. 3, a majority of Indiana would have needed over 150-mm of rain in July 1988. Based on historical July precipitation, this information can be further transformed into exceedance probability, and it suggests that the probability for recovering to normal conditions is small (less than 0.1 for most of the state). Such drought maps can be an effective way of relaying drought information, as most of the current indices are not amenable to statistical interpretation and are artificially converted into drought severity levels.

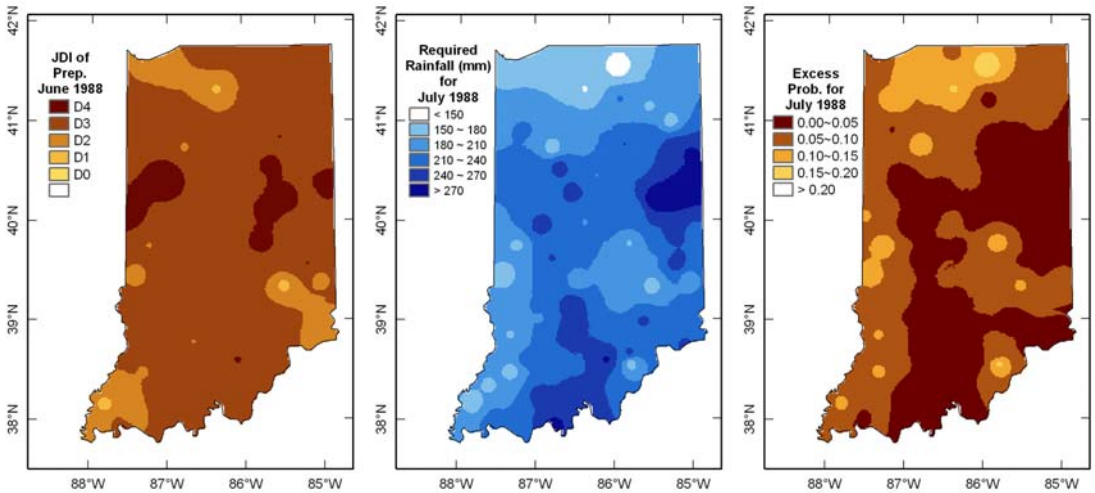

Figure 3. Illustration of (a) left: JDI for June 1988, (b) center: required precipitation for July 1988 to achieve normal status ($K_C = 0.5$ or JDI = 0), and (c) right: the corresponding excess probability of Indiana based on the observations made from Aug 1987 to June 1988

CONCLUSIONS

The complex relationships between drought-related variables have hindered characterization of overall drought status in the past. However, copulas provide a promising method for characterizing the complicated dependence structure by using a modified SI based on observed rainfall and streamflow data. The dependence structures of precipitation marginals with window sizes varying from 1- to 12-months were constructed via empirical copulas. The reliability of empirical copulas was founded on the large sample sizes adopted in this study. Study results can be summarized as follows:

(1) A joint deficit index (JDI) was proposed in this study using the distribution function K_C of copulas. The JDI offers a probability-based drought index from a set of SPIs with various temporal window sizes. This is an improvement over conventional drought status indices that could be estimated through subjective judgments or by linear weighted SPIs. Besides providing objective description of the overall drought status, the JDI was shown to be capable of capturing both emerging and prolonged droughts in a timely manner.

(2) Comparing to SPIs with various window sizes, the JDI is found to resemble behavior of PDSI especially for the eastern part of Midwestern US. Thus, JDI can effectively combine drought status with various temporal scales to form an overall deficit index. The similarity in the performance of two independently derived indices (PDSI and JDI) deserves further investigations.

(3) Drought severity can be assessed through the proposed JDI approach. For instance, the required precipitation for achieving normal conditions (JDI = 0) can be estimated. The required rainfall depth along with its exceedance probability provides good interpretation of drought status and mitigation needs.

The utilization of copulas in drought characterization was demonstrated in this study. Copulas can play an important role in drought analysis and perhaps in other hydrometeorological studies as they enable multidimensional stochastic analysis.

Abstract

Water-sharing in a river basin by different users as well as between different stakeholders along the river basin has been a serious problem and becomes more complex when there is an acute shortage of supply in the river basin. Many negotiations and interactions take place between the farmers as well as between the watersupplier and the farmers before the actual water allocation takes place. This paper presents a novel approach of agent based modeling for solving the water allocation problem. Agent based modeling using a multi-agent approach has been used to represent the various interactions between stakeholders during the process of water allocation. The spatial multi-agent programming model has been used for assessing the performance of the water allocation strategies. It is found that the developed model could provide the various possible scenarios and their consequences to the decision makers. The developed model is very generic and consists of a group of farmers with different farm sizes and crops, and a water supplier who does the allocation. The water allocation rules are built into the functioning of the models and are used to evaluate the performance of the developed rules. The performance indicators adopted in this model include individual farmers view point where one could observe the water needs and water allocated per unit area, global viewpoint with the overall yield, and the ethical viewpoint with disparities in water allocation and yields. It is found that the developed model has been proved to be successful to evolve a compromise and effective solution for the water allocation problem, when the model was applied to a case-study in Tamilnadu, India.

INTRODUCTION

Water Resources Management is the concept integrating the different aspects of water resource systems namely a number of water sub-sectors such as hydropower, water supply and sanitation, irrigation and drainage, and environment. An integrated water resources management perspective ensures that social, economic, environmental and technical dimensions are taken into account in the management and development of water resources (Lee and Dinar, 1995).

In this paper, a tool for water resources infrastructure planning has been developed by applying agent-based modeling to integrate physical, hydrological, social and economic aspects of water resource management. This tool is proved to provide insights into the social processes of water management, leading to consideration of a wider range of the environment in decision-making.

The main objective of the paper was set to evaluate the applicability of agent-based modeling of problems of water resources planning and management. For doing this, agent-based models are developed which are applied for assessing the economic, social, and environmental effects of alternative management policies. The situation of water sharing between different farmers is considered; and models are developed to evaluate the performance of different water allocation rules. Using these models it is shown to the policy makers the possible consequences of different water allocation rules.

Using **SeSAm** software, generic multi-agent models have been developed to test the efficiency of the four different sets of water allocation rules. The four different sets of water allocation rules are simulated using the four models and their performance is compared with respect to each other, based on different criteria such as realization of individual water needs, disparities between farmers, and global outputs.

Berger (2000) attempted to develop a new mathematical programming approach for prediction of diffusion processes, natural resource changes, and policy responses. The model class developed used a multi-agent/cellular automata approach by using heterogeneous farm-household models and capturing their social and spatial interactions explicitly. The individual choice of the farm-household among available production, consumption, investment and marketing alternatives is represented in recursive linear programming models. The models applicability is tested on an empirical policy-related research question in Chile.(Le Bars, 2007) in which the use of farm-based linear programming within a Cellular Automata framework was proved to be successful.

A tremendous amount of work has been accomplished during the past three decades in developing computer models for use in water resources planning and management. Powerful generalized software packages are playing an increasingly important role in all aspects of water management. With recent advances in computer technology, essentially everyone working in the water resources and environmental field now has convenient access to desktop computers providing all the hardware capabilities needed to execute a mighty arsenal of available models. Computer modeling is no longer limited solely to organizations that can afford expensive mainframe computers.

Mathematical models have been used in agriculture and water resource economies for almost half a century (Srbljinovic and Ognjen, 2003). Organizing data and processes in input and output vectors has proven to be the appropriate format for merging rather multidisciplinary information from farmers, agronomists and

agricultural engineers. In combination with a properly defined objective function, mathematical programming provides a way of integrating/including human decision making into agricultural production and resource use models.

However, if the portrayed real-world situations are characterized by spatial and behavioral heterogeneity together with economic and ecological instability, such models are often poor predictors of human behavior and might therefore fail to provide reliable information for policy analysis (Claudia, 2002). Since they largely neglect the complexity of human interactions and spatial relations, they are especially weak in analyzing the role of technological change and human organization.

AGENT-BASED MODELS FOR WATER RESOURCES PLANNING

Models associated with water resources planning and management; generally have various components which are spatially adjacent and generally interrelated. If one considers the situation of water sharing between farmers for example, during the process of water distribution a lot of interaction and negotiation takes place between all stakeholders, namely the farmers and the water supplier. The advantages of using agents-based models in such situation as well as the few limitations are discussed in the following sections.

Multi-Agent Systems (MAS) or Agent based models are computer systems composed of autonomous entities or agents which have only limited knowledge and information processing capabilities. While agents can b as simple as subroutines of a computer program, typically they are larger entities with some sort of persistent control. Good examples are personal electronic assistants that search for information on the Internet, arrange their owner's time schedules, and assist car drivers. Accordingly, on a more abstract level, their purpose is to solve larger, complex problems that one centralized unit cannot tackle, because too much information and computation power would be required. In MAS, agents instead interact and exchange information in a decentralized and somewhat 'social' manner, which explains why the term 'Distributed Artificial Intelligence' was coined. Particularly, this last aspect makes MAS an interesting tool for the social sciences. The idea is to use computer simulations with humanlike agents in order to study how an aggregation of individuals leads to complex macro behavior. These *in silico* experiments will help to test hypotheses on the fundamental social mechanisms in human societies. Typically, the agents occupy positions on a two-dimensional grid of cells and distances between them influence their interactions.

SeSAm model is the agent based model platform used in this study for the development of agent-based models. **S**e**SA**m stands for Shell for Simulated Agent Systems. SeSAm was and is further developed at the Universität Würzburg and can be freely distributed. It provides a generic environment for modelling and experimenting with agent-based simulation. It is a tool for the easy construction of complex models. The important features of SeSAm are:

- Agents consist of a body that contains a set of state variables and a behavior that is implemented in form of UML-like activity diagrams.
- Activities are seen as simple scripts that are initiated and terminated based on rules.
- The actions and conditions can be composed of an extensive number of primitive building blocks; a user is able to design visually a simulation without programming in a traditional language.
- User functions, features (set of variables and functions) and user defined data types provide a possibility to construct higher level building blocks.
- A component for evolutionary adaptation of parameters is also integrated. All is implemented visually in form of quasi declarative descriptions. These are executable in the same environment.
- Dynamics of this simulation may be observed in form of animation or user configured, autonomously updating curves.
- As there are freely configurable instruments for gathering data and scripting options for constructing simulation experiments, SeSAm is a highly valuable tool for MAS simulations especially for complex models with flexible agent behavior and interactions.

For running the simulation one has to choose the appropriate situation and analysis list and create a simulation. Now the simulation is ready for running. Before running one can choose to run to run it continuously or in pre-specified step sizes. After building the model one can run the simulation and observe the animation and on-line evaluation curves. All steps can be assessed in a visual way.

METHODOLOGY

The objective of the model is to show the evolution of a group of farmers over a number of years who use a limited water resource. A water supplier manages the resource and allocates the water to different farmers based on the water allocation rules of the system.

The current model is generic one and does not correspond to a local situation. The aim is not to provide the optimal solution but only to show the negotiators the possible consequences of the water allocation rules they decide to use. For this four different sets of water allocation rules are simulated using models and compared with each other, according to different criteria such as realization of individual water needs, disparities between farmers, and global outputs. However, in this paper one water allocation model has been demonstrated with an illustrative example. The model is mainly conceptualized on the Water allocation rules based on fair water requests by the farmers. In this model, **a**ll farmers evaluate their water requirements based on the farm sizes and type of crop being cultivated and send the requests based on the actual water requirement. All the farmers request only for the actual water requirement, as per the area of their farms and type of crop being cultivated.

If the total water available (with the water supplier) is more than the sum of all the water requests, then each farmer gets the amount of water he requested for i.e., the

water request. Otherwise, the water supplier water supplier allocates the available water to the farmers in proportion of the individual water requests.

For the model development, the suitable reasoning engine of the farmer agents needs to be adopted. The water supplier agent/water supplier-farmer as well as the test situation world are same, as the reasoning engine of the Farmer Agents takes care of all the interactions and information exchanges. In the simulation, each year consists of a sequence of four information exchanges which are:

- Each farmer determines the type of crop to be cultivated. The model considers two types of crops: crop 1 and crop 2. Each of these crops has its own water requirements and yield. The type of crop is decided based on the performance of farmers of each crop type in the previous year. For the first year the farmers are manually assigned to one type.
- The farmers send information to the water supplier based on which the water supplier has to allocate the water resource. The nature of this information depends on the rule being simulated. This information can either be as a direct water request or information about farm sizes, etc.
- The water supplier receives the information (the water requests on farm sizes information) from the individual farmers. Now he allocates water to the farmers in accordance with the water allocation rules and the amount of water available with him.
- The farmers receive the information about the amount of water that is allocated to them. Based on this the yield of each farmer can be calculated.

The model was run for 5 years and at the end of each year, farmers who perform badly change their crops. At the end of the simulations one can analyze the performance of the rules based on different criteria-individual farmers view point where we observe the water needs and water allocated per unit area, global view point with the overall yield, ethical view point with disparities in water allocation and yields. Also, the water allocation rules basically describe the interaction between the farmers (Farmers Agents) and the water supplier (Water Supplier Agent/WaterSupplier- Farmers World) which eventually leads to the water allocation. So, the reasoning engine for the Farmer Agents will be different for the four models accordingly.

The following set of variables which describe the state of the Farmer Agents. The state of the Farmer Agents in the four models is described using a combination of this set of variables. The main variables considered are Farm size, type of crop, Water Requirement per Unit Area, Water Requested by the Farmer, Informed Water Request by the Farmer, Water Allocated to the Farmer, Water Allocated to the Farmer per Unit Area, Yield of the Farmer, Ratio 1, Ratio2, and the change in the crop type. The functioning of models is based on the interaction between the Farmer Agents and Water Supplier Agent & Water Supplier-Farmers World. This interaction depends primarily on the reasoning engines of the Farmer Agents. The reasoning engines consist of a series of activities, which are performed when certain rules are satisfied. Each of the activity takes on time step of the simulation to complete.

- **Initialization:** Based on the Test Situation configuration the farmer agents will know their respective Size of Farm. For the first year the Type of Crop for each of the farmer agent is manually assigned randomly. For subsequent years, the each farmer agent first compare their Ratio1 and Ratio2 with those of a neighboring farmer (chosen randomly), if both ratios of the farmer are lesser than those of the neighbour the farmer switches to crop type, otherwise he continues with the same crop. Once the farmer agent decides the crop type, the total Water Requirement and Water Requirement per Unit Area will be evaluated.

- **Activity 1 – Sending the Water Request to the Water Supplier Agent:** In this model all the farmer agents request only for the required amount of water. Thus the amount of Water Requested by the Farmer will be the same as the water requirement. This information is sent in the following manner-all the farmer agents increment the value of Sum of all Water Requests (which is a variable of the Water Supplier/Water Supplier Farmers World) by the amount of their respective water requests.

- **Activity 2 – Water Allocation by the Water Supplier Agent:** As per the allocation Rule 1, the water supplier has to distribute the Total Available Water to the farmers in proportion of their individual Water Requested by the Farmer. The water allocated to each farmer will be the product of Water Requested by the Farmer and Alpha..

- **Activity 3 – Receiving the Water Allocation information by the Farmers:** The farmer agents receive the value of Alpha and based on that the each farmer knows the amount of water allocated to him. All the farmer agents evaluate the values of Water Allocated to the Farmer, Water Allocated to the Farmer per Unit Area and Yield of the Farmer.

Then the simulation elements namely the test situation and the analysis list are to be contrived.. It is to be noted that the configuration of the simulation elements, it is proposed to simulate the performance of the water allocation rules in the given environment, with the same configuration of map, with number of farmers placed in the same manner.

RESULTS AND DISCUSSIONS

For the demonstration of the proposed methodology, a 10 × 10 map is used as the world (Fig. 1). A total of 100 farmer agents have been considered, one for each of the hundred grids. Among these 100 farmers there are 10 big farmers, 30 medium farmers and 60 small farmers. These 100 farmers are placed on the map manually in a random manner. Then each of these farmers is assigned a crop type manually (Fig. 2). Then the value of total available water (MCM) for the world was given as the input and this completes the configuration of the test situation.

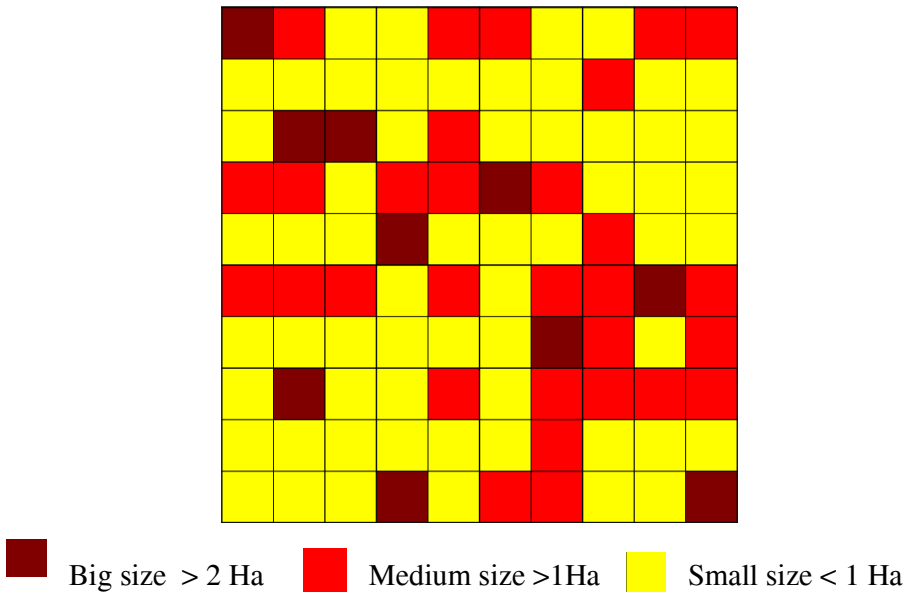

Fig 1. Map Configurations – Placement of Farmers

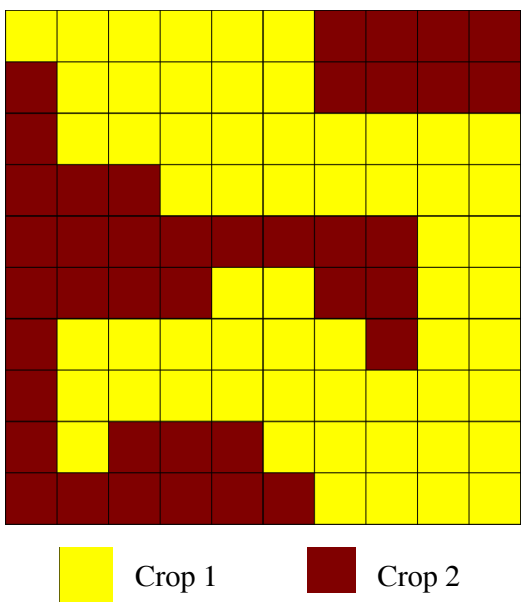

Fig.2 Crop types at the beginning of the first year

The analysis list can be used to specify what data is to be exported and in what format. We transfer the values of all the variables for each of the farmer agents to an excel spreadsheet, where we use to evaluate the performance of the four water allocation rules with respect to certain criteria. In the model, one year consists of initialization followed by three and the simulation was run for 5 such years, to see the performance of the rules both in the short term and long term. In our simulation

one step consists of one activity being performed, so four steps of the simulation make up one year (except the first year which has only three steps). The performance at the end of every fourth step starting from step three (3, 7, 11, 15 and 19 have been presented here.

For the first year the crop type of each farmer is manually assigned during configuration of the test situation. After the first year is over the values of the entire set of variables defined are calculated for the world and all the farmer agents.Then each farmer looks around selects one neighbor and compares his performance (in terms of yield) with the neighbors as well as the equitability of the water distribution process. If he performs badly, he will change his crop type otherwise he will continue with the same crop. So as the simulation continues, farmers who perform badly switch crop types. The criteria used for evaluating and comparing the performance of the water allocation rules are: global view point with the overall yield, individual farmers view point where we observe the water needs and water allocated per unit area, ethical view point with disparities in water allocation and yields.

During the simulation run, the change in the cropping pattern can be observed in the form of animation. At the end of the year the cropping patterns are captured in the form of image files for all the four models. Using these one can observe the behavior of farmers with respect to crop selection. The variations of overall yield of all the farmers with time for each model are shown in Fig. 3. It can be seen that there is a gradual increase in overall yield as time passes. This is because more and more farmers switch to Crop Type 1 as years pass by, and Crop Type 1 is more responsive to additional increments of water than Crop Type 2. The changes in crop pattern for the developed model are shown in Figure 4. It can be seen that as years pass by most of the crop 2 farmers change to Crop 1. This is because all Crop 2 farmers have higher water allocated per unit area and also productivity of Crop 2 is higher and more responsive to additional water. So, if Rule 1 is applied it is possible that after sometime all the farmers change to Crop 1 and totally abandon Crop 2.

CONCLUSIONS

The models developed are applied to the hypothetical case study and performance of the the typical water allocation rules is analyzed. It is found that Rule 1 leads to a fair satisfaction of all the farmers water needs, whereas all the other three rules result in inequitable situations with some of the farmers getting more than the required amount of water. If one looks at the equitability of the rules in terms of individual farmer yields, Rules 1 and 3 perform very well. Rule 3 results in the most inequitable distribution of individual farmer yields, with Rule 4 performing slightly better than Rule 3. It is concluded that the same rules may perform differently in a different situation, based on the configuration of farm placement, farm behavior, etc. Though the models developed are generic in nature, one can apply them to any situation and any set of water allocation rules by making changes in the agent behavior and configuration of the world. The present study also firmly establishes that agent-based

modeling is an appropriate modeling framework for testing water allocation rules. This is because, agent-based modeling is well adapted to modeling many types of agents with different rationalities. Further, multi-agent systems provide adequate structure to represent multiple and complex interactions between various kinds of agents (like farmers and water supplier) that have an important place in the process of water allocation

Analysis on effect to EVW from policy intervention

(Ruan Ben-qing Zhang Chun-ling Wang Cheng-li Xu Feng-ran)
(China Institute of Water Resources and Hydropower Research, Beijing, China, 100038)

Abstract: High benefit utility of water is one of the main goals on water management activity. Calculational economic value of water (EVW) of industry by appropriate method can express the benefit of water use, which may be intervened by some policies, such as industry structure adjusting, water pricing, and product techniques innovating ect. The effects to EVW from the policies intervention in Beijing are discussed, which will be propitious to perfect policy on water use.

Key Words: EVW Industry Structure Water Price Techniques Innovation Sensitivity

1 . Introduction

In addressing serious water scarcity in the Hai basin in China, one of goals of water resources management is to use water more efficiently by improving industries and policy interventions within the national macro-policy framework in accordance with resources conditions.

The national policy intervention is aimed at the maximization of the national interests as a whole rather than the maximization of EVW alone. In this section, by linking EVW with the national goals and policy orientation, major policy interventions with considerable influences on productivity, water use efficiency and EVW are analyzed to proposes recommendations on promoting rational water resources allocation and increasing EVW under the premise of maximizing the national interests.

2. Effect from Readjustment of Industrial Structure

In recent years, the governments at various levels have timely been readjusting the regional industrial structure by discouraging development of industries with high energy and water consumptions and serious pollution, encouraging clean and resources-conserved productions, raising production efficiency and benefit in accordance with local resources condition to increase social output and improve people's living quality for attaining the goal of establishing well-to-do and harmonious society. Taking Beijing for example, where targets of readjusting structure of three industry are clearly defined in the Eleventh Five-year Plan although no detailed data of sub-sectors and the primary industry are available, to analyze the impacts of readjustment of the secondary and tertiary industrial structures on economic value of water quantitatively.

In the 1990s, Beijing was focused on development of the secondary industry, when the proportions of outputs of the primary, secondary and tertiary industries in GDP were 8:52:40. As industrial structure adjusted from then, in 2004, Beijing has the proportions of outputs of the three industries in GDP of 2:38:60 with the tertiary industry dominant. According to the Overall Plan for the Development of Beijing Municipality, by 2020, the proportion of the tertiary industry will further increase, GDP of Beijing will reach 1,500 billion yuan (at 2000 price), or over 10,000 US$ per capita on the average, and the proportions of outputs of the three industries will be readjusted to 1:29:70.

In order to analyze the impacts of readjustment of industrial structure on EVW, with the output value of Beijing in 2004 (base year) as the basis, the EVW is calculated for the secondary and tertiary industries based on the industrial structures at the end of 1990s and in 2020, and the results are compared with the base year. Assuming that total output and water use per unit output do not change, readjustment of industrial structure will cause changes in the input, net benefit and water abstraction of each sector. The EVW for the secondary and tertiary industries and the integrated one are listed in Table1. The results indicate:

Table 1 Economic Value of Water for Different Industrial Structures in Beijing

Year	PI:SI:TI	Secondary		Tertiary		Integrated	
		EVW (yuan/m^3)	Change range(%)	EVW (yuan/m^3)	Change range(%)	EVW (yuan/m^3)	Change range(%)
1990s	8 : 52 : 40	33.65	-0.95	37.18	0.22	34.63	-1.85
2004	2 : 38 : 60	33.97	0	37.10	0	35.28	0
2020	1 : 29 : 70	35.47	4.4	37.02	-0.21	36.7	4.02

If the proportions of the three industries are readjusted to 1:29:70 from 2:38:60 in the base year, with the same social output value, the output value of the secondary industry decreases, associated with decrease in water abstraction and increase in EVW as compared with the base year. At the same time, the output value of the tertiary industry increases with its development, associated with increase in water abstraction and less change in EVW. As a result, with unchanged total output value of the secondary and tertiary industries and decrease in the total water abstraction, the integrated EVW increases by 4.02% over the base year (Table 1).

If the proportions of the three industries are readjusted to 8:52:40 from 2:38:60 in the base year, the integrated EVW decreases by 1.85% as compared with the base year, indicating an adverse impact on EVW (see Table 1).

According to the information on the proportion of full cost of water supply in total cost by industries of Beijing in 2004 (see Table 4.5 in Appendix 4), the proportion of the secondary industry (2.6%) is bigger than that of the tertiary industry (2.4%). Because the profit&tax to cost ratio of the tertiary industry is high, the water use per unit output is small, the economic value per m^3 of water is also high, and the pollution produced is low. Therefore the increase of proportion of the tertiary industry with high EVW is favorable to the increase of regional integrated EVW.

The future readjustment of industrial structure in Beijing Municipality will further decrease the proportion of the primary industry, thus decreasing the water consumption dramatically, favoring the relief of pressure on water supply. The saved water may be used to develop industries with high EVW, thus promoting the overall increase of regional EVW.

Based on the above analysis, for the Hai Basin with serious water scarcity and for the purpose of achieving efficient use of water resources, the regional industrial structure should be readjusted by further developing the tertiary industry, putting rational limitation to the secondary industry and reducing the primary industry, thus fully tapping the potential of regional EVW through actively developing industries or sectors of efficient use of water resources.

3.Effcet from Reformation of water pricing

The major indicator of inefficiency influencing EVW of the Hai Basin is water productivity, with the lower water price as the main reason. Water price directly affects productive cost and the benefit sharing coefficient of water supply. The impacts of water pricing reform on EVW occur in the pattern of "raising water price – encouraging water saving - improving EVW". Because of the economic leverage role of price, raising water price within the users' ability to pay will promote water users to save water and reduce water abstraction per unit of output value, thus improving water use efficiency.

As the basic industry of national economy, the primary industry has a low level of development and a weak bearing capacity and is related to national grain security. As price elasticity is small for the primary industry under a series of protection policies, the impacts of water pricing reform on EVW for the secondary and tertiary industries are analyzed in this study by taking Beijing for example.

By fitting the 1995-2001 relationship between water price and water use in Beijing, a price elasticity coefficient of water use of 0.462[1] is derived and, based on this coefficient, water use norms are adjusted for different sectors, then with the increase of water price, water use norms decrease. When water price doubles, the water use norms decrease by 46 % (Table 2). Then EVW is analyzed for all industries.

Table 2 Water Use Norms by Sector after Adjustment of Water Price in Beijing

% of Price Change	SI			TI			Integrated water use norm	
	Price	Water use norm		Price	Water use norm			
	(yuan/m^3)	($m^3/10^4$yuan)	Change (%)	(yuan/m^3)	($m^3/10^4$yuan)	Change (%)	($m^3/10^4$yuan)	Change (%)
-20	4.5	25.48	9.08	4.8	26.45	9.07	26.10	9.07
Base year[A]	**5.6**	**23.36**		**6.1**	**24.25**		**23.93**	
20	6.8	21.05	-9.89	7.3	21.85	-9.90	21.56	-9.90
100	11.2	12.57	-46.19	12.2	13.05	-46.19	12.87	-46.22

Note: A stands for the year of 2004

The water price of base year in Beijing was 5.6 yuan/m^3 for the secondary industry and 6.1 yuan/m^3 for the tertiary industry. Impacts of changes of water price on EVW are analyzed for the scenarios of varying water price by ±20% and +100% over the base year.

With increased water price by 20% and 100%, respectively, based on the base year, EVW increases for all sectors to a varying extent. The increases of EVW are 1.21% and 1.71% for the secondary industry, 0.12% and 0.74% for the tertiary industry, and 4.27% and 4.86% for combination of the secondary and tertiary industries, respectively (Table 3).

When water price decreases by 20% based on the base year for all the sectors, the integrated EVW decreases by 2.42%.

Table 3 EVW for Different Scenarios of Water Price Adjustment in Beijing

[1] Ni Hongzhen, A Study of Value and Price of Water Resources based on Green Accounting, Doctorate Thesis of IWHR, Oct., 2004

% of Price Change	SI		TI		Integrated	
	EVW (yuan/m^3)	Change (%)	EVW (yuan/m^3)	Change (%)	EVW (yuan/m^3)	Change (%)
-20	32.83	-3.36	37.07	-0.07	34.43	-2.42
The base year[A]	**33.97**		**37.1**		**35.28**	
20	34.39	1.21	37.14	0.12	36.79	4.27
100	34.56	1.71	37.37	0.74	36.99	4.86

Note: A stands for the year of 2004

The analytical results show that EVW is not sensitive to the change of water price. Even water price doubles, integrated EVW only increases by 4.86%. Because of the increase of water price, water using sectors have to reduce water abstraction, their expenditures on water charge and their net benefits also change accordingly, thus causing changes to EVW. EVW increases only if the impact of decrease of water abstraction on cost and benefit exceeds that of increase of water price on cost and benefit, or vice versa. Therefore, only if all sectors realize water saving and improvement of water use efficiency through water saving actions with the increase of water price, can their EVW increases. But the increase of water price has obvious influence on decreasing water use norms (Table 3), therefore a proper rise of water price may encourage water conservancy and efficient water use.

4.Effcet from Decrease of Water use norms

With the improvement and perfection of water use technologies, the water abstraction per unit of output value, i.e., water use norm, declines and EVW increases. Take Beijing as an example for analyzing impacts of improved water use efficiency on EVW for the secondary and tertiary industries.

The changes of EVW are analyzed for different sectors in Beijing for the scenarios of 10%, 30% and 50% decreases in water use norms with those in 2004 taken as the baseline value. Calculation shows that EVW by sectors and the integrated one for all sectors increase with the decrease of water use norms. As compared with the base year, if water user norm is decreased by 10%, 30% and 50%, EVW is increased by 0.40%, 1.05% and 3.14% for the secondary industry, by 0.22%, 0.68% and 1.13% for the tertiary industry, and the integrated EVW is increased by 1.87%, 3.88% and 6.07%, respectively (see Table4).

Table4 Economic Value of Water for Different Water Use Norms in Beijing

Change range of water use norm (%)	SI		TI		Integrated	
	EVW (yuan/m^3)	Change (%)	EVW (yuan/m^3)	Change (%)	EVW (yuan/m^3)	Change (%)
The base year[A]	**33.97**		**37.10**		**35.28**

Note: A stands for the year of 2004

The analytical results show that, with the same output value, total water use decreases significantly with the improvement of water use efficiency, thus resulting in reduction of water use cost and the total cost, and increase of net returns, hence increase of EVW for different sectors.

Because the water use norms change to the same extent for different sectors, EVW also practically changes to the same extent. Therefore, to formulate effective policies for water use, promote all sectors to improve productive technologies and processes, enhance water reuse rate and water use management level and reduce productive water abstraction can increase EVW and promote water saving greatly.

5. Notes

It should be noted that the above analysis of impacts of policies for the readjustment of industrial structure, change of water price and improvement of water use efficiency is all based on particular assumptions, which are quite different from realities. In realities, multiple influential factors for EVW usually change and act jointly, exerting impacts more significantly and effectively than the results of above analysis. Productive water abstraction and consumption of water resources can be effectively reduced by rationally readjusting industrial structure, appropriately increasing water price and actively improving productive water use technologies. Saved water may be used for expanding production and increasing output properly, or for improving the regional ecology and environment to bring about huge ecological and environmental benefits, which represents great significance for the Hai Basin with serious scarcity of water resources. As limited by data and time for the study, benefit of water saving is not evaluated, therefore, the EVW as affected by policy impacts on water saving is underestimated and that as affected by increased water use overestimated, and the sensitivity of EVW to policy impacts thus reflected is biased to the low side.

ABSTRACT

Flood routing through rivers and channels is an essential activity in hydrological analysis and this is particularly important because of the increasing emphasis that has been placed on dam-safety worldwide and due to the increasing urbanization near river channels. The routing of flood through river channels may be accomplished using two basic approaches namely hydrologic routing approach and hydraulic routing approach. There are different methods currently in usage and the Muskingum method is the most popular method and generally used by hydrologists and engineers. However, the reliability of this method is heavily depends upon the accuracy of the parameters namely K and x or C_0, C_1 and C_2 of the model. These parameters are usually estimated by trial and error procedure. Muskingum model together with the Model proposed by Loucks (1989) have been considered for the present study and the parameters of these models were estimated using genetic algorithms, new search procedures for function optimization that apply the mechanics of natural genetics and natural selection to explore a given search space. This paper presents the results of the study of application of genetic algorithm for optimal parameter estimation of both linear and non-linear flood routing models to a case study. The sensitivity analysis of these estimated parameters was also carried out. The results had clearly depicted that the genetic algorithm is an efficient and robust means for estimation of flood routing model parameters.
.

INTRODUCTION

Flood routing through rivers and channels is an essential activity in hydrological analysis and this is particularly important because of the increasing emphasis that has been placed on dam-safety worldwide and due to the increasing urbanization near river channels. The routing of flood through river channels may be accomplished using two basic approaches namely hydrologic routing approach and hydraulic routing approach. There are different methods currently in usage and the Muskingum method is the most popular method and generally used by hydrologists and engineers. However, the reliability of this method is heavily depends upon the accuracy of the parameters namely K and x or C_0, C_1 and C_2 of the model. These

parameters are usually estimated by trial and error procedure (Viessman et al. 1977). Muskingum model together with the Model proposed by Loucks (1989) have been considered for the present study. Genetic algorithms are used because they are able to quickly optimize the parameters of functions involving multivariate. The resultant parameter values are accurate and can be used for reliable routing and thus avoiding the difficult task of estimation of routing parameters. The details of genetic algorithms are presented in this context.

GENETIC ALGORITHMS

Genetic Algorithms (GAs) are adaptive algorithms with a probabilistic component, which may be used to solve search and optimization problems. They provide a means to search poorly understood, irregular spaces. Genetic algorithms have successfully been applied to a variety of function optimization, parameter searches and machine learning applications. The basic principles of GA were first laid down rigorously by Holland (1975) and are well described in many texts, for example Goldberg(1989). GA was developed to simulate some of the processes observed in natural evolution, a process that operates on chromosomes. Natural selection links chromosomes with the performance of their decoded structure. The process of natural selection cause those chromosomes that encode successful structures to reproduce more often than those that do not. Recombination processes create different chromosomes in children by combining material from the chromosomes of two parents, and this process is referred as reproduction. Mutation may cause the chromosomes of children to be different from those of their parents.

GA appropriately incorporates these features of natural evolution in computer algorithms to solve difficult problems in the way that nature has been doing, namely through evolution. GA requires the problem to be maximized in the form of an objective function. In GA, a set of variables for a given problem is encoded into a binary string or any other coding structure, analogous to a chromosome in nature. These strings are converted to a numerical value and then linearly mapped over the range allowed for the variable. This value is then used to evaluate the objective function, yielding the "fitness." GA selects parents from a pool of strings (population) according to the basic criteria of survival of the fittest. It reproduces new strings by recombining the parts of selected parents in a random manner. The population of the next generation is done using three methods: reproduction, crossover, and mutation. Reproduction means simply those strings with highest fitness should receive the multiple copies in the next generation while the strings with low fitness receive a lower number of copies or even none at all. Crossover refers to splitting a string into two parts at a randomly generated crossover point and recombining it with another string that has been split at the same crossover point. This procedure serves to promote changes in the best strings that will give them even higher fitness. Mutation is the random alteration of a bit in the string. This assists in keeping diversity in the population.

Genetic algorithms have many advantages over other methods. Currently most literature defines three main types of search methods: calculus-based, enumerative, and random (Goldberg, 1989). Calculus based methods can be divided into two classes: indirect and direct. In indirect methods, local extreme are determined by finding where the gradient of the objective function is equal to zero. Direct methods follow along the objective function in a direction related to the local gradient. Both classes share two main disadvantages that greatly limit their usefulness. First, both are local in scope; that is, if a function has multiple local maxima, these methods may drive toward one of these values without approaching the global maxima. The second deficiency of calculus-based methods is their dependence on the existence of their derivatives. However, many real-world functions are discontinuous and noisy, and therefore do not work well with a method that prefers smooth and continuous functions. Enumerative methods are very simple but one has to carry out enormous number of iterations to locate the maxima, thus carries a high cost. This method takes a discretized search space and examines the objective function at every point. Thus, even though this method is simple, it is quite inefficient, and its execution time becomes too long when the search space becomes larger. The random search method can perform as poorly as the enumerative methods in many respects because of its inefficiency. Randomly searching through a space and saving the best results can become time-consuming as the space becomes large.

The power of GA comes from the fact that the technique is robust, and can deal successfully with a wide range of problem areas, including those which are difficult for other methods to solve. GA works through function evaluation, not through differentiation and uses probabilistic rather than deterministic transition rules. Although GA begins with a randomly generated set of points, it exploits the information contained in those points to drive it through search space. Because GA is based on function evaluation, it can be applied to all types of optimization problems as long as they are properly coded.

GA has been used in optimization problems as diverse as image analysis by Grefenstette and Fitzpatrick (1985) and gaming strategy by Axelrod (1987). The first practical engineering example of GA's application is Goldberg's study of a system of 10 pipes and 10 pumping stations (Goldberg, 1986). Expert systems have also been improved by using GA, as shown by Davis and Coombs (1987). Wang (1991) has used GA for calibrating a conceptual rainfall-runoff model and proved that GA is robust and efficient in parameter estimation. Simpson et al. (1994) have used genetic algorithm for pipe network optimization and reported that GA resulted in efficient estimation of the design variables based on a comparison with the traditional optimization techniques.

The software used for this paper was developed in C++ language. The program allows evaluation of multiple parameters and multiple objective functions. Multiple parameters are incorporated by letting each string be divided into substrings that represent different variables. The substrings length need not be equal in order to

allow a smaller substring length for integer parameters. For example, if the problem has three floating point variables and one integer variable, a string length of 28 could be used to represent three substrings of length 8, and one substring of length 4 for integer variable may be used to have an acceptable precision. The precision of each substring is determined from the equation

$$p = \frac{V_{max} - V_{min}}{2^{l} - 1}$$

where p is the precision of the parameter, V_{max} and V_{min} are the maximum and minimum of the allowed value of the parameter, and l is the length of the substring. Obviously, longer string lengths are required if each variable or parameter is to have an acceptable precision.

FLOOD ROUTING MODELS

As already mentioned, two flood routing models namely Muskingum model and the Loucks model are considered for this study. These models are explained briefly in this section for completeness.

Muskingum Method

This method is one of the sophisticated of the hydrologic flood routing procedures. This method stems from an assumption of relating storage within a routing reach to outflows at each end of the reach, which results in the basic equation:

$$S = K [x I + O (1-x)] = KO + Kx (I-O)$$

where : i

S = storage in the reach,

K and x = routing constants and

I and O = simultaneous inflow and outflow, respectively, for the reach .

For any time period t , the above equation may be written as

$$O_t = C_0 I_t + C_1 I_{t-1} + C_2 O_t$$

The C_0, C_1,and C_2 are the three parameters that may be determined from the values of K and x, and this equation is commonly used in practice.

The values of K and x are determined using past records of I and O. These values are then assumed to be characteristic values for the channel reach in future flood routing. The commonly used procedure for determining the value of x is by trial and error. Assuming a value of x, the values of x I + (1-x) O are computed and plotted against the corresponding values of storage, S. The value of x for which the width of the loop is reduced to minimum (determined by visual judgment) is considered as best value. The coefficient K is the reciprocal of the slope of the line (Cudsworth, 1989). Although using this method, a reasonable value of x may be determined

within four or five trials, the method is subjected to criticism due to its tentativeness. For instance, commenting on this method, Kulandaiswamy (1966) observed that using this method, no two investigators may get the same value of x and K for a given flood movement. The other criticism is that this procedure is time-consuming and prone to subjective interpretation. The visual judgment may not correctly identify the best among several nearly collapsed loops when all may appear acceptable (Yoon and Padmanabhan, 1992). Thus, a better and wholly objective method of determining these parameters is warranted to reduce the bias. GA offers an excellent means for estimation of these parameters.

Loucks model

In case where the storage versus weighted flow relationship is not linear as implied in the original Muskingum model, using a linear form of the model may introduce considerable error. To consider this effect, two forms of non-linear Muskingum models may be used (Yoon and Padmanabhan, 1992). Loucks (1989) proposed another nonlinear routing model and used in the general Multipurpose, multireservoir simulation model namely IRAS, and this model is used in this study. The model is given by the following three equations:

$$R_{it} = (A \,.\, S_{it} + B \,.\, Q_{it})^{C}$$

$$S_{i,t+1} = S_{it} + Q_{it} - R_{it}$$

$$Q_{it} = R_{i-1,t}$$

where,

i = 1,2 , ...N: Number of reaches or stages

t = 1,2, ...T : Time periods

R_{it} = Outflow from reach i at time t.

S_{it} = Storage in reach i at the time t

A, B, C and N: Model Parameters.

It can be proved that as the parameter A decreases, the outflow is decreased and when it is equal to zero the reach tends to keep all the storage produced in the previous stage. The parameter B does not affect the amount of outflow from the reach, but causes the lag of outflow. On the other hand, the parameter C is the most sensitive and the outflow will be significantly decreased and lagged as its value decreases. It may be noted, the value of unity for C indicates a linear reach or linear reservoir as in the other models. Care must be exercised to see that the resulted value inside the bracket should be more than one, by adopting suitable units for the flows.

APPLICATION OF GA FOR PARAMETER ESTIMATION

The main purpose of this computational experiment is to examine the ability of GA to perform a multi-parameter function optimization of a flood routing problem. One linear routing model and one non-linear routing model are considered in this study. The parameter estimation through GA is explained with reference to two examples. The first example is taken from Hoggen (1989) and the second example is from the "Flood Hydrology Manual" by Cudsworth (1989).

There are three parameters in the Muskingum model and four parameters in the Loucks model and these parameters are estimated by GA. All these parameters are to be calibrated by minimizing the function F^2 defined as the sum of squares of differences between computed and observed discharges. The model efficiency is measured by the proportion of the variance accounted for by the model and is given by the following equation

$$R^2 = 1.0 - \sqrt{}(F^2 / n)$$

where n is the total number of values. A value of R^2 =1.0 indicates that the estimated parameters are equal to their true values.

In the Muskingum model the parameters C_0, C_1 and C_2 are the three continous decision variables ranging from 0 to 1. In the Loucks non-linear routing model, parameters A, B and C are the three continous variables ranging from 0 to 1 and the parameter N is an integer variable ranging from 0 to 15. In order to encode all these continous variables into binary code, three chromosomes strings, whose length is 8,10 or 12 bits are used in each model. This binary code represents each continous variable with a minimum precision of 0.004, which is considered to be enough for the routing models. In the case of the integer variable namely N, the number of fictitious reaches along the channel or reservoirs along the river, it was considered that a 4 bit string which can produce 16 distinct integer values. Thus each string corresponds to a parameter value with one-to-one scheme ranging from 0 to 15. The GA requires that the objective function needs to be maximized. To fulfill this requirement, it is considered that the inverse of F^2 is maximized, which in turn minimize the F^2 . In order to avoid too rapid dominance and too slow improvement, the linear scaling method (Goldberg, 1989) is used in evaluating the fitness values.

For the flood data reported by Hoggen (1989), runs were made with a population size of 100, cross-over probability of 0.9 and a mutation probability of 0.1 for different string lengths of 12,18,24,30 and 36. The lower string lengths were also considered to check the variation of objective function with these values. Each run was made with 200 function evaluations or in other words the number of iterations were used is 200. It was found for the flood routing problem the increased number of iterations does not produce the increase in accuracy. Since GA is initiated

randomly, the runs were repeated with 20 different seeds and the best value of the objective function was taken as the optimal value of the objective function. When the variation of minimum sum of squares with the different string lengths was analyzed, it was found that the sum of square value has been improved with increased string (chromosome) length and a minimum of 24 is necessary to estimate the parameters with reasonable accuracy. With the string length of 36 and the crossover probability of 0.9, and the mutation probability remaining at 0.1, the sensitivity of the results to the population size was explored. For this purpose the population size is varied from 50 to 250 in steps of 50. Here again, the runs were repeated 20 times with different seeds and the best value was taken as the optimal one. The results showed that the optimum value of the objective function was achieved both at population sizes of 100 and 250. However, the corresponding values at population sizes of 150 and 200 are not much different from these values. Perhaps contrary to expectations, there appears that increased number of populations may not result in better estimation, at least with the structure of problem addressed here. It is interesting to note that similar observations were made by Koumousis and Georgiou (1994) as the population size of 50 gave better optimum and was more stable in the optimization of steel truss roofs. For the population size of 100, the results converged within 45-65 iterations, notably lower when compared to 130-185 iterations with the population size of 250. A population size of 100 was therefore adopted in examining the sensitivity of the results to cross-over probability.

Retaining the string length of 36, mutation probability of 0.1 and the population size of 100, the cross-over probability was varied from 0.6 to 1.0 in steps of 0.1. The results of this analysis proved that the lowest value of the objective function was achieved with the cross-over probability of 0.9. Similarly, with the string length of 36, population size of 100 and with the cross-over probability of 0.9, the sensitivity of the mutation probability with the optimal value of the objective function was examined. The mutation probability was varied from 0.02 to 0.1 in steps of 0.02. From the results of these runs it was found that the variation of the objective function with the mutation probability was not very significant. The lowest value of the objective function was obtained with the mutation probability of 0.04. Thus the parameters of the genetic algorithm were identified as: population size=100; string length = 36; cross-over probability = 0.9; and the mutation probability = 0.04. However, the other values of the population size = 150, 200, 250; string length = 24, 30; cross-over probability = 0.6, 0.7, 0.8; and mutation probability of 0.02, 0.06, 0.08, 0.1 can also be adopted without much loss of the global optimal value of the objective function but perhaps with more number of iterations.

The estimated values of C_0, C_1, and C_2 through the genetic algorithm are listed along with the reported values in Table 1. The corresponding F^2 and R^2 values are also reported in the same table and one could see that the parameter values are almost same and the R^2 values are also higher. The computed outflow hydrograph with the genetic algorithm when plotted along with the reported values as shown in Fig. 3, reveals that the estimated values by the genetic algorithm exactly match with each

other. This proves that the genetic algorithm is robust in estimating flood routing parameters thus avoiding the subjective and inefficient trial and error procedure. More so, this algorithm simultaneously estimates all the parameters and doesn't require the assumption of x value before estimating the other parameter K as in the calibration procedures adopted by other researchers (Gill, 1978).

The optimal values of the genetic algorithm parameters namely population size, stringlength, cross-over probability and mutation probability were obtained for the Loucks model, for the first example, in the sameline as explained above. They are Population size =100; Stringlength = 40; Crossover probability = 0.9 and the mutation probability = 0.06. The resulted values of the parameters of Loucks model are also listed in Table 1. The computed outflow hydrograph from Loucks model was also shown in Fig. 1 and are indistinguishable from the reported outflows. This is also evident from the higher values of R^2. From the above discussions it can be said that the results obtained by applying GA are practically indistinguishable from the actuals and thus offers as an efficient tool in flood routing parameters estimation.

CONCLUSIONS

In this study, genetic algorithms have been applied to flood routing parameters estimation problem. Even though in most methods routing parameters estimation would be considered as a cumbersome procedure and also to yield only approximate values, GA handled the task quite successfully. Although the model used here to estimate the flood routing parameters consist only four parameters, the procedure would be exactly same with a more elaborate hydrological model with more parameters. Results of assorted runs agreed with actual data. The ability of GA to handle a problem of this nature could make it a very important tool in the future of water resources research.

ABSTRACT

Farmers in a water scarce environment have a problem of maximizing total income from farming. Irrigation planning is very important to prevent crop failures. DE, an evolutionary algorithm, which is a stochastic parallel direct search evolution algorithm known to be fast and robust in numerical optimization, is extended to multi-objective problems in this study. The new algorithm named multi-objective differential evolution algorithm (MDEA) adjusts the selection scheme of traditional DE to solve multi-objective problems. The algorithm also modifies the domination criteria for the population. The offspring generated in subsequent generations are improved before domination check is performed on the population in the final generation. MDEA is tested on three benchmark problems and later applied to an irrigation planning. The algorithm achieves the two goals in multi-objective optimization algorithm which are to discover solutions as close to the Pareto-front as possible and to find solutions as diverse as possible in the obtained non-dominated front.

Keywords: irrigation planning, differential evolution; multi-objective; optimization; evolutionary algorithm

INTRODUCTION

Optimization is a procedure of finding and comparing feasible solutions until no better solution can be found. It also refers to finding one or more feasible solutions which correspond to extreme values of one or more objectives (Deb, 2001). In engineering designs, it may be necessary to find the optimal solutions in a problem. There may be a problem of designing for minimum cost, or for maximum benefit. There may be optimization problem that involves one objective function. It is always called single-objective optimization. The procedures for solving this kind of problem are gradient-based and heuristic-based search techniques. If optimization problem involves more than one objective functions, then the problem is known as multi-objective optimization. Mostly real-world search and optimization problems naturally involve multiple objectives. All the objectives in a multi-objective problem are all important. Single objective problem involves finding the minimum and maximum of a single-variable function. The method used may be the techniques of finding an optimum of a first and second order derivative of a function. Also it may be the technique of finding an optimum in a multi-variable function. The optimization may also involve finding the true optimum in the presence of

constraints. The real world problems involve restricting some properties of the system to lie within some ranges. These constitute the constraints of the problem. Constrained optimization techniques include Lagrange multipliers, linear and non-linear programming, dynamic programming, quadratic programming, fractional programming, geometric programming, etc. The mathematical structure of the model will determine the application of each these constrained optimization procedure.

In multi-objective optimization, there may not exist a solution that is best with respect to all objectives, instead, there are equally good solutions which are known as Pareto optimal solutions (Deb, 2001). A Pareto optimal set of solutions is such that when we go from any one point to another in the set, at least one objective function improves and at least one other worsens (Babu and Jehan, 2003). Neither of the solution dominates over each other and all the sets of decision variables on the Pareto are equally good.

Evolutionary algorithms (EAs) have the ability to find multiple Pareto optimal solutions in one single simulation run because of their population-approach. EAs are general purpose stochastic search methods simulating natural selection and biological evolution (Salman, Engelbrecht, and Omran, 2007). EAs maintain a population of potential (or candidate) solutions to a problem. They are biologically-inspired optimization algorithms, imitating the process of natural evolution, and are becoming important optimization tool for several real world applications. They use a set of solutions called population to converge to the optimal solution. They are robust optimization method. They are less susceptible to problem dependent characteristics, such as the shape of the Pareto front (convex, concave or even discontinuous), and the mathematical properties of the search space, whereas these issues are of concerns for mathematical programming techniques for mathematical tractability (Angira and Babu, 2005).

Several studies have extended evolutionary algorithm to solve multi-objective numerical optimization problems (Angira and Babu, 2005; Babu and Jehan, 2003; Babu, Mubeen, and Pallavi, 2005; Deb, 2001; Deb, Agrawal, Pratap, and Meyarivan, 2001; Deb, Pratap, Agarwal, and Meyarivan, 2002; Fan, Lampinen, and Levy, 2006; Madavan, 2002; Reddy and Kumar, 2007; Robic and Filipic, 2005; Santana-Quintero and Coello, 2005; Xue, Sanderson, and Graves, 2003). Over the past decade, a number of multi-objectives evolutionary algorithms (MOEAs) have been suggested (Deb *et al.*, 2001).

Differential evolution (DE) is a very simple population-based, stochastic function minimizer which is very powerful at the same time (Price and Storn, 2008). It is a family of EAs and has the advantages of simple structure, ease of use, speed and robustness. Unlike other EAs, DE does not make use of some probability distribution function in order to introduce variations into the population (Salman *et al.*, 2007). Instead, DE uses the differences between randomly selected factors (individuals) as the source of random variations for a third vector (individual), referred to as the target vector. Hence, the trial solutions which will compete with the parent solution are generated by adding the weighted difference vectors to the target vector (Price and Storn, 2008).

Multi-objective differential evolution algorithm (MDEA)

Multi-objective differential evolution (MODE) is proposed by (Babu and Jehan, 2003; Babu *et al.*, 2005). In the algorithm, the dominated solutions are removed from the population in each generation. Only the non-dominated solutions are allowed to undergo DE operations of mutation, crossover and selection. The offspring are placed into the population if they dominate the parents. The algorithm worked well on the test problems but the number of non-dominated solutions generated is few. The dominated solutions that are removed from the population can still be improved using the DE operations. During mutation stage, they may be combined with other vectors to produce offspring that may replace them instead of just removing them. In this way, at the end of the generation, the number of non-dominated solutions is increased with quality members giving wider Pareto optimal fronts. In the original DE with single objective, most of the initial generated solutions are infeasible. They undergo mutation and crossover before they are improved to be feasible. In the same way, the solutions in each generation should be allowed to mutate, recombined and undergo crossover. The final solutions are the only one to be checked for domination. Therefore, domination check is done once instead of doing it in all the generations.

The algorithm proposed by (Fan *et al.*, 2006) is implemented by modifying the selection scheme of DE. In their selection scheme, the trial population is compared with its counterpart in the current population. If the trial candidate dominates the current population member it will survive from the tournament selection to the population of the next generation and replaces the current population otherwise the current population is retained. They suggest that if the trial solution is worse than the target solution in all the objectives, it should be discarded.

A new DE algorithm for multi-objective optimization problems (MOOPs) is proposed in this study and it is called multi-objective differential evolution algorithm (MDEA). The DE algorithm proposed is based on the existing DE algorithm proposed by (Price and Storn, 1997). The only difference is its implementation of multi-objectives. Though the proposed MDEA can be used on any strategy, the strategy used in this study is DE/rand/1/bin which is the most widely used of all the ten strategies of DE. MDEA combines the advantages of both algorithms described above while overcoming the shortcomings of the algorithms. In this way, MDEA runs faster with more quality Pareto optimal solutions. The description of the MDEA is as follows. The vectors are randomly generated to create initial vectors and solutions to the problem. The generated solutions are allowed to undergo mutation, crossover and selection for the number of generations. The solutions that evolve are checked for domination and the dominated solutions are removed. The selection procedure of (Fan *et al.*, 2006) is used. The trial solution survives to the next generation if its objective function is better or equal in all the objective. MDEA will produce many non-dominated solutions on the Pareto front than the algorithm by (Fan *et al.*, 2006) and (Babu *et al.*, 2005). Moreover, the algorithm by them has not been modified to handle constraints except bound constraints. Our algorithm can handle multiple constraints. If any of the constraints is violated, a high value (10^8) is added to the objective function to make the solution infeasible (Deb, 2001). In this

way, the solution will not be selected when compared with other solutions because of high value.

The pseudo code of MDEA is presented below. The proposed MDEA methodology can be summarized in the following steps.

1. Input the required DE parameters like population size, crossover constant, scaling factor, maximum generation, number of objectives, bound constraints etc.
2. Initialize all the vectors randomly in the limit of bound constraints.
3. Set the generation counter, G =0.
4. Perform mutation and crossover operations as explained in the DE algorithm above on all the population members
    a. For each parent, select three distinct vectors randomly from the current population. The selected vectors must not be parent vector.
    b. Calculate new mutation vector using the expression, $V_i(g) = X_{i3}(g) + F*(X_{i1}(g) - X_{i2}(g))$
    c. Perform crossover using any of the two crossover method. Binary crossover method is used because of the strategy DE/ran/1/bin used in MDEA in this study.
5. Evaluate each member of the population and check the offspring for domination. Replace the parents with offspring in the next generation if the offspring dominate the parents otherwise, the parents proceed to the next generation.
6. Increase the generation counter, G, by 1. i.e. G = G+1 and check if G = GMAX. If G < GMAX, then go to step 4 above and repeat mutation, crossover and selection. If G = GMAX, then goto step 7.
7. Remove the dominated solutions in the last generation. A solution is dominated if there is another solution which is better than it in all the objectives. The method used here is naïve and slow suggested by (Deb, 2001).
8. Output the non-dominated solutions

The steps above are followed, using the pseudo code below, to code the algorithm in MATLAB 7.0 (The MathWorks Inc., USA) and is executed on a 1.7GHz, 2GB RAM PC and tested on some test problems below to demonstrate its ability to solve linear and non-linear constrained multi-objective optimization problems. The results are presented in Figures 1, 2 and 3. The DE parameters used are population size(NP) = 50, crossover constant(Cr) = 0.5, scaling factor (F)=0.5 as suggested by (Price and Storn, 2008). The description of each of the three test problems are presented below.

The Pseudo code for multi-objective differential evolution algorithm (MDEA)

**Initialize the values of D, NP, Cr, F, k (number of objective functions) & maximum generation (MAXGEN)*
**input the boundary constraints of the problem*
**Initialize all the vectors of the population randomly*

For i = 1 to NP
For j = 1 to D
$X_{i,j}$ = $Dlower_j$ + *random number[0,1] * [*$Dupper_j$-$Dlower_j$*]*

Test Problems

Problem 1 (Lampinen, 2000):

Minimize $f1(x) = x_1^2 + x_2$,
$f2(x) = x_1 + x^2_2$
$-10 \le x_1, x_2 \le 10$

Problem 2 (Deb, 2001)

Minimize $f1(x) = 4x_1^2 + 4x_2^2$
$f2(x) = (x_1 - 5)^2 + (x_2 - 5)^2$
Subject to $C_1(x) = (x_1 - 5)^2 + x_2^2 \le 25$
$C_2(x) = (x_1 - 8)^2 + (x_2 + 3)^2 \ge 7.7$
$0 \le x_1 \le 5,$
$0 \le x_2 \le 3.$

Problem 3

Minimize $f1(x) = x_1$
$f2(x) = \frac{1+x_2}{x_1}$
subject to $g_1(x) \equiv x_2 + 9x_1 \ge 6$
$g_2(x) \equiv -x_2 + 9x_1 \ge 1$
$0.1 \le x_1 \le 1,$
$0 \le x_2 \le 5$

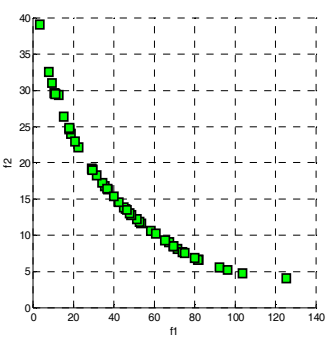

Figure 2. The non dominated solutions for test problem 2.

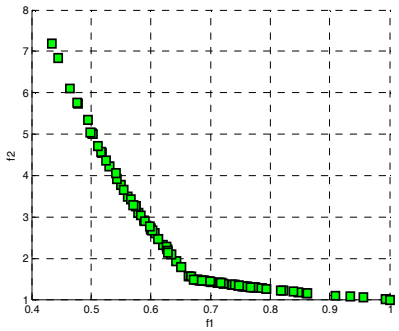

Figure 3. The result of the convergence of test problem 3.

IRRIGATION PLANNING MODEL

MDEA is further extended to irrigation planning where the aim is to minimize the area of land cultivated and to maximize the total farm income. There are 8 crops to be planted on the cultivated area. The crops are carrot, potato, water melon, pea, maize, wheat, bean and onion. The model is presented below:

Objective function 1: Minimize the cultivated land

The cultivated land area available for irrigation is minimized to reduce the number of employee that will be working on the farm. This will also reduce the complexity of management on the farm.

$$\text{Minimize } CA = \sum_{i=1}^{N} A_i$$

where CA is the total cultivated area in hectares and A_i is the cultivated area for $crop_i$.

Objective function 2: Maximize the total farm income

The total farm income in South African Rand (ZAR) on the total cultivate land is maximized.

$$\text{Maximize } FINC = \sum_{i=1}^{N} (\text{Price}_i * Yield_i) * A_i$$

Where,
FINC = total farm income
$Price_i$ = price of crop planted on land A_i
$Yield_i$ = yield of $crop_i$ on land A_i

The above objectives are subjected to the following constraints:

Constraint 1: Minimum and maximum cultivated areas
Each crop in the command area is planted on minimum and maximum cultivated areas. The minimum for all the crops is 500 ha and the maximum vary from crop to crop.

$$500 \leq A_i \leq A_{i\max}$$

Constraint 2: Canal capacity
Irrigation release in any month can not be more than the canal capacity.

$V_i \leq canal$ capacity $\forall$ i = 1 to 12

Constraint 3: Total volume of water
The total volume of water in the whole year should be less than the annual allocated irrigation water in the area.

$$TVOL \leq 10\ Mm^3$$

Constraint 4: Crop water requirement
The monthly irrigation release must meet the crop water requirements for all the crops in the month.

$V_i \geq (CWR_i * A_i) \quad \forall$ i = 1 to 12

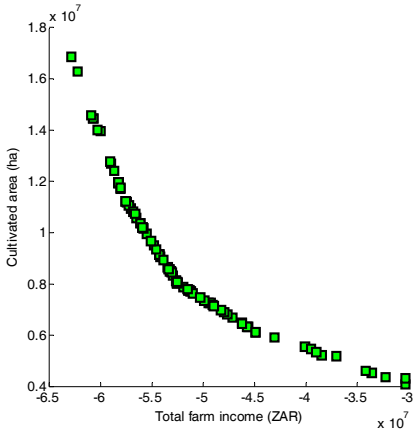

Figure 4. The non dominated solutions for the irrigation planning

Results and discussions

MDEA is used to solve the multi-objective problems above. Figures 1, 2, 3 and 4 above present the non dominated solutions for the test problems 1, 2, 3 and irrigation planning model. It is found that the solutions converge to Pareto front. It can also be found that MDEA achieved the two goals in multiobjective optimization problem. The goals are to discover solutions as close to the Pareto-front as possible and to find solutions as diverse as possible in the obtained non-dominated front. A good multi-

objective evolutionary algorithm will be known if both goals are satisfied (Deb, 2001). The non-dominated solutions will be evaluated using higher level knowledge to determine the appropriate solution to be chosen at a particular time.

In all the test problems and irrigation planning model, the number of non dominated solutions generated are 50. This shows that all the solutions become non-dominated after undergoing the operations of DE which are mutation, crossover and selection. The otherwise solutions that would have been infeasible or dominated produce offspring to replace themselves. All the problems converge to Pareto optimal front in less than 200 iterations.

Conclusions

Multi-objective differential evolution algorithm (MDEA) is illustrated in this paper. The selection scheme in the original DE is improved to be able to solve multi-objective problems. Also, dominated solutions are removed in the last generation only instead of removing them in all the generations. This saves us lots of simulation runs and also increases the number of non-dominated solutions giving us wider Pareto optimal fronts. The test problems used to validate the algorithm show that MDEA is a good optimizer. The algorithm gives good spread of solutions maintaining diversity and convergence. The algorithm is further applied to irrigation planning problem and the results are encouraging. Therefore, MDEA is a good alternative for solving water resources management problems and other engineering problems.

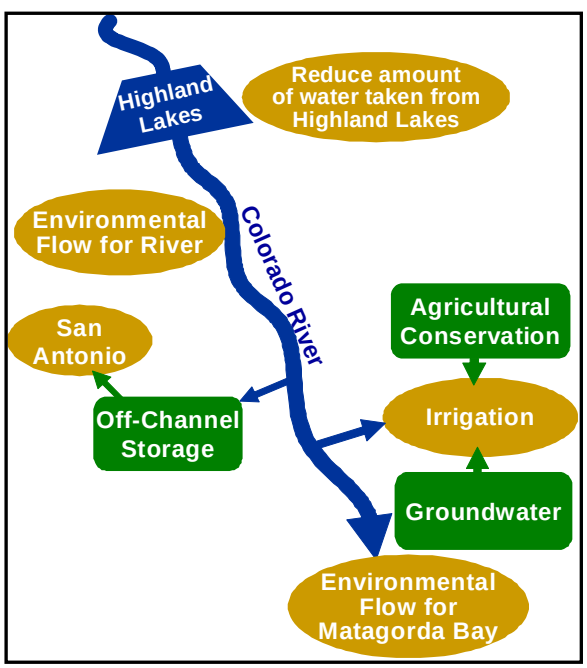
Lower Colorado River Authority * San Antonio Water System

Abstract

The Lower Colorado River Authority (LCRA) – San Antonio Water System (SAWS) Water Project is being studied to conserve water, develop conjunctive groundwater supplies, and capture excess and unused river flows to meet future water needs for two neighboring regions in Texas. Agricultural and other rural water needs would be met on a more reliable basis in the lower Colorado River basin through water conservation, surface water development and limited groundwater production. Surface water would be transferred to the San Antonio area to meet municipal needs in quantities still being evaluated. The project is in its sixth year of detailed studies addressing environmental, agricultural, socioeconomic, and engineering aspects of the project. Tools are being developed and used in project planning including instream flow criteria, water quality assessments, bay freshwater inflow criteria, surface water availability models and operating approaches, agricultural conservation measures, groundwater models, and economic models.

Models used to calculate water availability and environmental flow requirements have been developed largely within existing frameworks based on hydrologic data available from historical events. This is a standard approach used by water planners across the country as well as by many regulatory agencies for permit review. In view of the project's eighty-year planning horizon, contractual obligations associated with this particular project, comments from the project's Science Review Panel and increased public and regulatory awareness of climate change issues, the project team is exploring predictions of climate change in the region and methods to assess potential impacts on the LCRA-SAWS Water Project during the project's expected life.

After qualitatively assessing system vulnerabilities potentially resulting from changed climate conditions, the project team initiated a quantitative evaluation of possible future climate scenarios. Using a scenario approach identifies a broad range of possible future implications for the watershed and its various systems. Two atmosphere-ocean general circulation models and two carbon emission scenarios were selected from which to generate potential climate scenarios for future time periods of 2050 and 2080. Global-scale changes in key climate parameters (i.e., temperature, precipitation, evaporation and sea level rise) were then translated to the local watershed scale. The Variable Infiltration Capacity hydrology model was then used to simulate historical runoff, river flow and evaporation under future climate



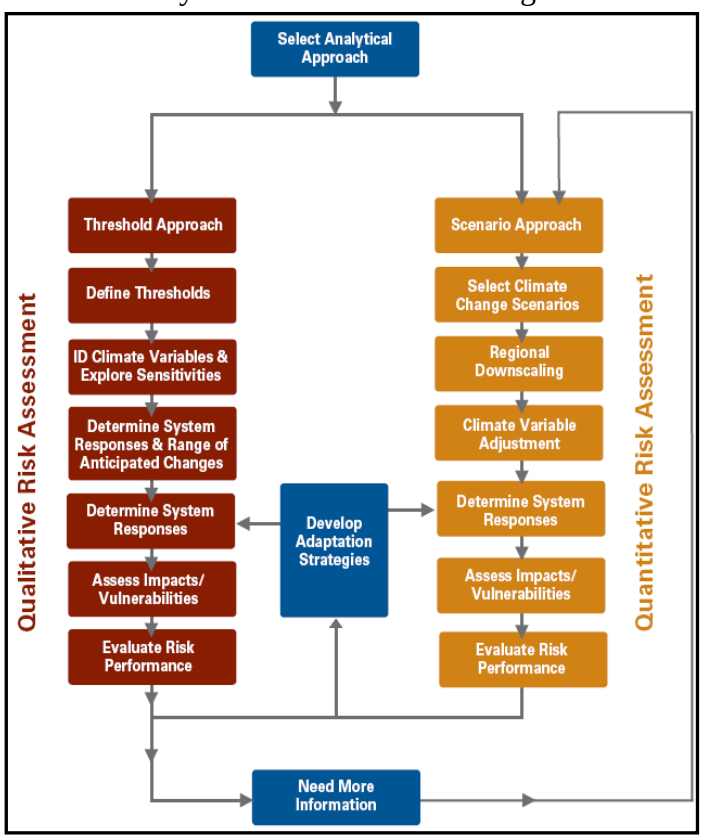
conditions and to generate "perturbation ratios" (adjustment factors) to be applied to historical data.

Climate-change adjusted hydrologic data sets were produced for use in simulating water availability that could result if the climate scenarios were to occur. Simulations using the "new" hydrologic flows were generated using the surface water model for project planning. Potential changes throughout the system including water availability, river water quality, affects to riverine habitat, and affects to Matagorda Bay were analyzed. Additionally, projected changes to agricultural water demand due to changes in atmospheric carbon dioxide levels, temperatures and precipitation were projected.

Introduction

The Lower Colorado River Authority (LCRA)-San Antonio Water System (SAWS) Project (LSWP) is a water sharing proposal to develop alternative supplies that could help meet long-term needs in the lower Colorado River basin and the San Antonio area. The LSWP contains three strategies that would conserve and develop water in the lower Colorado River basin for both regions:

1. Reduce agricultural irrigation demands for water with conservation practices and measures, such as laser-leveling fields, improving canals and growing more water-efficient rice,
2. Capture and store unused and excess river flows in an off-channel storage facility and,
3. Use a limited amount of groundwater for agriculture during dry periods when an adequate volume of surface water is not available.



LCRA and SAWS agree the project will not proceed if studies show the costs are too high, not enough water is

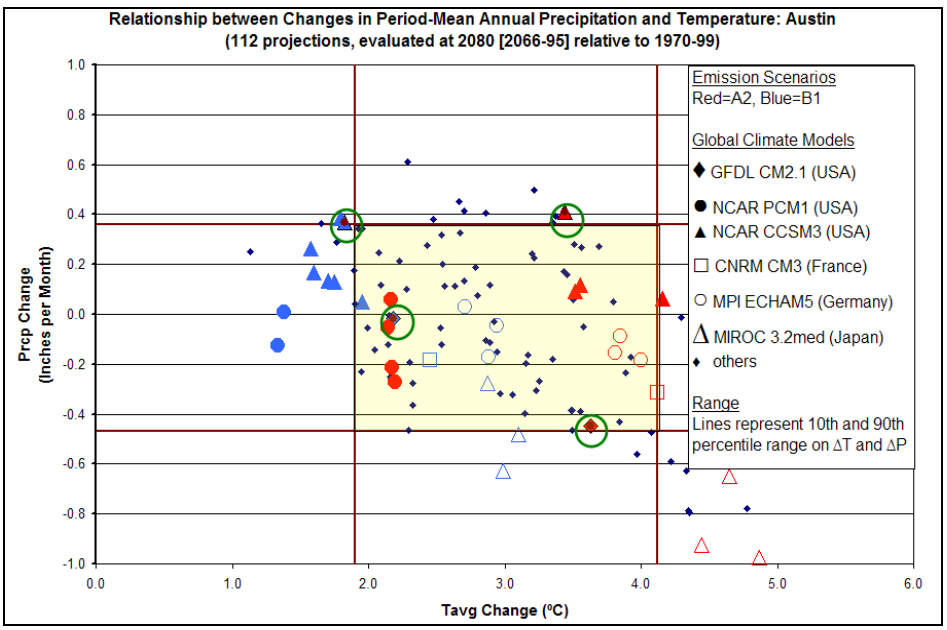
available, or if the project does not meet specific requirements adopted by the Texas Legislature to protect the lower Colorado River basin.

Climate change was considered a key aspect to overall project risk due to its potential effects on water availability, agricultural water use, and the Matagorda Bay system.

Framework for Evaluating Climate Change Risk

Climate change risk assessment is used to systematically evaluate the vulnerability of water systems to climate changes. A dual analytical framework consisting of both qualitative and quantitative approaches was applied in this assessment. The qualitative assessment involved focused workshops with experts in each of the key system component areas. Through guided discussions, the climate sensitivity, adaptive capacity, and vulnerability of various system components was explored, documented into a vulnerability matrix, and the most critical areas were identified.

Following the identification of key areas, a quantitative scenario approach was initiated. The scenario approach involved the selection of climate change scenarios, scaling global climate projections to the regional scale (downscaling), application of techniques to statistically-adjust historical climatology, assessment of water supply and ecological system responses to various changes in climate parameters and, finally, an assessment of the system vulnerability and risk.



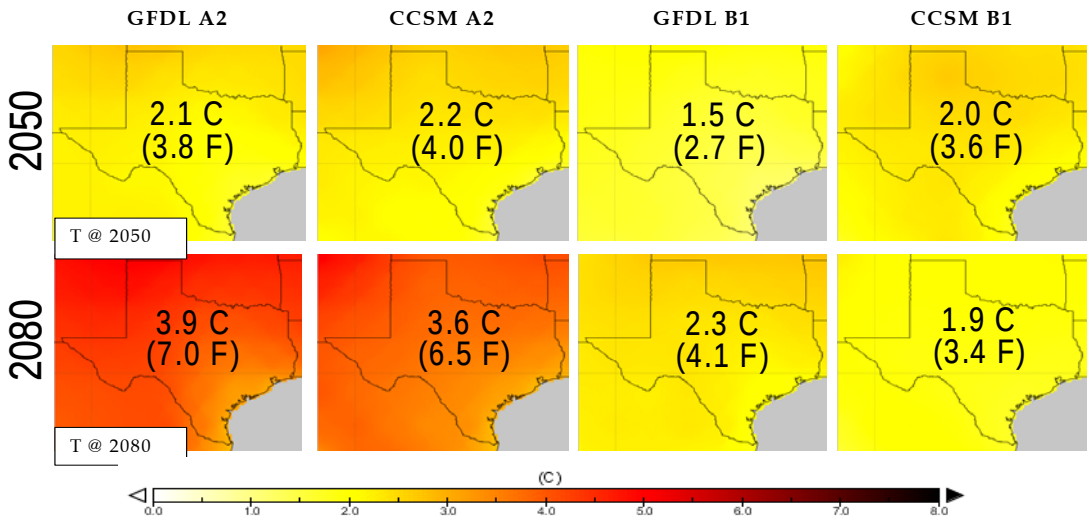
Climate Scenario Development

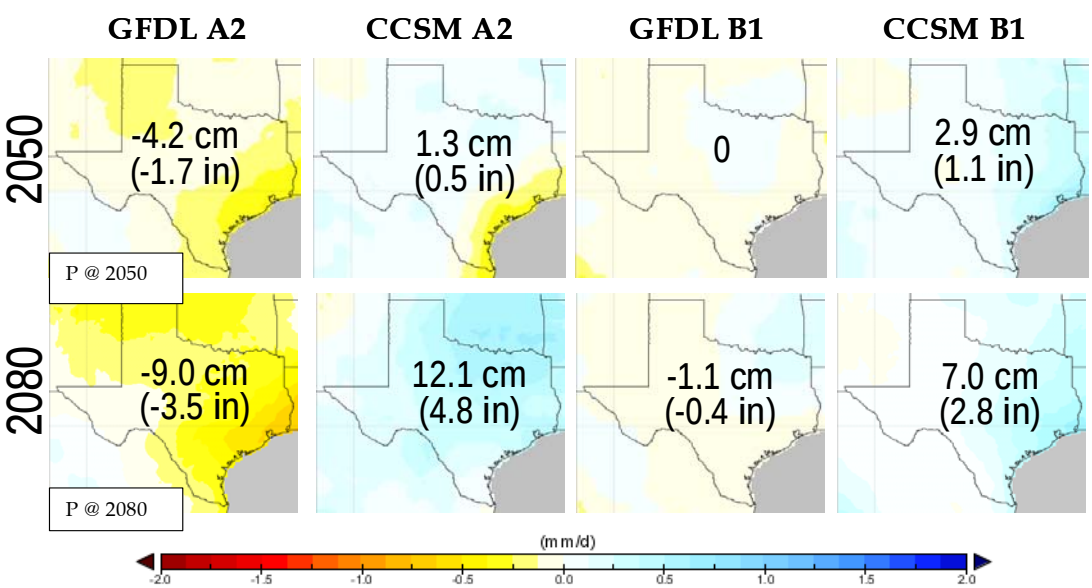
Methods

Given the uncertainty associated with future climate change projections and models, it was desirable to bracket a range of future conditions. Climate scenarios were developed by selecting a combination of future emission scenarios developed by the Intergovernmental Panel on Climate Change (IPCC) and simulated climate projections from coupled atmosphere-ocean general circulation models (AOGCMs).

Five basic criteria were considered in the selection of climate change projections for use in the project including:

- Climate parameters and metrics (annual mean temperature and precipitation)
- Future climate periods (2050 and 2080)
- Locations across the watershed (upper, mid, and lower basin)
- Range of projections (bracketed range to extent possible)
- Consistency of global circulation models and emission scenarios





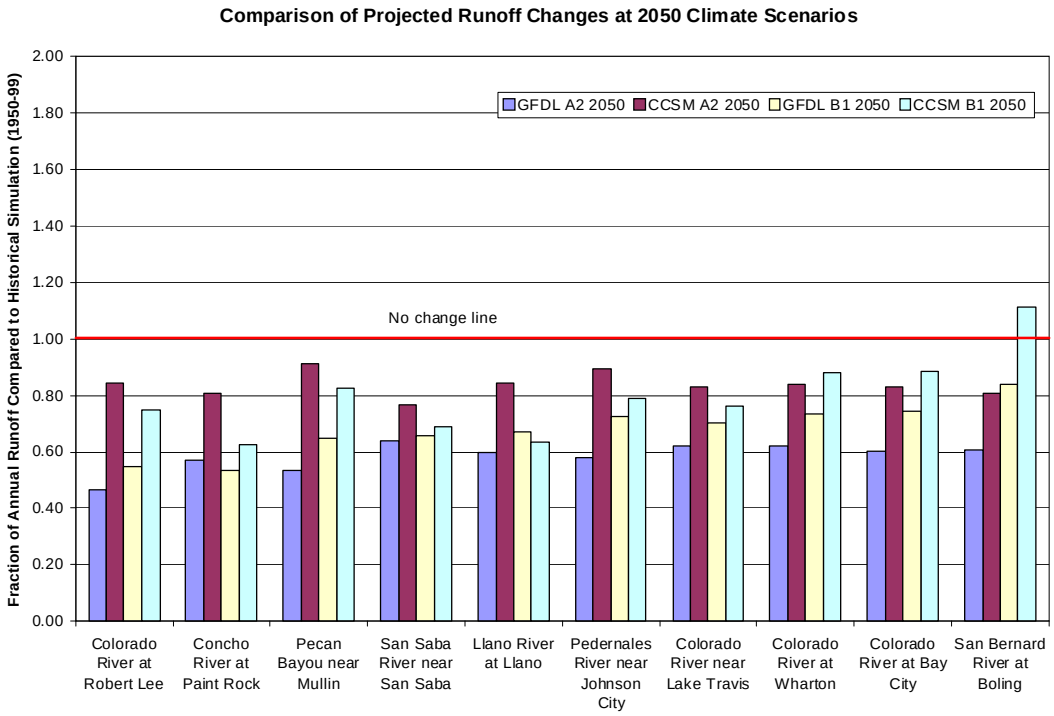
A total of 112 future projections developed for the IPCC, subsequently bias-corrected and statistically downscaled to 1/8th degree, were obtained from Lawrence Livermore National Laboratory (LLNL) under the World Climate Research Program's (WCRP) Coupled Model Intercomparison Project Phase 3 (CMIP3). The model projections were computed for several points in the Colorado River basin for two future periods: 2050 and 2080. Analysis bracketing the 10th and 90th percentile range of temperature and precipitation projections was developed and judged suitable for evaluating the range of future conditions. Two models were selected for the analysis: (1) the U.S. Department of Commerce National Oceanographic and Atmospheric Administration Geophysical Fluid Dynamics Laboratory (GFDL) model and (2) the National Center for Atmospheric Research model (CCSM). Simulations for relatively high and relatively low carbon emission scenarios (A2 and B1, respectively) were selected to create four scenarios that broadly captured the range of potential future climate conditions.

Results

The "A2" climate scenarios represent conditions with emissions of greenhouse gases somewhat higher than others developed by the IPCC and thus represent a warmer future climate. Under these scenarios, basin-wide annual average temperatures are

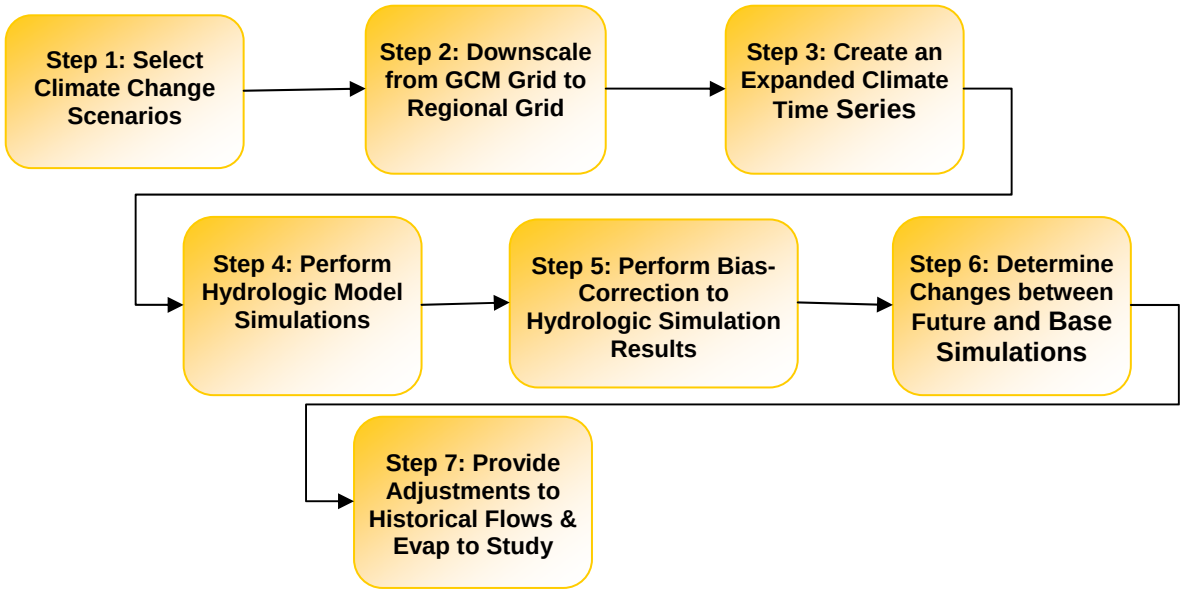
projected to increase by more than 2 degrees C (3.6° F) by 2050 and nearly 4 degrees C (7.2° F) by 2080. More modest warming is projected under the "B1" scenarios, with warming around 2 degrees C (3.6° F) by 2080. Precipitation trends, however, are more variable among the scenarios. The GFDL model consistently projects moderate to high drying conditions, while the CCSM model consistently projects wetter conditions. Regardless of the direction of the precipitation change, the annual projected changes are small by year 2050 [from a drying of 4.2 centimeters per year (1.7 inches per year) to a wetting of 2.9 centimeters per year (1.1 inches per year)]. The greatest warming is projected for the upper portion of the basin, but the precipitation projections appear more dependent on the general circulation model than on the emission scenario.

Hydrologic Modeling



Methods

While climate, primarily temperature and precipitation, is where changes are manifested, it is the interaction of climate and the land processes that are of greatest importance to surface water availability analysis. A survey of hydrologic models was performed to identify the most suitable physically-based model that could translate the changes in climate to changes in runoff, evaporation, evapotranspiration, and soil moisture. The Variable Infiltration Capacity (VIC) model application for the Gulf region was obtained from University of Washington's Climate Impacts Group (CIG) and was adapted for this study. The VIC model was calibrated for the Colorado River basin "naturalized" flows based on observed 1950-1999 climate. Future (2050 and 2080) simulations were developed for the four climate change scenarios: GFDL A2, GFDL B1, CCSM A1 and CCSM A2.



One difficulty that arises in implementing climate change into long-term water resources planning is that natural hydrologic variability is often greater than the magnitude of change expected over several decades. To effectively integrate the natural variability and climate change signal, modified historical temperature and precipitation time series were created by applying a "quantile map" approach. This approach maps the statistical properties of climate change data set onto the longer observed data set. This approach can reconcile shifts in the probabilities, where little change occurs in January, a consistent drying in May, and redistribution of rainfall in September.

Results

In each of the climate change scenarios for 2050, Colorado River streamflow was projected to decrease. Decreases were most substantial in the upper portion of the basin above the City of Llano and occurred even under modestly wet climate scenarios due to the overwhelming effect of increased evapotranspiration. Overall annual projected streamflow reductions ranged from 17 percent to 38 percent at Lake Travis (near Austin). However, the change in streamflow downstream of Lake Travis ranged from very small reductions to increases. The lower portion of the basin is more sensitive to the precipitation projections as the annual rainfall generally exceeds evapotranspiration. The projected changes in stream flow for each of the scenarios are compared in the figure below.

The results of the hydrologic modeling were consolidated into a time series of adjustments to the historical naturalized hydrology. This process is necessary since most of the assessment tools are configured to evaluate future changes under historical hydrology. Bias-correction was performed to the hydrologic simulation results to compensate for errors in calibration, gage records, climate data sets, or other errors. The changes, along with changes in non-hydrologic parameters, will be provided to the various impact assessment teams for evaluation of climate impacts on riverine and ecological systems.

Impact and Risk

The current phase of the climate change study is assessing possible impacts on key aspects of the LSWP. Projected changes in climate parameters, streamflow, evaporation and evapotranspiration, sea level rise, and carbon dioxide concentrations are being incorporated into assessments related to:

- Surface Water Availability
- Groundwater for Agriculture
- Agricultural Water Use and Conservation
- River Water Quality and Aquatic Habitat
- Matagorda Bay Health (Temperature, Salinity, Freshwater Flows)

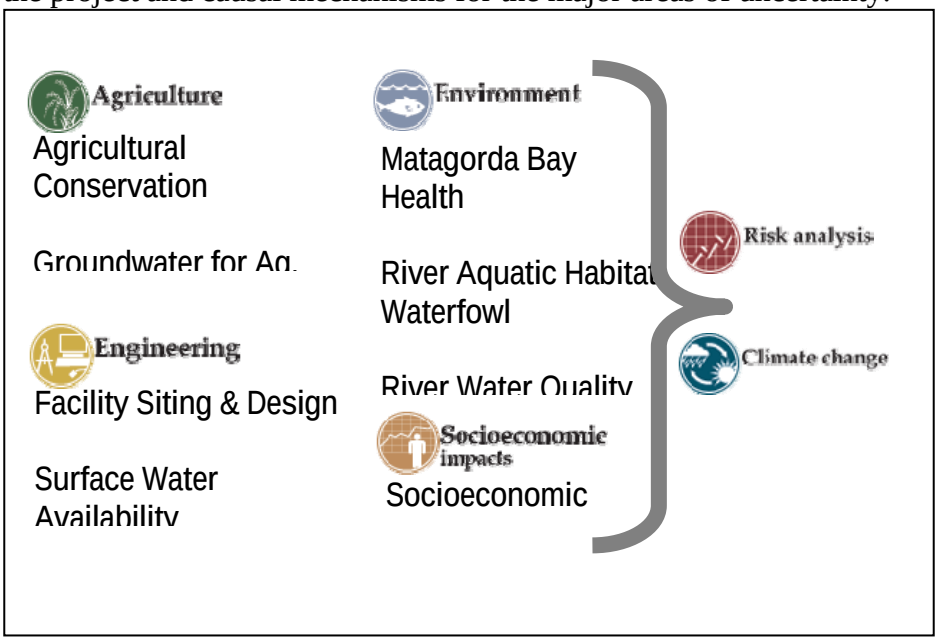
Surface Water Availability

The projects surface water availability teams is evaluating changes in reservoir operations, deliveries to various water users, hydropower generation, and general feasibility of the LSWP.

Groundwater and Agriculture

Project teams are evaluating the impact of climate change on rice yields, planting dates, groundwater recharge and water levels, water demands, and conservation potential.

Aquatic habitat and Matagorda Bay Health



Teams are evaluating changes to river water quality and habitat and estuarine ecosystems due to changes in temperature, flow, and sea level rise. Changes in coastal erosion, barrier islands, and salinity intrusion are being evaluated along with changes to freshwater flows to evaluate effects to Matagorda Bay.

A Comprehensive Risk Analysis

The next step planned for the climate change assessment includes comprehensive analyses that will consider the major identified areas of risk to the project. Climate change is only one, albeit important, factor being considered in this structured analysis. In 2009, the LSWP is expected to

complete its principal evaluations and will be able to understand risks associated with the project and causal mechanisms for the major areas of uncertainty.

Conclusion

The Lower Colorado River Authority and the San Antonio Water System are leading the efforts to assess the potential long-range implications of climate change on water resources. The approach comprehensively incorporates major elements of the river system including projected water demands, supply availability from groundwater and surface water sources and aquatic and marine ecosystems. While the results of the analyses from individual studies are not yet complete, the application of climate projections on historical hydrology data sets provides a strong foundation for understanding the range of uncertainty in future riverine and ecological systems.

ASYMPTOTIC VARIANCE OF REGIONAL GROWTH CURVE FOR GENERALIZED LOGISTIC DISTRIBUTION

ABSTRACT

The index flood method was introduced by Dalrymple to overcome the difficulties to obtain reliable estimates of the quantiles from relatively short record length. However, the application of index flood method must account for the additional uncertainty due to estimation of index flood at site. One must account for the uncertainties of the quantile estimates and those associated with the index flood. In this study, the generalized logistic distribution is considered as a an appropriate model for regional frequency analysis in Korea based on the method of probability weighted moments under the assumption that the regional quantiles and the index flood at site are independent. An approximate formulation of the variance of the quantile is introduced to evaluate the uncertainty of the estimated growth curve.

INTRODUCTION

Statistical quantiles of frequency analysis are influenced by increasing uncertainty with frequency occurrence as those are estimated from relatively short record length. It is difficult to obtain reliable quantile estimates with small exceedance probabilities because the frequency analysis generally used annual maximum series of 30-50 years of observations.

Benson (1962) showed that reliable quantile estimates can be obtained when the return period is less than twice of the record length, while reliable quantile estimates are obtained only for that nonexceedance probability is less than 1-1/T by Hosking et al. (1984). Regional frequency analysis is a method which tries to overcome these difficulties by using space to increase time, and this is done by normalizing annual maximum series in a region using index flood. The regional frequency analysis provides a reliable quantile estimate of the normalized sample for return periods for design purposes. However, the application of index flood method should be considered additional uncertainty from the estimation of index flood as well as the uncertainties of the normalized quantile estimates in a specified site.

The index flood method has been applied and provided appropriate procedures for estimating quantile in many countries; however, there have been not many studies about the uncertainty of quantile estimates.

Assuming a two-parameter regional Weibull model, Boes et al. (1989) derived an exact simple formula for the Cramer–Rao lower bound for the variance of unbiased estimator of the quantile and quantified the gain of regional flood frequency analysis over single-site analysis via this formula. Lu and Stedinger (1992) provided simple formulas based on PWM quantile estimator for estimating the sampling variances of the GEV distribution. Heo et al. (2001) derived and compared the asymptotic variances on a population quantile for the three-parameter Weibull model based on the methods of moments, maximum likelihood, and probability weighted moments. De Michele and Rosso (2001) evaluated the variance of quantile estimator for the regional probability distribution of normalized flood flows when the GEV distribution is used with the parameters estimated by the PWM method. They combined this with the variance of index flood estimator to obtain an uncertainty model for evaluating the variance of at-site flood estimators, and introduced an efficiency index to discriminate between single-site analysis and the regional analysis. In this paper, the variance of quantile estimates obtained from the index flood method was proposed to assess the uncertainty in regional frequency analysis following the procedures presented by De Michele and Rosso (2001).

The method of the probability weighted moments was considered for parameter estimation and the generalized logistic distribution recently recommended as an appropriate model for regional frequency analysis in Korea was used. Finally, we joined the variance of the normalized quantile estimator to that of the estimated index flood at a given site so as to yield the variance of the regional quantile estimator.

VARIANCE OF THE QUANTILE ESTIMATOR

Generalized Logistic (GL) Distribution

The GL distribution is a generalization of the 2-parameter logistic distribution and is also a special case of the kappa distribution. This generalization of the logistic distribution differs from other distributions defined in the literature. It is a reparameterized version of the log-logistic distribution presented by Ahmad et al. (1988). The name reflects the distribution's similarity to the generalized Pareto and generalized extreme value distributions (Hosking and Wallis, 1997). The cumulative distribution function and the probability density function of the GL distribution are defined respectively as (Hosking, 1986). Figure 1 shows some examples of the PDF of the GL distribution with $\beta = \mp 0.185, \mp 0.114, 0$ (corresponding to skewness coefficients $\gamma = \pm 2, \pm 1, 0$) for $x_0 = 0$ and $\alpha = 1$.

$$F(x) = \left[1 + \left\{ 1 - \frac{\beta}{\alpha}\left(x - x_0\right) \right\}^{1/\beta} \right]^{-1} \tag{1}$$

$$f(x)=\frac{1}{\alpha}\left\{1-\frac{\beta}{\alpha}(x-x_0)\right\}^{1/\beta-1}\left[1+\left\{1-\frac{\beta}{\alpha}(x-x_0)\right\}^{1/\beta}\right]^{-2} \tag{2}$$

where x_0, α, and β are the location, scale, and shape parameter, respectively.

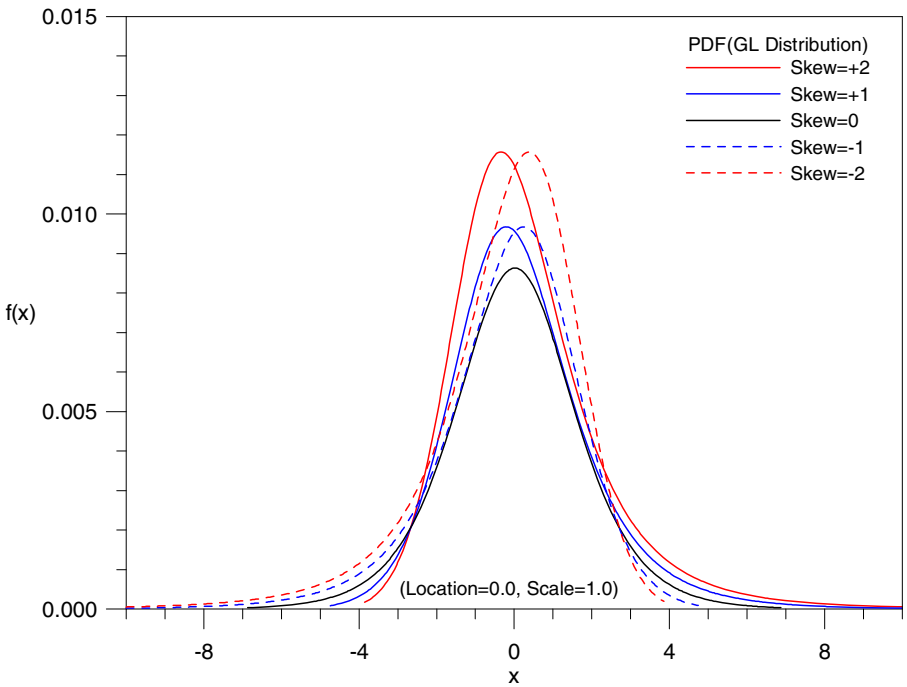

Figure 1. PDFs of the generalized logistic distribution ($x_0=0, \alpha=1$)

In this paper, the variance of quantile was estimated using the method of probability weighted moments as described below.

$$\begin{aligned}Var(\hat{x}_T)=&Var(\hat{x}_0)+Var(\hat{\alpha})\left(\frac{1-(T-1)^{-\hat{\beta}}}{\hat{\beta}}\right)^2+Var(\hat{\beta})\left(\frac{\hat{\alpha}}{\hat{\beta}}\frac{\log(T-1)}{(T-1)^{\hat{\beta}}}-\frac{\hat{\alpha}}{\hat{\beta}^2}\left(1-\frac{1}{(T-1)^{\hat{\beta}}}\right)\right)^2\\&+2Cov(\hat{x}_0,\hat{\alpha})\left(\frac{1-(T-1)^{-\hat{\beta}}}{\hat{\beta}}\right)+2Cov(\hat{x}_0,\hat{\beta})\left(\frac{\hat{\alpha}}{\hat{\beta}}\frac{\log(T-1)}{(T-1)^{\hat{\beta}}}-\frac{\hat{\alpha}}{\hat{\beta}^2}\left(1-\frac{1}{(T-1)^{\hat{\beta}}}\right)\right)\\&+2Cov(\hat{\alpha},\hat{\beta})\left(\frac{1-(T-1)^{-\hat{\beta}}}{\hat{\beta}}\right)\left(\frac{\hat{\alpha}}{\hat{\beta}}\frac{\log(T-1)}{(T-1)^{\beta}}-\frac{\hat{\alpha}}{\hat{\beta}^2}\left(1-\frac{1}{(T-1)^{\hat{\beta}}}\right)\right)\\&=\frac{\alpha^2}{n}v(\beta,T)\end{aligned} \tag{3}$$

where

$$Var(\hat{x}_0) = \frac{1}{n}\left[g_{00}{}^2 V_{00} + g_{01}{}^2 V_{11} + g_{02}{}^2 V_{22} + 2g_{00}g_{01}V_{01} + 2g_{00}g_{02}V_{02} + 2g_{01}g_{02}V_{12} \right] \quad (0.d)$$

$$Var(\hat{\alpha}) = \frac{1}{n}\left[g_{10}{}^2 V_{00} + g_{11}{}^2 V_{11} + g_{12}{}^2 V_{22} + 2g_{10}g_{11}V_{01} + 2g_{10}g_{12}V_{02} + 2g_{11}g_{12}V_{12} \right] \quad (0.e)$$

$$Var(\hat{\beta}) = \frac{1}{n}\left[g_{20}{}^2 V_{00} + g_{21}{}^2 V_{11} + g_{22}{}^2 V_{22} + 2g_{20}g_{21}V_{01} + 2g_{20}g_{22}V_{02} + 2g_{21}g_{22}V_{12} \right] \quad (0.f)$$

$$Cov(\hat{x}_0, \hat{\alpha}) = \frac{1}{n}\left[g_{10}g_{00}V_{00} + g_{11}g_{01}V_{11} + g_{12}g_{02}V_{22} + (g_{10}g_{01} + g_{11}g_{00})V_{01} + (g_{10}g_{02} + g_{12}g_{00})V_{02} + (g_{11}g_{02} + g_{12}g_{01})V_{12} \right] \quad (0.g)$$

$$Cov(\hat{x}_0, \hat{\beta}) = \frac{1}{n}\left[g_{20}g_{00}V_{00} + g_{21}g_{01}V_{11} + g_{22}g_{02}V_{22} + (g_{20}g_{01} + g_{21}g_{00})V_{01} + (g_{20}g_{02} + g_{22}g_{00})V_{02} + (g_{21}g_{02} + g_{22}g_{01})V_{12} \right] \quad (0.h)$$

$$Cov(\hat{\alpha}, \hat{\beta}) = \frac{1}{n}\left[g_{20}g_{10}V_{00} + g_{21}g_{11}V_{11} + g_{22}g_{12}V_{22} + (g_{20}g_{11} + g_{21}g_{10})V_{01} + (g_{20}g_{12} + g_{22}g_{10})V_{02} + (g_{21}g_{12} + g_{22}g_{11})V_{12} \right] \quad (0.i)$$

and $d_1 = \psi(1+\beta) - \psi(1-\beta)$, $g_1 = \Gamma(1+\beta)\Gamma(1-\beta)$, $g_{00} = \frac{1}{g_1}\left\{ \frac{(1-\beta)^2(g_1-1)}{\beta^2} + 1 - \frac{1-\beta}{\beta}d_1 \right\}$,

$g_{01} = \frac{2}{g_1}\left\{ \frac{(2\beta-3)(g_1-1)}{\beta^2} + \frac{(3-\beta)}{\beta}d_1 \right\}$, $g_{02} = \frac{6}{g_1}\left\{ \frac{(g_1-1)}{\beta^2} - \frac{d_1}{\beta} \right\}$, $g_{10} = \frac{1}{g_1}\{(1-\beta)d_1 - 1\}$,

$g_{11} = \frac{2}{g_1}\{1-(3-\beta)d_1\}$, $g_{12} = \frac{1}{g_1}\{6d_1\}$, $g_{20} = \frac{1}{g_1}\left\{ \frac{\beta-1}{\alpha} \right\}$, $g_{21} = \frac{2}{g_1}\left\{ \frac{(3-\beta)}{\alpha} \right\}$, $g_{22} = \frac{1}{g_1}\left\{ -\frac{6}{\alpha} \right\}$.

Index Flood Method

Regional frequency analysis is a procedure that used the all available data in a region that approximately satisfy hydrological homogeneity condition, thus the reliable quantile estimate for relatively large return period could be obtained. It is assumed that a statistically homogeneous region is defined as that region where the underlying data at each site have identical frequency distribution apart from the index flood. Index flood method is generally used in the regional frequency analysis and the sample data in a homogeneous region normalized by dividing the at-site index flood follows a growth curve that is identical for all sites. Therefore, the quantile at a certain site is estimated by multiplying the quantile of the growth curve by the mean annual data at the site. This procedure could be expressed following equation.

$$q_T = q_{index} \cdot x_T \quad (5)$$

where q_T is the T-year quantile at a certain site, x_T is the T-year normalized quantile in the region, q_{index} is index flood at a certain site.

The T-year quantile estimate is given by Eq. (6).

$$\hat{x}_T = \hat{x}_0 + \frac{\hat{\alpha}}{\hat{\beta}}\left[1-\left(T-1\right)^{-\hat{\beta}}\right] \tag{6}$$

From Eqs. (6) and (5), one gets

$$q_T = q_{index} \cdot \left[\hat{x}_0 + \frac{\hat{\alpha}}{\hat{\beta}}\left\{1-\left(T-1\right)^{-\hat{\beta}}\right\}\right] \tag{7}$$

The sampling variability of the quantile estimate can be investigated by assuming that $\hat{q}_T$ is a random variable, which is product of two variates, $\hat{q}_{index}$ and $\hat{x}_T$ with mean $E[\hat{q}_{index}]$ and $E[\hat{x}_T]$, respectively, and variance $Var[\hat{q}_{index}]$ and $Var[\hat{x}_T]$, respectively (Stedinger et al., 1992).

Although the procedure of estimating q_{index} is somewhat independent from that used to evaluate the regional growth curve, this does not make $\hat{q}_{index}$ and $\hat{x}_T$ statistically independent. However, it is assumed here that $\hat{q}_{index}$ and $\hat{x}_T$ are statistically independent in order to derive an uncertainty model useful for practical application. Accordingly

$$E[\hat{q}_T] = E[\hat{q}_{index}]E[\hat{x}_T] \tag{8}$$

$$\begin{aligned}
Var(\hat{q}_T) &= E\left[\left(\hat{q}_{index}\hat{x}_T\right)^2\right] - E^2[\hat{q}_{index}\hat{x}_T] \\
&= E\left[\hat{q}_{index}{}^2\right]E\left[\hat{x}_T{}^2\right] - E^2[\hat{q}_{index}]E^2[\hat{x}_T] \\
&= E\left[\hat{q}_{index}{}^2\right]E\left[\hat{x}_T{}^2\right] - E^2[\hat{q}_{index}]E\left[\hat{x}_T{}^2\right] + E^2[\hat{q}_{index}]E\left[\hat{x}_T{}^2\right] - E^2[\hat{q}_{index}]E^2[\hat{x}_T] \\
&= Var(\hat{q}_{index})E\left[\hat{x}_T{}^2\right] + E^2[\hat{q}_{index}]Var(\hat{x}_T) \\
&= Var(\hat{q}_{index})\left\{E\left[\hat{x}_T{}^2\right] - E^2[\hat{x}_T] + E^2[\hat{x}_T]\right\} + E^2[\hat{q}_{index}]Var(\hat{x}_T) \\
&= Var(\hat{q}_{index})\left\{E\left[\hat{x}_T{}^2\right] - E^2[\hat{x}_T]\right\} + Var(\hat{q}_{index})E^2[\hat{x}_T] + E^2[\hat{q}_{index}]Var(\hat{x}_T) \\
&= Var(\hat{q}_{index})Var(\hat{x}_T) + Var(\hat{q}_{index})E^2[\hat{x}_T] + E^2[\hat{q}_{index}]Var(\hat{x}_T)
\end{aligned} \tag{9}$$

If annual maximum series of length n' is available for a given site, one can estimate q_{index} as the sample mean of the observed series, hence the sampling variance of $\hat{q}_{index}$ is given by

$$\begin{aligned}
Var(\hat{q}_{index}) &= Var(\hat{\mu}_Q) \\
&= Var\left(\frac{1}{n'}\sum_{i=1}^{n'} Q_i\right) = \frac{1}{n'^2}Var\left(\sum_{i=1}^{n'} Q_i\right) \\
&= \frac{1}{n'^2}\sum_{i=1}^{n'} Var\left(Q_i\right) = \frac{1}{n'^2}n'Var\left(Q\right) = \frac{1}{n'}Var\left(Q\right)
\end{aligned} \tag{10}$$

APPLICATION

In this paper, the regional frequency analysis was performed with annual maximum 24hr rainfall data of 378 sites in Korea based on the method of forming homogeneous regions by Nam et al. (2005). And 378 sites were divided into 14 homogeneous regions by Fuzzy technique. The site characteristics were used in the cluster analysis as follows: longitude, latitude, altitude, annual mean precipitation over 12 months, and annual mean precipitation over rainy season.
The homogeneous regions divided by cluster analysis and the heterogeneity measures (H) of Hosking and Wallis (1997) of each region were summarized in Table 1. Table 1 showed that all regions were homogeneous except for NAK2. On the other hand, according to studies of Nam et al. (2005), the generalized logistic distribution was selected as an appropriate regional frequency distribution of Korea.

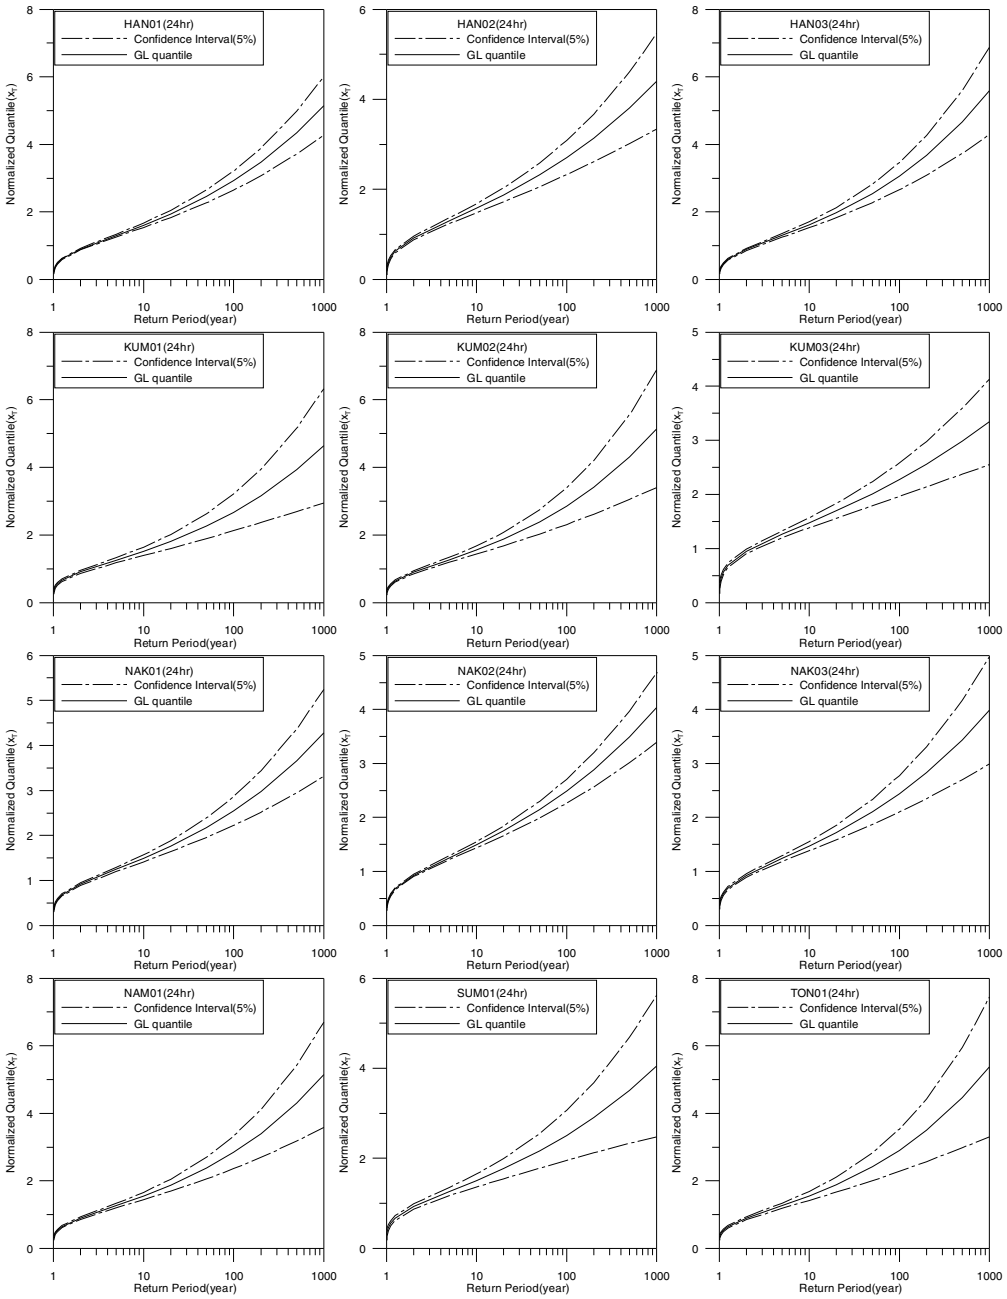

Table 1. Results of Regional Frequency Analysis (Nam et al., 2005)

Region	Sub Region	Number of Site	Number of Data	Location Parameter	Scale Parameter	Shape Parameter	Homogeneity
Hangang	HAN1	55	1209	0.899	0.246	-0.235	Hom.[1]
	HAN2	25	422	0.920	0.242	-0.192	Hom.
	HAN3	42	756	0.887	0.249	-0.254	Hom.

Figure 2 showed the quantile estimates and the corresponding 95% confidence intervals of 14 homogeneous regions with the normalized data, the index flood method, and the asymptotic variance. In Fig.2, KUM01, KUM02, NAM01, SUM01, and TON01 regions have relatively wide intervals for other regions. It may be caused by the relatively short record length and the small number of site of those regions.

CONCLUSIONS

The variance of regional quantiles for the generalized logistic distribution were introduced to assess the uncertainty of index flood method as a regional frequency analysis to overcome difficulties to obtain reliable estimates of the quantiles from relatively short record length. The asymptotic variance of quantile estimator for the generalized logistic distribution was introduced to evaluate confidence intervals and it was assumed here that the index floods and quantile estimates are statistically independent in order to derive an uncertainty model useful for practical application. In this study, the generalized logistic distribution is considered as a an appropriate model for regional frequency analysis in Korea based on the method of probability weighted moments under the assumption that the regional quantiles and the index flood at site are independent. An approximate formulation of the variance of quantile is introduced to evaluate the uncertainty of the estimated growth curve.

ABSTRACT

Floodplain or inundation mapping studies are performed for a variety of reasons, and are many times only one phase of a larger engineering or mapping project. As is often the case, many communities and agencies write their scope so that their project's flood studies are performed in accordance with FEMA guidelines, with the intention of incorporating those studies onto FEMA's flood maps in the future. More times than not, this results in the development of a project scope that would fit FEMA's definition of a "detailed study" – field survey, development of the 10-, 50-, 100-, and 500-year flood profiles, etc. However, in certain instances, it may be appropriate to apply a more "limited" detail approach to the study area, while still being able to meet project objectives.

This paper will focus on the various floodplain study methodologies that have been accepted by FEMA (approximate, limited detail, and detailed), when and where each study type can be used, and the similarities and differences between the three. The limited detail approach will specifically be explained and highlighted as a potential solution to bridge the gap that often exists between budget and accuracy needs. Several case studies will be presented to show the difference in steady flow HEC-RAS modeling and mapping results between the study types.

INTRODUCTION

Floodplain and/or inundation mapping studies are performed for numerous reasons. They are performed as a floodplain management tool and as a predecessor to flood hazard mitigation actions. They are often undertaken during the initial phases of larger construction projects to more accurately analyze the risk at the project site, or to compare the risk between pre- and post-construction plans. Flood studies help developers and business or home owners determine the water surface levels at which they must elevate their property in order to reduce the flood risk to which they are susceptible. They are also often important parts of emergency action plans, environmental impact statements, and comprehensive watershed master plans.

As the overseer of the National Flood Insurance Program (NFIP), the Federal Emergency Management Agency (FEMA) undertakes and incorporates flood studies onto their maps in an effort to provide the most accurate product to states, communities, and citizens to use for flood hazard identification and mitigation purposes. Because of floodplain management ordinances and regulations in NFIP communities, many of these non-FEMA-funded flood studies are nevertheless scoped in accordance with FEMA's guidelines so that they can be incorporated onto FEMA's maps at a later time,

either as part of FEMA's routine map updates, or through their Letter of Map Revision (LOMR) process.

FEMA FLOOD STUDY BACKGROUND

Flood insurance rates for any home, building, or habitable structure are determined in large part by two factors: (1) what flood zone the structure is mapped in, and (2) how the ground floor elevation of the structure compares to the 1%-annual-chance water surface elevations (known as base flood elevations, or BFEs) published in the Flood Insurance Study (FIS). With the exception of coastal flooding, shallow flooding, or flooding in areas protected by manmade structures, flood zones are most often mapped on FEMA's Flood Insurance Rate Maps (FIRMs) as either Zone A or Zone AE.

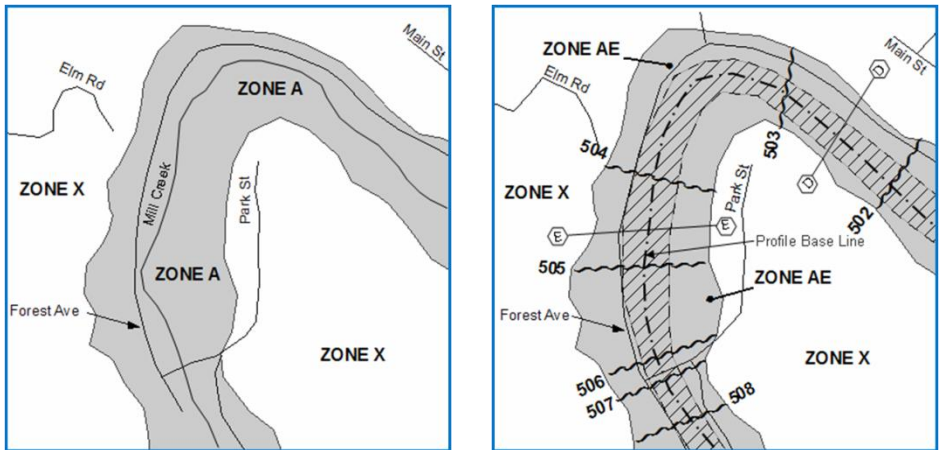

Figure 1. Comparison of Features Shown on Zone A vs. Zone AE Maps

Zone A floodplains on FEMA's maps are used to depict studies that are performed using approximate methods of analysis, and/or where the accuracy of the available topographic data used to develop the floodplain delineations is deemed too coarse to support published BFEs. Zone AE floodplains are used for studies that are performed using detailed methods of analysis. BFEs are published on FEMA's maps for Zone AE streams and are used by flood determination companies for flood insurance rating purposes. Because the flood elevations on Zone A-mapped streams are unknown, flood insurance premiums are often higher for structures in the Zone A floodplain than in the Zone AE floodplain, all things being equal. Therefore, in addition to the improved accuracy that the detailed methodologies provide, there are also insurance premium benefits to performing a study worthy of Zone AE mapping. The decision to do Zone A vs. Zone AE studies in the past has most often been based on budget, accuracy of the available data, and/or flood risk.

FLOOD STUDY TYPES

Historically, most riverine floodplain studies were performed with one of two methodologies. While tools and procedures may have varied from study to study, the general approach followed either the approximate or the detailed path.

Approximate Study. The approximate riverine study is the least rigorous and least expensive of the study types and is most often represented as a Zone A on FEMA's maps. Zone A floodplains have been determined using methodologies ranging from delineations of flood-prone areas using soils and wetlands maps, to simplified normal depth calculations at cross-sections, to actual hydraulic models developed through automated tools. As the name implies, the approximate study is an approximation of the floodplain using best available data, although as technology has improved, it has become more cost-effective to perform new approximate studies using acceptable hydraulic models, which has improved the accuracy of these studies.

Hydraulic structures such as culverts, bridges, and dams are typically not included in approximate models. The 1% annual chance flood (100-year) discharges are most often calculated through the use of regression equations. A regulatory floodway, or the area of the floodplain that must be reserved to be able to pass the base (or 1% annual chance) flood without increasing the water surface elevation by more than a specific height designated by the community, is also not computed for an approximate stream. Approximate studies are most often performed in rural areas, although they can also be useful elsewhere. Flood profiles showing the water surface elevations along each approximate stream are not included in the FIS report that accompanies the flood maps.

Detailed Study. The detailed riverine study, as FEMA terms it, is the study type that most closely translates to hydrologic and hydraulic (H&H) studies performed on other types of non-FEMA projects. The resultant floodplains from a detailed study are most often displayed as Zone AE with BFEs on FEMA's maps, although FEMA has other zone designations that can be used, depending on the circumstance. Cross-sections and hydraulic structures are surveyed in the field for a detailed study. Discharges are often estimated by hydrologic models or more in-depth analysis, although regression equations can be used as well. Regulatory floodways are typically computed for detail-studied streams, and the 10%, 2%, 1%, and 0.2% annual chance flood profiles are all calculated and published in the FIS report.

Until recently, new riverine flood studies undertaken for FEMA purposes followed one of these two paths. However, FEMA now recognizes a blend of these two methodologies, called the limited detail study, as an acceptable approach for updating their flood maps. The limited detail study is a cost-effective alternative to the traditional detailed study and, in areas where high quality topographic data is available (such as LiDAR or aerial surveys), has been shown to be compatible with publishing BFEs on FEMA's flood maps.

LIMITED DETAIL STUDY METHODOLOGY

In the early 2000s, as part of its statewide floodplain mapping program, North Carolina began funding what they termed "limited detail studies" to update the thousands of miles of Zone A riverine floodplain within their state and map them as a Zone AE with published BFEs. As one of the state's original floodplain study contractors, AECOM's Watershed Concepts group played an integral role in working with the state to define the limited detailed methodology and to begin implementing it throughout numerous

counties and watersheds within the state. Since then, thousands of miles of limited detail studies have been performed in multiple states throughout the nation for FEMA floodplain mapping projects in addition to North Carolina, including South Carolina, Georgia, Kentucky, Tennessee, Mississippi, Louisiana, Oklahoma, and New Mexico to name a few.

The decision to publish BFEs on the maps for limited detail studies is left to the discretion of the communities, states, and FEMA. One of the important distinctions between a limited detail study and a detail study is that floodways are typically not mapped for the limited detail study. According to Title 44 of the Code of Federal Regulations, part 60.3, communities where floodways have not been designated but BFEs have been provided are required that "until a regulatory floodway is designated, that no new construction, substantial improvement, or other development… shall be permitted… unless it is demonstrated that the cumulative effect of the proposed development, when combined with all other existing and anticipated development, will not increase the water surface elevation of the base flood more than one foot at any point within the community." [44 CFR Part 60.3(c)(10)] This is an important factor for communities to consider when performing limited detail studies. Because of this, several communities have actually determined floodways, or non-encroachment areas, for their limited detail study streams to satisfy these requirements and provide better information for their residents.

Limited detail studies have been used effectively in situations where a more detailed analysis has been necessary, but where budget constraints have prevented a full detailed analysis. In an economy where greater scrutiny is required for all spending, the limited detail approach has been an excellent balance between the need to produce a better estimate of flood risk than an approximate study can accomplish, but at a reduced cost of a full detailed study

The limited detail study is similar in many ways to a traditional detail study, although there are also several distinct differences between the two. The main difference exists in how survey data is collected and used in the model. Unlike detailed studies where hydraulic structure data are collected in the field using traditional survey methods, structures are only "measured" in the field for the limited detailed approach. Rather than establishing vertical control using published benchmarks, the survey crew for limited detail studies collects structure measurements, such as the stream invert from the top of the road, channel top and bottom widths, top width and toe width of bridge abutments, and culvert opening sizes, among others (see FEMA's *Guidelines & Specifications, Appendix N: Data Capture Guidelines*, pages N-51 – N-54 for full list of measurements collected; http://www.fema.gov/library/viewRecord.do?id=2206). Surveyors will often use a hand or automatic level to get more exact measurements, as shown in Figure 2. Once the size and shape of the hydraulic structure opening is measured, "vertical control" for the limited detail structure uses the elevation at the point from which the measurements were recorded, and all other associated structure elevations are referenced to that "vertical control elevation", or VCE, to come up with the placement and alignment of the structure in the model. The horizontal location of the VCE point is most often collected by GPS, and then the vertical elevation is

extracted from the underlying topography. Thus, the more accurate the available topographic data, the more "in-line" the structures will appear in the model. Advancements have also been made in the vertical accuracy that some types of GPS receivers and methods can achieve (RTK, Virtual Reference System network, etc.). As this technology continues to advance and become more efficient, it may become a useful and efficient alternative to obtain the vertical control elevation for limited detail measurements.

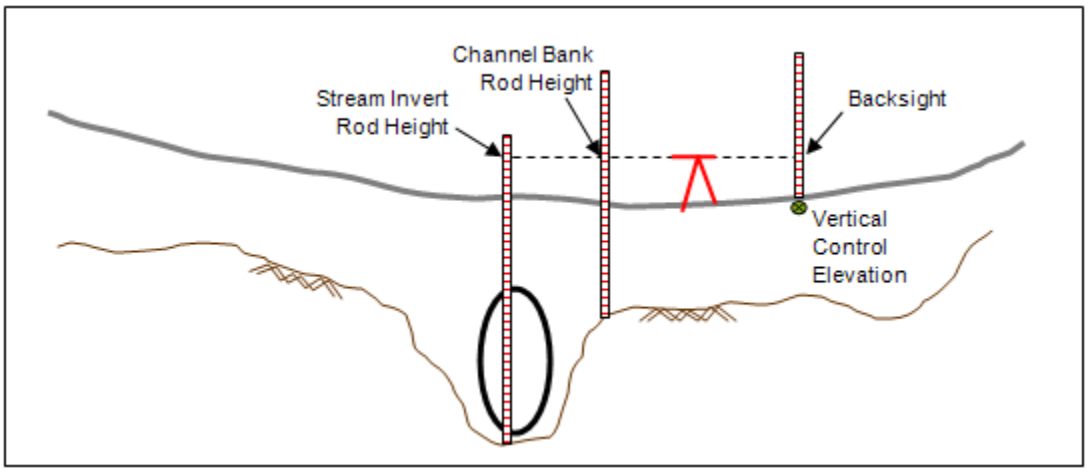

Figure 2. Limited Detail Structure Measurement

In addition to the differences in the way hydraulic structure geometry is estimated in the hydraulic model, the stream channel of the cross-section in the limited detail model is estimated as a trapezoid, as opposed to most detailed models, where the channel and possibly a few points on the overbanks are surveyed (with cross-section geometry supplemented by topographic data where the survey data stops). At limited detail structures, the top and bottom widths of the trapezoidal channel are measured in the field. In between structures at natural floodplain cross-sections, the trapezoidal channel geometry is estimated based on user-defined top width vs. drainage area curves and the channel depth is manually estimated prior to creating the model. The accuracy of the topographic data plays an important role in helping the modeler estimate channel widths once within the limited detail model. Channel depths can often be estimated using nearby measurements from limited detail structures.

Part of the theory behind the limited detail methodology is that the majority of the conveyance is in the overbanks, so having detailed survey dimensions of the actual channel often has little impact on the water surface. Because of this, it may be more appropriate to perform studies of streams that have wide channels or very narrow floodplains, or where the accuracy of the model at lower recurrence intervals (i.e. the 25% or 10% annual chance flood) is critical, using traditional detailed study methods.

Although the cost of a limited detail study is significantly less than that of a full detail study, it is nevertheless important to understand how the difference in approach affects model results, and how the calculated water surface elevations (WSELs) compare to one another based on different factors.

CASE STUDIES

Several detail streams throughout the country that had recently been studied and incorporated onto FEMA's maps were selected as case studies to evaluate how a limited detail version of the stream would compare to the detailed model results. For the purpose of this paper, streams were only considered that had been studied using steady flow HEC-RAS. The other criteria that was used in selecting streams for comparison is outlined as follows:

- Detail stream must have been completed, reviewed, approved, and incorporated onto FEMA's maps
- Detailed model must be available
- Topographic data used in the study must be available and be of high quality

In order to isolate the true differences between limited detail and detail studies, the only parameter that was varied in the limited detail model representation was the survey data. The survey data used within the detailed model was, in essence, "thrown out" and not used, and field measurements and trapezoid size/shape were estimated for the structure and channel geometry, respectively. All other model components (discharges, n-values and associated breaks, topographic data points, cross-section alignment and stationing, starting conditions, etc.) were kept the same between the detailed model and its limited detail equivalent. Ineffective areas were kept the same wherever possible, with the only exceptions being at a few structures, where they were changed according to modeling guidelines because of slight changes in measurements as compared to the detailed models. In the case study results that follow, the thicker, red lines in the profile figures represent the water surface elevations calculated in the original detail model, whereas the blue, filled-in water surface corresponds to the limited detail model results.

% Cross-Sections within 0.3ft Error	96%
% Cross-Sections within 0.5ft Error	100%

As Table 2 and Figure 3 indicate, the Brown Creek limited detail model results compare very closely with those in the detail model. As one would expect, the differences in channel geometry and at structures comprise the majority of the actual

error. The term "error" as mentioned here indicates how the limited detail model's WSELs compared to those in the detail model.

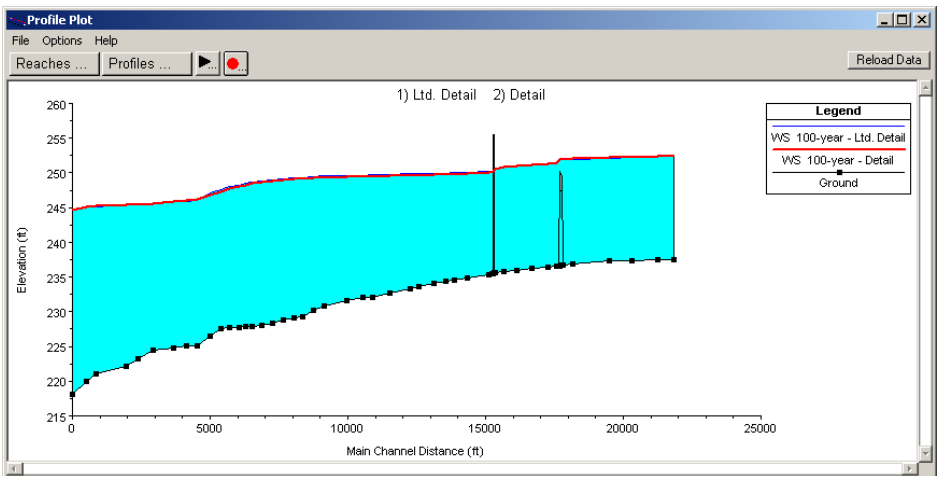

Figure 3. Brown Creek Profile Comparison

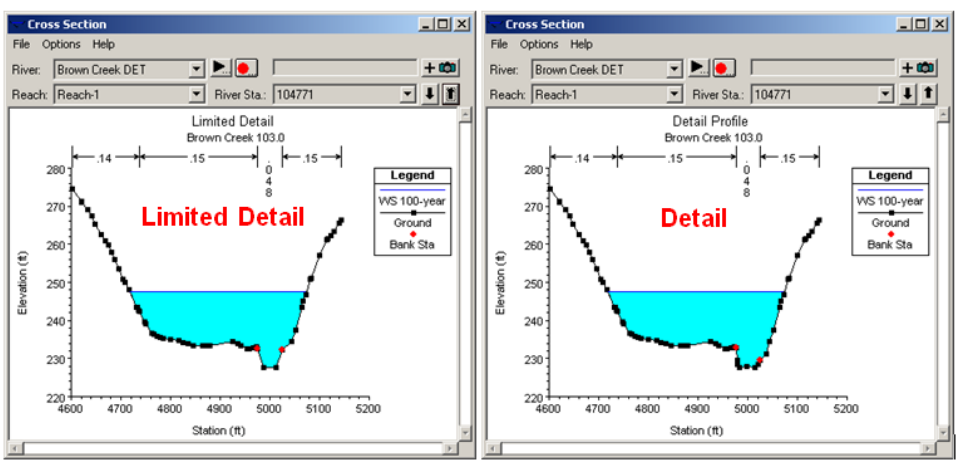

Figure 4. Brown Creek XS Geometry Comparison at Largest WSEL Error

CASE STUDY #2: BUCKNERS CREEK (Texas)

Table 3. Buckners Creek Model Background

Reach Info		Other	
Length	4.8 mi.	Drainage Area	185.4 mi^2
# Structures	2	Discharge Methodology	HEC-HMS
# Cross-sections	28	Topographic Data	2ft contours
Average Slope	0.00074 ft/ft	Starting Conditions	Known WSEL

Table 4. Buckners Creek Comparison Statistics

Statistic	Value
Average Absolute WSEL Error	0.28 ft
Maximum WSEL Error	-0.65 ft
% Cross-Sections within 0.1ft Error	13%
% Cross-Sections within 0.3ft Error	53%
% Cross-Sections within 0.5ft Error	94%

The error in the limited detail model of Buckners Creek as compared to its detailed model version is due to a difference in channel widths. Buckners Creek has fairly steep banks. Since channel bank locations in hydraulic models are often open to interpretation (especially on deeper channels), there were several cross-sections where the engineer performing the limited detailed model estimated a slightly wider channel than what was estimated in the detailed model. The cumulative effect of this resulted in a limited detailed WSEL profile that was on average 0.3ft less than that of the detailed model profile. The largest WSEL error in the Buckners Creek model occurred at the downstream face of the downstream-most bridge in the model. Figure 6 shows how the hydraulic structure using the limited detail representation can often differ from the field surveyed data, which in the case of the Buckners Creek model also had an impact on the overall WSEL difference.

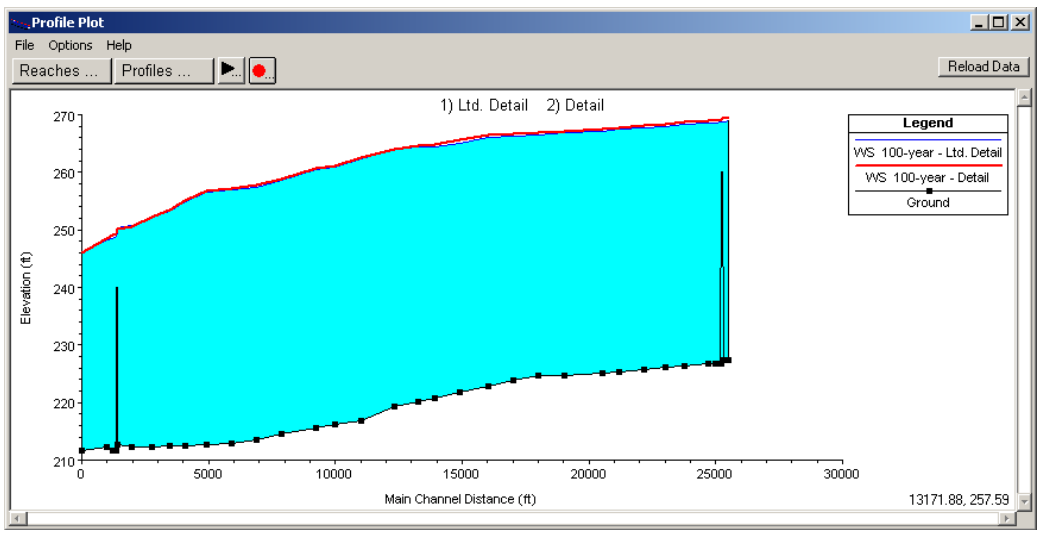

Figure 5. Buckners Creek Profile Comparison

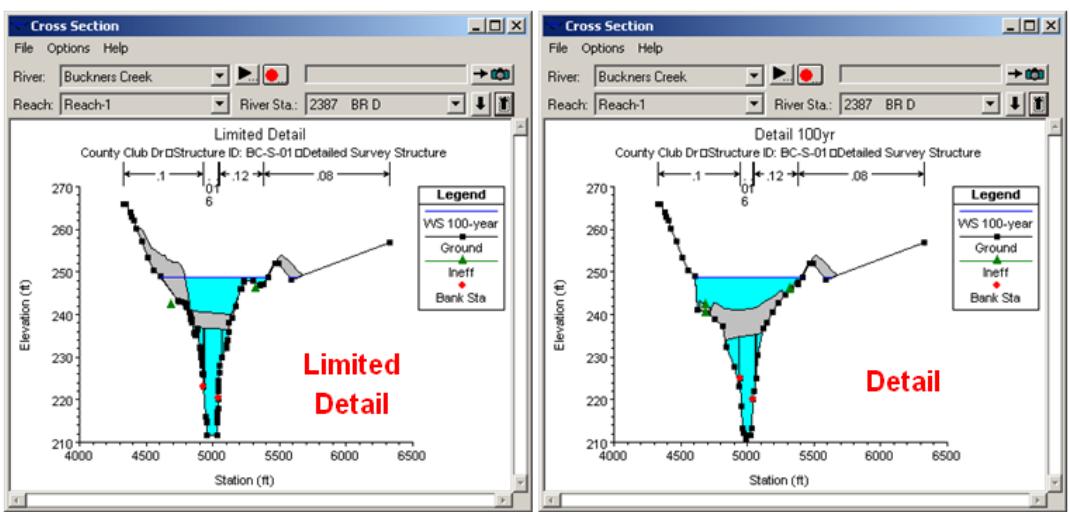

Figure 6. Buckners Creek XS Geometry Comparison at Largest WSEL Error

CASE STUDY #3: CHOUDRANT CREEK (Louisiana)

Table 5. Choudrant Creek Model Background

Reach Info		Other	
Length	5.6 mi.	Drainage Area	21.5 mi^2
# Structures	7	Discharge Methodology	Regression Equations
# Cross-sections	41	Topographic Data	LiDAR
Average Slope	0.0022 ft/ft	Starting Conditions	Normal Depth/Slope

Table 6. Choudrant Creek Comparison Statistics

Statistic	Value
Average Absolute WSEL Error	0.16 ft
Maximum WSEL Error	0.66 ft
% Cross-Sections within 0.1ft Error	42%
% Cross-Sections within 0.3ft Error	87%
% Cross-Sections within 0.5ft Error	96%

Similar to Buckners Creek, the source of the largest "error" as compared to the Choudrant Creek detail model was a result of several cross-sections where the channel width in the limited detail model was estimated to be narrower, as shown in Figure 8. However, once again, the water surface elevations between the two study types are very comparable, even with the inclusion of several additional structures as compared to the previous two case studies.

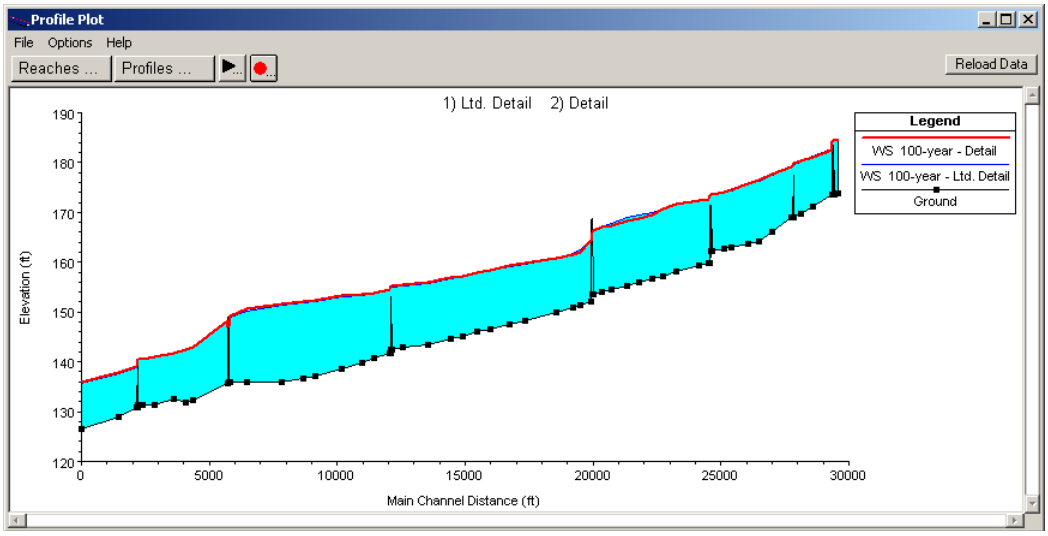

Figure 7. Choudrant Creek Profile Comparison

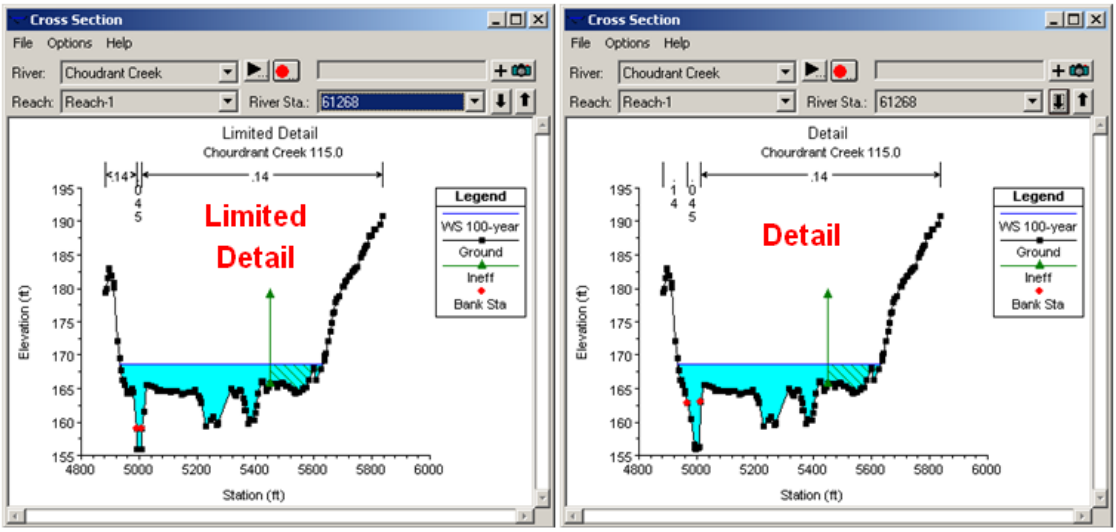

Figure 8. Choudrant Creek XS Geometry Comparison at Largest WSEL Error

CONCLUSIONS

Although the results of these particular three streams that were randomly selected show a very favorable comparison between the limited detail and detail modeling results, further investigation is warranted into other types of streams (i.e. smaller, steeper streams). As previously discussed, smaller streams (with lower discharges) or streams with very narrow floodplains may be more sensitive to the slight changes in geometry between the two different approaches.

However, it should be noted that none of these three streams had any historical data available to use for calibration purposes. Calibration of a limited detail hydraulic model to high water marks, stage-discharge information at gages, or other published data would be performed in a similar manner as it would for a detail model. Therefore, when calibration data is available, a limited detail study can be just as effective at establishing a defendable hydraulic model as a detail model could.

Since the limited detail approach is dependent upon topographic data for establishing its "vertical control" for hydraulic structures in the model, a limited detail study worthy of publishing BFEs on FEMA's maps may not be appropriate in areas where coarser topographic data is the best that is available. However, it is an option that should be considered when budget is a concern, but more accuracy is needed than an approximate study can provide.

Climate Flow Forecast Model for the Brazilian Hydropower System

by

Mario T. L. Barros[1], João E. G. Lopes[2], Renato C. Zambon[3], Alberto L. Francato[4], Paulo S. F. Barbosa[5], Fabio R. Zanfelice[6]

ABSTRACT --- The Brazilian Hydropower System (SIN) is composed today by 107 hydropower plants with 81,036 MW of installed capacity. The system is completely connected due to the Brazilian heterogeneous hydrology. The flow forecast is a very important tool to operate SIN and to other decisions involved in the Brazilian electrical sector. This paper aims to present a model for SIN flow forecasting done in a climate basis, in a monthly basis considering rainfall forecasts for six months ahead. The rainfall forecasts are done by the Brazilian Center for Weather Forecast and Climate Studies (CPTEC). The CPTEC climate forecasting model covers the South America continent and produces forecasts in two grids, 200 by 200 Km and 40 by 40 Km. The flow forecast is done by two hydrological methods. One is the rainfall-flow model SMAP (Soil Moisture Accounting Procedure) by (Lopes et al., 1982) and the other a stochastic linear model (MEL). The final forecasts are defined by a weigh function considering SMAP and MEL forecasts. The flow forecast model is called GERAVAZ and was design using a decision support system frame in order to be practical to users. GERAVAZ was applied to twenty basins covering the main Brazilian rivers. These twenty forecasts are the reference to produce the inflow forecasts to all SIN reservoirs. Preliminary results are quite promising and have great evidences of the potential application of this modeling tool.

Introduction

Short-term and long-term reservoir inflow forecasts represent a big challenge to operation managers of large hydropower systems. When considering the large-scale of the Brazilian Interconnected Power System, the availability of river flow forecasts is still more relevant for hydrothermal operation planning since the annual hydropower production is nearly 91% of the total electricity production. The stochastic modeling of river flows based on time series approach (e.g. Box-Jenkins methodologies) is too complex for practitioners at real time reservoir operation. Also, the quality of the resulting forecasts has been pointed out as a source of criticisms. In addition to potential impacts on operation planning, inflow forecasts can also be a source of great volatility for marginal operational costs, which are linked to electricity spot price formation in hydrothermal systems. Therefore, reservoir inflow forecasts have important impact on commercial strategies of hydropower generation companies.

This work presents a mathematical model with two methodologies for climate flow forecast, the SMAP model (Soil Moisture Accounting Procedure) and the MEL model (Linear Stochastic Model), both based on rainfall forecasts provided by CPTEC- Brazilian Centre of Weather and Climate Forecasting, as described by Sampaio and Nobre (2006). These monthly rainfall forecasts are distributed in a grid of 200 x 200 km, with a time horizon of 6 months ahead. The monthly rainfall forecasts are transformed in reservoir inflows by using rainfall-runoff models. The natural hydro-energy inflows (ENAs) are calculated taking the reservoir inflows (m3/s) multiplied by the unit turbine efficiency parameters (MW/m3/s), thus forming the basic input for hydrothermal system operation in use both by NEWAVE and DECOMP optimal dispatching models. This forecast information is also important for other sectors of power generation companies, including the power trading and the maintenance planning divisions, among other ones.

Methodology of the Forecasting Models

The rainfall forecast is provided by an atmosphere numeric model (oceanic) using approximate numeric representation of the fundamental mathematic equations that govern the air and water at atmosphere, and their corresponding interactions with Earth surface. The atmosphere is divided in millions of volumes (200 km x 200 km x 0.5 km) with calculation of the air moisture and temperature, wind velocity and pressure for future time intervals (Sampaio and Nobre, 2006).

The rainfall-runoff methodology is implemented by using two distinct modeling approaches:

- Physically based modeling for the rainfall-runoff process, with the SMAP model, which was developed by Lopes et al (1982);
- Linear stochastic model, using mixed models (Beven, 2001)

The SMAP (Soil Moisture Accounting Procedure) model is a simple monthly time step based rainfall runoff model of the lumped conceptual type. It is particular useful if only monthly input data is available. This is often the case in overall water resources planning or for analyses of long-term reservoir operations.

The model accounts for the water storage in two linear reservoirs representing the root zone and the groundwater reservoirs respectively. It has five calibration parameters and four transfer functions, with monthly up-to-dating of the four state variables. The main components of SMAP are shown in Fig.1.

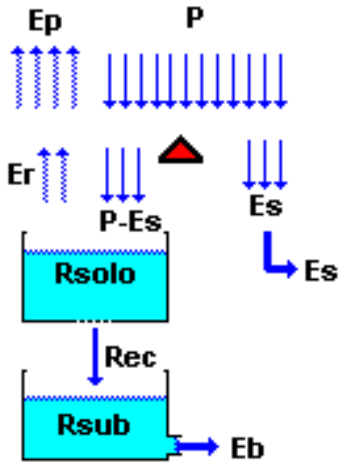

Figure 1 – Main components of the SMAP model
(Lopes et al, 1982)

The Stochastic Linear Model (MEL) is a mixed model, using as input both observed river flows and rainfalls on upstream areas of each reservoir. ARIMA models are used for forecasting purposes. The minimization of square sum of errors is used at calibration stage (Box and Jenkins, 1976).

Forecasting Models Applied to the Brazilian Interconnected Power System

The forecasting models described before were applied to selected river basins of the Brazilian Hydropower System (SIN). Specific river stations were selected in order to define the forecasts of inflow reservoirs. The main river basins of the SIN are shown at Fig. 2.

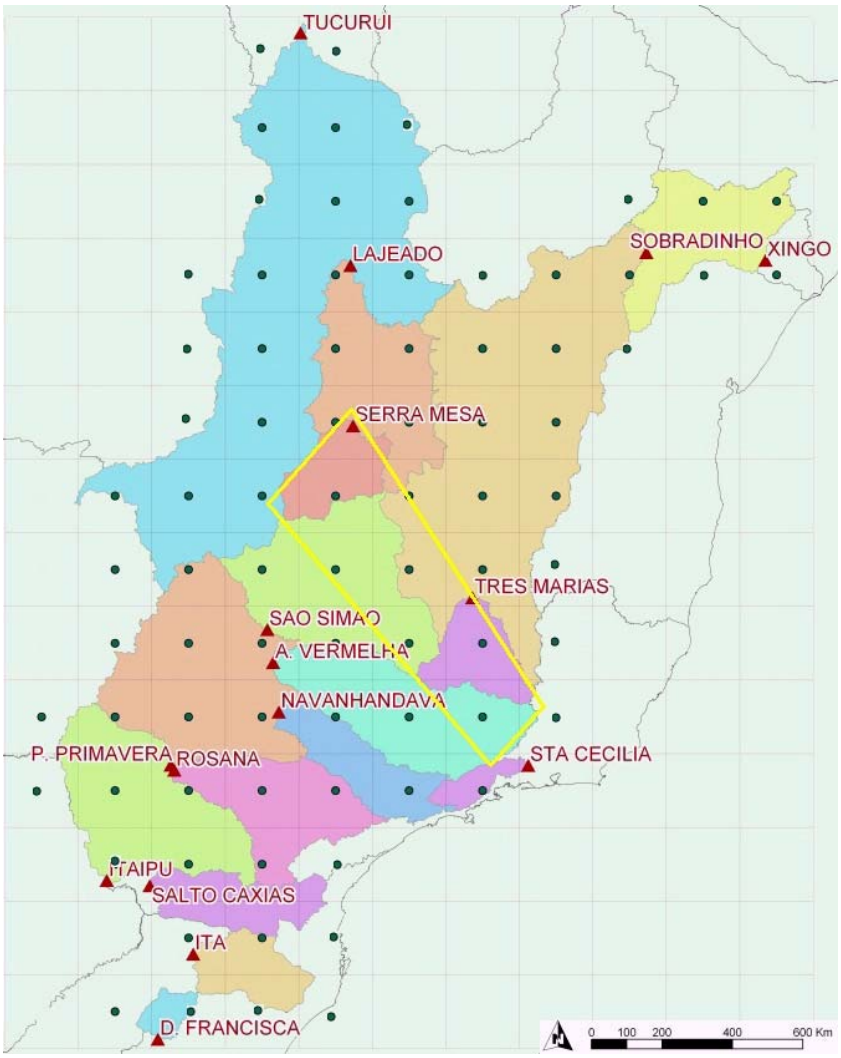

Figure 2 – Strategical Stations for Forecasting

Using the ArcView software, the axis of dams for each reservoir was taken as a reference to define the corresponding watershed polygonal limits of the drainage area, taking maps available at ANA (National Regulatory Agency of Water Resources). The grid defined by CPTEC for rainfall forecast was launched over the river basins that compose the Brazilian Hydropower System (SIN), as shown in Fig.2, where the black points represent the center of the corresponding cell for rainfall forecasting purpose, and the triangles represent the position of reservoirs.

The following river basins and sub-catchments areas are the main parts of the Brazilian Hydropower System (SIN), representing almost the total of inflows to the SIN:

• Paraná river basin upstream Itaipú hydropower plant, with 822.000 km2 (divided into 6 sub-catchments areas)

- Tocantins river basin upstream Tucuruí hydropower plant, with 758.000 km² (divided into 3 sub-catchments areas)
- São Francisco river basin upstream Xingó hydropower plant, with 609.000 km² (divided into 3 sub-catchments areas)
- Iguaçu river basin upstream Salto Caxias hydropower plant, with 57.000 km²
- Uruguai river basin upstream Ita hydropower plant, with 45.000 km²
- Jacuí river basin upstream D. Francisca hydropower plant, with 14.000 km²
- Paraíba do Sul upstream Sta Cecília hydropower plant, with com 17.000 km²

The following data were used for model calibration and validation purposes:

- Historical series of monthly rainfall (mm) in grids of 200 km x 200 km, for all the selected river basins and sub-catchments areas, from January 1995 to May 2007, available of CPTEC database;
- Historical series of monthly river flows (m3/s), for selected (16) stations corresponding to the drainage are upstream each hydropower plant, from January 1931 to May 2007,available at ONS (Independent Operator System) database;
- Long term mean of potential evaporation for the 16 river basins, available at database of DAEE (Dept. of Water and Power), CESP (Power Generation Company of State of Sao Paulo) and INMET(National Institute of Meteorology).

The results of the SMAP and MEL models calibration and validation processes are shown at Fig. 3 to Fig. 6.

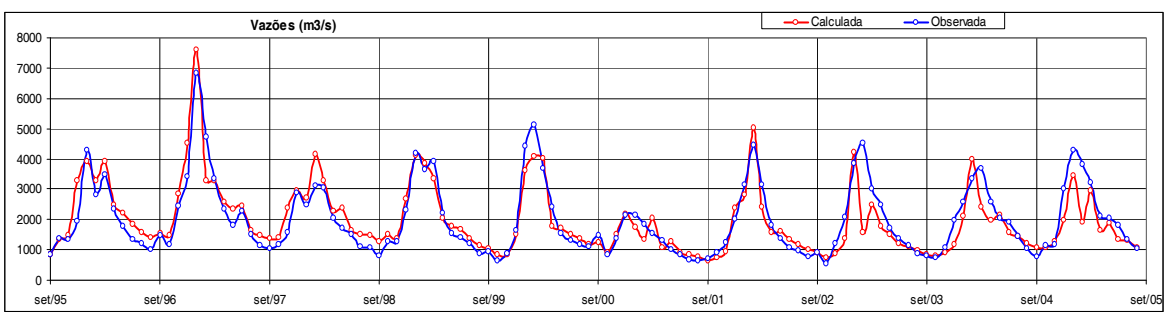

Figure 3 – Calibration of the SMAP model at Água Vermelha flow station (m3/s) (Red: SMAP flow calculations, blue: historical flow)

As can be seen from Fig. 3 to Fig. 6, the application results at Agua Vermelha station reveals good fit to both SMAP and MEL models. The Akaike criteria (1973) were adopted in the assessment of the fit goodness to avoid systematic errors in the rainfall-runoff modeling processes.

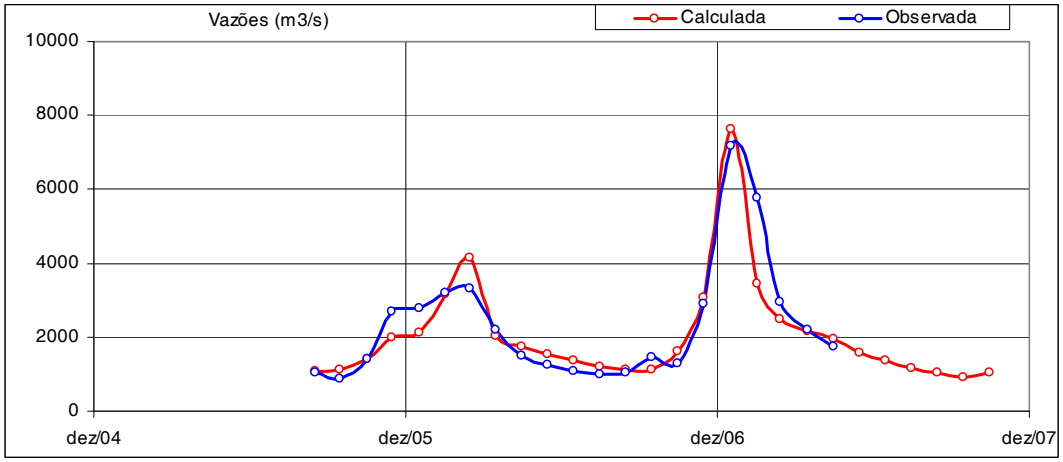

Figure 4 – Validation of the SMAP model at Água Vermelha flow station (m3/s)
(Red: SMAP flow calculations, blue: historical flow)

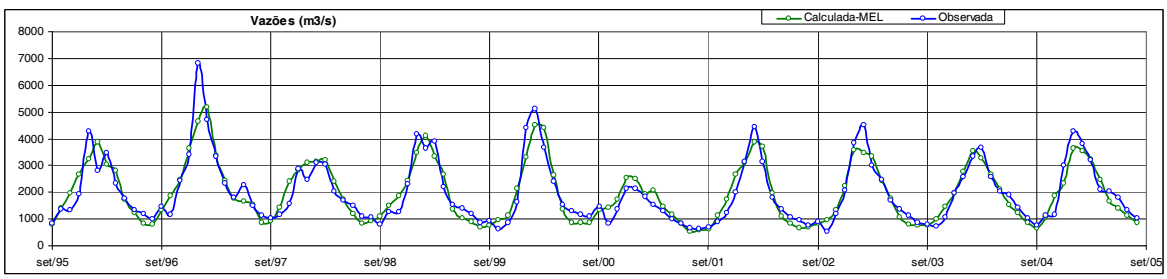

Figure 5 - Calibration of the MEL model at Água Vermelha flow station (m3/s)
(Green: MEL flow calculations, blue: historical flow)

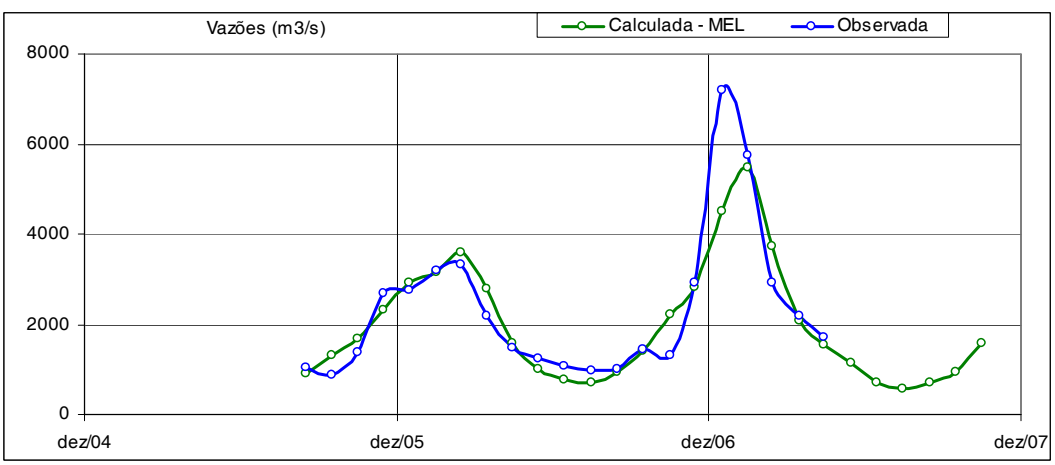

Figure 6 – Validation of the MEL model at Água Vermelha flow station (m3/s)
(Green: MEL flow calculations, blue: historical flow)

The GERAVAZ software

The GERAVAZ software was developed based on general concepts of decision support systems (DSS). As described by Porto et al (1997), DSS are computational systems especially designed to help taking decisions on problems with a not well defined structure or with a partially structured framework. There is no previously defined algorithm for solving such kind of problems, thus requiring intense interaction between man and machine (computers). A DSS typically requires a mix of data base, mathematical models and interfaces. An important aspect of a DSS is to provide multiple solutions to allow broader assessment and insight of the problem being studied. A DSS is not a substitute for decision makers, but a helpful tool to improve a decision making process.

The GERAVAZ decision support system is composed by a data base, interfaces and the SMAP and MEL forecasting models. The interface was developed with the Borland Delphi devices to be processed coupled with the Microsoft Windows operational system. It was designed using multiple pages and screens with options that allow data visualization, river basin maps, SMAP and MEL runs, and output results. Two examples of interface screens of GERAVAZ are shown in Figure 7.

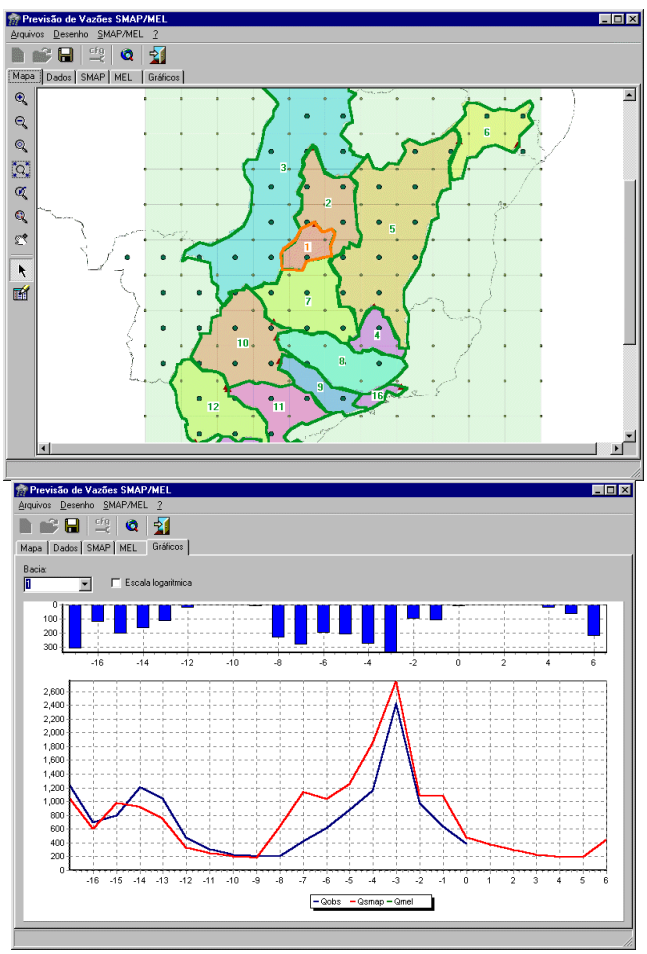

Figure 7 – Illustrative examples of GERAVAZ interface screens

Input and output data are stored in a Microsoft Access data base. It stores data of historical rainfall and river flows, rainfall forecasts, forecasting data generated by SMAP and MEL, potential evapotranspiration, long term means, cells of grid, parameters of the rainfall-runoff calibration process and hydropower plants that compose the Brazilian Hydropower System (SIN).

The GERAVAZ interface allows selecting rainfall forecasting options, by using outputs of both rainfall-runoff models or long term mean values of historical observations. In addition, rainfall scenarios can be constructed from the previous ones by multiplying specific factors to the original rainfall forecast values.

At the final stage of GERAVAZ use, after generating the river flow forecasts, specific routines prepare these flow output to be used as input to the NEWAVE and DECOMP optimal power dispatching models.

Conclusion

The development and results of the GERAVAZ decision support system, with the rainfall-runoff SMAP and MEL models, reveals its full success as a tool to provide river flow estimates for the main river basins of the Brazilian Hydropower System. From several applications it can be recognized that errors on rainfall forecast have significant impact on river flow forecasts. Actually, these errors are big when the regional rainfall forecasting model (ETA model, developed by CPTEC) was used.

As someone could expect, comparisons between GERAVAZ river flow forecasts and observed flows reveals smaller errors at the first time interval (monthly) ahead, when compared to the next five months. This suggest the use of GERAVAZ model in a dynamic fashion, with monthly up-to-dating (rolling horizon), or even at intervals smaller than one month wherever new climate information become available.

It should be highlighted the broad potential to improve river flow forecasts as a result of additional improvements on rainfall forecasts throughout river basins that compose the Brazilian Hydropower System. A possible alternative to be investigated is a further reduction of the cell size in the grid for rainfall forecasting, thus allowing better description of the precipitation process.

As a final comment, this work showed the potential for future scientific development and collaboration between researchers of hydrological sciences and meteorological sciences as an important aid to improve the quality of river flow forecasting.

ABSTRACT

In our day of increasing conflicts for water resources, water management decisions require the understanding of the hydrologic nature of the interactions between water use and the water resources. In Kansas, conflicts for water resources occur at both the interstate and intrastate level, and have led to the development of groundwater models as tools for water management decision-making.

In the past, groundwater model construction has typically been the responsibility of a single entity, with limited technical input from agencies and/or interested constituents, and peer review generally at the end of the model construction process. This has led to models with limited buy-in from the regulated community, limiting their usefulness in difficult and contested water management decisions.

A robust, collaborative model development process was used in the development of the Republican River Compact Administration groundwater model by the states of Colorado, Kansas and Nebraska as part of their settlement of their compact litigation in 2002. More recently this model development process was used to build the Middle Arkansas River Basin groundwater model in south-central Kansas. The model development process used allowed multiple experts to review model datasets and calibration targets, test modeling assumptions, explore various modeling approaches, and determine when model construction was complete.

While the process requires greater commitment of total resources, in both cases the process led to good, practical, defendable models, which are being used as tools to guide important water management decisions.

INTRODUCTION

In Kansas, as in other regions where dependable water supplies are less than demands, water resource conflicts occur at both the intrastate and interstate level. This has led us to develop and rely on groundwater models as a tool in guiding water management decisions. In the model development process, understanding of the

hydrologic system and its various components is increased and a tool to evaluate the impact of future management of the system is provided.

NEED FOR AN IMPROVED MODEL DEVELOPMENT PROCESS

However, this application of groundwater modeling is subject to legal and other challenges and past model development processes have been insufficient to withstand this scrutiny. In an effort to build better models able to significantly increase acceptance by the regulated community and to withstand legal challenges, Kansas has adopted a new model development approach that includes on-going collaboration of the lead contractor developing the model, a peer review modeler, stakeholders, and other experts in a given area. The approach's use of robust, on-going review of the model development has improved resulting models and buy-in from stakeholders.

The process provides for early decisions being made on model targets (groundwater levels, streamflows), rigorous joint data development and review, testing of alternate modeling processes to determine the most appropriate methodology and aids in eliminating bias. Kansas currently has completed two modeling projects using this approach: 1) interstate - Republican River Compact Administration and 2) intrastate - Middle Arkansas River. The state is at different levels of progress on four additional models being developed using this approach.

REPUBLICAN RIVER COMPACT ADMINISTRATION GROUNDWATER MODEL

The Republican River Compact Administration groundwater model was constructed as part of a comprehensive settlement of litigation among the states of Colorado, Kansas, and Nebraska regarding the Republican River Compact. The model is used as a significant input into the Compact accounting used to determine compact compliance. The model is run annually to determine streamflow depletions due to groundwater pumping and streamflow accretions to the Republican River basin from the Platte River. As a consequence, the model is also used by the States to target its activities to achieve compliance with Compact requirements.

The model was developed using the processes advocated here, except model development was not an open process since it was done as part of settlement discussions. Each state was represented by a team of modeling and other experts and state officials, with federal modelers also participating. This modeling committee

collaboratively gathered and agreed to calibration target data (groundwater levels and historic baseflows), developed and reviewed model data, and tested alternative model processes to develop a defendable model.

MIDDLE ARKANSAS RIVER GROUNDWATER MODEL

The Middle Arkansas River groundwater model was constructed to provide a tool for quantifying historical groundwater conditions and to evaluate how future changes might impact groundwater levels and streamflow conditions. The model development process used allowed for improvements to boundary conditions, refining model methods to develop recharge estimates and reducing model bias. The process resulted in a more reliable and defendable model and increased stakeholder. With an agreed-upon model, the focus of our remaining work will now shift from adequacy of a model to water management objectives and means to achieve them.

CONCLUSION

Groundwater models being constructed for water resource management decision-making require additional attention to detail via on-going robust participation by experts and stakeholders to withstand scrutiny associated with their application to such decision-making. Such model development needs a clearly defined purpose; a diverse team with multiple modelers, data experts and stakeholders; and joint testing of alternate model processes with robust data development and review. This process enhances model performance and acceptance by the regulated community.

Communicating drought severity and re-evaluating firm yield – Cumberland County, Tennessee as a case study

Lars Hanson[1] and Stuart Stein[2]
1 Water Resources Engineer. GKY & Associates, 4229 Lafayette Center Dr, Suite 1850, Chantilly, VA 20151 (ph) 703-870-7000 Email: lhanson@gky.com
2 President, GKY & Associates.

Abstract: The 2007 drought in Cumberland County, Tennessee greatly strained the three reservoirs that provide the large majority of the county's water supply and prompted a new analysis of the reservoirs' firm yield. With the reservoirs lacking long term streamflow and operations records, traditional yield analysis could not be performed directly. A multi-scale Standardized Precipitation Index (SPI) analysis was conducted, and the resulting multi-scale SPI plot was found to be a highly effective tool for communicating the drought severity of the current drought relative to past droughts. A simple, continuous-simulation HEC-HMS model was used to generate a synthetic streamflow record, and determine the critical drought period for each reservoir using the traditional sequent peak algorithm. Using the sequent peak algorithm, storage-yield relationships a multiple yield cumulative deficit plot were created as useful tools for explaining reservoir behavior. This is part of a County-wide water supply plan being developed by the US Army Corps of Engineers, which includes projecting future water demand, evaluating potential conservation measures, and evaluating sources to meet the growing demand.

1. Introduction

Estimating firm-yield of a small reservoir can be a relatively straightforward process when high quality records of inflows, withdrawals, and lake levels are available. Often, though, these data are incomplete or lacking entirely. The firm-yield can still be estimated, provided that sufficient information is available to estimate the water balance to the reservoir.

Cumberland County, Tennessee, located in the East-Central part of the state endured a severe drought from 2007 to the early part of 2008. Though its reservoirs did not fail, Cumberland County, with its rapidly increasing population, decided to restudy its estimates of firm yield in light of the recent drought. The county located on top of the Cumberland Plateau is entirely a headwater area, and gets nearly all of its water from three small reservoirs. Two of the reservoirs, Meadow Park Lake and Lake Holiday, are controlled by the City of Crossville Utility District and the third, Otter Creek Lake is controlled by the Crab Orchard Utility district. Figure 1 shows Cumberland County, the three reservoirs and their watersheds.

There are several challenges that complicate the calculation of firm yield in Cumberland County, which are typical to counties with relatively small water distribution systems. Due to Cumberland County's small population and relatively wet climate, water has always been plentiful, and has only recently been a concern. As a result, records of the reservoir levels and streamflow monitoring have been

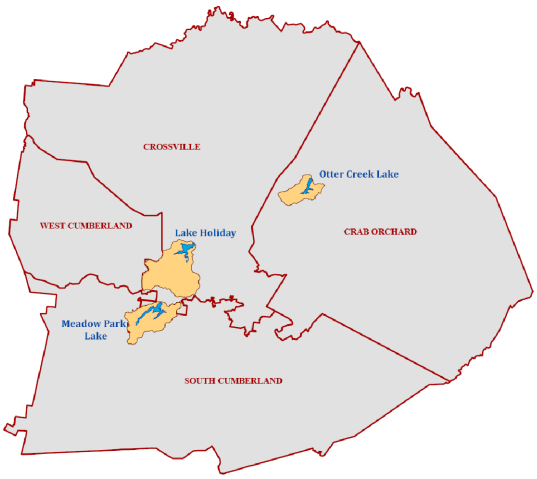

Figure 1. Cumberland County, utility district boundaries (red), and three reservoirs with catchments

largely absent except for in the last few years. While firm-yield can still be calculated through other methods, the resulting estimates are subject to more uncertainty than if long term reservoir or streamflow records were available. Further complicating the situation is that there is little consensus on the total available storage in each reservoir due to conflicting estimates and unknown rates of sedimentation. For small water systems in relatively humid environments, this is not an uncommon scenario.

The goal of this study was to use all available data to investigate the relative magnitude of the 2007 drought, establish solid estimates of firm-yield for the three reservoirs, and explain the results as clearly as possible to the stakeholders in Cumberland County.

2. Methods

This study was completed in three stages. First, historical precipitation records were analyzed to determine the most severe drought periods in the County over the last 95 years. Second, the historical inflow to the reservoirs was simulated using the Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS) rainfall runoff model. The simulated historic inflow sequence was then used in the traditional sequent peak algorithm to estimate the critical drought sequence.

Drought Analysis with the Standardized Precipitation Index

To analyze the relative magnitude of the current drought, a drought metric had to be selected to compare droughts from different periods. Aside from temperature and precipitation, each of which has a 95-year record length in Cumberland County, hydrologic indicators such as soil moisture, evaporation, solar insolation, and others were not available. As a result, many of the most common drought indicators and indices (Palmer indices) were rejected. The Standardized Precipitation Index (SPI) was chosen because it only requires monthly precipitation as an input, and can be computed at multiple time scales.

The SPI index value reflects the probability of certain rainfall totals occurring for the given analysis duration. Instead of reporting this probability as a percentile, the SPI index uses a standard normal variate (or Z-score). The rainfall totals are fitted to a gamma distribution and then transformed to a normal distribution, and the score is roughly analogous to the number of standard deviations the rainfall total falls from the median. Below average precipitation, therefore, has a negative index value. A

drought occurs when the index value falls below -1, and a severe drought is triggered when the index drops to -2. (McKee et al., 1993)

The Crossville Exp Stn precipitation gage, with a 95-year record length was used to compute the SPI at durations of 3, 6, 9, 12, 15, 18, 24, 30, 36, 42 and 48 months. Viewed through the lens of the SPI (or likely any other metric), it is difficult to declare any single drought as the most severe. Table 1 displays critical SPI values from seven droughts at various durations, with the highest SPI value for each duration in bold, and the highest value within each drought in italics. Unfortunately, several droughts could be considered the most severe, depending on the duration of interest.

Table 1 - Critical 3 to 48 months duration SPI values for droughts at Crossville Exp Stn

Drought	3	6	9	12	15	18	24	30	36	42	48
1924-1926	-2.49	-2.71	-2.73	**-2.83**	***-2.86***	-2.53	-2.69	-2.49	-2.41	-2.22	-2.01
1930-1934	-2.18	-2.25	-2.38	-2.55	***-2.86***	**-2.81**	**-2.77**	-2.45	-2.39	-2.28	**-2.59**
1940-1942	**-2.66**	***-2.92***	-2.53	-2.48	-2.37	-2.57	-2.48	**-2.59**	**-2.62**	-2.16	-2.14
1952-1953	-2.54	-2.89	***-2.95***	-2.21	-1.78	-2.14	-1.93	-1.94	-	-	-
1980-1982	-2.1	-2.44	*-2.82*	-2.51	-2.03	-1.83	-	-	-	-	-
1986-1988	-1.8	-1.99	*-2.35*	-2.11	-2.18	-2.25	-1.74	-2.03	-1.94	**-2.33**	-2
2006-2008	-2	-2.17	-2.55	*-2.56*	-2.18	-2.18	-1.91	-1.83	-1.9	-	-

Table 1 demonstrates there is uncertainty in declaring one drought as most severe, but communicating that uncertainty to clients and stakeholders can be difficult. To better explain the uncertainty in severity and duration of droughts, a surface plot (Figure A1 in the Appendix) was devised to show the SPI value as contours on surface plot with base axes showing time versus SPI analysis duration. Drought periods appear as yellow, orange and red. Figure A1 very effectively illustrates how droughts evolve over time with some severe droughts starting as long mild dry spells, and other severe droughts rapidly abated with months.

HEC-HMS Modeling

The HEC-HMS (Hydrologic Engineering Center – Hydrologic Modeling System) model is used for a very limited and specific purpose in this application. The HEC-HMS model is often used to compute peak flows, but this study has no use for them, as droughts are the hydrologic phenomenon of interest, and the model is used only to transform historical rainfall values into the most representative daily streamflow sequence possible for the three catchments. As a result, the model is run in an atypical fashion, as a long-term simulation rather than a single storm event.

Precipitation and Basin Model

The HEC-HMS model requires precipitation data at a daily or finer scale. The Crossville Exp Stn precipitation gage has been recoding daily precipitation values nearly continuously for over 95 years. A record length from September 1, 1913 to August 31, 2008 is used in this model. Data gaps were filled with daily precipitation values from nearby stations with concurrent records. Wherever, possible, the nearby Crossville Mem Ap station was used to substitute values. In the HEC-HMS model, the rainfall data is entered as a precipitation gage in the time series data editor.

Constant monthly evaporation was chosen as the evaporation method in the meteorological model ("Met model" in HEC-HMS). Expressed in inches per month, the evaporation rate (in addition to the constant infiltration rate) controls the rate at which water exits the single soil layer. The rate can be specified by month, but each month has a constant rate for the entire simulation period. Pan evaporation data (1978-2005) for the Crossville Exp Stn gage were used to determine the average monthly rates. The pan coefficient was assumed to be 0.7.

There are a limited number of options for running long term simulations at a daily time step. Essentially, the Deficit and Constant Loss method and the Soil Moisture Accounting method are the only potential loss methods for this study. The soil moisture accounting method is a complex model that requires a large number of parameters that are difficult to estimate with available data in the Cumberland County area. Therefore, the Deficit and Constant Loss method is chosen.

The Deficit and Constant Loss method is a very simple soil moisture tracking model. The surface soil layer is treated as a simple reservoir with two losses and one input. The soil layer is assumed to cover the entire subbasin. The soil layer thickness is characterized by the maximum depth, which is assumed to represent the available void space in the soil layer for flow to pass. **Error! Reference source not found.** shows a conceptual model of the single soil layer model. The soil layer loses water to deeper soil layers through infiltration. The soil layer can also lose water to evapo-transpiration (ET). And of course, the soil layer receives water only through precipitation. When the soil layer is full, runoff occurs.

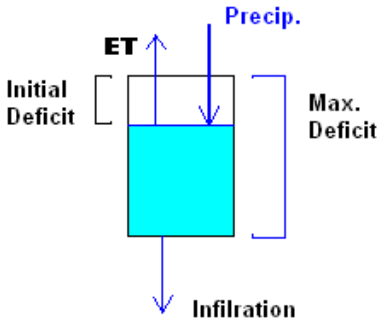

Figure 2. Conceptual model of single soil layer Deficit and Constant Loss method

In the HEC-HMS model, the constant baseflow method was selected as most applicable for this study. This method assumes constant baseflow within each month. While Eastern Tennessee has relatively little seasonality in its rainfall totals, there is a strong seasonal pattern in its baseflow pattern. While there are no stream gages on the streams that feed the reservoirs of interest, streamflow data from several stream gages on other streams in Cumberland County and surrounding counties were downloaded from the United States Geological Survey (USGS). Using the streamflow records, the USGS's PART program was run to determine the baseflow, expressed as specific discharge (flow per unit of drainage area). (Ries, 2006)

Watershed times of concentration (Tc) for the three reservoirs' catchments were computed via the Kerby, Kirpich, and SCS equations and were found in all cases to be less than five hours. With the model time step of one day, this factor becomes insignificant, and the model has to automatically extend Tc to allow the model to run. Therefore, the routing and storage option was turned off as it proved insignificant. Since the HEC-HMS model is only used to compute volume of runoff and not within-day timing or peak values, this is acceptable.

Calibration of the HEC-HMS model

Since long term, high-quality records of the reservoirs could not be obtained, calibrating to the reservoirs' actual data could not be performed. USGS's PART model, in addition to computing baseflow, also computes the monthly streamflow as specific discharge. The mean and median discharge for each month were computed from the stations whose records were used for the baseflow estimation. Though the streamflow records are fairly well distributed through the simulation time period, they are not uniformly distributed enough to assume that the computed average (or quantile values) of discharge are good estimators of the true average because differences in rainfall have a large effect on the quantity of discharge. Therefore, to normalize these statistics, the runoff ratio is used instead of specific discharge. Runoff ratio is calculated by dividing a month's specific discharge by the total precipitation for the same month. Thus, the discharge from the stream gages, which are all near Cumberland County, is divided by precipitation from the Crossville Exp Stn.

The calibration strategy is to get the model's monthly mean and median discharge to match that of the streamflow gages as closely as possible. As an example, **Figure 3** displays the calibration results for Meadow Park Lake in comparison to the monthly median and average runoff ratio for the USGS streamflow gages. The model calibration was completed by adjusting the loss parameters for the watersheds and lakes. **Figure 3** shows the calibration is generally good, especially considering the limitations of the modeling options chosen. Most notably, the runoff ratio for the entire period of record (PoR on the graph) was nearly a perfect match between the model and gage data. On the whole, the model values follow the general pattern of the runoff ratios month to month fairly well. The model medians drop below the model averages in the summer much as the gage medians and gage averages. The winter months tend to somewhat under-estimate the runoff ratios, while the summer months tend to overestimate, though by a lesser amount. The red and blue dotted lines indicate the 40th and 60th percentiles of the runoff ratios of the monthly USGS streamflow data to give some indication of the monthly variation in values.

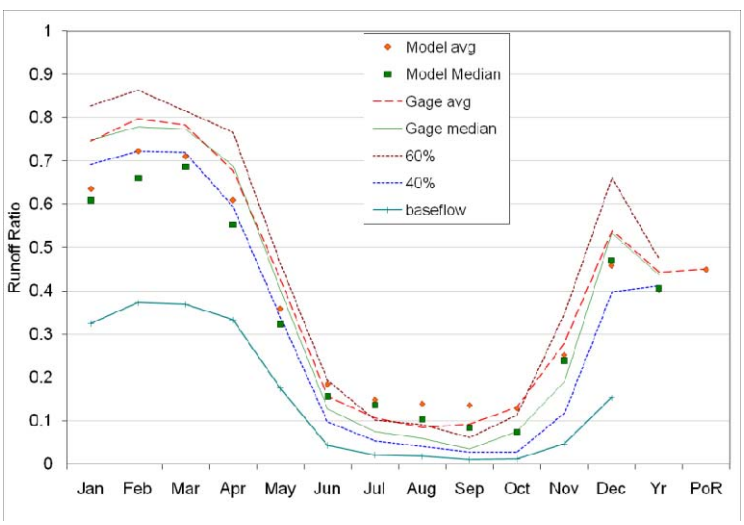

Figure 3. Calibration chart comparing monthly average runoff ratio from the model and stream gages

The next section goes over the calibrated parameter values for the loss method, and the monthly climate parameters.

3. Sequent Peak Algorithm to Identify Critical Drought

The HEC-HMS model provides daily runoff as an output, and from this, the sequent peak algorithm can be used to develop an estimate for the yield the reservoir can support. The sequent peak algorithm (based on the work of Rippl, 1883; Thomas and Burden, 1963) tracks the daily (or monthly, yearly, etc) water balance for a real or theoretical reservoir with known inflow and a specified demand pattern. For this study, the sequent peak algorithm is computed on a daily time step, as the HEC-HMS model output is also daily.

The sequent peak algorithm is based on Equation 1.

$$K_t = (D_t - Q_t) + K_{t-1} \qquad \text{if } K_t>0, \text{ else } K_t=0 \qquad \textbf{Equation 1}$$

Where:

K_t is the cumulative deficit at time t
D_t is the demand at time t
Q_t is the inflow at time t
K_{t-1} is the cumulative deficit at time (t-1)

Essentially, equation 1 tracks the cumulative deficit at each time step. The rate of change in the deficit for each day is equal to the demand minus the inflow for that day. Adding that difference to the cumulative deficit of the previous day (K_{t-1}) gives the current day cumulative deficit (K_t). Typically, demand is assumed to be constant each day, though the algorithm allows for the demand to vary with time. For a firm yield study such as this one, demand remains constant. The firm yield is the yield at which the maximum value of K is equal to the reservoir storage.

The sequent peak algorithm is useful because it generates an estimate of the storage required for a no-failure condition at a given yield. Running the sequent peak algorithm at many different demand levels (yields) generates a relationship between storage and yield for a 100% reliability condition. This relationship, when plotted with yield on the x-axis and required storage (i.e. maximum deficit) on the y-axis produces a smoothly increasing curve called the Storage-Yield curve. **Figure 4** displays the storage yield curves for the three reservoirs in Cumberland County. The yield in MGD is displayed on the x-axis and the required storage to support that yield on the y-axis.

The red diamonds on each curve show the best estimate of actual storage in each reservoir. Many of these estimates are old, and may not reflect actual storage available for use in the treatment plants. Fortunately, the Storage-Yield curves are an excellent tool for analyzing the uncertainty in these estimates. For example, if Meadow Park Lake's storage estimate was 100 million gallons too high, the yield would be reduced to about 3.75 from 4.02. Otter Creek Lake would not see such a big reduction from the same decrease as the curve is steeper at its current storage estimate. In similar ways, these curves can guide management decisions. If one wanted to raise a dam, for instance, Lake Holiday and Meadow Park would make the most sense, as the current storage is on the flat part of the storage-yield and there is substantial increase in yield to be gained. The storage-yield curves in **Figure 4** also have a short blue vertical line at the end of each curve, with the yield at that point labeled. These lines indicate where the yield becomes equal to the average total

inflow to the lake. This is a practical limit to the yield since withdrawals cannot sustainably exceed inputs.

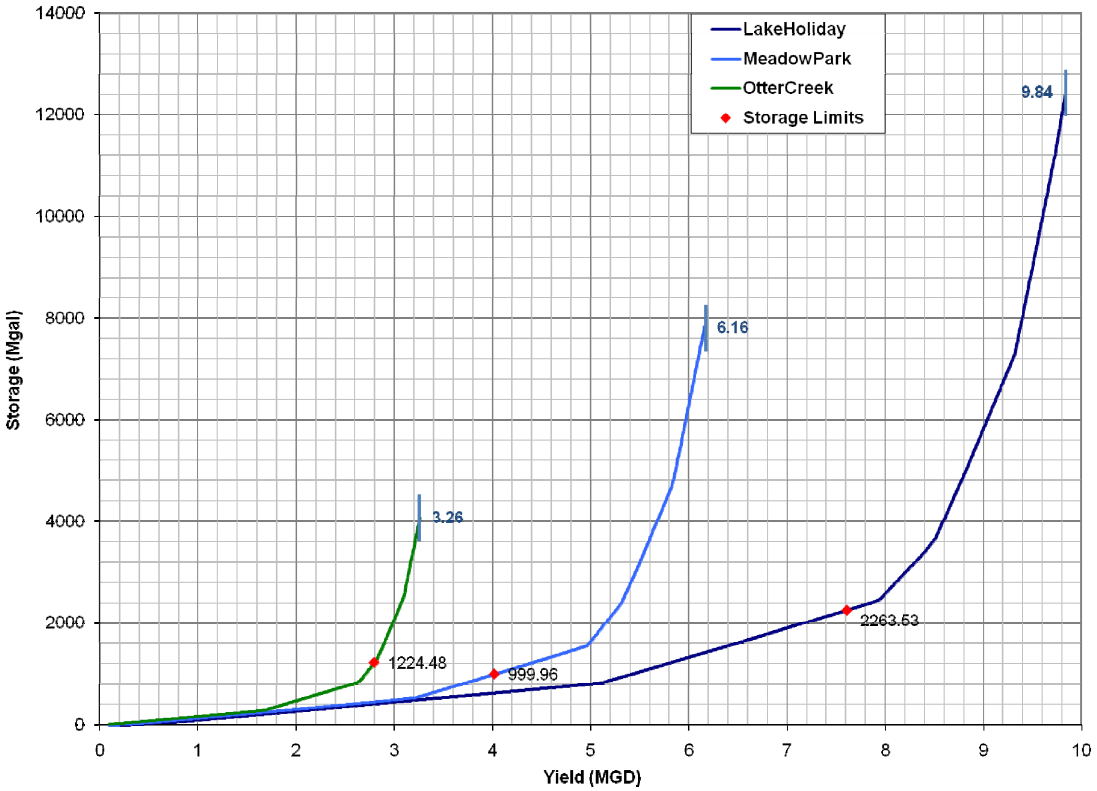

Figure 4. Storage-Yield Curves for the three Cumberland County reservoirs

The total inflow also controls the overall size of the curve, which is clearly demonstrated by the three curves. While the firm yield estimates of 2.80, 4.02, and 7.61 MGD for Otter Creek Lake, Meadow Park Lake, and Lake Holiday, respectively, could have been simply delivered to the stakeholders, the Storage-Yield curves are a much more valuable tool. It would be yet more valuable, however, to relate the storage yield relationships to the drought analysis already completed.

4. Relating Drought Analysis to Firm Yield

When the daily sequent peak algorithm is run at the firm yield, the critical drought length can be computed relatively easily by plotting the cumulative deficit versus time. The length of the critical drought sequence is simply the time difference between the maximum deficit and the last time the cumulative deficit was zero. Figure 4 displays a short sequence of the sequent peak algorithm's cumulative deficit values for Meadow Park, and contains the critical drought sequence. It is relatively easy to calculate the critical drought length as 19 months. Suppose, however, that the storage volume was calculated incorrectly, or a stakeholder wants to know which drought will lead to a maximum deficit at a current yield level. Instead of replotting Figure 4, plotting cumulative deficit at multiple yields simultaneously can answer these question and explain much more about the reservoir's behavior.

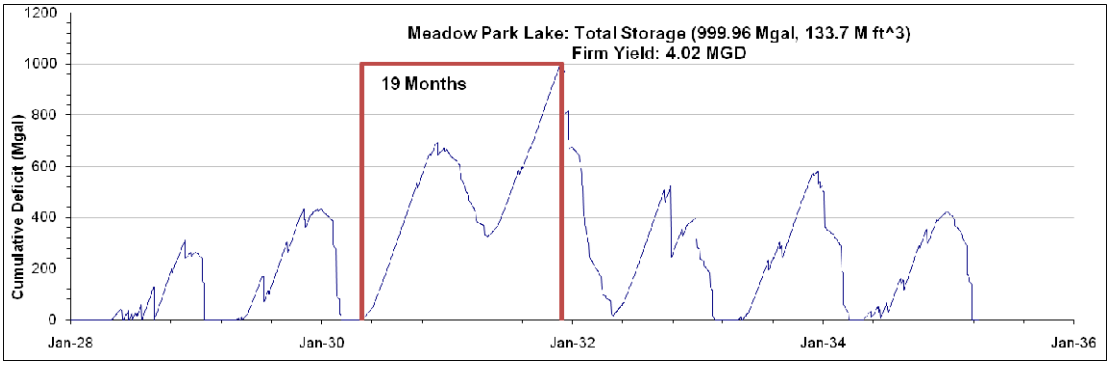

Figure 5. Cumulative Deficit plot showing critical drought sequence of Meadow Park Lake

Figure A2 in the Appendix plots the cumulative deficit at multiple yields as surface plot with yields across the x-axis and time down the y-axis. To normalize the plot, the cumulative deficit is plotted as the percentage of the maximum deficit for the given yield. Additionally, the monthly maximum series of cumulative deficit is plotted instead of the daily series to smooth the plot. Since the peaks of the cumulative deficit plot are of the greatest concern, cumulative deficits less than 68% of the maximum deficit are not plotted. The peaks are plotted in orange, red, with the absolute maxima shown in black. Figure A2 shows quite clearly that the 1930-1931 drought is clearly the critical one for a range of yields from 3 MGD to over 4.75 MGD. The 1952-1953 drought, however, is the most critical when yield is between 2 and 3 MGD. At 5 MGD and beyond, the peaks begin blending together and the maximum moves steadily later in time. This is a fairly clear indication that the critical drought sequence is lengthening significantly. Increasing yield further simply moves the peak later as the refill amounts aren't enough to bring the deficit down to zero. After a break in the plot, the 2007 drought is shown at the bottom. The red coloration indicates a clear peak, but with no black, 2007 does not show evidence of being the critical drought.

Placing the cumulative deficit plot next to the multiple duration SPI plot, some very interesting parallels emerge. Consider the firm yield of 4.02 on the cumulative deficit plot. A green arrow drops down to find the maximum deficit occurs during the 1930-1931 drought. A second arrow crosses over to the SPI plot to locate a wide patch of dark red, indicating a severe drought period. Two green arrows extend upward from the edges of this patch to cross the duration axis at 15 and 24 months. Logically, this would seem to indicate that 15 to 24 months is a good estimate for the length of the critical drought sequence. Not surprisingly, Figure 4 showed that the actual length is 19 months. If the firm yield were instead 2.5 MGD, a similar method shows the critical drought length of the 1952-1953 as 3 to 9 months. At the higher yields, the SPI plot is not wide enough to perform the same procedure.

5. Conclusion

Computing the firm yield of a small reservoir is often difficult because they often lack the long records that larger reservoirs have, and are nearly always located on ungaged streams. Cumberland County is a perfect example of a community that

depends on small reservoirs, and due to population pressures and recent drought experience needs a better understanding of it reservoirs.

This study falls back on standard hydrologic methods to study the behavior of Cumberland County's reservoirs. Drought identification is performed using the Standardized Precipitation Index. Lacking a long, high quality streamflow record, we used a very common rainfall-runoff model (HEC-HMS) to generate a synthetic streamflow sequence using rainfall as an input. Nearby evaporation, soil survey, and baseflow data were used to parameterize the model. Once the streamflow sequence is generated, the well-known sequent peak algorithm is used to complete the analysis. These methods can generate reasonable approximation of the reservoirs' behavior relatively quickly and within a modest budget.

By carefully considering the presentation of results, however, a great deal more information about the reservoirs can be given to the stakeholders. The (100% reliability) Storage-Yield relationships provide a very useful tool for reservoir management and can make up for uncertainty about the available storage in the reservoir. The multiple duration SPI plot was found to be a tremendously useful communication tool for showing how droughts evolve over time. The multiple yield cumulative deficit plot was found to be useful in showing when the critical drought sequence occurs at any yield. When the two are placed next to each other, we discovered a quick and convenient method of estimating critical drought length. All of these items can be created with minimal additional computation, but the value added for the client and stakeholders in comprehending reservoir behavior is considerable.

ABSTRACT

This paper presents a computer aided system for managing, controlling and analyzing data from hydroelectric plants. The proposed system consists of three modules. The first is a relational database that organizes, standardizes and manages data from hydroelectric plants. The second module allows a user to build, store and manage advanced queries on this or certain other databases. The third is a simulator of the hydroelectric plants operation which can be used for planning the future operation or reproducing the past operation. The computational implementation of these modules uses the Object-Oriented Paradigm, the C++ Programming Language and the Structured Query Language *(SQL)***.** The data manager, the queries builder and the simulator were tested with data from Brazilian hydroelectric plants and the results show the potential of this system for the analysis and consistency evaluation of data from hydroelectric plants.

INTRODUCTION

The hydroelectric operation planning of a plant involves the manipulation of the static and dynamic data recorded by the plant. Static data are those that do not vary with the operation, while dynamic data depend on the operation interval and can be measured or calculated. The quality of these data has great importance to the operation planning because they supply the mathematical models of the computational tools developed for optimization, simulation and streamflow forecasting.

However, all measurements are prone to errors that can be either systematic or random. Systematic errors are caused by imperfect calibration of measurement instruments, imperfect methods of observation, or changes in the environment which

interfere with the measurement process. Sources of random errors may be unpredictable fluctuations in the readings of a measurement apparatus, or in the experimenter's interpretation of the instrument's reading (Lind et al. 2006).

The objective of the system presented in this paper is to aid, in different ways, the managing, controlling and analyzing data from hydroelectric plants. It consists of three modules: a data manager, a queries builder and a simulator of the hydroelectric plants operation. This paper is organized as follows: the first section presents the Brazilian model for hydroelectric operation planning; the second describes the three modules that make up the system presented and the third shows some case studies to assess the performance of the system.

BRAZILIAN MODEL FOR HYDROELECTRIC OPERATION PLANNING

The most common formulations of the Brazilian system for hydroelectric operation planning include: the production function and the water balance equation (Barros et al. 2003; Vinhal 1998; Pereira and Pinto 1985).

Production Function

The goal of the production function, Eq. (1), is to quantify the power generation of a hydroelectric plant.

$$p = k.\eta_t.\eta_g.[h_{fb}(x) - h_{tr}(u) - h_{pl}].q \qquad (1)$$

where:

- p Is the instantaneous power obtained in the conversion process of the hydraulic potential energy to electric energy (MW).
- k Is the gravity constant, multiplied by the water specific weight and divided by 10^6. Its value is 0.00981 (MW/(m³/s)/m).
- η_t . η_g Is the efficiency of the turbine-generator set in the conversion process of the mechanical energy to electrical energy.
- x Is the water storage in the reservoir of the plant (hm³).
- $h_{fb}(x)$ Is the forebay elevation which is function of the water storage x (m).
- u Is the water release of the plant, that is, the sum of the water discharge and the water spillage (m³/s).
- $h_{tr}(u)$ Is the tailrace elevation which is function of the water release u (m).
- h_{pl} Is the penstock head loss which is function of the water discharge (m).
- q Is the water discharge by the turbines of the powerhouse (m³/s).

Water Balance Equation

The water balance equation, Eq. (2), is used to calculate the water mass conservation balance of the reservoir.

$$x = x_0 + \left(y + \sum_{j \in \Omega} u_j - (q + s + ev + uc) \right) \frac{\Delta t}{10^6} \qquad (2)$$

where:

- x_0 Is the reservoir volume at the beginning of period t (hm³).

y Is the incremental water inflow during the period t (m^3/s).
Ω Is the upstream plants index set from the analyzed plant.
s Is the water spillage during the period t (m^3/s).
ev Is the reservoir evaporation during the period t (m^3/s).
uc Is the reservoir water advisory use during the period t (m^3/s).
Δt Is the size of the period t (s).

In order to aid the calculation of the parameters involved in the equations presented above are used eight static functions: polynomial area x level, polynomial level x volume, polynomial level x release, function maximum power, function maximum water discharge, function turbine-generator efficiency and function penstock head loss (Arce et al. 2002).

MODULES THAT MAKE UP THE SYSTEM

The computer aided system for managing, controlling and analyzing data from hydroelectric plants consists of three modules: a data manager, a queries builder and a simulator of the operation. The software project and the computational implementation of these modules use the Object-Oriented Paradigm (Cicogna 1999; Horstmann 1997), the C++ Programming Language (Hollingworth et al. 2001; Josuttis 1999) and the Structured Query Language (SQL) (Elmasri and Navathe 2000; Bowman et al. 1996). However, the use of the tools does not require specific software knowledge by the user.

Data Manager

The data manager is used for the organization, standardization and management of data from hydroelectric plants. Its graphical resources allow a critical view of the quality of the information it contains. It is possible, for example, to graphically view the polynomials that relate: reservoir area x forebay level, forebay level x reservoir volume and tailrace level x water release. Additionally, the functions related to the plant's operational limits, such as maximum power and maximum water discharge can be graphically analyzed. In relation to turbine efficiency hill curve, it is possible to do cuts, either horizontally or vertically, across the three dimensions to create two-dimensional planes in order to assess the quality of the information. This module also has a calculator that allows a user to provide the plant's reservoir volume and water release and obtain its power, turbine-generator efficiency, spillage and forebay and tailrace levels. Finally, this module shows graphics and tables with the dynamic data of a hydroelectric plant (Cicogna 2003).

Queries Builder

The queries builder allows a user to build, store and manage advanced queries on databases from hydroelectric plants. It does not require knowledge of the SQL Language and the analyzed database structure. Its queries can be applied for all plants at one time; therefore, it facilitates keeping track of data for an entire

hydroelectric system. This module can also be used as a generator of reports and as a viewer of the database. It enables one to manipulate the data from the query's result using mathematical operations. For this, there is a specific button that sends the data to electronic spreadsheets, like Excel. This module has two other capabilities. One of them is the possibility of exporting queries from database to a text file and the other is the possibility of importing queries from a text file to the database of the module. That means that the queries managed by this application can be easily transported from one machine to another because, in general, text files are smaller than database files. In addition, the text files created by this module can be stored as backup or easily interchanged by the users (Hidalgo 2004).

Simulator of the Hydroelectric Plants Operation

The simulator of the hydroelectric plants operation can be used for planning the future operation or reproducing the past operation for a hydroelectric plant. It has two major modules. One module can represent in detail the active operational restrictions on medium and long term horizons. The other module can represent a large collection of restrictions related to operating conditions in short term horizons. The simulation process is based on Eq. (1) and Eq. (2). It was created for the computational representation of several operating rules for hydrothermal systems (Cicogna 2003). Among the set of available operating rules, this study uses a short term rule that allows simulating the reservoir operation from the initial volume, the trajectories of generation, water spillage and inflow. The choice of this operating policy is due to the fact that the forebay and tailrace levels, the electric generation and the water spillage in a plant are measured variables. Water inflow is calculated based on the polynomial level *x* volume (Cicogna et al. 2009).

CASE STUDIES

In this section the data manager, the queries builder and the simulator will be used as tools for controlling of the data which have major influence on the hydroelectric operation planning. A detailed analysis of the production function, Eq. (1), and the water balance equation, Eq. (2), shows that there is a relationship of dependency between static and dynamic data. For example, the calculation that converts the forebay water level in storage volume uses the inverse function of the polynomial level *x* volume, which is static information. However, the data involved in the representation of storage, the level and the volume, are dynamic. In the same way, the function maximum water discharge is static; however the gross head and the water discharge related to this function are dynamic. It may be said that all the dynamic variables that are not measured depend on the static data to be calculated.

Thus, the computer aided system proposed in this paper will have as focus the managing, controlling and analyzing of the following static data: polynomial area *x* level, polynomial level *x* volume, polynomial level *x* release, function maximum power, function maximum water discharge and function turbine-generator efficiency. This system has been applied to more than 110 Brazilian hydroelectric plants. These plants are under the coordination of the Brazilian Electric System National Operator.

Polynomials area x level, level x volume and level x release

The analysis of the polynomials area *x* level, level *x* volume and level *x* release can be made using either the data manager or the queries builder.

Although the data manager has as main goal to organize and standardize the data from hydroelectric plants, the bulk of its graphical resources allows this module to also be used as a tool to evaluate data consistency. For example, the polynomial that describes forebay level *x* volume is expected to have a shape that looks like Fig. 1. However, if there is some simplification of this historical information, then the graph will be presented as in Fig. 2.

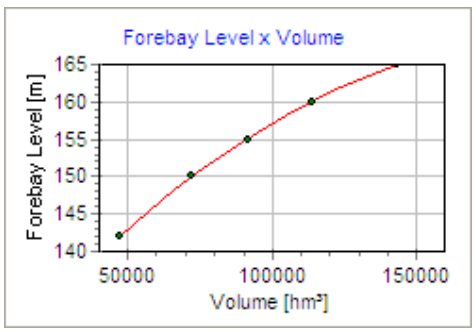

Fig. 1. Variable polynomial

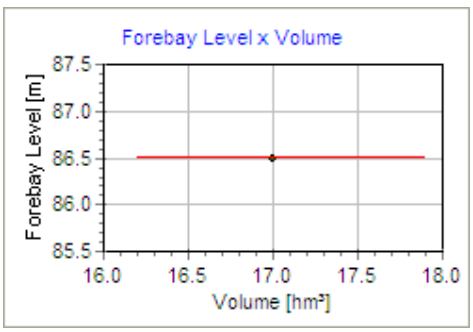

Fig. 2. Constant polynomial

If the objective is to analyze this information for all the plants at one time it is better to make use of the queries builder. Using the queries builder it is possible to list all the recorded plants which do not have a representation of the forebay level variation as a function of the water storage in the reservoir.

As an illustration, Fig. 3 shows the SQL command automatically built by the queries builder to this example query. This query lists the fields: cod, name and coef0 (rows 1, 2 and 3). These fields belong to tables "plant" and "polevo" (rows 4 and 5). The rows 6 and 7 relate the tables of this query. The filters of this query are: coef1, coef2, coef3 and coef4 equal to null because this mark a constant function (rows 8, 9, 10 and 11). These filters are connected by the conjunction operator "AND". The order to show the result of this query is ascending name (rows 12 and 13). Fig. 4 displays an example of result for the SQL command shown in Fig. 3.

```
1  SELECT
2    plant.cod, plant.name,
3    polevo.coef0
4  FROM
5    plant, polevo
6  WHERE
7    plant.cod = polevo.cod AND
8    polevo.coef1 is null AND
9    polevo.coef2 is null AND
10   polevo.coef3 is null AND
11   polevo.coef4 is null
12 ORDER BY
13   plant.name
```

Fig. 3. SQL command automatically built by the queries builder

Cod	Name	Coef0

Fig. 4. Example of result for the SQL command of Fig. 3

Functions maximum power and maximum water discharge

The analysis of the functions maximum power and maximum water discharge can be made using the data manager and the queries builder at the same time. For example, in order to analyze the maximum power function, Fig. 5, the data manager is responsible for providing the graph of this function (broken line). The queries builder is responsible for retrieving from the database the gross head and the power output for a certain plant operation period (small circles). According to Fig. 5, this maximum power function is coherent with the post-operation data of the analyzed plant, that is, there is no value above the function limit.

The same comparison can be done for the maximum water discharge function, Fig. 6. Again, the data manager provides the graph of the function (broken line) and the queries builder provides the post-operation data (small circles). However, for this example, the post-operation data of the analyzed plant are not coherent with the function because some values exceeded its limit. It is necessary to check the measuring process of water discharge and the graph recorded in the database that relates maximum water discharge to gross head.

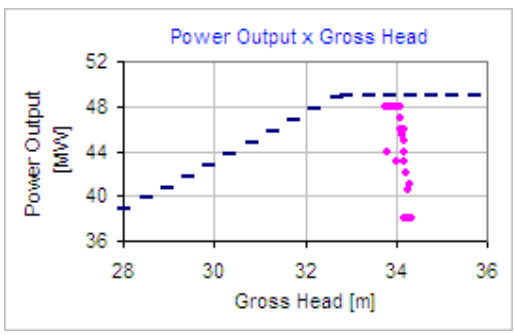

Fig. 5. Maximum power function *x* post-operation data

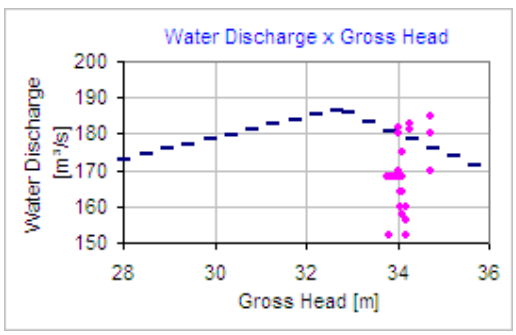

Fig. 6. Maximum water discharge function *x* post-operation data

Function turbine-generator efficiency

The function turbine-generator efficiency can also be graphically examined using the data manager or it can be numerically analyzed using the queries builder. Data manager shows it as a graph in three dimensions, as illustrated in Fig. 7. It is possible to do cuts across the three dimensions to create two-dimensional planes in order to assess the quality of the information. Fig. 8 illustrates a horizontal cut over an efficiency hill curve. It is easy to realize that this cut was done over a hill curve with data problems because the resulting line is not smooth.

Similar to what was done for the polynomials, using the queries builder it is possible to check all the recorded plants to see if there is some incoherence with respect to the efficiency of the turbine-generator sets, that is, if at some moment the value of efficiency of these sets was higher than 94%.

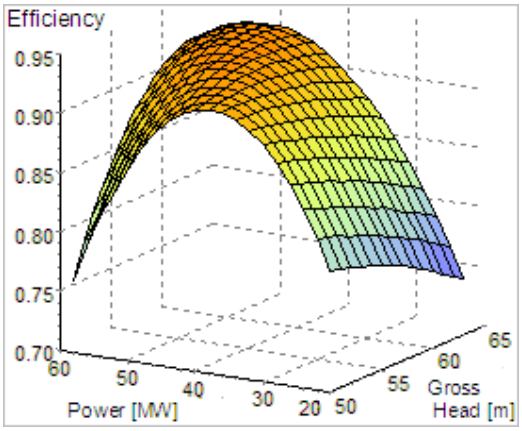

Fig. 7. Example of efficiency hill curve presented by data manager

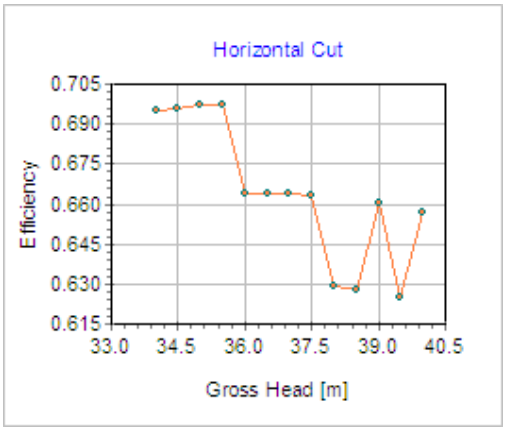

Fig. 8. Horizontal cut over a hill curve with problem

Analysis of data using the simulator

All the static data mentioned above can be analyzed together using the simulator of the hydroelectric plant operation. This simulator becomes a tool for analyzing of data when it is used for reproducing the past operation. If the simulated trajectories move away from verified trajectories, as illustrated in Fig. 9, means that the static data recorded by the plant are not coherent with the real operating.

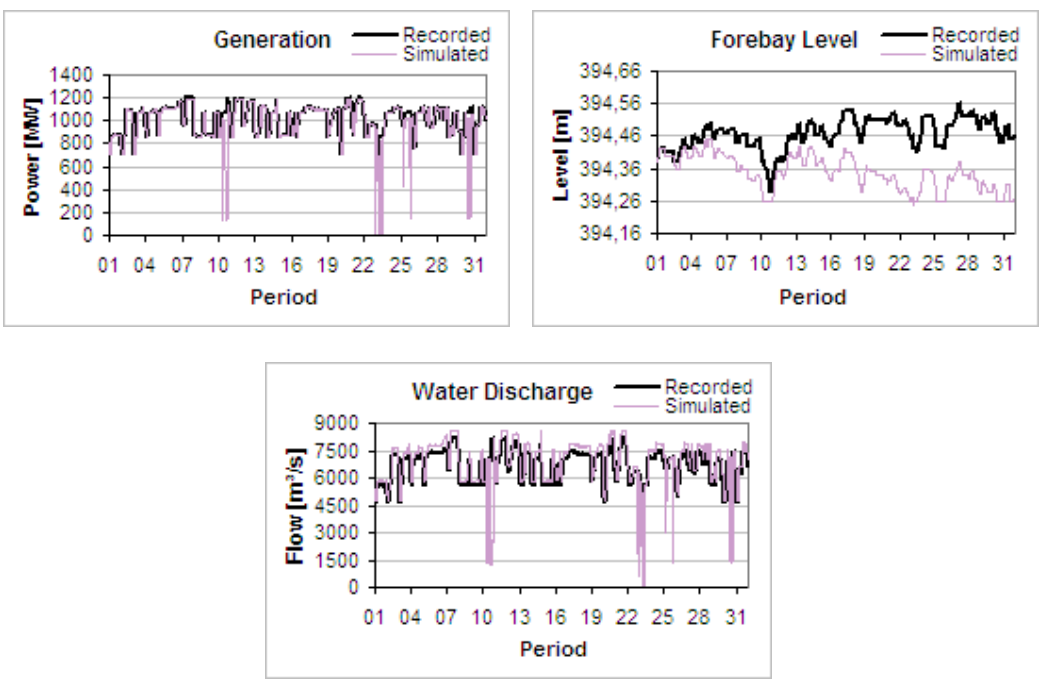

Fig. 9. Recorded data *x* simulated data with information not coherent with the plant's real operating

Otherwise, the proximity of the simulated and verified trajectories, shown in Fig. 10, indicates that the plant's static data are consistent with its operation.

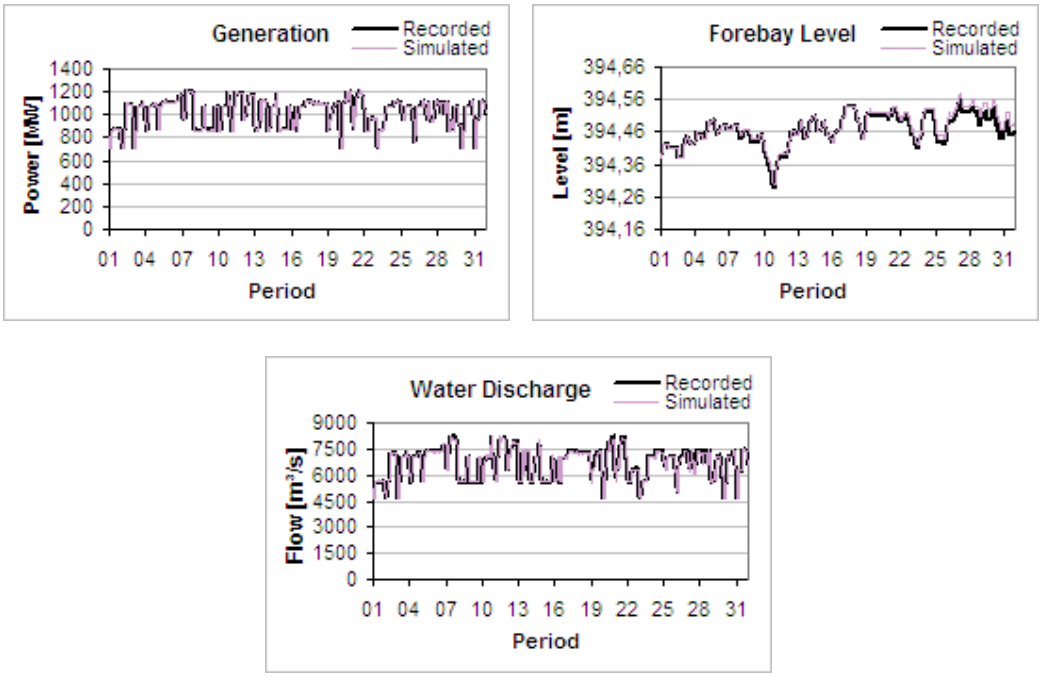

Fig. 10. Recorded data *x* simulated data with information consistent with the plant's real operating

CONCLUSIONS

Each of the modules that makes up the system presented in this paper has a specific objective. In summary, the data manager organizes information from hydroelectric plants, the queries builder extracts information from database and the simulator predicts the plant's operation under a given set of conditions. However, they all can be used as tool for managing, controlling and analyzing data. The data manager enables the graphic data analysis for a plant, the queries builder facilitates the numerical data analysis for a whole hydroelectric system and the simulator shows, at one time, the quality of the data involved in the operating planning when it is used for reproducing the plant's past operation.

Besides the applications mentioned in Case Studies section, the modules of the presented system allow others analyses. For example, the data manager can also be used for assessing the quality of the post-operation variables. The queries builder enables testing the limits of reservoir, tailrace, water discharge and spillage. The simulator is also capable of checking the water balance of the plants.

The computational models used by the energy sector for optimization, simulation and streamflow forecasting depend on data quality to provide reliable results. Therefore, the critical view of the quality of the information allowed by these modules can bring a significant improvement in terms of efficiency to the operational planning of electric power systems.

ABSTRACT

Sufficiently long period of data is required for making sound flood estimates corresponding to the design return periods. Such long-term and good quality flow data is often a difficult proposition, especially in developing and under-developed countries. Most watersheds in these countries that are of immediate interest and concern are either completely ungauged or are insufficiently gauged. Flood estimates in situations of inadequate length of data invariably involve large amounts of uncertainties. There is a growing interest in investigating if these uncertainties in flow estimates can be reduced by supplementing the limited flow data with that available at adjoining river gauging station(s) on the same river or that in the adjoining river basins. It is expected that additional information can be derived from the dependence among flow characteristics at these adjoining flow stations when they are considered together. The maximum likelihood procedure, with likelihood function involving univariate and joint probabilities corresponding to exclusive and concurrent periods of data availability, is employed for estimating parameters of flood frequency distributions. Copula-based bivariate distribution approach offers advantage over conventional functional forms by admitting arbitrary marginal types that are dictated by the nature of the flow regimes at these river stations under consideration. This paper presents a comparison of uncertainties in the estimated flood quantiles at a station with limited data, as obtained from the univariate consideration and that from the simultaneous consideration of additional flow data from a neighboring river gauging station. A significant reduction in uncertainty achieved by this approach indicates that substantial improvements in the accuracy of flood estimates can be made by multivariate consideration of flood frequency analysis that is facilitated by copula approach.

INTRODUCTION

Flood frequency analysis typically involves fitting univariate distributions to annual maximum (AM) flows or to peak over threshold (PoT) flows observed at a location of interest along a river. Commonly employed distributions include 2 and 3-parameter lognormal (LN and LN3), 2-paramter gamma (G2), Pearson type III (P3), log-Pearson type III (LP3), the extreme value type I (EV1) or largest extreme value

(LEV) or Gumbel, the generalized extreme value (GEV), and Wakeby distribution, among others. The main objective of various hydrological designs, e.g., for dam spillways, bridges, etc., is to estimate a flow that shall have an average inter-arrival period more than a specified design (return) period. Sufficiently long period of data is normally required for estimating design flood values with desirable narrower confidence widths. Availability of such long-term data is an exception in many cases, especially in developing and under-developed countries. Most watersheds in these countries that are of immediate interest and concern, owing to ever-increasing human activity and development, are either completely ungauged or are insufficiently gauged. Flood estimates in situations of inadequate length of data invariably involve large amounts of uncertainties. There is a growing interest in investigating if these uncertainties in flow estimates can be reduced by supplementing the limited data at a flow station with that available at adjoining river gauging station(s) on the same river or that in the adjoining river basins. Simultaneous consideration of data from two or more stations or variables that exhibit certain level of interdependence requires undertaking bivariate or multivariate frequency distribution analysis. A variety of bivariate distributions, such as bivariate normal, lognormal, exponential, or Gumbel (called mixed Gumbel) distributions have been traditionally applied for hydrological variables such as flood peaks, and associated flood volume and duration. These distributions are generally limited to having same type of marginals. A newer approach in multivariate frequency analysis, called copula approach, facilitates admittance of arbitrary marginals in the distributional forms and thus provide tremendous flexibility. This study demonstrates achieving substantial reduction in uncertainty of the parameter estimates and consequently of the design flood estimates at a station, by way of augmenting it with data at a neighboring station and including a copula-based bivariate distribution in the likelihood function.

Several studies in the past, even as early as 1950s, aimed at utilizing inter-station dependence or inter-variable dependence for augmenting limited data available at a station. Most of these studies assumed the involved random variables to be jointly normally distributed. Anderson (1957) presented maximum likelihood estimates of bivariate normal distribution when some data for one of the variables were missing. It involved linearly regressing the missing data with the help of additional data of the other variable. This note also listed similar contributions by Lord (1955) and Edgett (1956) that handled trivariate normally distributed variables, with a different arrangement of the missing data. Fiering (1960) extended these works by introducing the random errors about the simple and multiple linear regressed flow values. The paper also presented exact and asymptotic maximum likelihood formulations for relative information corresponding to small and large samples, based on results obtained by other researchers (Cochran, W.G. and Thomas, H.A. Jr.) cited therein. It was concluded that for most cases of large sample sizes and adequate correlation there is a gain in information with respect to mean and variance estimates. However, for very small sample sizes and/or having very small correlation, there sometimes can be loss of information and in such cases univariate consideration with short data record is better than bivariate or trivariate analysis. Graphical results were given and tabular results cited in this study in order to know if a certain combination of correlation and length of short and long records will result in improvement in

relative information. Matalas and Jacobs (1964) concluded that for the two cases when the noise component to the regressed estimates is added or not added a minimum correlation coefficient of 0.5 and 0.85, respectively, is required for reducing uncertainty in mean and variance estimation.

Extending investigation of reduction in uncertainty of parameter estimates to non-Gaussian distributions, Clarke (1980) considered augmenting shorter annual flood records with longer precipitation records that were assumed to be bivariate Gamma distributed. A significant gain in information by way of employing bivariate over univariate distribution was reported. Reuda (1981) worked with the cases of bivariate normal distribution as well as two forms of bivariate extreme value Gumbel distributions. This study concluded that the information gain for the parameter estimates of the shorter series depends upon the ratio of sizes of longer series and the concurrent data period, for both normal and Gumbel distribution types. This gain was not found for the bivariate normal case when the size of the concurrent period was very small (i.e., when the ratio was close to unity) or when there was very low correlation. Another important result was that whereas for the bivariate normal case there was no information gain for the estimated parameters of the longer series there was such significant gain in the two cases of bivariate Gumbel distributions. It was also inferred that the information gain for the two Gumbel distributions was larger for higher correlation between the two series. Furthermore, for the shorter series it was higher when the abovementioned ratio was larger whereas for longer series it was higher when the ratio was closer to unity. The applicability of the asymptotic formulations in the above cases was also confirmed for small sample size of 10 on the basis of simulation studies. It was conjectured that further information gain may be possible by multivariate considerations as compared to bivariate cases and also recommended similar studies with other distributions, involving for instance the gamma and the log-Pearson III distributions. Raynal (1985) also employed three types of bivariate extreme value distributions and found that there was reduction of uncertainty in the flood estimates even when the sample sizes of the marginals were equal.

Escalante and Raynal (1998) employed trivariate distributions, with extreme value Type I (Gumbel) marginals, to regional flood frequency analysis in a region of Mexico, in order to investigate if there was reduction in uncertainty of estimated parameters. The conclusions made were similar to those by Rueda (1981), with respect to gain in information for shorter and longer series. It was also reported that the gain of information was more for quantile estimates of larger return periods. The study also confirmed appropriateness of maximum likelihood based asymptotic estimates for small sample sizes of 20 by conducting simulation analysis. Similar conclusions of uncertainty reduction were drawn by Escalante (2007) and Escalante and Raynal (2008) with respect to the use of bivariate Weibull, and mixed Weibull and trivariate general extreme value (GEV) distributions respectively. Comparisons of standard error of fit (SEF) and mean absolute relative deviations (MARD) was made by Raynal and Salas (2008) for two pairs of flood data series with unequal sizes and employing univariate and bivariate forms of general extreme value distribution. Univariate procedure was found to be better in one case whereas obtaining parameter estimates by bivariate consideration was better in the second case.

In all of the above studies the involved bivariate or multivariate distributions had the same type of marginals, such as normal or extreme value type I (Gumbel) or general extreme value or Weibull or mixed Weibull. Intuitively, the choice of marginal must be dictated by the type of distribution that best represents the data under consideration. And in many cases the multivariate data may involve different types of marginal distributions to be best suiting the data. The conventional bivariate or multivariate distribution forms do not admit arbitrary marginals. In such cases where arbitrary marginals are desired to be included in the multivariate distributions, copula-based formulations have distinct advantage and may offer many possibilities. This paper employs a copula-based bivariate distribution that involves largest extreme value (LEV) and log-Pearson Type III (LP3) as marginals and shows that the estimated quantiles for the shorter series have lesser uncertainty as compared to when they are obtained on a purely univariate basis.

COPULA-BASED DISTRIBUTION FOR CASES OF INCOMPLETE DATA

Copula is a simple concept wherein bivariate or multivariate probabilities are expressed in terms of marginal probabilities and more advantageously in terms of uniform marginals. This theory has been in vogue for some time, especially with respect to actuarial science and finance applications. In recent years, this approach has also made an impressive beginning in the field of hydrological engineering. Several illustrative and review studies, such as Favre et al. (2004), Salvadori and De Michele (2004), De Michele et al. (2005), Genest and Favre (2007), Poulin et al. (2007), Salvadori and De Michele (2007), Serinaldi and Grimaldi (2007), Zhang and Singh (2007) provide elaborate discussion on copula applications related to flow variables and explain its advantages and limitations. There are several other studies that have also been reported recently covering applications related to rainfall variables. In simple terms the copula-based joint distribution function for any random variable (X,Y) may be written as

$$F(x,y) = C[F_X(x), F_Y(y)], \qquad x,y \in R$$

where $F_X(x)$ and $F_Y(y)$ are marginal probability distributions and $C:[0,1]\times[0,1]\rightarrow[0,1]$, a mapping function, is the "copula". In turn, it means that a valid model for (X,Y) is obtained whenever the three constituents (C, F_X, and F_Y) are chosen from given parametric families, viz.

$$F_X(x;\boldsymbol{\delta}), \quad F_Y(y;\boldsymbol{\eta}), \quad C(u,v;\boldsymbol{\theta})$$

where $\boldsymbol{\delta}$ and $\boldsymbol{\eta}$ are the parameter vectors of marginal distributions and $\boldsymbol{\theta}$ is the parameter vector for the dependence structure. u and v are the quantiles of the uniformly distributed variables $U = F_X(X)$ and $V = F_Y(Y)$ respectively.

Several classes and families of copulas, such as the meta-elliptic copulas, extreme value copulas, and Archimedean copula, exist. Of the several families that exist, the one that has been frequently applied in the field of hydrology is the Archimedean family. This copula family has the following form

$$\phi[F(x,y)] = \phi\{C[F_X(x), F_Y(y)]\} = \phi[F_X(x)] + \phi[F_Y(y)]$$

where ϕ, a continuous and strictly decreasing function, from $I\,[0,1]\rightarrow[0,\infty]$ and $\phi(1)=0$, is called a generating function. The joint probability function can then be written as

$$\begin{aligned} F_{X,Y}(x,y) &= C\left[F_X(x),F_Y(y)\right] = \phi^{[-1]}\left\{\phi\left[F_X(x)\right]+\phi\left[F_Y(y)\right]\right\} \\ &= C(u,v) = \phi^{[-1]}\left\{\phi(u)+\phi(v)\right\} \end{aligned} \tag{1}$$

Parameter θ is hidden in the generating function. For example, the generating function of the Gumbel-Hougaard copula family involves θ in the form

$$\phi(t)=(-\ln t)^{\theta}\ , \quad \theta\in[1,\infty)$$

Employing the above generating function and the form of Archimedean copulas given in Eq. (4), the bivariate cumulative probability distribution is obtained as

$$\begin{aligned} F_{X,Y}(x,y) &= \exp\left\langle-\left\{\left[-\ln F_X(x)\right]^{\theta}+\left[-\ln F_Y(y)\right]^{\theta}\right\}^{1/\theta}\right\rangle \\ &= \exp\left\{-\left[(-\ln u)^{\theta}+(-\ln v)^{\theta}\right]^{1/\theta}\right\} \\ &= \exp\left[-\left(\tilde{u}^{\theta}+\tilde{v}^{\theta}\right)^{1/\theta}\right] = C(u,v) \end{aligned}$$

where $\tilde{u}=-\ln u=-\ln F_X(\mathrm{x})$ and $\tilde{v}=-\ln v=-\ln F_Y(\mathrm{y})$. Here, $C(u,v)$ is called the copula probability. Double differentiating the above bivariate probability function results in the joint density function as

$$\begin{aligned} f_{X,Y}(x,y) &= f_X(x)f_Y(y)\left\{\frac{1}{uv}\frac{(\tilde{u}\,\tilde{v})^{\theta-1}\left[\left(\tilde{u}^{\theta}+\tilde{v}^{\theta}\right)^{1/\theta}+\theta-1\right]}{\left(\tilde{u}^{\theta}+\tilde{v}^{\theta}\right)^{\left(2-\frac{1}{\theta}\right)}}C(u,v)\right\} \\ &= f_X(x)f_Y(y)\ c_{\theta}(u,v) \end{aligned} \tag{2}$$

where $f_X(x)$ and $f_Y(y)$ are the marginal probability densities and $c_{\theta}(u,v)$ is the copula density. Chowdhary and Singh (2008) lists expressions for probabilities of few more commonly used copula families and their corresponding parameter space and generating functions.

The present study considers a bivariate data set (X,Y) having some concurrent period and some individual data series availability as depicted in Figure 1. Here, N_X and N_Y are respectively the total number of data in the two data series individually. Of these lengths, the concurrent period has n_{XY} elements. Similarly, n_X and n_Y are respectively the number of elements when series X or Y is exclusively available. Presence of these exclusive and concurrent periods of data lengths n_X, n_Y and n_{XY} is expressed by the indicator variables I_X, I_Y and I_{XY}. A value of 1 or 0 is assigned to these indicator variables as per the presence or absence of the corresponding part of the two series. The maximum likelihood parameter estimates of a univariate flood frequency distribution, say of series Y, are conventionally obtained using the likelihood or log-likelihood functions as

$$L_U = \prod_{1}^{N_Y} f_Y(y) \text{ or } LL_U = \sum_{1}^{N_Y} \log f_Y(y) \quad (3)$$

The objective of the study here is to know if, in order improve the accuracy of parameter estimates as obtained from the above likelihood function, is it advantageous to consider a composite likelihood function L_C of the form

$$L_C = \left[\prod_{1}^{n_X} f_X(x)\right]^{I_X} \left[\prod_{1}^{n_{XY}} f_{X,Y}(x,y)\right]^{I_{XY}} \left[\prod_{1}^{n_Y} f_Y(y)\right]^{I_Y}$$

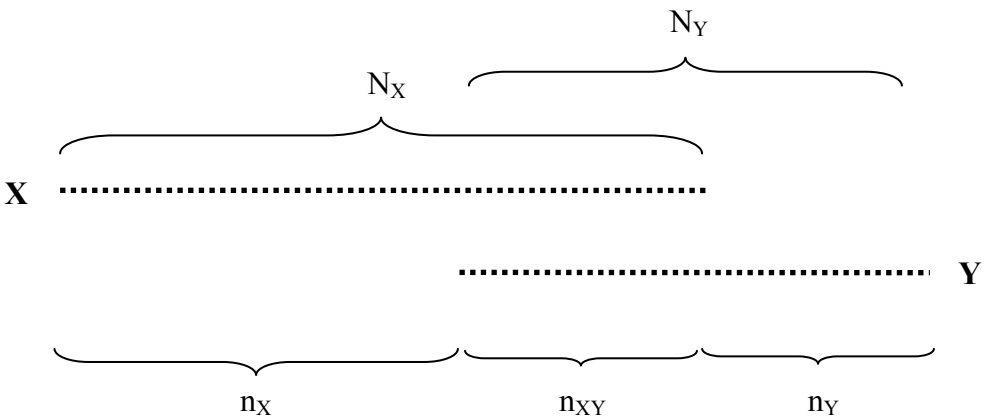

Figure 1 Arrangement of occurrence of series X and Y.

The above composite likelihood function incorporate both, the bivariate nature of the process (X,Y) and the exclusive occurrences of X or Y in the remaining periods. The univariate densities for the exclusive periods are given by the marginal densities $f_X(x)$ and $f_Y(y)$. And the choice of these distributions is dictated by the nature of the two processes. The bivariate probability density $f_{X,Y}(x,y)$ is based on copula-based distribution function, e.g., the one given in Eq. (2), allowing arbitrary marginals to be considered as per the nature of the individual processes. The simpler composite log-likelihood function LL_C can be expressed as

$$LL_C = I_X\left(\sum_{1}^{n_X} f_X(x)\right) + I_{XY}\left(\sum_{1}^{n_{XY}} f_{X,Y}(x,y)\right) + I_Y\left(\sum_{1}^{n_Y} f_Y(y)\right) \quad (4)$$

As is apparent from the above composite log-likelihood function, if any one or both of the exclusive period lengths n_X and n_Y are non-existent then the value of the indicator variables I_X and I_Y will correspondingly take a value of 0. In that case such part(s) will not be present in the above likelihood function. It may also be noted here that there is no requirement for the individual or concurrent portions of the data series to be contiguous. In other words, there can be any number of gaps at arbitrary points of time within the exclusive or the concurrent portions. Furthermore, the exclusive periods of the two series may lie on one or both sides of the concurrent period, unlike on only one side as schematized in Figure 1.

PARAMETER AND UNCERTAINTY ESTIMATION

The maximum likelihood approach is considered for obtaining parameter estimates based on the composite log-likelihood function (LL_C) given in Eq. (4). A numerical solution for maximizing the log-likelihood function will be sought, as obtaining and solving the score equations would be a formidable task when likelihood function includes mathematically involved function such as $f_{X,Y}(x,y)$ given in Eq. (2). The numerical solution is obtained by employing "BFGS" method, published simultaneously by Broyden, Fletcher, Goldfarb and Shannon (Goldfarb, 1970). In cases when this method results a local minima, the simulated annealing algorithm (Belisle, 1992) is used instead.

The reduction in uncertainty of quantile estimates is reflective of reduction in uncertainty of parameter estimates. The standard errors of the quantile estimates would be compared for the two cases, when distribution parameters are obtained: (a) on the basis of the composite likelihood function LL_C given in Eq. (4), and (b) on a purely univariate basis, i.e., using likelihood function LL_U given in Eq. (3). Letting $\boldsymbol{\psi} = \{\boldsymbol{\delta}, \boldsymbol{\eta}, \boldsymbol{\theta}\}$ imply a combined vector of the three parameter vectors $\boldsymbol{\delta}$, $\boldsymbol{\eta}$ and $\boldsymbol{\theta}$ defined earlier. The variance of the quantile estimate, based on parameters that are estimated by composite likelihood (LL_C) approach, using the Cramer-Rao lower bound limit for large samples, is given as

$$\mathrm{Var}\left[q_{CY}(\boldsymbol{\eta}|T)\right] \approx -\left(\frac{\partial q_{CY}}{\partial \boldsymbol{\eta}}\right)' \left[\frac{\partial^2 LL_C(\boldsymbol{\psi}|\mathbf{x},\mathbf{y})}{\partial \boldsymbol{\psi}\,\partial \boldsymbol{\psi}'}\right]^{-1} \left(\frac{\partial q_{CY}}{\partial \boldsymbol{\eta}}\right)$$

where $q_{CY}(\boldsymbol{\eta}|T) \Rightarrow$ the quantile function for the series Y, for a given value of return period T. The derivatives of q_{CY} and the information matrix are evaluated at the estimated values of parameters, say $\hat{\boldsymbol{\psi}}_C$, and the standard error is thereby given as

$$\mathrm{S.E.}(q_{CY}) = \sqrt{\mathrm{Var}\left[q_{CY}(\boldsymbol{\eta}|T)\right]}\,@\,\hat{\boldsymbol{\psi}}_C$$

Similar procedure is followed for obtaining the uncertainty estimates of quantile estimates obtained for the case when distribution parameters are obtained purely on univariate basis as

$$\mathrm{S.E.}(q_{UY}) = \sqrt{\mathrm{Var}\left[q_{UY}(\boldsymbol{\eta}|T)\right]} \approx \sqrt{-\left(\frac{\partial q_{UY}}{\partial \boldsymbol{\eta}}\right)' \left[\frac{\partial^2 LL_U(\boldsymbol{\eta}|\mathbf{y})}{\partial \boldsymbol{\eta}\,\partial \boldsymbol{\eta}'}\right]^{-1} \left(\frac{\partial q_{UY}}{\partial \boldsymbol{\eta}}\right)}\,@\,\hat{\boldsymbol{\eta}}_U$$

where $\hat{\boldsymbol{\eta}}_U \Rightarrow$ the vector of parameters estimated purely on the basis of univariate likelihood given in Eq. (3). It may be noted that the functional form of the quantile and its gradient in the above two equations are essentially the same. These are subscripted differently only to indicate that they are evaluated at different sets of parameters obtained from two approaches.

APPLICATION

An application is presented here with the objective of investigating if indeed there is some reduction in uncertainty in parameter estimates when a neighboring flow data series, having some inter-dependence with the series under investigation, is simultaneously considered. Composite likelihood function, as outlined previously, combines the concurrent and exclusive periods of the two data series. A copula-based bivariate distribution function represents the concurrent period whereas the best distributions fitting the marginals are chosen to represent the exclusive parts of the two series. As copula-based probability density functions are expressed in terms of marginal densities, the parameters are estimated commonly for exclusive and concurrent parts of the two series.

Data Set

The Annual peak flows of Greenbrier River at Alderson (USGS station # 03183500) and Buckeye (USGS station # 03182500) stations in West Virginia State are obtained from USGS website. The Greenbrier River is a tributary of the New River in southeastern part of the state and is approximately 165 mi long. Through the New, Kanawha and Ohio Rivers, it is part of the Mississippi River watershed. River gauging station at Alderson is located at Latitude 37°43'27" and Longitude 80°38'30" and Buckeye at Latitude 38°11'09" and Longitude 80°07'51". These command drainage areas and contributing areas of 1,364 and 540 square miles respectively. The datum of the gages at the two stations is respectively at 1,529.42 and 2,085.69 feet above sea level. A length of 112 years of data for Alderson, from 1896 to 2007, and 78 years for Buckeye, from 1930 to 2007, is considered for this analysis. The bivariate scatter plot of time series of these two data sets, in 103 cusec, is given in Figure 2.

Potential Marginal Distributions

Several candidate distributions, such as 2 and 3-parameter lognormal (LN2 and LN3), 2-paramter gamma (G2), Pearson type III (P3), log-Pearson type III (LP3), largest extreme value (LEV), and Weibull are considered for fitting the annual peak flows of Alderson (series X) and Buckeye (series Y) stations on univariate basis. On the basis of Kolmogorov-Smirnov, Anderson Darling, and Chi-Squared fit statistics and overall fit of the Q-Q plots, LEV and LP3 distributions were taken to be better representing the flood peak distributions at the two stations, respectively. The overlay of density curves of these distributions and the corresponding histograms is shown in Figure 3. The probability and density functions for LEV (for X) and LP3 (for Y) are given as

$$F_X(x) = \Phi_{\text{LEV}}\left(\frac{x-\mu}{\sigma}\right) \quad \text{with} \quad \Phi_{\text{LEV}}(z) = \exp[-\exp(-z)]$$

$$f_X(x) = \frac{1}{\sigma}\phi_{\text{LEV}}\left(\frac{x-\mu}{\sigma}\right) \quad \text{with} \quad \phi_{\text{LEV}}(z) = \exp[-z-\exp(-z)]$$

$$f_Y(y) = \frac{1}{\alpha\, y\, \Gamma(\beta)} \left(\frac{\log(y) - \gamma}{\alpha} \right)^{\beta - 1} \exp\left[-\left(\frac{\log(y) - \gamma}{\alpha} \right) \right]$$

$$F_Y(y) = \frac{1}{\alpha\, \Gamma(\beta)} \int_{\gamma}^{y} \frac{1}{y} \left(\frac{\log(y) - \gamma}{\alpha} \right)^{\beta - 1} \exp\left[-\left(\frac{\log(y) - \gamma}{\alpha} \right) \right] dy$$

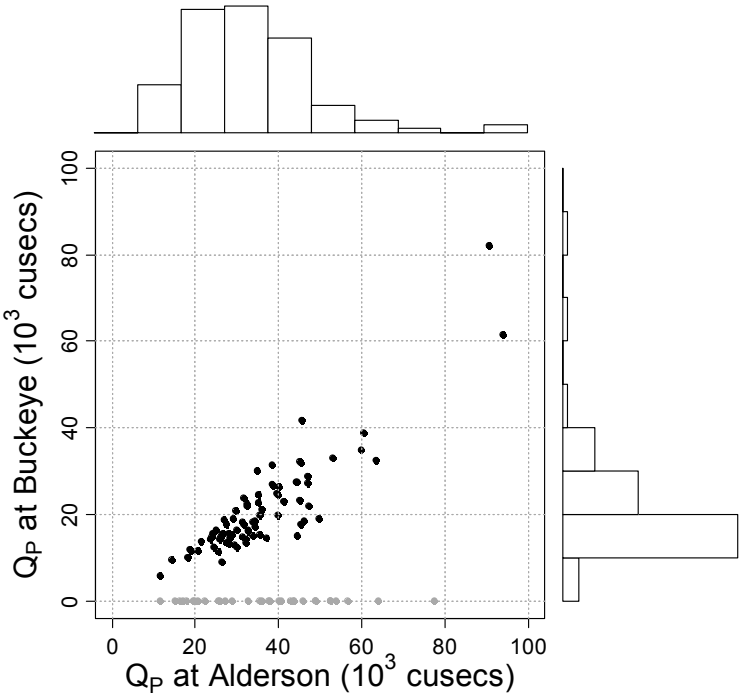

Figure 2 Scatter plot of peak flows at Alderson and Buckeye river gauging stations. Data from concurrent period are plotted in black whereas those from the exclusive period of Alderson are plotted on the x-axis in grey.

Comparison of Univariate and Composite Likelihood Approaches

The flow peak data series at Alderson is for a period of 112 years and that for Buckeye station is for 78 years. The last 78 years is the concurrent period between the two series. Normally, such data availability is considered more than adequate for making sound parameter estimates on the basis of purely univariate consideration. However, these two data series are used here for demonstrating if accuracy of parameter estimates for Buckeye station improves when data of Alderson station is also used and composite likelihood approach employed. Moreover, the effect of relative sizes of the two series is seen by artificially blanking out certain period of Buckeye station data. Six such cases are considered for which number of elements and values of indicator variables for both series are given in Table 1.

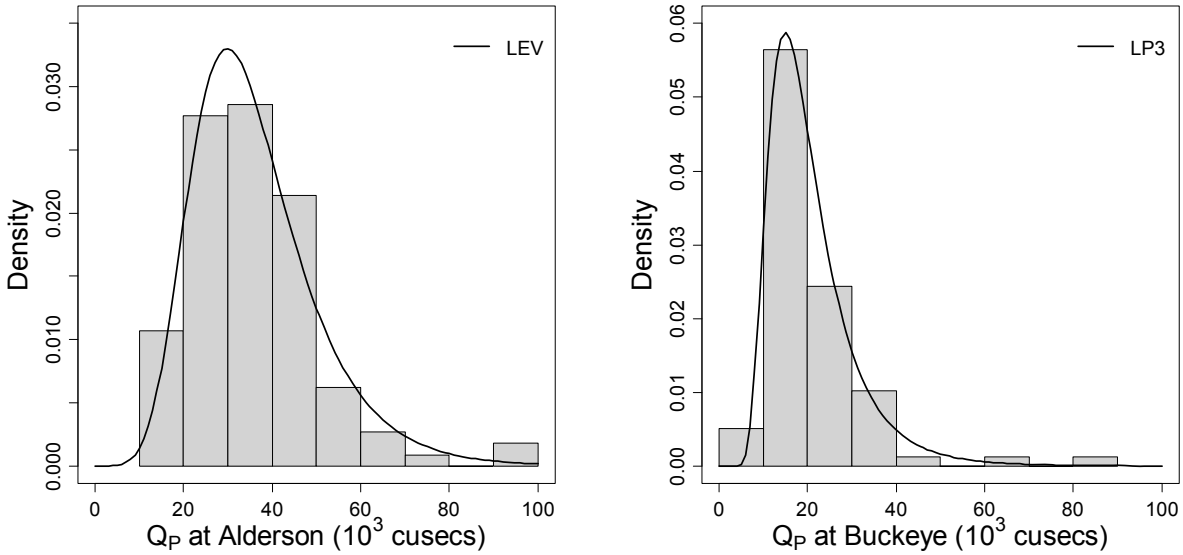

Figure 3 Histograms and plausible probability density functions for peak flows at Alderson and Buckeye river gauging stations.

Parameter estimates and variance covariance matrices are obtained for the Buckeye data series (Y) on the basis of maximum likelihood method employing the two approaches: (a) on a purely univariate basis using LL_U, and (b) on the basis of the composite likelihood function LL_C. The comparison of probability plots resulting from these two approaches for Buckeye station is shown for cases I, III, and V in Figure 4. Other cases also show similar pattern of reduction in widths of confidence intervals. As LP3 is the assumed distribution for this station, the plots are drawn on log-gamma probability papers. The quantile estimates and the associated standard errors are computed with respect to return periods equal to 50, 100, 200, 300, 500, 1000 years. These quantile estimates, associated standard errors, and widths of 95% confidence intervals for both these approaches are given for return periods of 100, 200 and 500 years in Table 2. The percent reduction in uncertainty, in terms of standard error and confidence interval, is also given. Apart from the computation of reduction of uncertainty based on standard errors of quantile estimates and widths of confidence intervals, few more error statistics, such as root mean square error (RMSE), standard error of fit, bias (BIAS), and mean absolute relative deviations (MARD) are also computed for the two approaches and are given in Table 3. The reductions based on these error statistics is also given in the table.

Table 1 Lengths and indicator variables for different lengths of Buckeye series

Case	Alderson Data Series (X)				Buckeye Data Series (Y)				Concurrent Period	
	Years	N_X	n_X	I_X	Years	N_Y	n_Y	I_Y	n_{XY}	I_{XY}
I	1896-2007	112	82	1	1930-1959	30	0	0	30	1

DISCUSSIONS

It is apparent from the narrower confidence intervals in the probability plots of composite likelihood approach of Figure 4 (right side plots) that there is visible reduction in uncertainty of the quantile estimates, in all the three cases I, II, and III for most ranges of return periods. Table 2 shows this improvement in accuracy in quantitative terms. There is across-the-board substantial reduction of about 25 to 75% in the standard error or the confidence width, when parameter estimation is done by employing composite log-likelihood in place of univariate log-likelihood. The improvement in all six cases is slightly more for increasing return periods. Furthermore, baring one of cases (Case I) the relative improvement is greater for shorter period of concurrent period for the same length of the exclusive period of series X. In the first three cases the quantile estimates are same for both approaches whereas for the last three cases the estimates from composite approach are conservative up to about 20%. Besides improvement in accuracy of the quantile estimates, there is marked improvement in the four error statistics considered, i.e., RMSE, SEF, BIAS, and MARD. The absolute values of these error statistics and the percent improvements are given in Table 3. The improvement is of the order of 5 to 30% with respect to the last three cases whereas there is no change in the first three cases. Overall, it can be stated that substantial gain by bivariate consideration of data and making use of the composite likelihood approach instead of the pure univariate approach.

CONCLUSIONS

The results of this study show that there is substantial gain in information and consequent reduction of uncertainty in design flood estimates by considering data from inter-dependent stations. The reduction in uncertainty of estimated quantiles is quite substantial and ranges from 25 to 75% for this particular case study. It is also found that the relative gain in information is higher for increasing return periods. Also, that there is a general trend of gain being higher for smaller length of concurrent period for the same length of exclusive period of the additional station considered. Another interesting result of the study is that not only there is reduction in uncertainty of the estimated quantiles, the other error statistics such as root mean square error, standard error of fit, bias, and mean absolute relative deviations also show significant improvement. Thus, it is concluded that composite likelihood approach, which simultaneously considers bivariate and univariate occurrences of inter-dependent data, provides encouraging avenues for reducing the uncertainty in design flood estimation. Furthermore, copula-based joint distribution functions included in the composite likelihood functions provide desired flexibility for choosing the required distribution types for representing the marginals. It is opined that this approach is not only valid for extending incomplete data in one of the series but may also be equally useful where both series are of equal but limited lengths.

Abstract

A common method of design and operation of hydropower dams in Iran is based on peaking hours. In other words, monthly network demand (peak hours multiplied in install capacity) will be fully produced if the water level of reservoir in that month is between Minimum Operating Level (MOL) and Normal Water Level (NWL). If it is located under MOL or above NWL, the water level will be fixed on MOL or NWL and energy production will be lowered or increased, respectively. In order to take into account different monthly values of energy, implementing of an operating policy and rule curve is indispensable. The main goal of this study is to derive a set of monthly target storage elevation as a rule curve to operate the powerplant of Seymareh reservoir in West-South of Iran. The main simulation model of Seymareh reservoir and powerplant is developed in Vensim Environment using System Dynamics (SD) approach. In this process, all the technical and practical details of this reservoir are taken into account. Relations between discharge and turbine efficiency and tail water, volume-area-elevation relations, reservoir evaporation, overload coefficient and maximum and minimum allowable head and turbine discharge are some of these details. Energy production will be occurred if the water elevation of a particular month of reservoir is located above the defined target elevation of that month. This process is performed on historical time series aiming to maximize mean annual value of generated energy. In the next part of this study, to avoid the trial and error process of target elevation selection of above discussed simulation model, a simple ACO algorithm with an embedded coded simulation model is implemented. Results show the ability of this algorithm in defining a rule curve for an absolutely practical case study.

INTRODUCTION

Nowadays in the world, especially in developed countries, water resources planning and management is one of the most controversial tasks and its benefits justify tendency and studies in this area. The limitations in the use of fossil fuels and the benefits of use of the clean and renewable hydro-energy have led to the increased development of hydroelectric projects. In order to design and construct hydroelectric systems, their operation should be analyzed over a representative hydrologic period.

(Afzali et al, 2008). This may be done by using mathematical modelling and system analysis tools. Mathematical simulation and optimization models are extensively used in hydropower reservoir systems analysis. Descriptive simulation models, due to their computational advantages, are able to consider more details of real systems than optimization models. However, they require that the model builder specifies an operating policy. Use of rule curves (Loucks and Sigvaldason 1982), heuristic rules such as space rule (Bower et al. 1962), New York City (NYC) rule (Clark 1950, 1956) and hedging rules (Tu et al. 2003) are common ways of defining operating policies required in simulation models.

The main goal of this study is to derive a set of monthly target storage elevations as a rule curve to operate the powerplant of Seymareh reservoir in West-South of Iran. A system dynamics approach is used for assessing the energy potential of hydroelectric system. In order to find a set of initial solutions, a simple simulation-optimization model is used. The main prepared simulation model in Vensim environment enhances us to see the variation of desired objectives like total generated energy, energy value and summer energy to choose the best combination of 12 monthly target elevation of reservoir. In order to maximize the total energy value and because of the trial and error nature of selecting end-of-month target elevations in Vensim simulation environment, in the next part of this study, Ant Colony Optimization (ACO) algorithm is used to determine these end-of-month target elevations. To do so, an embedded monthly hydropower simulation model is used to operate Seymareh reservoir by any proposed rule curve of each ant. Using this approach, it is expected to find better target storages in comparison with trial-error method of Vensim simulation. In this study, all the practical functions and parameters of a real powerplant is taken into account.

ELECTRICAL ENERGY CONSUMPTION

Reservation of electrical energy, especially in large scale, is impossible. So, the production of hydropower energy should be adjusted to the current demand of network. In the peak time of energy consumption, all the powerplants of system have to work with their maximum power. In short term, the electrical energy consumption is affected by environmental parameters like temperature, humidity and wind velocity and varies by time period like hours of weak, month and even especial ceremonies. In long term, it is affected by social and economical improvements and population growth. In general, the electrical energy load varies by hour, day, weak, month and year, but the trend of energy demand variation is constant over the time period. Energy demand variation curve in Iran's electrical network, in 24 hours of a day, is a curve with two peaks. The second and biggest peak starts around sunset and continues to around 10 or 11 at night. The other information regarding energy demand variation in Iran which is out of scope of this paper result in:

- 24 hour electrical energy demand curve in Iran has two local peaks.
- The peak time length of daily consumption varies by season. Maximum length occurs in summer and minimum length occurs in spring.

- Generally, beginning of the spring has the minimum energy demand in contrast with late July.
- Monthly consumption shows the maximum demand for summer months and the minimum demand for March and April.
- The long peak of summer days shows the great value of energy in these months.

According to the above discussion, two basic parameters of operation of hydropower reservoirs are as follows.

Value of energy in different months

Introducing different energy values for different months of a year enhance us to operate the hydropower reservoirs and their powerplants more efficiently. In order to do so and according to the above information, different proportional energy values are assigned to each month (Table 1).

Minimum peak energy generation

The peaking capability of powerplant in current study is as shown in table 1. Different monthly energy values for base, intermediate and peak load emerges us to develop an operating rule to optimally operate hydropower reservoirs. The aim of this study is to derive a rule curve consisting of 12 end-of-month target elevations considering different energy values which leads us to maximum energy value.

Table 1. Monthly distribution of electrical relative energy value and minimum peak hours

	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Agu.	Sep.	Oct.	Nov.	Dec.
Relative Energy Value	8	9.5	5	3.5	5	11	14.5	16	12.5	3.5	5	6.5
Minimum Peak Hours	2	2	2	3	4	5	6	6	5	3	2	2

CASE STUDY; SEYMAREH DAM

The Seymareh concrete dam, currently under construction on Seymareh river (main branch of Karkheh river), is located in Ilam province, south-west of Iran. According to the latest information, the NWL and MOL of dam are fixed to 720 and 705 masl, respectively. Seymareh powerplant is consists of 3 units of 160 MW with design inflow of 153.5 cms which can conduct 156.1 cms in its critical period. In the phase of design, all the calculations were made on the basis of 4 peak hour operation. In this study, peaking hours of powerplant is calculated using proposed rule curve, considering different monthly energy values.

SIMULATION-OPTIMIZATION; DERIVING INITIAL SOLUTIONS

Hydropower rule curve consists of two main parameters: 1) End-of-month reservoir target elevation, 2) Minimum peak hour operation of hydropower plants.

According to the energy value in Iran, the minimum peak hours of Seymareh powerplant is fixed as shown in table 1. In order to define the end month target elevation, a simple simulation-optimization model is developed. The 12 month end target storages obtained from the model is considered as an initial solution for the main simulation model using system dynamics approach. To develop the discussed simple simulation-optimization model the following objective function are taken into account: 1) Maximization of long term energy production, 2) Maximization of flood control volume of reservoir in flooding months, 3) Minimization of energy production deficit in comparison with monthly minimum peak hours of operation (table 1), and 4) Minimization of spill.

As it can be seen, the first two objectives are completely in conflict. The first objective is trying to maximize storage and net head and the second one is trying to keep water elevation near to minimum operation level. The total relative energy value is calculated by long term summarization of produced energy multiplied in monthly relative energy value. For the second objective function, the sum of long term free storage of reservoir in flood control months (December to April) are taken into account. In addition, the following constraints are implemented to the prepared model: 1) Mass balance equation, 2) Inflow to powerplants, 3) Elevation-Area-Volume of the reservoir, 4) Outflow and tail water elevation, 5) Energy production, 6) Minimum and Maximum Storage of reservoir, 7) maximum 24 hours of energy production, and some more constraints. The previously discussed simulation-optimization model is prepared by Lingo and the derived end target elevations are considered as an initial solution for the main system dynamics simulation model. Table 2 shows the derived target elevation of the reservoir.

Table 2. Initial end-of-month target elevation values derived from simulation-optimization model

	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Agu.	Sep.	Oct.	Nov.	Dec.
Target Elevation	709.5	710	713.5	718	720	720	717	709.5	705	705	707	709

HYDROPOWER RESERVOIR OPERATION WITH RULE CURVE

In order to start the main simulation process, an estimation of installed capacity is needed. As mentioned before, our case study, Seymareh dam, is currently under construction and its install capacity is fixed to 3*160 MW. In the next step, an initial storage of reservoir is needed. In this study, an average of minimum and maximum operation storage of reservoir is assumed as an initial storage capacity. In long term reservoir operation, the value of initial storage has no major influence on total generated energy except few first time periods. In absence of power market and network analysis, it may be desirable to maximize the system's energy yield that can reliably be produced. The following equations show the generated energy as a term of reservoir release and powerplant's firm energy.

$$E(t) = 2.73 \times R(t) \times H(t) \times e_p \quad (1)$$

$$H(t) = h(t) - h_{tail}(t) - h_f(t) \quad (2)$$

$$FE(t) = IC \times hours \times PF(t) \quad (3)$$

Where E(t) is the generated energy of month t, ep is powerplant efficiency in month t, R(t) is turbine release of month t, H(t) is the net head on the turbine, h(t), $h_{tail}(t)$ and $h_f(t)$ are storage level of reservoir, tail water level and total minor and frictional losses in conveyance structures all in month t, respectively. IC is install capacity of powerplant, hours is number of hours in month t, FE(t) is system's monthly firm energy and PF(t) is powerplant's plant factor. The monthly turbine release would then be calculated as follows:

$$R(t) = \frac{FE(t)}{2.73 \times \left(0.5 \times \left(h_2(t) + h_1(t)\right) - h_{tail}(t) - h_f(t)\right) \times e_p(t)} \quad (4)$$

In the above equation, $h_2(t)$, $h_{tail}(t)$ and $h_f(t)$ depend on the turbine release making the equation implicit with respect to R(t). Therefore it has to be solved iteratively. Assume an end-of-month reservoir storage that that yields the initial R(t) from above equation. The new end-of-month reservoir storage is then determined from the mass balance equation of reservoir. The new end-of-month storage is compared with the one initially assumed. If they are not the same, the next estimation of the turbine release is determined from the new end-of-month storage. The procedure is repeated to get the end-of-month storages and releases converged to same values in two successive iterations.

The result end-of-month storage is checked with end target storages of the same month. In the case that the end-of-month storage is less than end target storage, the energy production of powerplant will be reduced. If the end-of-month storage is more than end target storage, the turbine discharge and energy production will be increased until the storage of reservoir will fixed to target storage. In this case if there is more water than powerplant's energy production capacity, the excess water will be spilled to the river.

SYSTEM DYNAMICS APPROACH

Dynamic simulation allows us to observe the behaviour of a modelled system and its response to interventions over time. Dynamic simulation models consist of equations describing dynamic changes. If system state conditions are known at one point in time, the system state at the next point in time can be computed. Repeating this process one can move through time step-by-step over any desired interval. Simulation aids our capacity to make predictions of future states. In System Dynamics Methodology (SDM) the underlying premise is that the structure of a system gives rise to its observable and thus predictable behaviour (Forrester, 1968, 1987). Using the Vensim software, one can easily develop complicated simulation models with various numbers of variables and interrelation among them. The user can define the relations of variables in various pages. In addition, there are some sliders which help users to see the influence of each variable changes on predefined parameters. Generally, system dynamics prepares a forum to analyze the complicated

systems. In this study, some of the basic assumptions of prepared model are as follow: 1) Simulation time step is monthly, 2) Energy demand is defined as the installed capacity of powerplant multiplied to minimum operation hours, 3) After each time period operation of powerplant, if the target elevation of reservoir is between MOL and NWL, the end month storage will be fixed to the end target elevation by lowering the energy production. In the case of locating the storage elevation above the target elevation, again, the end month storage will be fixed to the end target elevation by releasing more water up to 24 hours of energy production. In this case, the excess water will release from reservoir directly to the river, 4) In addition to the limitation of energy production according to the maximum and minimum storage volume, there are some other constrains like minimum and maximum head and inflow to the powerplant. If the inflow to the powerplant is more than allowable, the inflow will be limited to the maximum allowable flow of powerplant. 5) In addition to the discussed basics and constraints, the generated power in time step is limited to the installed capacity of powerplant multiplied in an overload factor.

DERIVING RULE CURVE; SD APPROACH

As it mentioned, the result of simple simulation-optimization model is entered to the main simulation model as an initial solution. In this step, the main goal is précising the target elevation values using graphical and sensitivity analyses abilities of Vensim. In order to perform sensitivity analysis of different target elevation and because of the importance of generated summer energy, this factor is also taken into account as an important operative factor. In addition, because of the different monthly energy values for low, medium and high peak energy, the mean total annual energy value is considered as another operative factor other than total generated energy. Table 3 and 4 shows the relative energy values and variation of low, medium and high peak hours of a year.

Table 3. Relative energy value in different hours and month of the year

	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Agu.	Sep.	Oct.	Nov.	Dec.
Low Peak Hours	1.2	1.2	1	1	1	1.6	1.6	1.6	1.6	1	1	1.2
Medium Peak Hours	1.9	1.9	1.6	1.6	1.6	2.5	2.5	2.5	2.5	1.6	1.6	1.9
High Peak Hours	8	8	6.6	6.6	6.6	10.6	10.6	10.6	10.6	6.6	6.6	8

Table 4. variation of low, medium and high peak hours during a year

	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Agu.	Sep.	Oct.	Nov.	Dec.
Low Peak Hours	6	5.5	5	6	5	5	5	4	5	8	7	6
Medium Peak Hours	16	16.5	17	15	15	14	13	14	14	13	15	16
High Peak Hours	2	2	2	3	4	5	6	6	5	3	2	2

The definition of peak, medium and low bar enhanced us to calculate the long term mean relative energy value in simulation model. So, the other operative factor is

mean annual relative energy value. Finally, the following three operative parameters are taken into account in sensitivity analysis of different monthly storage target elevation: 1) Total energy, 2) Summer energy (four months), 3) Annual relative energy value. In this study, the annual relative energy value is considered as the first and most important operative objective. The summer and total energy are considered following to the first one, respectively. According to the preferences of decision makers and stakeholders, in some cases a trade off analysis is needed to select a monthly target elevation series. The final monthly target elevation is derived by trial and error using previously discussed initial solutions (obtained from simulation-optimization model).

In order to find 12 monthly target elevations a sensitivity analysis process is performed. To do so, all the end-of-month target elevations are first set to their initial values. Starting from October (a non critical month regarding to the flood and high energy demand), all the possible end-of-month target elevations of this month (705 masl to 720 masl, 0.5m discrete) is checked while the end-of-month target elevations of other months are fixed to their initial values. Total energy values are calculated for all 31 possible combinations and the optimum end-of-month target elevation is derived. As soon as the précised end-of-month target elevation of October is fixed to its optimum value (705 masl), the same process starts for November. Again in this step, the end-of-month target elevation of all months are fixed to their initial values except fixed target elevation of October (705 masl) and varying target elevation of November (705 masl to 720 masl). Figure 1 shows the discussed process for the month of March. In this figure, the relative energy value of all 31 possible combinations of end-of-month target elevations to the first combination of this month is plotted against 31 different values of end-of-month elevations. As it can be seen, the target elevation of 710.5 is selected for this month. Table 5 shows the target elevations.

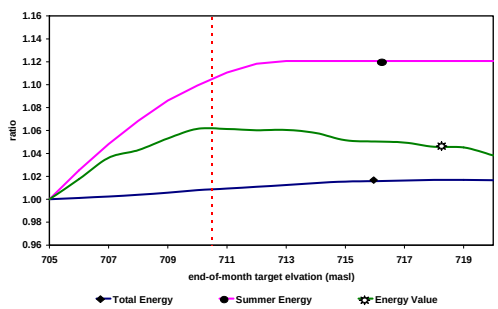

Figure 1. Results of sensitivity analysis of energy value, total energy and summer energy to the end-of-month target elevation of reservoir in March

Table 5. Final values of end-of-month target elevation of Seymareh reservoir of each month

	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.	Agu.	Sep.	Oct.	Nov.	Dec.
Target Elevation	708	708.5	710.5	716	720	720	715	709	705	705	706	708

As mentioned before, in the various phase of designing of Seymareh dam, the operation peak hours of its powerplant was set to 4 hours. In addition, there is not any rule curve for target storages of reservoir. In this study, by introducing different monthly peak operation hours, some changes are occurred in operation of reservoir and powerplant. Although the amount of 6 GWH reduction is occurred in the case of using derived rule curve, 110 GWH energy is added to the 4 month more valuable summer energy. These changes results in about 400 million dollars of increased mean annual energy value.

DERIVING RULE CURVE; ACO APPROACH

As mentioned before, the task of a part of ACO algorithm, ants generate trial monthly target elevation by choosing a target elevation for end of each month. The probability that a particular target elevation will be chosen from the set of available options at a particular decision point is a function of the pheromone and the local desirability of that option based on heuristic information, as shown in Equation 5:

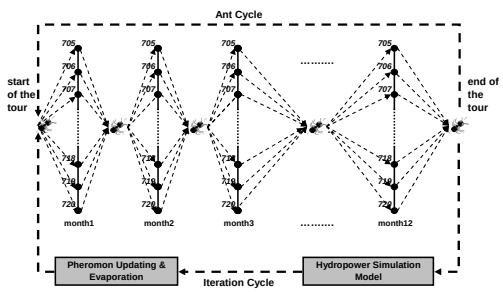

Figure 2. ACO algorithm applied to hydropower rule curve problem

$$P_{ij}(t) = \frac{[\tau_{ij}(t)]^{\alpha}[\eta_{ij}(t)]^{\beta}}{\sum_{j=1}^{n}[\tau_{ij}(t)]^{\alpha}[\eta_{ij}(t)]^{\beta}} \quad (5)$$

where $P_{ij}(t)$ is the probability that target elevation j is chosen of month i in iteration t; $\tau ij(t)$ is the pheromone intensity deposited on target elevation j of month i in iteration t; ηij is the heuristic value for target elevation j of month i in iteration t; n is the total number of target elevation choices available for month t; α is the relative importance of pheromone intensity; β is the relative importance of the heuristic which was set to 0 in this study. The pheromone level associated with a particular option (i.e. target elevation level of a particular month) is a reflection of the quality of the 12 target storage elevations that have been generated that contains this particular option. Once a trial target elevation has been constructed by choosing a target elevation at each decision point, taking into account pheromone levels, one ant-cycle has been completed (Figure 2). After r ant-cycles, where r equals the

number of ants used, the ACO algorithm enters the iteration-cycle (Figure 2). During this stage, the quality of the r trial solutions is evaluated using a simulation model coded according to the process discussed in former sections, as part of which the objective function values, such as energy value, summer energy and total energy calculated and violations of any constraints are identified. The objective function value which is taken into account in this study is energy value. In contrast with trial and error method of system dynamics approach, all the process of seeking best target elevation is done by artificial ants. In the proposed ACO algorithm, a single colony of 75 ants is used. In order to attain acceptable values for decision variables, total number of 200 iterations is used. Next, pheromone is updated in a way that reinforces good solutions. Generally, in metaheuristic algorithms, constraints are implemented to the optimization model as a penalty function. Here in this study, some limitations regarding to the mean monthly generating hours of Seymareh powerplants should be introduced. Three kind of limitations studied here are as follows and table 6 shows the final energy value, summer energy and total energy of each case:

1- No limitation

If there are no limitations regarding to the mean monthly generated hours of powerplants, in consequence, the penalty function would then set to zero for any chosen target elevation. It is expected to attain maximum energy value (see ACO1 in table 6).

2- Limited to the mean generating hour of Vensim simulation

If the mean monthly generating hours of Seymareh powerplants are limited to the mean monthly generating hours derived from Vensim simulation, the penalty function would then be calculated by summarizing the 12 constraint violations of a year. Because of the nature of ACO algorithm (see ACO 2 in table 6), it is expected to find better set of target elevations in comparison to Vensim simulation considering annual energy value.

Tabele 6. Annual energy value, summer energy, total energy and monthly generated hours of powerplant

	Mean Annual Energy Value	Summer Energy (GWH)	Total Energy (GWH)	Mean Monthly Generated (hr)

CONCLUSION

In practical powerplant's operation of hydropower reservoirs, operating policies or operation rule curves may be employed considering objectives like

maximum annual total energy or value. The main objective of this study is to find a rule curve (consisting of 12 end-of-month target elevations) for operating Seymareh reservoir in order to maximize mean annual energy value. Dynamic and graphical enhancements of system dynamics approach and Vensim software convince us to develop the main simulation model of hydropower operation in this environment. In order to have an estimation of these target elevations, a simple simulation-optimization model is prepared. Final target elevations (rule curve) are derived from the main simulation model using trial and error. It should be mentioned that in this study, all the practical parameters and equations of a real powerplant is implemented. In the next part of this study, because of the trial and error nature of using system dynamics approach, a metaheuristic algorithm is developed and used for deriving target elevation of Seymareh reservoir. Results show the performance of ACO algorithm in finding end-of-month target elevations.

Detection of Streamflow Trends and Variability in Karun River-Iran as parts of Climate Change and Climate variability

[a] *Graduate Student of Water Resources Engineering,* [b] *Professor.*
Department of Civil Engineering, Sharif University of Technology, Tehran, Iran.

Abstract

This paper describes the application of statistical and spectral procedures that identifies trends and periodicity in streamflow time series. The results of Mann-Kendall and seasonal Kendall tests (non-parametric tests which are known as appropriate tools in detecting linear trends of hydrological time series) shows negative trends especially during low water months (August to November). This downward trend is more significant in October. But these methods can not interpret periodic behavior. Hence spectral procedures were applied on data series to investigate periodicities in streamflow data series. Fourier and Continuous Wavelet Transform (**CWT**) analyses produce evidence of interannual variability (3-4 and 5-6 years), especially in Karun River. These oscillations can be related to **ENSO** phenomenon. Also we observed near decadal, PDO-related variability. However, the short length of the streamflow series can obscure such these results.

Keyword**:** Climate change, Trend detection, Streamflow variability, Wavelet analysis

1. Introduction

Today there is not any doubt that Global warming as the result of human-induced 'greenhouse effect' will lead regional water resources and hydrological cycles to the changes in different spatial and temporal manners (Qader, 2002; Labat et al., 2004).
Climate change and climate variability may affect human society and enforce them to undergo much harm in their life. Of all of the elements of the hydrologic cycle, streamflow may be the most consequential to human life, especially as the primary source of drinking water in arid areas. Also streamflow time series have advantage, over precipitation records, that they integrate the influences of many variables over a watershed like of rainfall, evapotranspiration, vegetation cover and topography.

Consequently accurate forecasts of streamflow are very valuable for planning water supplies and managing demands. But without recognition and perception of these changes and variations, we are not able to determine any long-term water policy for our future.

Historical streamflow data may not always serve as the best tool for prediction of the future. Some fluctuations in the streamflow records from year to year may correspond to phases of large-scale global atmospheric circulation patterns. In particular, the El Nino Southern Oscillation (ENSO) is an irregular oscillation with a period and amplitude that have undergone a considerable change over the last century and has become a leading focus of research involving earth-atmosphere relationships (e.g., Ropelowski and Halpert, 1987; Cayan and Peterson, 1989; Cayan and Webb, 1992; Kahya and Dracup, 1993).

Establishing the connectivity between such low-frequency climate events (ENSO and PDO) and local hydrology (i.e., streamflows), with correlation and spectral analysis, can increase our knowledge about interannual, decadal and multidecadal variation of land surface hydrological cycle in regional scale and make it possible to predict streamflow for time periods greater than a few days or weeks. Labat, 2005 showed Asian annual runoff comport low-intensity but statistically significant 5- to 6-y ENSOrelated interannual variability and multidecadal 30-y oscillations. Timing is another valuable characteristic of streamflow, especially for snowmelt dominated basins. Any shift in streamflow timing can increase the conflict between water supply and demand.

Therefore in this paper we have investigated and detected streamflow trends and periodicity, both aspects of runoff variability, during the past years.

2. Study Area

The Karun River basin (Fig. 1), with an area of approximately 67,000 km2, is Iran's most effluent, and the only navigable, river with 450 miles (720 km) long. It is located in the southwest (from 30º 16´ to 32º 40´ N latitude and 49º 33´ to 52º 0´ E longitude) of Iran and rises in the ZardKuh mountains district in the Zagros range, receiving many tributaries, such as the Dez and the Kuhrang, before passing through the Ahvaz, capital of the Khuzestan province. The Karun continues toward the Persian Gulf, forking into two primary branches on its delta: the Bahmanshir and the Haffar that joins the Arvand Rud, emptying into the Persian Gulf. Also lower Mesopotamia basin has been affected form Karun and Karkeh rivers by the buildup of sediment brought from the Zagros (Mesopotamia is a trench in front of the Zagros mountains, partly occupied by the sea and gradually being infilled by sediments brought down by the Tigris and Euphrates rivers).

More climatologist confirm that the basin covers three climatic zones, with elevations between 800 and 4400 m,: a high mountain zone containing the dam site and reservoir basin, a foothill and inland desert zone containing the irrigation areas, and a coastal desert zone containing the downstream water use areas. The climate of the region varies from an extremely hot, dry summer accompanied by air temperatures as

high as 54°C to mild winter with sub-zero temperatures for most areas of the region (Khodjeini 1994).

Total annual precipitation, occurring mainly in the November through April or May ranges from 100 to 1200 mm/y in the plain and high mountains respectively, and the low flow season generally begins in July and ends in November. Agriculture (especially sugar production) is by far the biggest user of the Karun River, consuming around 10 billion m3 per year.

Drinking water and other subsistence demands of 1.5 million inhabitant populations in cities of Khoramshahr and Abadan, extremely depend on this river. Excessive use of water by Iran and Iraq, urgency of need for electricity and thereupon operation of inordinate hydropower dams on upstream and brittle ecosystem of the region has intensified conflictions in recent year (Ghadiri 2005).

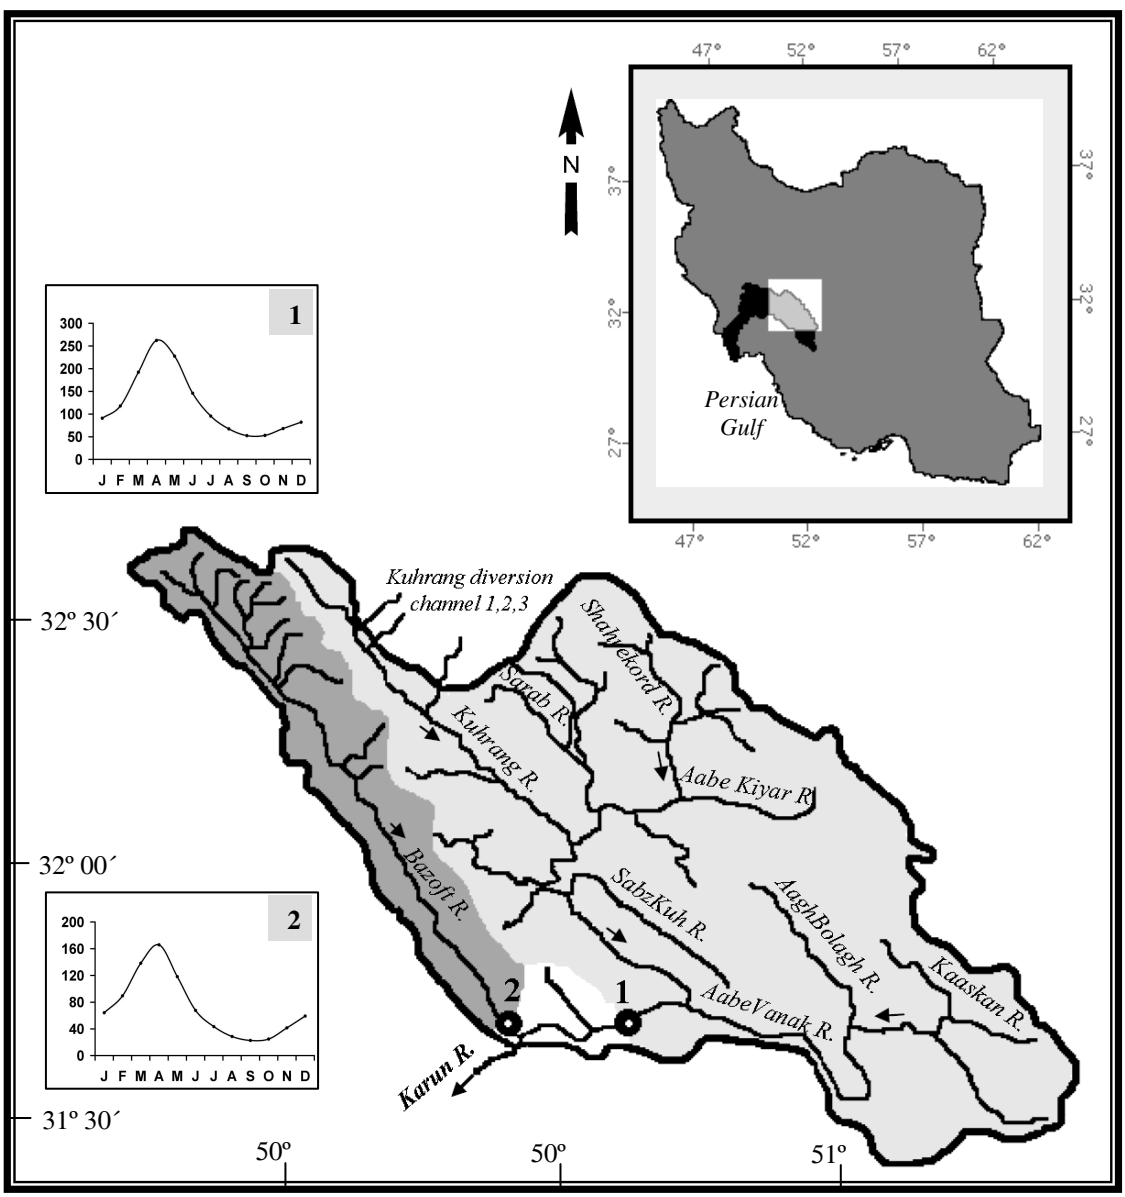

Figure 1 Map of the Karun River basin (full-black area) and Karun-4 sub-basin showing the location of selected stations (shown by numbers keyed in Table 1) and corresponding typical hydrographs.

Whereas climate change and variability can unbalance such system and consequently make many problems, we have decided to investigate discharge characteristics of Karun River in this research. Any research on the basis of detection of climate change and variability, require intact and unregulated flows. Hence we choose one of the most important sub-basins of vast Karun basin, called Karun-4 (Fig. 1) that located on up-stream of Karun-4 dam in Chaharmahal province. This basin (from 31º 20´ to 32º 40´ N latitude and 49º 35´ to 51º 50´ E longitude) covers an area of approximately 12,800 km2. Recent years unfortunately several harmful and inclement floods have occurred in this region and affected the construction of Karun-4 dam and its hydro-electric power plant (Karimi 2006).

3. Data and Methods

In this study we used daily, monthly and annual streamflow records (will remark accurately on the next section), in a period of thirty years from 1975 to 2004, were gathered from Water Resources Research Organization (TAMAB Co.). Table 1 lists two major analyzed stations located throughout the Karun-4 basin. Fig. 1 shows the location of each station and the areas were covered by each sub-basin.
To identify characteristics of observed streamflow data, we have employed statistical and mathematical analysis. Existing any relation between streamflow and known climatic indices (such as the Pacific Decadal Oscillation and the El Nino–Southern Oscillation) were investigated by statistical and spectral analysis. The outline of methods were employed in this research, are described in the sections that flows.

3.1. Trend Detection Test

Tests for trend have been of keen interest in environmental sciences during the last century. Trend analyses in this study were conducted by the nonparametric Mann–Kendall (MK) family tests (Mann, 1945; Kendall, 1975). These tests are widely used for hydrologic data analysis, because of their robustness towards non-normally distributed data, missing values and values below detection limit, and can detect

Table 1 Main characteristics of studied discharge stations

Drainage basin	No. of station	Name of station	Latitude (N)	Longitude (E)	Record period	Elevation (m a.s.l.)	Area (km^2)	Ave. annual runoff (m3/s)
Karun-4	1	Armnad	31º 41´	50º 46´	1975-2004	1050	9986	121.28
	2	Morghak	31º 39´	50º 28´	1975-2004	860	2355	72.26

The numbers of stations correspond to stations in Fig. 1

trends that are monotonic but not necessarily linear (Burn and Elnur, 2002; Yue et al., 2003). We have used the Mann–Kendall test to analyze annual streamflow data, whereas we have employed the seasonal Kendall test (Hirsch et al., 1982) to examine monthly trends. The computational procedure for Mann-Kendall test is described below.

In these tests, the null hypothesis Ho states that the data (x1;…; xn) are independent and identically distributed random variables (Yu et al.,1993) and the alternative hypothesis H1 says that there is a trend in the records. Let the time series consist of n data points and Xi and Xj are two sub-sets of data where i=1, 2, 3, . . . , n−1 and j=i+1, i+2, i+3, . . . , n. Each data point Xi is used as a reference point and is compared with all the Xj data points. The Kendall's S-statistic is computed by Eqs. (1) and (2), then variance for the S-statistic is defined by Eq. (3) which:

$$S = \sum_{k=1}^{n-1} \sum_{i=k+1}^{n} \mathrm{sgn}(x_i - x_j) \tag{1}$$

$$\mathrm{sgn}(x_i - x_j) = \begin{cases} +1 & if \quad (x_i - x_j) > 0 \\ 0 & if \quad (x_i - x_j) = 0 \\ -1 & if \quad (x_i - x_j) < 0 \end{cases} \tag{2}$$

$$Var(S) = \frac{1}{18}\left[n(n-1)(2n+5) - \sum_{p=1}^{q} t_p (t_p - 1)(2t_p + 5) \right] \tag{3}$$

In witch tp denotes the number of ties for the pth value and q is the number of tied values. For the cases that n is larger than 10, the standard normal variable z is computed by using the following equation (Douglas et al., 2000).

$$Z = \begin{cases} \dfrac{S-1}{\sqrt{Var(S)}} & S > 0 \\ 0 & S = 0 \\ \dfrac{S+1}{\sqrt{Var(S)}} & S < 0 \end{cases} \tag{4}$$

This test statistic is used to test the null hypothesis (Ho). If $|Z|$ is greater than $Z_{1-\alpha/2}$, where α represents the chosen significance level (usually 5%, with $Z_{1-\alpha/2}$=1.65), then the null hypothesis is invalid, meaning that the trend is significant. A positive value of S indicates an 'upward trend' and a negative value indicates a 'downward trend'. The slope of the trend was estimated using Sen's slope estimator (Sen, 1968). The Sen Slope is the median of the slopes calculated from all pairs of values in the data series, a method that is little affected by data outliers and missing data (Salmi, 2002).

The Seasonal Kendall (SK) test for trend (Hirsch, 1982 and Slack, 1984) was developed by the U.S. Geological Survey (USGS) in the 1980s to analyze trends in surface-water quality throughout the United States. This test performs the Mann-Kendall (MK) trend test for individual seasons of the year, where season is defined by the user. It then combines the individual results into one overall test for whether the dependent (Y) variable changes in a consistent direction (monotonic trend) over

time. When serial correlation occurs, p-values for significance tests will be too small, and trends may be incorrectly found (we know, so the smaller the p, the more significant the trend). Thus adjusted p-value was suggested in the presence of serial correlation. Recently the test was modified to form the Regional Kendall (RK) test for trend. In this form, trends at numerous locations within a region are tested to determine whether the direction of trend is consistent across the entire region. (USGS Report 2005 Helsel, Mueller and Slack).

In this research Seasonal Kendall test was developed to examine monthly trends. The test statistic is a sum of the Mann-Kendall statistic (S; similar to that in Eq. (1)) computed for each month. But serial correlation between months can lead to overestimation of the significance level when the test statistic is summed by month to test for the overall trend. Hence we have calculated and showed each monthly test statistic separately.

3.2. Spectral analysis for flow dynamics

Spectral analysis of long-term climatic records has been widely used to identify quasi-oscillatory signals and their connections across large-scale circulation indices and hydroclimatic variables throughout the world (see Trenberth, 1990; Ghil and Mo, 1991; Mann and Park, 1993, 1994; Mann et al., 1995). In this study we have used two spectral procedures to investigate periodicities in streamflow time series: Fourier analysis and wavelet transform.

These methods were used to analyze the deseasonalized streamflow records that obtained by subtracting the monthly historical means from monthly means. The traditional Fourier transform uses sine and cosine base functions that have infinite span and are globally uniform in time. It does not contain any time dependence of the periodicity, and only reveals what spectral component is present in the signal (Lau and Weng, 1995). Thus Fourier analysis allows a preliminary determination of the characteristic periods in land surface runoff.

Wavelet transform is a powerful way to characterize the frequency, the intensity, the time position, and the duration of variations in a climate data series (Jiang et al., 1997), which reveals the localized time and frequency information without requiring the time series to be stationary unlike the Fourier transform and other spectral methods (most of the climatic oscillations are nonstationary and do not persist for the entire span of the time series (Labat 2005)). The basic objective of the wavelet transform is to detect the temporal changing characteristics of the streamflow and their correlation with climatic indices. Continues wavelet transform (CWT) was used to determine the temporal variation of frequency content of signals. The coefficients of the wavelet transform of a continuous-time signal $x(t)$ are defined by the linear integral operator:

$$C_x(a,\tau) = \int_{-\infty}^{+\infty} x(t)\ \psi^*_{a,\tau}(t)dt \qquad with$$
$$\psi_{a,\tau}(t) = \frac{1}{\sqrt{a}}\psi\left(\frac{t-\tau}{a}\right) \tag{5}$$

where * corresponds to the complex conjugate. The parameter a can be interpreted as a dilation (a >1) or contraction (a <1) factor of the wavelet function $\psi(t)$, corresponding to different scales of observation. The parameter τ can be interpreted as a temporal translation or shift of the function $\psi(t)$, which allows the study of the signal $x(t)$ locally around the time τ. The wavelet spectrum $W_x(a,\tau)$ of a continuous-time signal $x(t)$ is defined, by analogy with the Fourier analysis, by

$$W_x(a,\tau) = C_x(a,\tau)C_x^*(a,\tau) = \left|C_x(a,\tau)\right|^2 \tag{6}$$

Additional explanations of wavelet and Fourier transform are abundant in the literature (e.g. Torrence and Compo, 1998; Labat, 2005).

4. Results

4.1. Trend detection

Fig. 1 shows a map of the Karun-4 basin along with two hydrographs of selected stations, which we have used here to investigate their historical streamflow trends. According to hydrographs, we can distinguish dominant regime in the region: in both sub-basins (Armand and Morghak), high water month occur during March to May (approximately in the spring), with peak flow in April and low waters during August to October (approximately in summer and autumn).

Fig. 2 shows average annual rainfall and temperature in the region with their linear trends. Obviously increasing trends were observed in annual temperature series, especially in the period of 1992-2004, while most regional rainfall has decreased significantly during the period of 1975-2004 and have been pointed out by several researchers (e.g., Saghafian et al., 2006; Raziei et al., 2005; Rahimzadeh et al., 2002).

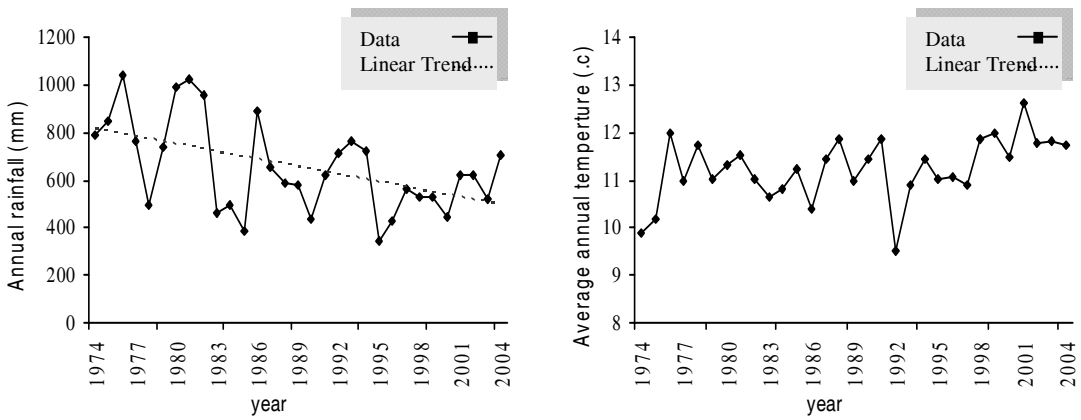

Figure 2 average regional rainfall and temperature with their linear trends.

Table 2 Mann–Kendall trend test results for mean annual discharge series

River	station	Latitude (N)	Longitude (E)	Record period	No. of years	Test Z	*p* value	Sen's slope
Karun	Armnad	31º 41´	50º 46´	1975-2004	30	-1.677	< 0.05	-0.63
Baazoft	Morghak	31º 39´	50º 28´	1975-2004	30	-0.535	n.s.	-0.13

n.s.: not statistically significant.
Positive Z values indicate increasing trend, negative values would indicate decreasing trend.

Table 2 shows the resulting of Mann–Kendall trend test for two annual streamflow time series. All test Z parameter indicate decreasing trends, but only significant at $p<0.05$ in Armand station. Also Sen's slope estimator represents the trend's true slope (change per unit time (i.e. one year)). Insignificant trend in Baazoft River can probably due to its short length records (30 years) and small area of its sub-basin (9986 km2). The seasonal Kendall test (Hirsch et al., 1982) was applied to monthly streamflow time series of Karun-4 basin and summarized in Table 3. The results show significant decreasing trends during low water months (August to November), especially in October. The shaded areas in Table 3 indicate different levels of statistical significance (99% to 90% levels with darkest to lightest gray), where algebraic signs (''+'' and ''_'') denote positive and negative trends respectively. For most months, the results of trend test are negative, consistent with the annual analysis (however not significant in high water months).
There were operated several dams and hydraulics structures in the Karun River basin, which can affect on natural flows and consequently unsettle our analysis. For example Kuhrang diversion channels (located on up-stream of Kuhrang River), convey high volume of annual flows to its main neighbor basin (ZayandehRUD River basin).

Table 3 Seasonal–Kendall test results for monthly mean streamflow time series

River	Station	Seasonal–Kendall test											
		Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Karun	Armand	1.36	0.86	0.32	0.61	0.68	0.82	1.18	2.71	3.14	3.18	2.14	1.18
		-	-	+	-	-	-	-	-	-	-	-	-
Baazoft	Morghak	0.07	0.09	0.05	0.37	0.41	1.02	1.05	0.66	1.95	1.98	0.27	0.48
		-	+	+	-	-	-	-	-	-	-	-	+

The shaded cells indicate different confidence levels, from 99% (darkest gray) to 90% (lightest gray) and white cells indicate not statistically significant results.

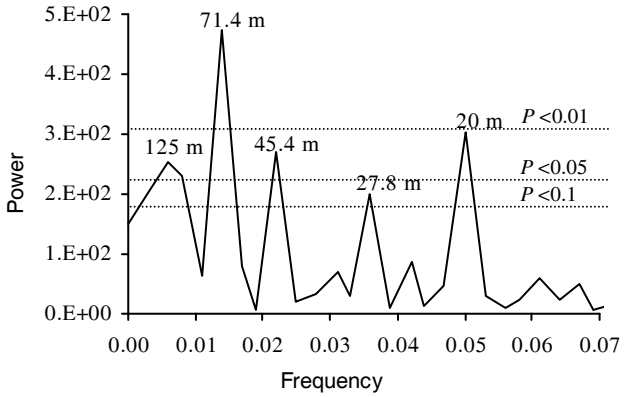

Figure 3 Fourier periodogram of averaged deseasonalized monthly streamflow.

This irregular transmission has produced uncertainties and doubts on accuracy of results. Moreover some factors can determine the variability of the tests results (e.g. increasing use of ground water supplies and deforestation).

4.2. Spectral analysis

During the recent years, many researchers have focused on connection between river discharge and ENSO for achieving better prediction systems (e.g. Tajrishi and Abrishamchi 2006, Labat et al. 2005, Ames 1998). Summarized results of these researches, show interannual oscillations in the range of 2-7 years, which apparently correspond to ENSO phenomenon (especially streamflow decreases during La Nin˜a (cold event of ENSO)). However there are some evidences of decadal and quasi-decadal fluctuations that have been linked to PDO (Barton and Ramirez, 2000). Spectral analysis was used to investigate the main periodicities in streamflow series. Fig.3 shows Fourier periodogram of deseasonalized monthly streamflow time series. Because of consistent behavior in the rivers, we have represented only one chart for whole region. Our Fourier spectral analysis shows 4 peaks (confidence levels > 90%) at interannual scale (6, 3.8, 2.3 and 1.7 years) and 1 peak at decadal scale (10.4 years). The power of spectrum is low because we have short length records.

Fig. 4 shows the Fourier periodogram of the 1975–2004 series of the SOI (Southern Oscillation Index) and PDO (Pacific Decadal Oscillation) index. It shows series of significant peaks that seem to be correlated with regional flows, especially at interannual scale. The results represent one important fact: that the ENSO is an effective driver in Karun River basin. Moreover, coherency spectral analysis of streamflow with SOI index shows good significant coherency at the interannual frequencies. For example, there were observed ENSO-related variation with 5.3, 3.5 and 2.5 years peaks.

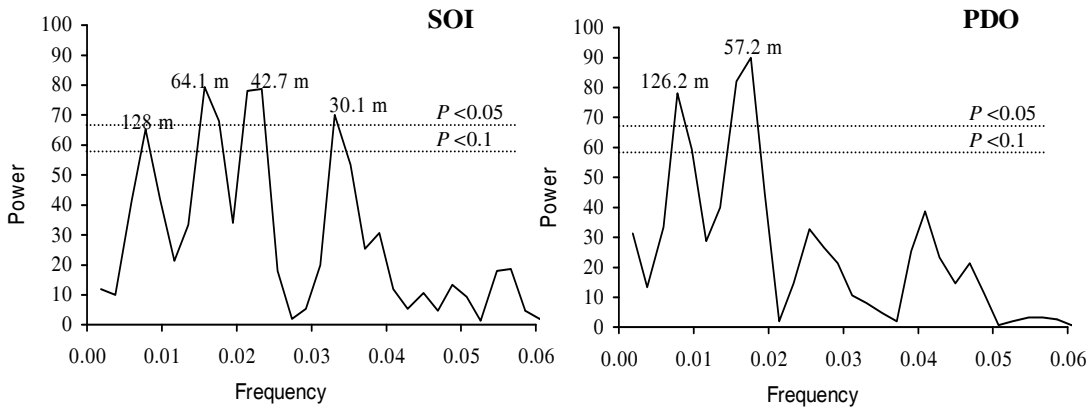

Figure 4 Fourier periodogram of the 1975–2004 series of SOI and PDO.

We have used wavelet spectral analysis to represent temporal variability of periodic signals on deseasonalized monthly streamflow time series. This method has been used for various studies, especially in hydrologic and atmospheric sciences. Torrence and Compo 1997 and Labat 2005 are considerable studies that focused on climatic index, specifically on SOI index. Labat 2005 showed low-intensity but statistically significant 6-y ENSOrelated interannual variability corresponding to the Pacific Coast Rivers in global asian rivers. Fig.5 shows Karun River 3-4 and 5-6 years interannual variability with maximum power peaks on 1991 (corresponds to the 95% statistical confidence level). Whereas Bazoft River shows weak 3-4 years but strong 2-3 years variability (restricted from 1991 to 1996). Such oscillations may be related to the already ENSO occurrences. It is also evident in Fig. 5, the decadal (and near decadal) signal that could be related to PDO phenomenon.

5. Conclusions

In this paper, appropriate analyses of streamflow variability are exposed. Both statistical and spectral analyses highlight existence of trends and oscillations in different state. Mann-Kendall and seasonal Kendall analyses showed downward direction of trends in general. However, negative flow trends vary in significance through the region. Karun River exhibits powerful and significant decreasing trend, especially during low water months (August to November). Such behavior is obvious in Bazoft River, although with low intensity. These negative trends (especially during summer and autumn) are probably corresponding to temperature increasing, specifically in snowmelt season (due to global warming).

Our spectral analysis has produced evidence of interannual variability (3-4 and 5-6 years), especially in Karun River. Connection between these impermanent variations

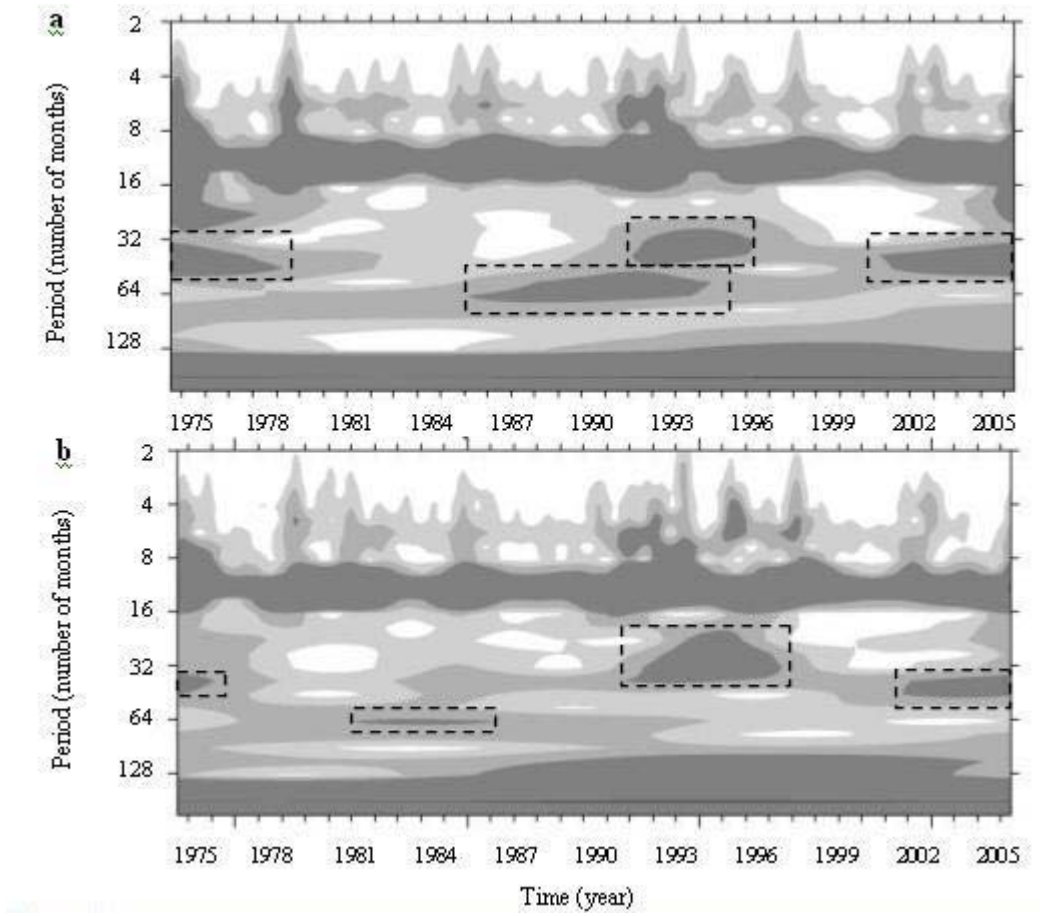

Figure 5 Wavelet spectrum of deseasonalized monthly streamflow time series at Armand (a) and Morghak (b) stations.

and ENSO is clearly discernible and useful for long-term fluctuations prediction in this arid region. Also we observed near decadal variability. However, the short length of the streamflow series can obscure such these results (quasi-decadal and decadal results).

Our results show that changes of the streamflow regime in this region were partly complex and need to be reanalyzed with inclusion of the influences of precipitation and temperature variables to be better understood. Therefore it will be plausible to investigate whether relations exist between trend and periodicity.

ABSTRACT

Impacts of 1 ft and 2ft sea level rise on Delta operations and salinity increases at export locations are quantified in this memo. California Department of Water Resources (DWR) uses many numerical models to study the Sacramento- San Joaquin Delta operations. Delta Simulation Model (DSM2) was used to calculate the salinity at some key locations in the Delta and to train Artificial Neural Networks (ANN) for each of the sea level rise scenarios. ANNs generated here are flow salinity relationships that calculate electrical conductivity (EC) at a given location using Delta boundary flows. CalSim II (Central Valley Project and State Water Project operation model) was used to determine the extra cost of water to mitigate the sea level rise. In this study current operation rules specified in State Water Resources Control Board's (SWRCB) Water Right Decision 1641 (D 1641) were assumed unchanged.

INTRODUCTION

Sacramento San Joaquin Delta

Sacramento-San Joaquin Delta (Delta) covers 738,000 acres interlaced with hundreds of mile of waterways. Much of the land is below sea level and relies on more than 1,000 miles of levees for protection against flooding. The Delta is unique and valuable resource and an integral part of California's water system. It receives runoff from 40 percent of the State's land area including Sacramento, San Joaquin and east side streams (DWR, 1987). Its land and waterways support communities, agriculture, and recreation and is the focal point for water distribution throughout the State.

The Sacramento-San Joaquin Delta is a tidal estuary. Water levels vary greatly during each tidal cycle, from less than foot near Sacramento to more than five feet at Martinez (down stream end of Figure 1). During the tidal cycle flows can vary in direction and amount. Tidal action and Delta outflow creates a gradual salinity gradient from the Pacific Ocean into the interior Delta.

Two major water export facilities are dependent on Delta waterways and the levees. Banks pumping plant provides water to the State Water Project (SWP) via the California Aqueduct while the Tracy (renamed Jones) pumping plant provides water to the Central Valley Project (CVP) via the Delta Mendota Canal. These water projects are operated under strict guide lines spelled out in D1641 (SWRCB, 2000). Upstream reservoir releases, Delta cross channel operation, amount of pumping are controlled to satisfy the standards in D1641.

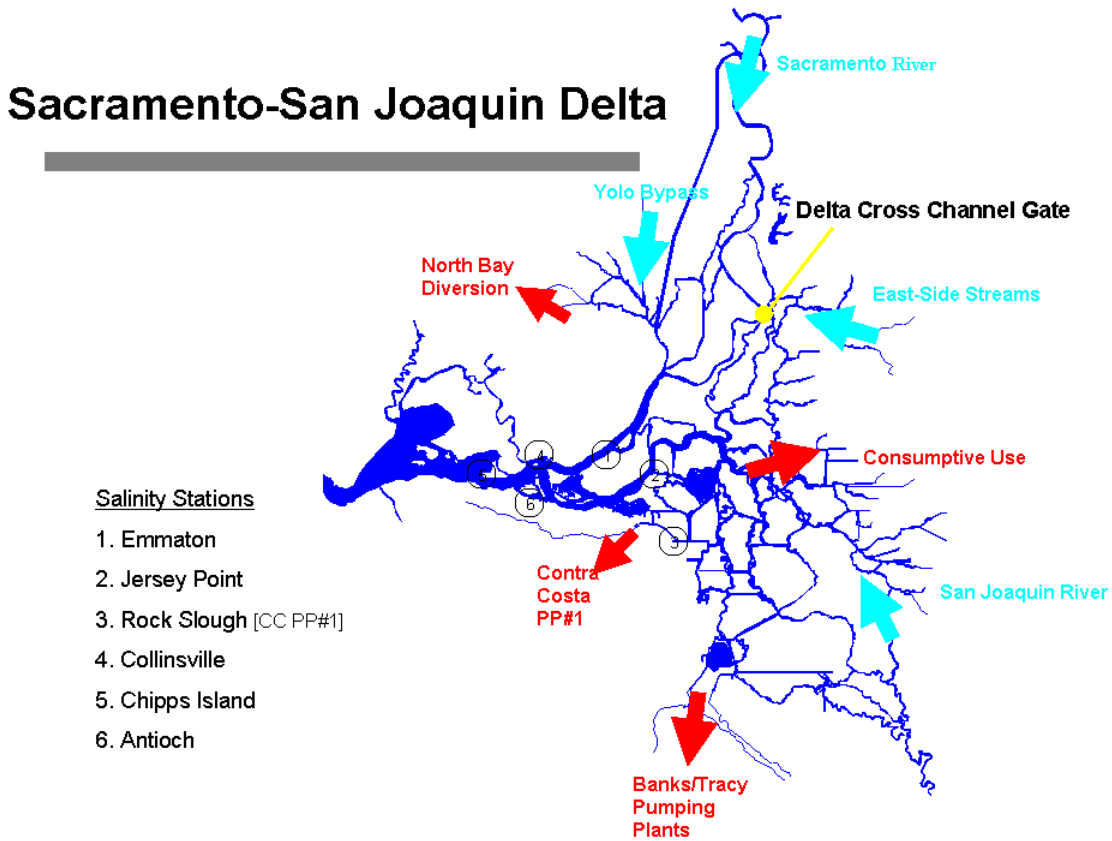

Figure 1: Locations where Delta salinity Standards are specified

Numerical Models

California Department of Water Resources (DWR) uses the following models for long term planning of SWP and CVP operations. Field data and outputs from many other models are used to derive inputs to these models.

Water Resources Integrated Modeling System (WRIMS), is a generalized water resources simulation model for evaluating alternatives in a Water Resources System. CalSim II is the application of WRIMS, and specifically used as a planning tool to simulate the State Water Project (SWP) and the Central Valley Project (CVP). CalSim II (DWR, 2002a) model has been applied to simulate the CVP and SWP systems at various levels of development, system configurations, and demand scenarios and operations rules. One such operation rule is the

salinity standards imposed at various locations in the Delta to protect the environment of the Delta. Currently the controlling locations in CalSim II are Rock Slough, Jersey Point, Emmaton, Collinsville, Chipps Island and Antioch. In addition to these 6 stations X2 (approximate location of 2000 parts per million total dissolved solids) locations are specified during certain months of the year. An 82 year simulation of CalSim II takes approximately 30 minutes.

Delta Simulation model (DWR, 2002b) is one dimensional hydro dynamics and water quality model. The model can calculate stages, flows, velocities; many mass transport processes, including salts, multiple non-conservative water quality constituents, temperature, and tracking of individual particles for given upstream flow boundary condition and downstream stage boundary. Conceptually DSM2 simulates flow conditions and concentration of water quality constituents (conservative and non-conservative mass) and tracks movements of individual particles in a network of channels. To simulate 1 year of salinity in the Delta, DSM2 takes about 1 hour of computing time in a 3.0 GHz windows XP machine. Therefore due to extensive computing time using DSM2 to calculate salinity at controlling locations in CalSim II would not be feasible.

Artificial Neural Networks (ANN) was used to develop flow salinity relationships (Sandhu et al., 1999) in the Delta enabling fast predictions of salinity at the controlling locations. ANN is considered a universal approximator and it is capable of theoretically modeling any continuous nonlinear function. With a proper network setup and training, an ANN can be reasonably accurate and robust on new data.

Sea Level Rise Estimates

Most mainstream scientists agree that global climate change causes an increase in temperature, thus an increase in global sea level rise. What is uncertain is the extent of the sea level rise at a given future time. Sea level rise increases the threat of salinity intrusion, floods, levee failure, coastal inundation and habitat changes.

Acceleration of global sea level changes has been observed in both tide gauge and satellite altimeter data. Ranges of future sea level changes have been projected by international climate change panel and several leading scientists. However, there have been no previous reports on designing probability curve for practical planning purposes.

Rising sea levels would enter the Delta though San Francisco Bay and would bring higher water levels and salinity concentrations. Water managers need methods for quantifying the increased salinity intrusion to develop strategies for protecting the Delta's future water quality and California's future water supply. The California Department of Water Resources (DWR) has developed a methodology for creating Artificial Neural Networks to estimate salinity intrusion for sea level rise scenarios. The ANNs can be incorporated into decision making tools to assess potential impacts of sea level rise on water project operations.

As shown in Figure 2 (Roos, 2004) sea level at the Golden Gate of California has been increasing by 0.08 inches per year over last century. If the historical rate of sea level rise were to

continue in the future additional 0.3 ft rises occur at mid century and 0.7 ft increase at the end of the 21st century.

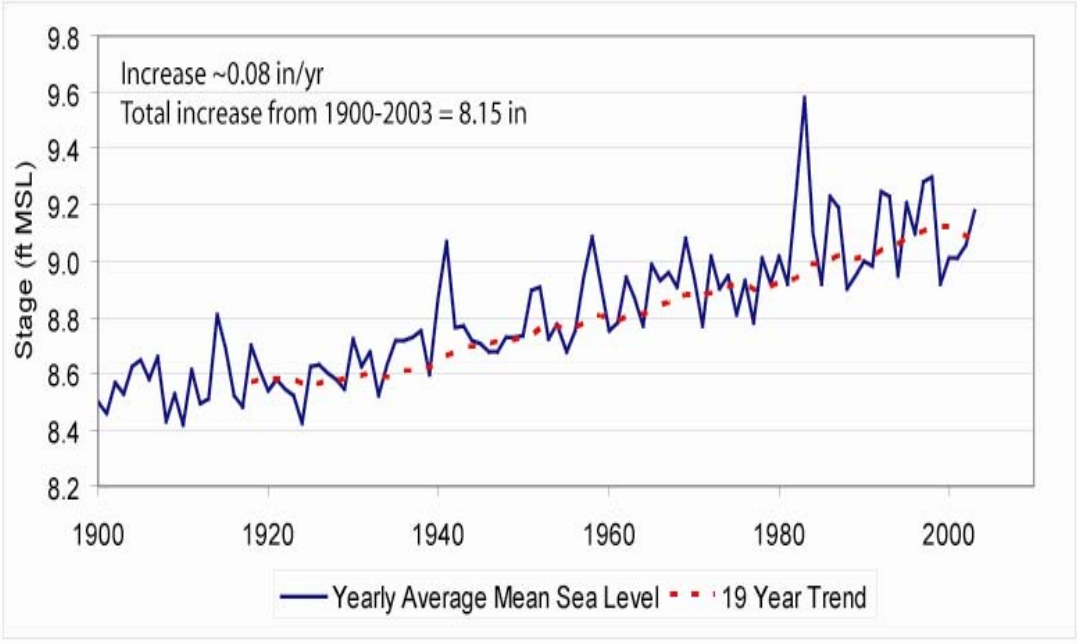

Figure3: Historical sea level at Golden Gate Bridge, San Francisco

The Third Assessment report of the Intergovernmental Panel on Climate Change (IPCC 2001) projected a global mean sea rise by 0.3 ft to 2.9 ft between 1990 and 2100 for the full range of greenhouse gas emissions described in IPCC Special Report on Emission Scenarios (IPCC SRES, 1996). The IPCC Fourth Assessment Report (IPCC 2007) projected a sea level increase from 0.6 ft to 1.93 ft for this century (2000 to 2100) depending on selected emission scenarios. Compared to the third assessment, the fourth assessment reduces the estimated projection of sea level rise by nearly 1 foot. CalFed Independent Science Board (Mount) using Rahmstorf's semi empirical approach predicted an increased uncertainty of projections in sea level rise. Figure 3 summarizes the sea level rise estimates from 3 different sources.

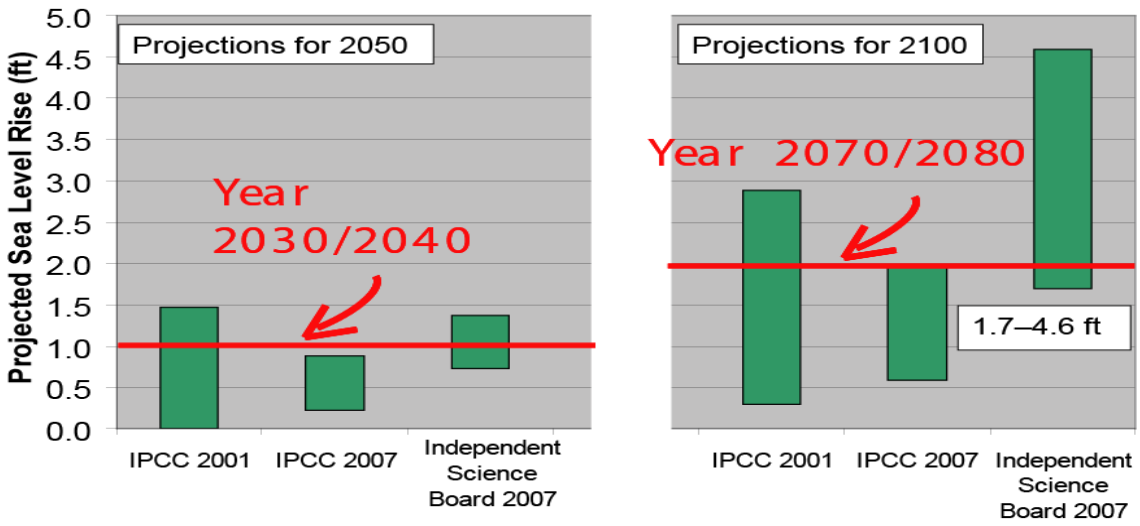

Figure 3: Mid and End of century sea level rise projections

MODELING

Delta Simulation Model assumes that Delta levees are high enough to prevent water overflowing the banks at peak sea level rise (two feet sea level rise). To prevent any tidal reflection from the upstream boundary both Sacramento river and the San Joaquin river were extend upstream by about 10 miles to gain an elevation increase of 3 feet.

DSM2 uses Martinez as its seaward boundary condition which is 54 km away from the ocean. At present for 16 year planning tide Martinez EC is calculated using a complex relationship between several EC stations and net Delta outflow. However with changes in sea level this relationship cannot be used to compute Martinez EC. A preliminary study was done to measure the sensitivity of salinity changes at export locations for different values of boundary (Martinez) salinity. Assuming zero sea level rise, Martinez salinity was increased by 2%, 5%, 7% and 9%. DSM2 model was used to model the salinity increase at the export locations.

DSM2 being a one dimensional model cannot handle vertical dispersion that arises due to sea level rise. Hence salt propagation into the Delta modeled by DSM2 is much less than salt propagation by multi dimensional models. Therefore in order to propagate salt in DSM2 tidal amplitude had to be artificially increased. A study for the Public Policy Institute of California report (PPIC, 2008) used a one dimensional tidally averaged model called WAM (water analysis module) developed by Resources Management Associates to explore the effects of 1 ft and 3 ft sea level rise. WAM uses dispersion algorithms developed from three dimensional modeling work (Gross et al, 2007). From the WAM studies (URS, 2007) it was found that Martinez EC for 1ft and 2ft is approximately 6% and 11% higher than the DSM2 base study. Jersey Point is considered the gateway for salt intrusion into interior Delta. Tidal amplitude was increased in DSM2 studies to match the percent increase of salt from WAM study outputs at Jersey Point. It was found that incorporating a 4" (9%) and 8" (18%) tidal increase propagated enough salt. In reality it is unclear whether the amplitude will change with the sea level rise. For the last century

San Francisco tidal amplitude increase by 2.5 inches while at Monterey the tidal amplitude reduced over 6 inches (Flick et al., 2003).

ANN tool in MATLAB was picked to develop flow salinity relationships mainly because of better graphics and plotting capabilities. Five different hydrologic scenarios were used in the training process. These 5 scenarios were picked to ensure that training data (calibration data) encompasses a wide range of hydrology. For the purpose of training ANN, 117 antecedent conditions were used with the following inputs. Inflows into the Delta from the north, Inflows from the south, channel depletions, exports, cross channel operation and tidal range. Each study was randomly perturbed with a maximum limit of ±30% to ensure that the training data captures extreme events. 80% of all results were used for training ANN and the remaining 20% were used as verification. The data used for training was randomly selected. Results obtained from ANN were compared with DSM2 results to ensure validity of using ANN in CalSim II (Seneviratne and Wu, 2007)

At present CalSim II uses Kimmerer-Monismith (KM) (Jassby et al., 1995) equations to calculate X2 locations in the Delta for a given Delta outflow. The empirical formula developed by KM used real time data. This equation ceases to be valid when down stream boundary elevation (mean sea level) is different from historical conditions. DSM2 model was used to develop new ANNs for X2 for the base case and different sea level scenarios and these were implemented in CalSim II. CalSim II model had to be restructured to accommodate this feature.

RESULTS

ANN development

ANN predicted salinity and DSM2 generated Salinity were compared at salinity controlled stations. Figure 4 shows a very good comparison between ANN and DSM2 at Jersey Point for the base case. All control stations had a similar good fit between ANN and DSM2.

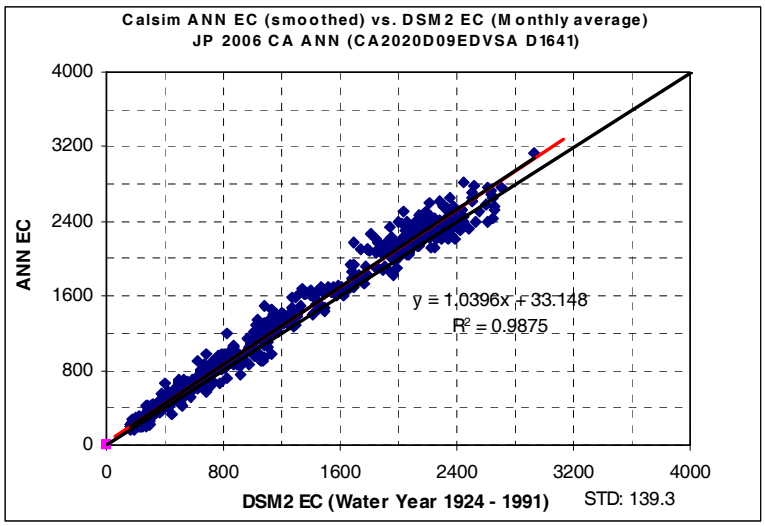

Figure 4: Comparison between DSM2 and ANN predicted salinity.

Sensitivity Analysis of Boundary salinity

Table 1 shows the average monthly sensitivity of Martinez EC at some key export locations in the Delta. The table below shows the increase in EC at Banks and Jones (Tracy) export locations purely due to a hypothetical increase in EC at Martinez. For the six month period between February and July the impact due to an increase in Martinez EC is negligible. This is because during this period high Delta outflows tend to push the ocean salt away from the Delta. For the period between August to January the Delta outflow is at its lowest. Even during this period the salinity impact at the pumping locations are not highly sensitive to changes in the boundary EC.

Table 1: Sensitivity Analysis of Boundary salinity.

Martinez	SWP Intake		CVP Intake	
(EC increase)	(Aug-Jan)	(Feb-July)	(Aug-Jan)	(Feb-July)
2%	0.75%	0.19%	0.64%	0.16%
5%	1.88%	0.47%	1.60%	0.41%
7%	2.63%	0.66%	2.23%	0.57%
9%	3.38%	0.85%	2.87%	0.73%

Salinity Increase due to Sea level Rise

Without changing any operations (Inflows to Delta, Exports and Delta Cross Channel operation) DSM2 studies were conducted for base case (zero sea level rise), 1ft and 2ft sea level rise scenarios. The following table shows a summary of EC impacts at SWP and CVP export locations in the Delta for the 2 different sea level rise scenarios.

Table 2: Sensitivity Analysis of Boundary salinity.

Alternatives	CCFB Intake		CVP Intake	
	(Aug-Jan)	(Feb-July)	(Aug-Jan)	(Feb-July)
1 ft Mean sea level rise	23%	8%	20%	7%
2 ft Mean sea level rise	53%	20%	45%	16%

As discussed before for periods of high Delta outflow (February through July) the increase in salinity is lower than for low outflow periods (August through January). Impacts at CVP intake is a little less than the SWP intake because the CVP intake is further away from the ocean influence.

Reduction in Exports

CalSim II model was run for a period of 82 years. The following tables show the reduction in the ability to deliver water due to sea level rise scenarios for three significantly important periods, long term average (1921-1994), long term drought periods (1928-1934 and 1986-1992) and the most severe drought (1976-1977).

Table 3: Reduction in Exports due to 1ft sea level rise.

	Exports		
Periods	Base	change	%change
1928-1934	3553	-117	-3.3%
1976-1977	3598	-59	-1.6%
1986-1992	3941	-305	-7.7%
1922-1993	5939	-130	-2.2%

Table 4: Reduction in Exports due to 2ft sea level rise.

	Exports		
Periods	Base	change	%change
1928-1934	3553	-489	-13.8%
1976-1977	3598	-341	-9.5%
1986-1992	3941	-647	-16.42%
1922-1993	5939	-472	-7.9%

CONCLUSIONS

a) Successful ANNs were developed for all salinity controlled stations in the Delta for base case and the 2 sea level rise scenarios.
b) Sensitivity of salinity at export locations due to changes in Martinez salinity is low. Hence for the existing Delta boundary conditions any error in computing the Martinez boundary EC becomes insignificant. This is especially so during the period February – July when Delta outflow is high. For the period between August-January where ocean salt tends to dominate the estuary rather minimal impact is observed due changes in Martinez salinity.
c) For sea level rise scenarios the water quality at export locations increase approximately 50% during certain periods of the year. This will increase the treatment cost for the end user to meet the drinking water standards. In addition to lower water quality the amount of water that can be delivered is reduced significantly during drought years. For example for 2ft sea level rise, the ability to export due to sea level rise dropped by 16% during the recent prolonged dry years.

ABSTRACT

Computer aided dispute resolution (also known as collaborative modeling or shared vision planning) combines technical analysis and modeling with collaboration and traditional planning principles in order to address complexity, manage conflict, promote learning and understanding, and build relationships among stakeholders. The participatory process enhances model credibility, while the model supports the decision-making process and promotes group learning. Computer aided dispute resolution is a relatively new field, and current practitioners generally have a unique mix of technical and process skills that enable them to conduct this groundbreaking work. To train the next generation of practitioners and to ensure high quality work, we must identify and communicate the necessary skills and practices that support successful processes. With this objective, in the fall of 2008, the Environmental and Water Resources Planning and Management Committee established a task committee to formulate and document best practices in this developing field. The task committee will deliberate and advise which elements of the case study context, team member skills, process design elements, and modeling approaches are critical for incorporating computer aided dispute resolution into water resources planning and management successfully. The products of this task committee will include a written monograph, dissemination of results at conferences, and an evaluation of next steps. In this presentation, we will share progress to date and invite audience feedback and participation.

INTRODUCTION

In a recent editorial in the Journal of Water Resources Planning and Management, Werick and Palmer called for a new Standards of Practice in Water Resources Planning, stating that "now is an excellent time to assemble the emerging approaches that have universal appeal to planners and that can be applied to a broad range of problems." They also note that they "are not alone in the belief that water planners should publish best practices" (Werick and Palmer, 2008). The Environment and Water Resources Institute (EWRI) has established a Best Practices in Collaborative Modeling task committee to produce a manuscript that will help meet this need regarding the use of computer aided

dispute resolution (CADRe) in water resources planning and management for the next generation of practitioners.

CADRe is a relatively new field, and current practitioners generally have a unique mix of technical and process skills that enable them to conduct this groundbreaking work. To train the next generation of practitioners and to ensure high quality work, we must identify and communicate the necessary skills and practices that support successful processes.

CADRe DEFINED

Computer Aided Dispute Resolution (CADRe) is a general title for the methodology used by a number of agencies, university researchers and private consultants who have been marrying technical decision support tools with collaborative processes. In CADRe, the technical tools are collaboratively developed by actively engaged stakeholders, so that all parties are aware of and in agreement about the system characterization and data used to support it. The approach addresses complexity, manages conflict, promotes learning and understanding, and builds relationships among stakeholders. The participatory process enhances model credibility and helps ensure that the full breadth of stakeholder concerns are reflected, while the model supports the decision-making process and promotes group learning. Consensus is not the single goal of the process; however, CADRe may increase the chance of identifying win-win alternatives.

CADRe IN USE

CADRe traces its roots to water supply planning for the Washington DC region in the mid-1970s. CADRe has been applied to the full spectrum of stages in the planning process. A recent collection of case studies (Stephenson, Shabman, et al., 2008) shows CADRe being used in situations as varied as anticipatory processes intended to lay the groundwork for future exercises, to examination of alternatives for changing dam operations. CADRe is being utilized within both the public and private sector. For example, the Corps of Engineers' path in developing CADRe began with Drought Preparedness Studies in the early 1990's, which evolved into Shared Vision Planning: a process that uses traditional Corps planning principles but modified to include earlier and more intensive collaboration with a wide variety of stakeholders. Sandia National Laboratories has also developed models through collaborative processes to support watershed planning. In recent years, the U.S. Institute for Environmental Conflict Resolution, which supports Alternative Dispute Resolution, is exploring and fostering the use of technical tools to support their collaborative processes. CADRe has also been employed by private firms to solve complex water resources issues. Its growing use by a variety of practitioners creates an expanding body of expertise and knowledge.

CHALLENGES TO FUTURE AND IMPROVED USE

Although CADRe has been used successfully in numerous projects, challenges exist to increasing and improving future use. Perhaps first and foremost is awareness.

Computer modeling provides a common basis for decision-making, but the deliberate early and continuing integration of public participation with computer modeling is not widely used, and the potential benefits of this deliberate integration are not always readily apparent. Furthermore, terminology and practice can be confusing or misleading. There is a wide spectrum of public involvement, ranging from broad-based early and ongoing collaboration to more limited back-end information sharing with an opportunity to submit comment. There is also a wide spectrum in the adaptability of computer models or systems of computer models, ranging from the application of standard single-purpose models with pre-determined input and output to relational models (or suites of linked models) capable of being adjusted to incorporate new input, new relationships, and new ways of displaying output. CADRe strives for early and iterative collaboration with key stakeholders using adaptable computer models. So while some may say that they use computer aided dispute resolution, and may in fact both involve the public and use computer models, the degree to which the two facets are integrated may be limited, possibly with consequent limits in potential benefits (see Figure 1.)

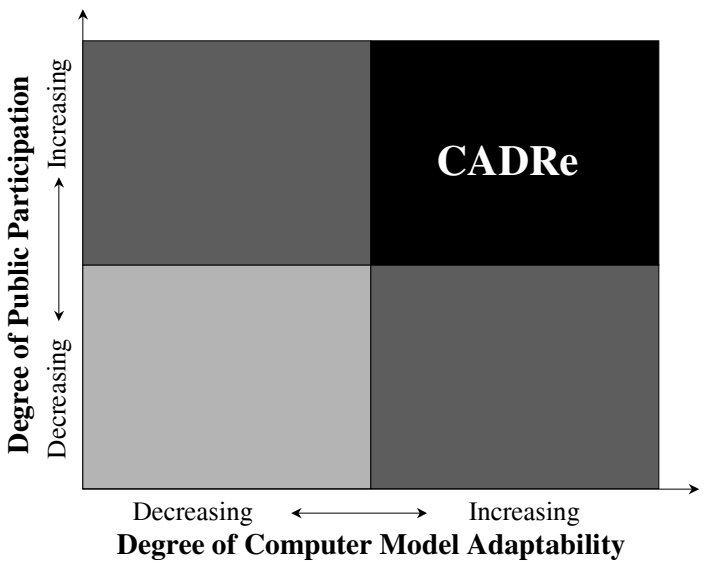

Figure 1. Integration in CADRe

The unique skill sets required to implement CADRe pose a second challenge to its further use and improvement. Computer modelers abound, but more are comfortable with applying existing models than with changing the models themselves, and fewer still have skills so important to involving the public: listening skills, the ability to communicate effectively with both technical and non-technical partners, and an understanding of how the process itself can support successful participation. Professional facilitators are trained in these important skills but may lack access either to appropriate technical tools, or to those with the expertise to adjust models in response to changing expectations and understanding. Opportunities to learn the full suite of needed skills, or to connect experts that in partnership encompass effectively the full suite of needed skills, have to date been limited.

Uncertainty regarding CADRe processes and their outcomes can also pose challenges to its further use and improvement. Modelers may wonder why they should consider adjustments to models they may have used for years, or may question how participation by non-technical partners might improve technical models. Organizations may raise concerns about the time needed up-front to understand various participants' concerns and how that time fits with their more standard processes and expectations. They may worry that including unaccustomed partners, particularly early in the process but also throughout, may lead to some loss of control. There may be comfort with historical approaches, uncertainty regarding what the results may be if change is instituted, and questions as to whether the risk inherent in those changes is worth undertaking them. While many case studies exist, and some have been documented, there is limited systematic documentation of what works, what doesn't, and what it all means.

EWRI TASK COMMITTEE ON CADRe BEST PRACTICES

A Task Committee under the Environment and Water Resources Institute (EWRI) of the American Society of Civil Engineers is an ideal vehicle for helping overcome the challenges to further CADRe use and improvement in water resources planning. EWRI's vision includes the integration of technical expertise and public policy for planning related to water resources, and it is committed to accomplishing this vision through a diverse membership, excellence in products and services, collaborative partnerships, and innovative programs and solutions. Its 22,000-strong membership encompasses its foundation within its traditional civil engineering base, but also includes non-civil engineer allied professionals. And EWRI's committee structure provides a way to establish an interested team of professionals and to give that team some organizational support so that it can help advance and serve the profession through such means as publications, reports, conferences, and continuing education seminars.

Goals and Products. Seeking to share the lessons learned by CADRe practitioners, increase awareness, and raise the bar for CADRe's further use, a group formed an EWRI Task Committee in the fall of 2008 entitled "Best Practices for Collaborative Modeling." The Task Committee, housed under the Environmental and Water Resources Planning and Management Committee, will focus on developing best practices for incorporating computer aided dispute resolution processes into participatory water resource planning, documenting the results, and summarizing key findings. Its efforts can yield increased level of detail over what is now available, provide guidance on when and how to use computer aided dispute resolution processes, and offer ways to evaluate the success of participatory processes in water resources planning. Work by the Task Committee will take note of cutting-edge efforts now underway by the U.S. Army Corps of Engineers' Institute for Water Resources to develop means to evaluate the success of CADRe processes.

The Task Committee's primary product will be a monograph that documents and summarizes key findings, with anticipated completion in 2010. The monograph will help address the need for systematic documentation of high-caliber CADRe practices and their

evaluation. Dissemination of the monograph will increase awareness of CADRe process goals and benefits, and will help ensure high quality work as the relatively new field develops and matures. The Task Committee will also seek to disseminate information in other ways as appropriate and feasible, such as at conferences. At the conclusion of its work, the Task Committee will evaluate what further steps may be appropriate.

Next Steps. Reaching out to partners and practitioners is important for ensuring a high quality product. The Task Committee continues to welcome new members interested in participating. Possible contributions range from providing references, to writing a short case study that illustrates a "best practice," to presenting Task Committee results.

The Task Committee has established a core group of anticipated monograph authors, and has begun to frame a conceptual monograph outline, to be discussed by contributors. We anticipate later identifying a select group to review the draft monograph.

CONCLUSION

The EWRI Task Committee on Best Practices for Collaborative Modeling provides a valuable role in furthering the use of CADRe in water resources planning. The Task Committee is in its early stages and welcomes feedback on its plans, additional information from CADRe practitioners regarding best practices, and participation by those interested in helping to advance this developing field.

ABSTRACT

The deterioration of pipes in water distribution systems is a serious problem for water utilities. In order to rehabilitate the deteriorated pipes in a planned and proactive way, there is a need to have a better understanding of pipe condition assessment.

Pipe condition assessment can be regarded as a multiple criteria decision making problem. A new model for pipe condition assessment is developed using fuzzy PROMETHEE II. The model processes four first-level and seven second-level pipe condition indicators and then generates a pipe condition index for each pipe in the system. The weight for each indicator is generated by using Analytic Hierarchy Process (AHP).

The paper presents the application of the new method to some pipes in a water distribution system. This application demonstrates both the stability of the new method and its ability to generate results that will greatly assist decision makers in the development of their rehabilitation strategies.

KEY WORDS:

Pipe condition assessment; Multi-criteria decision making; PROMETHEE; Water distribution system

INTRODUCTION

Pipe breakage is caused by numerous human and natural factors. Proactive rehabilitation and replacement is an effective way to avoid excessive financial losses.

Budgetary constraints make prioritizing pipe rehabilitation and/or replacement essential. An important component of the prioritization process is pipe condition

assessment that should be based on available and reliable data.

Pipe condition assessment models can be generally classified into three categories: physical based models, statistic based models and data mining models (Kleiner and Rajani 2001).

Physical based models usually involve several main influence factors of pipe deterioration, and their limitation is the requirement of extensive data and a detailed understanding of the various deterioration mechanisms. Statistical models also rely on an abundance of data but have more adaptability. Data mining models utilize both objective data and also experts' experience. For example, Yan and Vairavamoorthy (2003), applied the Fuzzy Compromise Programming techniques for pipe condition assessment, where the most important influence factors were identified and combined through a hierarchical process. Geldermann et al. (2000) proposed the use of a fuzzy algebra throughout PROMETHEE algorithm, which is flexible.

Pipe condition assessment involves several components such as breakage rate, water loss, water quality deterioration in distribution system etc. Pipe breakage rate is one of the main indicators to reflect pipe condition and also influence several other aspects. Therefore, pipe breakage risk (possibility of pipe breakage in the future), can be considered as a useful surrogate of pipe condition.

In this paper a new techniques for pipe condition assessment is proposed. The method is based on PROMETHEE, an outranking method, which brings together flexibility and simplicity for user. It includes two phases: the first one is the construction of an outranking relation on a criterion/indictor, and the second one is the exploitation of this relation in order to give a rank to each pipe.(Brans and Vincke 1985; Brans, Vincke et al. 1986),

In the first phase, a preference function is defined and a valued outranking graph, representing the preference of the decision maker, is obtained.

The exploitation of the outranking relation is realized by considering for each pipe a multi-criteria preference index (in terms of a leaving and an entering flow) in the valued outranking graph.

The main requirement of PROMETHEE is the weight and preference function of each criterion (Figueira, Greco et al. 2005). The proposed method falls into the category of data mining models. Compared with pervious data mining models, the model in this paper has several improvements. It places greater emphasis on the data that can be expected to be available. Another one is that only a few parameters are to be fixed in this method and they all have a pipe breakage signification so that expert is able to determine their values easily. Furthermore, the stability analysis at the end of this paper shows that some small deviations in the determination of weights do not often induce important modifications of the obtained rankings.

In this paper the PROMETHHEE method is first described and then demonstrated by means of a simple application.

MODEL ESTABLISHMENT AND SOLUTION

Influence factors. Numerous factors influence pipe breakage, e.g. ground load, pipe material, soil corrosion, pipe age, construction quality, pipe length, soil condition, breakage history, etc. Generally, the data available from water utilities include pipe diameter, pipe age, pipe material, length, and record of rehabilitation, and incident repair records (Boxall, O'Hagan et al. 2007). Data requirement of this model mainly rely on the generally available data from water utilities.

Structure of the model. The structure of the proposed model is shown in Figure 1.

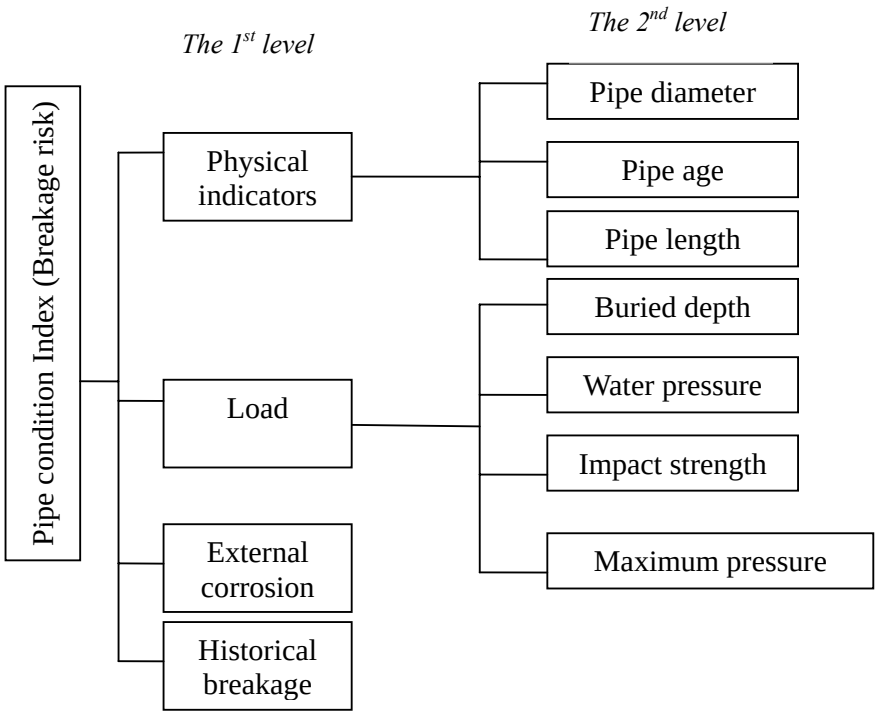

Figure 1 Structure of pipe breakage risk assessment model

As shown in Figure 1, two of the first level indicators (load and physical indicators), are aggregated indicators (from the 2nd level). Most of the 2nd level indicators used to generate these 1st level indicators can be obtained from water utilities. In addition, the 1st level indicator, historical breakage data can also be obtained from the water utility.

The external corrosion indicator is determined by a combination of soil corrosion and pipe material corrosion resistance(Vairavamoorthy, Sunil D. Gorantiwar et al. 2006). This method involves normalizing the score of soil corrosion and material resistance and then combining to generate an external corrosion indicator (that is then further normalized).

It should be noted that high values in the indictors: pipe age; buried depth; water pressure; external corrosion; and historical breakage rate; all suggest a higher

breakage risk for a pipe. These indicators are termed high risk indicators for the purpose of this paper. In contrast, the remaining indicators suggest a lower breakage risk (termed low risk indicators in this paper).

Weight for each indicator. The weights associated with different indicators reflect their relative importance to other indicators.

In the proposed method, the weights for the indicators are generated using Analytic Hierarchy Process (AHP). The foundation of this subjective weight method is experts' experience and opinion. As this is subjective, the weights can be regarded as fuzzy numbers that are distributed randomly in the neighborhood around the mean value of weights. The uncertainties associated with these weights are described later on in the paper.

Preference function. A key aspect of the PROMETHEE method is the preference function that is defined for each indicator. This function is used to compute the degree of preference associated to the high breakage risk in case of the pair-wise comparisons. It is often a function of the difference between two pipes. Brans and Vincke (1985) put forwards six basic types of PROMETHEE preference functions. In this research, the type and parameters of the functions are usually obtained from expert according to the specified indicator's influence to pipe breakage.

The linear preference function is continuous and easy to understand. Hence this type of preference function is used in this model. The function expression is as follow:

$$p(d) = \begin{cases} 0 & (d \le 0) \\ d & (d > 0)) \end{cases} \tag{1}$$

Where, d is two pipe's normalized difference in a specific criterion, $|d| \le 1$.

Calculation steps.

Let's consider the multi-criteria problem: ranking all pipe condition assessment with the finite set of pipes K, if there are k criteria f_i, ($i=1,2, \ldots,k$).

The basic steps of PROMETHEE are as follows:

1. Normalization

In order to compare and calculate, data must be first normalized before inputting into the RPOMOTHEE model.

For the high risk indicators the normalization formula is as follows:

$$y_{ij} = \frac{x_{ij} - x_{i\min}}{x_{i\max} - x_{i\min}} \tag{2}$$

For low risk indicators the normalization formula is as follows:

$$y_{ij} = \frac{x_{ij} - x_{i\max}}{x_{i\min} - x_{i\max}} \tag{3}$$

where, y is the normalized value, i, j is the ID of criteria and pipe; x_{ij} is the *j-th* pipe's

data in the *i-th* criteria/indicator; x_{imax} and x_{imin} is the maximum and minimum value in the *i-th* criterion.

2. Calculate multi-criteria preference index $\pi\ (a, b)$

Suppose that experts have specified a preference function p_i and weight w_i for each criterion f_i *(i=1, 2,…, k)*. The multi-criteria preference index $\pi\ (a, b)$ is defined as weighted average of the preference function $p_i\ (a, b)$:

$$\pi(a,b) = \frac{\sum_{i=1}^{k}(w_i \cdot p_i(a,b))}{\sum_{i=1}^{k} w_i} \tag{4}$$

$\pi\ (a, b)$ represents the experts preference intensity that Pipe *a* over Pipe *b*, when considering simultaneously all the criteria. It is a figure between 0 and 1 and:

If $\pi\ (a, b) \approx 0$, denote a weak preference of *a* over *b* for all the criteria.

If $\pi\ (a, b) \approx 1$, denote a strong preference of *a* over *b* for all the criteria.

These weights are fuzzy and are generated using the AHP (as mentioned earlier). Preference function $p_i\ (a, b)$ are obtained through expert's experience and knowledge. In this research,

$$p_i(a,b) = p_i(f_i(a) - f_i(b)) = \begin{cases} 0 & (f_i(a) \le f_i(b)) \\ f_i(a) - f_i(b) & (f_i(a) > f_i(b)) \end{cases} \tag{5}$$

where, $f_i(a)$ and $f_i(b)$ are the degree of preference for the comparison of pipes *a* and *b* in the *i-th* criterion respectively.

This preference index determines a valued outranking relation on the set *K* of pipes. This relation can be represented as a *valued outranking graph*, the nodes of which are the pipes of *K* (see Figure 2). Between two pipes (nodes in Figure 2), *a* and *b*, there are two arcs having values $\pi(a, b)$ and $\pi(b, a)$ (there is no particular relation between $\pi(a, b)$ and $\pi(b, a)$).

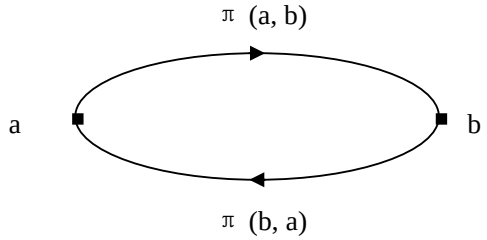

Figure 2 Flows in the valued outranking graph

3. Calculate net flow $\phi^{net}(a)$

For the node *a* in the valued outranking graph, the *leaving flow* can be defined as

$$\phi^{+}(a) = \sum_{b \in K} \pi(a,b) \tag{6}$$

The leaving flow is the sum of the values of the arcs leaving node *a* and provides a measure of the outranking character of *a*.

Similarly, the entering flow can be defined by:

$$\phi^{-}(a) = \sum_{b \in K} \pi(b,a) \tag{7}$$

The entering flow measures the outranked character of *a*.

Then the *net flow* of pipe *a* is as follow:

$$\phi^{net}(a) = \phi^{+}(a) - \phi^{-}(a) \tag{8}$$

Basically, the higher the leaving flow and the lower the entering flow, the higher breakage risks this pipe.

4. Rank all the pipe condition

The last step is to sort the order of each pipe's net flow by a complete preorder:

a outranks *b* , if $\phi^{net}(a) > \phi^{net}(b)$;

a is indifferent to *b* , if $\phi^{net}(a) = \phi^{net}(b)$

Stability of model. Because this model involves weights, whose influence to the ranking under minor changes always concerned by decision makers. Therefore, the model stability analysis is very important(Brans, Vincke et al. 1986). In this research, model stability analysis is needed due to weights from subjective uncertainty. Moderate stabilization is necessary for a good model. An unstable model's conclusion will change greatly due to some parameters' minor variations. Some random changes in a small interval will be applied for weights to simulate expert opinion's uncertainty. Then the variation's effect will be tested.

APPLICATION OF THE MODEL

The model has been applied to a sample of eight pipes, of four materials, with diameters varying from 200 to 900 mm. Table 1 shows the 10 indicators for each of the 8 pipes in the sample.

The value of parameters. The mean values of criterions' weights are generated using the AHP and are shown in Table 2, 3 and 4. As described in previous section, a liner preference function (Equation (5)) is used and the results of applying the PROMTHEE II are given in Table 5.

From the results shown in Table 5, it is clear that the net flow of Pipe 3 is the highest. This suggests that Pipe 3 has the highest breakage risk in this sample. Similarly, Pipe 6 has the lowest breakage risk. One of the main benefits associated with the calculated net flows, is that they indicate the sensitivity of the rank order of pipes in

relation to pipe breakage risks. This sensitivity can be analyzed by considering the interval size of net flow between adjacently ranked pipes. Where this interval is large, this indicates that a pipe's ranking position will not be affected by changes in the weights used (and where intervals are small then the rankings will be affected).

For example, in Table 5, the difference of net flow between Pipe 3 and 4 is 0.022, which is the smallest. And the difference of net flow between Pipe 6 and 8 is 0.082, which is the secondly smallest. This implies that these pipes' rank is easy to be affected by weights because the net flow is very close to that of its adjacent rank pipes.

To demonstrate the sensitivity of the rank order to changes in weights, and to highlight the role that the net flow can play in predicting changes in rank order, several applications of the PROMTHEE method were undertaken where the weights were varied between ±30% of mean value of weights.

The test calculation repeated numerous times. Table 6 shows the calculation results in five tests. If the result in Table 5 is a benchmark, Pipe 3 and 4 exchanges position three times, and Pipe 6 and 8 exchanges position twice. For most of the other pipes, their rank in this pipe set is stable because their net flows have a greater difference with other pipes. If more test calculations are taken, these two pairs of pipes often exchange their rank positions while others seldom do. These results agree with the previous analysis.

This example proves that the pipes with close net flow of other pipes are sensitive to the change of weights. It is difficult to make a fixed rank of pipe condition with close net flows. The general rank for all the pipes will not be greatly affected by the weight's variation. So the model has good stability though weights change within a small variation.

On the other aspect, in order to examine the validity of the model, test calculation of changing some variables' value (e.g. historical breakage rate) sometimes result the change of the pipe's rank of position. If such test calculation is done one indicator by one indicator, the results show that all the variables changing tendencies agree with that of general experience. For example, according to experience and statistic analysis, pipe condition is good if historical breakage rate is low and without any changes in other variables. If the breakage rate in Pipe 1 change from 0.329 to 0.20, its rank of position also change from 6 to 4. This denotes that this pipe's breakage risk decrease, which agree with general experience.

Table 1 Input data

No.	Criterion	Pipe ID							
		1	2	3	4	5	6	7	8
1	Pipe material	DI	DI	CI	CI	PVC	PVC	AC	AC
2	Diameter（mm）	500	700	900	600	300	200	400	500
3	Pipe age（year）	17	20	34	29	10	8	30	25
4	Pipe length (m)	530	565	698	974	1733	1509	1097	1462
5	Buried depth （m）	1.01	1.00	2.01	1.18	1.00	0.54	2.37	1.61

The rank in the 5th test	6	4	7	8	3	2	5	1

CONCLUSION

In this paper, the new method, fuzzy PROMETHEE II is proposed for the problem of pipe condition assessment. The method calculates pipe breakage risk to reflect the condition assessment. The proposed model is different from previous model in that it only requires usually available data, and that it gives an insight into expert opinion's uncertainty and preference that has a pipe breakage signification in each criterion. By including these components into the condition assessment process, we are able to achieve better understand. This is the improvement of previous method as they failed to account for these uncertainty and preference.

In PROMETHEE method, there are only a few parameters to be determined in each criterion (e.g. one parameter if linear preference function is applied). And these parameters all have a pipe breakage signification so that experts are able to determine their values easily.

An interesting aspect of the proposed method is the net flow values generated. This net flow reflects each pipe's relative condition. The utility of net flow is that it provides a strong indication of sensitivity of pipe rank position in relation to the subjective weights which are obtained from experts' opinion. The benefit of net flow is that two adjacent ranking pipes with larger difference of net flow are not so affected by these weights.

Development of Regression Models to Estimate Flow Duration Statistics at Ungaged Streams in Oklahoma Using a Regional Approach

Rachel A. Esralew, US Geological Survey Oklahoma Water Science Center, Oklahoma City, Oklahoma; email: resralew@usgs.gov Tel. 405-810-4425

Abstract

Multiple-regression analysis was used to develop equations for estimating annual and seasonal flow-duration statistics at ungaged streams in and near Oklahoma that are not substantially affected by human alteration. Ordinary least-squares and left-censored (Tobit) multiple-regression techniques were used to develop equations that relate these statistics, from continuous streamflow data at gaged locations with 10 or more years of record, to physical and climatic basin characteristics. Separate equations were developed to estimate these statistics for stations within similar hydrologic and geologic regions. Use of separate regressions by region substantially improved the accuracy of the estimate for streams in eastern and central Oklahoma when compared with estimating equations developed for the entire State, especially for regressions estimating lower flow duration values. For all regions, the equations were more reliable for estimating higher flow duration values. The accuracy of regressions for estimating flow duration statistics in western Oklahoma was very poor, especially for lower flow duration values.

Introduction

Effective planning in water resources management requires knowledge of streamflow conditions on streams which are to be regulated for water-supply permitting, water-quality regulation, and other water-rights issues. Successful management of reservoir operations, permitting for stream withdrawals, and maintenance of water quality standards is supported by knowledge of the magnitude of flow that can be expected in a stream at any given time. Flow duration statistics, which describe the percentage of time a stream discharge value is equaled or exceededare commonly used by the Oklahoma Water Resources Board (OWRB) as a guideline for making informed decisions regarding water resources planning and management.

The long-term historical continuous daily streamflow information collected at streamflow gaging stations by the U.S. Geological Survey provides a valuable resource for estimating streamflow values that are expected to be equaled or exceeded for a given percentage of time under a range of temporal conditions, including annual and seasonal time periods. However, most streams in Oklahoma are ungaged.

Because of the need for flow duration statistics at ungaged stations that describe annual and seasonal flow conditions, the USGS, in cooperation with the OWRB began a study to develop techniques for estimating long-term streamflow statistics at ungaged locations based on data from gaged locations. The OWRB had identified several statistics that are effective in water resources planning, including developing estimates of daily mean discharge at ungaged locations that are exceeded 20, 50, 80, 90, and 95% of the time (referred to as the Q20, Q50, Q80, Q90, and Q95, respectively) on an annual and seasonal basis.

Statistics calculated at streamflow gaging stations with long-term daily mean streamflow record are highly variable among stream locations, but are strongly related to physical characteristics of the drainage basin such as size, topography, geology, land-use and climate. Statistical models that describe these relations for gaging stations can be developed in order to estimate streamflow statistics, including annual and seasonal flow duration values, at ungaged locations that are not in close proximity to gaged stream locations. Regression estimates of these statistics at ungaged locations using easily obtainable physical basin characteristics provide a low cost and efficient means for assessing flow conditions at ungaged locations when obtaining

direct or nearby flow measurements or developing site-specific digital models is too costly or infeasible.

One of the challenges involved with development of regression equations that accurately describe flow conditions at ungaged sites is selecting appropriate basin characteristics for the model that adequately account for the annual and season variability of streamflow. Differences in the response of streamflow to climate, landscape, and geologic diversity can increase the error and decrease the accuracy of the regression model estimates.

Oklahoma has diverse physical and climatic characteristics which can affect streamflow. Oklahoma contains a variable topography and physiography, including vast plains, extensive alluvial deposits, elevated karst plateaus, and folded, low mountains. Annual precipitation increases gradually eastward (figure 1), but variability in rainfall duration and frequency increases westward. Basin characteristics such as annual and seasonal precipitation, basin or channel slope, landcover, and soil characteristics, and the response of streamflow to these basin characteristics, can vary across Oklahoma. This regional variability can pose challenges to selecting optimal explanatory variables for use in regression equations to produce equally accurate estimates of flow duration and mean annual flow conditions for streams throughout Oklahoma.

In order to utilize model parameters that are easy to obtain while minimizing the error of the streamflow estimate, regression equations can be developed for smaller, more homogeneous regions as long as there are enough sample locations (Haan, 1977). This method has been applied to other states with distinct regional geologic and climatic diversity, such as Idaho (Hortness and Berenbrock, 2001) and Oregon (Risley and others, 2008). While physical and climatic diversity can be observed in Oklahoma, the topographic relief is generally low, and the variability of precipitation changes gradually throughout the state (figure 1), making regions more difficult to define solely by use of observational analysis of spatial characteristics. There are 12 ecoregions in Oklahoma which can be used to define regions (figure 2), however, a lack of streamflow gaging stations with long-term streamflow data within certain ecoregions of Oklahoma may limit the size and number of regions that can be used to produce meaningful regressions for those regions.

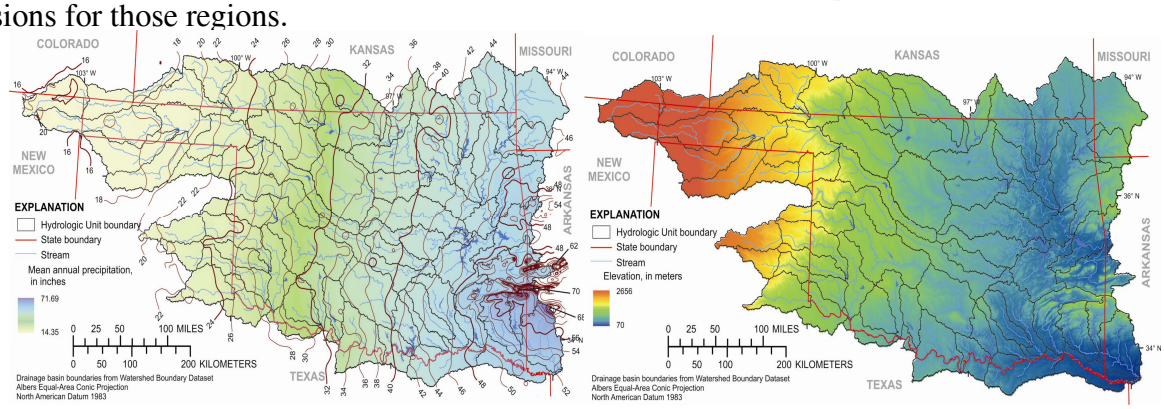

Figure 1. A.) Mean annual precipitation, in inches, and B.) elevation, in meter, in and near Oklahoma

As an alternative, statistical methods can be used to group gages with similar physical drainage characteristics (Hortness and Berenbrock, 2001). Statistical groupings of streams with similar characteristics can be supplemented by visual analysis of spatial characteristics to define regression regions for Oklahoma. Comparison of the regression models developed for each region can be used to observe differences in the response of streamflow to basin characteristics throughout Oklahoma. The results from the statistical analysis can also be used to evaluate of hydrologic variability across the state.

Purpose and Scope

Statistical analyses were used to develop regression models to estimate annual and seasonal flow duration statistics at ungaged sites throughout Oklahoma. The ungaged sites selected for analyses are not affected by water-supply regulation. This report provides a discussion of a) the methods used to develop the regional regression equations, b) variables used in the regression equations, including the accuracy of the regressions and how these results varied between models, and c) the limitations to the application of the regional regression equations.

Methods

Selection of Data for Regression Equations

Streamflow-gaging stations selected for use in constructing the regression equations had a minimum of 10 years of record and were not substantially affected by water-supply reservoirs or large-scale groundwater or surfacewater withdrawals. Additionally, the data set included all gage sites contained within USGS 8-digit hydrologic boundaries (HUC 8) that touch the Oklahoma border.

Periods of record for gages that were significantly affected by diversion and withdrawals for irrigation and other water use were determined by historical hydrographer remarks, analysis notes from previous publications (Tortorelli and Wahl 1997, Smith and Wahl 1993), and supported by inspection and analysis of the annual hydrograph. A streamflow gage was considered significantly affected by regulation if 20% or more of the drainage basin upstream from the gage was regulated by a major water supply reservoir. The year in which a reservoir was constructed and which resulted in this threshold being met was considered the cut-off year for defining an unregulated period of record. Floodwater retention structures were not considered an act of regulation for purposes of this study because these structures are unlikely to have a significant effect on median flows (Tortorelli and Bergman, 1985).

Flow duration and mean annual flow statistics from gages in the Beaver/North Canadian River Basin and Upper Cimarron River Basin of Oklahoma and the eastern panhandle of Texas were not included in the final regression analysis because streams in this region are significantly affected by irrigation withdrawals and diversions. (Tortorelli and Wahl 1997; Dale Boyle, oral and written communication). The effects of these activities on the hydrology of the area cannot be appropriately characterized by a regional regression approach. Figure 3 shows gages considered for analysis.

Calculation of Flow Duration and Mean Annual Flow Statistics

A flow-duration curve (FDC) is a graphical representation of the percentage of time that streamflow for a given time step (in this case, a daily time step) is equaled or exceeded during a specified period. Flow duration statistics are points along the FDC. For example, the 95-percent flow duration streamflow is equaled or exceeded 95 percent of the time, whereas the 50-percent duration streamflow (median) is equaled or exceeded 50 percent of the time. Strictly interpreted, flow duration statistics reflect only the period for which they are calculated; however, when the period of record used to compute the statistics is sufficiently long, the statistics can be used as an indicator of probable future conditions (Searcy, 1959). The period of record used for flow-duration curve calculation can be for the complete period of record, or daily flows during a specified period within the period of record, such as for a group of months (or a season).

The computer software program SWSTAT was used to format input data and complete the flow-duration statistics and mean annual flow analysis (Lumb and others, 1990). Flow duration curves were constructed for daily flow data in SWSTAT for annual flow duration curve (all daily flow data in the period of record), and seasonal flow duration curves (daily flow occurring the summer-fall period, June 1st through October 31st; and daily flow occurring during

the winter-spring period, November 1st through May 31st), resulting in 15 values (5 values for three FDCs) for each gage.

Computation of Drainage Basin Characteristics

Climatic and physical characteristics of the drainage basins upstream of the streamflow-gaging stations were used as independent variables in the regression equations to predict streamflow statistics. Using Geographic Information System (GIS) techniques, 23 different basin characteristics initially were computed for 167 streamflow-gaging stations (121 of which were included in the final regression analysis). The final selection of 9 basin characteristics that were used in the regression equations are listed in table 1. The computations were made using Arc Macro Language (AML) scripts run in ArcInfo, version 9.2 (Environmental Systems Research Institute, 2007). Data sources include the National Hydrography Dataset Plus (NRD) (http://nhdgeo. usgs.gov/viewer.htm, accessed July, 2008), Parameter-elevation Regressions on Independent Slopes Model (PRISM) (http://www.prism.oregonstate.edu/, accessed July, 2008), U.S. Natural Resources Conservation Service (NRCS) State Soil Geographic (STATSGO) datasets, and USGS National Land Cover Dataset (NLCD) (http:// landcover.usgs.gov/ natllandcover.php, accessed July, 2008).

Development of Regions

In regional streamflow frequency analyses, attempts are made to define regions that are hydrologically similar in terms of physical characteristics being studied (Haan, 1977). The climate and geology of Oklahoma vary greatly across the state, mostly with respect to longitude (see figures 1 and 2). A k-means cluster analysis was performed in SPlus (Insightful Corporation, 2007) using selected basin characteristics obtained for all gaging stations used in this study, including those which were later removed because they were considered substantially altered by anthropogenic activities. The results of the cluster analysis are a grouping of datapoints, in this case stations, that are similar to each other with respect to the variables used in the algorithm. Basin characteristics that were used as variables in the cluster analysis were those that were not related to drainage size or specific to gage location (such as channel slope, mean basin slope, or mean and outlet elevation). Final basin characteristics included in the cluster analysis were forested area, soil permeability, and mean annual precipitation at the gage location.

Description of Regions

On the basis of the cluster analysis, the state was divided into three regions and separate equations were developed for stream locations within each region. Regional boundaries were determined spatially by manual delineation, and are shown in figure 2. Delineated boundaries were determined on the basis of the following 5 factors: (1) the grouping of similar basin characteristics at gaged locations as a result of the cluster analysis; (2) hydrologic boundaries such as the HUC 8; (3) geographic features, such as mountains, geologically heterogeneous areas, or other distinct geologic divides; (4) ecoregion boundaries (Woods and others, 2005) which are helpful in delineating a combination of climate and geologic distinctions between areas; and (5) author's judgement based on general knowledge of the area. Hydrologic boundaries (such as the HUC 8 and smaller subcatchments) were used where possible to delineate regions in order to avoid arbitrary boundaries that cut across natural drainages.

This analysis revealed several unique groupings of basin characteristics across Oklahoma. Figure 4 and 5 show locations of the regions with respect to forested area and soil permeability. Figure 6 shows the Regions with respect to Ecoregions and large topographic and hydrologic features in Oklahoma.

Gages in Region 1, the western region, had little to no forested area, and higher average soil permeability. Region 1 contains most of the Central Great Plains Ecoregion, the western slopes of the Wichita Mountains, and eastern edges of the High Plains Ecoregion. Note that

Region 1 in figure 2 contains the panhandle region, but this region was excluded from the Region 1 regression because streamflow is impacted by irrigation.

Region 2, the North and South Central Region, was divided into two parts (Region 2A and Region 2B). Region 2A, in the Arkansas River Basin, is separated on the eastern border by the Neosho River and contains the Central Irregular Plains and the Flint Hills ecoregions, as well as a portion of the Cross Timbers Ecoregion. Region 2B, in the Red River Basin, was divided on the eastern slopes of the Wichita Mountainsand contain the Arbuckle Mountains Region. Gages in Region 2 had lower average soil permeability than Region 1 or Region 3. Gages in Region 2 also had intermediate forested area and intermediate annual precipitation.

Region 3, the Eastern and Central Region, included the Ozark Highlands ecoregion east of the Neosho River and the Ouachita Mountains to the south. Region 3 contains more forested area, greater annual rainfall, and more variability of annual rainfall in the southeastern mountain region, compared to Regions 1 and 2.

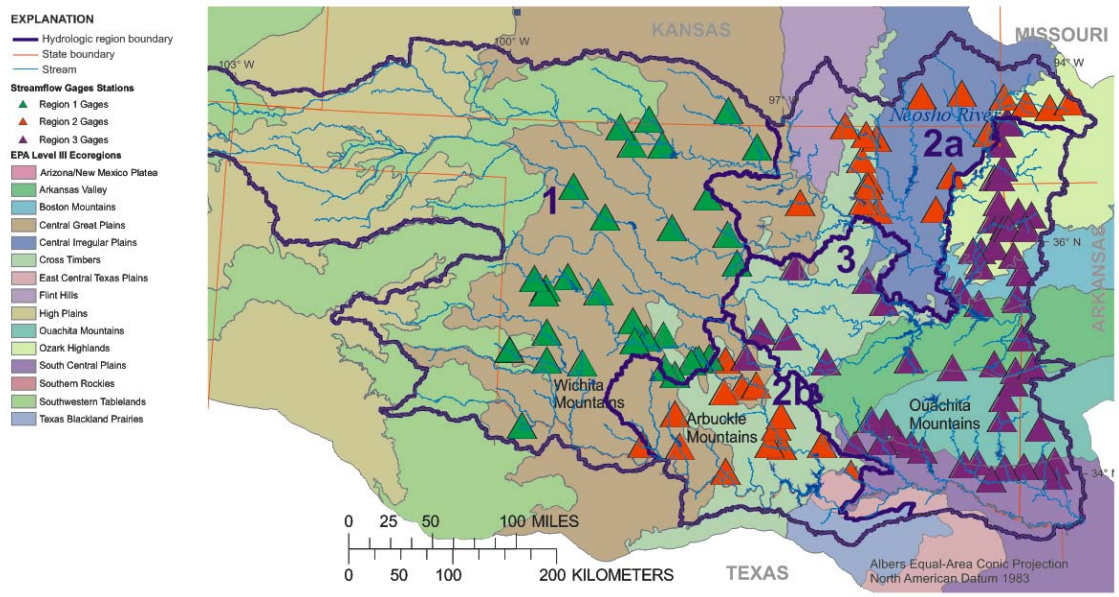

Figure 2. Study area showing regional boundaries, EPA Ecoregion boundaries, and streamflow gaging stations selected for regression analysis.

The distribution of streamflow values also varied for gages in each Region. Gages in all three regions had similar distributions for the Q20 and Q50 flow duration values. The summer flow duration values were lower for all three regions. However, for the Q80, Q90, and Q95, Region 2 had the lowest flows compared to Region 1 and Region 3. Region 2 also had the highest frequency of zero flows. Figure 7 shows a comparison of the logarithmic distributions of flow duration statistics for gages in all three regions. Zero flows were set equal to the log of 0.004 so that they could be plotted.

Development of Regression Equations for Each Region

The development of regressions and selection of explanatory variables, or basin characteristics, for each regression equation was determined using a combination of automated and manual techniques. An outline of the process is shown in figure 5. An effort was made to ensure that the explanatory variables had a physical or hydrologic reason to be used to predict flow duration values.

Regressions were developed separately for both annual and seasonal flow duration statistics. Regression equations for each annual, summer, and winter flow duration statistic (5 flow duration statistics, each on 3 FDCs) were developed separately for each of the three regions.

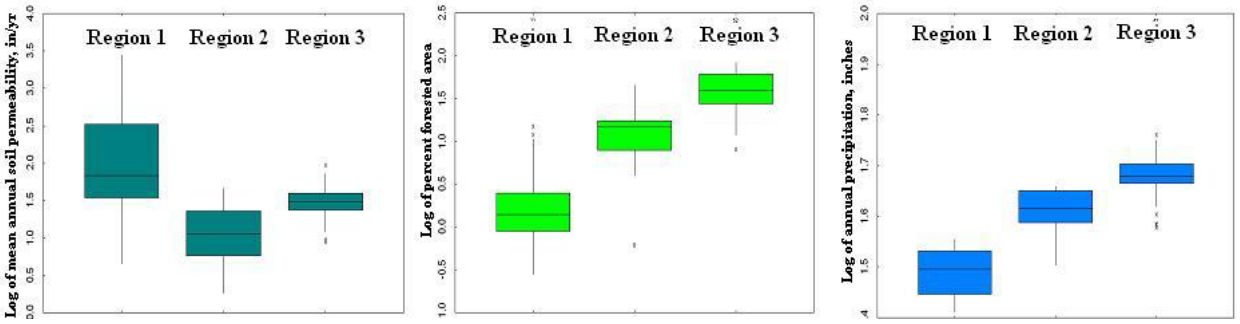

Figure 3. Comparison of logarithmic distributions of basin characteristics for three regions in Oklahoma

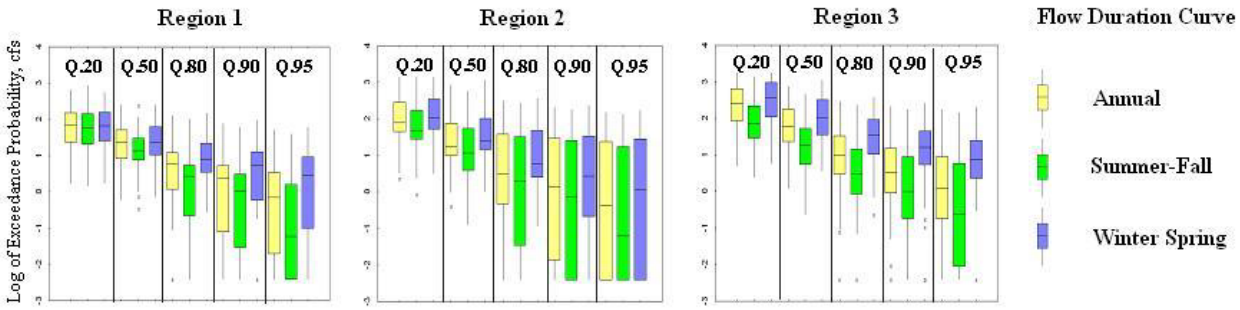

Figure 4. Comparison of flow duration values along three flow duration curves (annual, summer-fall, and winter-spring) in three regions

This produced 45 separate regression equations. A summary of the variables used in the models and the standard error and coefficient of determination are presented in table 1. Final regression equations will be reported in a US Geological Survey Scientific Investigations Report, "Estimating Flow-Duration and Mean Annual Flow Statistics at Ungaged Streams in and near Oklahoma" (Esralew and Smith, in press).

Regression Equation Format

To develop regression equations, all streamflow and basin characteristic data were transformed to base-10 logarithms. This transformation was performed to develop a linear regression model with equal variance about the regression line. Streamflow statistics with values of zero were commonly observed for flow duration statistic datasets, especially for the Q90 and Q95 datasets in Region 2. The log of zero cannot be taken. To avoid this, any dataset that had an occurrence of a flow statistic equal to zero had a small delta value added to all values in the dataset prior to log transformation. When testing possible regression equations (described in the next section), the delta constant was varied until the standard error was minimized and the adjusted R^2 was maximized. The delta constant can be subtracted from the final regression equation after retransformation from log-space to real-space has been performed.

Final regression equations will be reported in the following form:

$$Q = aB^{b1} * C^{b2} \ldots . N^{bn} - D$$

where Q is the desired dependent variable (streamflow statistic); a is the multiple regression constant; $b1$, $b2$,..bn are the regression coefficients; and B, C,…N are the values of the required explanatory variables (basin characteristics). D is the delta constant.

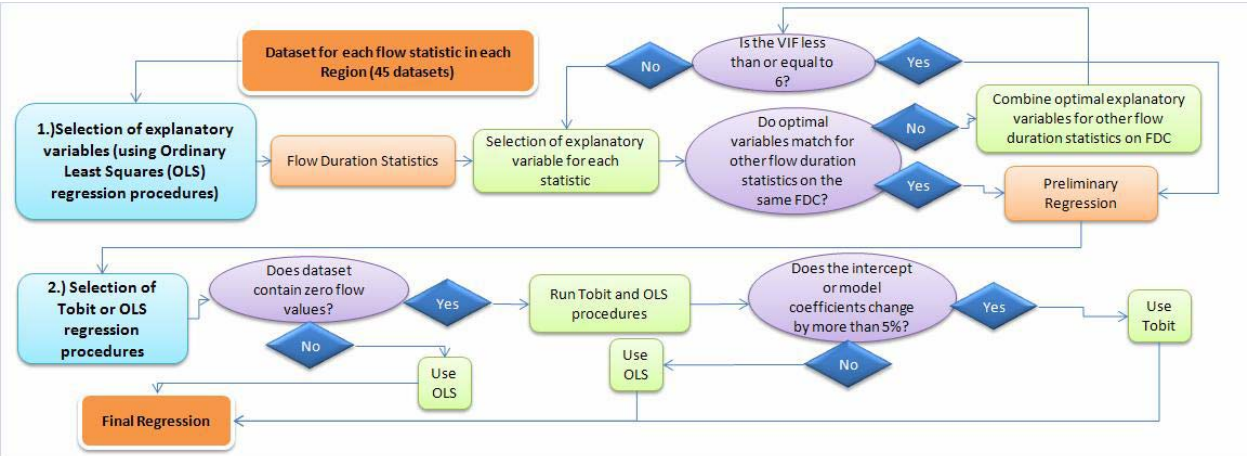

Figure 5. Flow chart outlining procedure used to develop regression equations to estimate streamflow statistics using physical basin characteristics.

Selection of Explanatory Variables from Drainage Basin Characteristics

To select optimal explanatory variables for the regression equations, a step-wise procedure and an overall method (Helsel and Hirsch, 1992) were used. The possible explanatory variables included each of the 23 basin characteristics selected for potential inclusion in the final regression models. Common diagnostic statistics were used to evaluate and select the final regression equations. These diagnostic statistics include the PRESS, Mallow's Cp, variance inflation factor (VIF), root mean standard error (*RMSE*) adjusted coefficient of determination (R^2), and results of partial t-tests. Further documentation on these regression selection methods can be found in Helsel and Hirsch (1992). If PRESS statistics and Mallow's Cp values were similar for models including a variable number of explanatory variables, the model with the least number of explanatory variables was selected. The VIF, which is a measure of correlation between explanatory variables, was minimized for any possible combination of explanatory variables to avoid multi-collinearity in the regression. Multi-collinearity can result in unreasonable slope coefficients. Combinations of explanatory variables were not accepted if the VIF was greater than 6.

An effort was made to use the same explanatory variables in the regression equations for flow duration statistics on the same FDC in each region. For any given FDC for any given region, if the explanatory variables were different between flow duration statistics on the curve, the explanatory variables were combined in the final equation as long as the variance inflation factor for the explanatory variables did not exceed 6. This ensures that the correlation structure between streamflow for each FDC is preserved. This procedure resulted in stable and consistent estimates of the statistics (Haan, 1977; Hortness and Berenbrock, 2002). For example, for the summer FDC in Region 1, contributing drainage area and annual mean precipitation at the gage were the best variables to estimate the Q20, Q50, and Q80, but mean June precipitation and channel slope were the best variables to estimate the Q90 and Q95. The variance inflation factor for the combined variables did not exceed 6, and so the variables were combined for the final regression equation.

Selection of the Modeling Procedure

Various approaches can be used to develop regressions that have zero flow values. One approach involves treating zero flow values as "censored" at or below zero. At times the streamflow may actually be zero, while in other cases flow values may be nonzero but too small to be measured and therefore reported as zero.

If there is a sufficient number of dependent variables that are censored (in this case, a sufficient number of streamflow values equal to zero), it is possible to use a Tobit regression (Ludwig and Tasker, 1993). A Tobit regression is a model in which the dependent variable is censored, and the model supposes that there is a latent (i.e. unobservable) variable below the censor. The Tobit procedure uses an MLE to assume a distribution of values below the lowest censored value, which in this case would be the delta value which was added to all values prior to log transformation. (Tobin 1958).

Kroll and Stedinger (1999) found that use of an OLS model, under conditions where there are left-censored data (data where values below a minimum value are considered latent variables), did not perform as well as a Tobit model. The error residuals for an OLS model using left-censored data will be biased higher, especially at the lower end of the linear regression. According to their study, for small amounts of censoring, however, an OLS is acceptable.

If there are no censored values, Tobit model procedures will result in the same model coefficients as an OLS. As more values are censored, or equal to the censoring value of zero, the resulting model coefficients and intercept will start to differ between OLS and Tobit procedures. A Tobit model is more computationally intensive than an OLS. For ease of reporting and data processing, a Tobit model was only applied if the regression determination procedure resulted in an intercept that was 5% different from the model that was developed using OLS procedures.

Results

A summary of the 45 final regression equations are presented in table 1. To test whether the regional regressions offered improved estimates of flow duration statistics compared with a regression equation developed for the entire study area, the adjusted R^2 and standard errors were compared between the regional regression equations and a regression equation, using the same procedures outlined above, for all regions combined (121 gages), as shown in figure 7.

Basin characteristics used in the final regressions include contributing drainage area; mean annual, summer-fall, winter-spring, and June precipitation; channel slope, elevation of the stream location, mean basin elevation, and forested area.

Average soil permeability was not selected as an explanatory variable for any regression, or the regression using all sites. This result was unexpected. Lower soil permeability should reduce low-flow duration values because contributions from shallow groundwater during baseflow would be reduced; the Region with the lowest permeability, Region 2, had the highest frequency of flow duration values equal to zero.

Differences between resulting explanatory variables for regression estimates

The importance of explanatory variables in each of the resulting regressions differed between regions and flow duration curves. This difference can be evaluated using results from a partial t-test. A partial t-test can be used to indicate whether or not an explanatory variable is accounting for a significant amount of variation of the dependent variable when other explanatory variables are present (Helsel and Hirsch, 1992). Using a two-sided t-test with $\alpha = 0.05$ and the number of variables being greater than 20, the critical value of t is greater than 2 or less than -2 for the null hypothesis (which states that the variable does not account for variation in the dependent variable). If the t-value for an explanatory variable is in this range when used in a regression with other variables, then the null hypothesis can be rejected and an assumption can be made that thethe variable is accounts for a significant amount of variation of the dependent variable; when comparing t-values, an assumption can be made that variables with higher absolute t-values are more important to the regression.

[Q.xx, daily mean discharge which is exceeded xx percent of the time during the specified time period, in cubic feet per second; Qa, mean annual discharge; DA, contributing drainage area; SL, channel slope between points 10 and 85 percent of the stream length s tarting from the stream location and along the longest flow path; OE, station elevation; ME; mean basin elevation; FR, percent of forested area in the drainage basin; PRC, mean annual precipitation at the gage location, PRC_J, mean precipitation during June, at the gage location; PRC_{JO}, mean summer-fall precipitation from June to October, at the gage location; R^2_A, adjusted R2, SEE, standard error of the estimate]

Table 1. Summary of results from determination of regression equations developed to estimate flow duration statistics for three regions and combined regions in and near Oklahoma.

Figure 5 shows an example comparison of t-values for annual FDC regressions for all three regions. Because optimal explanatory variables may have been different for statistics along the same FDC, and those variables were combined in the final regressions, some regressions contained explanatory variables where the critical t-value was between 2 and negative 2.

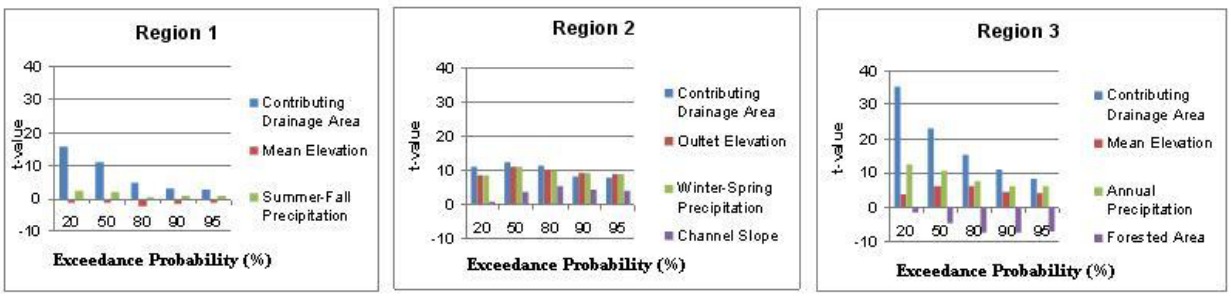

Figure 6. Comparison of t-values for explanatory variables for regressions estimating flow duration statistics on an annual flow duration curve.

For almost all regression equations, drainage area and precipitation (annual and seasonal) were more important for determining higher flow estimates than they were for lower flow while forested area, channel slope, and June precipitation were increasingly important for determining lower flows. For Region 3, forested area was increasingly important for lower flows and had a negative relation to flow (the more forested area, the lower the flow). An explanation to support this observation is increased evapotranspiration from vegetation, which can lower baseflow. Forested area was not included in other regressions, which contained less forested area than Region 3.

Elevation parameters (outlet and mean elevation) were equally important for most flow statistics in Region 2 and 3, but were not overly important. There is no direct hydrologic explanation for inclusion of this variable aside from the possibility that streams that are closer to one another (and thus have an increased probably of having similar hydrologic characteristics)

may be similar in elevation. Inclusion of this parameter typically decreased the standard error by more than 20% for most regressions, and so a decision was made to use these variables in the final regressions.

Comparison of Performance of Regressions between Regions and Flow Duration Curves

For all three flow duration curves, the regional regression equations improved the estimates for the Q50, Q80, Q90, and Q95 for gages in Region 2 and Region 3. However, use of regional regressions instead of a combined regression did not substantially improve the estimates for Region 1 at the low flow portion of the flow duration curve (Q80, Q90, and Q95), which were also very poor.

The performance of most regional regressions showed improvement over a regression developed using all gages, which can be seen by looking at the standard error and adjusted R^2 in table 1 and the plot of R^2 values in figure 7. The regression estimate using all gages was extremely poor for estimates of low-flow (Q80, Q90, and Q95).

For Regions 2 and 3, the winter-spring flow duration regressions produced slightly better estimates than the summer and annual flow duration regressions. A possible explanation for an increased uncertainty associated with estimating summer flow may be increased water-use for agricultural activities during the growing season or increased evapotranspiration which can affect low flow. For Region 1, the summer and winter estimates were slightly more accurate than the annual flow duration regressions, but all regression equations estimating low-flow values (the Q80, Q90, and Q95) were extremely poor.

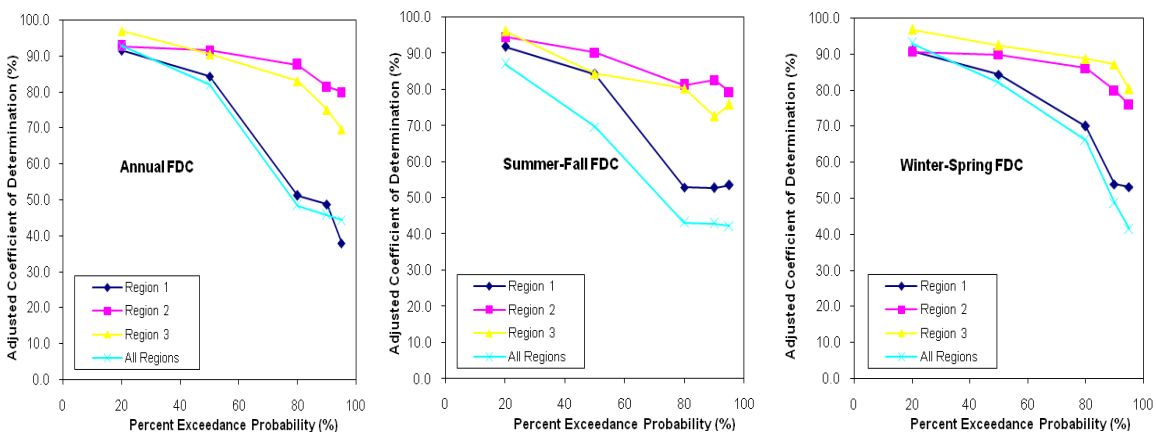

Figure 7. Comparison the adjusted coefficient of determination (R^2) for regressions developed for annual, summer-fall, and winter-spring flow duration curves for three separate regions compared to regressions developed using all sites.

For all three regions, the regressions for lower flow duration values tended to have decreased accuracy compared with higher flow duration values along the same flow duration curve. Low-flow estimates are less accurate than high-flow estimates most likely because streamflows are largely affected by localized geology that cannot be easily quantified (Riggs, 1972).

Region 1 low-flow estimates were extremely poor compared to low-flow estimates for Regions 2 and 3, which suggests that there is a high uncertainty associated with low-flow estimates in Region 1 and that the basin characteristics selected for regression analysis do not adequately describe the variability in low-flow estimates in Region 1. A possible source of variability in low-flow estimates in this region could be regional alteration from irrigation activities. Figure 8 shows how irrigation water-uses vary across Oklahoma (Tortorelli, 2009, in press) and are more pronounced in the western portion of the state. Irrigation water-use, whether water is derived from groundwater or surface-water sources, can have a significant effect on the

variability of low-flow due to nearby withdrawals and irrigation returns. Although an attempt was made to eliminate gages that were affected by local or regional irrigation and other water-use activities, these activities may not be sufficiently documented or were hard to detect from hydrograph inspection if they occurred during the entire period of record used for analysis.

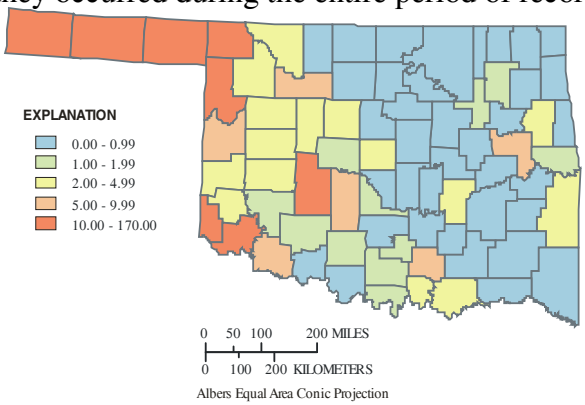

Figure 8. Map showing irrigation withdrawals from surface water and groundwater, in millions of gallons per day (adapted from Tortorelli, 2009, in press)

Another source of uncertainty for estimating low-flows in Western Oklahoma may be associated with increased variability of precipitation in west-central Oklahoma. Garbrecht (2009) found that the variability of mean precipitation between wet and dry periods in this region had a pronounced effect on the variability of annual water yield. The minimum period of record for inclusion of gages was 10 years, which may not have been a long enough period to encompass climate variability in this region. However, a requirement of a longer period of record for gages would have substantially reduced the number of gages that could be included in the analysis.

Limitations

Regressions for regions should only be applied to streams located in that region. If a drainage basin extends outside of a region, regressions from both regions can be used to estimate the flow statistic by using an average of the estimated values weighted by the percent of drainage area located in each region.

Regression equations may not be reliable for sites where the basin characteristics are outside the range of values of explanatory variables that were used to develop the equations. Use of regressions for streams with basin characteristics more than or near extremes of values used in the regression might result in unreliable estimates as well. Maximum and minimum values of basin characteristics used in each regression region will be published in Esralew and Smith (2009, in press).

Summary and Conclusion

The U.S. Geological Survey used multiple-regression analysis to develop equations for estimating daily-mean discharge exceeded 20, 50, 80, 90, and 95 percent of the time annually and seasonally (June through October and November through May). The equations were developed in order to estimate these statistics at ungaged streams in and near Oklahoma.

Separate equations were developed to estimate each of these statistics for stations within similar hydrologic regions in Oklahoma. Three groups of streamflow gaging stations were determined using a k-means cluster analysis to group gages that had similar soil permeability, annual precipitation, and forested area. Gages tended to fall in spatial regions that were distinguishable along longitudinal, hydrologic, and geologic boundaries. Based on the clustering

of gages and a delineation of distinguishable boundaries, three regions were developed.: 1.) western, 2.) north and south central, and 3.) eastern and central Oklahoma.

Ordinary least-squares and left-censored (Tobit) multiple-regression techniques were used to develop estimating equations that relate these statistics at gaged locations with 10 or more years of record to physical and climatic basin characteristics. Basin characteristics found to be significant independent variables in the regression analyses were contributing drainage area, mean annual, seasonal, and monthly precipitation, stream elevation at the outlet, mean basin elevation, channel slope, and percent forested area.

Basin characteristics selected for the final regressions varied significantly by region. Drainage area was the only basin characteristic included in all regressions for all regions. For all three regions, drainage area was more important for determining higher flows than lower flows. Depending on region, forested area, channel slope, and June precipitation were more important for determining lower flows. Forested area was important for low flows in the eastern region while it was not included in the regressions for other regions.

The equations were more reliable for estimating higher streamflow exceedance probabilities (Q20 and Q50) than for estimating low streamflow statistics (Q80, Q90, and Q95). This may have occurred because low streamflows are largely affected by localized geology which was not quantified by the basin characteristics selected for use in the regression equations.

Use of separate regressions by region significantly improved the accuracy of the estimate for streams in eastern and central Oklahoma when compared with estimating equations developed for the entire State, although no significant improvement of the models were observed in western Oklahoma and no significant improvement of the models were observed for any of the regions for regressions estimating the Q20.

The standard errors of estimate of equations for western Oklahoma were significantly larger than those for other regions, especially for lower flow durations. This could be a result of greater variability in low flow because of increased irrigation activities in the basin and lower and more intermittent precipitation in this region compared with other regions.

The equations are not accurate for streams regulated by water-supply reservoirs or streams that are significantly affected by local irrigation withdrawals and diversions from groundwater or surface water.

ABSTRACT:

The development of societies is dependent upon the sustainable water supply through sound management of resources. It is important to determine the sustainable capacity of the water resources if further development is needed. Reservoirs play an important role in water supply of basins in arid and semi-arid regions. In this paper a methodology is proposed to find a sustainable water supply scheme in reservoir operation considering the impacts of climate change on inflow and water demand variations. Different approaches such as deterministic and chance constraint optimization models are utilized for this purpose in both monthly and annual time scales. The objective function of the optimization model is to maximize the minimum reservoir release. As extreme dry or wet years can highly affect the model results, their effects on the reliable water supply are also evaluated. The proposed method has been applied to the Sattarkhan Reservoir located in Ahar-chay basin in northwest Iran. Through the probabilistic approach, the reservoir operation can be managed with different risk levels and potential hazards. The results show that the reservoir has been overdesigned and it could carry only 60% of its capacity. Furthermore, the potential water resources in the studied basin are decreasing.

Keywords: Reservoir Operation, Reliable Water Supply, Climate Change, Sustainability.

INTRODUCTION

The main factors that cause changes in water resources availability and also water demand should be considered in developing long-lead water resources development strategies. Climate change has caused considerable changes in the global water cycle in recent years. Assessment of regional hydrologic characteristics shows significant

variations due to climate change impacts which should be considered in evaluation of water resources and demand. Determining the reliable water supply could help diminish undesirable effects of dry years and provide a view of water resources for future planning.

Brekke (2008) has assessed reservoir operation risks under climate change. He used the risk analysis to study climate change effects on California's Central Valley Project (CVP). Burn and Simonovic (1996) have assessed the sensitivity of reservoir operation performance to climatic change. Wolock and McCabe1 (1999) proved warming may create substantial water supply shortages in the Colorado River basin. The results of all of these studies demonstrate the increasing risk in operation of water resources under the effects of climate change. They have concluded that the effects of these phenomena should be considered in developing water resources operation schemes.

In this study an algorithm is proposed for assessment of reliable water supply from the Sattarkhan reservoir located at Ahar-chay basin in the north-western part of Iran. An agricultural development project is underway in this region and for maximizing the benefits of this project and avoiding unexpected situations, a precise water allocation scheme is necessary. Different deterministic and probabilistic approaches are considered in order to establish meaningful results of monthly reliable water supply. Also the effects of climate changes and project progress on reliable water supply and water demand in a 5-year periods are considered.

The paper is followed by the description of the methodology. Then the study area is introduced. The results of study are discussed in the next section and finally a summary and conclusion is given.

METHODOLOGY

For evaluation of reliable water supply as the first step, it is important to provide a vision of probable future condition of the system. For this purpose, the effects of climate change on reservoir input is evaluated using downscaled GCM output data; moreover, the changes on water demands are simulated in the planning horizon. Even though global climate models in the future are run at a low resolution, the need will remain to "downscale" the results from such models to individual sites or localities for impact studies (Department of the Environment, 1996). There are enormous downscaling methods that are used due to site characteristics and data availability. In situations where low-cost, rapid assessments of localized climate change impacts are required, statistical downscaling (currently) is more effective. In this study, SDSM (Statistical DownScaling Model) developed by Wilby et al. (2002) has been used for long-lead rainfall simulation for an individual site at daily time–scales using grid resolution GCM output. In downscaling with the SDSM, a multiple linear regression model is developed between selected large-scale predictors and local precipitation based on some statistical analysis.

The downscaled rainfall data are imported into a rainfall-runoff simulation model called IHACRES developed by Jakeman and Hoernberger (1993). This model needs limited data including basin area, historical series of basin rainfall and temperature and a meteorological parameter such as evaporation or temperature. The general

structure of the model is illustrated in Figure 1. The model includes two modules: first a non-linear loss module that simulates the effective rainfall, and second a linear unit hydrograph module that estimates the stream flow.

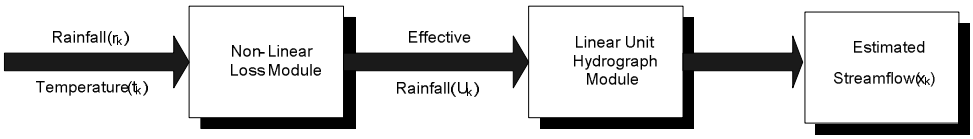

Figure 1: The structure of the IHACRES model (Jakeman and Hornberger, 1993)

Then the simulated long-lead reservoir inputs are employed as optimization model input to determine the reliable water supply of the future under climate change effects. The optimization model maximizes the minimum yearly water supply of the reservoir using deterministic and probabilistic approaches.

Deterministic Approach

In this approach linear programming is applied to maximize the minimum yearly water supply (R_{Min}) from reservoir which is considered as the available water in yearly development and allocation projects. The model is formulated as follows:

Maximize (R_{Min}) (1)

Subject to:

$$S_t + I_t - R_t - S_{t+1} = 0, \quad t \in \{1,...,T\} \tag{2}$$

$$S_{\min} \le S_t \le S_{\max} \tag{3}$$

$$R_t \ge R_{Min} \tag{4}$$

where I_t is the yearly reservoir inflow, S_t is the reservoir storage at the beginning of the year, R_t is yearly reservoir outflow, T is reservoir operation lifespan and $S_{\min}$ and $S_{\max}$ are the maximum and minimum possible reservoirs water storages in the planning horizon.

Probabilistic Approach

In this approach chance-constraint modeling is applied for determining R_{Min}. LP structure with probabilistic constraints is used in this paper. Normal distribution functions fitted to the reservoir inflow are used for conversion of the probabilistic constraints to deterministic equivalent. For this purpose Eq.s 2 and 4 are presented as follows:

$$P(S_t - S_{t+1} + I_t \geq R_{\min}) \geq p_\alpha \quad (5)$$

where p_α corresponds to the desired level of reliability in determining the reliable water supply. For example if p_α has been considered equal to 0.9, Eq. 5 can be rewritten as follows:

$$\begin{aligned} &P(S_{t+1} - S_t + R_{\min} \leq I_t) \geq 0.9 \\ &P(I_t \leq S_{t+1} - S_t + R_{\min}) \leq 0.1 \end{aligned} \quad (6)$$

CASE STUDY

The Aharchay river basin in northwestern Iran (Figure 1) has been selected as the case study of this paper. Aharchay river basin is located between 47° 20' and 47° 30' north longitude and 38° 20' and 38°45' east latitude. The Sattarkhan dam is the only available water storage resource in the study area. There are two meteorological stations, namely Kasanagh and Ahar, and a hydrometeorological station, Orang, just upstream of the Sattarkhan dam, whose recorded data is considered in this study. The stations' characteristics are presented in Table 1.

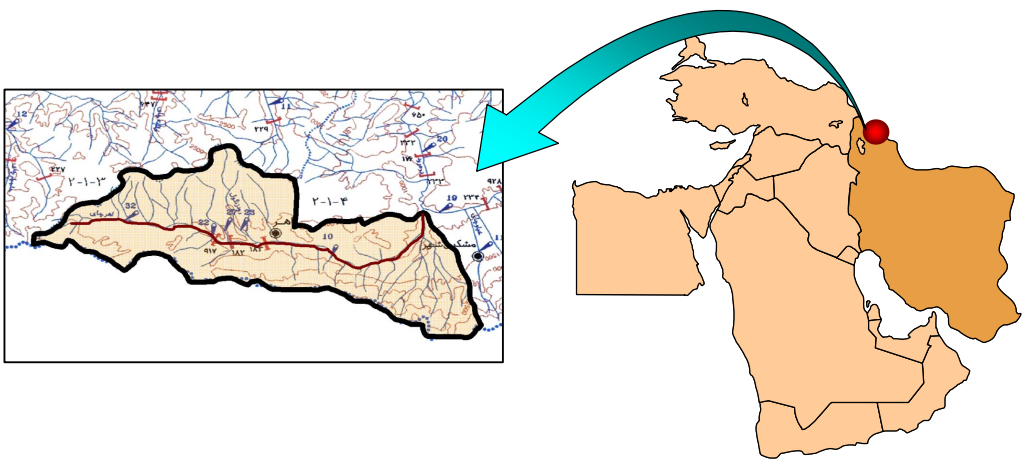

Figure 1: The location of the study area on the map of Iran

Table 1: The characteristics of hydrological and meteorological stations in the Aharchay basin

Station	Kasanagh	Ahar	Orang
Longitude	46° -51′	47°-04′	46°-52′
Latitude	38°-31′	38°-26′	38°-28′
Type of station	Rain gage	Synoptic	Hydrometer
Operation time periods (year)	1971-2000	1986-2003	1983-2004

Water supply in this part of Iran depends on seasonal rainfall, temperature and resulting runoff. Assessing the climate change and water availability, is therefore important in sustainable development of this region. The demand of the Aharchay basin is currently 68.28 MCM/year. There is an agricultural development program in this area that will increase future water demand of the basin. The monthly Aharchay streamflow variations with long lead average streamflow (6.8 MCM) are shown in Figure 2. This figure shows that this region has experienced a drought during years 1998-2006. In these years most of the months have an inflow less than 5 MCM and the yearly peak inflows which are about 20 MCM in normal years don't exceed 15 MCM. The minimum and maximum values of the reservoir storage are 18.2 and 131 MCM. The monthly variations of reservoir storage have been depicted in Figure 3. The results demonstrate that the reservoir is overestimated since at the present situation the largest storage of the reservoir does not exceed 75 MCM (60% of reservoir maximum storage capacity). So the reservoir capability to supply reliable water should be reassessed.

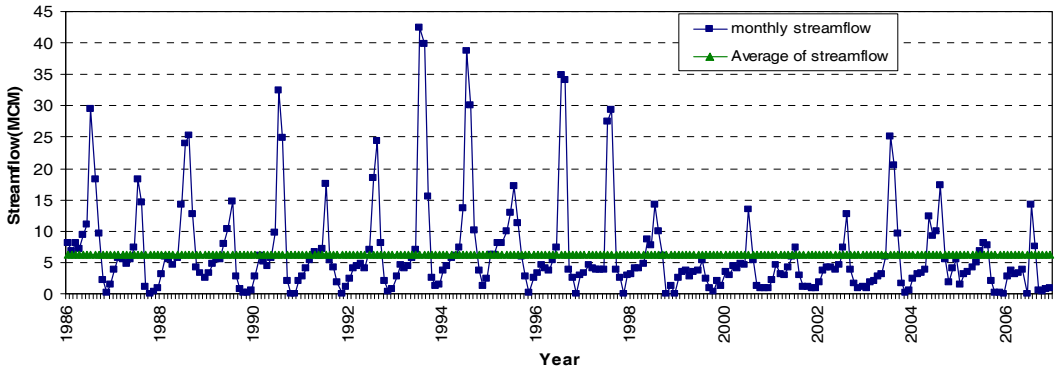

Figure 2: Monthly variation of Ahar river streamflow

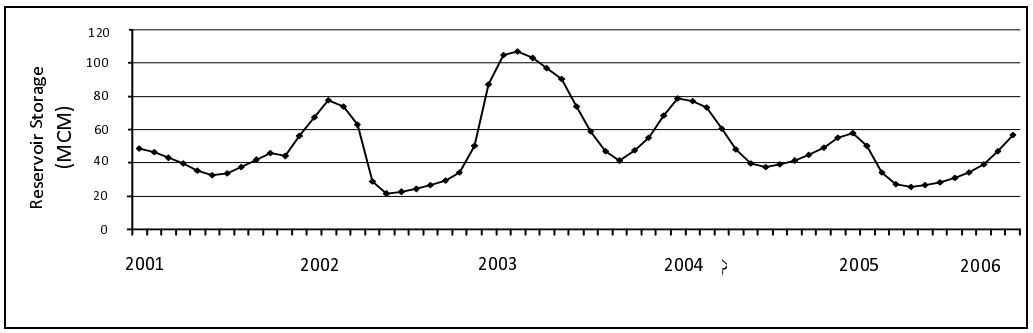

Figure 3: Monthly average storage of Sattarkhan dam

RESULTS

The simulated Sattarkhan inflow under climate change effects, within the next 35 years, is illustrated in Figure 4 (Karamouz et al., 2007). As can be seen, there is a considerable change in the basin runoff regime. In the next 10 years, the yearly

streamflow considerably decreases and is less than 30 MCM, the long term average. An interesting point is that in the first years there are high variations in yearly streamflow (about 10 MCM) which show intense dry and wet periods, however in time the difference between dry and wet years' streamflow decreases.

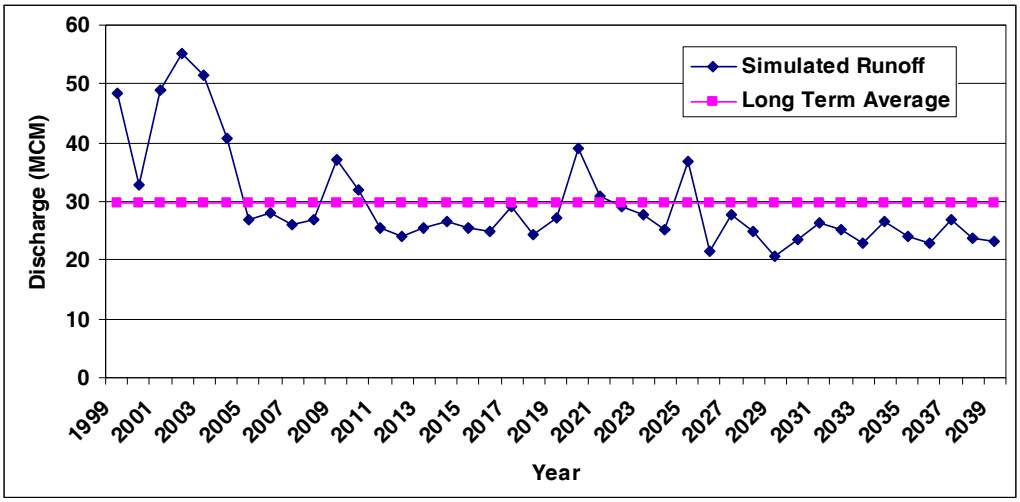

Figure 4: Simulated runoff of the Aharchay basin under climate change effect

Two approaches are considered in this study for evaluation of reliable water supply: In the first approach, the data for all years are considered, in the second approach, however, the years are divided into dry, wet and normal periods in order to evaluate reliable water supply for each condition. In other words, in the second case the two most optimistic and pessimistic scenarios of reservoir operation are evaluated.

First Approach

Using the simulated runoff, the reservoir reliable water supply is determined as presented in Table 2. It should be noted that the initial reservoir has been considered equal to 40 MCM. The reliable water supply is about 20.5 MCM in a year in the reservoir operation period. There are some fluctuations in reliable water supply value in different wet and dry periods but its value decreases with time. The minimum simulated reliable water supply is about 18 MCM in period of 2019-2025. By comparing the yearly water demand of basin which is about 69 MCM and about 40% of it is vital for continuing basin life; the initial water shortage is about 7 MCM (25%) which by considering a fix demand will increase up to 32%.

The probabilistic approach has also been applied in this study to estimate reliable water supply. Different probability thresholds have been considered including 95%, 90%, 80% and 60%. The results are given in Table 3 for different time periods. By decreasing the considered probability threshold the risk of not satisfying the reliable water supply in the year increases so that the reliable water supply would increase as it is obvious in Table 3. But the percentage of variation depending on the humidity situation of the different periods (inflow condition) is considerably different. For

example, the difference between reliable water supply with 60% and 95% of reliability, in periods 2012-2018 and 1999-2004 are 7% and 22%, respectively.

Table 2. The reservoir deterministic reliable water supply

Period	Average inflow (MCM)	Reliable water (MCM)	Average reliable water (MCM)
1999-2004	46.264	24.70	20.51
2005-2011	28.97	19.2	
2012-2018	25.70	23.69	
2019-2025	30.85	17.96	
2026-2032	24.27	19.47	
2033-2039	24.37	22.25	

Table 3. The reservoir probabilistic reliable water supply

Period	Average inflow (MCM)	Reliable water (MCM)			
		60%	80%	90%	95%
1999-2004	46.264	44.82	41.88	38.95	36.47
2005-2011	28.97	30.01	28.54	26.75	25.22
2012-2018	25.70	27.96	27.38	26.69	26.08
2019-2025	30.85	31.15	29.37	27.34	25.44
2026-2032	24.27	25.83	24.92	24.06	23.17
2033-2039	24.37	26.58	26.04	25.32	24.70

However the water demand of the region is not fixed and it changes because of development projects as well as climate change effects. Based on the estimation of Karamouz et al. (2007), the water demand of the region will increase by an average rate of 2% per year, which will make the situation much worse. In this case, managerial solutions such as conjunctive use of surface and ground water and demand management could help reduce the water shortage severity.

Second Approach

The reliable water supply for each of the considered scenarios for wet, dry and normal situations are given in Table 4. The wet, normal and dry situations are determined based on the reservoir inflow. The water supply in normal situations is about 10% more than the deterministic water supply achieved in the previous approach. Although the average input in wet periods is considerably higher than other periods, it seems that dry seasons have affected the reliable water supply because the number of dry years is much more than wet years. In this way different water allocation strategies could be employed in wet and dry years and it helps decrease the possible damages using on-time strategies to deal with extreme events.

SUMMARY AND CONCLUSION

In this study a process for the evaluation of reliable water supplies in probabilistic and deterministic approaches are presented. The effects of climate change on the

future basin runoff are simulated using SDSM and IHACRES to obtain more sound results. The proposed algorithm is applied to the Sattarkhan reservoir in Aharchay basin. The reservoir capability is assessed in order to modify the reservoir operation scheme in the coming situation considering the changes in water availability of the region. Since different levels of risk are considered for different water allocation purposes, the reliable water supplies with different probabilities are determined using chance-constraint optimization model. Also for considering the effects of inflow variations in dry, normal and wet years, the reservoir reliable water supply has been determined for characterized wet, normal and dry periods.

The reliable water supply fluctuates in different periods up to 15% from the long term average which is 20.51 MCM. The results show the significant effect of climate change on reliable water supplies. Also, there is considerable difference between reliable water supply of wet years and other years. In this way the high potential of water resources in normal and especially wet years could be employed for further development of the basin and better management of dry seasons through appropriate methods.

Table 4. The reservoir probabilistic reliable water supply

Period	Average inflow (MCM)	Reliable water (MCM)				Deterministic reliable water (MCM)
		60%	80%	90%	95%	
Wet period	44.72	43.05	40.98	38.32	35.72	25.41
Normal period	26.82	26.33	25.54	24.64	23.79	22.62
Dry period	22.47	25.38	25.00	24.60	24.25	20.41

Developments on Stochastic Analysis, Modeling, and Simulation (SAMS 2009)

J.D. Salas[1], O. Sveinsson[2], T.S. Lee[3], W. Lane[4] and D. Frevert[5]

Abstract

Stochastic Analysis Modeling and Simulation (SAMS) is a software where stochastic techniques are utilized for simulating synthetic water resources data such as monthly streamflows. The current version, SAMS 2007, includes alternative modeling approaches and data analysis features. The stochastic models included in SAMS 2007 are parametric models such as multivariate autoregressive and disaggregation linear models. SAMS 2009 is now available. Various alternatives and options have been added particularly nonparametric techniques. The main purpose of this paper is to summarize the capabilities of SAMS 2009.

Introduction

Stochastic simulation of water resources time series, in particular hydrologic time series, has been widely used for several decades for various problems related to planning and management of water resources systems. Typical examples are determining the storage capacity of a reservoir, evaluating the reliability of a reservoir with a given capacity, evaluating the adequacy of a water resources management strategy under potential hydrologic scenarios, and evaluating the performance of an irrigation system under uncertain irrigation water deliveries. Stochastic simulation has been performed through the built-in functions of general software packages such as S-PLUS, SAS, SPSS, R, and Matlab, etc. While these built-in functions for general time series simulation are useful, they are often meant for general purpose and do not reproduce features inherent in hydrological data. Therefore, specialized software for stochastic simulation and data analysis of hydrology data is attractive because they are built in such a way as to reproduce the special features that are characteristic in hydrologic time series such as long memory, periodicity, skewed marginal distributions, and intermittency. In addition, river network systems generally involve spatial dependency and connectivity requiring special modeling concepts and schemes such as aggregation and disaggregation.

The LAST package was developed during 1977-1979 by the U.S. Bureau of Reclamation

(USBR). Originally, the package was designed to run on a mainframe computer but later it was modified for use on personal computers (Lane and Frevert, 1990). While various additions and modifications have been made to LAST in the late 1970's and the 1980's, the package has not kept pace with either advances in time series modeling or advances in computer technology. Thus USBR in collaboration with Colorado State University developed the SAMS software. SAMS is a computer software package that deals with the stochastic analysis, modeling, and simulation of hydrologic time series. The main purpose of SAMS is to generate synthetic hydrologic data. It is not built for hydrologic forecasting although data generation for some of the models can be conditioned on most recent historical observations.

The basic concepts and procedures of stochastic simulation are discussed in the next section. And the capabilities of SAMS 2009 are described in a later section.

Brief review of basic concepts and procedures of stochastic simulation

Stochastic simulation of hydrologic time series hinges on a mathematical model that is built in such a way that the synthetic records derived from such a model reproduce key statistical properties observed in the historical records. For this purpose alternative parametric models and nonparametric algorithms have been suggested. The autoregressive moving average (ARMA) model is likely the most popular parametric model for simulating stationary processes such as yearly streamflows at a single site (e.g. Salas, 1980; Loucks et al., 1981). ARMA models assume that the distribution of the underlying variable is normal, and in most cases this requires that the hydrologic variable under consideration is transformed (to normal) prior to fitting the model. As an alternative to avoid this process of transformation a limited class of gamma autoregressive models has been suggested (e.g. Fernandez and Salas, 1987; 1990). Also shifting mean models have been developed to reproduce the patterns of shifting means that may be observed in some hydrologic records (Salas and Boes, 1980; Sveinsson et al., 2003). Likewise, to account for periodicity in hydrologic time series, periodic ARMA (PARMA) models have been developed (e.g. Salas 1993) for single site. In addition, multivariate ARMA, contemporaneous multivariate ARMA (CARMA), and contemporaneous PARMA (CPARMA) are also available for stationary and periodic series such as monthly streamflows (e.g. Salas 1993; Stedinger et al. 1985). Furthermore, to model large river basin networks such as the Colorado River system, aggregation and disaggregation models have been developed (Valencia and Schaake 1973; Mejia and Rousselle 1976; Stedinger and Vogel 1984; Lane and Frevert, 1990). All the models summarized above represent a class of parametric models that are defined by one or more mathematical equations involving a set of variables and parameters (to be estimated from observations.)

Besides parametric models alternative nonparametric algorithms and procedures (also denoted here as "models") have been developed in literature. For example, the index sequential method (ISM) has been employed by the Bureau of Reclamation (Ouarda et al. 1997; Prairie et al. 2005) because of its simplicity. Block bootstrapping (BB) is a useful resampling technique that has been popularly employed in literature (e,g, Vogel and Shallcross, 1996). The k-nearest neighbor resampling (KNN) has been originally developed by Lall and Sharma (1996). It has been modified and widely employed in hydrologic and environmental systems (Gangopadhyay et al. 2005; Prairie et al. 2007; Prairie et al. 2006; Rajagopalan and Lall 1999). Recently, Salas and Lee (2009) developed a resampling technique employing KNN and gamma kernel perturbation (KGK) for a single site variable. Also a multivariate nonparametric model using BB and genetic algorithm (Lee and Salas, 2009) and a nonparametric disaggregation model (NPD) (Lee et al. 2009) have been developed recently. The foregoing parametric and nonparametric models are

available in the current software SAMS 2009.

Using one type of model or another for a particular case depends on several factors such as physical and statistical characteristics of the process under consideration, data availability, the complexity of the system, and the overall purpose of the simulation study. Given the historical record, one would like the model to reproduce important historical statistics. This is why a standard step in streamflow simulation studies is determining the historical statistics. Once a model has been selected, the next step is to estimate the model parameters, then to test whether the model represents reasonably well the process under consideration. This may be accomplished through goodness of fit tests such as the Akaike information criterion (AIC), and by comparing the statistics obtained from the generated data with those obtained from the historical data.

Capabilities of SAMS 2009

The procedures of stochastic simulation mentioned above are included in SAMS 2009. The main menu of SAMS 2009 is summarized in Fig. 1 and the capabilities for each menu item are briefly indicated. Here we will explain them in some detail. To illustrate some of the key features we use monthly data of the Colorado River System. The historical gaged data at 29 sites have been naturalized (Prairie and Callejo, 2005) for the period 1906-2003 and part of the data have been extended by Lee and Salas (2006) back to 1906 employing linear regression and nonparametric bootstrapping with trace selection method.

File

Firstly the historical data must be imported into SAMS. There are two ways to import historical data: by reading the data directly from a text file and by copying the data from a table (e.g. from Excel). In the first case the user must prepare a data file (*.dat) with the format readable by SAMS. This is a common way to upload data into SAMS, but formatting the data readable by the program may lead to errors especially for a new user. The second way of importing data is easier and more reliable. In this case the user needs to insert some basic information such as, the record length, the number of stations (sites), and starting year, as shown in Fig. 2 and to paste the data that the user may have in Excel (or an equivalent format/program) into the table that will be prompted by SAMS. In addition, the information about data transformation that is performed in the module Data Analysis can be saved and imported in the File menu bar. This is useful especially when working with complex systems involving a large number of sites and large number of seasons in the year (e.g. 12 seasons) and the user may want to preserve the data transformation parameters for future operations.

Data Analysis

Generally hydrologic data are significantly skewed especially for seasonal data while parametric models (with some exceptions) generally assume that observed data are normally distributed. Therefore, the data must be transformed into normal prior to fitting stochastic models. Various transformations are included in SAMS 2009 such as logarithm, power, Box-Cox, and gamma. Test statistics such as skewness and Filliben tests as well as graphical displays are available to check whether the transformed data are normally distributed.

The statistical characterization of hydrologic data is useful for selecting the type of model to be fitted and the model order as the case may be. In addition, it is useful for comparing against statistics that are derived from generated data. For this purpose, SAMS 2009 has various tools to investigate the characteristics of historical data such as plotting time series, visual and tabular representation of key statistics (e.g. mean, standard deviation, skewness, and correlations), spectrum analysis, histogram and kernel density estimation (KDE), and operational statistics

such as drought, surplus, and storage related statistics. An example of the histogram and KDE is shown in Fig. 3 for the monthly streamflows (May) of the Colorado River at Lees Ferry (site 20). Also a three-dimensional plot of the lag-0 cross-correlation coefficients of annual streamflows is illustrated in Fig. 4 for the 29 sites of the Colorado River system.

Model Fitting

As indicated above, alternative parametric and nonparametric models have been suggested in literature for stochastic streamflow generation. The various stochastic models that are available in SAMS 2009 are summarized in Table 1. The parametric models include: ARMA, GAR, PARMA, MPARMA, CSM-CARMA, PMC-ARMA, and linear disaggregation. One of the major improvements in SAMS 2009 is the addition of nonparametric models such as ISM, BB, KNN, and KGK for both annual and seasonal data as well as disaggregation approaches, as shown in Table 1. In some cases the parametric and nonparametric models that are available in SAMS 2009 may be combined to tackle the generation of complex water resources systems.

An example of parametric and nonparametric model selection is shown in Fig. 5 where menu options for the PARMA(p,q) model (left in Fig. 5), and KNN with gamma KDE and pilot variable (nonparametric KGKP) model (right in Fig. 5) are shown. Note that Fig. 5 (right panel) shows how a parametric model (ARMA) and a nonparametric model (KGKP) are combined.

Fitted Model

After fitting a model, the user may like to see a summary of the fitted model, the parameters, as well as some results of goodness-of-fit tests of the fitted model. Some test statistics are available only for some of the parametric models. However, for all models the tests of the fitted model can be done by comparing the historical and generated statistics. For this purpose, tables of the mean and standard deviation of various key statistics obtained from the generated samples are displayed along the historical statistics. Also box plots of the generated statistics along with the historical statistics are available.

Generate Series

The stochastic generation option is activated by entering a number of parameters such as the generation length, the number of samples, and additional information pertaining to the output. Once data are generated, the fitted model can be tested by comparing the statistics of generated data and the historical data. For example, the comparisons of the generated and historical annual key statistics are shown in the boxplots in Fig. 6 for a SKGKA model fitted to the Colorado River at the Lees Ferry station, and similarly in Figs. 7-8 for a SKGKP model. In the boxplots, the triangles in Figs. 6 and 8 and the line of segments in Fig. 7 represent the historical statistics. And the end lines of the box are the 25 and 75 percentiles while the cross lines above the box on the whisker correspond to the 90 percentile and the maximum, while the cross lines below the box on the whisker represent the 10 percentile and the minimum. In Fig. 6 there is indication of a significant underestimation of the annual standard deviation when using the SKGKA model, while analyses of the generated data based on a SKGKP model (refer to Fig. 8) indicate a better performance of the SKGKP than SKGKA with regards to reproduction of the annual key statistics. Additionally, Fig. 7 shows that the monthly data generated using model SKGKP reproduce the monthly statistics reasonably well.

Final Remarks

SAMS 2009 is a versatile software that may be applicable for any number of seasons in the year. While in principle it may be applicable all the way to daily series it is advisable not to apply it for more than 26 seasons (biweekly). Modeling weekly time series may require smoothing weekly statistics using Fourier series. Alternatively modeling weekly and daily time series may be done using disaggregation techniques. But up to now these capabilities are not available. Plans are to add further features as soon as practicable.

Acknowledgments. Thanks are due to the U.S. Bureau of Reclamation (Denver Office and Lower Colorado Office) for the financial support through a number of projects that allowed us the development and further updates to SAMS. In addition, the support of HydroQuebec (Canada) and the Great Lakes Environmental Research Laboratory, NOAA are acknowledged.

ABSTRACT

Shared Vision Planning (also known as Collaborative Modeling or Computer Aided Dispute Resolution) is a relatively new but growing field. Advocates claim that the method increases the quality of decisions and policies in a way that is "cheaper, better, and faster" than traditional decision making or dispute resolution without computers. But can we prove this? In an attempt to find out, the Corps of Engineers' Institute for Water Resources and SRA International developed an array of performance measures to see if the benefits of shared learning and better policies are achieved, as well as to explore what factors (e.g., transparent model, trusted facilitator) are critical for producing the intended outcomes. The performance measures seek to characterize the quality of the participatory process, the quality of the resulting model, what impact the model had on the process and any policy recommendations, and if the process produced any longer-term impacts such as building institutional capacity and social capital. Results of assessing case studies using the performance measures will be presented.

INTRODUCTION

Collaborative modeling as an approach to resource management has evolved from several different fields, as technological developments have allowed us to generate transparent, integrated models through a collaborative process. Current practitioners include representatives of federal agencies, academia, and private consulting. The Institute for Water Resources at the Army Corps of Engineers has developed a version they named "Shared Vision Planning" and refers to the process more generally as "Computer Aided Dispute Resolution." Many claim that collaborative modeling is a means to better water management; that it is "cheaper, better, and faster" than traditional planning approaches. However, the question arises, do people just feel better for having participated in a process that fosters shared understanding, trust, and social capital, or does it really have the potential to improve resource management?

Many of the benefits achieved by collaborative modeling processes are intangible. However, without some concrete measurement of benefits, government agencies have trouble justifying choosing a collaborative modeling process that may be viewed as riskier and that requires more upfront investment of resources than the status quo. Documenting measurable benefits from collaborative modeling processes will not only encourage resource managers and agencies to consider the approach more seriously, but

will give them the ability to weigh whether the option is appropriate given their particular circumstances and justify it to those to whom they are held accountable.

To fill this need, the Institute for Water Resources began developing performance measures and related survey instruments in fall 2007. The surveys will be used for both retrospective case study analysis and for future case studies. In addition to providing evidence of benefits, the results will provide insight as to which context and process design factors are critical for increasing the chances of a successful outcome.

MEASURING THE PERFORMANCE OF COLLABORATIVE MODELING

To develop an approach for evaluating the effect of collaborative modeling on resource management decisions, IWR and SRA identified elements and outcomes of the planning process that would be useful to measure. We mapped these elements and outcomes to an existing approach used by the U.S. Institute for Environmental Conflict Resolution (USIECR) and developed a survey instrument to be used to gather systematic data regarding collaborative modeling processes.

To start, IWR and SRA developed a logic model describing the manner in which Shared Vision Planning is intended to improve resource management decisions. With the logic model as a framework, we identified six areas where systematic data collection could prove useful for measuring the effect of collaborative modeling:

- *Planning setting* – characteristics of the setting within which water resources planning processes are convened, including factors such as the type of resource management issue being addressed, level of conflict at the outset of the process, institutional constraints, etc.
- *Stakeholder participation process* – qualities of the design and implementation of the overall stakeholder participation process, including factors such as the degree to which stakeholders participating in the process represented all key interests, opportunities provided for influencing the process design, conflict resolution processes, etc.
- *Model setting and modeling* – qualities of the design and implementation of collaborative modeling processes, including level of stakeholder participation in developing the model, model type, quality of the modeling team, etc.
- *Model-level outcomes* – the performance of the model itself, including the degree to which the model integrates available information, the handling of stakeholder interests, model transparency, capability of the model to support the timely evaluation of alternatives, etc.
- *Modeling process-level outcomes* – the performance of the modeling process in terms of its effects on stakeholders' awareness and understanding of others' interests, trust in the planning process, evolution and clarity of resource management objectives, etc.
- *Planning-level outcomes* – the effect of the collaborative modeling and planning processes on resource management decisions, including the extent to which the

process influenced the ultimate outcome, the quality of the resource management decision, institutional changes that could improve future decisions, etc.

As the performance measures strategy took shape, IWR and SRA noted that several of the areas of interest aligned with the Multi-Agency Evaluation Study (MAES) developed by USIECR. IWR recognized the potential benefits of building on the USIECR work – use of tried and tested survey questions, the possibility of being able to extrapolate the IWR findings to a broader set of circumstances, and the value of exposing the concepts of collaborative modeling to a wider policy/process dialogue – and decided to pursue an integrated approach.

The existing survey instruments developed under the MAES project are focused on evaluating collaborative processes used for alternative dispute resolution in general. We built on the MAES questions to achieve a specific focus on collaborative modeling. We also explored alternatives for measuring the effect of a collaborative process on not only the quality of the agreement, decision, or recommendation but also the effect of the process on the actual management of a resource.

With regard to the latter issue – evaluating the effect of collaborative planning and modeling processes – IWR and SRA identified the types of measures that would be required to attribute resource management outcomes to specific processes. However, we recognized that a survey approach alone would likely not achieve this objective. More intensive explorations such as mixed-method evaluation or a "constructed counterfactual" approach such as the Systematic Evaluation of Environmental and Economic Results (SEEER) method developed by US Environmental Protection Agency (EPA) and US Department of Interior (DOI) could provide useful alternatives. The logic model and strategy developed by IWR and SRA provide a useful framework for pursuing such alternatives.

DEVELOPMENT OF A SURVEY INSTRUMENT

To take advantage of the potential benefits of integrating IWR and USIECR data, we adopted the MAES mediation process "participant" questionnaire in its entirety. To the 15 multi-part questions included in the MAES questionnaire, we added 10 questions focused on collaborative modeling and related areas. Other than questions designed to collect descriptive information, the majority of the questions ask the respondent to rate their agreement to statements about the collaborative process and resulting outcomes.

While the draft survey organizes questions according to logical subject groupings (e.g., all questions about the design of the collaborative process are lumped together), each of the questions is mapped to a specific performance measure identified through the logic modeling process. In this way, the survey is efficiently focused on information that will be useful for assessing performance. The mapping will also facilitate the compilation of survey data into meaningful performance measures in the future.

To test the instrument, IWR and SRA selected a range of Shared Vision Planning case studies at or near completion that represent a variety of settings, project sizes, and approaches to applying collaborative methods. We invited representatives of those case studies to participate, and a total of eight participants (all of those contacted) agreed to complete the survey and participate in follow-up interviews to provide feedback on their

experience. As of this writing (January 2009), six of the participants completed the test survey, and SRA is currently conducting the interviews. After completion of this review stage, we will make final modifications to the survey questions as required.

PLANNED USE OF THE TOOL

In spring 2009, IWR will apply for full approval of the survey instrument from the Office of Management and Budget (OMB) to use this survey on future Shared Vision Planning and related collaborative modeling projects. In order to measure participant learning and changes in views, IWR is pursuing approval to administer preliminary as well as post surveys, and, for multi-year processes, interim surveys. In the near term, IWR's focus will be on using the survey as new projects arise.

IWR and SRA have discussed the tool with other federal agencies (USIECR, DOI, EPA) who may be interested in using this survey as they increase their use of technical tools in their agreement seeking processes.

EXPECTED RESULTS

The results of the survey will provide both short-term and long term insights. For each case study for which we are able to use the survey, the tool will provide insight as to the level of success achieved. It will give indication as to how satisfied participants were with both the process (their level of involvement, learning experience, trust in the model, the quality of facilitation, and if the frequency of meetings and attendance was appropriate); and the outcome (were the goals achieved, did the group reach consensus on a decision, was a policy implemented). When interim surveys are given, the information will provide feedback to the facilitators who may choose to modify the process or procedures.

Over the longer term, follow up surveys or interviews will help us to track the success of implementation and success of the policy while minding other external factors that influence outcomes.

Once we accumulate results for enough case studies (over time or through a retrospective study), we will analyze the data more holistically and identify critical factors for success. Although each case study is different, once enough case studies are included, we may be able to provide evidence of the specific benefits of collaborative modeling over traditional collaborative alternative dispute resolution approaches and the circumstances under which collaborative modeling is most suitable.

In addition, by creating a close linkage with the MAES study, we may be able to draw conclusions about the broader universe of cases that might benefit from collaborative modeling processes. For example, if the IWR data suggest that collaborative modeling is particularly beneficial in certain settings that are common to both the IWR and USIECR cases, this could provide insights for the broader application of this approach.

It is hoped that the systematic evaluation of collaborative modeling processes and the interactions created by working with other agencies in this area will help improve our understanding of the benefits of collaborative modeling and expand its appropriate use within the resource management and dispute resolution fields.

Flow Augmentation for Dissolved Oxygen Improvement in Chicago Waterways

ABSTRACT

Even though treatment plant (water reclamation plant [WRP]) effluent concentrations meet the applicable standards and most reaches of the Chicago Waterway System (CWS) meet applicable water quality standards, dissolved oxygen (DO) standards are not met in the CWS during some periods. DO deficiencies particularly result in reaches subject to periods of limited flow, such as the upper North Shore Channel (NSC). Thus, an Use Attainability Analysis was initiated to evaluate what water-quality standards can be achieved in the CWS. Flow augmentation practices evaluated for the upper NSC included: i) a portion of the North Side WRP (NSWRP) effluent was transferred to the upstream end of the NSC, ii) the flow was transferred to and divided between two discharge points—one at the upstream end of the NSC and the other at 2.80 km upstream from the NSWRP. It was found that shifting the entire NSWRP effluent flow to the upstream end of the NSC could not achieve 100 percent compliance with a 4 mg/L DO criterion along the upper NSC. Another augmentation alternative was to add oxygen to the NSWRP effluent in the force main, and this transfer of oxygenated effluent was found to effectively improve DO in the upper NSC.

INTRODUCTION

The Chicago Waterway System (CWS) is composed of the Chicago Sanitary and Ship Canal (CSSC), Calumet-Sag Channel, North Shore Channel (NSC), lower portion of the North Branch Chicago River (NBCR), South Branch Chicago River (SBCR), Chicago River Main Stem, and Little Calumet River (north). The CWS is a 122.8 km branching network of navigable waterways controlled by hydraulic structures in which the majority of flow is treated sewage effluent from 3 of the largest wastewater treatment plants in the world. The dominant uses of the CWS are for commercial and recreational navigation and for urban drainage, i.e. draining combined sewer overflows (CSOs), stormwater runoff, and treated wastewater from the Chicago area

away from Lake Michigan, which is the water supply for Chicago. The Calumet and Chicago River Systems are shown in Figure 1.

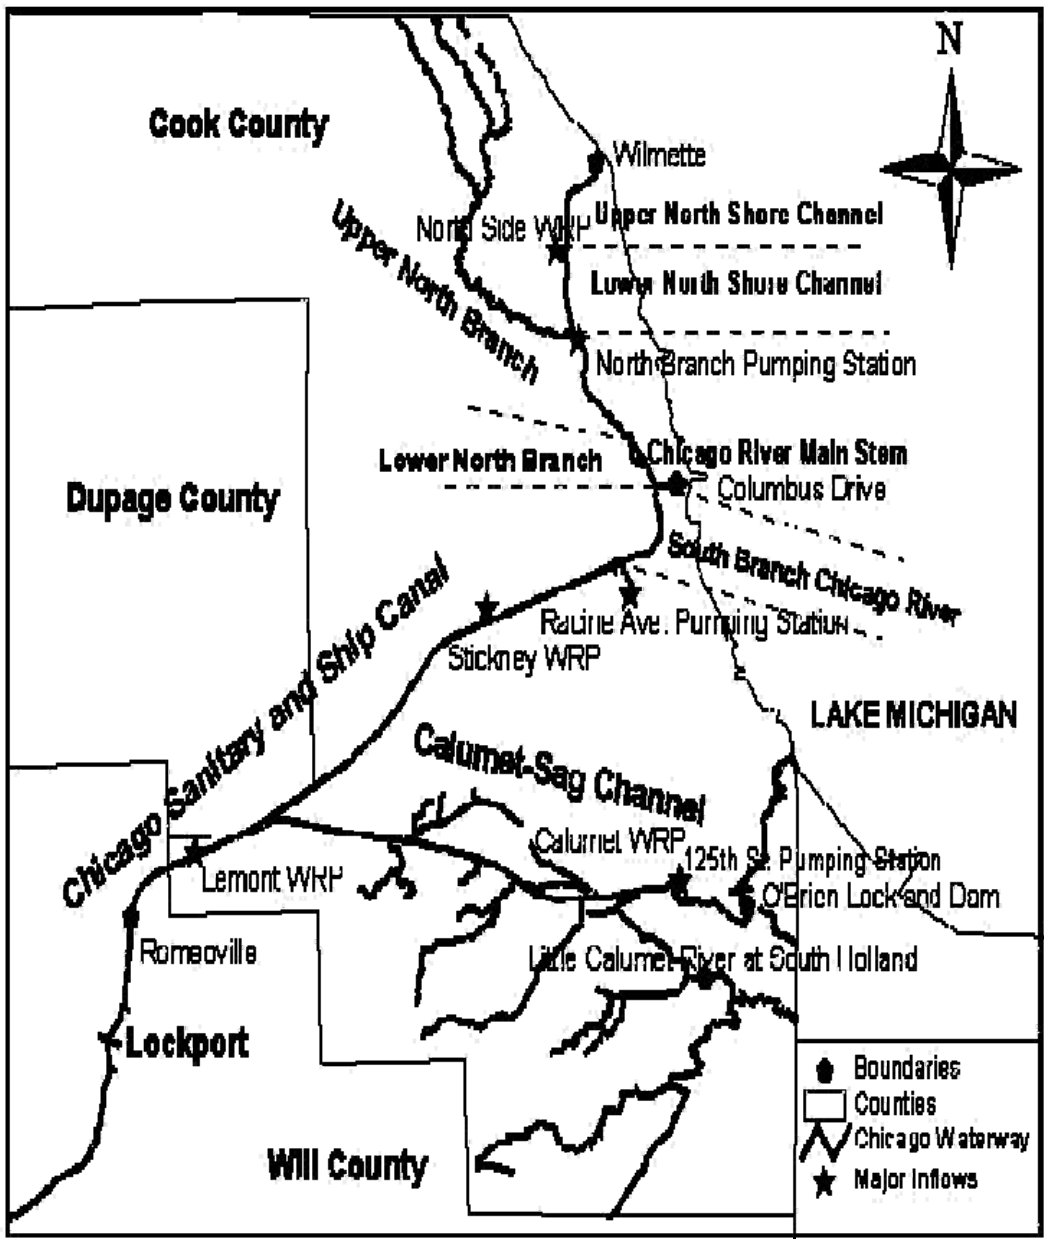

Figure 1. Schematic diagram of the Calumet and the Chicago River Systems.

The Illinois Pollution Control Board regulations (Title 35, Section 302.206 and Section 302.405) state that for General Use waters the dissolved oxygen (DO) concentration shall not be less than 6 mg/L during at least 16 hours of any 24 hour period, nor less than 5 mg/L at any time. In the CWS, only the upper NSC and the Chicago River Main Stem are considered General Use waters. The remainder of the CWS is considered Secondary Use waters wherein the DO concentration shall not be less than 4 mg/L at any time except that the Calumet-Sag Channel shall not be less than 3 mg/L at any time. This regulation was established in 1972 with a modification

for the Calumet-Sag Channel in 1988, and since that time the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC) has made many improvements to the wastewater treatment plants (water reclamation plants, WRPs), CSOs, and aeration resources of the CWS. Thus, in 2003 the Illinois Environmental Protection Agency initiated an Use Attainability Analysis (UAA) for the CWS to see if DO in the CWS could be brought closer to the General Use standard at a reasonable cost. In anticipation of this UAA and to meet other water-quality management needs the MWRDGC began an intensive sampling of hourly DO and temperature throughout the CWS in 1998, and entered into an agreement with Marquette University in 2000 to develop a water-quality model for the CWS that was suitable for simulating constituent concentrations during unsteady-flow conditions. The DUFLOW (2000) water-quality model developed in the Netherlands was selected for this study for the following reasons.

1) Includes several options for water quality simulation, one that is identical to the WASP4 model of the U.S. Environmental Protection Agency (Ambrose et al., 1988) and another that adds the DiToro and Fitzpatrick (1993) sediment flux model to the WASP formulation.
2) Compatible with Geographical Information Systems.
3) Microsoft Windows based including a powerful graphical user interface.
4) Low license cost.
5) Low computational time.
6) Successfully applied to several European rivers (e.g., Manache and Melching, 2004).

DUFLOW was calibrated and verified for the periods of July 12 to November 9, 2001, and May 1-September 23, 2002, respectively. An extensive data set including hourly in-stream DO data at 25 locations, monthly in-stream water-quality measurements at 18 locations, daily treatment plant effluent measurements, and detailed hydraulic data were used to calibrate and verify the model at a 1-hour output time step. Details of the calibration procedure and results are given in Alp and Melching (2006) and Melching et al. (2004).

The UAA (CDM, 2007) found that although treatment plant effluent concentrations meet the applicable standards and most reaches of the CWS meet the applicable water-quality standards, periods occur when DO standards are not met in the CWS, especially during and after wet-weather periods with CSOs. The upper NSC is particularly prone to low DO concentrations because the flow upstream of the North Side WRP (NSWRP) typically is less than 1 m^3/s during dry weather periods allowing effluent from the WRP to back up into the upper NSC and stagnate because of the low hydraulic gradient throughout the CWS. Further, 21 major gravity CSOs discharge to the upper NSC during storm periods, leaving substantial benthic deposits of organic material. Thus, the UAA (CDM, 2007) recommended that one way to solve the problems related to stagnant/low flow in the upper NSC channel would be to pump a portion of the effluent from the NSWRP 6.6 km to the upstream end of the NSC to create a substantial dry weather flow and to dilute CSO flows such that DO concentrations could be substantially improved. This paper reports the results of different flow augmentation scenarios for the upper NSC.

SCENARIOS EVALUATED

Three classes of flow augmentation scenarios were evaluated: (1) NSWRP effluent pumped effluent pumped to the upstream end (50%) and to a mid-point (50%) of the upper NSC, and (3) aerated NSWRP effluent pumped to the upstream end of the NSC. The UAA found that reaching the General Use standard would be unrealistic for the upper NSC, and the model was used to determine what would be needed to achieve DO standards of 4, 5, and 6 mg/L. The results for these three cases are summarized in the following sections.

Flow Augmentation to the Upstream End of the NSC. For this case two types of flow transfer were considered—the transfer of (1) a fixed amount (2.19 or 4.38 m^3/s) and (2) a percentage (10, 50, 75, or 100%) of the NSWRP effluent—for the period July 12–November 9, 2001. The minimum one hour flow from the NSWRP was 4.81 m^3/s. Thus, it was necessary to consider a percentage flow transfer rather than a fixed amount transfer to evaluate higher transfer levels. In Alp and Melching (2006) the performance of flow augmentation in improving DO concentrations was considered at two DO monitoring sites on the upper NSC—Simpson Street and Main Street. Main Street generally had lower DO concentrations, and, thus, only results for Main Street are reported in detail here due to space limitations. The percentage of hours that target dissolved oxygen (DO) concentrations of 3, 4, 5, and 6 mg/L are equaled or exceeded for July 12–November 9, 2001 are listed in Table 1 for Main Street. The wet periods listed in the tables in this paper correspond to times when flows at the downstream boundary at Romeoville were higher than typical dry weather flows (i.e. greater than 100 m^3/s).

Table 1. Percentage of time that dissolved oxygen concentrations are higher than the target concentrations at Main Street for July 12 – November 9, 2001 for different transfers of the North Side Water Reclamation Plant effluent

	3 mg/L		4 mg/L		5 mg/L		6 mg/L

10 %	61.7	28.3	41.6	7.8	24.2	0.0	5.8	0.0
50 %	94.8	99.7	86.0	89.1	47.3	62.9	17.9	19.0
75 %	98.0	100.0	90.6	97.7	64.8	79.7	26.6	42.0
100 %	98.7	100.0	94.5	99.8	74.1	87.0	31.3	49.3

The simulation results in Table 1 and Figure 2 show the improvement of DO concentrations in the upper NSC resulting from the flow transfer. It can be seen that even transferring the complete NSWRP flow does not result in attainment of DO concentrations in excess of 3 mg/L at Main Street during dry weather 100 percent of the time. This target DO concentration is achieved 100 percent of the time during wet

weather. Surprisingly, for nearly all target DO concentrations and all transfer scenarios higher percentages of compliance are achieved for wet weather than for dry weather. Thus, extra flow for dilution of CSOs is effective in improving DO concentrations in the upper NSC during storms. The simulation results at Addison Street on the NBCR 9.0 km downstream of the NSWRP showed only small decreases in DO concentrations resulting from the transfer because the operation of the Devon Avenue Instream Aeration Station reduces the negative impacts of the flow transfer (Alp and Melching, 2006).

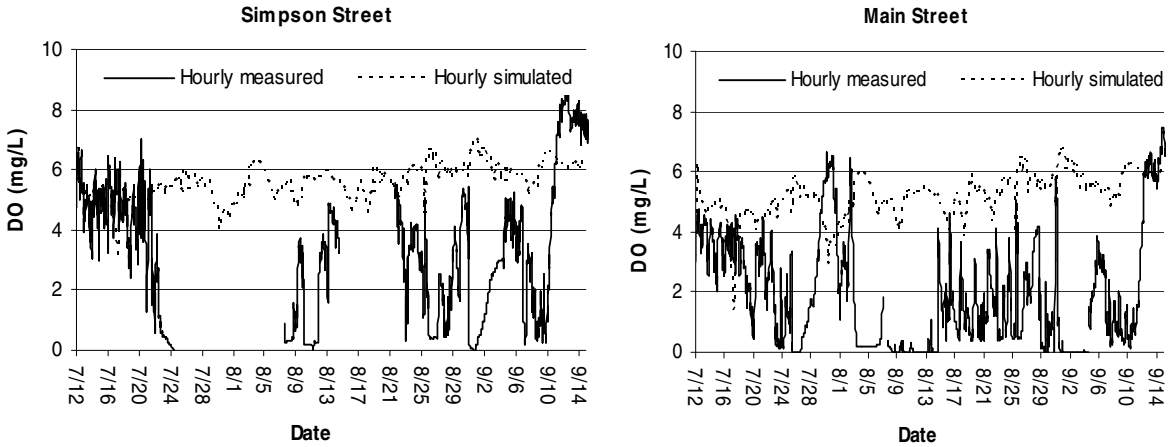

Figure 2. Simulated hourly dissolved oxygen concentrations at Simpson Street and Main Street on the North Shore Channel for a 100 percent transfer of the effluent of the North Side Water Reclamation Plant to the upstream end of the North Shore Channel compared with measured concentrations for July 12 to September 14, 2001.

The surprising result that transferring the entire flow from the NSWRP to the upstream end of the NSC does not result in DO concentrations greater than 4 mg/L at all times during dry weather flow is because of two causes. The first is that for most days in July and August 2001 the DO concentration in the NSWRP effluent is 6 mg/L or less (Figure 3). Thus, there is a small margin between the effluent DO concentration and the 4 mg/L target, and the carbonaceous biochemical oxygen demand (CBOD) and ammonia loads and sediment oxygen demand are sufficient to reduce DO concentrations below the 4 mg/L target. The second is that occasionally higher concentrations of CBOD and ammonia are present in the NSWRP effluent. Figure 2 shows the simulated hourly DO concentrations at Simpson Street and Main Street on the upper NSC resulting from a 100 percent transfer of the NSWRP effluent to the upstream end of the NSC for July 12-September 14, 2001. The occasional instances of low DO concentrations are the result of periods with relatively higher CBOD and ammonia concentrations in the NSWRP effluent. For example, on July 17, 2001, the daily mean CBOD and ammonia concentrations in the NSWRP effluent were 10.0 and 3.49 mg/L, respectively (and the daily mean DO concentration was 5.4 mg/L). Whereas, these concentrations are not high relative to the NSWRP permit limitations and general performance of wastewater treatment plants in the U.S., they are more than double and triple, respectively, the CBOD and ammonia concentrations

in the NSWRP effluent on most days. Thus, occasional higher concentrations in the effluent, and the small difference between the effluent DO concentration and DO concentration targets means that 100 percent compliance with targets will be difficult to achieve.

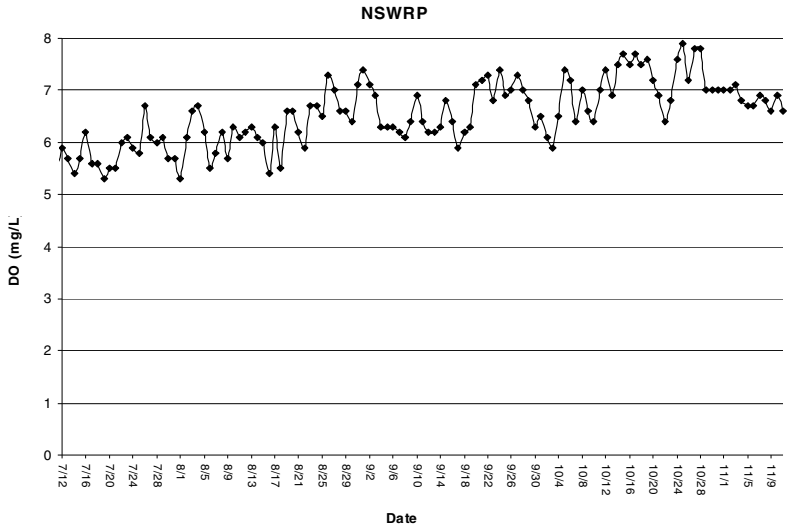

Figure 3. Daily mean dissolved oxygen concentration in the North Side Water Reclamation Plant Effluent for July 12 – November 9, 2001.

One final aspect of the results that requires discussion is the reduction in the percentage of the time in compliance with various target DO concentrations when small amounts of effluent (2.19 m^3/s or 10 percent) are transferred to the upstream end of the NSC relative to the no transfer (calibrated model) case. For the no transfer case compliance with the various target DO concentrations is achieved at certain times. For some of these times the addition of a CBOD and ammonia load in the transferred effluent may result in a decrease in DO concentrations below the targets. For small flow transfers the number of hours with reduced DO may be greater than the number of hours improved by the effluent transfer. At higher levels of flow transfer, the number of hours improved is substantially more than those that are adversely affected.

Flow Augmentation with Two Discharge Points. In this case, the NSWRP effluent is transferred to and divided between two discharge points: one at the upstream end of the NSC and the other 2.80 km upstream from the NSWRP. Again results were obtained for the period of July 12 to November 9, 2001, and the results for Main Street are listed in Table 2.

For flow transfers less than 100 percent, splitting the flow results in slightly worse (a few percentage points less) percentages of compliance with the various target DO concentrations at Simpson Street (Alp and Melching, 2006), but substantially improved percentages of compliance at Main Street. For complete (100 %) flow transfers the results with one or two outlets are nearly identical in terms of percentage of compliance. These results indicate that if a transfer of NSWRP effluent is utilized a final design with multiple outlets would be most efficient as it would

yield nearly identical (or even improved) DO concentrations at smaller construction and operation costs.

Table 2. The percentage of time that dissolved oxygen concentrations are higher than the target concentrations at Main Street on the North Shore Channel for July 12 – November 9, 2001 for different transfers of the North Side Water Reclamation Plant effluent with two discharge points

Flow Augmentation with Aeration. It was previously found that even shifting the entire NSWRP effluent discharge to the upstream end of the NSC could not achieve 100 percent compliance with a 4 mg/L DO criterion at Main Street during the period July 12 to November 9, 2001. It was speculated that this resulted because DO concentrations in the NSWRP effluent often were relatively low (between 5 and 6 mg/L) in July and August 2001. The review of aeration technologies by CTE (2007) as part of the UAA alternatives review found that it would be relatively easy to bring the flow to saturation in the force main used to transfer flow from the NSWRP to the upstream end of the NSC. Thus, it was decided to consider a case of flow augmentation wherein oxygen would be added to the NSWRP effluent in the force main.

Daily mean temperature data for the NSWRP effluent for the periods July 12 to November 9, 2001 and May 1 to September 23, 2002 were used to determine the saturation DO concentration in the force main. Some of this DO would be consumed during travel from the NSWRP to the upstream end of the NSC, but this would be matched by a decrease in the CBOD. Thus, for simplicity the quality of the transferred flow was taken as that of the NSWRP effluent with the DO concentration raised to saturation. The transfer amount was taken as the lesser of the selected transfer value or the actual effluent flow for a particular hour.

In the charge to CTE for the NSWRP Facility Plan a target of 90 percent compliance with DO criteria of 4, 5, and 6 mg/L over all flows was set for developing cost estimates. Thus, the aerated transfer amount necessary to meet 90 percent compliance with the DO criteria during the simulated periods is evaluated. The simulated periods are dominated by summer (July-September) conditions during which temperature stresses on DO concentrations are greatest. Thus, 90 percent compliance in the summer implies much higher compliance over an entire year, and the transfer amounts determined are conservative relative to 90 percent compliance over the entire 2 year period. Figure 4 shows the overall percentage compliance with the 4, 5, and 6 mg/L DO criteria resulting from different amounts of flow transfer from the NSWRP to the upstream end of the NSC. Ninety percent compliance with

the 4, 5, and 6 mg/L criteria is achieved at Main Street with a transfer of approximately 2.85, 3.94, and 5.69 m^3/s, respectively, of aerated effluent (Figure 4). As part of the UAA, CTE (2007) estimated that transferring 4.38 m^3/s of aerated NSWRP effluent to the upstream end of the NSC, where U-tubes (Speece, 1969) are used for aeration, would involve a capital cost of US$60 million and an annual operational cost of US$744,000. The higher flow rate than derived from Figure 4 is necessary to ensure 90% compliance throughout the upper NSC.

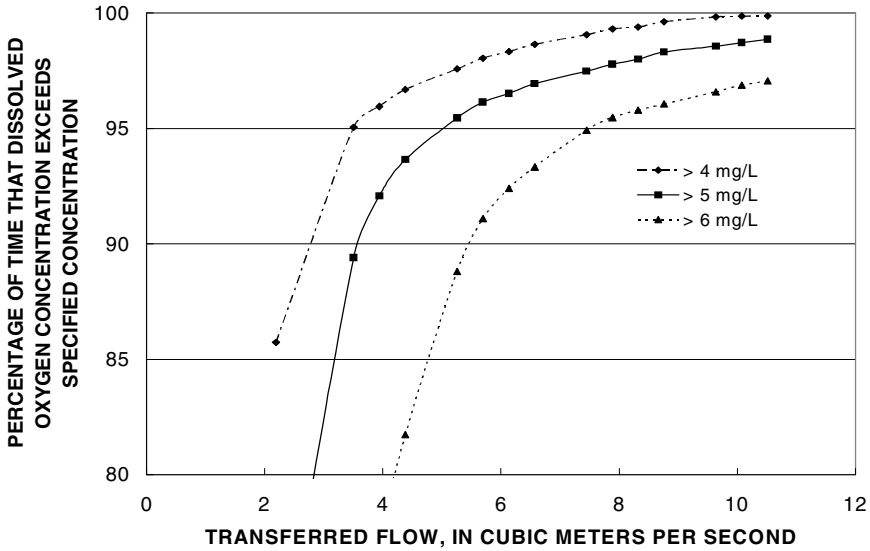

Figure 4. Relation between aerated North Side Water Reclamation Plant effluent and percentage compliance at Main Street with dissolved oxygen concentration criteria of 4, 5, and 6 mg/L for the periods of July 12-November 9, 2001 and May 1-September 23, 2002.

The overall percentage compliance with the 4, 5, and 6 mg/L DO criteria resulting from transfer of 3.50, 5.26, 7.45, and 8.32 m^3/s NSWRP flow to the upstream end of the NSC at the locations downstream from NSWRP are shown in Tables 3 and 4. Even though the increase in DO is not as drastic as that observed along the NSC, at least 10% improvement is achieved by transferring 8.32 m^3/s compared to 3.50 m^3/s at Addison Street, 9.0 km downstream from the NSWRP, for the 6 mg/L DO criterion (Table 3). The DO criterion of 5 mg/L could be met 95 and 94.1 percent of the time for dry and wet weather periods, respectively, at Addison Street by a transfer of 3.50 m^3/s. However, even a transfer of 8.32 m^3/s aerated NSWRP flow could not result in 90 % compliance with a 5 mg/L criterion at Fullerton Avenue, 12.1 km downstream from the NSWRP (Table 4).

Thus, additional instream aeration stations would be needed to achieve 90% compliance with a 5 mg/L DO standard on the NBCR downstream from Addison Street. Results show that the effect of flow augmentation with aeration decreases considerably at locations downstream from the junction of the NBCR and SBCR (Alp and Melching, 2006).

Table 3. The percentage of time that dissolved oxygen (DO) concentrations are greater than the target concentrations at Addison Street on the North Branch Chicago River for July 12-November 9, 2001 and May 1-September 23, 2002 for different transfers of North Side Water Reclamation Plant effluent brought to saturation DO concentration.

CONCLUSIONS

Simulation of the period July 12-November 9, 2001 with the DUFLOW model calibrated and verified for the CWS found that transfer of even the entire flow from the NSWRP to the upstream end of the NSC would not result in 90% compliance with the 5 mg/L DO criterion. Splitting the transferred effluent between the upstream end of the NSC and a point 2.80 km upstream of the NSWRP yielded similar results to the case of transferring all the flow to the upstream end of the NSC at a potentially reduced cost. Aeration of the transferred effluent in the force main was found to be an effective and efficient means to improve the DO concentrations to acceptable levels (5 mg/L, 90% of the time) in the upper NSC with estimated construction and operation costs of US$ 60 million and 744,000/year, respectively. The benefits of this aeration also allow compliance with target DO criteria for about 10 km downstream of the NSWRP, whereas, compliance further downstream will require supplemental aeration stations.

Refined design of the flow augmentation for the upper NSC channel is currently under study as part of the development of an integrated strategy for water

quality improvement throughout the CWS. This design will test flow augmentation performance against new dissolved oxygen standards proposed by the Illinois Environmental Protection Agency for selected representative wet and dry years for the CWS. Single and multiple discharge points for the transferred flow will be considered. Combination of the aerated flow augmentation with addition of instream aeration stations will also be considered.

Abstract

This paper uses observed daily streamflow data to examine the flow regime alteration and how these changes might potentially affect freshwater ecosystems. The earth surface temperature has been observed gradually increase and associate with precipitation and atmospheric moisture changes over space and time. Climate induced flow regime changes are examined by Indicators of Hydrologic Alteration approach. The annual extreme water conditions (1-, 3-, 7-, 30-, 90- day annual minima or maxima) reveal larger alteration from analyzing twenty-three gauging stations throughout Taiwan. More severe flood and drought events happen in the period of after 1991 than the period of 1961-1990. Frequency and duration of the flood and drought events also reveal high fluctuation. Flow regime is being altered and is going to continue into the foreseeable future. The aquatic organisms not only need to defend themselves from the anthropogenic damage to the river system but also are facing the on-going threat from thermal and flow regime altering under changing climate. This paper tries to raise this issue to allow water resources managers taking some precautionary measures to reduce the cumulative effects from anthropogenic influence and changing climate.

Introduction

Water in a river system provides aquatic ecosystems maintaining with fisheries, wildlife habitat, recreations, and other tremendous values. The different quantities of the water at different locations and different timing affect aquatic ecosystems significantly. Over the thousands of years, the river system sustains some level of natural and seasonal patterns of rising and falling water levels that shape the instream and riparian habitat, provide cues for organisms breeding and migration, and allow the aquatic ecosystems to function properly (Poff et al., 1997). Many aquatic organisms have adapted to the predictable flow variation associated with natural fluctuations; deviation from these patterns may increase the threat for their survival in the rivers (Poff and Ward, 1989; Bunn and Arthington, 2002). Altering the natural flow patterns may strongly affect the aquatic organisms that depending on them. Streamflow has been considered as a dominated variable that influences many fundamental ecological processes in aquatic ecosystems.

In the past century, the earth surface temperature has been observed approximately 0.56 to 0.92 ℃ increases in average in the world (IPCC, 2007) and 1.0 to 1.4 ℃ increases in Taiwan (Hsu and Chen, 2002). It is expected this increasing trend is going to continue into the foreseeable future. Ecosystem responses to the recent global warming trends have been widely observed and documented (Walter et al., 2002). In addition to the direct warming effect, the increasing temperature may cause changes in global atmospheric circulation, and affect precipitation and atmospheric moisture over space and time. Streamflow is more or less reflecting the changing precipitation patterns and reveal a certain level of alteration. The alteration including changes in the magnitude and timing of extreme flow events, frequency and duration of high or low flow events, and magnitude of monthly or yearly flow may result in a severely altered river system which will threaten to native aquatic ecosystems in it. Climate change is perhaps one of the greatest on-going threats to the aquatic ecosystems. Although aquatic organisms are commonly resilient to most of the anthropogenic disturbance, current environmental condition changes caused by climate change are probably too rapid for some of the organisms to adapt (Dudgeon et al., 2006; Angeler, 2007).

Most recent climate change impact analysis on water resources or streamflow management focus on the trend determination (Yu et al., 2002; Burns et al., 2007; Novotny and Stefan, 2007) with paying special attentions on extreme water conditions (e.g. flood, drought) (Milly et al., 2002; Lehner et al, 2006), and very few of them consider the changes of whole flow regimes. The trend of water quantity is very important for water resources management purpose, but the changes of whole flow regime characteristics are rather crucial, especially in aquatic ecosystems. In this paper, the Indicators of Hydrologic Alteration (IHA) developed by The Nature Conservancy (Richter et al., 1996) will be used as a tool to assess streamflow alteration potentially caused by the changing climate in Taiwan. The aim is to examine these changes and understand possible effects on aquatic organisms. Unlike most climate change research using global circulation models (GCMs) to project future climatic conditions (e.g. Caballero et al. 2007), this paper uses observed daily streamflow data to examine the flow regime alteration happened in the past. By realizing the hydrologic alteration and the potential impact to freshwater ecosystems, new management strategies could be developed to mitigate the impact and benefit to aquatic ecosystems.

Method

Streamflow Alteration and Ecological Responses

In a natural stream, the aquatic organisms evolve strategies for surviving in different kinds of environmental conditions, particularly driven by the magnitude, frequency, duration and timing of flow (Poff et al., 1997). There is a large and rapidly growing literature trying to identify the connection of hydrologic conditions to the organisms (e.g. Poff et al., 1997; Petts et al., 2006). Engineers and system

analysts are trying to use numerical models to simulate hydrologic variability and river hydrodynamics in relation to species populations or biological indexes (e.g. biodiversity index) (Yang et al., with editor). These models built the mathematical relationships between the inputs (hydrologic valuables) and outputs (biological/ecological parameters). Then engineers and system analysts can manipulate the hydrologic variables to predict the biological/ecological responses. On the other hand, ecologists and biologists continue to develop understanding how organisms interact with these hydrologic variables, paying special attention on life history requirements, microhabitat conditions, and movement behaviors. Experimental designs and field work samplings are conducted to provide more solid scientific basis at a holistic level over different temporal and spatial scales (Herbert and Gelwick, 2003; Jowett et al., 2005). Both attempts from engineers and ecologists are reflecting the importance of the connections between streamflow and aquatic organisms. Due to the highly stochastic characteristics of hydrologic variables and extremely complicated responses of aquatic ecosystems, the connections between hydrology and ecology still focus on target or dominant species and are still site specific in most cases.

Station Selection and Data

Taiwan is an island located at east of Mainland China and south of Japan in the Western Pacific with a total area of 36,000km^2. The island is long and narrow with the Central Mountain Range in the middle. The annual rainfall in Taiwan reaches about 2,500 mm which is around 2.6 times the world average, but rainfall concentrates in the period from May through October with an amount of 3/4 of annual average, which is wet season. Rivers are basically short but steep in Taiwan with large runoff differences in wet and dry seasons. Discharges respond rapidly with rainfall intensity and flood flows. Because of the subtropical climate and high elevation gradient change, Taiwan has very plentiful aquatic ecosystems from upstream high mountain stream to downstream estuary.

Gauging stations throughout Taiwan are considered based on the available length of daily streamflow data and natural flow condition. The length of data is very crucial in climate change research. Longer period of data can reduce the effects caused by short term natural fluctuations and show trend (if there is any) developed by climate change. Unfortunately the streamflow data of most gauging stations in Taiwan are either relatively short or are affected by upstream hydraulic constructions (e.g. dams). Therefore only twenty-three stations with minimal anthropogenic influence are considered suitable for this analysis. The drainage area ranges from 82 to 812 and the elevation ranges from 20 to 1,630 m.

Indicators of Hydrologic Alteration

Hydrologic indicators have been widely applied in ecological water resources management (Suen and Eheart 2006). Those indicators are recognized having highly ecological relevance and can be easily calculated (e.g. Richter et al., 1996; Poff et al., 1997; Suen and Herricks, in reviewing). One of the most frequently used methods is the Indicators of Hydrologic Alteration (IHA) approach (Richter et al., 1996). The

IHA uses daily streamflow data to characterize flow regimes in terms of five ecological significant aspects: magnitude, frequency, duration, timing, and rate of change. Thirty-one hydrologic parameters are categorized in five groups: magnitude of monthly water conditions, magnitude and duration of annual extreme water conditions, timing of annual extreme water conditions, frequency and duration of high and low pulses, and rate and frequency of water consecutive daily means condition. These parameters can be easily calculated by a Windows-based computer software developed by The Nature Conservancy, USA. Olden and Poff (2003) review 171 currently applied hydrologic indicators and suggest that the IHA could adequately represent the majority of the variation of the flow regime for hydroecological studies. The detailed IHA development, please refer to Richter et al. (1996).

In this research, the observed daily streamflow data are transferred to the whole set of hydrologic indicators by IHA for examination. There is no justification can be found to show one IHA group is more important or can replace other groups. Therefore, whole suite of IHA is considered equal weight in the analysis in terms of each group or each indicator. Altering any of the groups or indicators will affect the flow regimes in various ways.

The Range of Variability Approach

The primary function of the IHA is to examine changes in flow regimes caused by hydraulic constructions. By comparing data between pre- and post-impact periods, the percentage change in each ecological relevant statistics shows the degrees of hydrologic alteration and it can be applied to assess potential impact to the aquatic ecosystems. The Range of Variability Approach (RVA), proposed by Richter et al. (1997), offers a more quantitative way to evaluate the degree of alteration by giving a target range for each hydrologic indicator. In this research, the percentage change between the 25th- and 75th-percentile pre-impact baseline indicator values is set as a target for alteration assessment. The post-impact values should have similar frequency as that which occurred in the natural or pre-impact baseline flow regimes if there is no obvious climate change happening. The measure of hydrologic alteration A, expressed as a percentage, is defined as:

$$A = \left| \frac{Y_o - Y_e}{Y_e} \right| \times 100\% \quad (1)$$

where Y_o is the observed count of post-impact years for which the value of the hydrologic indicator falls within the RVA target range, and Y_e is the expected count of post-impact years for which the value of the hydrologic indicator falls within the RVA target range.

Results and discussion

The daily streamflow data of twenty-three gauging stations are calculated by Indicators of Hydrologic Alteration software. In order to determine the flow regime alteration under changing climate, historical daily streamflow data over the period of

November 1960 to October 1990 (1961-1990) are used as the baseline condition based on the IPCC guidelines (IPCC-TGCIA, 1999), and streamflow data after November 1990 (after 1991) are used to assess the potential impact on climate change influence. For each of the thirty-one hydrologic parameters, the absolute percentage changes both in mean and in coefficient of variation (CV) between baseline and post-baseline periods are calculated. Table 1 shows the mean absolute percentage changes of twenty-three gauging stations calculated from whole Taiwan Island and separated in four sub-regions. Noted that the absolute percentage changes of Julian date of annual 1-day minimum and maximum (IHA group 3) should consider to be neglected because the value of the Julian date is not the magnitude of the parameters. Besides that, the annual 1-day minimum in Taiwan usually happens in dry season, which is from November to next April, so the value of Julian date of annual 1-day minimum may have a large variation because it may happen in November and December (large Julian date number) or from January to April (small Julian date number).

In order to compare how much hydrologic alteration happened between 1961-1990 and after 1991 periods, the before 1990 data are divided into two periods for further analysis. Data over the period of 1976 to 1990 are used as the *post-impact* condition to test the hydrologic alteration to the *pre-impact* period (before 1975). Table 2 shows the comparisons of the mean absolute percentage changes between baseline and post-baseline periods and between two sub-periods within the baseline period. Table 2 also shows the probability of post-baseline value larger than baseline value of twenty-three gauging stations in mean and in CV. A close to 100% probability value means the post-baseline value is larger than the baseline value in most observed gauging stations. In other words, it is very likely having an increasing tendency in this hydrologic parameter.

The differences of mean absolute percentage changes between baseline and post-baseline periods and between two sub-periods within the baseline period are not so obvious. Only the annual extreme water conditions (IHA group 2) shows consistently larger absolute changes. It means these extreme water conditions (1-, 3-, 7-, 30-, 90-day annual minima or maxima) alter more in period of after 1991 than in period of 1961-1990.

The RVA method is originally used to guild the streamflow management strategies for sustaining native aquatic ecosystem biodiversity and integrity after a hydraulic construction was built (Richter et al., 1997). In this research, the RVA is adapted to measure the hydrologic alteration between two periods of streamflow data under changing climate. The full range of pre-impact period data for each hydrologic indicator is divided into three categories: middle, high, and low. The middle RVA category expresses the value of each hydrologic indicator of post-baseline period lies between 25th- and 75th-percentile pre-impact baseline indicator values, i.e. the RVA target. The high or low RVA category expresses the value of each hydrologic indicator of post-baseline period lies above 75th-percentile or below 25th-percentile pre-impact baseline indicator values, respectively. For each gauging station, the hydrologic alteration A can be calculated by equation (1). Richter et al. (1998)

suggested that the value of A ranging between 0 and 33.3 % represents low alteration, 33.3-66.6 % represents moderate alteration, and 66.6-100 % represents high alteration. If the percentage value of low alteration in the middle RVA category is low, it means fewer stations can reach the RVA target, i.e. hydrologic alteration is higher. Again, the annual extreme water conditions (IHA group 2) show smaller percentage values in low alteration in the middle RVA category. The values of "Frequency and duration of high and low pulses (IHA group 4)" and "Rate and frequency of water consecutive daily means condition (IHA group 5)" have similar results as the IHA group 2. Hydrologic alteration is much more in period of after 1991 than in period of 1961-1990.

The annual extreme water conditions show more alteration both in magnitude and in CV of each extreme hydrologic parameter. Most of these parameters show smaller mean values with larger fluctuation within years (i.e. low predictability) in post-baseline period than they are in baseline period. Increased incidents of flooding and drought events may threaten to the aquatic ecosystems. Invertebrate community might be impacted by increased frequency of drought events at some locations that will be swapped by drought-resistant fauna (Hogg and Williams, 1996). Increased frequency of flood events will interrupt riparian plant succession and reduce available low-energy, backwater habitat for aquatic organisms (Poff, 2002). High magnitude, short duration events may create high velocity and turbulence that lead to injury or death of fish (Harvey, 1987). Correspondingly extended duration of low flows are expected to reduce available channel habitat and increase the risk of loss of organisms due to changing water quality or increased predation risk (Magoulick and Kobza, 2003). Altered annual extreme water conditions change original flood and drought patterns and their primary functions for the aquatic ecosystems.

An important impact to aquatic ecosystems under changing climate is the temperature alteration and it has been widely discussed in worldwide and in Taiwan (Meyer et al., 1999; Han et al., 2007). This paper raises another issue, flow regime alteration, which might have strong potential impact to aquatic ecosystems. The complexity in determining responses of aquatic ecosystems to climate change is mixed from above concerns and moreover will be intensified by the direct or indirect interactions with other forms of anthropogenic impacts (e.g. landuse change) (Meyer et al.,1999; Gibson et al., 2005). It is almost impossible to precisely predict the impact of climate change to freshwater ecosystems, even in the near future (Malmqvist and Rundle, 2002). People in Taiwan have suffered from strong competition for limited water resources between agricultural, municipal, and industrial water demands right now and hydrologic alteration caused by climate change will make the situation more complicated. Proper actions should immediately be applied to reduce future harm to nature and to human society. More flexible management strategies that could effectively response to both long term and short term flow regime change need to be developed for water resources management. These strategies also need to preserve the potential capacity in adapting streamflow change to maintain healthy aquatic ecosystems.

Summary

This study examines the flow regime alteration in Taiwan and the potential impact to freshwater ecosystems since 1961. The annual extreme water conditions, frequency and duration of the flood and drought events, rising rate and hydrograph reversal reveal more alteration from the IHA analysis by using current available historical data. Unlike using GCMs to project future climate scenarios, the results show what kind of hydrologic changes are current happening in a full range of flow regime type analysis. The potential threat caused by flow regime alteration can be analyzed as precautionary information for water resources and aquatic ecosystems management.

It is important that policy makers and water resources managers recognize the potential impact to freshwater ecosystems caused by changing climate and develop prompt strategies to maintain healthy aquatic ecosystems that will preserve their ability to adapt to the changing climate. Engineers and ecologists need to collaborate for better defining the influence of hydrologic alteration to aquatic ecosystems. New polices and water resources management strategies need to reduce anthropogenic influence and climate changing effects in a river system to sustain a healthy freshwater ecosystem.

FEMA Flood Map Accuracy

David R. Maidment[1]

ABSTRACT

FEMA is completing $1 billion 5-year program to modernize its flood insurance rate maps and convert them to digital form. At the request of FEMA, the National Academies of Science and Engineering have established a Committee on FEMA Flood Maps to review the accuracy of these maps and to recommend cost-effective improvements to them. The Committee's report "Mapping the Zone: Improving Flood Map Accuracy" was released in January 2009. The Committee examined the relative effects of accuracy of hydrologic, hydraulic and terrain information on riverine flood maps, the factors affecting the accuracy of coastal flood mapping, and the costs and benefits of various levels of detail of flood mapping and modeling, using case studies set in North Carolina. This paper focuses on the riverine flood map accuracy portion of the report, and concludes that accuracy of the terrain data is the most important factor influencing riverine flood map accuracy.

INTRODUCTION

From 2003 to 2008, the Federal Emergency Management Agency (FEMA) conducted a Map Modernization program. The goal of this program was to upgrade and convert to digital form the Flood Insurance Rate Maps of the nation. The budget for this effort was $200 million per year, or $1 billion total in federal funds. Many state and local communities contributed additional matching funds for improved base map input data and flood modeling. During these years, this was the nation's largest investment in new hydrologic information, and it spawned new innovations in automated hydrology and hydraulics and in Lidar measurement of land surface terrain.

---

[1] This paper summarizes a report of National Research Council Committee on FEMA Flood Maps, of which the author served as Chairman. The other members of the Committee were David S. Brookshire, J. William Brown, John Dorman, Gerald E. Galloway, Bisher Imam, Wendy Lathrop, David Maune, Burrell E. Montz, Spencer Rogers, Karen L. Schuckman, Y. Peter Sheng and Juan B. Valdes. The NRC Study Director was Anne Linn. The author wishes to acknowledge the contribution of these colleagues to the Committee's study and conclusions.

As the program evolved, it became clear that the original goal of achieving complete digital flood map coverage of the nation could not be accomplished within the existing budget, and there were concerns about the quality of some of the digital flood maps being produced. This led to a "mid-course adjustment" (FEMA, 2006), during which the mapping goal was changed to ensure that 92% of the nation's population and 65% of the land area would have a modernized map. In addition, more formal procedures were introduced to ensure that the floodplain boundaries match available topography within a tolerable error, and that adequate engineering studies underlie flood maps. As of March 31, 2008, 21% of the population had a flood map meeting those standards, and new maps continue to be produced. Figure 1 shows a typical riverine flood map. Zone A is the Special Flood Hazard Area within the 100 year floodplain, while Zone X is outside the 100 year floodplain but inside the 500 year floodplain.

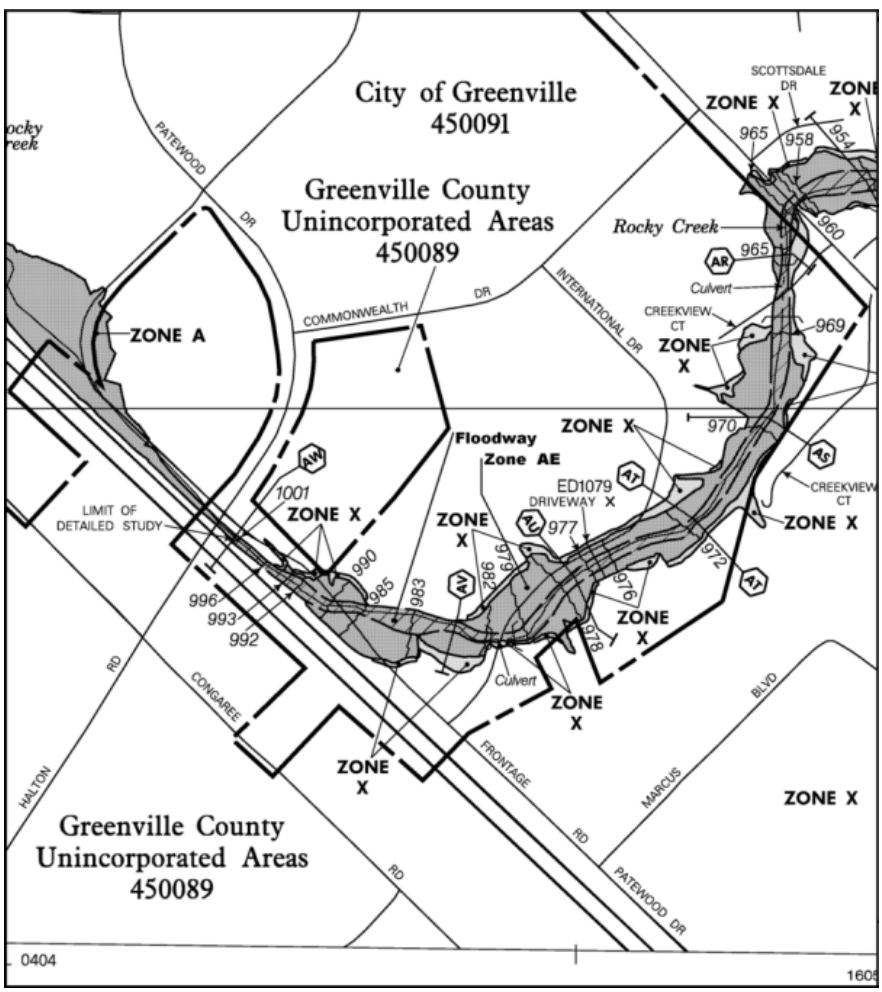

Figure 1. A portion of a floodplan map for Greenville, SC.

FEMA flood maps are produced to support identification of properties to be covered under the National Flood Insurance Program. Since the NFIP does not operate on federal lands, this means that about 1 million of the nation's 4 million miles of rivers and streams are not covered under this program. In addition, about 60,000 miles of coastlines need flood maps.

FEMA and NOAA commissioned a study conducted by the National Academies to examine flood map accuracy, and to make recommendations for its improvement. While the Committee's Report (NRC, 2009) also covers coastal flood mapping, economic analysis of mapping alternatives, and risk communication, this paper focuses on the portion of the Committee's report dealing with the effects of accuracy of hydrologic, hydraulic and terrain information on riverine flood map accuracy. Coastal flood mapping is more complicated than riverine flood mapping, because coastal mapping is more dependent on predictive models of flood storm surge and wave action, and less on observed data on historical floods.

RIVERINE FLOOD MAP ACCURACY

A continual challenge for FEMA Map Modernization is how investment in flood mapping can be matched to the degree of flood risk in the floodplain area. Several alternative mapping methods are available:

- *Detailed* studies in which extensive land surveying of structures is combined with accurate terrain information measured by lidar or aerial photogrammetry and hydraulic models are constructed;
- *Limited Detailed* studies, similar to detailed studies but less land surveying information is acquired;
- *Redelineation* studies where the base flood elevation from an existing study is remapped onto new terrain information;
- *Approximate* studies where flood maps are constructed using best available data.

The costs of these studies may vary from $250 per stream mile for an approximate study to $25,000 per stream mile for a detailed study, but are typically in the range of $900 to $13,500 per stream mile.

It is understood that while the edge of the floodplain boundary is drawn as a line, it actually represents a zone of some unknown width because the base flood elevation used to create the floodplain boundary is not known precisely, and neither is the terrain or land surface representation upon which the floodplain is drawn. The

relative role of uncertainties in hydrology, hydraulics and terrain information contributing to uncertainties in floodplain mapping has been unclear.

There are two aspects of riverine flood map accuracy – the *base flood elevation*, which is the elevation of the water surface during a flood event equaled or exceeded on average once every 100 years, and the *special flood hazard area*, which is the area of inundation around a stream, river or coastline resulting from this flood event. Both of these items are important. The base flood elevation is used in floodplain regulations by local communities who limit construction so that first floor elevation of structures is at or above the base flood elevation. The special flood hazard area is used by insurance companies to define which properties are eligible or required to have federal flood insurance under the National Flood Insurance Program.

CASE STUDIES

In an attempt to quantify the effect of uncertainties on flood mapping and flood risk, the Committee collaborated with the North Carolina Floodplain Mapping Program to conduct several case studies of riverine flood mapping in North Carolina. As shown in Figure 2, representative counties and river reaches were chosen from mountainous Western North Carolina (City of Asheville and Buncombe County), from the hilly Piedmont (City of Charlotte and Mecklenburg County), and from the flat coastal plain (Pasquotank and Hertford Counties for economic and hydraulic studies, respectively.

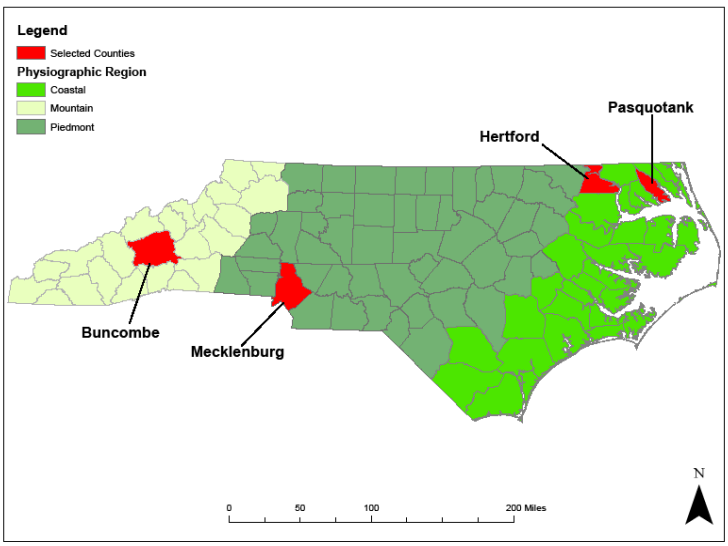

Figure 2. Location of flood mapping case studies in North Carolina. Source: NCFMP (2009). Used with permission.

These studies cover a range of topography and enable detailed study of the effects of alternative choices in floodplain mapping and modeling. A representative river reach from 5 to 7 miles long was selected in each of the three regions. These river reaches were on the Swannanoa River (Mountains), Long Creek (Piedmont), and Ahoskie Creek (Coastal).

UNCERTAINTY IN FLOOD STAGE

The nation has no repository of historical flood inundation maps, and the only place where flood elevation has been measured consistently over a long period of time is at USGS streamflow gaging stations. Flood frequency analysis is normally carried out over the record of annual maximum flood discharges, but the USGS also records the annual maximum flood stage at each gage, regardless of whether it occurred at the same time as the peak discharge or not. Annual maximum flood stages were subjected to frequency analysis at 31 long-term streamgaging sites in North Carolina and Florida. Data from Florida were studied in addition to those in North Carolina to assess whether the pitted landscape and karst terrain in Florida lead to different peak stage uncertainties. The Corps of Engineers HEC-SSP program was used for these analyses, and for each stream gage site, a flood discharge frequency curve and a flood stage frequency curve were generated. The two curves were similar to each other in appearance at all sites.

The HEC-SSP program provides 5% and 95% confidence limits on these extreme value estimates, and from this confidence interval, the sampling uncertainty in the peak flood stage, can be defined. This is approximately equivalent to the standard error of estimate of the base flood elevation because the only difference between the flood stage and the flood elevation is that one is determined with reference to a gage datum and other to a geodetic datum. As shown in Figure 3, there is no discernable pattern in the distribution of these sampling errors either with size of the drainage area, or with topography, or whether the landscape was pitted with sinkholes in karst terrain or not. This is a quite remarkable result because it suggests that there is some underlying unifying mechanism that makes the sampling uncertainty of extreme stage heights consistent across landscape types that otherwise might be considered to have very different flood flow processes.

One gage site has a very large sampling error because of a highly skewed frequency curve there. Leaving aside this site, the average sampling error of extreme flood stages at 30 of the 31 USGS gage sites is approximately 1 foot with a range from 0.3 to 2.4 feet. The results of this stream gage study should be considered representative only of the gage sites studied – it is possible that an exhaustive analysis of the more than 27,000 sites at which the USGS documents peak discharge

data might reveal patterns in the sampling uncertainty of peak stage heights for different landscape types.

Three of the stream gages analyzed lie within the three river reaches used in the flood mapping case studies. For these reaches, detailed flood studies using HEC-RAS models were available, and from these the lateral slope at the edge of the floodplain can be estimated from the HEC-RAS cross-section data. These data showed that a one foot uncertainty in the base flood elevation translates to a horizontal uncertainty of from 8 feet in the mountains to 40 feet in the coastal plain. These estimates are lower bounds on the true uncertainty in the floodplain boundary at ungaged locations where more approximate modeling and mapping methods are used.

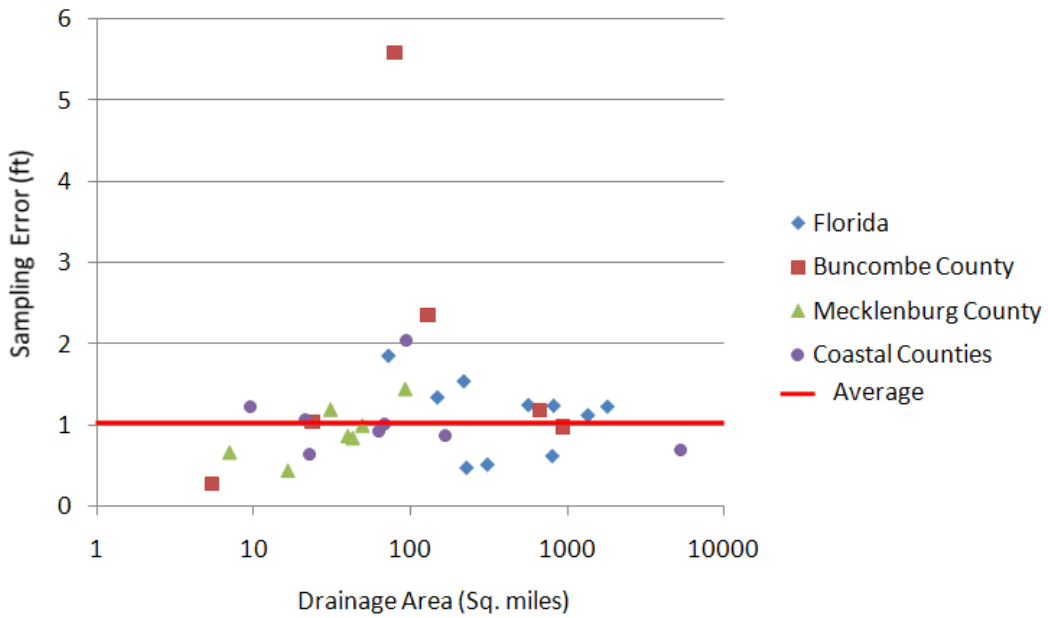

Figure 3. Sampling error in peak stage at 31 gages in North Carolina and Florida. Source: NRC (2009) Reprinted with permission from the National Academy of Sciences, Washington, D.C.

HYDROLOGIC UNCERTAINTY

Three approaches are used to define the peak discharge in FEMA flood mapping studies: rainfall-runoff modeling, flood frequency analysis, and the USGS Regional Regression equations. The latter two methods can be combined by adjusting the regional regression equation results so that they are consistent with the flood frequency results at gage locations. In each of the three study reaches, the sensitivity of the base flood elevation to alternative choices of hydrologic method

was examined. A typical result is shown in Figure 4, which shows the base flood elevation profiles at Long Creek, in Mecklenburg County. The only hydrologic method which produced significant variations in base flood elevation is to take the regional regression equations and choose the discharge at the upper and lower limits (+/- 47% of the estimated flow). This produces an effect of from one to three feet in the base flood elevation.

It is possible that these results are biased by the fact that it is a standard practice in FEMA flood mapping studies to calibrate the results of all methods to the flood frequency curve produced at stream gages, and all three study reaches had a stream gage in them, so this calibration dominated the results and diminished the variation in discharges among alternative methods that might otherwise have resulted.

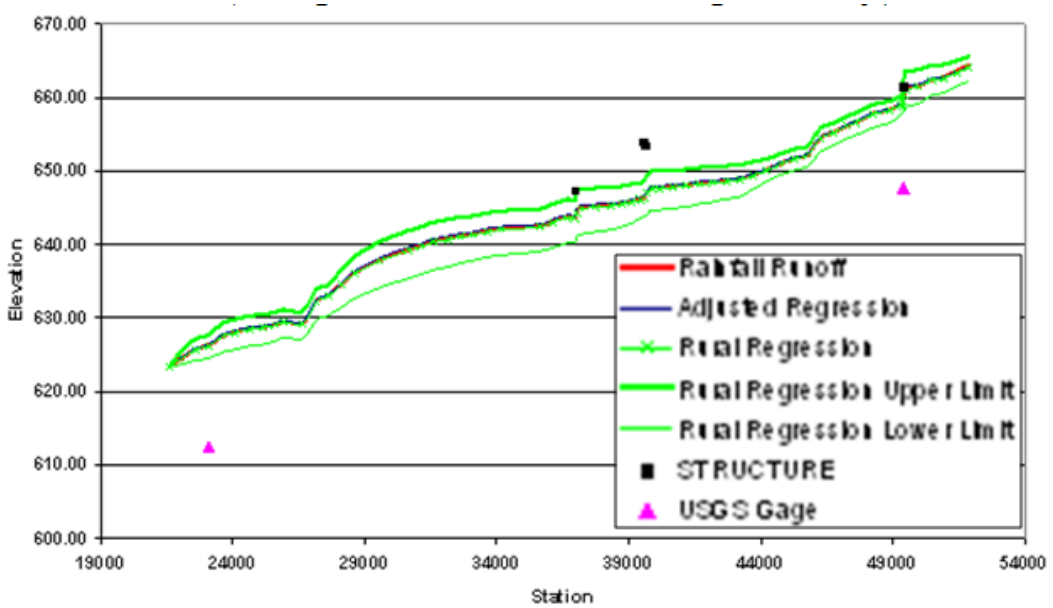

Figure 4. Effect of alternative hydrologic methods on base flood elevation at Long Creek (Mecklenburg County). Source: NCFMP (2009). Used with permission.

HYDRAULIC AND TERRAIN UNCERTAINTY

Similar to the hydrologic studies, several alternative combinations of hydraulic modeling and terrain data were examined. The North Carolina Floodplain Mapping Program has a comprehensive Lidar program for mapping the terrain of the state and these data are available at our study sites. An alternative is to use the 30m Digital Elevation Models available as part of the National Elevation Dataset, which with its associated tagged vector contour data from USGS topographic maps, is used in many Approximate floodplain mapping studies. Similarly, three alternatives were examined for surveyed structure information: full surveys as used in Detailed

Studies, limited surveys as used in the North Carolina Limited Detailed Studies, and no surveys in a method called Limited Detailed Studies National approach. Figure 5 shows the effects of these alternatives at Long Creek. There is little difference among any of the alternatives (a standard deviation of 1 to 3 feet), except for the alternative of approximate modeling on the National Elevation Dataset, which here produces a base flood elevation on average 21 feet higher than that produced by a Detailed Study. This large systematic discrepancy is produced because of a similar difference between the mean elevation of the Lidar and NED data at Long Creek and because of differences in the location of the stream centerline between these two data sources.

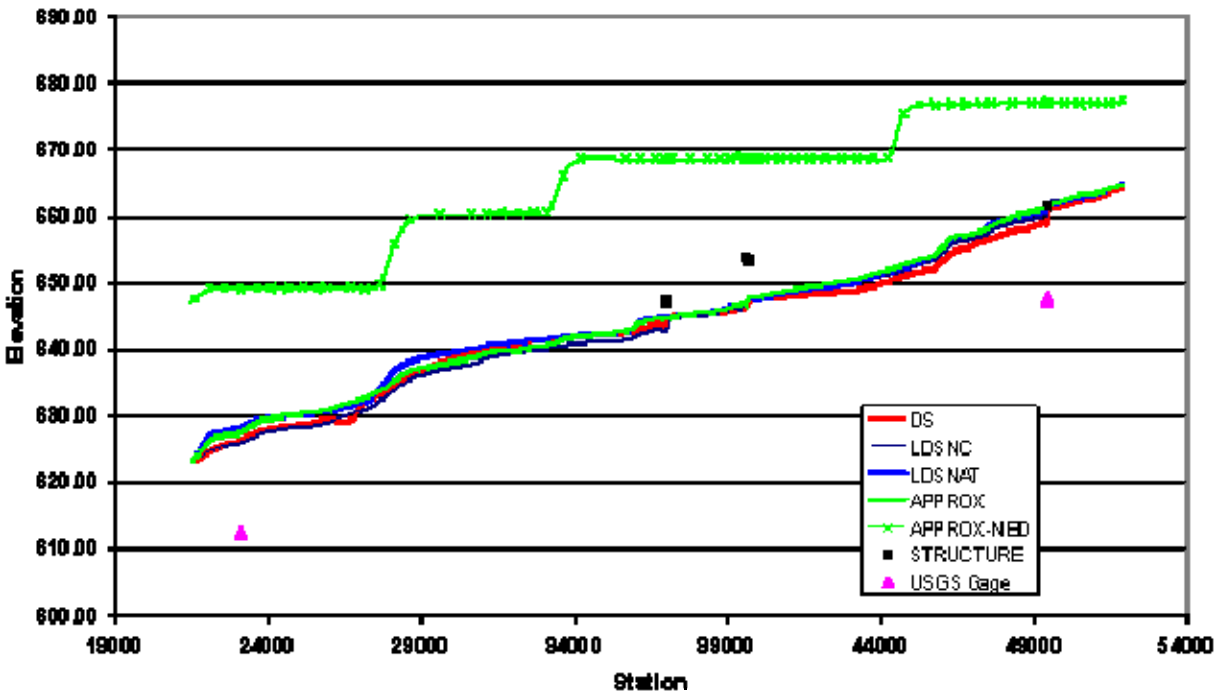

Figure 5. Effect of hydraulic and terrain data alternatives on base flood elevation at Long Creek. Source: NCFMP (2009). Used with permission.

Differences in elevation information between Lidar and the NED in the floodplain zone of our three study reaches are large, as illustrated in Table 1, which shows that besides the large systematic difference at Long Creek, there are random differences of the order of tens of feet at all locations. These differences are much larger than any differences induced by variations in hydrologic and hydraulic methods at these locations.

Stream	Mean (feet)	Standard Deviation (feet)	Minimum (feet)	Maximum (feet)
Ahoskie Creek (Coastal Plain)	0.5	3.9	34.8	−25.3
Long Creek (Piedmont)	14.7	15.6	81.5	−46.0
Swannanoa River (Mountains)	−2.0	17.5	89.7	−139.3

Table 1. Differences in elevation information (NED-Lidar) in the three study reaches. Source: NRC (2009) Reprinted with permission from the National Academy of Sciences, Washington, D.C.

DISCUSSION

The relative role of hydrologic, hydraulic and terrain information accuracy on the accuracy of base flood elevation and floodplain mapping has long been uncertain. From the viewpoint of the hydrologist, the size of floods that nature can generate seems so uncertain that it is hard to conceive of why this is not the dominant uncertainty in the picture. Terrain information seems so fixed and immutable, that it cannot be uncertain. It turns out, however, that the National Elevation Dataset has an elevation error when compared to survey bench marks at the same locations of 14.9 feet at the 95% confidence level (NRC, 2007). Thus, the statistical variations between the National Elevation Dataset and Lidar mapping of the same terrain shown in Table 1 are not unexpected. It might also be argued that it is not the absolute elevation compared to a geodetic datum that matters but rather the height of the water relative to the elevation of the channel in which it flows. The problem with this approach is that base flood elevations, as shown in Figures 4 and 5, are established with respect to a geodetic datum (the North American Vertical Datum of 1988), and these elevations govern all subsequent land development in the area, which is also referenced to this geodetic datum.

The result of this study (NRC, 2009) confirms in greater detail the insight that was presented in a previous study of the accuracy of flood map input information (NRC, 2007). That study concluded the average USGS topographic map was completed in 1970, that the terrain information in the 30m National Elevation Dataset are an order of magnitude less accurate than is called for by FEMA's standards for terrain data accuracy, and thus that a remapping of the nation using Lidar is called for. This proposed program is termed "Elevation for the

Nation", by analogy with the existing "Imagery for the Nation" program for updating digital orthophoto coverage of the United States. As Lidar from existing mapping programs like the one in North Carolina, are incorporated into the National Elevation Dataset, its accuracy will improve.

CONCLUSIONS

The key to accuracy of base flood elevation is accurate data on the elevation of the land surface that underlies the flooded landscape. The 30m National Elevation Dataset is about an order of magnitude less accurate than is needed for floodplain mapping. New terrain mapping of the nation is needed. When Lidar data are available, the relative effects of hydrologic, hydraulic and terrain data are much more balanced, with variations within reasonable ranges producing effects on the base flood elevation of from one to three feet. A lower bound on the uncertainty of the base flood elevation of approximately one foot is established by analysis of extreme stage heights measured at gages in North Carolina and Florida. This translates to a horizontal uncertainty in the location of the floodplain boundary of from 8 feet in mountains to approximately 40 feet in a flat coastal plain area. There is no discernable pattern in the distribution of these sampling errors either with size of the drainage area, or with topography, or whether the landscape was pitted with sinkholes in karst terrain or not.

Abstract. A multi-objective optimization technique, Non-dominated Sorting Genetic Algorithm (NSGA-II), is coupled with a semi-distributed hydrological model, Soil and Water Assessment Tool (SWAT) with the objective of generating a set of non-dominated solutions. The model is formulated to optimize two conflicting objectives: the cost of structural Best Management Practices (BMPs) and the treatment goal. The cost of the BMPs is the function of type, size, and location of BMPs; whereas, the treatment goal considered is the reduction in annual sediment load the watershed outlet. Structural BMPs included in the modeling include detention ponds, infiltration type detention ponds, parallel terraces, filter strips, and grade stabilization structures which are applicable in agricultural watersheds. The model is demonstrated on Silver Creek watershed, a sub watershed of Lower Kaskaskia in Illinois. SWAT delineates watershed into 159 subbasins and are considered as potential locations of BMPs. The model came up with a Pareto front, which comprises a set of non-dominated solutions, a set of least cost solutions for different level of annual sediment load reduction.

Keywords. NSGA-II, watershed modeling, treatment goals, SWAT, Silver Creek, BMPs.

Introduction

Structural best management practices (BMPs) are often used to control runoff, sediments and nutrients, both in urban and rural or agricultural watersheds. Structural BMPs generally applicable in agricultural watersheds include detention and retention basins, filter strips, grade stabilization structures, grassed waterways, and field terraces. The current practice is to design an individual BMP structure where required on-site. Few recent studies have pointed out that the on-site practice could lead to the implementation of many BMPs in the watershed, and still could not assure that the

treatment goals at the watershed outlet are achieved. An on-site approach is not particularly effective in collectively reducing watershed-wide peak flows, and can potentially increase peak flow rates for detention-based systems by negatively impacting each other (Emerson et al., 2005). Harrell and Ranjithan (2003) emphasized that fewer regional basins can be implemented in place of many on-site basins to achieve the same treatment goals when they are implemented at a watershed scale. To address the watershed scale design of BMPs, Kaini et al. (2008) developed a single objective optimal control model which can optimize the cost of BMPs for user specified level of annual sediment load and peak flow reduction. In this study, a multi-objective optimization model is formulated which can find a set of optimal or near optimal solutions for various level of treatment goals. The multi-objective model generates various cost effective solutions for different level of water quality goal at the same time. This can serve as a valuable tool in formulating a watershed management plan.

A multi-objective optimal control model (OCM) is developed by coupling a semi-distributed hydrological model, the Soil and Water Assessment Tool (SWAT), with the contemporary multi-objective algorithm, Non-Dominated Sorting Genetic Algorithm-II (NSGA-II), to identify the optimal designs (sizes, types, and locations) of structural BMPs for varying level of annual sediment load reduction goals at a watershed-scale. A multi-objective optimal control model (MO-OCM) has been developed which optimizes the cost of BMPs (by selecting type, size, and location) and the environmental goal (e.g.annual sediment load) simultaneously.

Problem Formulation

The current problem can be stated as the design of BMPs (type, size and location) at a watershed scale that:

Minimize: Total cost of BMPs
Annual sediment load at the watershed outlet

Subject to the following constraints:

(1) Water balance in the watershed
(2) BMP size constraints
(3) Landuse constraints

Mathematically, this can be expressed as

Minimize:

$$1)\ BMPC = \sum_i \sum_j BMPC_{ij}$$

$$2)\ SedL_{annual}$$

Subject to:

$$\sum_{k=1}^{n} A_k \le A_{\max}$$

$$A_k = A_{k,sb} \times fr$$

$$Sj \leqslant Sj_{\max}$$
$$SedL_{\max} = g_2(x,u,t)$$

where, *BMPC* is the total cost of BMPs implemented in a watershed. $BMPC_{ij}$ is the cost of a *j* type of BMP implemented in a subbasin *i*. A_k is the area of the pond in subbasin *k* whose value lies within the user-defined maximum and minimum limits, A_{max} is the maximum limit of the total pond area assigned to the watershed, $A_{k,sb}$ is the area of subbasin *k*, and *fr* is the fraction of the subbasin area that drains to the pond. *Sj* is the size of *j* type of BMP and Sj_{max} is the maximum size limit of the corresponding BMP. The final two relationships represent simulation constraints, where *g* generally represents all pertinent hydrologic and hydraulic relationships, as a function of dependent (state) and independent (decision) variables, *x* and *u,* respectively, and time, *t*. BMPs are not implemented in a subbasin where the dominated land use is either forest or water body.

Silver Creek Watershed

The model is developed and applied to the 1,189 km^2 (459 sq. miles) Silver Creek watershed (Figure 1). The primary landuses in the watershed are cropland, grassland, and forest; however, the area is currently experiencing moderate to high levels of urbanization (Kaini et al., 2008).

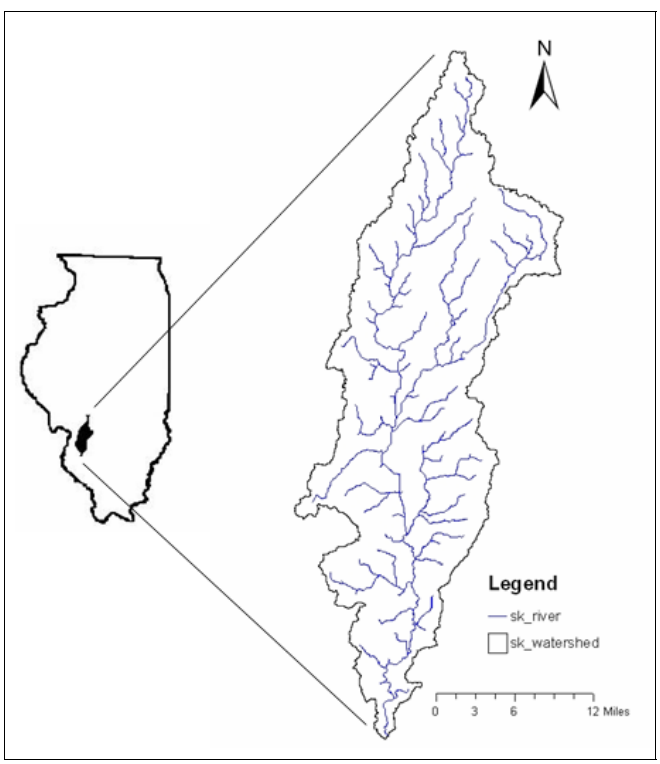

Figure 1 Location of Silver Creek Watershed, Illinois

The basic data required to run SWAT were obtained from various government agencies. Climate data for the study area, which include the daily precipitation and

maximum and minimum daily temperatures, were obtained from the National Climate Data Center (NCDC). A 30-m resolution Digital Elevation Model (DEM) and hydrologic data (daily flow) for the hydrological station USGS-05594800, located near Freeburg (St Clair County) in Illinois were obtained from US Geological Survey (USGS). The digital soil map and the land use map were obtained from the Natural Resources Conservation Service (NRCS).

SWAT

SWAT is a physically based, spatially-distributed, continuous-time watershed model that operates on an ArcView GIS (i.e., AVSWAT) platform. It was developed by the US Department of Agriculture (USDA) to predict the impact of land management practices on water, sediment and agricultural chemical yields in large complex watersheds with varying soils, land use and management conditions over long periods of time (Neitsch et al., 2002). The main purpose of SWAT is the computation of runoff, sediment and nutrient loads from a watershed. SWAT requires specific information about climate, topography, soil properties, land use and management of a watershed for simulation (Neitsch et al., 2002). To account for the spatial heterogeneity of climate, topography, land use and soil, SWAT delineates the watershed into spatially defined sub basins by using Digital Elevation Model (DEM). Each subbasin is further sub-divided into hydrologic response units (HRUs). A HRU is the total area in a subbasin with a particular land-use, management and soil type. SWAT simulates the surface and subsurface flow accounting for rainfall/snowfall and snow melt and sub surface flow processes. SWAT employs Modified Universal Soil Loss Equation (MUSLE) to evaluate sediment load from HRUs.

Calibration of SWAT

SWAT is calibrated for the Silver Creek watershed using mean daily flow and daily sediment load, observed at station USGS 05594800, located near Freeberg, Illinois. The station lies just upstream of the Silver Creek River and Kaskaskia River confluence. SWAT is simulated for the period of 1990 through 1996, and calibration is performed for the period of 1992 through 1994. Simulation from 1990 through 1991 is considered as a warm-up period to reduce the initial condition impacts, whereas the simulation from 1995 through 1996 is used for verification. Daily measured sediment data were available only for 134 days for calibration within the calibration period (1/1/1992 to 12/31/1994) and 113 days of data were available for validation within the validation period (1/1/1995 to 12/31/1996). Therefore, statistical evaluations of sediment calibration are based on these limited data. Only the data of the particular days where the measured data were available, were used. This is one of the major data limitations in model calibration. Considering the complexity due to large number of parameters in a distributed model with 159 subbasins, and with reference to Neitsch et al. (2002), Muleta and Nicklow (2005) and Bekele and Nicklow (2007), only 19 important parameters for stream flow and 7 important parameters for sediment load are considered in calibration.

A genetic algorithm is coupled with SWAT to set up an automatic calibration model. The objective function of the calibration routine is the Root Mean Square Error (RMSE) between the observed and the simulated flow. The objective of the

calibration is to search a set of parameter values having minimum RMSE between the mean daily observed and the simulated output.

The results obtained here, Nash and Sutcliffe Efficiency (NSE) equal to 0.703 for flow calibration and 0.826 for flow validation based on daily data, are higher than the generally acceptable minimum NSE value (0.5) for flow calibration (Moriasi et al., 2007). NSE values for sediment calibration and validation obtained are 0.502 and 0.512, respectively, which are within the acceptable limits.

Structural BMPs

Detention pond, filter strip, parallel terrace and grade stabilization structure are implemented in the model as solutions to reduce sediment load from the watershed. Different sets of SWAT model parameters and their values are identified to represent these BMPs (Bracmort et al., 2006; Kaini et al., 2008). A detention pond is employed by adjusting appropriate parameters including the pond area, volume, subbasin area draining to the pond, and the permeability coefficient in the pond subroutine. A pond reduces suspended sediments, metals and dissolved nutrients by sedimentation and biological processes. In this study, the infiltration type of detention pond is represented with the bottom permeability coefficient (K) of 1.0 mm/hr where as normal detention pond is represented with the value of K equal to 0.0 mm/hr.
A filter strip, also known as field border, is a uniformly graded and densely vegetated area at the border of the field where excessive sheet and rill erosion is likely to occur. A filter strip is represented by the width of the edge of field filter strip (FILTERW). The value of FILTERW is 0.0 m for no filter strip and 5.0 m if a filter strip is applied (Bracmort et al., 2006). The trapping efficiency of the strip is a function of the filter width (Neitsch et al., 2002).

Terraces are formed by earthen embankments or channels or a combination of the two to reduce the sheet and rill erosion, peak flow, retain moisture and reform the farm to increase the productivity. Bracmort et al. (2006) identified parameters initial SCS runoff curve number for moisture condition II (CN2), USLE equation support practice factor (USLE_P) and average slope length (SLSUBBSN) to represent the effects of parallel terrace in a HRU scale in SWAT. Neitsch et al. (2002) recommends the adjustment of CN2 for parallel terraces. USLE_P for the terrace implemented case is recommended to be 0.4 (Bracmort et al., 2006), whereas the initial value is 1.0 (without parallel terrace). To represent the parallel terrace, SLSUBBSN is defined as (ASAE, 2003):

$$SLSUBBSN = (X \times S + Y)\frac{100}{S}$$

where, X and Y are constants. X depends on location of the watershed; it is 0.21 for the watershed considered (ASAE, 2003). The value of Y depends on the soil erodibility, cropping system and management and the value varies from 0.3 to 1.2 (ASAE, 2003), with lower values for more erodible soil. It is assumed to be 0.9 for the case considered.

A grade stabilization structure is a structure designed to reduce the channel grade in natural or constructed water course. It reduces or prevents the erosion due to higher grade on the channel bed. This practice is applicable where structures are required to prevent head cutting or stabilize gully erosion and also where the intersecting channels have different elevations. They may be vertical drop, weir spillways, chutes, or pipe drop structures and may be made of reinforced concrete, steel sheet piling, concrete block, riprap, corrugated metal, plastic, or concrete pipe, depending on-site conditions. The structure is represented by a CH_EROD value equal to zero and by reducing the average slope of a subbasin main channel (CH_S2) by 10%.

Non-dominated Sorting Genetic Algorithm (NSGA-II)

Non-dominated Sorting Genetic Algorithm (NSGA-II), developed by Deb et al. (2002), is an improved version of the original NSGA (Srinivas and Deb, 1994). NSGA-II is recognized as one of the high-performing contemporary multi-objective EAs, and has been successfully applied in various disciplines (Reed et al., 2003). Deb et al. (2002) demonstrated that NSGA-II outperformed two other contemporary multi-objective evolutionary algorithms, Strength Pareto Evolutionary Algorithm (SPEA) and Pareto Achieved Evolutionary Algorithm (PAES), in terms of finding a diverse set of Pareto optimal solutions close to the true Pareto front in a number of test functions. The stepwise procedure of NSGA-II, as outlined by Deb (2001), is as follows:

(a) An initial population of P is randomly generated which is considered as the set of parent solutions (P_t) with population size N.

(b) The offspring population, Q_t, with population size N, is generated from P_t solutions applying GA operation. The GA operation includes crowded tournament selection, crossover and mutation operators.

(c) Parent and offspring solutions are combined to create combined population of R_t of population size 2N.

(d) Combined solutions (R_t) are then sorted into different non-dominated fronts (F_i)

(e) The new generation solutions are selected starting from the best Non-dominated fronts until the N number of solutions are found. Since R_t contains 2N solutions, all the solutions will not be accommodated in the new generation.

(f) All fronts which are not accommodated in the new generation are simply deleted.

(g) In the last allowed front, it may have more than required solutions. Solutions are selected based on their crowding distance. The crowding distance criteria make sure that the most diverse solutions are selected from the last front.

(h) The step (b) through (g) is repeated until the termination criterion is met.

NSGA-II assures elitism by including the best parent solutions and best offspring solutions obtained in a population, whereas the diversity of solutions is preserved by the crowding tournament selection operator. The operator, on the basis of non-domination ranking and local crowding distance, selects solutions in the non-

domination ranking. The crowding distance is the average distance between an individual solution and those solutions nearest to it in the objective space (Deb, 2001). Binary tournament selection and uniform crossover are considered as genetic operators because the decision variables in the problem considered are represented by integers.

Methodology

A multi-objective OCM is developed by coupling SWAT with NSGA-II to generate alternate designs of BMPs at a watershed scale. SWAT is run for a 2 years, from 2001 through 2002. SWAT delineates the watershed into 159 subbasins, and each subbasin is considered as a HRU. Types of structural BMPs considered in the study are detention ponds, infiltration ponds, filter strips, grade stabilization structures and parallel terraces. The NSGA-II operation starts with a random generation of an initial set of solutions which consists of a combination of different BMPs located in different sub basins. The decision parameters include the area of detention pond, part of subbasin area draining to the detention pond, permeability coefficient of the pond bottom, size of filter strip, subbasin length and curve number (for terracing), and height of the grade stabilization structure. Two objective functions considered are the total cost of the BMPs implemented and the annual sediment load at the watershed outlet. The schematic representation of optimal control model is presented in Figure 2.

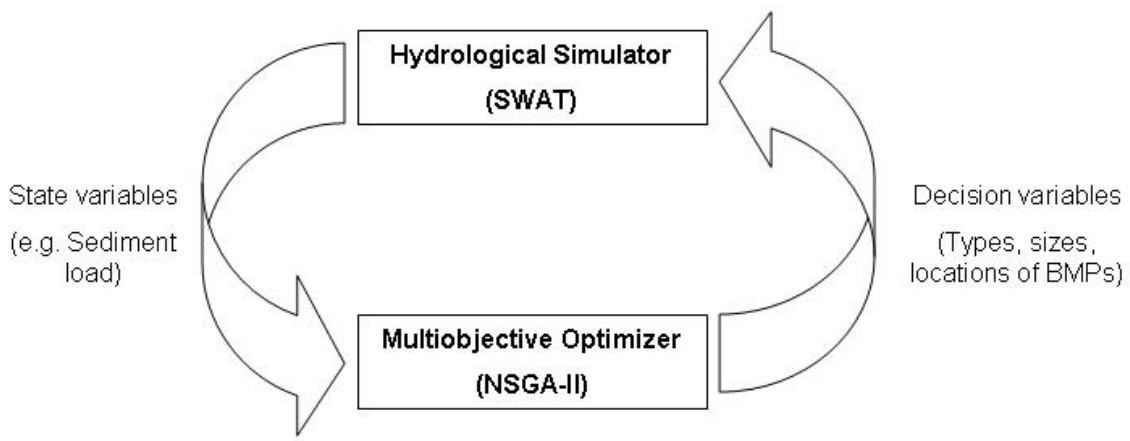

Figure 2 Schematic representation of Optimal Control Model

The costs of BMPs are evaluated based on the unit costs presented in Table 1.

Table 1 Unit Costs of BMPs

SN	BMP	Unit	Unit Cost (US$)
1	Detention pond	Acre- ft	500.00
2	Filter strip	Acre	250.00
3	Parallel terrace	Acre	500.00
4	Grade stabilization structure	Number	6000.00

Results and Discussion

As an example, the OCM is run with a population of 50 chromosomes and for the maximum generation of 50. Figure 3 shows the results found in the 20th and 50th generation. The default value of annual sediment load at the watershed outlet is 48177 tons. With the implementation of BMPs, the model found the set of solutions for various levels of sediment reduction criteria. The maximum reduction of 18% was found with the cost of 77 million USD which corresponds to the implementation of 119 detention ponds, 79 filter strips, 71 parallel terraces, and 44 grade stabilization structures. The minimum reduction (9%) corresponds to the cost of 42 million USD which requires 76 detention ponds, 52 filter strips, 47 parallel terraces, and 44 grade stabilization structures. The results show that the Pareto front should further extend on either side of the curve. By extending towards higher values on y-axis, it should hit the solutions with much lower cost and higher sediment load; and similarly on the other extent of the curve, solutions with further reduced sediment loads can be expected.

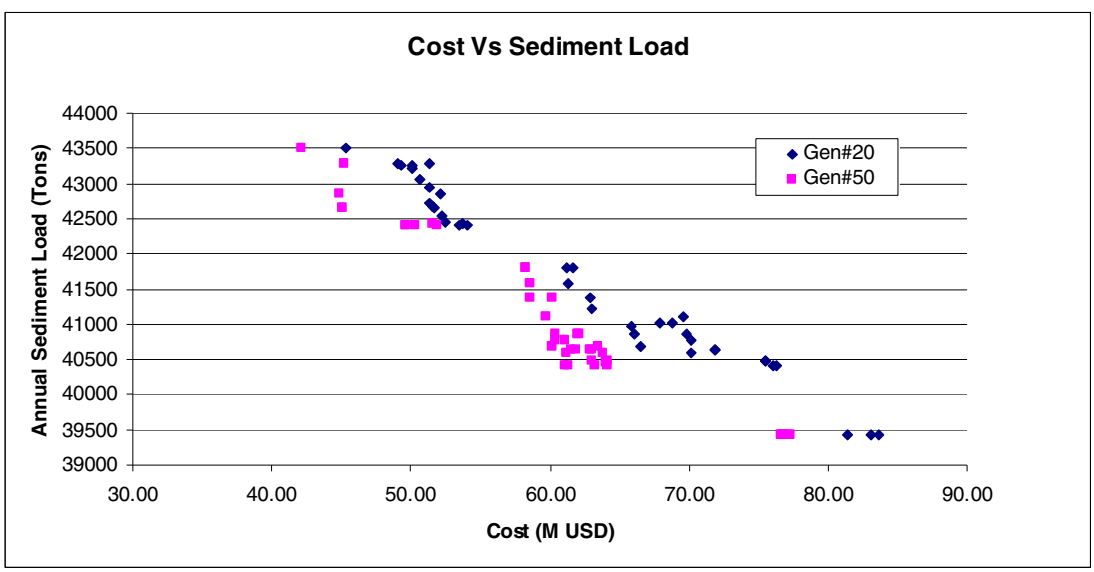

Figure 3 Pareto Curve for 20th and 50th generation

Conclusion

The results on Figure 3 shows the trend of the Pareto curve, but these results may not represent true optimal solutions. It can be expected that the curve can extend on either side: reduction on cost and reduction on sediment load. The future work will further improve the algorithm as well increase the number of population and generation. The costs are based on the unit costs for the example watershed considered. Therefore the results are site specific; however, with the specific model data and unit costs, OCM can be applied to other similar watersheds.

Hardening a Great and Growing City's Water Supply

Abstract

Cities across the West face the threat of dwindling water supplies. Issues such as climate change, competing supplies, and litigation threaten water availability for municipal uses. In Colorado, where approximately 86 percent of water is used for agriculture (CFWE 2005) and the system of administration is prior appropriation, adequate water supply in an increasingly competitive market is no longer a certainty. Many municipalities whose systems are based on junior water rights have been forced to turn to innovative – and expensive – projects to develop the water supplies of the future.

The City of Aurora, Colorado is a suburb to Denver and the third largest city in the state, with a 2008 population of nearly 312,000. For Aurora Water, meeting the increased thirst of a burgeoning city is a challenge. Continued growth and a possibly dwindling water supply have necessitated an evaluation of the city's water infrastructure and "out-of-the-box" planning to ensure that a reliable water supply is available for the future. In 2002, low rainfall and runoff brought the system's vulnerability to attention. With seemingly no water available to increase storage levels, reservoir levels fell to 25 percent full in March 2003, well below the desired minimum level and an adequate supply for only six months of indoor use in the City. This situation made perfectly clear the need for guaranteed reliability in the face of continued pressure on available water supplies.

To meet these needs and enhance the ability to protect against prolonged drought many projects are being undertaken. The Prairie Waters Project, slated for completion in mid-2010, is an example of insightful planning that is taking place in Aurora. When completed, this project will deliver reusable water from approximately 35 miles away, pumping the supply back to the City for treatment and incorporation in the City's water system. An additional effort being undertaken is the acquisition of senior agricultural water rights along the South Platte River for increased water supply. The City is also purchasing and negotiating with several mining companies to develop large sub-surface open water storage reservoirs to improve operational flexibility and increase the ability to capture every drop of reusable water before it is permanently lost from the system. This paper will examine these projects and other ways Aurora is "hardening" its water supply to protect existing users and provide for future citizens.

Colorado is unique among western states because of its large water exports to other states. Because the Rocky Mountains are situated in the center of the state, Colorado receives significant amounts of precipitation which is then used in-state and exported based on a series of Interstate Compacts as shown in Figure 1. The Rocky Mountains also serve as the Continental Divide splitting the eastern and western United States hydrologically. To further complicate issues more than 80% of the states population lives on the eastern, "Front Range" side of the mountains (State of Colorado, 2009), and the greatest water supply is located on the western side of the mountains.

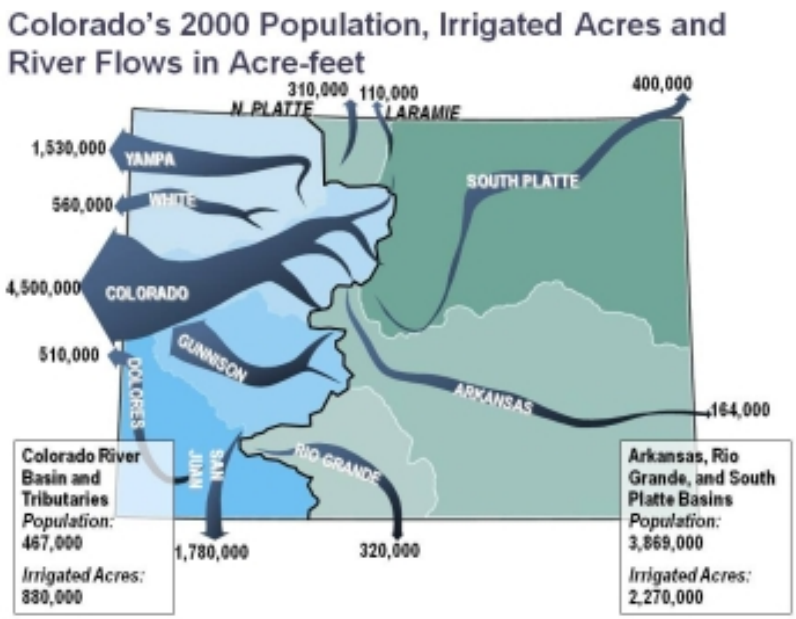

Figure 1 – Colorado Water Exports (CWCB 2009)

To maintain a prosperous and thriving population it has become necessary to develop and maintain a vast water distribution system. Beginning in the 1850s a water system was developed to capture, divert, and use the water. By the mid- to late-1800s, the prior appropriation system had been developed to manage the ownership and use of water in Colorado. The prior appropriation doctrine in its simplest form is that the first person to divert and use the water has a right to continued use of the resource into the future. It is also defined by the colloquial sayings, "Use it or lose it" and "First in time, first in right." Over time and with increasing technological improvements and demand for water, the prior appropriation system has evolved and increased in complexity.

City of Aurora Water Supply

The City of Aurora is the third largest city in the state of Colorado, behind Denver and Colorado Springs, with a 2008 population of about 312,000 people. The city has had difficulties with water from the start. Formed in the 1890's and founded in 1928, the City of Aurora is relatively new compared to the City of Denver which was founded in 1861. Beginning in the early 1890's the suburb had inadequate water supplies for its residents.

Aurora was heavily reliant on Denver for water supply. This changed when in the 1950s, Aurora began its major quests to develop independent water supplies.

Since its creation, but especially beginning in the 1950s, Aurora has striven to maintain an adequate and independent water supply to support its development and population. This has included the development of new water rights and reservoirs as well as the purchase and transfer of existing water rights. Beginning in the 1960s, the City developed a series of reservoirs including Homestake, Spinney Mountain, and Strontia Springs (Mehls et al., 1985). During this period the City also acquired water rights in the South Park area, upstream of Spinney Mountain Reservoir. Figure 2 below shows a simplified schematic of Aurora's water supply system.

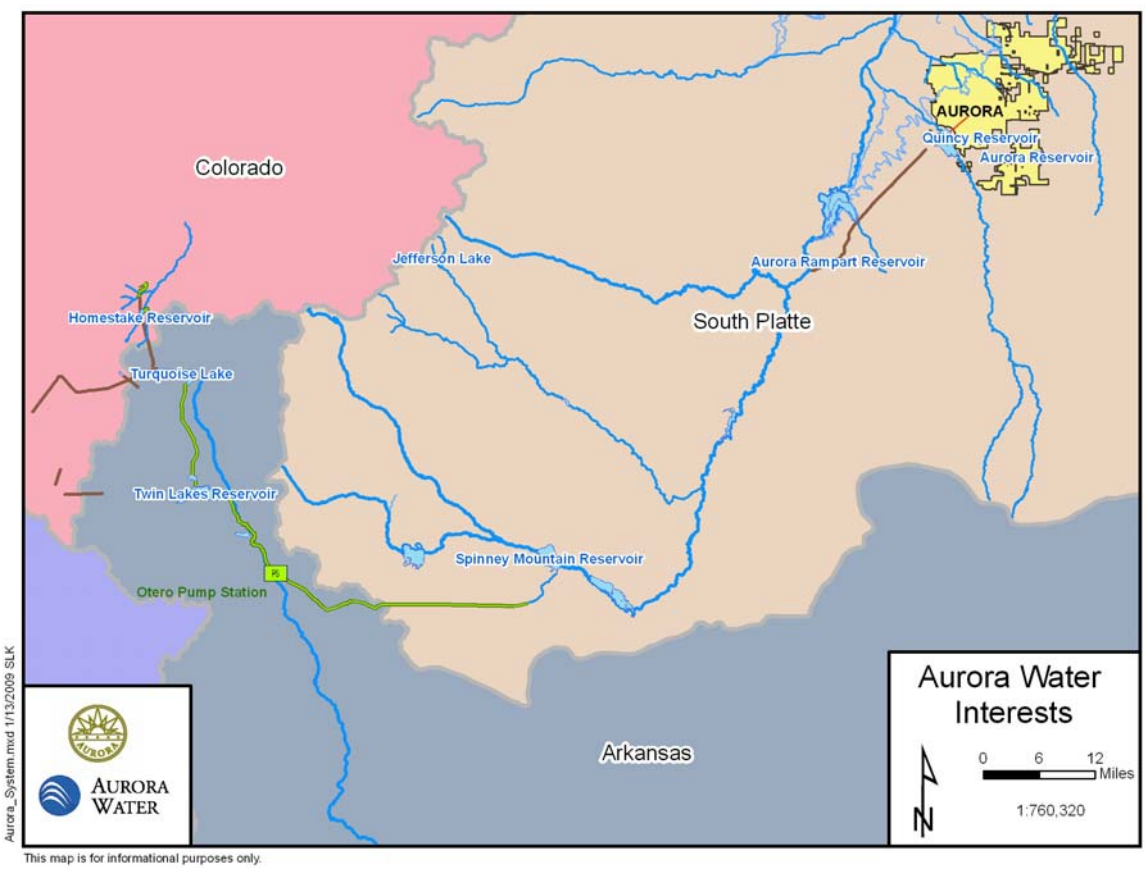

Figure 2 – Aurora Water System Schematic

With the development of additional water rights and storage the City helped ease some of the problems of the past by ensuring a reliable water supply. However, in 2002 one of the worst droughts in recent history occurred. This caused nearly all water providers to struggle to meet the needs of their citizens while also preserving water in storage to protect against a worsening drought. During this period the City of Aurora had its water reservoir storage plunge to 37,576 acre-feet or 25% of its total capacity. This volume of water represented only six months of supply for indoor water uses in the City. Once again, the City found itself in a position where water could dictate its future development

As a result of this drought and the realization of what a multiple year drought could do, the City began to consider ways to increase their water portfolio and "harden" the system by ensuring that all water the City owned could be used. This effort has led to new and novel thinking that has helped keep the City of Aurora active in pursuing its mission to "enhance and protect the quality of life for Aurora citizens" (Aurora Water, 2009).

Hardening the City's Water Supply

To improve the reliability of the City's water supply several methods have been applied. A multi-faceted approach has appeared to be the most likely for success because of the changing conditions for the City, water in Colorado and the nation as a whole. The methods under consideration and use include: cooperation with other municipalities, conservation, water rights acquisition, increased operational flexibility, and investing in new and improved infrastructure. Each of these areas has become a focus for the City in a well-rounded approach to address diminishing water supplies and increased competition.

Cooperation and Collaboration

While the City of Aurora is working to meet its future municipal needs it is certainly not alone. Many municipalities are struggling to find the water to ensure a healthy and prosperous future for their citizens. This has led to struggles and increased competition for available water supplies. Several Front Range municipalities have relied almost solely on groundwater. This reliance has led to decreased groundwater levels in the aquifers and increases in pumping cost because of increased drawdown. These municipalities have now begun to look to other sources for renewable water supplies.

Because competition serves no purpose, but to drive up prices, efforts are now being made to work collaboratively and collectively with other municipalities. These efforts allow money to be spent more effectively and water to be used more efficiently through design and construction of regional projects that can squeeze more use out of every drop of water. Examples of these efforts include the formation of the South Metro Water Supply Authority, of which Aurora is not a member. This group was formed by 13 individual water providers to allow for collaboratively developing long-term water supplies (South Metro, 2009). These projects are typically expensive; therefore, having members with similar interests can help make a project that is too expensive for one member affordable for the group.

In addition to guaranteeing a water supply there is also a desire to examine and predict future water supplies. This has become even more important with the recent national focus on climate change. To better understand the potential effects of climate change on their water supplies, the City of Aurora and several other municipalities have started the Joint Front Range Climate Vulnerability Study. This project is examining the potential impacts on stream flow as a result of increased temperatures and decreased precipitation.

The City of Aurora has also joined with agricultural and wildlife interests to examine the potential for leasing water to municipalities. This project is discussed further in the section on Water Rights Acquisition.

Conservation

In an effort to make every drop of water go further, Aurora has consistently employed an aggressive conservation program. This has included the use of restrictions, rebates, education, and certifications. Beginning as early as 1896 the town enacted watering restrictions on outdoor vegetation (Mehls et al., 1985). This has continued throughout the history of Aurora and exists to this day. More recently, the City has also begun other methods of encouraging citizens to conserve water. These have included rebates on toilets and washing machines that meet certain efficiency requirements, tiered water rates, education on alternative landscaping methods, and rebates on alternative landscaping methods. Rebates have proven very successful in Aurora where more than 1254 people have taken advantage of the rebates on toilets, 1797 on washing machines, and 145 on xeriscape landscaping in 2008. Tiered water rates have also helped cut down on water wasting in the City. The rates were set up to encourage conservation by increasing the price per 1,000 gallons as more water was used. The current residential water rates are shown in the table below.

	Gallons	Rate
Tier 1	**≤ 20,000**	**$4.90**
Tier 2	**20,001 – 40,000**	**$5.58**
Tier 3	**≥ 40,001**	**$6.98**

Table 1 – City of Aurora 2009 Water Rates (Aurora Water, 2009)

Water Rights Acquisition

To further add to the City's water supply, additional water rights are being purchased. Water sources that are available include new water rights, transferring agricultural water rights, and water rights trades. New water rights in the South Platte Basin can be adjudicated if a need is shown and water is shown as being available. However, the South Platte River Basin is over appropriated, meaning that in any given year not all water rights holders will be able to withdraw their allotment. Adjudication, therefore, is not a preferred method of acquiring new rights since the water rights are so far down (junior) in priority that they are unlikely to yield much, if any, water.

In addition to new water rights, Aurora is also acquiring water rights on the Lower South Platte. The primary source of water in this area is agricultural water from mutual ditches. These water rights are purchased from interested sellers. To negotiate a value for the shares of ditch water the City develops a consumptive use model. This looks at farming practices, crops grown, irrigation method, historic weather patterns, and mutual ditch

right that can be changed to municipal use in court. This water, once decreed for municipal use, can be used by the City to increase their available water supply. The decreed consumptive use portion of this water can also be reused to extinction. The remainder of the water right is assumed to return to the stream system for the benefit of other water rights holders.

To use these water rights, generally, the water must be removed at or downstream of the historic place of use. This ensures that water can be delivered to the users on the ditch who relied on the hydraulic head from that water right. This means that to deliver the water right from the ditch requires an augmentation station, or a diversion. On one of the ditches that the City of Aurora has an interest, the Brighton Ditch, the City owns four augmentation stations and a diversion that allows their shares to be delivered either back to the South Platte River or to one of their storage reservoirs.

Since 2000, the City of Aurora has acquired water on six ditch systems. These shares amount to approximately 2,700 acre-feet of water in an average year. Figure 3 below shows ditches that the City of Aurora owns or leases shares in, on the Lower South Platte River.

An unfortunate side effect of the transfer of water from agricultural to municipal uses is the dry-up of the farm. This means that water from the purchased ditch can no longer be used to irrigate the property (e.g. a farm that sells water from the Brighton Ditch can no longer use water from the Brighton Ditch for irrigation). In general this means that the farm goes out of production. This has caused these transactions to be termed “buy and dry” and has led to a negative view of municipalities as “water buffaloes” taking all the water from “poor” farmers.

To combat the loss of farm land and “agricultural heritage” the City of Aurora has begun cooperating with the Colorado Corn Growers Association and several other entities to look at a rotational fallowing and leasing program. These types of programs can be beneficial to farmers and cities because they allow farmers to lease their water in years when there is water needed by the cities due to a drought or a lack of yield. This is also beneficial to farmers because during these “bad” water years they may have difficulty successfully growing a crop because of weather conditions or water availability.

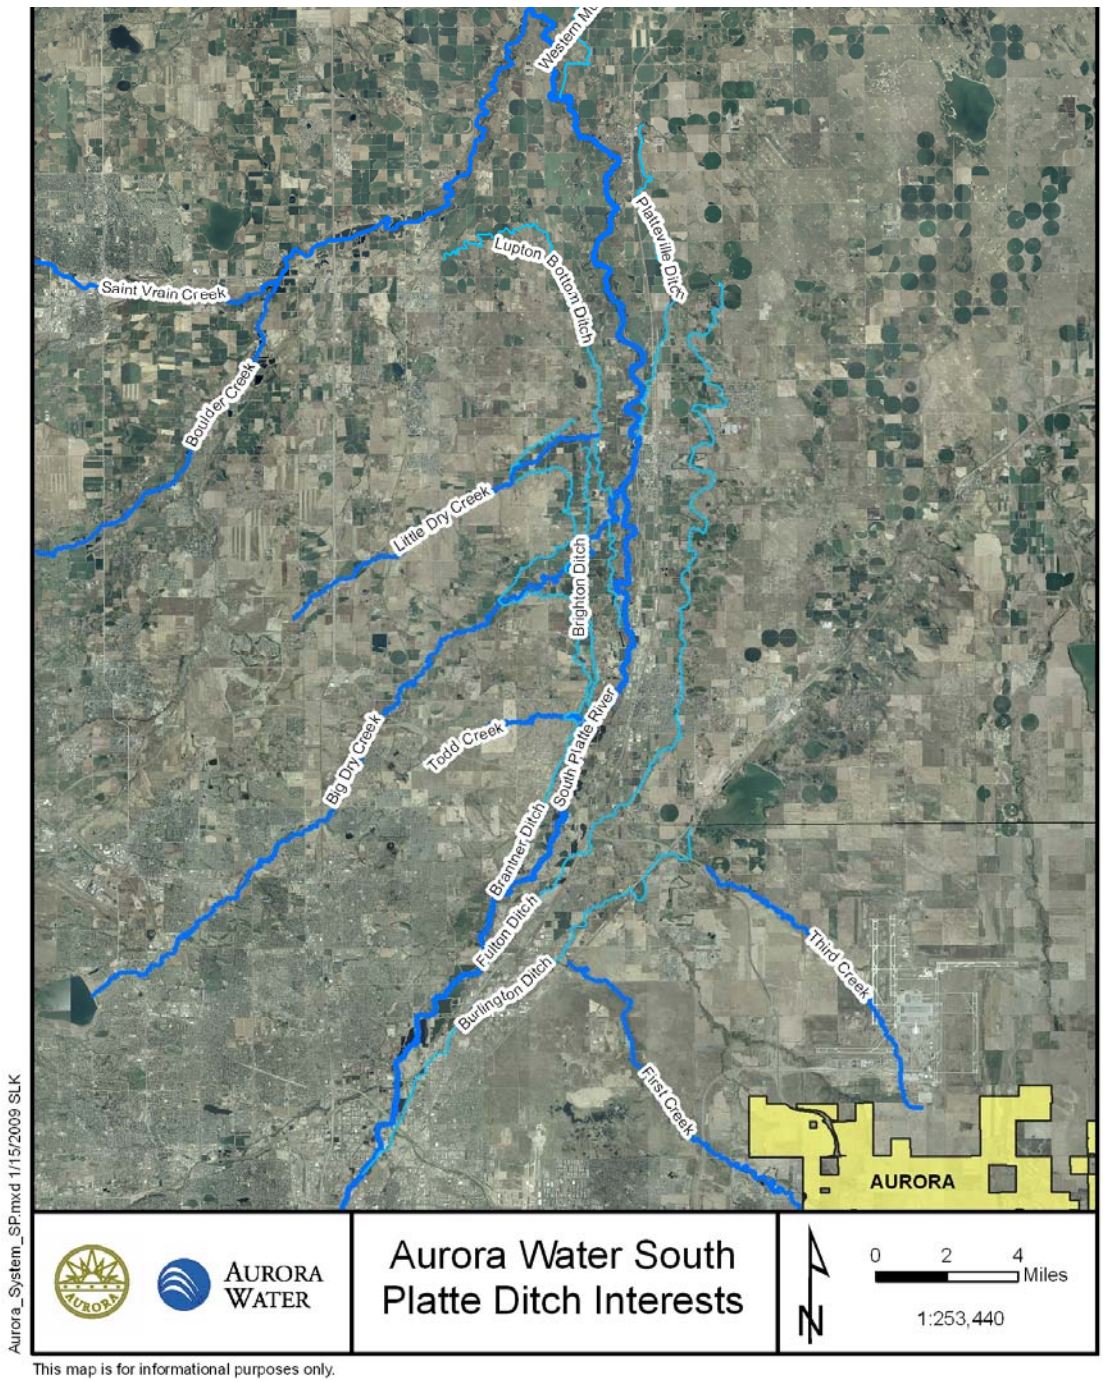

Figure 3 – Aurora Water South Platte Ditch Interests

System Flexibility

In an effort to develop a robust water system, Aurora has a significant amount of flexibility in its system. This includes multiple reservoirs, multiple pipelines, and two treatment plants. This redundancy makes it easier to adjust if a problem in one portion of the system takes down a component. This flexibility also ensures that when possible,

storage where it can be delivered to the city by gravity. This operational flexibility also allows for infrastructure to be taken off-line to allow for maintenance without affecting the overall delivery to the City.

Infrastructure

The final piece of the puzzle to improve the reliability of the water system and harden it against adverse conditions has been the construction of infrastructure in key locations. This infrastructure will allow for durability of the water supply in the face of prolonged drought, and use of the City's existing water rights to the fullest extent. A majority of this infrastructure is being developed in the Lower South Platte River Basin north of the City of Aurora. The infrastructure in these areas includes large in-ground reservoirs, wells, pumps, and pipelines. This infrastructure is being developed to move water from areas where it is being purchased back to the City, and to transfer its reusable water back to the City. In Colorado, some water can be reused to extinction. Water that meets this reusability standard is: water transferred from another River Basin (imported/foreign water), the consumptive use portion of transferred water rights, some groundwater rights, and water that is decreed to be reusable (newly decreed water rights). Water from these sources can be used and any portion of that water which is not consumed (removed from surface or groundwater basins) can be captured and reused successively to extinction.

This also applies to outdoor irrigation. When areas are irrigated, some portion of the water applied is not fully consumed. These lawn irrigation return flows (LIRFs) are allowed to be captured and reused in the City's water system. LIRFs in the City were decreed in Caser No. 02CW341 in 2008 and allow for approximately 14% of the water applied in outdoor irrigation to be reclaimed based on their lagged timing to the receiving water body. Specific LIRF percentages were developed for each of the City's receiving basins. The percentages can fluctuate based on continued monitoring.

As of January 2009, the City of Aurora has approximately 10,000 acre-feet of storage on the Lower South Platte River. These sites are in-ground reservoirs that are constructed as a byproduct to the mining of sand and gravel. These sand and gravel mines remove the aggregate from the historic river bed and leave large holes which are then isolated from the alluvial groundwater with clay-slurry cutoff walls. These reservoirs can then be used to store City water for augmentation, direct use, or repayment of obligations. The location of the City's future Lower South Platte reservoirs is shown in Figure 3.

The reservoirs shown in Figure 4 are Walker, Everist, Kirby-Dersham, and Aquifer Recharge and Recovery Site A (ARR-A). Walker, Everist, and Kirby-Dersham will be in-ground excavated reservoirs like those described above. ARR-A is a portion of the Prairie Waters Project, discussed in more detail below. This site, in the near term, will serve as a cutoff wall isolated, insitu storage basin that will provide water quality improvements through infiltration.

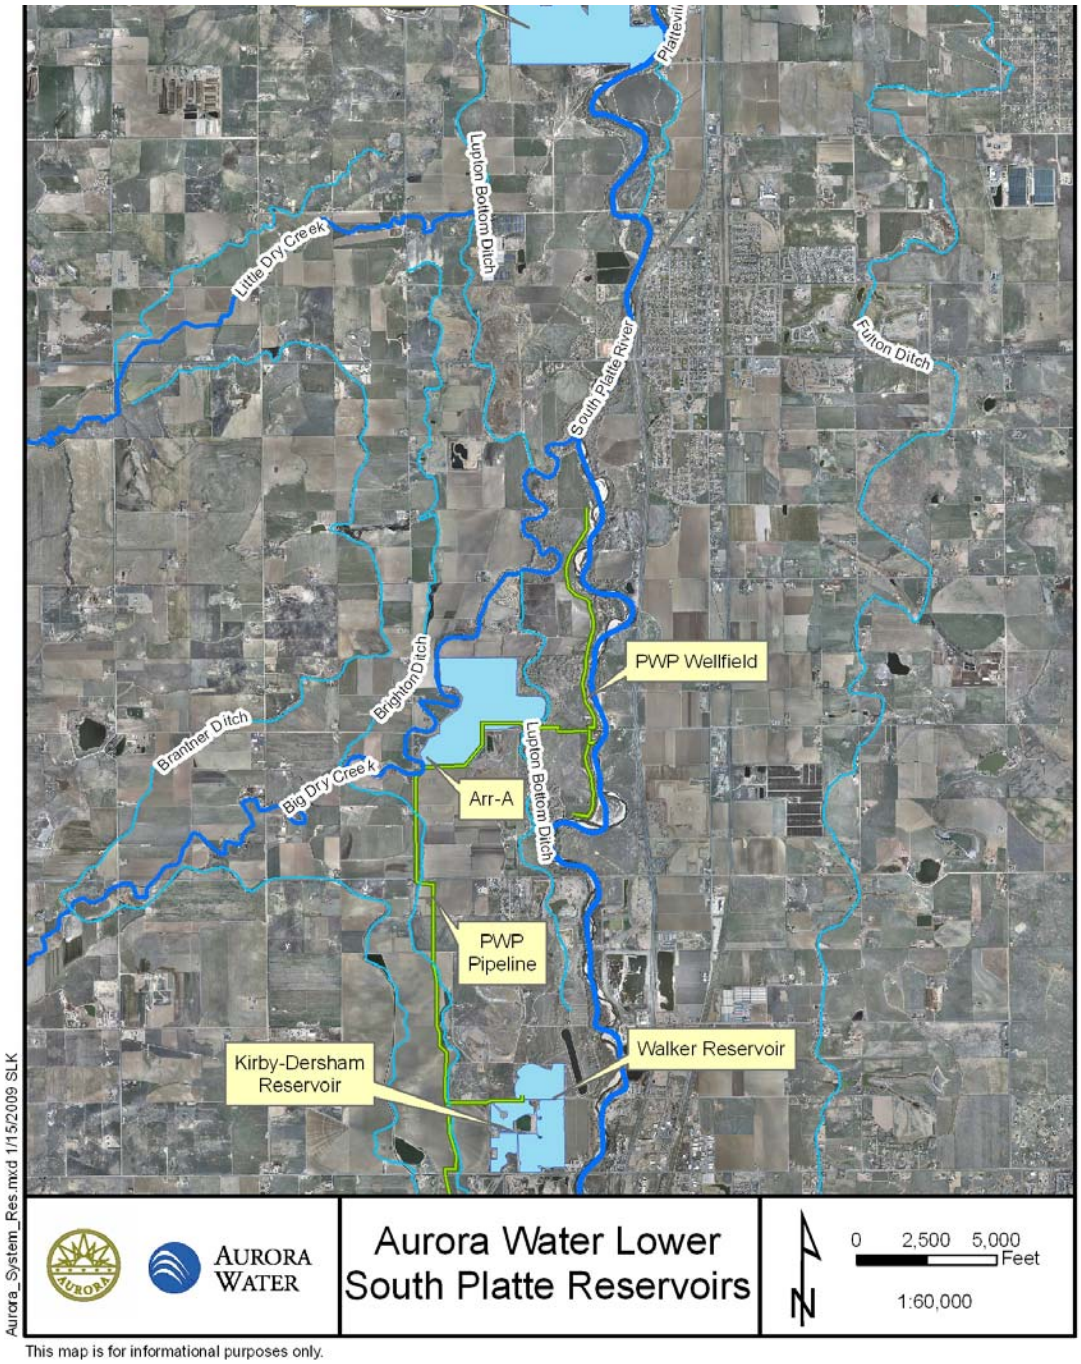

Figure 3 – Aurora Water Lower South Platte Reservoirs

The largest infrastructure project the City has ever built is currently under construction. This project, termed the “Prairie Waters Project” (PWP) pumps water from about 30 miles north of the City back to Aurora where it is treated in a cutting-edge water purification facility. The idea for this project was developed after the drought of 2002 and the project was quickly initiated and moved forward. Final completion for the project is scheduled for 2010. The PWP is designed to pump water from alluvial wells on the banks of the South Platte River, near Fort Lupton, Colorado, into infiltration basins located within ARR-A. These infiltration basins in concert with the riverbank filtration at the

From this in-ground reservoir, pumps will draw the water out and put it in a pipeline back to the City. This pipeline is capable of moving 10,000 acre-feet per year, or about 9 million gallons per day. The water from the pipeline is then treated in a state-of-the-art water purification facility and blended with the rest of the City's supply. Figure 4 shows the location of the well field parallel to the river and the beginning of the pipeline.

This project is being completed at a cost of nearly $750 million and will, when completed, allow the City to reuse its return flows in the South Platte River. The water available for reuse will include the agricultural water rights being purchased, LIRF credits, reusable effluent discharged from the Metro Wastewater Treatment Plant, any lease water acquired on the South Platte, and any other water sources decreed for use in the City. This project is also being designed to allow for expansion in the future with a larger pipe running most of the distance to the City. This large infrastructure project will also provide the potential for partnering with other entities in the future that need a firm water supply.

Conclusion

Aurora is just one of many cities in Colorado that have a concern over future water supply. With more people moving to the state every year and a population expected to double by about 2050, water supply issues are here to stay. To further exacerbate the problem there are predictions that climate change could lower the amount of streamflow the state currently enjoys or significantly alter the runoff pattern. There is also increasing competition for what water is available. This has pitted municipalities against eachother as well as municipalities against agricultural water users. Steps are starting to be made in the right direction, and Aurora is on the forefront of several of these efforts. To combat the dwindling water supplies Aurora has employed a multi-faceted approach. Cooperation is helping Aurora work better with its neighbors in a less hostile setting; conservation is helping preserve what water the City already has; new water is being acquired through leases and purchases to ensure an adequate supply; and new infrastructure is being built to allow the City to maximize the use of its new and existing water rights. With these novel approaches the City of Aurora can "harden" its supply and help ensure that services to citizens are always adequate to maintain the high quality of life that keeps people moving to the state.

Abstract

A series of experiments were undertaken to determine if any operational benefit might be realized from an upgrade of WSR-88D hourly precipitation products to the highest spatial resolution now possible, namely 0.5º x 250 m. The precipitation products are currently disseminated in arrays of 1.0 º x 1000 m spacing. Reflectivity from the NCAR S-Pol S-band radar (a radar with similar characteristics to the WSR-88D) in east-central Florida during the summer of 1998 were converted into precipitation estimates and collated with 1-hour gauge accumulations collected from several high-density rain gauge networks that were deployed simultaneously in the region. Radar-gauge correlations were calculated for several degrees of spatial aggregation, ranging from 1.0º x 150 m to 1.0º x 900 m. Correlations were estimated from over 8000 radar-gauge pairs, for both single points and areal averages. It appears that the degree of spatial aggregation of the radar estimates has little effect on radar-gauge correlations.

Overview and Problem Investigation

An enhanced version of the Weather Surveillance Radar-1988 Doppler (WSR-88D) that was phased in to operation beginning in the summer of 2008 will provide base reflectivity data at an 8x higher spatial resolution (i.e. 0.25 km x 0.5°) than that which was the standard (1 km x 1°) during the first nearly twenty years of operation of the legacy system. This very high resolution (termed "Super Res") data may provide an opportunity for achieving greater refinement in the discretization of rainfall to delineated stream and river basins and hence, to improved accuracy in radar-based, quantitative precipitation estimates and forecasts (QPE and QPF). However, sub-beam factors that could cause gauge-radar discrepancies, such as advection, evaporation, and hydrometeor interactions may be magnified at higher spatial resolutions.

The goal of this research is to investigate the potential for realizing improved accuracy in radar-based precipitation estimates – and subsequently, improved results in hydrological applications – from the processing of radar reflectivity data at higher spatial resolutions than previously available. Focus herein will be on the exploration of this question via performance of gauge-radar statistical evaluations.

Approach

The basic methodology employed is to compute quantitative rainfall estimates for selected hours from an S-band radar similar in characteristics to the operational WSR-88D, using an independently-implemented QPE algorithm modeled after the present WSR-88D Precipitation Processing System (PPS). The rainfall estimates are determined through a span of discrete spatial resolutions, ranging from approximately that used in the PPS to approximately that now becoming available operationally. These estimates are then compared against co-located, hourly, rain gauge reports and – after quality control (QC) measures are taken – statistical results are determined for the resultant set of "gauge-radar pairs" (G-R pairs) at each discrete radar resolution. Furthermore, this basic approach is undertaken for three distinct configurations of the rain gauges within the radar umbrella: (1) all (quality-controlled) individual gauge reports under the entire radar umbrella; (2) clusters (sub-sets) of more densely-packed gauges covering areas < 20 km^2 (representing multiple, idealized small basins of a theoretical stream network); and (3) gauge-reported mean-areal precipitation (MAP) in the same clusters, over areas < 20 km^2.

In order to conduct this study, good datasets of both high-resolution reflectivity data from an S-band radar (similar to the WSR-88D) and rain gauge reports from dense rain gauge network, gathered simultaneously, had to be available. The most suitable combination of datasets found consisted of the National Center for Atmospheric Research (NCAR)'s S-band, dual polar, Doppler radar (known as "S-Pol") while it was located in the vicinity of Melbourne, Florida during the summer of 1998 (July 20 to Sept. 29), coincidentally with deployment of the National Aeronautics and Space Administration (NASA)'s dense (as closely spaced as 1-km) Tropical Rainfall Measurement Mission Ground Validation (TRMM-GV) rain gauge network.

Studies with related goals were reported by Habib and Krajewski (2002) and by Gebremichael and Krajewski (2004), though their primary focus was on spatial variability of rainfall and its relationship to gauge-radar correlations in general.

While the NCAR S-Pol radar has dual-polar capability, the study here is confined to evaluations of radar-rainfall estimates derived from the traditional, single-polar "Z-R" relationship, for consistency with legacy QPE analyses. The finest spatial resolution of the S-Pol data is 0.15 km x 1.0°, and although not the same as the new NEXRAD "Super Res" data (i.e. 0.25 km x 0.5°), those resolutions are close to one another (e.g. at 57.5 km from the radar, a sample bin in "Super Res" NEXRAD will have an area of .125 km^2 while one in S-Pol has an area of .150 km^2 - just 20% larger). Furthermore, S-Pol sample bins can be successively aggregated (i.e. averaged, by rain rate) in the radial direction, in multiples of 150 m, to simulate discrete resolutions ranging from the future to the present WSR-88D. This is done for each of the following levels of aggregation: 150m; 300m; 450m; 600m; 750m; and 900m.

In each of the three analysis phases described above and at each of the above spatial

resolutions, some or all of the following statistical parameters are determined: Radar Mean Accumulation (after correction for Mean Field Bias (MFB) - i.e. ratio of gauge-mean to radar-mean accumulations among all co-located pairs at all aggregation levels); Ratio of (bias-corrected) radar accumulation to gauge accumulation (for each radar aggregation level); Correlation Coefficient (CC); Mean Absolute Error (MAE); and Root Mean Square Error (RMSE).

Data Processing

Determination of the gauge-radar pair datasets

Both the TRMM-GV rain gauge reports and the precipitation estimates from the S-Pol radar were assembled for one-hour ("clock-hourly") blocks, i.e. beginning/ ending at the 'top' of an hour (and also matching the accumulation periods of the DPA products from the nearby WSR-88D KMLB (Melbourne, FL) radar).. In order for a set of gauge-radar pairs for a given hour to be included in our analysis dataset, either the rain gauge report or the radar estimate determined at one (of the six) spatial resolutions would have to be non-zero. The number of hours for which gauge-radar pairs were found for the principal dataset used in our study was 96.

Rain gauge data and Quality Control

The distribution of gauges within a radius of 171 km from the S-Pol unit is shown in Figure 1. The figure shows only the 125 gauges retained after the QC procedures explained below. Because part of our study dealt with the ability of the radar to represent small-scale spatial variability in rainfall, attention was also focused on several sub-networks shown in Fig. 1

Several steps of quality control (QC) were performed before the rain gauge data could be used. The first step was about consistency of the gauge locations, as reported by two sources: the header lines of each gauge data file and a list file showing latitude/longitude information of all gauges within the network. Differences between the two of up to 0.8km were found; those gauges with differences greater than 100 meters were discarded.

The second step of QC was to identify and remove suspect gauge reports by comparing the rainfall records of nearby gauges with one another, as well as with the estimate from the corresponding 4x4 km grid box of the Digital Precipitation Array (DPA) 1-hour rainfall product from the nearby KMLB radar. We focused our efforts on situations of multiple gauges located in the same DPA grid box. To perform this analysis, time series depictions of hourly rainfall accumulation data from pairs of closely located gauges were compared first against each other, and then against the time series from the corresponding DPA grid box.

For example, Figure 2 shows the time series of hourly rainfall accumulation data of TFB0112 (in green) and TFB0115 (in red). The X-axis is the time index, in hours,

when at least one record from each of the gauges in the DPA grid box was non-zero. Rainfall values (Y-axis) of one gauge were plotted upside-down to better show the differences or similarities between the two gauges. The series from the two gauges are seen to match each other very well until around 09/04/98 14:00Z (time index of about 90). After then, reports from TFB0115 appear to have been shifted about 39 hours earlier.

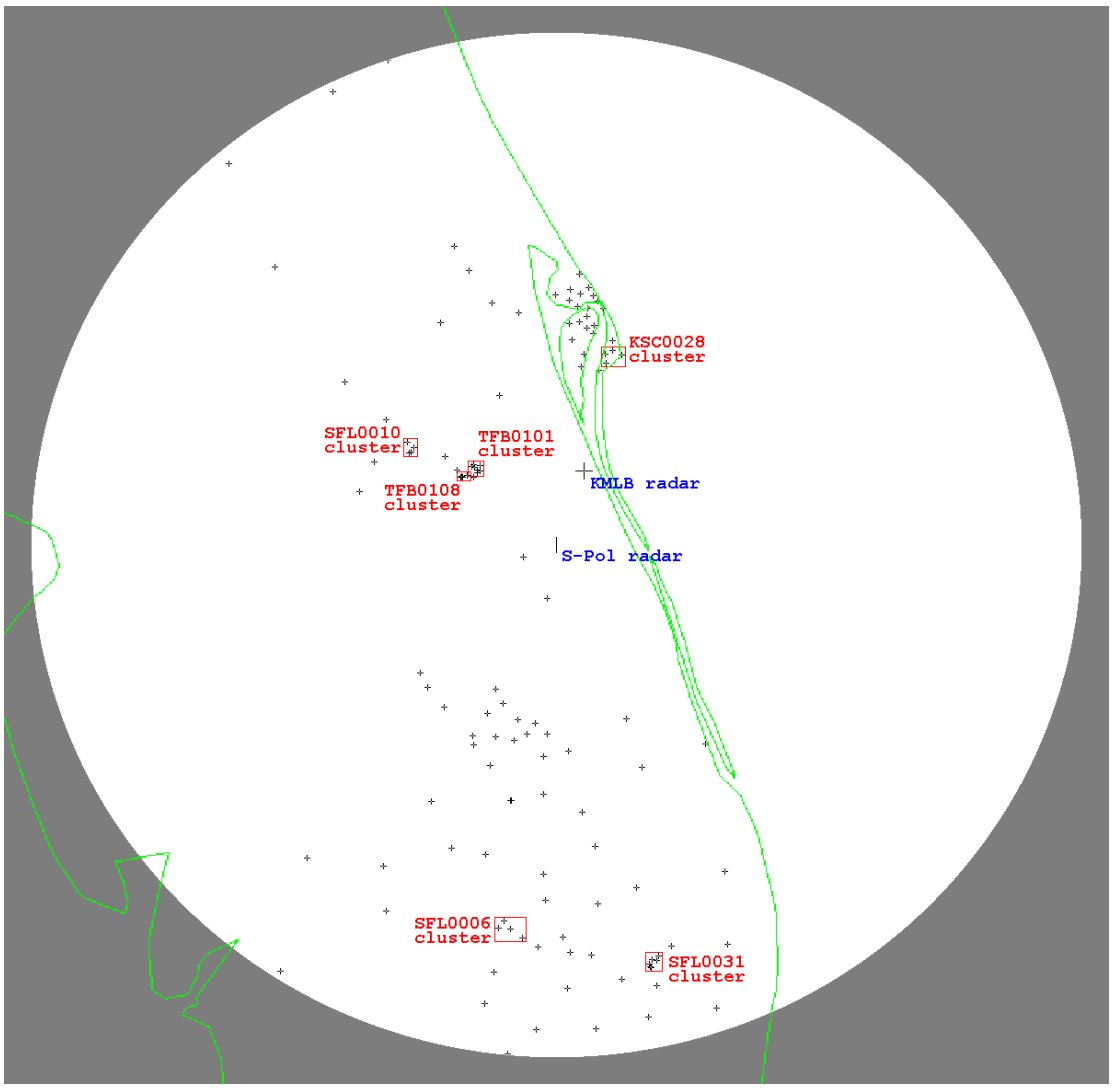

Figure 1. Distribution of gauge sites (small crosses) relative to S-pol radar site (large cross at center). Six sub-networks or 'clusters' of closely-located gauges are shown in red. The white circle indicates a radius of 171 km. WSR-88D Melbourne radar (KMLB) also shown.

Similar time series accumulation depictions were formulated for each of TFB0112 and TFB0115 against the DPA product for the grid box in which they were both located. Gauge TFB0112 matched the DPA product very well throughout, while TFB0115 did so during the early hours, then revealed significant differences in the latter hours. In this instance, the latter part of the record of TFB0115 was removed

from the ensuing analysis.

The third step of QC was to deal with gaps (i.e. prolonged periods of no reported rain) in the gauge data. Since we have no simple means of distinguishing between missing data and true 'no rain' data, we would assume the presence of a gap simply to mean 'no rain' for most situations. However, for gaps at the end of the PRECIP98 (or TEFLUN-B) experimental period, we treat them as missing data and remove them from our study, feeling it is reasonable to assume that gauges might stop operating at the end of the field experiment.

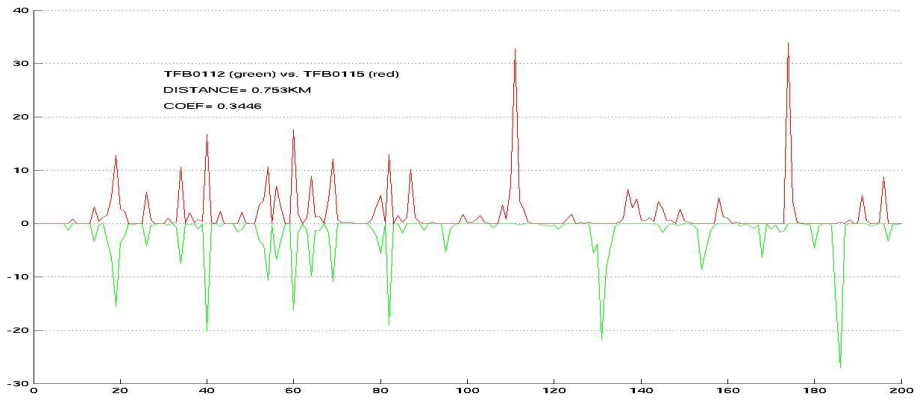

Figure 2. Time series of hourly precipitation rates at rain gauge sites TFB0115 (above horizontal axis; red) and TFB0112 (below the axis; green). Serial hours are indicated. Note close correlation through beginning of analysis period, then lack of correlation after ~hour 90.

A fourth QC operation was performed after the gauge data had been paired with radar data. On one occasion, the S-Pol radar data at one or more resolutions corresponding to a gauge location appeared to be contaminated by ground clutter; in this instance, the gauge was removed (i.e. no gauge-radar pairs were included at any of the trial resolutions).

Radar data - one-hour rainfall estimates from S-Pol

Radar rainfall estimates from the S-Pol data were calculated using an independently-implemented, in-house, QPE algorithm modeled after the WSR-88D Precipitation Processing System (PPS) (Fulton et al. 1998). Time intervals between S-Pol volume scans were approximately 5 minutes, corresponding well with WSR-88D scanning strategies. Therefore, data from ~13 volume scans were typically used to calculate the one-hour radar-rainfall accumulation estimates.

The reflectivity field from the 0.5° elevation scan was used to calculate the rainfall rates by employing the default (i.e. 'Convective') Z-R relationship from NEXRAD (i.e. $Z = a R^b$, where Z = backscattered Reflectivity Power (mm^6/m^3); R = Rainfall Rate (mm/hr); a = 300; and b = 1.4). To get rainfall rates at the aggregated 300m to

900m resolutions, the rates from 2 to 6 contiguous radar bins at 150m resolution were averaged along the radial direction.

Overview of weather during test period and significant events

The weather situation during the course of the experiment (20 July to 29 September 1998) was typical of mid-to-late summer over Florida, with some intense local rainfall and some cases with mesoscale organization of precipitation features. Data from 27 days were utilized. Overall, approximately 37% of the hourly gauge reports indicated measurable rainfall ≥ 0.25 mm rainfall; 11% had ≥ 2.5 mm, and about 0.7% had ≥ 25 mm.

Findings

Phase 1 – all G-R pairs considered

In this phase, correlation and error statistics were calculated based on radar-gauge pairs meeting the criterion that either a gauge or radar value must be non-zero. This was done first for all G-R pairs under the radar umbrella (8211 pairs were found), then for subsets of those pairs falling within three discrete range-bands. Our aim was to test the effect of spatial aggregation of radar data on radar-gauge correlation in general, when rainfall was measured by rain gauges at individual points (this methodology is one that has been used in correction of radar bias and in validation of radar rainfall). A conceptual depiction of this phase of the analysis is shown in Figure 3.

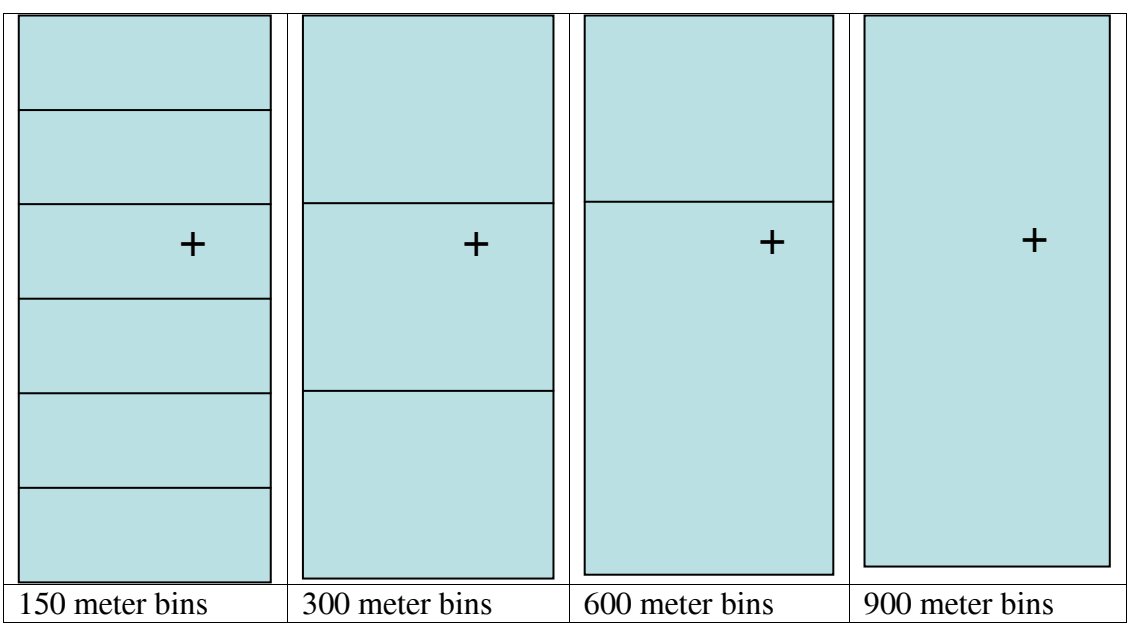

Figure 3. Schematic diagram for radar QPE aggregation in radial direction, PHASE 1 (+ indicates rain gauge location). Note that aggregation volumes are

not necessarily symmetric about the gauge point – the location of the grid volumes is arbitrary, as is the case in operations.

Results for the various G-R statistical measures are shown in Table 1, first for all G-R pairs under the radar umbrella, then for the pairs stratified by distance from the radar (i.e. near: 0-67 km; middle: 67-106km; far: 106-171 km). For each statistic in each set, the "best" result is depicted in **bold** (i.e. highest CC; lowest MAE or RMSE) and the "worst" result in ***bold italics*** (opposite criteria).

Table 1. Gauge-radar correlation coefficients, mean absolute errors, and root-mean-squared errors listed by spatial aggregation distance for radar data. All gauge-radar pairs considered together (1a); then stratified by range from the radar (1b-1d). Gauge or radar value must be non-zero for a G-R pair to qualify. For each statistical measure, the 'best' result among all spatial resolutions (aggregation distances) is shown in **bold** and the 'worst' in ***bold-italics***.

Table 1a - All ranges: # R/G-data-pairs: 82; Gauge mean: 1.92(mm)

Radar:	Mean(mm)	R/G Ratio	CorCoef	MAE(mm)	RMSE(mm)

Table 1c - 67-106 km: # R/G-data-pairs: 27; Gauge mean: 1.98(mm)

150m-res	1.82	0.92	0.85	1.07	3.12
300m-res	1.83	0.92	**0.85**	**1.07**	**3.11**
450m-res	1.83	0.93	0.85	1.07	3.12
600m-res	1.86	0.94	0.84	1.08	3.12
750m-res	1.86	0.94	***0.84***	1.09	***3.14***
900m-res	1.87	0.95	0.84	***1.09***	3.13

Table 1d - 106-171 km: # R/G-data-pairs: 23; Gauge mean: 2.23(mm)

150m-res	2.18	0.98	***0.78***	1.42	***3.18***
300m-res	2.19	0.98	0.78	1.42	3.17
450m-res	2.21	0.99	0.78	***1.43***	3.16
600m-res	2.20	0.98	0.79	1.41	3.12
750m-res	2.21	0.99	0.78	1.42	3.15
900m-res	2.21	0.99	**0.79**	**1.40**	**3.10**

It is apparent that in each instance, the results across all resolutions are quite similar. For example, with all G-R pairs within the radar umbrella included, the difference between the lowest Correlation Coefficient (i.e. 0.7742) and the highest (i.e. .7951) is only 2.7%. However, within the narrow range in each instance, it is seen that the 'better' statistical results are more often than not found at the coarser resolutions and

the 'lesser' results at the finer resolutions. In the top part of the table, it is seen that the 'best' results for two of the three statistical measures (i.e. CC and RMSE) are found at the coarsest resolution of 900m and the 2nd best results at the 2nd coarsest of 750m; only for MAE are the better results found at the finer resolutions.

When stratified by distance from the radar, the better/lesser results in both the near range band (0-67 km) and the far range band (106-171 km) are also found at the coarser/finer resolutions for all statistical measures (except MAE at the near range). However, in the middle range band (67-106 km), the opposite holds – i.e. the better/lesser results are found at the finer/coarser resolutions.

These results may indicate that there could be an advantage in achieving more accurate rainfall estimates when base radar data are available – and analyzed – at finer resolutions, but only in certain circumstances. Sub-beam effects, for example, could play a significant role. Near to the radar, biota and/or radar side lobes could play a role in contaminating radar estimates and hence, obscuring gauge-radar correlations. At the far ranges, where the radar beam is more elevated, wind advection would have a longer time to act upon falling hydrometeors, causing them to drift to adjacent locations from where they were first sampled aloft; the relative impact of this effect being greater when overlaid on a finer-resolution grid than a coarser one. Perhaps only at the mid ranges would neither of these effects predominate and would an advantage (in accuracy of QPE) be gained in performing the analysis at finer resolution.

Phase 2 – Gauge-radar spatial correlation within small gauge networks

The second phase of the experiment was designed to determine if spatial aggregation of the radar data had an effect on representation of the spatial rainfall pattern, and not necessarily the absolute amount. This question is important because some NWS operational practices are based on the assumption that the radar can properly depict sharp spatial gradients in rainfall and differentiate between rain amounts over adjacent, small basins. Therefore, we examined the spatial correlations between radar and gauge estimates within small sub-networks or clusters of four-to-seven closely-located gauges, occupying only a few tens of km^2. A conceptual depiction of this phase of the analysis is shown in Figure 4.

Six such 'clusters' were identified (refer to Fig. 1). An individual hour's data was included when the difference between the largest and smallest 1-h gauge report was at least 2.5 mm, to insure some appreciable variability in the small-scale rainfall pattern. The gauge and radar estimates for that hour were ranked by order of amount and then correlated We found (not shown) that, for most clusters in individual hours, the radar did show appreciable skill in depicting the rainfall distribution over these very small areas. That is, for 1-h rainfall, in many cases the gauge-radar correlation (across all levels of aggregation) within the gauge network was ≥ 0.7 (indicating ~50% reduction of variance).

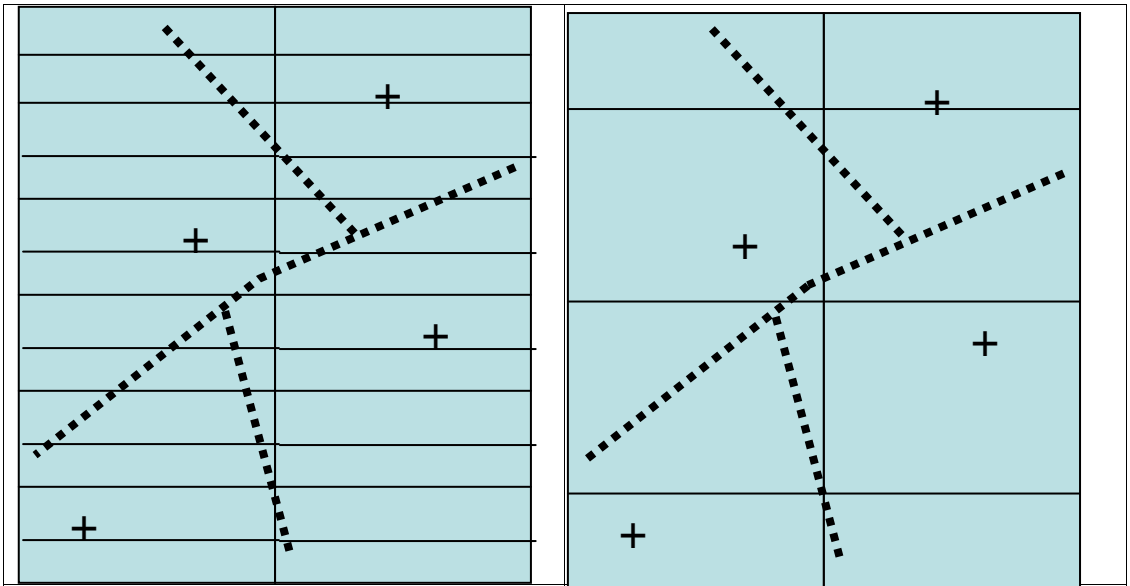

Figure 4. Schematic diagram for radar QPE aggregation - patterns, PHASE 2. (+ indicates rain gauge locations). Dashed lines indicate basin boundaries. Note: radar sample bins correlating with rain gauges change with radar spatial resolution.

Shown in Table 2 are the Mean Correlations as a function of aggregation distance over all qualifying hours, and the Fraction of Hours for which the gauge-radar correlation was ≥ 0.7, with the clusters ordered from highest to lowest in terms of overall correlation (i.e. average of the Mean Correlations). (Note that for each cluster, the Mean Separation Distance among the gauges and the Mean Range of the gauges from the radar are also shown.)

Findings overall were quite similar to those of Phase 1 when all G-R pairs under the radar umbrella were considered – i.e. the higher mean correlations were found at the larger aggregation distances (i.e. 600 to 900 m) while the lower correlations were found at the smaller aggregation distances (i.e. 150 to 450 m). This was pretty much a universal finding among the six 'clusters', indicating again that the spatial aggregation of the radar data had relatively little effect on the correlations to rain gauge reports. (It should be noted that the variations in correlation statistics within clusters as a function of aggregation distance tended to be relatively minor compared to other factors concerning the clusters as a whole, such as the distance of their centroids from the radar or the average separation distance among their constituent gauges.)

Table 2. Mean value of gauge-radar linear correlation coefficients within individual rain gauge clusters (subnetworks), averaged over multiple 1-h events, and number of hours in which the gauge-radar correlation was ≥ 0.7. Highest and lowest values of any given field across the range of spatial aggregation are indicated as in Table 1 (in cases of "ties", all are so indicated). The clusters are shown in order of highest to lowest Mean Correlation (averaged over all aggregation distances).

Phase 3 – G-R correlation for small-area hourly mean precipitation

In the final phase of the experiment, gauge and radar values for individual gauge points were each separately aggregated within network clusters. These values approximate gauge and radar mean-areal precipitation (MAP) such as might be

observed over small stream basins. Spatial aggregation might have some effect on radar MAPs because with greater aggregation, precipitation immediately outside the area would be included. A conceptual depiction of this phase of the analysis is shown in Figure 5.

Once more, the degree of radar spatial aggregation generally was found to have little, effect on the gauge-radar MAP correlation or error, though again, an overall tendency was seen toward higher/lower correlations at the coarser/finer resolutions (i.e. for all but one of the clusters, the highest gauge-radar correlations were realized at aggregation ranges of 600 - 900 m).

150 meter bins Approximation to Mean Areal Precip is from 4 radar data points.	900 meter bins Approximation to Mean Areal Precip is from 4 different, larger radar data points.

Figure 5. Schematic diagram for radar QPE aggregation – Mean Areal Precipitation (MAP), PHASE 3. (+ indicates rain gauge locations). Shaded area represents a basin over which gauges are averaged for MAP.

Summary, Conclusions, and Future Work

Overall, in the three phases of analysis of gauge-radar statistical correlation that we performed, we generally found no appreciable difference among gauge/radar correlation statistics computed at the various radar spatial resolutions, which ranged from 150 to 900 m. Indeed, we found slightly better results at the coarser, rather than the finer, resolutions overall. However, in one circumstance – i.e. with all G-R pairs included in the middle range of our analysis (i.e. 67-106 km from the radar), we did find the best statistical correlations at the finest resolution. This suggests that, perhaps, the availability of base radar data at finer resolution could result in more

accurate measures of one-hour QPE, but only in certain circumstances, as iterated above (i.e. 'Findings – Phase 1' section).

One potential avenue for future study would be to attempt to factor in sub-beam wind effects on falling hydrometeors by performing statistical correlations of individual rain gauges not just with rainfall estimates from the immediately-corresponding sample bin (in which that gauge is contained), but rather, with surrounding sample bins in all directions and within a prescribed distance. If an offset distance and direction (i.e. vector) could be identified that would yield superior results, that vector could then be analyzed against ambient wind conditions (as recorded by ground or upper-air measuring devices or estimated by model). Ultimately, it may prove possible to incorporate ambient wind conditions in a predictive capacity in relating rainfall estimates determined at high spatial resolution, aloft, to distribution of rainfall at the surface.

Another potential future pursuit would be to perform a similar analysis to the above, but with rainfall estimates derived via a dual polar methodology such as that which is to be implemented within WSR-88D operational radars in future years (Ryzhkov et al, 2005b).

Acknowledgements

We are indebted to Scott Ellis and the NCAR staff for assistance with obtaining and interpreting the S-pol radar data. As noted above, rain gauge reports were obtained from the TRMM SVO office.

Abstract

This paper presents a hydrologic modeling application to assess climate change impacts on the water resources of the Rio Conchos basin, especially for agriculture and domestic water uses. The study basin is located in the Mexican State of Chihuahua, with a drainage area around 67,862 km2. It is one of the most important Mexican tributaries of the binational Rio Grande basin and contributes major water deliveries (about 55%) to US through the 1944 treaty between Mexico and the US. However, during period of drought, for instance in the 1990s, there has been conflict and competition for the water resources in the basin, and as a consequence Mexico accumulated an important water debt to the US. In addition, the hydrological behavior of the basin has recurrent periods of water stress, problems with long drought periods, allocation and release, and water pollution. Under this reality, it is important to evaluate and predict the available water resources in the next 50 or 100 years taking account of possible climate change impacts in the basin as well as assessing the policies to be implemented in order to face drought periods and preserve the agreements treaty between Mexico and the US. For this purpose, the Water Evaluation and Planning (WEAP) model is used. The model was calibrated and validated comparing the simulated flows resulting from the input of climatic time series with naturalized flows. Monthly climate time series from 1980-1999 (20 years) were used and some soil parameters were adjusted for calibration. Also, comparisons between simulated and naturalized flows were performed for different stations. In addition to this, calibration considering all water management infrastructures, such as, reservoirs, operation rules, canals, and diversions, was also carried out. The results show good correlation between simulated and observed flows which indicates that the model reproduces the hydrologic behavior of the basin, including, natural and historical flows, storage in reservoirs, water supplies, and water demands for agriculture and urban activities.

Key words: Hydrological modeling, Water Management, Climate Change

1. Introduction

Changes in temperature and precipitation patterns as a consequence of increasing greenhouse gas concentrations may affect the hydrology process, water resources availability, and water uses for agriculture, population, and mining industry, aquatic life in rivers and lakes, and hydropower. Climate changes will accelerate the global hydrological cycle, with increase in the surface temperature, changes in precipitation patterns, and evapotranspiration rate. The spatial change in amount, intensity and frequency of the precipitation will affect the magnitude and frequency of stream flows; consequently, it will increase the intensity of floods and droughts, with substantial impacts on the water resources at local and regional levels. In addition to this, global climate simulations indicate that precipitation will decrease in lower and mid latitudes and increase in high latitudes (IPCC, 2008). Results indicate that precipitation will decrease in part of North American (Mexico), central America and South America, Caribbean regions, sub tropical western coasts, and over the Mediterranean. Evaporation, soils moisture content, and groundwater recharge will also affected. Consequently, drought conditions are projected in summer for sub tropics, low and mid latitudes. These facts arouse the interest of many researchers to analyze basin-wide (local scale) effects. In addition, to evaluate and quantify these impacts at local scale, several tasks must be carried out. One of them is hydrological modeling of the basin. This paper focuses on the hydrological modeling in the Rio Conchos basin (67,862 km2), a main Mexican tributary of the Bi-national Rio Grande (Figure 1) . It contributes water deliveries to the USA according to a 1944 water sharing treaty. Several hydrological studies have been carried out in the different places of the world such as in the Nile basin (Yates and Kenneth, 1998), Sacrament Valley in California (Joyce, Sebastian Vicuna, Larry Dale, 2006); however, there are few studies related to this issue in the study area. The main goal of this research is to perform the hydrological modeling to assess climate change impacts on the basin, using the Soil Moisture Method incorporated into the Water Evaluation and Planning Model (WEAP) (SEI, 2007).

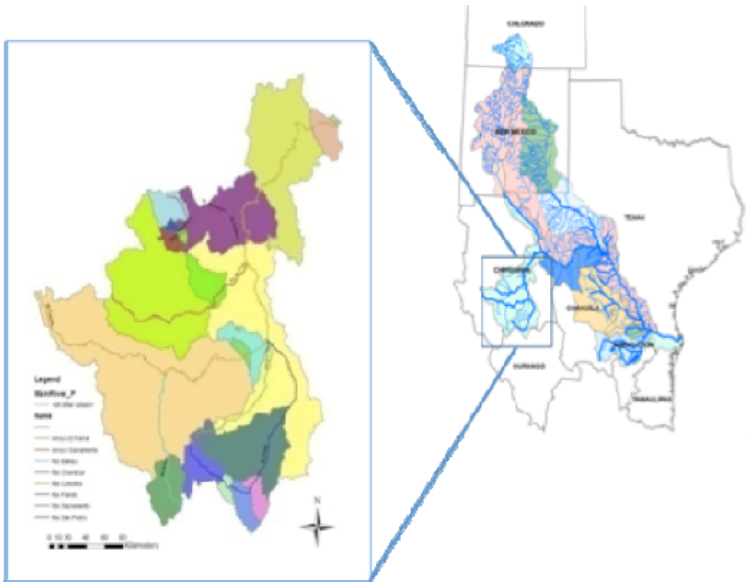

Figure 1. Location of the Rio Conchos basin

2. Climate and Land Use Data

Precipitation - Daily precipitation from 1980 to 1999 was used to calibrate and validate a WEAP model of the Rio Conchos basin as well as to analyze its temporal behavior. These data were collected for control stations in each sub-catchment, and monthly cumulative values were calculated. Monthly maximum values observed range of 200 to 310 mm and, the annual average is 425 mm/year with seasonal variation indicating that the rainy period is from June to September. On the other hand, spatial variation shows that the rainfall varies with altitude, with higher values in the Llanitos subbasin, 740 mm/year on the average lower values in the Luis Leon and Peguis subbasins located in the lower basin, with annual average of 325 mm.

Temperature - Surface temperature in the basin was obtained from the North American Regional Reanalyis (NARR) (NOAA, 2008) for the period 1980 -1999. First, these data were processed using GIS in order to estimate the monthly averages in each sub-catchment. Maximum temperatures occur from June to August and minimum from November to February. Spatial variation indicates that, high values occur in the lower basin (desert region), with values around 32 ^{o}C for Ojinaga and Peguis, and 21 ^{o}C for Llanitos and Puente. Lower values vary from 7–11 ^{o}C and 12-16 ^{o}C. On the other hand, temperature and precipitation showed a negative correlation during the period of analysis, which means that the temperature tends to rise and rainfall to decrease.

Relative Humidity - Data for 1980 to 1999 was obtained from the NARR. In addition to this, GIS tools were used to compute the monthly average of each sub-catchment. Spatial variation indicates that lowest values in Fco Leon, Pegui, and Ojinaga catchments located in the lower basin, and the highest values are in the upper basin. The average for the whole basin is around 42 % and the temporal variation indicates that maximum values are recorded from July to September.

Wind Velocity - In the Rio Conchos, the dominant winds come from Southwest to Northeast. Two components of velocity were obtained from the NARR for different sub catchments of the basin and processed in order to get the wind velocity. There is a seasonal variation with high values in November to April, with an average of 12 km/h for the whole basin. In the upper basin the wind speed is greater than the lower basin, with 18 km/h and 6 km/h, respectively.

Land Use Data - Twenty sub-basins were identified by soil groups and land use categories (Amato and McKinney, 2006) and were applied for using the Soil Moisture Method in the WEAP model.

3. Methodology

Model calibration was carried out using historical observed data inputs (precipitation, temperature, relative humidity, and wind velocity) to obtain stream flow outputs. Naturalized flows (TCEQ, 2001) for a period of 10 years (1980 - 1989) were used to compare to model outputs. The calibrated model was then validated for a period of ten years more from 1990 to 1999.

Soil Moisture Method - Land use data are used in this method considering the movement of water through the soil composed for two simple layers: (1) water retained near the surface and available for plants, and (2) a deep layer that can transmit water as base flow or groundwater storage.

Root zone water capacity - Initially 900 mm of root zone water capacity were considered for irrigated areas, small pastures grasses, and cultivated grassland, and 2500 mm for forest. Adjustments of this parameter were carried out taking account the depth of soils in the basin (Pro Fauna, 2003) with variation due to type and formation of soils located in each zone.

Root zone conductivity - This parameter controls the transmission of flow to the lower layer as well as interflow. Interflow depends of the preferred flow direction; in this case, ranging from 0.05 to 0.20 and zero in other subbasins.

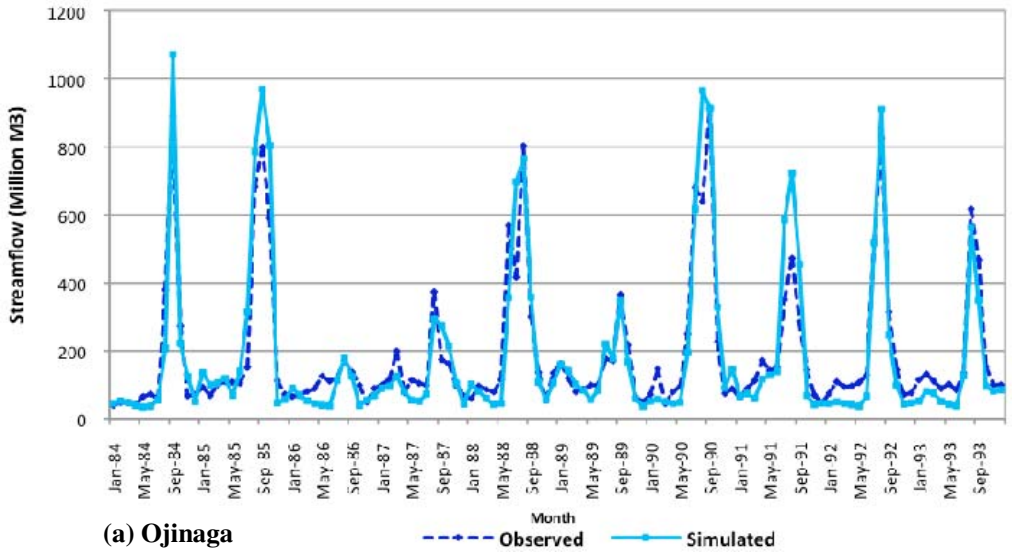
Root zone water capacity - Estimated values of the root zone capacity vary from 5 to 30 % in some sub basins with lower values in the sub catchments Luis L. Leon, Peguis, and Ojinaga located in the lower basin where less relative storage of water in the first layer exist (desert area).

Lower zone water capacity - Lower zone water capacity values are higher in some subbasin where deep aquifers exist. Large values of this parameter can result in high base flow.

Lower zone conductivity - Deep conductivity, together with lower zone water capacity, controls the transmission of base flow in each subbasin. Rough calculations of the base flow were made using the straight line method.

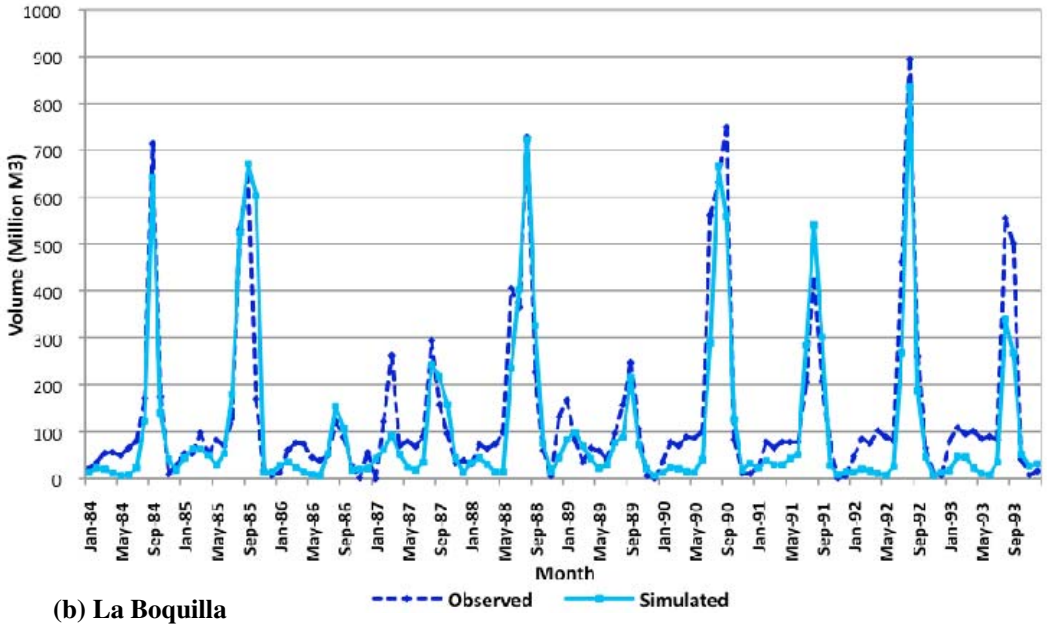
Initial deep storage - Storage to the lower soil layer were also calibrated, which also has a large effect on base flow.

4. Results



In this part, results simulated in WEAP model are compared with the naturalized flows observed in each control station. For this research, stream flow data from 6 streamflow – gaging stations located along to the basin were used to compare the results of the model; the location can be seen in figure….). In general, the results indicate that the model built in WEAP can be able to reproduce the hydrological dynamic of basin as is shown in the calibration and validation processes. Table 1 and 2 show the soil parameter values calibrated for the period from 1980 to 1989 whose stream flow results were validated with the period 1990 to 1999 (10 years), noting that in the validation process, some adjustments have been carried out basically in the second layer. Small depths proposed for this layer reproduced high base flows at the end of the simulation period.

4.1 Calibration



Monthly stream flows simulated and observed for the calibration period (1980 - 1989) can be seen in figures 2a-b for stations Ojinagaand la Boquilla, respectively. It is

observed that in most months, the simulated flows look very close to the observed, with a volumetric error 2 - 19 % for the simulation period, for Ojinaga (lower basin) and La Boquilla (middle basin), respectively. Maximum errors produced in the upper basin are due to the important differences between simulated and observed base flows. For instance, for the La Boquilla station, simulated base flows are generally lower than the simulated values from January to May. Probably, the uncertainties in naturalized flow calculations and a more accurate representation of the groundwater system in the middle and upper basin would improve the estimations. Despite this, the model reproduces the hydrological response of the basin, with simulated stream flows representing between 85 to 95 % of naturalized flows.

The trend of the model to reproduce the observed values is also seen in Figures 3a-d. Relationships between monthly simulated and observed streamflows indicate a high correlation ranging from 91% to 95% for La Boquilla and Ojinaga, respectively. The spatial variation indicates that the model is more accurate in reproducing the streamflows in the lower basin. Special conditions such as the topography in the middle and upper basin (high slope), size of sub division catchments (for instance La Boquilla), and other factors mentioned above could be influencing in this behavior. Similarly, calibrated annual flows show slight differences with the annual naturalized flows, with an error in volume around 10 % on average. The biggest error is in the Jimenez station located in the upper basin.

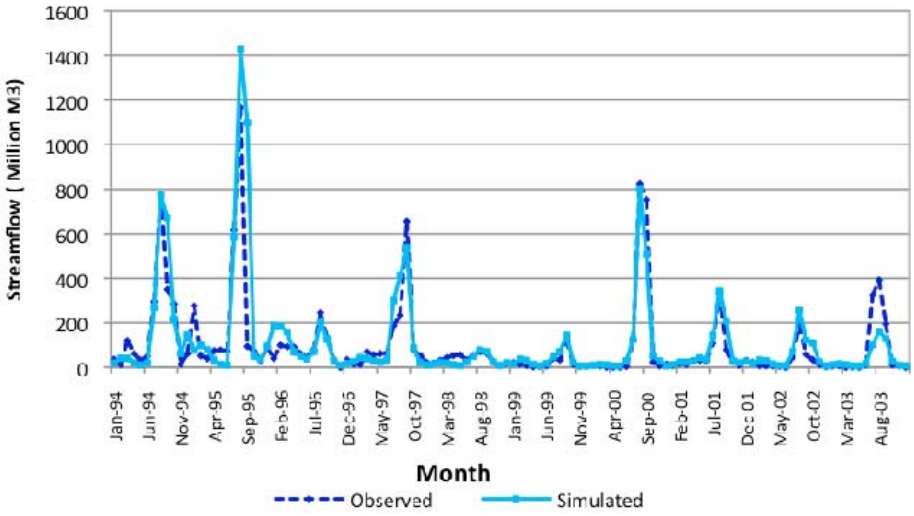
(a) Ojinaga **(b) La Boquilla**

Figure 3. Relationship between monthly observed and simulated streamflows in control stations: (a) Ojinaga and (d) La Boquilla.



4.2 Validation

In order to evaluate the calibration of the hydrological model, it was run for a time period out of the calibration period; from 1990 to 1999 (10 years). The results of the model validation are present in Figures 4a-b. For all the stations, the simulated monthly results are quite good compared to the naturalized flows. On the other hand, the relationship between these flows indicates a high correlation for the Ojinaga, Granero, and Granero, with rates higher than 0.94 (Figures 5a-b). Additionally, the model shows a good performance in reproduce the flows in the control stations La Boquiilla, Villalba, and Jimenez. For all cases, the model calculates efficiently the peak and base flows.

Likewise, from the seasonal analysis, the model tends to be more accurate for the summer and fall flows.

(a) Ojinaga **(b) La Boquilla**

Figure 5. Relationship between monthly observed and simulated streamflows for the validation period in the control stations: (a) Ojinaga and (b) La Boquilla.

4.3 Statistic Analysis

Table 1 shows a summary of the comparison statistics between simulated and naturalized values. The root mean square error (RMSE) and the mean absolute error were used to measure the deviation between the model outputs with the naturalized flows. Likewise, the error in volume measures the deviation between the naturalized and simulated flows, expressed in percentage. The biggest differences between the naturalized flows and the simulated flows are at the La Boquilla, Jimenez, and Las Burras stations, with errors in volume from 6.3%, -6.4%, and 9.0 %, respectively. Negative error indicates the model overestimate the stream flows in that control station. The overall correlation coefficient varies from 0.87 to 0.94, indicating a strong correlation between simulated and naturalized flows. The correlation is bigger in the stations in the lower basin such as Las Burras, El Granero, and Ojinaga. Uncertainties in the naturalized flows, averaged climatology data used for each sub-catchment as well as the complex hydrological characteristics of the upper basin influence this behavior.

Table 1. Summary of Statistical Results for Monthly Comparison in Simulated and Naturalized Flows.

Statistic	Rio San Pedro at Villalba	Rio Conchos at Presa La Boquilla	Rio Florido at Cd. Jimenez	Rio Conchos at Las Burras	Rio Conchos at El Granero	Rio Conchos at Ojinaga
Number months	240	240	240	240	240	240
Mean observed flow (m3/s)	12.0	44.7	5.6	75.1	73.4	68.1
Mean simulated flow (m3/s)	11.5	41.9	6.0	68.4	73.1	67.9

Abstract

Due to high water demand, the scarcity of water resources, and the complexity of water allocation in the Rio Grande/Bravo basin, environmental flows have not been considered as an integral part of the water management in this basin. Important environmental habitats such as the Big Bend National Park in the US, the Northern Chihuahuan desert, the Maderas del Carmen and the Cañon de Santa Elena natural reserves in Mexico are ecologically threatened because of the lack of environmental water management policies in the basin. Several efforts have been undertaken by government agencies and non-governmental organizations in order to determine the environmental flows requirements for the basin. Even though environmental flows in several locations along the basin have been determined (e.g., the Rio Conchos tributary), the quantification and availability of the water necessary to provide these environmental flows has not been determined. In this paper we evaluate the hydrological feasibility of environmental flows in the Rio Conchos tributary to the Rio Grande. This evaluation is done in a basin model constructed in the Water Evaluation and Planning system (WEAP) software. An analysis of the available water has been defined to determine the amount of water required to provide the environmental flows. The description and evaluation of the environmental flows are presented along with a comparison against the current water management policies.

Introduction

The Rio Grande/Bravo basin is a transboundary basin between Mexico and the United States (U.S.). Historically, this basin has been manipulated in an exclusive human water resource management mode (Enriquez-Coyro, 1976), not considering the environmental needs of the native ecosystems. The Convention of 1906 signed between Mexico and the U.S. (IBWC 1906) and the Rio Grande Compact (TCEQ 1939) ratified in 1939 between the States of Colorado, New Mexico and Texas prove the fact that the water in this basin was thought to be used exclusively for human benefit. The water allocation in these agreements obeys exclusively the human concerns, leaving out the natural water requirements of the basin. As a result of the previous agreements, the quantity of water in the Rio Grande/Bravo reach between El Paso to Presidio Texas were reduced so dramatically, that this reach is now referred

as the "forgotten river" where almost no water flows. Another example is the signature of the treaty of 1944 between Mexico and the U.S. (IBWC 1944). In this treaty, the environmental issues are not considered and the priority assigned to the environment is not even specified, leaving it in disadvantage with respect to the other water uses. In addition, because of the water scarcity in the basin and the high competition among water users for the resource, the environmental requirements has been denied or not even considered for a long time.

In 2002, a consortium of eight institutions integrated by universities, non-governmental organizations (NGO's) and governmental research agencies from both countries was formed to assess the hydro-physical opportunities to improve the water management in the Rio Grande/Bravo basin. By conducting extensive interviews with water users, planning agencies, research institutes, NGO's and local, state and national government institutions the consortium defined a set of 33 scenarios that have some possibility to improve the water management in the basin (NHI 2001 and 2006, PAP 2006).

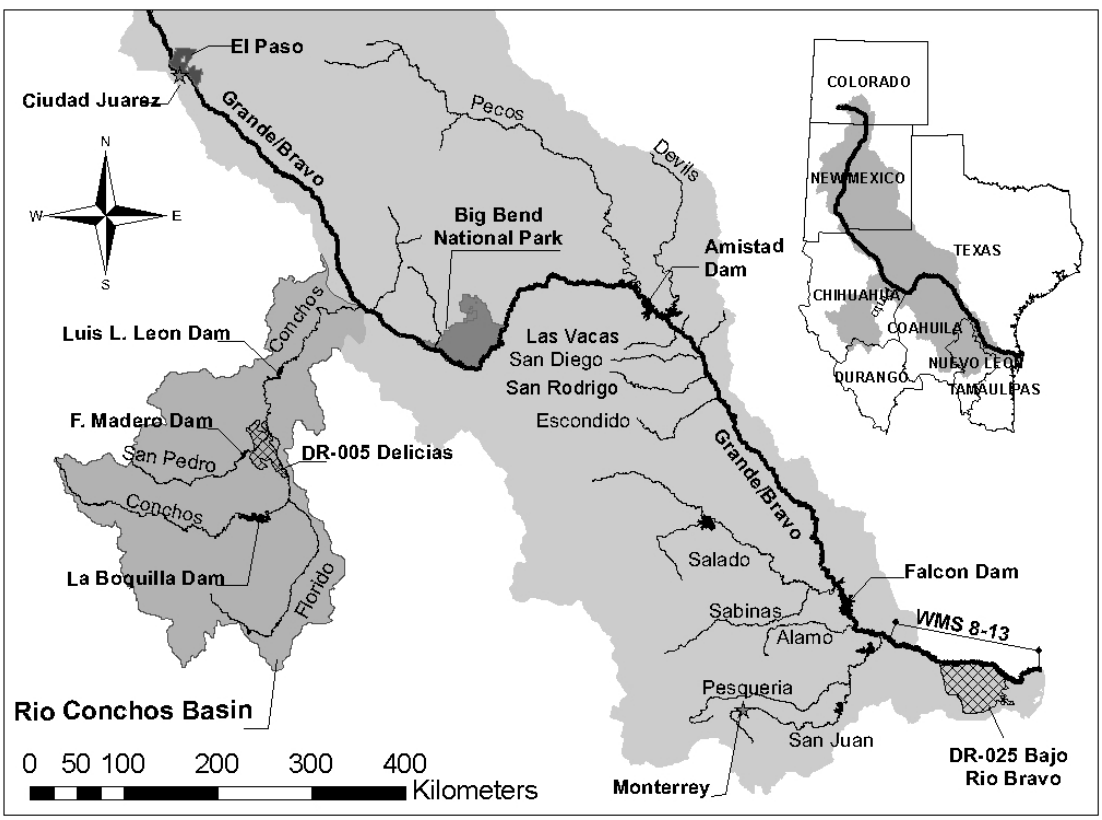

Figure 1. Rio Grande/Bravo Basin.

The aim of this paper is to present the results of one scenario that evaluates the hydrological feasibility of environmental flows in the Rio Conchos, a tributary of the Rio Grande/Bravo. This evaluation is done in a basin model constructed in the Water Evaluation and Planning system (WEAP) software. The description and

evaluation of the environmental flows are presented along with a comparison against the current water management policies.

Environmental flows in the Río Conchos Basin

The Rio Conchos basin is a sub-basin of the Rio Grande/Bravo Basin, it has an area of 25,872 square miles (67,008 Km^2) (Patiño-Gomez and McKinney 2005) and is the main tributary to the Rio Grande/Bravo. Downstream the *forgotten river* reach, where almost no water flows in the Rio Grande/Bravo, Rio Conchos' waters revitalizes Rio Grande/Bravo at their confluence in Ojinaga/Presidio. Environmental flows downstream this point, such as the ones for the Big Bend National park, Maderas del Carmen and Cañon de Santa Elena natural reserves, depends on the water coming from the Rio Conchos.

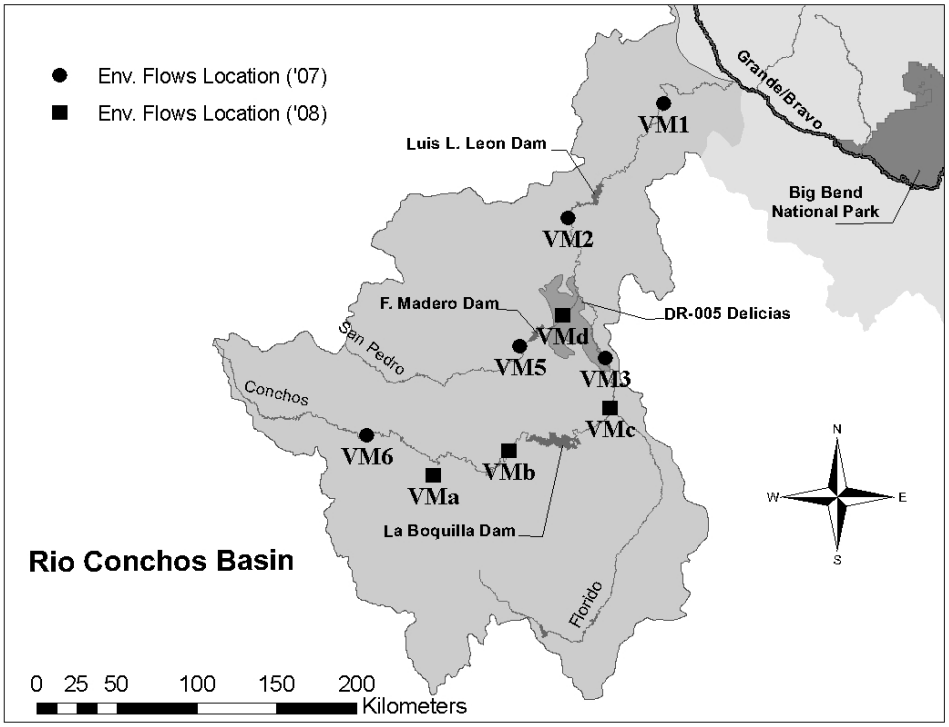

Figure 2. Environmental Flows Locations in the Rio Conchos Basin.

As part of an environmental flow assessment for the Rio Conchos, the World Wildlife Fund estimated the environmental flows in 9 locations along the Rio Conchos basin through the use of the Building Block Method (WWF 2006). The geomorphology, flora and fauna (fish and invertebrates) were considered to determine the maintenance and drought flows necessary to meet the environmental requirements. Figure 2 shows the location where the environmental flows were determined. Table 1 shows the name, stream and annual volume required for each location where environmental flows were defined. A monthly variation for each condition, maintenance or drought, was determined for each location.

Table 1. Location of Environmental flow control points

Site	Name	River	Environmental Flow Maintenance ($1X10^6$ m^3/year)	Drought ($1X10^6$ m^3/year)
VM1	Cuchillo Parado	Conchos	381.5	47.7
VM2	El Potrero	Conchos	323.6	36.2
VM3	Estación Conchos	Conchos	27.1	14.2
VM5	San Pedro de Conchos	San Pedro	114.2	34.1
VM6	Agua Caliente	Conchos	134.5	24.4
VMc	Camargo	Conchos	50.6	23.6
VMd	C. Ortíz	San Pedro	60.8	45.3

One of the goals in this research is to determine if there is enough water in the basin to satisfy the environmental requirements at the locations selected and how much it affects other users in the basin. Ideally, we are looking for an alternative policy that meet the environmental needs without harming other water users, in other words, an alternative policy that is hydrologically feasible. In reality, it is necessary to evaluate several alternative water management policies and chose the one that brings the best tradeoffs between the delivery of water to the environment and the damages to other water users. Once the alternative policy is determined, more detailed operation policies must be developed to assess the facilities operation to meet the environmental flows in time, volume and space. The last assignment is out of the present research.

For this paper, 5 control points were selected to evaluate the environmental flow compliance at these locations: VM1 Cuchillo Parado, VM2 El Potrero, VM3 Estacion Conchos, VMc Camargo and VMd C. Ortiz. These control points were selected because they are spatially located downstream control structures, such as dams, that made available the intentional delivery of environmental flows to these locations. The control points VMa and VMb do not have any control structure that made possible the intentional delivery of environmental flows.

Methodology

The following methodology is proposed to evaluate the hydrological feasibility of environmental flows in the Rio Conchos basin.

1. An evaluation of the environmental flows proposed with the actual water management policies is done to identify the conflict points where the environmental requirements are more threatened.
2. An alternative operation policy is proposed.
3. The alternative operation policy is evaluated to determine if it improves the environmental requirements and how much this policy affects or benefits other water users in the basin.

The Rio Grande/Bravo WEAP model was used to evaluate the actual and proposed water management policies in the Rio Conchos basin. The model has an hydrologic period of analysis of 60 years, form October 1940- to September 2000, it has been calibrated, validated (Danner et al. 2006) and it has been used to evaluate other alternative water managements policies (Sandoval-Solis et al. 2008).

Status Quo of the Environmental flows in the Rio Conchos Basin

A Baseline scenario that follows the actual policies of water management in the basin was constructed in the Rio Grande/Bravo WEAP model. The alternative water management policies will be compared with the Baseline scenario to evaluate the improvements in the system. Three performance criteria are used to evaluate the environmental flow compliance at each location: Reliability, Resilience and Vulnerability (Loucks and van Beek 2006). Reliability refers to the frequency in time an event is successful in relation to the total period of time analyzed (Hashimoto et al. 1982 and Klemes et al. 1981). We define a successful event as the event when there is no deficit in the delivery of environmental flows to the location in concern. Resilience is the probability that once the system is in a deficit, the next period the system recover to a successful event (Hashimoto et al. 1982). Vulnerability is the expected value of the deficits, in other words, it is the average deficit of environmental flows experienced (Hashimoto et al. 1982). For this paper, we are going to use the dimensionless vulnerability by dividing the average annual deficit by the environmental annual requirement (McMahon et al. 2006). These three performance criteria we are used to analyze the environmental flows.

Table 2. Reliability Resilience and Vulnerability for the Baseline Scenario

Location	Reliability (%)	Resilience (%)	Vulnerability (%)
VM1	60	58	3
VM2	42	37	9
VM3	2	0	69
VMc	2	0	70
VMd	2	0	74

Table 2 shows the reliability, resilience and vulnerability for the 5 control points selected with the actual water management conditions. For VM1, 60 percent of the time the environmental flows were met properly (Reliability); the average annual deficit to meet the environmental requirements is 3% (Vulnerability), and the probability of coming back from a deficit is 58% (Resilience). For VM2, 42% of the time the environmental needs were delivered properly (Reliability), the average annual deficit is 9% of the environmental flow requirements and the probability of coming back from a deficit is 37%. Notice that these two control points, which are located in the lower part of the Conchos basin, have the best results among the 5

control points evaluated. For the control points VM3, VMc and VMd, located in the middle of the Conchos basin, only 2% of the time the environmental flows were met among the 60 year period of analysis, the average deficit to meet the environmental requirements was 69, 70 and 74% respectively, and when the system fall into a deficit, it never come back again, 0% of Resilience. From these results is possible to affirm that the environmental flow are better accomplished in the lower Rio Conchos basin than in the middle and upper region.

Environmental Flow Scenario

The previous results showed that the conflict zones are located in the middle Conchos basin, at the control points VM3, VMc and VMd. As an initial approach, we propose an alternative water management policy that delivers water to the control points VMc and VMd. These control points are the most upstream control points to be analyzed and they are located just downstream La Boquilla and F. Madero reservoirs. Two reasons were considered for this decision. First, these are locations where water can be delivered properly from the dams in time and quantity, making the alternative policy operationally feasible. Second, we would like to evaluate if meeting the environmental requirements in the most upstream sites, it will provoke the rest of the control points downstream also meet their environmental requirements.

An analysis of La Boquilla–Francisco I. Madero reservoir system was done, in order to decide what kind of environmental flows, maintenance or drought, is allocated each year to the environment. First, at the beginning of each hydrological 0) in the reservoir system is estimated as the sum of the available storage in La FM). The available storage for each reservoir is calculated by subtracting the storage $+Losses$).

FM
$+Losses$
$+Losses$

Second, the *diversion* required to satisfy all the users from this reservoirs system is estimated. The *diversion* is calculated dividing the surface water right (SW) from these reservoirs by the conveyance efficiency ($Conv.Eff.$) from the reservoir to the delivery point.

$Conv.Eff.$

Finally, the *available storage* is compared with the *diversion*. Based on this comparison a decision is made:

1. If the *available storage* is larger than the *diversion*, the maintenance flow is assigned,

$$Maintenance$$

2. If the *available storage* is less than the *diversion*, the drought flow is assigned.

$$Droug\square t$$

The philosophy of this decision is that if the water users are expecting a shortage in their water supply, it is reasonable to ask only for the minimum volume of water for the environment, that in this case is the drought volume. If there is enough water in the reservoir system to supply properly all the water users, it is reasonable to ask for the normal flow for the environment than in this case is maintenance flow.

Evaluation of the Environmental Flow Scenario

Table 3 shows a comparison of the reliability, resilience and vulnerability between the Baseline and the Env. Flow scenario for the 5 control points selected. As can be seen, all the performance criteria were improved significantly. The reliability for all the points except of VMd is almost 100%. This means that almost all the time the environmental flows were delivered at these locations. Similarly, the resilience follows in all the control points, except VMd, has a value of 100%. This means that when a deficit happens in the environmental requirements, the next period the system recovers delivering the adequate water quantity to the environment. In addition, the vulnerability also decreased significantly almost to 0%. This means that when a deficit in the environmental requirements happens, the quantity of the deficit is small, 0% in almost all locations and 4.6% at VMd downstream F. Madero.

Table 3. Comparison of the Reliability Resilience and Vulnerability between the Baseline and the Environmental Flow Scenario

	Reliability		Resilience		Vulnerability	
	Baseline	Env. Flows	Baseline	Env. Flows	Baseline	Env. Flows
Location	(%)	(%)	(%)	(%)	(%)	(%)
VM1	60	100	58	100	3	0
VM2	42	100	37	100	9	0
VM3	2	97	0	100	69	0.3
VMc	2	97	0	100	70	0.2
VMd	2	78	0	46	74	4.6

Even thought there is a significant improvement in the delivery of environmental flows in all the locations, the three points located in the middle Rio Conchos basin will not meet all the times the environmental requirements. For VM3 and VMc, the failures may be ignored since it has a reliability of 97% and an average deficit (Vulnerability) close to 0% (0.3% and 0.2% respectively). In contrast, the failures for VMd cannot be ignored, since 22% of the time the environmental flows will not be meet by an average of 5%. These results show that during drought periods,

there is not enough water in the La Boquilla – F. Madero reservoir system to satisfy the environmental minimum request that is the drought flow volume.

Now, let's evaluate how the implementation of the Environmental Flow scenario may affect or benefit other water users along the basin. For this purpose, the three biggest water user consumers were selected, two irrigation districts from Mexico, DR-005 Delicias and DR-025 Bajo Rio Bravo; and one irrigation district from the U.S., WMS-8-13 Agriculture "A". Table 4 shows the performance criteria results for these water users.

As can be seen, irrigation district DR-005 Delicias will be affected by the alternative policy proposed since the period of time this user was supplied properly (Reliability) will be reduced from 72% to 65%. Besides, its average deficit (Vulnerability) increases from 36% to 48 %. These results were expected since DR-005 Delicias relies on La Boquilla and F. Madero dams as its main source of water. In contrast, the performance of irrigation district DR-025 Bajo Rio Bravo improved since its reliability increases from 93 to 95%. However, the Environmental scenario also increased the vulnerability for DR-025 Bajo Rio Bravo.

Table 4. Performance criteria for main water users

	Reliability		Resilience		Vulnerability	
	Baseline	Env. Flows	Baseline	Env. Flows	Baseline	Env. Flows
WaterUser	(%)	(%)	(%)	(%)	(%)	(%)
DR-005	**72**	**65**	29	29	**36**	**48**
DR-025	**93**	**95**	25	25	**25**	**29**
WMS 8-13	85	85	22	22	15	15
Treaty Obligations	83	83	50	50	**38**	**33**

Considering the distribution of water between Mexico and the U.S., the Treaty of 1944 (IBWC 1944) specifies the water distributions and allocation among both countries. In summary, for the Rio Grande/Bravo, Mexico has the obligation to deliver a volume of $431.721X10^6$ m^3 to the U.S. on average, per year in cycles of 5 consecutive years; this means a total of $2158.605\ X10^6$ m^3 per cycle. This volume must be achieved by 1/3 of the waters reaching the main channel of the Rio Grande/Bravo from 6 Mexican tributaries (Rio Conchos, San Diego, San Rodrigo, Escondido, Salado and Arroyo Las Vacas). Results for the treaty obligations presented in Table 4 showed that the number of deficits will not be reduced (Reliability doesn't change), and the system will recover as fast as it does with the actual policy (Resilience does not change), however, there is an improvement in the reduction of the expected deficit amount (Vulnerability), from 38% estimated with the actual policy to 33% estimated with the policies proposed in the Environmental Scenario. These results show that as a consequence of the policies proposed in the Environmental Scenario, the delivery of treaty obligation from Mexico to the U.S. will be improved.

Conclusions

Results presented in this paper show the alarming situation of the environment in the Rio Grande/Bravo basin, specifically at the Conchos basin. The actual water management does not meet the environmental requirements by far. Results obtained in the Environmental Flow scenario showed a significant increase in meeting the environmental requirements in the Rio Conchos basin. Besides, the policies proposed also benefit the treaty obligations and water users located in the lower Rio Grande/Bravo basin, such as irrigation district 025 Bajo Rio Bravo. In contrast, the application of the Environmental Flow scenario will affect irrigation district 005 Delicias. These conclusions are discussed in detail as follows:

1. The actual environmental conditions in the basin are unsustainable. Results for the 5 control points evaluated with the actual water management show the lack of compliance of the environmental flows in the Rio Conchos basin. The area more affected is the middle Rio Conchos basin, where the environmental requirements are almost never met. In the lower Rio Conchos basin, the situation is better than in the middle basin but is still worrying. The analysis of the actual conditions let us determine the where the conflicts areas are in order to propose actions to solve the situation in these locations.
2. Results from the policies proposed in the Environmental Scenarios showed a significant improvement in the environmental situation for the entire basin. Meeting the environmental flows in the most upstream control points, VMc and VMd, increases significantly the environmental flows in all the control points evaluated. The improvements can be listed as follows:
   a) Increase in the period of time the environmental needs are met (Reliability);
   b) Increase in the resilience of the environmental flows; the system was able to recover faster when it fails; and
   c) Decrease in the environmental flows deficit (Vulnerability). When the system was not able to deliver the environmental requirements, the failure was smaller than in the actual conditions.
3. Even though the environmental requirements can be improved significantly, it will not be satisfied completely by the alternative policies proposed. The results showed that not all the times the environmental requirements will be met because during drought periods, there is not enough water in the reservoirs systems to supply the water users and the environmental needs.
4. The policies proposed in the environmental scenario will affect irrigation district 005 Delicias with a decrease in the time this irrigation district is supplied properly and an increase in the amount of the deficits. On the contrary, the Environmental scenario will benefit the Treaty obligations by reducing the volume of the deficits and irrigation district 025 Bajo Rio Bravo by increasing the period of time this water user is supplied properly.

Recommendations

The policies proposed in the Environmental scenario are recommended because they will improve the environmental situation of the Rio Conchos basin. However, further research is need to find out a policy that mitigates the ravages provoked to DR-005 Delicias, one of this policies may be the delivery of the water savings established in Minute 309 in an environmental pattern.

Besides, it is also necessary to determine the environmental flow requirements in other parts of the Rio Grande/Bravo basin, such as the Big Bend area. The determination of these flow requirements in other regions will make possible the evaluation of the environmental faith with the actual water management policies and will also make possible the proposition of alternative water management policies that can improve the environment situation of the basin.

Impacts of the Upstream Storage Reservoirs on Itaipu Hydropower Plant Operation

by
Mario T. L. Barros[1], Renato C. Zambon[2], João Eduardo G. Lopes[3], Paulo S. F. Barbosa[4], Alberto L. Francato[5] and William W-G. Yeh[6]

Abstract

This paper presents some results related to the operation of the Itaipu hydropower plant. Itaipu is one of the largest hydropower plants in the world. It is a binational undertaking run by Brazil and Paraguay at the Paraná River on the border section between the two countries. Each country owns 50% of the installed capacity (14,000 MW). This study evaluates the impacts of the upstream storage reservoirs on the hydropower production of Itaipu. The analysis involves a system of 55 hydropower plants. Itaipu hydropower plant operates as a run-of-river reservoir and itself does not have storage capacity. However, there are many upstream storage reservoirs located in Brazil. The analysis is conducted using the HIDROTERM decision support system (DSS), which is basically an optimization model. HIDROTERM is designed for the management and operation of large hydrothermal systems. In its formulation the hydro plants are considered individually and the thermal plants are aggregated into subsystems. The optimization model is capable of handling different types of constraints, such as water transfers, multiple purposes and environmental requirements. Its objective function is to produce energy at a minimum cost. HIDROTERM integrates a database with basic information (hydrological and technical) to run the model and an interface to manage input and output data. The optimization model is written using the General Algebraic Modeling System (GAMS) package and so it can run with different nonlinear programming (NLP) routines. The results from the analysis show that the upstream reservoirs located in Brazil have significant impacts on the hydropower production of Itaipu.

Introduction

This paper presents some results related to the operation of the Itaipu hydropower plant. The Itaipu dam was built from 1971 to 1982 and the first generating unit started running in 1984. Two or three units were installed per year until 1991 and the last two units in 2006 and 2007, completing the today installed capacity of 14,000 MW, with 20 generating units of 700 MW each. The total length of the dam is 7,235 m. The reservoir area is 1,350 Km², with a storage capacity of 29,000 hm³ and an average head of 120 m. It is a binational undertaking run by Brazil and Paraguay at the Paraná River on the border section between the two countries. Each country owns 50% of the installed capacity, but Brazil uses most part of it, buying the surplus produced by Paraguay. While Brazil consumes its entire half, Paraguay only consumes five percent of its share and sells the rest back to Brazil. In 2008, Itaipu produced 94,684 GWh which supplied 90% of the energy consumed by Paraguay and 19% of the energy consumed by Brazil. Note that, in terms of annual energy production, Itaipu ranks number one in the world, but it is second only to the Three Gorges plant in terms of installed capacity.

Itaipu hydropower plant operates as a run-of-river reservoir and itself does not have storage capacity. However, there are many upstream storage reservoirs located in Brazil. The Paraná river basin has a system of 55 hydropower plants, the most important basin in the Brazilian electrical system.

The Brazilian electrical system is one of the largest in the world due to its hydro and thermal plants. The system is completely linked and called SIN (*Sistema Interligado Nacional*). Recent data from ANEEL (2009) indicates that during the period from 2005 to 2008, on average, 91% of the electricity was produced by the hydro system and 9% by the complementary thermal system, which includes natural gas, nuclear, biomass and other sources. Brazil has, including hydro, thermal and other systems, 2,019 power plants with 110,979 MW of installed capacity, Itaipu contributing 13% of it.

This study evaluates the impacts of the upstream storage reservoirs on the hydropower production of Itaipu.

The analysis is conducted using the HIDROTERM decision support system (DSS) developed by Barros et al (2008), which is basically an optimization model. HIDROTERM is designed for the management and operation of large hydrothermal systems. In its formulation the hydro plants are considered individually and the thermal plants are aggregated into subsystems. The optimization model is capable of handling different types of constraints, such as water transfers, multiple purposes and environmental requirements. Its objective function is to produce energy at a minimum cost. HIDROTERM integrates a database with basic information (hydrological and technical) to run the model and an interface to manage input and output data. The

optimization model is written using the General Algebraic Modeling System (GAMS, 2008) package and so it can run with different nonlinear programming (NLP) routines.

Optimization models have been developed for reservoir management and operation. Yeh (1985), Simonovic (1992), Wurbs (1993), Momoh et al (1999a,b), and Labadie (2004) have reviewed and evaluated various optimization methods and their corresponding models. In Brazil the ACQUANET model developed by Porto et al. (2005) and the SISOPT model developed by Barros et al (2003, 2005) are being used to optimize large-scale and complex reservoir systems.

Yeh et al. (1992) developed a real-time optimization model for hydrothermal system operation in China. The model considered the seasonal variations of inflow to the reservoirs, the variation of transmission losses with hydro and thermal plant loadings, and thermal unit commitment and dispatch.

HIDROTERM Model Methodology

The HIDROTERM model consists of a hydro module/model (HIDRO) and a thermal module/model (TERM). These two modules are connected. The optimization process can proceed in different combinations: with the HIDRO module alone, the TERM module alone, the HIDRO and TERM connected by an iterative process, and the automatically coupled HIDRO and TERM. In this paper only the HIDRO module was used.

The HIDRO module employs an operation policy that considers individualized hydropower plants producing electrical energy with maximum efficiency: reservoirs empty or fill, keeping the maximum value of the energy production factor and following the demand curve variation in time so that the thermal complement is minimum. In mathematical terms the problem lends itself to nonlinear programming (NLP) with the following objective function and subject to a set of constraints:

$$\min ZH = \sum_{t=1}^{nt} dt_t \cdot \left[D_t - \sum_{i=1}^{ni} P_{i,t} \right]^2 \qquad (1)$$

where:
i = hydropower plant/reservoir index
ni = number of hydropower plants/reservoirs
nt = number of time periods
t = time period index
dt_t = time period duration (10^6 s)
D_t = objective demand, usually the total demand minus the fixed generation, though it can be defined arbitrarily by the user (for example, as the maximum installed power capacity MW)
ZH= HIDRO model objective (10^6 s.MW²)

The HIDRO model is subject to the following set of constraints:

Total release is the summation of the turbine release and non-power release or spill:

$$R_{i,t} = R'_{i,t} + R''_{i,t} \tag{2}$$

Continuity equation:

$$S_{i,t} = S_{i,t-1} + dt_t \left[\sum_{m_i=1}^{nm_i} R_{m_i,t} + I_{i,t} - R_{i,t} - UC_{i,t} - DT_{i,t} \right] - E_{i,t} \tag{3}$$

Evaporation:

$$E_{i,t} = \frac{A_{i,t} + A_{i,t-1}}{2} \cdot IE_{i,t} \tag{4}$$

Storage limits, with time-varying flood control:

$$S_i^{\min} \le S_{i,t} \le S_{i,t}^{\max} \tag{5}$$

Power generation capacity:

$$P_{i,t} \le P_i^{\max} \cdot ID_{i,t} \tag{6}$$

Ending storage:

$$S_{i,t=nt} \ge S_{i,final} \tag{7}$$

Total, turbine and non power release limits:

$$R_{i,t} \ge R^{\min}{}_i \tag{8}$$

$$R'^{\min}_i . ID_{i,t} \le R'_{i,t} \le R'^{\max}_{i,t} . ID_{i,t} \tag{9}$$

$$R''_{i,t} \ge 0 \tag{10}$$

Water head:

$$Hg_{i,t} = \frac{H_{i,t} + H_{i,t-1}}{2} - HT_{i,t} \tag{11}$$

Power generation:

$$P_{i,t} = \eta_i \cdot Hg_{i,t} \cdot R'_{i,t} \tag{12}$$

Forebay water level:

$$H_{i,t} = a_{0i} + a_{1i} \cdot S_{i,t} + a_{2i} \cdot S_{i,t}^2 + a_{3i} \cdot S_{i,t}^3 + a_{4i} \cdot S_{i,t}^4 \tag{13}$$

Tailrace water level:

$$HT_{i,t} = b_{0i} + b_{1i} \cdot R_{i,t} + b_{2i} \cdot R_{i,t}^2 + b_{3i} \cdot R_{i,t}^3 + b_{4i} \cdot R_{i,t}^4 \tag{14}$$

Reservoir area:

$$A_{i,t} = c_{0i} + c_{1i} \cdot H_{i,t} + c_{2i} \cdot H_{i,t}^2 + c_{3i} \cdot H_{i,t}^3 + c_{4i} \cdot H_{i,t}^4 \tag{15}$$

Turbine flow maximum limit:

$$R_{i,t}^{\acute{}\max} = d_{0i} + d_{1i} \cdot Hg_{i,t} + d_{2i} \cdot Hg_{i,t}^2 + d_{3i} \cdot Hg_{i,t}^3 + d_{4i} \cdot Hg_{i,t}^4 \tag{16}$$

where:

j_k = hydropower plant/reservoir index in subsystem k
k = subsystem index
m_i = index for upstream hydropower plants/reservoirs to i
nj_k = number of hydropower plants/reservoirs in subsystem k

nm_i = number of upstream hydropower plants/reservoirs to i
$A_{i,t}$ = reservoir forebay area (Km²)
$DT_{i,t}$ = deviation or transposition uses (m³/s)
$E_{i,t}$ = evaporation (10^6 m³)
$Hg_{i,t}$ = water head (m)
η_i = power generation efficiency ($0 \leq \eta_i \leq 1$) (-)
$H_{i,t}$ = reservoir forebay water level (m)
$HT_{i,t}$ = reservoir tailrace water level (m)
$ID_{i,t}$ = availability index due to maintenance and system expansion ($0 \leq ID_{i,t} \leq 1$) (-)
$IE_{i,t}$ = evaporation rate during time period t (m)
$I_{i,t}$ = natural inflow (m³/s)
$P_{i,t}$ = energy production (MW)
$P^{max}{}_i$ = maximum energy production (MW)
$R''_{i,t}$ = spill or non-power release (m³/s)
$R'_{i,t}$ = power release (m³/s)
$R'^{max}{}_{i,t}$ = maximum power release (m³/s)
$R'^{min}{}_i$ = minimum power release (m³/s)
$R_{i,t}$ = total release (m³/s)
$R^{min}{}_i$ = minimum total release (m³/s)
$S_{i,t}$ = storage (10^6 m³)
$S^{max}{}_{i,t}$ = time-varying maximum storage for flood control (10^6 m³)
$S^{min}{}_i$ = minimum storage (10^6 m³)
$UC_{i,t}$ = consumptive use (m³/s)

Case study: Itaipu Dam and Upstream Reservoirs

The input data for the case was based on the official data from ONS published in July 2008 (ONS, 2008). The data set includes the existing system and planned expansion for the next five years. But in this study only the existing system and subsystem of 55 hydropower plants and reservoirs in the Paraná river basin are used, which include Itaipu, as shown in figure 1. Out of the 55 plants, 31 are run-of-river and 24 have storage to regulate flows in the basin.

To evaluate the impacts of the upstream storage reservoirs on the hydropower production of Itaipu two operation scenarios were used: first, operating the system in a simulation mode with run-of-river operation and natural inflow; that is, without the effect of the upstream storage reservoirs; and second, optimizing the system to minimize the hydropower quadratic complementation for the entire basin, with the 55 hydropower plants. The optimization was applied to obtain the best results for the entire basin production. The historical natural inflow series from 1940 to 1999 was divided into six segments (one for each decade) and used as inputs to the optimization model.

One important aspect as shown in figure 2 is that the historical series is non-stationary. This is mainly due to changes in soil use in the last decades which were

basically from forests to agricultural occupation, thus reducing evapotranspiration and increasing the runoff.

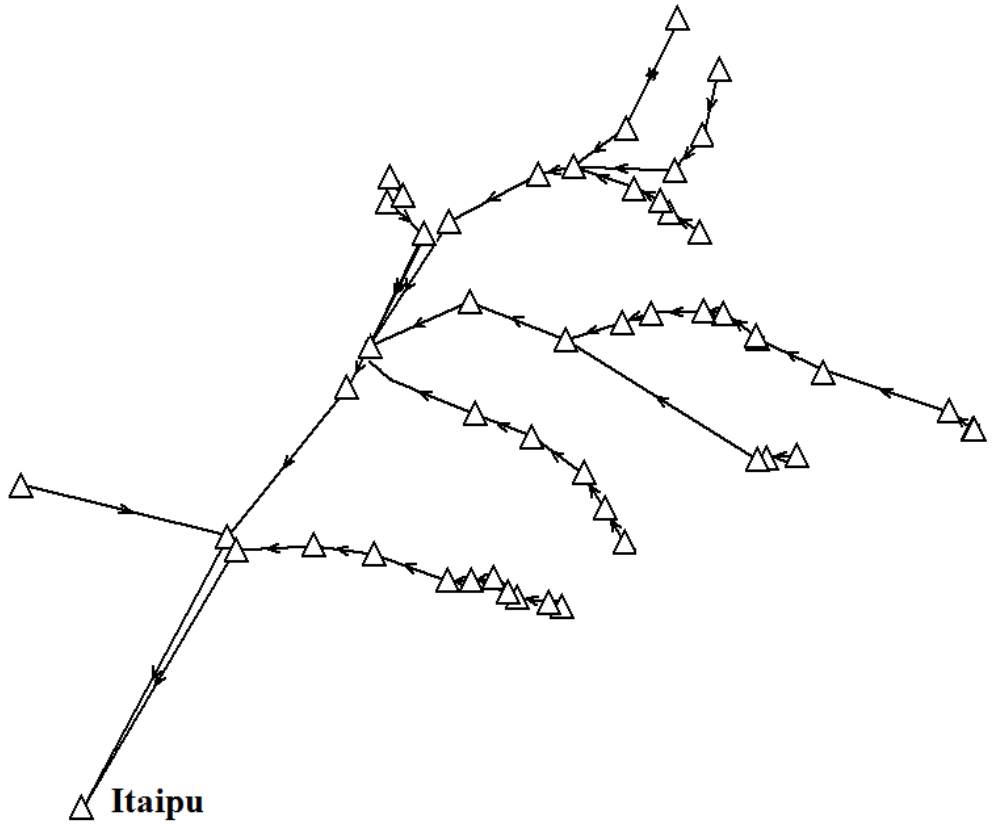

Figure 1 - Network of hydropower plants in the Paraná river basin, including Itaipu

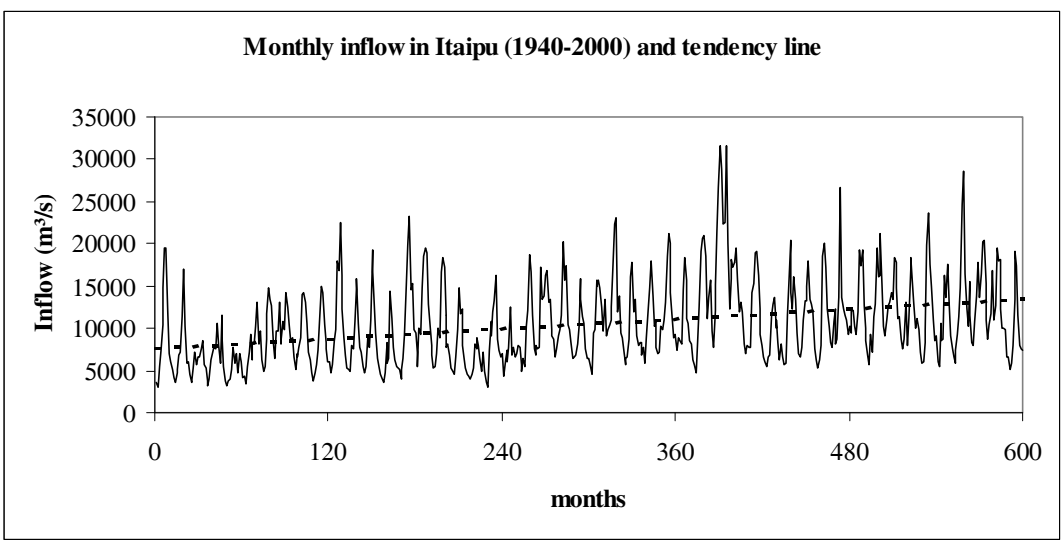

Figure 2 - Natural inflow at Itaipu

Table 1 and figure 3 show the results of Itaipu average production with run-of-river operation and natural inflow as well as the optimized results with upstream regularization. In all six scenarios of inflow the production in Itaipu was significantly increased due to the regularization of the upstream reservoirs in the basin.

Table 1 - Itaipu average production with run-of-river operation and natural inflow (Pror) as well as with upstream regularization (Pres)

decade	Pror(MW)	Pres(MW)	Δ(%)	Δ(MW)
1940	8186	9123	11.4%	937
1950	7839	8315	6.1%	476
1960	8499	9771	15.0%	1272
1970	9822	11283	14.9%	1460
1980	10398	11851	14.0%	1453
1990	10613	11977	12.8%	1363

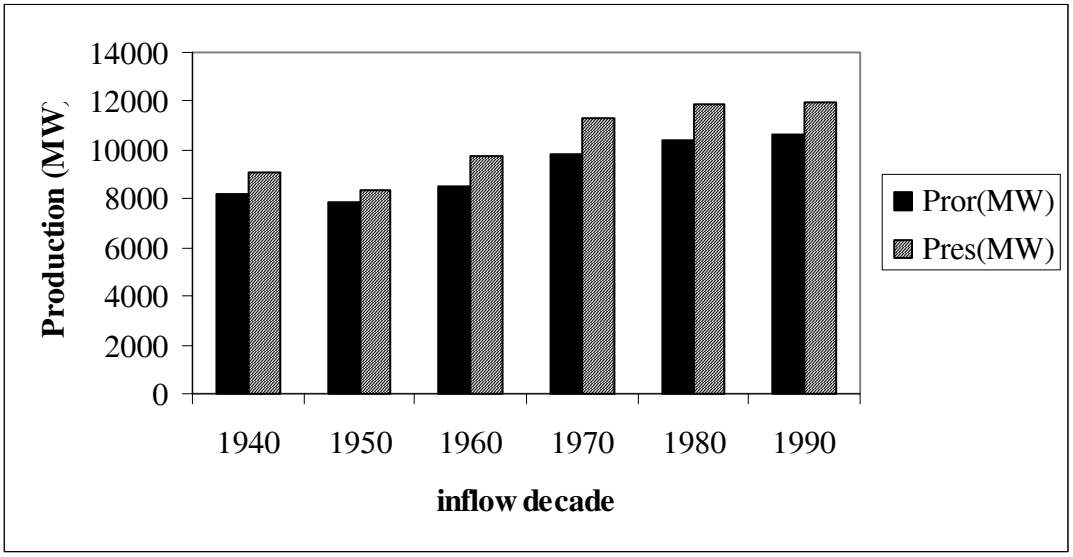

Figure 3 - Itaipu average production with run-of-river operation and natural inflow (Pror) as well as with upstream regularization (Pres)

In this example the HIDRO problem size was reasonably large, with 15,360 decision variables. The optimization was done using MINOS, a nonlinear programming routine. The process required from 17 to 24 minutes on a notebook with an AMD Turion64 X2 TL-58 (1.9GHz) processor to run each decade scenario (55 hydropower plants and 120 time steps).

Final Comments

This paper has presented an application of the HIDROTERM DSS to evaluate the impacts of the upstream storage reservoirs on the hydropower production of Itaipu. Using the last three decades of historical inflow data, the optimized power production when considering the upstream regularization was on average 14% or 1426 MW higher than the power production obtained without upstream regulation. This conparasion indicates that there are significant impacts and benefit of the upstream regularization not only for the entire system but also for the Itaipu power production.

The methodology presented is suitable to different applications, such as planning operation and studies of reliability, capacity expansion, environmental constraints, operational rules, tradeoff between multiple uses of water and other technical aspects related to hydrothermal systems.

ABSTRACT

Artificial neural network (ANN) is used for inflow forecasting of reservoir up to the next 12 hours. Numerical weather forecasting information (RDAPS), recorded rainfall data, water level of upstream dam and stream gauge site, and inflow of the current time are employed as input layer's training values, and target value is +3, +6, +9, and +12 hours later inflow to Hwacheon reservoir in South Korea. Comparison result between ANN with RDAPS and without RDAPS shows that RDAPS information is useful for forecasting inflow of reservoir.

INTRODUCTION

Accurate inflow forecasting for reservoir operation is essential for proper and reliable operation (Labadie 2004). Especially for flood season operation in order to prevent flooding from downstream area, at most next 12 hours inflow should be forecasted with accuracy. However, most of physically based rainfall-runoff model such as HEC-1 in real-time reservoir operation show very poor model performance and they need a lot of time and effort to be modified for incorporate rainfall forecasting information which is able to be acquired by numerical weather forecasting model that is a common tool for weather forecasts.

Artificial neural network (ANN) has been adopted widely to forecast lots of hydrological variables like runoff, water-level, or occasionally rainfall amount itself (Dibike and Solomatine 2001; Tokar and Markus 2000; Wu et al. 2005). It has strong

points to compute a response resulted from many nonlinear impact factors, and this nonlinearity is very common phenomenon in hydrologic modeling. Moreover, hydrologic model should consider the lack of data by malfunction of recording device or disconnection from network in real-time operation. Therefore, the conventional physically based hydrologic model would not be proper to applied to real-time operation, especially for reservoir operation.

In addition, the recent advanced numerical weather forecasting model (Guo and Senior 2006) like RDAPS (Regional Data Assimilation and Prediction System) of South Korea show reliable prediction result with regard to qualitative analysis that forecast "on and off" of rainfall in the next 24 hours, thus the rainfall forecasting information from RDAPS could be used for inflow forecasting although quantitative analysis result shows very poor performance.

The goal of this study is to evaluate the usefulness of RDAPS data into reservoir inflow forecasting in real-time operation. A short length of data confines a limited evaluation of ANN using only training data set without calibration, and verification data sets, however, comparison study of two cases with- and without-RDAPS information simply shows the advantage of ANN with numerical weather forecasting data.

ANN AND RDAPS

ANN has been widely used for inflow or runoff forecasting from lots of researches. The ANN model here has very simple structure that has only one hidden layer with 4 hidden nodes, and backpropagation, one of the most implemented error propagating method, is applied also (Bishop 1995). As mentioned before, we have very short record lengths of RDAPS, namely at most 4 years, and during this period only one rainfall-runoff event can be used for evaluation of ANN. Therefore, only training process can be applied here, and if the more RDAPS data and corresponding rainfall-runoff events are gathered, whole procedure of evaluation for ANN would be employed.

RDAPS data are computed by Korea Meteorological Administration (KMA) and its data format is GRIB that is popular in meteorological science field. It has 191 by 171 grids with 30km distance and is projected on Lambert Conformal surface. RDAPS has been calculated at 00UTC and 12UTC that is 09:00 and 21:00 local time with 3-hours interval, and forecasting time horizon is 66 hours. Usually, next 48 hours forecasting information which is 16 time steps is used for operational use. Fig. 1 shows APCP variable layer at the ground level with GrADS software.

INFLOW FORECASTING FOR REAL-TIME RESERVOIR OPERATION

Inflow forecasting with artificial neural network and regional numerical weather forecasting model, namely RDAPS mentioned in the previous section, is applied to Hwacheon reservoir basin in South Korea (Fig. 2). The basin area of Hwacheon reservoir is about 3,845 km^2 and there are two local streams in the basin. Peace dam that is located at the very upstream of Hwacheon reservoir has four tunnels for releasing water downstream and it has no spillway with gate. Peace dam is in the lake of Paroho that is made by Hwacheon dam, thus water level of Peace dam is one of the measuring tools for forecasting inflow of Hwacheon reservoir. The other water level gauge located at YangGu SeoChun that is another local stream in Hwacheon reservoir basin is used also for inflow forecasting.

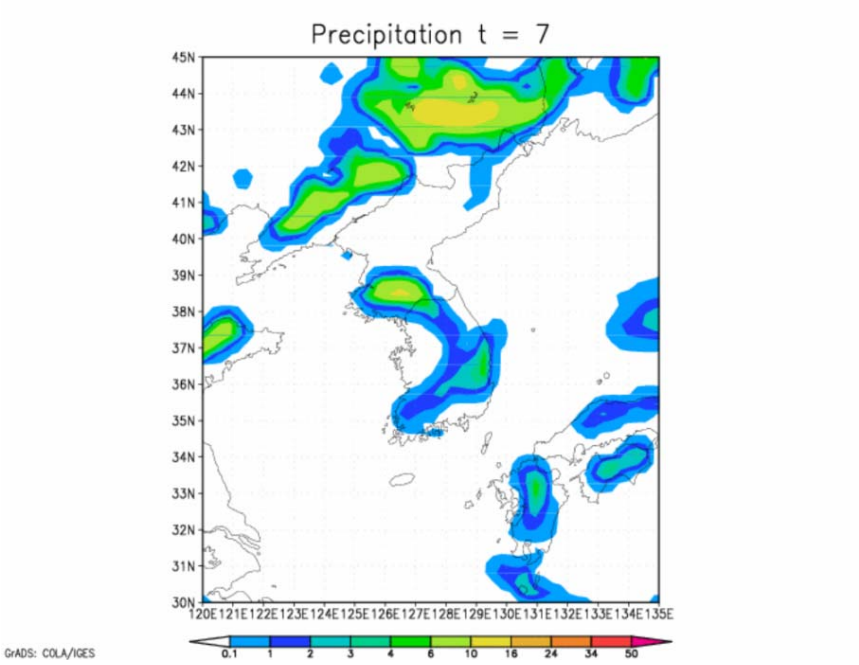

Fig. 1 Surface precipitation data extracted from RDAPS 30km

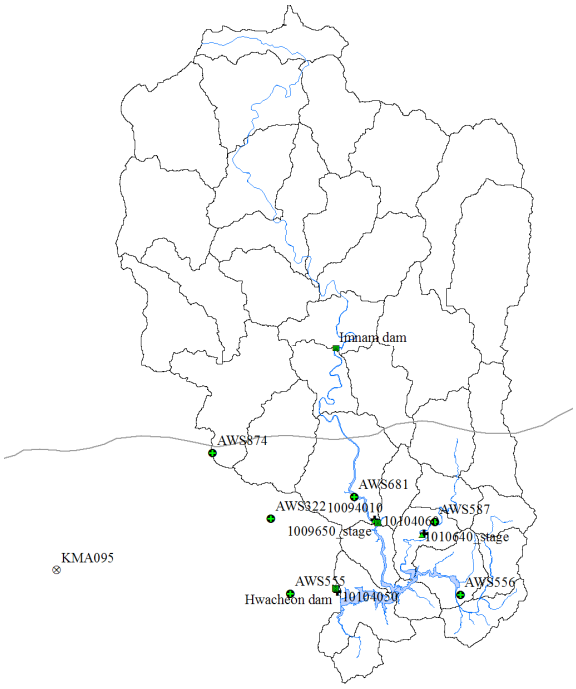

Fig. 2 Hwacheon and Peace dam basin and rainfall and water level recording sites

The experiment is performed with two cases. The first one uses rainfall data gathered from total 10 rainfall recording sites. Seven sites are inside of Hwacheon reservoir basin and the other are in the west outside region of basin. Because Korea Peninsula is located in the westerly wind area, the rainfall that is recorded at the west side of basin can be used to forecast the future time's rainfall. The second one applies only RDAPS data as rainfall input of ANN model. None of any rainfall data from recording sites is employed in this case. All of these two experiment use inflow data of Hwacheon reservoir at the current time as additional input of ANN model. Therefore, the first case has 13 input data that are 10 rainfall data, 2 water level data, and 1 inflow data, and the second one has only 4 input data such as 2 water level data, 1 RDAPS data, and 1 inflow data.

RDAPS data can be acquired during only about 4 years from January 1 of 2005 to September 30 of 2008, and corresponding inflow data of Hwacheon reservoir that are relatively large enough to release water through spillway can be achieved only in July 2006. Thus, the experiment is performed with a rainfall-runoff event which was occurred in between July 12 and 18 of 2006 (Fig. 3). This event has a maximum inflow as 5,254 m^3/sec at 1:00 pm, July 15 and has a smaller peak (978 m^3/sec) at 21:00 pm, July 12.

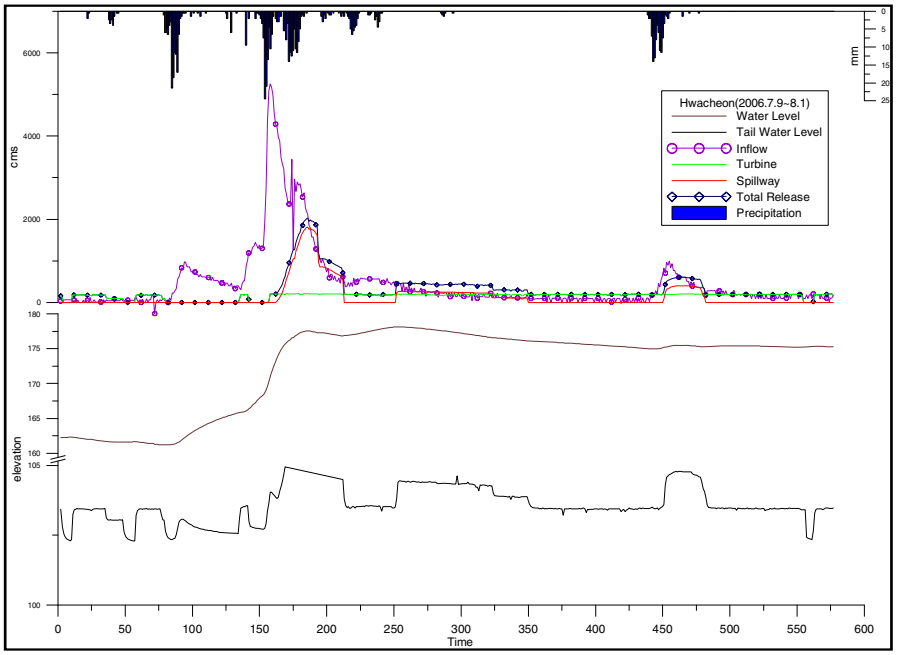

Fig. 3 Rainfall-runoff event in July 12 and 18 of 2006 at Hwacheon basin

Since RDAPS model computes results twice a day at 00UTC and 12UTC, only 14 data sets can be achieved during July 12 and 18 of 2006 and this is very insufficient number of data sets for verification and calibration, thus all data sets should be used as training data set and comparison between case 1 that uses only gauged rainfall data inside and outside of basin, and case 2 which uses numerical weather forecasting model's output is performed in order to evaluate the effect of numerical weather forecasting model into improvement of accuracy for reservoir inflow forecasting

Table 1 shows rainfall data from 10 recording sites, water level data from 2 gauges at local streams in the basin and inflow at the current time and next 3, 6, 9, 12 hours. 4 ANN models are formulated for the sake of forecasting next 3, 6, 9, and 12 hours inflow to Hwacheon reservoir. Each ANN model has 1 hidden layer and 4 hidden nodes, and trained using back-propagation with delta-rule. All training procedure has 10,000 epochs and error tolerance is set to 0.001. Since rainfall, runoff and water level data has very different data units, normalization should be introduced. All input and output layer data are normalized not to be over 0.99.

* KMA is rainfall recording sites managed by Korea Meteorological Administration. AWS is automatic weather system also by KMA. Next 8-digit means the identical number for rainfall recording sites by Korea Government. “stage” means water-level recording sites. +3, +6, +9, and +12 hours are lead-time from the current time at the most left side column.

Training results from case 1 and 2 show good agreement to the observed data (Fig. 4). X-axis means 3-hours interval since the minimum time interval of RDAPS is 3-hours. The first x-axis value that is 3 means +3 hours forecasted inflow using case 1 and 2, and corresponding observed data. The starting time of experiment is 09:00 of July 12, thus this first value is for 12:00 pm which is +3 hours from 09:00. Because a new RDAPS data can be acquired after next 12 hours later that is 21:00 pm, 5th value in Fig. 2 whose x-axis’ value is 15 can be computed using 2nd RDAPS data which is made at 21:00 pm. Therefore 5th value is actually +3 hours forecasted value from 2nd RDAPS data.

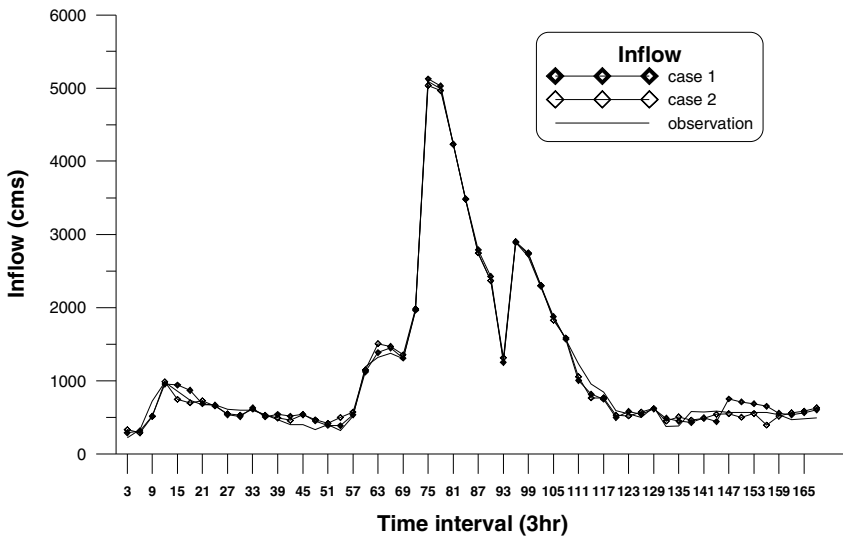

Fig. 4 Training result and observed data from case 1 and 2. All data points mean serial 3-hours interval values from July 12 at 12:00 to 18 at 21:00.

Next figures (Fig. 5) show another analysis result of ANN model. The first graph whose title is "3-HR_INFLOW" shows comparison between forecasted inflows from case 1 and 2, and observed inflow of Hwacheon reservoir. The x-axis values are 7 00UTC and 12UTC, respectively. Since experiment period is only 7 days, 14 data sets can be computed. All of these 4 graphs show the results from ANN are very similar to the observed data even though forecasting time horizon is expanded to 12 hours.

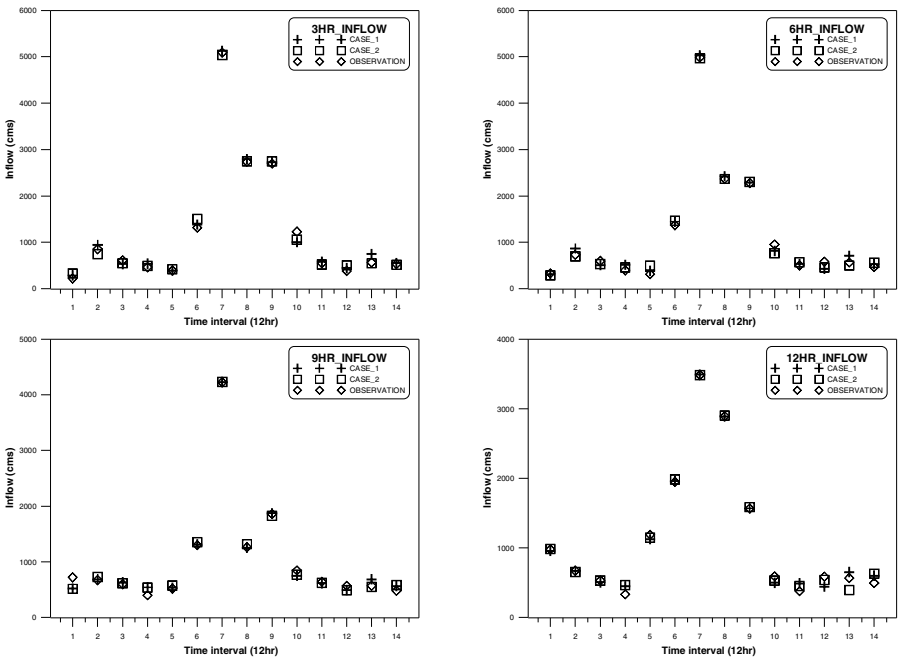

Fig. 5 Comparison between training and observed data sets. Each point is for 00UTC or 12UTC of July 12 to 18.

Another comparison results (Table 2) show the observed data and computed data using ANN model, and RMSE (root mean square error) value also. RMSE of case 2 in 3, 6, 9-hours lead-time are smaller than that of case 1. However RMSE of 12 hours lead-time show the opposite result. This could mean that the accuracy of RDAPS become deteriorated after 12 hours lead-time. On the other hand, it is noted that the results from case 2 that uses only RDAPS data as rainfall information are better than those from case 1 which apply much more information with regard to rainfall.

Table 2. Inflows from ANN and observed data. Case 1 uses all the rainfall data from recording sites; Case 2 apply RDPAS information as input layer. Three RMSE of case 2 out of total 4 different lead-time values are smaller than that of case 1.

Lead-time		case 1	case 2	observed			case 1	case 2	observed

CONCLUSION

ANN is useful to forecast inflow of reservoir especially for the real-time operation since it can be used in case of input data missing. In this study, two ANN model are formulated using recorded rainfall data and numerical weather forecasting data. Owing to very short record length of RDAPS data, only one rainfall-runoff event can be used, thus training data set is just examined. The first case uses 13 input variables for input layer and one output layer's target like Hwacheon reservoir's +3, +6, +9 and +12 next hours inflow. And, the other case has only RDAPS data as rainfall information and no recorded rainfall data is used. All of these two models

show good performance comparing with the observed records. However, the accuracy of ANN model using only RDAPS data is generally smaller than that of ANN model with recorded rainfall data.

This study is a kind of preliminary research. The performance of ANN model is largely affected by a method of selecting training data sets, and it is also important to maintain accuracy and reliability of training process through verification and calibration processes. All of these processes need a lot of data sets including a various different input and output patterns. However, even though a very short record length is applied comparison study shows that including numerical weather forecasting data like RDAPS is somewhat promising for inflow forecasting.

Integrated Management of a Finite Water Supply in the Desert

Daniel Wendell, Steve Shultz, and Aditya Tyagi

CH2M HILL, 155 Grand Ave, Suite 1000, Oakland, CA 94611; PH (510) 251-2888

ABSTRACT

Fort Irwin is located in California's Mojave Desert, adjacent to Death Valley, and receives about five inches of rain per year. Local water supply comes from three separate groundwater basins that have no significant natural recharge and therefore provide a finite supply of water. The base is an important Army training facility and extending the life of water supplies is of critical importance. This work was undertaken to maximize the "lifespan" of local water supplies, minimize costs, and avoid adverse impacts to the extent possible.

To meet the needs of this project, the entire water cycle of the area was evaluated in an integrated and quantitative manner, including: modeling local groundwater supplies; evaluating potential development of remote water supplies and associated costs; conducting an end-use water demand and conservation analysis; developing a recycled water irrigation program; implementing an indirect wastewater reuse (i.e., recharge) program; developing an operations program designed to mitigate adverse impacts such as land subsidence; and assessing cost, power consumption, and greenhouse gas emissions from the various alternatives.

This work effort was integrated in a quantitative fashion using the system dynamics model "GoldSim". Use of Goldsim allowed modeling the entire water system in an integrated fashion while assessing feedback relationships in the various water management alternatives that might have otherwise been lost. For example, water demand management yields less available wastewater for groundwater recharge, which in turn affects the lifespan of the local groundwater basins. GoldSim was used to optimize lifespan of the basins, cost, and greenhouse gas emissions by varying the water management alternatives. Key output included: "lifespan" of each of the three local groundwater basins; timing of projected onset of land subsidence; water savings and costs of water demand management alternatives; and greenhouse gas emissions. A key advantage of the model is that it is packaged into a "player" version that can be used by planners without detailed understanding of the feedback loops.

INTRODUCTION

Fort Irwin currently has a population of approximately 19,300 people composed of 10,000 resident soldiers and dependents, 3,500 civilian and contractor day-workers and a monthly average of 5,800 rotational trainee forces. Local water supplies for Fort Irwin are very limited. To best manage this critical resource and help meet

potential growth in water demand, the Army assessed potential benefits of water conservation measures.

In most respects, military installations are much like small cities in that they contain many of the same services and recreational opportunities needed by Post residents as do civilian communities. However, one key difference between military installations and civilian communities is the typical lack of on-Post water meters. Fort Irwin is no exception.

Effectively determining water use and conservation potential requires professional experience and judgment to supplement available meter data. Professional judgment was especially critical in this case due to the limited amount of meter data. Base Command highlighted the fact that all proposed water conservation measures, as well as the overall Fort Irwin Water Demand Management Plan, meet the following criteria:

- Fully support, and not interfere with, Fort Irwin's mission.
- Maintain the existing quality of life for Fort Irwin residents and employees.
- Allow for "smart growth" of residential and commercial activities.
- Be fiscally prudent.

BACKGROUND

The water cycle at Fort Irwin is relatively unique in that it is essentially a closed system; that is, there is negligible outflow from the system by streams or other methods. The water consumed by humans in homes, at work, and in commercial operations is collected, sent to the wastewater treatment plant (WWTP) and, except for evaporation losses and reclaimed water uses, is returned to the groundwater by percolation. The only water lost from the system is through evaporation and evapotranspiration. Accordingly, reducing water loss by reducing evaporation and irrigation is the most meaningful way to conserve water and the only way to extend the life of the local groundwater basins. However, there are other benefits to reducing overall water use and, therefore, groundwater extraction, including:

- Increasing lifespan of local groundwater resources.
- Providing additional water to help meet future growth.
- Reducing overall cost by reducing pumping, transmission, and treatment costs.
- Lowering the rate of TDS increase in local basins by reducing cycling of water.
- Reducing buildup of nitrogen and other compounds in groundwater with less irrigation.
- Delaying need for capacity upgrades to water and wastewater treatment facilities.
- Reducing greenhouse gas emissions from reduced energy usage.
- Providing a public showcase of water conservation measures and an example for others.

Water Supply

Groundwater is the only source of water supply to Fort Irwin. Currently, production comes from the three local groundwater basins present on the Post: the Irwin,

Bicycle, and Langford Basins. Production well meter readings from 2003 to 2007 indicate that past average annual pumpage is about 2.5 million gallons per day (mgd). This is equivalent (less transmission and distribution system losses) to average annual demand for 2003-2007. However, due to the new WTP, "annual average year" irrigation requirements, and changes to residential neighborhoods and associated irrigation, the future annual average demand is expected to be 2.57 mgd. Monthly average pumpage varies seasonally from about 1 mgd in the winter to over 3 mgd in the summer, with daily pumpage as high as 5 mgd. Allocation of pumpage amongst the three basins is variable and changes frequently. For the purposes of evaluating the lifespan of local basins, pumping distribution was assumed to be 46 percent from Bicycle Basin, 32 percent from Langford Basin, and 22 percent from Irwin Basin.

Water Treatment and Distribution

The potable water distribution systems at Fort Irwin currently consist of two separate networks. Treated drinking water is provided across the cantonment from an existing reverse osmosis (RO) WTP. This RO plant will soon be replaced by a new WTP facility, scheduled to be online in late 2009. The existing RO plant produces about 0.09 mgd, with product brine averaging about 0.08 mgd. A second, separate "domestic water" (DO) network provides disinfected groundwater throughout the Post that is used for fire protection, irrigation, toilets, and bathing. There are a total of nine storage tanks on the two systems that provide water to meet peak demands, maintain system pressure, and provide emergency supplies. These storage tanks have a combined capacity of approximately 5 million gallons (MG).

The new WTP will provide water to the existing DO distribution system, which will become the single source of drinking water and water for all other uses (except those areas irrigated by reclaimed water). Data from the existing RO and DO water systems were used to determine baseline 2004-2005 water production rates. However, in the future the water system will be operated in an integrated fashion, and therefore projected future water budgets are based on the new WTP, with effectively zero brine, and combined water distribution system.

Wastewater

All wastewater from Fort Irwin is processed at a secondary wastewater facility located within the cantonment. Metered influent to the WWTP from January 2003 to November 2006 indicates average flows of about 1 mgd, with very little seasonal fluctuation. Treated water effluent from the WWTP is reclaimed and used to irrigate the pitch-and-putt golf course. The reclaimed water distribution system is planned to be expanded into the cantonment to provide irrigation to selected recreation and parade fields. The WWTP has been modified to allow for tertiary treatment of the wastewater but these facilities have not yet been brought online.

Total Water Demand and End-use Categories

Projected potable water demand at Fort Irwin is assumed to be equal to total pumpage (2.57 mgd), minus a small amount of water exported to a satellite facility

("Goldstone", 0.08 mgd). This leaves a total onsite demand estimate of 2.49 mgd. An additional 0.06 mgd of reclaimed water is currently used to irrigate the pitch-and-putt golf course. To assess the feasibility of specific conservation measures, indoor and outdoor demands for each user type were quantified according to end use. End uses for indoor demands consist of toilets, laundry, showers, dishwashers, faucets, baths, leakage, and "other." End uses for outdoor demands consist of irrigation, air conditioning, car washes, leakage, and "other."

ANALYTICAL APPROACH AND MODEL DEVELOPMENT

To assess costs and benefits of various conservation options a "system dynamics" model of the water cycle at the base was developed using the "GoldSim" code. The model was developed to provide a general-purpose, probabilistic simulation framework used for planning and risk management. The GoldSim model was developed to simulate all aspects of the Fort Irwin water system, including water demand, water supply, managing water supply to meet demand and evaluate longevity of the water supply, and to evaluate cost and water demand savings associated with conservation measures and combinations of measures. The model was used to evaluate effectiveness of conservation measures and develop a recommended Water Demand Management Plan based on: total water savings; 5-year cost (referenced to present value); ongoing O&M costs, following implementation of scenario; 20-year cost-benefit ratio; and basin life.

Water demand is broken down into user type and end use. A total of 35 end uses were identified in the following categories: indoor residential, outdoor residential, indoor commercial, and outdoor commercial. The model is set up for the user to specify the percentage of total demand that is satisfied by each of eight local groundwater basins. The first three already have infrastructure built. If any of the other basins is pumped, a capital cost developed is added. Each groundwater basin is simulated as a separate "reservoir" in GoldSim. Inflow to and outflow from the basins are specified. All basins except Irwin were assumed to be closed basins, i.e., there is no natural recharge or discharge. Based on results of previous groundwater modeling, lookup tables were utilized to track groundwater levels in the basins. A minimum water level is set by the user, below which the basin can no longer be utilized. At that time, pumpage is reallocated evenly amongst the other basins.

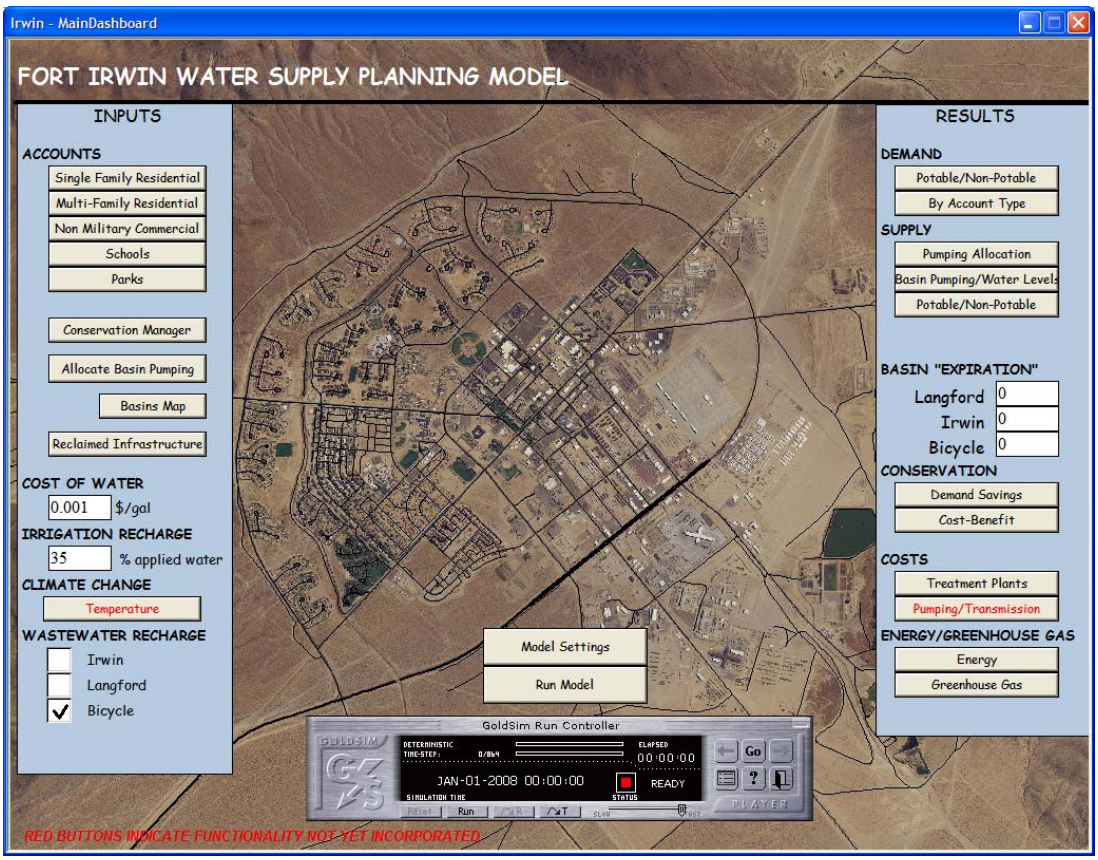
The model calculates wastewater production as a specified percentage of all indoor water use, which is currently set to 90 percent. A percentage of the wastewater is assumed to be lost at the wastewater treatment plant. The user specifies the annual average of reclaimed water that can be used to satisfy demand. If there is a deficit (i.e., non-potable demand exceeds reclaimed supply with current infrastructure), then the excess non-potable demand is supplied by potable water. Whatever reclaimed water that is not used to satisfy demand gets routed to wastewater ponds. A mass transport calculation is run on the wastewater ponds, based on evaporation and percolation rates. Whatever is not evaporated is assumed to percolate into the groundwater system. The user specifies both the infiltration rate of the ponds, and the basin where the ponds are located.

Conservation Measure Evaluation

Costs and related water demand savings were calculated for a wide range of conservation measures. The impact of interactions between conservation measures was considered within each scenario. Overlapping measures do not have a cumulative effect on indoor or outdoor end uses and are therefore not included in percent reductions. This evaluation targeted the end use and cumulative effect of measures impacting the same end use within an alternative were reduced based on a calculation of the total combined effect of each measure, refereed to as "Net Effect."

For the purposes of cost evaluation, it is assumed that the cost of water is $3.67 per 1,000 gallons. This cost was estimated based on cost of water and wastewater services ($1.20/1,000 gallons), total energy used in the water and wastewater system (including raw water supply, conveyance, treatment, and distribution, as well as wastewater collection, treatment, and discharge), and an assumed average energy cost of $0.14/kilowatt-hour (kWh) (total $2.46/1,000 gallons). Present worth costs assume a nominal rate of 3 percent (6 percent interest rate less 3 percent inflation rate).

Energy and Greenhouse Gas Evaluation



Energy usage in the water system at Fort Irwin includes: Raw water supply and conveyance, water treatment, water distribution, wastewater collection and treatment, wastewater treatment plant discharge, reclaimed water distribution, and energy associated with end use. Because energy usage for these components are not metered, energy rates were estimated based on previous experience and figures referenced by the California Energy Commission (CEC 2005). Greenhouse gas emissions (CO2, N2O, and CH4) were calculated based on region-specific factors from the Climate Leaders GHG Protocol (October 2004), a method sanctioned by the EPA. Energy consumption, and associated greenhouse gas emissions, are tracked by the model and presented in the results of all management scenarios.

Model Input

Inputs to the model include: number of accounts; basin pumping allocations; minimum allowable basin water levels; average annual reclaimed water usage (the model calculates seasonal usage); cost functions, including the cost of water, inflation and interest rate for present-worth analysis, and year for benefit/cost ratio analysis; irrigation recharge, which is the percent of applied irrigation water that recharges the basin; wastewater recharge; and WTP capacity, which is the maximum rate of water supply.

Model inputs related to demand rates include check boxes to "turn on" any number of 13 pre-defined conservation programs, and optional input of any number of additional user-defined conservation programs. Each conservation program uses the following input: a base water usage rate by fixture type (gpd per account), cost parameters for conservation, implementation schedule for conservation program, and water savings. Implementation and water savings are both time series data. Several other types of

data are input as a time-series, including number of accounts and "suppliable reclaimed demand."

Model Output

Model output provides detailed plots of water supply and demand, water demand savings due to conservation measures, available reclaimed water supply, "expiration" dates for basins, and costs and benefits of water conservation. An example of the cost-benefit analysis is presented below,

In addition, greenhouse gas emissions and greenhouse gas savings due to implementation of conservation measures are output (see example plot below).

Model Calibration

The model was calibrated to 2004 water demand. Total water demand at Fort Irwin is assumed to be equal to total pumpage (2.46 mgd in 2004) minus RO treatment plant brine discharge (0.08 mgd) and export water to Goldstone (0.08 mgd). This leaves a total demand estimate of 2.3 mgd. Total average annual outdoor water use is estimated to be 1.23 mgd in 2004, based on a total demand of 2.3 mgd minus an indoor water demand of 1.07 mgd. The model was calibrated against the primary sources of available data: total water supply, and total indoor use.

SUMMARY MODEL RESULTS

Improvements in irrigation management practices provide the greatest potential for water savings, both in terms of quantity of water saved and ratio of benefit to cost. If all irrigation measures with quantified savings are implemented, total savings could be on the order of 0.5 mgd, or about 20 percent of total water used at the site (note that overlapping measures result in non-additive savings, due to "net effect"). Some of these measures have relatively insignificant capital costs, relatively minimal O&M costs, and yet save significant amounts of water. These measures represent "low hanging fruit".

A key indicator of the financial benefit of conservation measures is the payback period. This indicator shows that irrigation management and replacement, education, and faucet aerators offer the quickest payback periods and greatest return on investment. The payback period is less than ten years for all seven of these measures. The same seven measures have the highest benefit/cost ratio.

In addition to evaluation of conservation measures based on financial benefit, it is also worthwhile to consider total water savings. Five measures stand out as having very high water savings potential, all greater than 0.1 mgd: replace turf and trees, replace toilets, education, frequent irrigation schedule changes, and rate structure. All other measures have potential water savings of less than 0.05 mgd. The measures with the highest water savings are not all financially favorable, particularly the financial incentives, since it involves an expensive meter-reading and replacement program.

Impact of Assumed Projected Growth

Water demand and cost analyses assumed that Fort Irwin will grow by 50 percent in the future. It was assumed that the all types of accounts would grow at the same rate (i.e., residential units, commercial units, schools, and athletic fields). It was also assumed that all new development would use water-efficient fixtures, specifically: toilets, faucets, laundry machines, dishwashers, and urinals. This is consistent with practice at the newest development. Accordingly, the water savings during the Plan phases would not be expected to increase proportionally to the growth at the Post.

Reclaimed Water Options

Use of reclaimed water for irrigation, in place of potable water, is both a good and established water resource management practice. It reduces groundwater pumping, along with its associated power costs and carbon emissions, and provides a direct offset of potable water, allowing the potable water to be used for other, higher needs. A small "pitch-and-putt" golf course is currently the only area irrigated with reclaimed water at Fort Irwin. Plans are in place for facilities needed to transmit reclaimed water to athletic fields and parade grounds for irrigation.

Although a reduction in groundwater pumpage will occur as a result of expanding the reclaimed irrigation system, the life of local groundwater basins would not be

significantly extended by this action. This is because a high percentage of treated wastewater already percolates back into the local aquifer. As more reclaimed water is used for irrigation, a decrease in this recharge will occur, thus counteracting the effect of reduced groundwater pumping. This does not mean that the basin does not realize a significant benefit from these activities. There are the cost and carbon emission benefits noted above, as well as a decrease in the cycling of water through the basin that results in reduced TDS and nitrate buildup in the underlying aquifer.

In order to evaluate the combined effect of water conservation and irrigation with reclaimed water, the model was used to assess affects of decreased groundwater pumpage and extension of local groundwater resources for the various reuse options and Plan phases. With the planned expansion of the reclaimed system, annual average groundwater pumping would be reduced by between 0.13 and 0.19 mgd, as compared with the current reclaimed irrigation system. This results in an extension of basin lifespan of about three years. If the reclaimed system were expanded to include about 45 irrigated acres, pumping would be reduced by an additional 0.18 to 0.26 mgd, extending the basin lifespan an additional three to five years. These results suggest that expansion of the reclaimed system, combined with the Plan, would be an effective strategy to reduce groundwater pumpage and, to a lesser extent, to increase lifespan of local groundwater resources.

RECOMMENDED WATER DEMAND MANAGEMENT PLAN

Results of this investigation indicated that improvements in irrigation management practices provide the greatest potential for water savings at Fort Irwin, both in terms of quantity of water saved and ratio of benefit to cost. If all irrigation measures with quantified savings were implemented, total savings could be on the order of 0.5 mgd, or about 20 percent of total water used at the Post. These measures also provide the greatest effect on extending the life of the local water resource.

The recommended Water Demand Management Plan is divided into three phases designed to be implemented in sequence. This phased approach places work that achieves relatively large water savings at a low cost in the immediate future. More costly measures are then phased in over time as experience and greater understanding of water demand characteristics of the Post are obtained. This is especially important at Fort Irwin given the lack of meter data for many critical uses. The three phases are:

- **Phase-1: Measures with No Capital Costs.** This phase consists of projects with zero capital costs and a benefit/cost ratio greater than one at 10 years. It represents “low-hanging fruit.” Phase-1 total average annual water savings are estimated to amount to about 0.26 mgd with zero capital costs and an estimated O&M cost of $77,000 per year. The calculated benefit/cost ratio is 4.5 at year 10. Phase-1 measures should extend the lifespan of local groundwater supplies by about 2 years.
- **Phase-2: Measures with Payback of <10 Years.** Phase-2 consists of conservation measures with capital costs that have a payback period of less than

10 years. These are the most cost-effective conservation measures that are not otherwise included in Phase-1. The average annual incremental water savings achieved by implementation of Phase-2 is estimated to be about 0.45 mgd at a capital cost of about $1.9 million, and no additional O&M costs. The benefit/cost ratio for these incremental measures is 2.7 at year 10. Phase-2 measures would extend the life of local groundwater supplies an estimated 16 additional years, which, in combination with Phase-1, results in an overall increase in basin lifespan of 18 years.

- **Phase-3: Meter Installation and Reading Measures**. Phase-3 consists of conservation measures that require water meters to be installed and a meter reading and replacement program implemented. The average annual incremental water savings achieved by implementation of Phase-3 is estimated to be about 0.18 mgd at a capital cost of about $500,000 and additional O&M costs of $180,000 per year. The benefit/cost ratio of these incremental measures is 1.0 at year 10. Phase-3 measures should extend the life of local groundwater supplies an estimated four additional years which, in combination with Phase-1 and Phase-2, results in an overall increase in basin lifespan of 22 years.

Because there are no capital costs associated with Phase-1, it was recommended that these measures be implemented as soon as possible. Phase-2 measures have relatively nominal capital costs, realize significant water savings, have a payback period of about four years, and significantly increase the life of local groundwater basins. Accordingly, it was recommended that Phase-2 measures be implemented as soon as is practicable. Phase-3 water savings are about 25 percent of those realized in Phase-2, with a payback period of about nine years. Although these conditions are not as favorable as Phase-1 or Phase-2, a key benefit of Phase-3 is that the metering associated with this phase will help better quantify benefits of all conservation measures. Accordingly, it was recommended that Phase-3 be implemented as soon as adequate funds are available.

While the above Plan focuses on reduction of demand, use of reclaimed water for irrigation, which provides a direct offset of potable water requirements, could be performed in conjunction with the Plan. With the planned expansion of the reclaimed irrigation system (17 acres, in addition to the current system of 6 acres), annual average groundwater pumpage would be reduced by an additional 0.13 to 0.19 mgd and basin lifespan could be extended by an additional three years. Model results suggest that the maximum area that could be serviced by reclaimed irrigation is about 45 acres (about 35 percent of total irrigation on the Post), without demand exceeding reclaimed supply during peak periods. This would reduce groundwater pumpage by about 0.3 mgd and extend basin lifespan by about seven years, as compared with the existing 6-acre reclaimed irrigation system.

Long-lead Forecasting of Monthly Rainfall Using Large Scale Climate Signals and Statistical Disaggregation Models

ABSTRACT

Monsoon, one of the most dynamic climate systems, controls rainfall variation in some countries in Asia such as India, Bangladesh, Pakistan, and Iran. It delivers the main component of annual rainfall in these regions. In this study, the relationship between Iran monsoon rainfalls and some large scale climate signals such as SLP (Sea Level Pressure) and SLP differences over certain effective regions have been examined. The correlation coefficient between various combinations of climate signals with the rainfall at different time lags demonstrates some significant correlations which are used to identify the predictors for the rainfall forecasting.
In this paper, a fuzzy rule model has been developed to predict the six-month rainfall in the southeastern part of Iran. Then the long-lead forecasting rainfall is disaggregated to a monthly scale using statistical disaggregation models and by considering the historical share of each month from total 6 month precipitations. In real time, the predicted value of each month during the 6 month time horizon is modified once the observed precipitation in any of the prior months becomes available using the Bayesian Theory. This way the accuracy of prediction will be significantly increased as we approach the last 3 months of the forecast period. The proposed model makes adequate lead time for estimation of the water resources potential for mid-term planning. Since the planning scale of water resources planning is usually monthly, disaggregated rainfall could increase the accuracy of operating schemes in the study area.

Keywords: Climate Signals, Fuzzy Rule, Disaggregation, Forecasting, Bayesian Theory

INTRODUCTION

Different optimization techniques are developed in order to define operating policies for operation of water resources systems and facilities. Forecasts of precipitation and streamflow in the next few months or even seasons are necessary for the real-time operation of water resources systems such as reservoirs. Different methods have been widely used for precipitation prediction. These methods followed different approaches ranging from pure statistical methods to methods that are mostly based

on the conceptual modeling of meteorological conditions.

The summer monsoon is one of the dynamic climate systems and the livelihood of more than 60 percent of the world's population depends on them. Furthermore, the Asian summer monsoon is a key component of the earth's climate system, having important teleconnections with global weather and climate in Iran and delivers a component of annual rainfall in the southeastern part of Iran. The sum of rainfall during the month of July, August and September is the seasonal monsoon in the southeastern part of Iran. Many investigations have been done to understand the relation between monsoons and other global phenomenas and large scale climate signals such as El Nino southern oscillation, (SST), (SLP) and other large scale climate signals. (Karamouz et al., 2004)

Following the great Indian drought of 1877, Blanford, who established the Indian Meteorological Department in 1875, forecasted Indian monsoon rainfall in 1884. Later, in the early part of the 20th century, Walker initiated extensive studies of global teleconnections which led him to the discovery of Southern Oscillation. Walker introduced the concept of correlation for long-range forecasting of Asian summer monsoon and his findings are relevant even today (Krishna Kumar et al., 2004). The models established later by Gowariker et al. (1989), Thapliyal (1990), and Sahai et al. (2003) belong to the category of Walker's studies. Among these, the model of Sahai et al. (2003), which links global SST with Indian monsoon seasonal data, appears to be the most successful.

In recent years, many efforts have been devoted to development of mid to long-term (monthly and seasonal) precipitation forecasting models for major river basins in different parts of the world. Most of these models incorporate the effects of large scale climate signals. Chiew et al. (1998) studied the correlation between the El-Nino Southern Oscillation (ENSO) events and the precipitation in Australia. Nicholson and Selato (2000) studied the effects of La-Nina events on the precipitation in Africa. Mariotti et al. (2002) studied the effects of ENSO on the Mediterranean precipitation in Europe.

In this study, a method for predicting the range of probable precipitation for two season in southwest of Iran is developed. These seasons are defined based on dry and wet periods of the year. The wet season is considered during December to May and the dry season is considered during June to November. In this method, Fuzzy Set Theory (FST) is used to develop the fuzzy rules for predicting the precipitation.

Fuzzy logic provides a framework for dealing with imprecise, vague and/or linguistic information in modeling. Fuzzy logic accepts overlapping boundaries. In other word, instead of assigning one as the degree of belonging and zero as the degree of not belonging to an element within a set (Classical Set Theory), partial membership (degree of belonging) in any given set is possible (Ozelkan et al., 1996). Karamouz and Mousavi (2003) have developed a Fuzzy Stochastic Dynamic Programming Model for reservoir operation optimization. Results of application of their model to Karoon and Dez reservoirs in Iran have shown significant improvement of operating policies of these two major reservoirs in the Middle East.

In this study, attempts have been made to explore the relationship between the rainfall in the south western part of the Iran and some large scale climate signals such as SLP (Sea Level Pressure) and SLP differences over certain effective regions all

over the world to find the appropriate predictors for forecasting precipitation. Then a fuzzy rule model has been developed to predict the rainfall at wet (Dec-May) and dry (June-Nov) seasons in the southeastern part of Iran from six months before. The proposed model makes adequate lead time for estimation of the water resources potential for long-term planning. Since the planning scale of water resources planning is usually monthly, disaggregated rainfall could increase the accuracy of operating schemes in the study area. Therefore the 6-month predicted rainfalls are disaggregated into included months using statistical disaggregation models considering the historical share of each month from total six month precipitations in different seasons. The disaggregated predictions are modified by using real time observations to make the necessary changes in reservoir operation if it is needed.
The paper is followed by an introduction to the study area and then the methodology applied for rainfall prediction and desegregation of the results are described. The results of applying the method in the study are presented in the next section and finally a summary and conclusion is given.

STUDY AREA

The study area including South Baloochestan, Kerman and Hormozgan provinces are located between 53° and 63° northern latitude and 25° and 32° eastern longitude, in the south-east part of Iran (Figure 1). The area of the considered watershed is about 25000 square kilometers and the mean annual precipitation is about 218 millimeters.

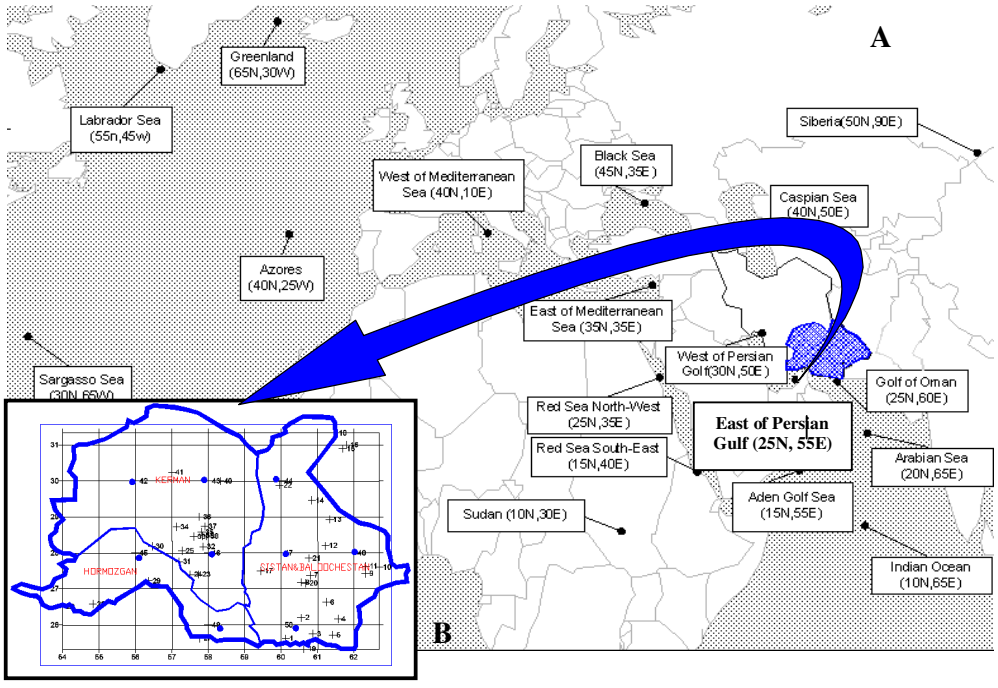

Figure 1: Location of the study area in Iran and the key points affecting its climate

The spatial variation of precipitation of this region is estimated using a multivariate geostatistical algorithm in forms of the Kriging method. In order to estimate the average precipitation of the region using the Kriging method, the stations with more than 30 years recorded data out of 41 stations shown in Figure 1-b are selected.
The average precipitation of the region is estimated to be about 155.1 mm in which 87% of the annual precipitation occurred during the wet season. Precipitation in the dry season is usually flash flood which causes flood damages. Therefore in order to use the flood potential and to estimate the water availabilities for water resources planning, precipitation forecasting is requisite.
The precipitation is forecasted considering some large scale climate signals such as SLP (Sea Level Pressure), SST (Sea Surface Temperature) and SLP differences over certain regions. These points, shown in Figure 1-a, have been determined to be effective signals on Iran's climate in previous studies by Karamouz et al. (2004).
SLP data between the years 1973 to 2004, which is estimated for the National Science Foundation by the National Center for Atmospheric Research (NCAR) in USA, has been used in this study. Monthly SST data is also derived from NOAA Advanced Very High Resolution Radiometer (AVHRR). The spatial resolution is approximately 5.689 pixels per degree.
The effective signals on the case study climate are determined considering correlation coefficient between average precipitation and all of the considered signals, and scatter plots for accuracy control. The selected signals are considered as the fuzzy inputs for six month precipitation forecast, then the forecasted results are disaggregate to monthly values. In the next section the Fuzzy Rule and statistical disaggregation models are explained.

MATERIALS AND METHODS

Fuzzy Rule Model

In this study, a method for seasonal precipitation prediction using the FST (Fuzzy Set Theory) is developed. In general, a fuzzy set consists of a set of explanatory variables called premises, $A_{i,n}$, given in the form of fuzzy numbers with membership functions $\mu_{A_{i,n}}(a_n)$ and a consequence B_i also in the form of a fuzzy number:

$$If\ a_1 \in A_{i,1} \Theta\ a_2 \in A_{i,2} \Theta \ldots a_n \in A_{i,n}, Then\ b \in B_i \quad (1)$$

where Θ is a logical operator that can be selected based on the application. The membership function $\mu_{A_{i,n}}(a_n)$ measures how much each observed data a_n belongs to the set $A_{i,n}$. In contrast to the crisp rules, fuzzy rules allow partial and simultaneous degree of fulfillment of rules. The following steps should be taken for development of fuzzy rules (Karamouz and Zahraie, 2004):

- Divide input-output space into fuzzy regions (intervals)
- Generate fuzzy rules from given data
- Calculate the degree of fulfillment for each rule (see Zimmerman, 1996)
- Assign a weight to each rule

- Predict using the rule-based system

The following structure has been used for defining fuzzy rules:
Rule number z:

$$If \quad G_1(t) \in G_i^f \otimes G_2(t) \in G_j^f \otimes G_3(t) \in G_k^f \otimes G_4(t) \in G_l^f \otimes G_5(t) \in G_m^f \otimes G_6(t) \in G_n^f \quad (2)$$
$$Then \quad P(t+1) = P_h^f$$

where:
$G_i(t)$: i^{th} SLP index in season 2 of the year t
$P(t+1)$: Average precipitation in season 1 of the year t+1
G_k^f : k^{th} fuzzy interval defined for standardized SLP and SLP gradient
P_h^f : characteristic value of the h^{th} fuzzy interval defined for precipitation
Then the degree of fulfillment of rule z is calculated using the following equation:

$$v_z(t) = \mu_{G_i^f}[G_1(t)] \cdot \mu_{G_j^f}[G_2(t)] \cdot \mu_{G_k^f}[G_3(t)] \cdot \mu_{G_l^f}[G_4(t)] \cdot \mu_{G_m^f}[G_5(t)] \cdot \mu_{G_n^f}[G_6(t)] \quad (3)$$

where $\mu_{G_i^f}[G_k(t)]$ is the value of the membership function of related fuzzy intervals. To show which portion of the data is explained by a given rule, the weight associated with each rule (ξ_z) can be estimated as:

$$\xi_z = v_z(t) \cdot \mu_{P_h^f}[P(t+1)] \quad (4)$$

where $\mu_{P_h^f}[P(t+1)]$ is the value of the membership function of related fuzzy interval for the precipitation in each season of the year t+1. Elimination of the rules can be done if desired, by setting a threshold so that the rules having weights below or equal to that limit are not considered. In this study, a 10 percent threshold is considered.

Statistical Disaggregation

The basic goal of any disaggregation model is to allow the preservation of statistical properties at more than one level. Disaggregation facilitates the use of long-term persistence levels, particularly in multi sites, multi seasons time series modeling. Salas et al. (1980) classified disaggregation models into temporal and spatial disaggregation models. In the case of seasonal disaggregation, the sub-series (seasonal data) sum exactly to give the original series (annual data). In this study, the basic disaggregation model proposed by Valensia and Schaake (1973) is used. The linear dependence model is as follows:

$$Y_t = AX_t + B\varepsilon_t \quad (5)$$
$$\hat{A} = S_{YX} S_{XX}^{-1}$$
$$\hat{B}\hat{B}^T = S_{YY} - \hat{A} \cdot S_{XY}$$

where X_t is the annual rainfall matrix of year t, Y_t is the current observation of the series being generated, ε is the matrix of the independent random variables, A, B are the parameters matrix, and S_{YX} is the matrix of covariances' between the seasonal series.

Modification of Monthly Data

Because of high uncertainties in long lead rainfall prediction, the observed value may be completely different from what has been forecasted. Therefore modification of the rainfall forecasts based on the recorded data in each coming month could help in achieving more reliable results to be applied in water resources management practices.

In this study for modifying the disaggregated rainfalls a similarity based approach has been applied. For this purpose at first, the Equilidian distance between the observed rainfall values in the present year and the historical years (D_{ij}) is calculated as follows:

$$D_{ij} = \sqrt{\sum_{n=1}^{m} (R_{ni} - R_{nj})^2} \quad (6)$$

where R_{ni} and R_{nj} are the rainfall value in month n in the present year and year j, respectively. m is equal to the number of the observed months plus one because the situation of the last month before starting the forecasting season is also considered in rainfall modification.

The year with the minimum distance from the present situation has been considered for monthly rainfall modification. The monthly weight for rainfall in the subject year are calculated and averaged with the weights obtained by disaggregation. The monthly rainfall predictions are modified based on the resulting weights as follows:

$$R_{\mathrm{mod}\,k} = R_k \frac{W_{\mathrm{mod}\,k}}{W_{dk}} \quad (7)$$

where R_{modk} and R_k correspond to the modified and disaggregated rainfall in month k respectively. W_{modk} is the modified weight of month k and W_{dk} is the resulting weight of month k from disaggrigation.

RESULT

The effective signals on the case study climate are determined for two seasons. The used signals for June to November (dry season) are:

- SLP difference of west of the Persian Gulf and the Aden Gulf
- SLP difference of east of the Persian Gulf and the Oman Gulf
- SLP difference of east of the Persian Gulf and the Aden Gulf
- SLP of the Caspian Sea
- SST of the Oman Gulf
- SST of west of P the Persian Gulf

The selected signals for December to May (wet season) are:

- SLP difference of Siberia and Sudan
- SLP of west of Mediterranean Sea
- SLP difference of east of the Persian Gulf and Arabian sea
- SST of Black Sea

- SLP difference of the Aden Gulf and the Arabian Sea

The results show that during the dry season, effective signals are local such as the Persian Gulf, Oman Gulf, Aden Gulf and the Caspian Sea and close to the case study. For more accurate results, more studies are needed to investigate the effects of local signals in finer grids on the model performance.

One of the effective signals during the wet season is SLP the difference of the Siberia high pressure zone and Sudan low pressure zone on the precipitation over the study area. The Sudanese system is formed over Sudan when the air pressure is low. This system can absorb the water vapor due to the high temperature of its air mass. The humidity of this system is significantly increased after moving toward east over the Red sea. Some times, this system becomes over humid after movement over the Persian Gulf and it can create heavy rainfalls in the study area. In some cases, both Mediterranean and Sudanese Systems enter the country contemporaneously.

After a sensitivity analysis to find the number of fuzzy regions, the precipitation standardized SLP and SLP gradient are descritized into five fuzzy regions. The extents of fuzzy regions are defined based on the variability of the observed signals and precipitation data in the historical records. The fuzzy regions are used to classify the data into very low, low, normal, high, and very high categories as shown in Figure 2.

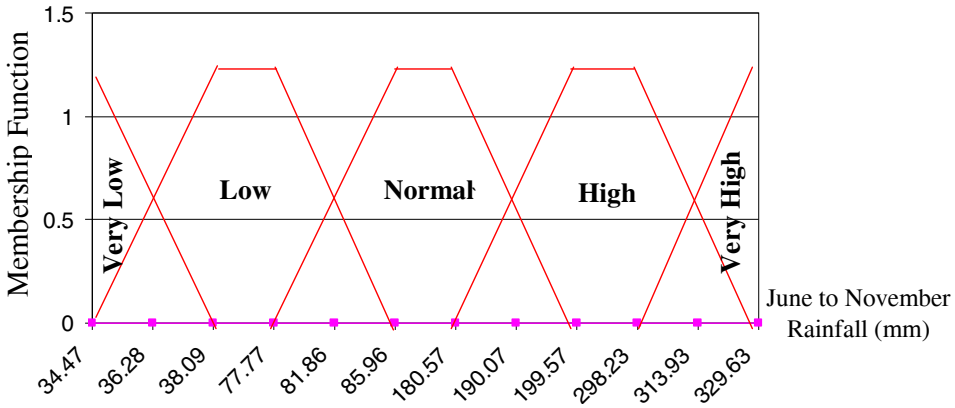

Figure 2: The fuzzy classification for observed rainfall

After developing the structure of fuzzy rules, the rules are used for reproducing the historical records. The effectiveness of the rule structures were tested in order to reproduce the actual observations for 21 years of historical records (calibration period) and then simulate and validate them for 11 years. The forecasting results are presented in Table 1 and show even though the average of low and high bounds for each year is not exactly the same as observed data, but the forecasted bounds include the observed value.

Disaggregation is used to obtain the monthly precipitation. Matrix A includes 0.08, 0.17, 0.19, 0.05, 0.22, 0.28 values for June to November respectively. The results show the share of July and August is relatively high and it is because of the flash flood in the study area.

Table 1: The results of forecasting model for dry and wet seasons

Year	Forecasted precipitation (June- November)		Observed	Forecasted precipitation (December- May)		Observed
	Low Bound	High Bound		Low Bound	High Bound	
1996	8.73	39.83	38.2	77	170	122.1
1997	18.16	47.60	42.18	126	272	142.9
1998	8.52	36.31	11.29	77	170	110.8

2004	14.16	13.21	6.12	3.0	1.39	2.82	2.97	2.11	0.00	1.18	0.00	0.78
RMSE	1.03		2.42		1.59		1.43		1.92		5.60	

The Root Mean Squared Error (RMSE) is used to evaluate prediction accuracy:

$$RMSE = \sqrt{\frac{\sum_{t=1}^{n}(y_t - \hat{y}_t)^2}{n}} \qquad (6)$$

where y_t is the observed data, $\hat{y}_t$ is the associated modeled value and n is the total number of data. The RMSE for the forecasted model in dry season is about 2.4 mm. Because of local phenomena that cause perturbations in monthly rainfall variations, the downscaled data are not well compatible with the observed data. Therefore the modification process has been employed to achieve more reliable results in monthly time scale.

The modified monthly rainfall forecasts from year 1996 to year 2004 are tabulated in Table 3. As can be seen by using the modification method the forecasted monthly rainfall data becomes more similar to the observed values. The results show the most important period in forecast modification is from June to September and after that the modification does not result in high variations in monthly forecasted values. Considering more local parameters in rainfall forecast modification could considerably help in increasing forecasts reliability.

Table 3. Comparison between modified (mod) and monthly observed (obs) rainfalls (mm)

	July		August		September		October		November	
	obs	mod	obs	mod	obs	mod	obs	mod	obs	mod
1996	2.88	2.63	3.20	3.19	2.09	1.30	9.91	6.11	16.13	18.92
1997	2.04	3.31	5.01	5.44	2.86	3.34	16.34	15.34	15.21	13.08

SUMMARY AND CONCLUSION

The long lead rainfall forecasting plays an important role in developing reliable water resources management schemes. Since there are different sources of uncertainties affecting the rainfall variations, applying the methods that could incorporate these uncertainties could help achieve reliable results. In this study, Fuzzy set theory has been employed for forecasting rainfall in two seasons (Jun-Nov and Dec-May) in the south-eastern part of Iran. The most correlated climatic signals with rainfall of the study area have been considered as predictors and the 6 month rainfall is considered as the predictant. The considered signals include SLP, SST and SLP difference.

The observed values of the six month rainfall are in the forecasted interval of rainfall by Fuzzy model but in some cases they are near boundaries. The six month forecasted values are disaggregated using statistical models to monthly time steps to be applied for practical purposes. The best results are obtained for September and the worse correspond to November. The perturbations in the results are related to local climatic variability that effects the rainfall variations. For employing these effects in rainfall forecasting a modification method has been developed based on the similarity of the present year to historical data. The forecasts reliability has been improved up to 50% by this method. This improvement could result in more

flexibility in water resources operation.

Abstract

This paper summarizes ongoing efforts by Colorado's Front Range water providers to assess changes in the timing and volume of hydrologic runoff that might be expected from selected climate change scenarios for the years 2040 and 2070. Many utilities across the United States believe that climate change poses a threat to their water supplies, and have a desire to evaluate potential impacts. This cooperative research will provide water utilities in the Rocky Mountain Front Range with the knowledge and methodology necessary to evaluate potential climate change impacts on their water supplies. Furthermore, this study will set the stage for future advances in procedures and technologies.

1. Introduction

Water is essential for the continued economic development of the western United States. With the increasing recognition of global and regional climate changes, Metropolitan water providers along Colorado's Front Range are concerned about the possible impacts these changes may have on their future water supply availability. This is of particular concern given that recent studies indicate global warming may lead to unprecedented drought conditions in the Southwest U.S. (IPCC 2007). Several Front Range water providers including the City of Aurora, City of Boulder, Colorado Springs Utilities, Denver Water, City of Ft. Collins, and Northern Colorado Water Conservancy District have come together to participate in a study intended to provide the education, tools, and methodology necessary to examine the possible effects of climate change on several shared watersheds.

The study area that includes the service area of the Front Range providers is shown in Figure 1.

Figure 1. Project Study region over which temperature and precipitation offsets will be are derived. Boundaries of the study region are 107.526-104.4375 W and 38.5625-40.5625 N. This area in the data set contains 17 N-S grid points by 26 E-W grid points.

This study is designed to enable entities that obtain their water supplies from the upper Colorado, South Platte, Arkansas, Cache la Poudre, St. Vrain, Boulder Creek, Big Thompson, and other similar river basins to examine potential effects climate change may have on those supplies. This regional unified approach is intended to help Colorado water providers communicate with their customers and the media cohesively by working with the same historic and projected hydrometeorological data, historic natural streamflow, and methodology. Lessons learned from this collaborative approach can be used to encourage and establish other regional efforts in Colorado and throughout the country.

The central objective of this project is to assess changes in the timing and volume of hydrologic runoff that might be expected from selected climate change scenarios for the years 2040 and 2070. Two hydrologic models will be calibrated and implemented in this study including the WEAP (Water Evaluation and Planning) Model run by Dr. David Yates of NCAR, and the linked Sacramento Soil Moisture model with the Snow-17 model (hence forth called the "Sacramento Model") run by Riverside Technology, inc. The Colorado Water Conservation Board (CWCB) will aid in the compilation of historic naturalized streamflow sequences (1950-2005) for use as a baseline comparison for river basin gauge locations of primary interest to the participants. Based on regionally downscaled temperature and precipitation projections (developed by the Bureau of Reclamation and others) and discussions with the Western Water Assessment (WWA),

the future temperature and precipitation scenarios to be used to generate corresponding future streamflow have been established. These future scenarios of temperature and precipitation are based on the results of 16 global climate models (GCMs) driven by three future greenhouse gas emissions scenarios, A2, A1b, and B1. The streamflows obtained by running perturbed sequences of temperature and precipitation through the hydrologic models will be compared to historic streamflows to estimate the sensitivity of water supplies to climate change. The outputs from this research will include climate-adjusted natural-flow time series at selected locations, and statistical evaluations of differences between these and historic natural flows for water availability assessments.

2. Project Description

Metropolitan water providers along Colorado's Front Range are concerned about the impact climate change may have on their future water supply availability. To better understand the possible impacts of climate change several Front Range providers are working together to provide the education, tools, and methodology needed to study these effects. This project is designed to enable entities that obtain their water supplies from the upper Colorado, South Platte, Arkansas, Cache la Poudre, St. Vrain, Boulder Creek, and Big Thompson River Basins to examine potential effects climate change may have on these supplies. The participating group, called the Project Steering Committee (PSC), consists of representatives from Aurora Water (Aurora), City of Boulder (Boulder), City of Fort Collins (Fort Collins), Colorado Spring Utilities (Colorado Springs), Denver Water (Denver), and Northern Water (Northern). The role of the PSC is to ensure the study meets each provider's needs. Additional expert resources have been and will continue to be utilized through the help of the Western Water Assessment (WWA) and the Colorado Water Conservation Board (CWCB). The WWA aids the PSC in selection of greenhouse gas emission scenarios used to drive Global Climate Models (GCMs), and interpreting and selecting downscaled GCMs temperature and precipitation output data. The selected datasets will be used to drive the hydrologic models necessary to assess the sensitivity of streamflow to changes in climate. The CWCB is working with the PSC to establish the sets of historic naturalized streamflow data on a daily timestep for use in the hydrologic models: these datasets will be useful to all study participants. This unified approach is intended to help Front Range water providers communicate with their customers and the media cohesively, through use of the same hydrometeorological data and use of the same methods and climate change scenarios. Lessons learned from this unified approach could also be used to encourage and establish further regional efforts in Colorado and throughout the country.

The goal of this study is a streamflow sensitivity analysis of the PSC's watersheds focused on the development of future naturalized streamflow data using selected climate change scenarios. Each provider can use these future streamflow scenarios in conjunction with their water rights allocation assumptions to estimate the impacts of various climate change scenarios on their water supply. Throughout this process each participant will have the opportunity for education in:

- climate variables and modeling techniques (including emissions scenarios, global climate models (GCMs), and downscaling approaches) through educational sessions with the WWA,
- the standardization process of historic naturalized streamflow sequence development with oversight from the CWCB,
- two hydrology models calibrated for several river basins in Colorado,
- the procedures required for this type of sensitivity analysis, and
- correctly interpreting study results with guidance from WWA.

Scientific understanding of the Earth's long-term and short-term climate trends has increased over the past several years. In parallel with this increased understanding, have been improvements in modeling techniques used to project current changes, past trends, and future possibilities at the global, regional, and local levels. Future global climate projections have been modeled using different emission scenarios determined by variables including economic growth, population growth, varying energy sources, and environmental sustainability. These models consistently predict that global average surface temperatures will rise. The most current quantitative results predict that the mean global surface temperature will increase by 0.8 to 4ºC by 2099 (these values are considered "Best estimates" in the IPCC 2007 AR4).

Possible changes in North America's climate include greater annual warming across the continent as compared with global projections, decreases in snow depth and season length, and across the southwest United States in particular, a decrease in annual precipitation and an increase in average summer temperatures (IPCC 2007 AR4). Though this information comes from the latest scientific studies, it is important to note that the uncertainty in these projections is large and the stated results should be considered only as possibilities.

Snowpack is the most important water source in the western U.S., and thus it is critical that water managers be provided with, 1) estimates of changes in future snowpack under various scenarios; and 2) an improved understanding of the mechanisms that give rise to snowpack variability from year-to-year. Previous climate studies have shown a wide variety of possible impacts, from no change (Duffy et al. 2006), to significant reductions in snowpack (Leung et al. 2003). Observations over the past 50 years of winter precipitation and temperature in the Western United States are shown in Figure 1 (Edwards and Redmond, 2005). The figure shows no obvious trend in winter precipitation but indicates that winter temperatures are on the rise. A recent analysis of the 2007 IPCC Fourth Assessment global models by Hoerling and Eischeid (2006) indicates that the combination of increased temperature and a weak to non-existent trend in snowpack may produce unprecedented drought conditions over the next 50 years in the Southwestern United States due to a strong increase in evapotranspiration resulting from increased temperature. Seager et al. (2007) came to similar conclusions regarding future runoff in the Southwest through an independent analysis of the IPCC Fourth Assessment global models. This study suggested that drought conditions will be unlike any previously observed in this region because of significant drying in sub-tropical

regions due to shifts of the Hadley cell circulation and extratropical jet stream pattern northward combined with El Niño events.

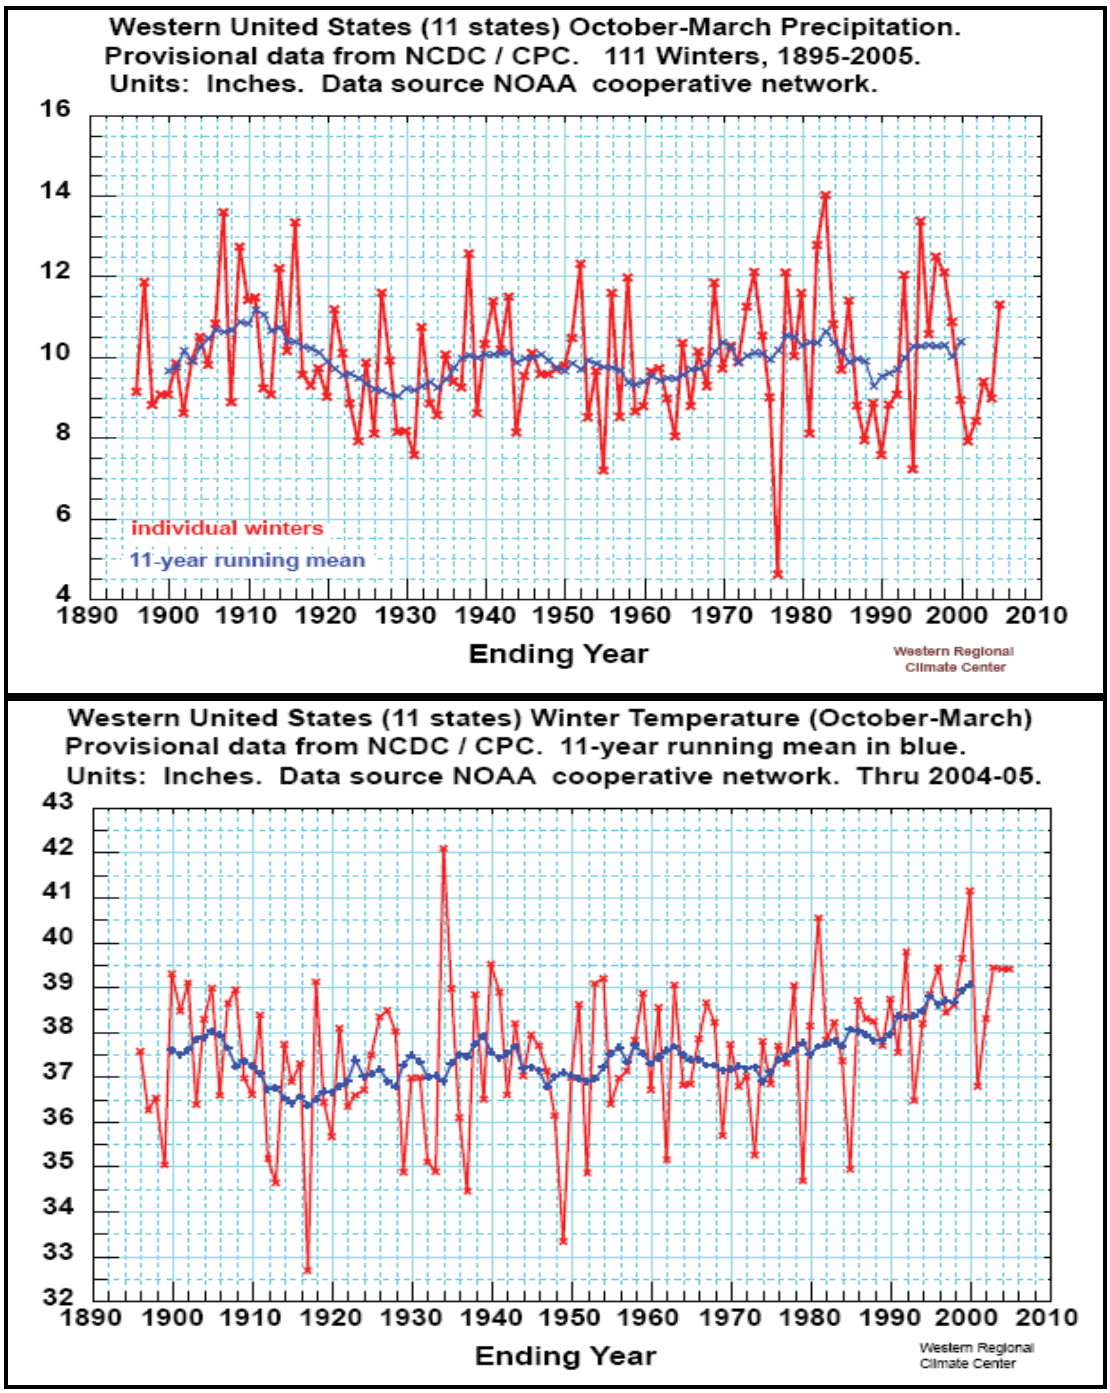

Figure 1. Western U.S. winter precipitation (Oct.-March; left) and western U.S. winter temperature for October-March from 1895-2005 (note: units on right graph are °F not inches, which is mislabeled). From Edwards and Redmond, 2005.

Scientific studies have shown that hydrologic systems and water resources are sensitive to climate change and variability, and that such changes add further stress to already over-allocated river basins. The June 2006 Western Governor's Association Report stated that average temperatures in the West have risen 2-5º F during the 1900s and are predicted to continue rising. The possible vulnerabilities to river basins in Colorado due to the previously described climate change include:

- Changes in precipitation including:
  - frequency and intensity,
  - phase (rain vs. snow),
  - temporal distribution (seasonality), and
  - spatial distribution (location),
- Increases in water use,
- Decreases in snowpack,
- Earlier snowpack melt-off,
- Increases in evaporation,
- Changes in soil moisture,
- Frequent and extended extreme conditions (droughts and floods),
- Increases in the frequency and duration of wildfires,
- Erosion and sedimentation changes,
- Water quality changes, and
- Recreational and environmental impacts

Such impacts are likely to change the historic timing and yield of water systems throughout Colorado. This study will aid in the understanding of how some of these changes may impact water supplies for Front Range users.

3. Project Duration and Cost.

This project is being co-funded by all of the participating entities with a matching research fund from the American Water Works- Research Foundation (AwwaRF). The following values and Table 1 below indicate the amount of contributions made by all of the participants in the project.

The total cost of this 13-month project has been estimated to be $379,900.

AwwaRF Funds Requested:	$80,000
Amount of Funds eligible for AwwaRF match:	$82,400
Amount of Funds not eligible for AwwaRF match:	$37,600
Total Cash Budget (AwwaRF Funds + All Co-Funding Cash):	$200,000
Total In-kind Contributions:	$179,900
Total Project Budget (Cash + In-kind):	**$379,900**

Table 1 - Joint Front Range Study Participant Cost

Organization Name	Cash Co-fund Amount	In-Kind* Contribution Amount
City of Aurora	$48,000	$14,000
City of Boulder	$8,000	$5,500
Colorado Springs Utilities	$10,000	$16,000
Denver Water	$24,000	$16,000
City of Fort Collins	$10,000	$5,500
Northern Colorado Water Conservancy District	$20,000	$10,500
Western Water Assessment		$22,400
National Center of Atmospheric Research		$54,000
Riverside Technology, Inc.		$36,000
TOTAL	**$120,000**	**$179,900**

Overall, we envision the project to take 13 months, as shown in **Table 2**. This schedule assumes a project start date of November 1, 2008.

Objective	Start	Finish	2008 Nov	Dec	Jan	Feb*	Mar	Apr	May*	2009 Jun	Jul	Aug*	Sep	Oct	Nov

* Depicts the beginning of every month a quarterly report is due.

Table 2. Joint Front Range Climate Change Vulnerability Study Schedule. Regular progress and communication meetings will occur at the end of every month.

4. Conclusions

As of the date this document was written, the Joint Front Range Study is in its third month and results have not been obtained. Data continue to be gather and models being

calibrated. It is expected that by the time of the conference, the authors will be able to show preliminary results.

One of the most important aspects of this project relates to education. Although climate change has been documented and advertised intensively, this phenomenon and its effects need to be really understood in order to make sound decisions in the water supply arena, especially at the regional and local level.

The cost of building projects to ameliorate the effects of climate change appear to be prohibitive but with the proper education and sound policy decisions, adaptation seems to be a more reasonable approach, but in order to adapt one needs to understand the cause and effects of a phenomena such as climate change.

ABSTRACT

The Santa Clara River in Southern California provides beneficial uses that include agricultural water supply, groundwater recharge, and rare and endangered species habitat. Significant urbanization has contributed to elevated chloride concentrations along portions of the river in the Santa Clarita Valley and downstream areas. The affected reaches of the Santa Clara River are included on California's list of impaired waters with respect to chloride. A total maximum daily load for chloride, which was originally adopted by the Los Angeles Regional Water Quality Control Board in 2002 and later amended in 2004 and 2006, required special studies to provide the technical basis for establishing appropriate chloride water quality objectives. As part of these studies, a fully integrated groundwater/surface-water numerical model was developed to facilitate the implementation of the chloride total maximum daily load. Modeling results indicated that implementation of expensive water treatment alternatives at two water reclamation plants would not likely lead to consistent compliance with existing chloride objectives in local streams or underlying groundwater basins. Accordingly, the model was used to develop a cooperative alternative water resources management approach. Once implemented, this approach could protect beneficial uses, aid in managing salinity (specifically chloride concentrations) in the Santa Clara River system, improve salt exportation from the study area, and provide enhanced water-supply benefits to water users in affected areas, while providing flexibility and more feasible chloride compliance solutions.

INTRODUCTION

Hydrologic Setting

The Santa Clara River (SCR) is the largest river system in Southern California that flows in a relatively natural state (Los Angeles Regional Water Quality Control Board [Regional Board], 2006). This river originates in the San Gabriel Mountains in Los Angeles County and flows into the Pacific Ocean in Ventura County. The SCR provides beneficial uses including agricultural water supply, groundwater recharge, and rare and endangered species habitat. The study area includes Reaches 7, 6, 5, and 4 (as designated by the Regional Board) of the SCR near the Santa Clarita Valley and Piru Subbasin (Figure 1).

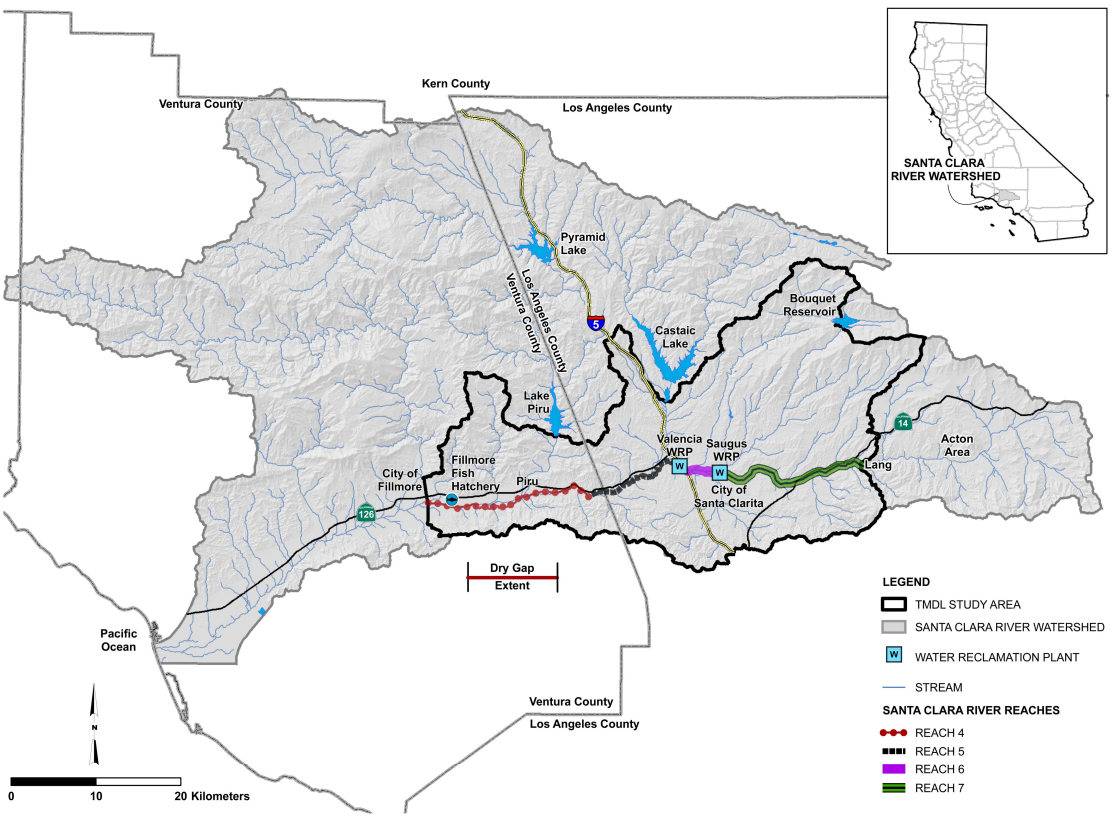

Figure 1. Map of Study Area and Surrounding Vicinity.

The Santa Clarita Valley is a thriving urbanized area located in Los Angeles County, 56 kilometers (km) (35 miles [mi]) north of downtown Los Angeles along Reaches 7, 6, and 5 of the SCR. The Santa Clarita Valley Sanitation District of Los Angeles County (SCVSD) owns and operates the Saugus and Valencia Water Reclamation Plants (WRPs), which provide primary, secondary, and tertiary treatment of domestic wastewater from residential, commercial, and industrial areas in the Santa Clarita Valley. These WRPs discharge tertiary-treated recycled water to Reaches 6 and 5 of the SCR, respectively. The Piru Subbasin is located in Ventura County, downstream and west of the Santa Clarita Valley along Reach 4 of the SCR. The Piru Subbasin is predominantly an agricultural area that includes cultivation of salt-sensitive crops,

such as strawberries, avocadoes, and nursery crops. Significant surface-water reservoirs exist upstream and north of the Santa Clarita Valley and Piru Subbasin, including Bouquet Reservoir, Pyramid Lake, and Castaic Lake in Los Angeles County, and Lake Piru in Ventura County (Figure 1).

The only location of perennial streamflow in the study area includes Reaches 6 and 5 of the SCR, located downstream of the Saugus and Valencia WRPs, and an eastern portion of Reach 4 of the SCR (Figure 1). This section of perennial flow in the SCR results from groundwater discharge and discharge from the WRPs.

Water Use

Potable water in the Santa Clarita Valley is either imported (mostly from the State Water Project [SWP]) or pumped from local groundwater basins. Water from the SWP is transported to the Santa Clarita Valley via the California Aqueduct and stored in Castaic Lake (Figure 1). The stored SWP water is delivered by Castaic Lake Water Agency (CLWA) to retail water purveyors known as the Upper Basin Water Purveyors[1], who also operate groundwater production facilities. These purveyors sell their potable supplies to users in their respective service areas of the Santa Clarita Valley and surrounding communities. The sources of irrigation water in the Santa Clarita Valley include potable water provided by the Upper Basin Water Purveyors and minor amounts of recycled water from the Valencia WRP.

Potable water in the Piru Subbasin comes solely from locally pumped groundwater from private wells. Irrigation water in the Piru Subbasin is mostly derived from groundwater, but a few surface-water diversions on the SCR and Piru Creek are also operated to supplement irrigation water supply.

Regulatory Background

The Santa Clarita Valley and Piru Subbasin are both semiarid regions with an average annual precipitation of less than 50 centimeters per year (less than 20 inches per year) and managing salinity in such regions is challenging. Chloride concentrations in imported water from the SWP have historically exceeded local chloride water quality objectives (WQOs) during drier-than-normal climate conditions (WQOs were established in the Basin Plan [Regional Board, 1994]). Increased urbanization in the Santa Clarita Valley and the prevalent use of self-regenerating water softeners in local residences and commercial and industrial facilities have also exacerbated salinity problems in portions of the SCR and underlying groundwater basins.

Portions of the SCR receiving discharge from the WRPs and downstream agricultural areas are included on California's list of impaired waters with respect to chloride. This listing occurred in response to claims of impairments to beneficial uses in agricultural areas downstream of the WRPs and led to the Regional Board's adoption of the Upper Santa Clara River Chloride Total Maximum Daily Load (TMDL) in 2002. Implementation of this TMDL would have required the Saugus and Valencia WRPs to meet a chloride WQO of 100 milligrams per liter (mg/L). This would have

[1] The Upper Basin Water Purveyors consist of Los Angeles County Waterworks District #36, Newhall County Water District, Santa Clarita Water Division of CLWA, and Valencia Water Company.

required construction and operation of advanced-treatment facilities at both WRPs and a 69 km (43 mi) brine conveyance pipeline to a new ocean outfall costing nearly a half-billion dollars. Recognizing the potentially costly implementation and time required for construction of such measures, the Regional Board amended this TMDL in 2004 and 2006 to require special studies to help provide a scientific basis for implementation of the chloride TMDL. The SCVSD provided funding for these special studies, which were managed jointly by the SCVSD and the Regional Board.

Scope

This paper describes results of the groundwater/surface-water interaction model required by the special TMDL studies. The purpose of developing the model was to improve the understanding of the interaction between surface water and groundwater and the linkage between surface-water quality and groundwater quality with respect to chloride. Particular emphasis was placed on evaluating the impact of the WRP recycled water discharges to the SCR on downstream surface water and groundwater chloride concentrations. The project also required significant collaboration among members of a TMDL stakeholder group consisting of individuals representing SCVSD, the Regional Board, local utilities, city and county entities, state and federal agencies, academia, contractor organizations, environmental groups, and the general public.

The outcome of this TMDL study included development of a cooperative alternative water resources management approach to comply with the TMDL that, once implemented, could protect beneficial uses and aid in managing salinity (specifically chloride concentrations) in the SCR system. Modeling results also indicated that implementation of this management approach could provide enhanced water-supply benefits to water users along the SCR in portions of Los Angeles and Ventura Counties.

METHODOLOGY

Code Selection

This TMDL study required a modeling code that could simulate the flow of water and solutes over the land surface and through the subsurface. This model was built using a proprietary code called MODHMS (HydroGeoLogic [HGL], 2007), which has its origins in the popular United States Geological Survey (USGS) Modflow model (McDonald and Harbaugh, 1988). MODHMS has been enhanced and further developed by HGL to include numerous features that are not included in the original USGS code. MODHMS is a physically based, spatially distributed numerical model that includes several packages for simulating fully integrated groundwater and surface-water flow (including three-dimensional saturated and unsaturated flow) and solute transport. This code was selected for the following reasons:

- Project scope required a code that is capable of simulating unconfined subsurface flow interacting with a stream channel flow domain, and the associated solute transport therein. The code also needed to be capable of simulating drying and re-

wetting of both surface and subsurface domains. MODHMS meets these requirements.

- The SCR watershed is characterized by complex hydrogeology, mixed and evolving land uses, dynamic groundwater/surface-water interactions (including gaining and losing river reaches), and variable climatic conditions. These factors would challenge the applicability of most readily available numerical codes, but MODHMS is well suited to address these factors.
- MODHMS treats the flow of water and transport of solutes in a rigorous and mechanistic manner by mathematically representing surface and subsurface domains as one holistic system. Thus, it is neither necessary to estimate locations of losing or gaining stream reaches outside of the model, nor to manually link numerical solutions of the groundwater and surface-water systems separately.
- MODHMS is the product of more than 15 years of development and is built on the USGS Modflow model. Modflow has been used extensively in groundwater evaluations worldwide for more than 20 years.
- MODHMS has been benchmarked and verified (HGL, 2007).

Model Development

MODHMS mathematically separates the field problem into two hydrologic flow and solute transport regimes: surface and subsurface. The surface flow regime includes an overland flow (OLF) domain and channel flow (CHF) domain. The subsurface flow regime includes the unsaturated and saturated groundwater flow (GWF) domains of the materials underlying the OLF and CHF domains.

A grid that mathematically represents an area of 1,083 square kilometers (418 square miles) was developed for this study and is illustrated on Figure 2. The domain boundaries were debated and selected collaboratively by the stakeholder group to coincide with natural hydrologic divides around an area downstream of Bouquet Reservoir, Castaic Lake, and Lake Piru. A curvilinear grid type was selected for this model because of its ability to be warped along nonlinear features of interest, such as the domain boundaries and the SCR. Use of a curvilinear grid also facilitated assignment of smaller cell spacings (i.e., finer discretization) within areas of interest along Reaches 6, 5, and 4 of the SCR. Grid resolution varies in the x-direction from 15 to 915 meters (m) (50 to 3,000 feet [ft]) and in the y-direction from 15 to 3,353 m (50 to 11,000 ft). The surface regime was discretized using an OLF grid and CHF grid. The subsurface regime was discretized into nine GWF layers using an extension of the OLF grid with depth to provide a three-dimensional representation of the surface and subsurface system. The OLF grid has a two-dimensional connectivity and represents the land surface within the domain. The CHF grid consists of a network of interconnected one-dimensional channel segments, which vary in length between 52 and 134 m (170 and 440 ft), with most of the segments being approximately 91 m (300 ft) long.

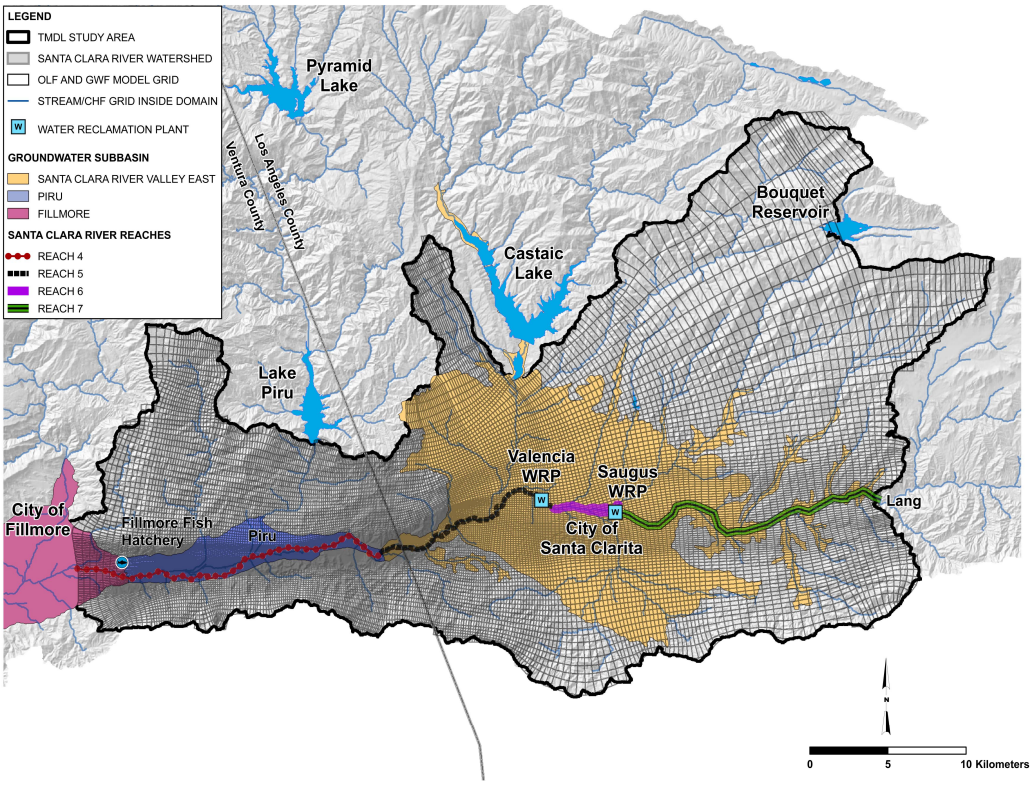

Figure 2. Map of Curvilinear Model Grid.

The model was initially developed using parameters and assumptions from previously developed models of the area (Systech Engineering, 2002a and 2002b; USGS, 2003; CH2M HILL, 2004 and 2005). Additional details related to the spatial discretization and parameterization of the groundwater/surface-water interaction model can be found in CH2M HILL-HGL (2008).

To fulfill the modeling objectives, the model was developed and calibrated using daily input data over a historical period including calendar years 1975 through 2005 (CY 1975-2005). This historical period and the requirement of model output at a daily frequency were debated and selected collaboratively by the stakeholder group. The available data and conceptual model that provided the basis for model development can be found in CH2M HILL-HGL (2006a, 2006b).

RESULTS

Model Calibration

The Modeling Team selected qualitative and quantitative calibration targets for the surface and subsurface flow of water and chloride in the model. Calibration targets selected for this study included 88 groundwater-level locations, 50 groundwater-chloride locations, 6 streamflow locations, and 12 surface-water quality locations, as well as general patterns and characteristics of the hydrologic system.

Calibrating the model to daily streamflow data and available groundwater elevation and chloride concentration data over the CY 1975-2005 period resulted in a model

that was suitable for its intended applications. Following are the primary attributes that made the model appropriate for its intended uses:

- It can simulate historical short-term and long-term trends in groundwater elevations, groundwater discharge, streamflows, dry gap locations, and chloride concentrations over a 3-decade period that reflects increased urbanization, increased SWP water imports, wet and dry periods, and associated changes in land use and water use.
- It can simulate the interacting surface and subsurface flow regimes, the transport of chlorides throughout these regimes, and the complex process of evapotranspiration and evapoconcentration of chlorides.
- The numerical solution is adequately constrained by the many, and sufficiently distributed, calibration targets that include flow rates, flow volumes, groundwater elevations, and surface and subsurface chloride concentrations.
- The modeling results are consistent with the conceptual model that was described in CH2M HILL-HGL (2006b).

Additional details regarding model calibration can be found in CH2M HILL-HGL (2008).

Model Application

Although it is impossible to predict future hydrology, land use, and water use conditions with certainty, future water use and WRP waste load allocation assumptions for calendar years 2007 through 2030 (CY 2007-2030) were developed collaboratively by the stakeholder group. Following calibration, the model was used to evaluate future site-specific hydrologic system and chloride transport behavior resulting from implementation of assumed chloride management activities. Twenty-one scenarios of future conditions were ultimately evaluated using the model, which incorporated a variety of technical and policy-related considerations. The range of assumptions included in these scenarios of future conditions fall into five general categories including (1) level of recycled water use in the Santa Clarita Valley; (2) level of wastewater treatment at the Saugus and Valencia WRPs; (3) timing related to the removal of self-regenerating water softeners from the Santa Clarita Valley; (4) alternative WRP discharge locations in the SCR; and (5) alternative water resources management options. Several of the scenarios of future conditions included assumptions from multiple categories.

Results from the first 20 scenarios of future conditions included elements from the first four categories listed above. These results indicated that compliance with groundwater and surface water WQOs for chloride would not be consistently achieved at all locations and under all climatic conditions, especially during drought periods. Thus, the 21st scenario incorporated an alternative water resources management approach in conjunction with developing proposed chloride site-specific objectives (SSOs) ranging from 117 to 150 mg/L in the SCR for consideration by the Regional Board. This scenario was designed to achieve compliance with chloride SSOs at all times at receiving water locations with mitigation measures established to

protect downstream agricultural beneficial uses as needed (Geomatrix Consultants, 2008b). This alternative water resources management approach was developed jointly by the SCVSD and the Upper Basin Water Purveyors in Los Angeles County, and stakeholders representing downstream water users in Ventura County. A Memorandum of Understanding among these entities is being developed to provide a more feasible regional solution as an alternative for compliance with the existing chloride WQO of 100 mg/L in the SCR. The alternative water resources management scenario included the following elements:

- Implementing measures to reduce chloride in the recycled water at the WRPs by removing self-regenerating water softeners from the Santa Clarita Valley and incorporating ultraviolet disinfection technology at the WRPs
- Incorporating advanced treatment measures for a portion of the recycled water from the Valencia WRP to further reduce chloride concentrations in recycled water when needed
- Procuring local groundwater or an alternative water supply to be either discharged to the SCR as supplemental water supply or otherwise provided to protect salt-sensitive agricultural beneficial uses of the SCR
- Constructing and operating groundwater extraction wells in eastern Ventura County to facilitate exportation of groundwater with elevated chloride concentrations from the Piru Subbasin
- Expanding recycled water uses in the Santa Clarita Valley
- Revising groundwater and surface-water WQOs to support all of these elements

DISCUSSION

Results from the 21 scenarios of future conditions indicated that there is no simple solution to managing salinity in the TMDL study area. Use of the groundwater/surface-water interaction model for this collaborative study promoted an enhanced understanding of how chloride is routed between the surface and subsurface flow systems, as compared to previously developed models. This enhanced understanding of the hydrologic system has led to improved collaboration among stakeholders. Implementation of an alternative water resources management program could protect beneficial uses, increase salt exportation from the TMDL study area, and enhance water-supply benefits to water users in affected areas, while providing flexibility and more feasible chloride TMDL compliance solutions.

Results of this study were subject to significant scrutiny including discussions over the site conceptual model, level of protection required for downstream beneficial uses, and competing interests from a diverse stakeholder group. The degree of collaboration required in such a challenging hydrologic study area made this TMDL study very complex and often contentious. However, the advanced modeling capabilities of the code and modeling team facilitated constructive dispute resolution on the basis of objective scientific analyses. Additional details of this study can be

found in CH2M HILL-HGL (2006a, 2006b, 2007, and 2008) and Geomatrix Consultants (2008a and 2008b).

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the organizations that provided hydrologic, well construction, climatic, and operational input data for the model development effort. These organizations include, but are not limited to the Santa Clarita Valley Sanitation District, Los Angeles Regional Water Quality Control Board, Ventura County Watershed Protection District, United Water Conservation District, Systech Engineering, United States Geological Survey, Upper Basin Water Purveyors, Newhall Land and Farming Company, Los Angeles County Department of Public Works, Fillmore Fish Hatchery, United States Army Corps of Engineers, Ventura Regional Sanitation District, Los Angeles Department of Water and Power, Southern California Association of Governments, and United States Environmental Protection Agency.

Modeling Techniques to Incorporate Low Impact Development Features into Detention Analyses

Kristin White, P.E., CFM, LEED AP[1] and Jennifer J. Walker, P.E., CFM[1]

ABSTRACT

Developments that include Low Impact Development (LID) features or integrated management practices (IMP)s can achieve both storm water quality and quantity benefits. The greatest quantity and quality benefits may be achieved when the site is designed with a holistic approach to LID from the beginning. To maximize the benefits of the LID features, it is often beneficial to integrate the volume and infiltration capacities into the detention analysis. This paper examines various modeling techniques to incorporate IMPs into detention analyses. Simplistic analysis as well as complex modeling techniques are included.

INTRODUCTION

Low impact development (LID), a term coined by Prince George's County (PGC), Maryland, is a method of designing and planning stormwater management systems using integrated management practices (IMPs) to minimize the effects of development on rainfall runoff. In particular, the goal is to limit the post-development runoff conditions (volume and quality) to the pre-development runoff conditions. LID methods either focus on retaining the runoff for future non-potable use, ground water recharge or detaining for a delayed slower release to a larger system. Significant water quality benefits are commonly associated with both the retention and detention of runoff. Water quality benefits occur either as an integral part of the design or a beneficial side effect. In general, water released from any LID configuration has improved water quality over the raw stormwater even if the LID device is only a grassed separation of impervious areas.

The intent of LID is to focus collection and pollutant removal efficiency on smaller, more frequent storm events rather than large, infrequent events. Although certain LID devices may provide enough storage volume for a larger design storm event, the design intent is to collect and/or treat common wet weather events.

LID technology is widely used in the northeastern, mid-Atlantic and Pacific Northwestern parts of the Country. Some Texas communities are beginning to analyze these methodologies to determine if they provide sufficient protection from common large floods. Below are some of the major conceptual-level benefits and disadvantages of using LID; however, true benefits and disadvantages vary by the type of LID device as well as site and region specific characteristics:

[1]Dodson & Associates, Inc. 5629 FM 1960 West, Suite 314 Houston, Texas 77069-4216
281-440-3787 (phone) 281-440-4742 (fax)

Advantages	Disadvantages
Lower or no impact on community resources such as regional detention or collection systems	May require a direct connection to a traditional system to handle large flood volumes
Encourages groundwater recharge through significant infiltration	Effectiveness is significantly reduced when soil or pavement is completely saturated
Improves water quality of discharge by collecting debris and absorbing pollutants before releasing	Large storage volumes will be required for design storms
Space efficient for small, urban areas such as rooftops and smaller parking lots	Not space efficient for larger, heavily impervious sites such as warehouses or airports
For smaller sites, cost is often lower than updates to a larger collection or detention	For larger sites, cost is typically higher than updates to a larger system due to required land
Focuses on managing frequent stormwater events to limit all peak flows rather than only the design storm peak flow	IMPs will require regular maintenance since they are used for frequent storm events

COMMON LID IMP EXAMPLES

Listed below are several LID IMP examples with their description and suggested use. These devices are all different; however are all used similarly on a site to lower the total impervious area, separate the impervious areas and increase the time of concentration. The applicability of each device depends on the intended project and desired result.

Integrated Management Practice	Description	Suggested Use
Bioretention	Depressed landscaping feature with soil and ponding storage volume	Runoff storage for small sites or use overflow or underdrain system for larger storm events
Filter Strips	Vegetated strip of land along side an impervious cover to accept and sometimes store sheet flow	Along the side of a road or highway to treat and sometimes collect impervious runoff
Wet and Dry Vegetated Swales	Vegetated, linear depressed area to collect, store and sometimes convey runoff	Runoff collection on smaller sites. Dry systems may have a second recreational use
Trees	Grouping or line of trees to intercept rainfall and separate impervious areas	As separation of streets from sidewalks or similar

Porous Pavement	Surface with large pore volume to infiltrate and store initial rain fall, not runoff	As driveways, parking lots or lightly traveled roads
Rain Cisterns	Cistern to collect runoff directly from impervious areas	Collect runoff from roofs of houses or commercial buildings
Underground Detention	Local system to collect runoff through inlets and store underground for infiltration, future non-potable use or later release	Collect runoff from large commercial sites with minimal available pervious area
Green Roof	Roof structure with soil and planted vegetation to limit runoff from roof surface	Commercial buildings and business centers
Blue Roof	Roof structure to collect rainfall for future non-potable use or release	Commercial buildings, centers and warehouses

METHODOLOGY

Conceptual Differences Between LID Planning and Traditional Stormwater Management

LID planning typically involves breaking the development area down to micro-drainage areas or individual development pieces such as driveways, parking lots, roof tops, etc whereas traditional methods analyze the development with larger drainage areas. LID IMPs are most effective when used to capture and treat runoff from these smaller, concentrated areas. In particular, LID planning relies on separating the impervious areas from each other.

Traditional methods are designed to collect combined runoff from larger areas through conveyance systems and/or regional detention. This type of system works to capture and convey the runoff from the entire site. Therefore, the conveyance system is designed to collect all of the rainfall (after the initial abstraction) that falls on the site.

Modeling and Sizing

The modeling of LID IMPs is based both on a retention/detention storage volume as well as a peak flow. For this reason, the Rational Method is typically not recommended when assessing LID features due to its reliance on peak flow rather than total volume. Accounting for LID IMPs can be accomplished using several basic methodologies:

- Manipulate the post-development hydrograph to account for LID IMPs
- Analyze and plan IMPs using the PGC methodology
- Enter IMP design and layout into a hydrologic model with LID capability

Modifying the Post-Development Hydrograph

Modifying the post-development hydrograph can be done in a variety of ways, depending on the analysis method used. If using the National Resources Conservation Service (NRCS) TR-55 method, the IMP storage volume can be accounted for as conventional detention, or by altering the curve number, runoff or rainfall. Alternatively, the conventional post-development hydrograph can be directly manipulated.

IMPs accounted for as conventional detention use the available ponding storage only. This is done by subtracting the total storage volume from the total runoff volume. This method will be equivalent to using a conventional detention pond. This method is simple to follow and uses commonly followed hydrologic calculations; however the resulting required ponding volume will be oversized due to no exfiltration calculations.

Modification of the key terms in the NRCS runoff depth equation, shown below, can also be used to account for LID IMPs:

$$Q = (P-I_a)^2 / (P-I_a)+S$$

Where Q = Runoff Depth
P = Rainfall Depth
I_a = Initial Abstraction
S = 1000/CN – 10
CN = Composite Site Curve Number

The curve number can be adjusted to account for similarly sized, evenly distributed LID features. This method can be completed by determining the total detention volume offered by the LID arrangement, including estimated soil volume, and subtracting that volume from the total runoff volume. With the adjusted runoff volume, a new curve number can be solved for and used to develop the LID post-development hydrograph.

The runoff volume can be adjusted by subtracting the total retention volume from the $(P-I_a)$ term. This method alters the rainfall volume prior to incorporating the soil or ground cover type. This creates a post-development hydrograph that accounts for all IMP storage as complete retention or infiltration with no runoff leaving the site.

The post-development hydrograph may be altered directly by taking the conventionally calculated post-development hydrograph with no detention and removing the total provided IMP retention volume from the curve, starting at the leading edge. This results in a new perpendicular leading edge rather than a standard curve. Alternatively, the hydrograph may be altered by reducing the amplitude by a percentage of retention volume provided. For example, the total

flow at each point in the hydrograph would be lowered by the percentage of LID storage volume to total runoff volume. This method will reduce the height of the hydrograph, however the base duration will remain the same.

These methods can be employed in conventional models (such as HEC-HMS or SWMM) by modeling the site with no LID features, exporting the conventional resulting runoff hydrograph, altering the hydrograph using one of the above methods and then importing the altered hydrograph back into the model for routing. In some cases, this may require an iterative effort to provide the appropriate retention volume within the LID IMPs. These methods will not be able to assess the compared effectiveness of separate LID methods, or disconnected impervious areas but will provide an estimated comparison between using an LID system over a more traditional system.

PGC Methodology

The PCG method focuses on minimizing the impervious area, disconnecting the impervious area and increasing the post-development time of concentration to meet the pre-development time. Accomplishing these goals results in a post-development hydrograph with a lower peak flow (when compared to conventional methods) with a peak time equal to the pre-development time. Assuming the LID design peak flow and runoff volume are still greater than the pre-development conditions, the volume difference must be retained to meet the pre-development conditions. The PGC methodology was developed to determine this volume using a more accurate LID design hydrograph that accounts for disconnected impervious areas, IMP retention volume and evenly dispersed IMPs. In addition, this method can also be used for IMP sizing.

The method follows the below basic steps:

1. Calculate the pre-development time of concentration (T_c) and curve number using the TR-55 (SCS, 1986) method. These values should be determined assuming the pre-development conditions are woods in good condition.
2. Prepare a preliminary layout with estimated LID surface areas and disconnected impervious areas.
3. Calculate the proposed curve number as a weighted area average rather than using a standard TR-55 value for the development type. The PGC method also includes a refined CN equation to account for disconnected impervious areas. This equation is shown below:
    a. $CN_c = CN_p + (P_{imp}/100) * (98 - CN_p) * (1 - 0.5*R)$

        Where CN_c = the weighted average CN from the preliminary layout

        CN_p = the weighted average CN from the pervious areas only

        P_{imp} = the percent of the impervious area to the entire site

        R = the ratio of unconnected impervious area to the total impervious area

4. Calculate the proposed Tc. If this value is greater than the pre-development Tc, the preliminary layout should be revised to increase the Tc at least to the pre-development time.
5. Determine the design storm event by calculating the rainfall required to initiate direct runoff during pre-development (well wooded) conditions and multiplying it by 1.5. This formula is shown below:
    a. Design Rainfall Depth = 1.5 * (0.2 * [1000/CN_c – 10]) where CN_c is the composite (weighted average) pre-development curve number.
6. Use PGC design charts to determine required IMP retention volume to maintain the existing CN. This chart is based on the design rainfall, geographic region, the pre-development and post-development CN.
7. Calculate required volume for water quality based on local regulations. This is typically the first 0.5-inch or 1.0-inch of rainfall.
8. Use the higher of the 2 values in steps 6 and 7 as the required retention volume.
9. Use PGC design charts to determine required IMP detention volume to maintain the pre-development peak discharge. This chart is also based on the design rainfall, geographic region, the pre-development and post-development CN.
10. If the retention volume (step 8) is higher than the detention volume (step 9) then use the retention volume as total required LID volume and size the LID IMPs. This may be an iterative process if IMP surface areas need to be resized as they will change the composite CN.
11. If the retention volume (step 8) is lower than the detention volume (step 9) then a hybrid of retention and detention must be used. The detention volume is calculated using the PGC design charts based on the design rainfall, geographic region, the pre-development and post-development CN. The hybrid ratio of retention to detention volume is determined by creating a linear relationship between the two storage values and assessing the reasonably available retention volume on the design site. This will be an iterative process if the IMP surface areas are resized as they will change the composite CN.

Computational Models

Certain models have been either specially created or retrofitted to account for the use of LID IMPs. Several common hydrology models have been retrofitted with ex-filtration and water quality volume calculation options to help in the modeling with an LID feature. These require advanced knowledge of exfiltration rates for the design site for a hydrologic analysis. Conventional models which have not been retrofitted, such as HEC-HMS, should not be used for modeling LID, but rather only for developing a conventional hydrograph.

More complex hydrologic models have been developed or enhanced specifically to design and model LID IMPs within a watershed. These models have the capability to analyze the effectiveness of specific IMPs and size them based on set requirements. The following table

outlines common and complex models with their suggested use. Two specific models, CH2M HILL's LIFE™ and PGC's BMP Module and discussed in more detail.

Model	Brief Description	Recommended Use for LID
EPA's SWMM	Hydrologic, hydraulic and water quality model with optional continuous simulation	Detailed analysis of watershed with storage-focused LID IMPs Does not account for impervious separation
XP SWMM	Enhanced hydrologic, hydraulic and water quality model with optional continuous simulation	Detailed analysis of a watershed with different IMPs where removal efficiency of each device is known
Bentley's Pond Pack	Hydrologic model to design and analyze detention ponds with optional exfiltration option	Analysis of larger storage and exfiltration based IMPs within a watershed
Hydro-CAD	Hydrologic model to calculate runoff and detention pond routing with exfiltration option	Analysis of storage and infiltration based IMPs within a watershed
Hydrologic Simulation Program-Fortran (HSPF)	EPA model to analyze water quality effects based on continuous rainfall	General continuous analysis of LID water quality benefits, not for flood control design
Western Washington Hydrologic Model (WWHM3 PRO)	HSPF-based model to analyze hydrology and water quality of particular IMPs in WA	Continuous analysis of a watershed with multiple, different IMPs Can be modified for areas outside of WA
Bay Area Hydrology Model (BAHM)	Created for west coast hydrology for sizing detention and water quality systems	Sizing particular IMPs: bioretention swales, gravel trench beds, sand beds or irregularly shaped ponds
HEC-HMS	Model to develop standard hydrograph based on precipitation input	Obtaining standard, non-adjusted hydrographs. Not recommended for modeling IMPs
LIFE™	CH2M HILL model to analyze and design IMPs using continuous simulation	Continuous analysis of a watershed with multiple, different IMPs or design of a specific IMP
PGC BMP Module	PGC model to analyze effectiveness of IMPs or size IMPs	Continuous analysis of an IMP or network of IMPs, each with detention rate > 1 hour IMPs should all be similarly sized and equally distributed

Prince George County's BMP Module

The Prince George's County BMP Module (the module) is a tool developed to evaluate the effect of a particular LID Best Management Practice (BMP) on the resulting water quality and outflow for a general area. The model was developed between 1999 and 2000 by Prince George's County and Tetra Tech, Inc. In general, this model is best for site-level analysis or evaluating small watersheds. It can be used for a single LID device or with an LID network. The module takes the following factors into consideration for evaluation:

- Evapotranspiration
- Infiltration
- Orifice outflow
- Weir controlled overflow
- Underdrain capacity and flow
- Feature design (sloping and shape)
- Roughness of device
- Soil media filtration capacity for particular pollutants
- First order loss or decay of pollutants

This model requires a separate hydrologic input on an hourly time series for computation. The time series may come from a conventional model such as HSPF, HEC-HMS or SWMM. Because of the hourly time step requirement, this model would not be effective for an LID device with a retention/detention time less than one-hour. The results of the model provide hourly pollutant load and flow discharge data. If using the module to incorporate an LID device in a detention analysis, a series of models would need to be used. A possible flow chart for the model set up is shown below in Figure 1. Due to its emphasis on water quality and the LID design method of designing for more common storms, this module is most effective when run over a long-term period or multiple storm simulation.

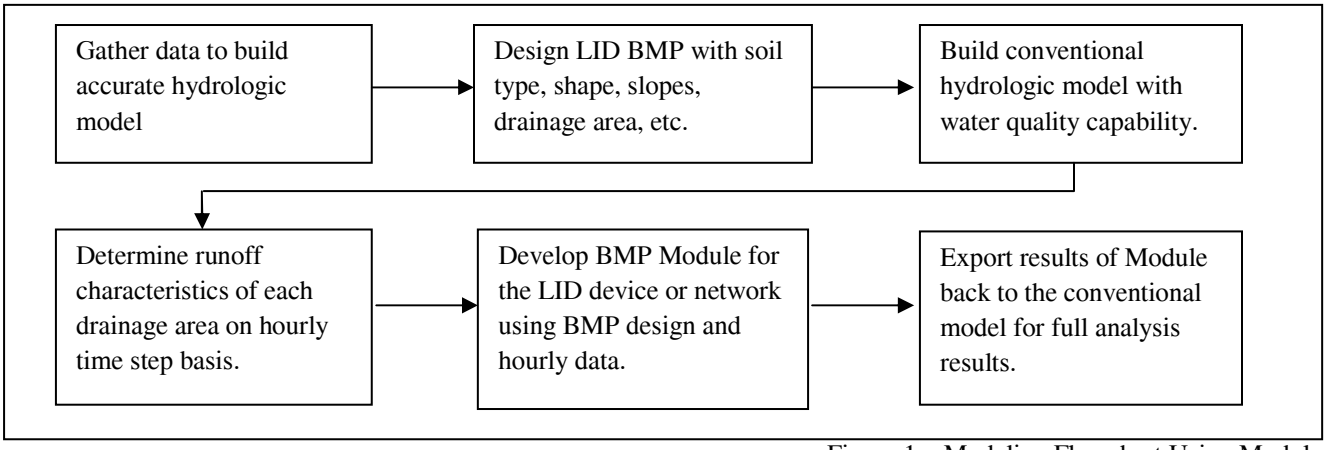

Figure 1 – Modeling Flowchart Using Module

LIFE™ Model by CH2M HILL

The LIFE™ model developed by CH2M Hill uses very similar inputs to the BMP module however the LIFE™ model is a full analysis and design model with the capability to determine runoff volumes and water quality characteristics as well as optimize designs. It is also a continuous simulation model but includes the option to have a time step less than one hour, making it suitable for devices with shorter detention or retention times. A flow chart of the model process is shown below in Figure 2.

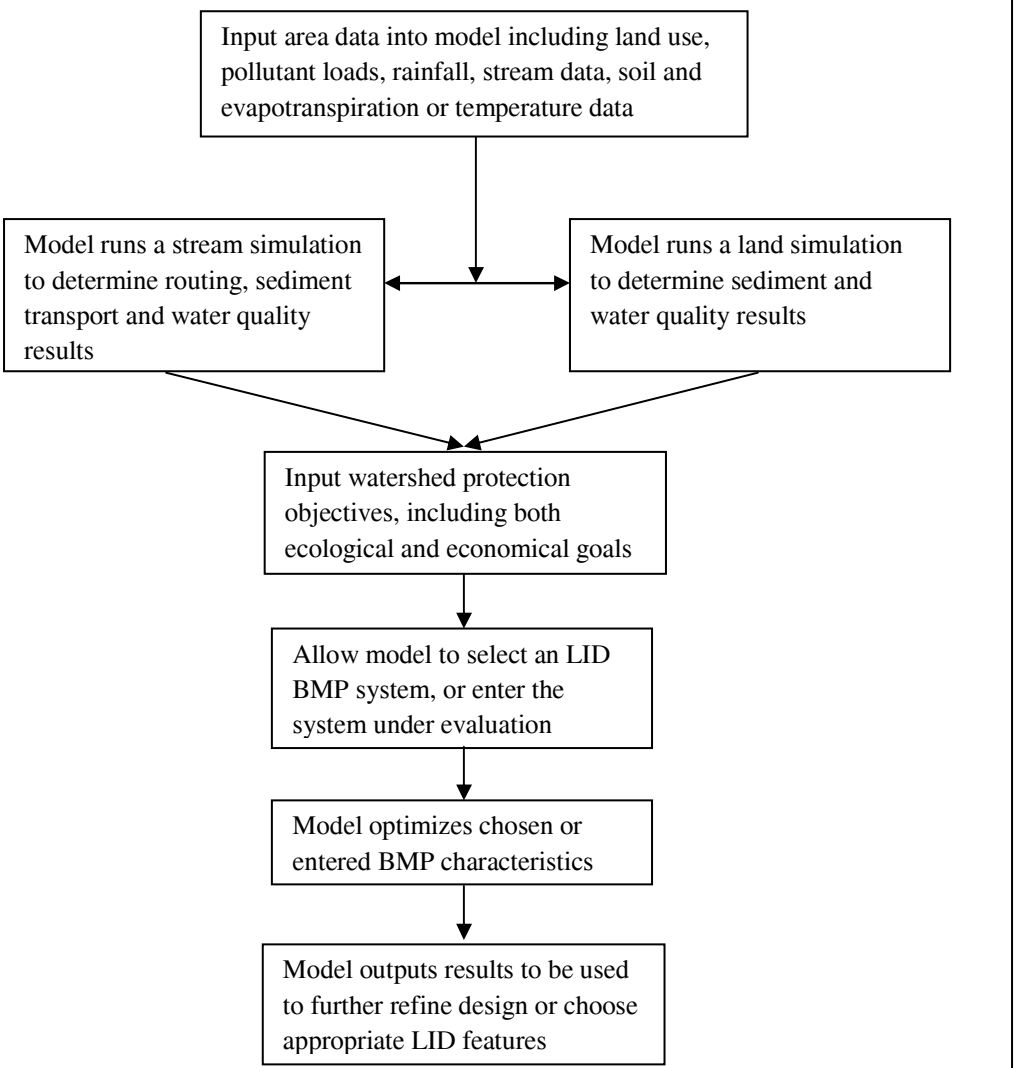

Figure 2 – Modeling Flowchart Using LIFE™

CONCLUSION

Low Impact Development planning techniques are very beneficial for stormwater collection, storage and treatment in smaller areas with new impervious cover added. LID methodology is continuously growing and improving as it becomes a more accepted method for treating and collecting stormwater runoff. LID analysis may be done by estimating the storage effectiveness of IMPs through standard calculations, using the PGC developed algorithm or by using complex modeling system to model a detailed design. Sizing LID components can be done either through direct volume calculations or by using a more complex model. The following table summarizes the discussed models with their recommended hydrologic and hydraulic (H&H) analysis, water quality (WQ) analysis, specific analysis concentration and sizing availability.

Abstract

Complexity of engineering problems, especially in the field of water resources, makes traditional optimization tools less efficient and enhances the popularity of evolutionary algorithms. Traditional optimization methods present just a single point as the optimal solution even in multi-objective problems. Thus, the main necessity to apply evolutionary algorithms is to present a set of nondominated solutions/Pareto-fronts as the optimal/near-optimal solutions, whereas most of problems in the field of water resources management are considered as a compromise between several objectives. In this paper, the Multi-Objective Particle Swarm Optimization (MOPSO) is applied to the operation of a multipurpose reservoir system. The objectives are: (1) maximization of reliability; (2) minimization of vulnerability; and (3) minimization of resiliency of the reservoir system, satisfying the downstream demand. The proposed algorithm is compared to a traditional method (weighting method). Results show that the MOPSO algorithm is successful in finding near-optimal, Pareto-front solutions.

Keywords: Multi-objective particle swarm optimization (MOPSO); multipurpose; reservoir operation.

1. Introduction

Reservoirs are one of the main sources of surface water and are commonly operated with several conflicting objectives. To determine the optimal operation of a reservoir, simulation and optimization models have been used. Simulation models do not provide an optimal operation policy, but optimization models use mathematical relations to archieve optimal/near-optimal solutions. Labadie (2004) presented a list of reasons which causes a continuing gap between theoretical development and real-world implementation for optimal operation of reservoir systems which include: (1) many reservoir system operators are skeptical about models purporting to replace their judgment and prescribe solution strategies and feel more comfortable with use of existing simulation models; (2) computer hardware and software limitations in the past have required simplifications and approximations that operators are unwilling to accept; (3) optimization models are generally more mathematically complex than

simulation models, and therefore more difficult to comprehend; (4) many optimization models are not conducive to incorporating risk and uncertainty; (5) the enormous range and varieties of optimization methods create confusion as to which to select for a particular application; (6) some optimization methods, such as dynamic programming, often require customized program development; and (7) many optimization methods can only produce optimal period-of-record solutions rather than more useful conditional operating rules. In addition, there are difficulties in solving large-scale, convex optimization models. To find an optimal or near-optimal solution to those problems, evolutionary algorithms and metaheuristic methods have been considered.

Evolutionary algorithms are stochastic search methods that mimic the natural biological evolution and/or the social behavior of species. Examples include how ants find the shortest route to a source of food and how birds find their destination during migration (Elbeltagi et al., 2005). Most applications of evolutionary algorithms have been to mathematical benchmark problems. Cieniawski et al. (1995) applied genetic algorithm (GA) to solve a multi-objective groundwater monitoring problem under uncertainty conditions. Prasad and Park (2004) presented multi-objective GA for design of water distribution networks, considering minimization of the network cost and maximization of reliability measure. Prasad et al. (2004) applied multi-objective GA in booster disinfection of water supply networks. Baltar and Fontane (2006) applied Multi-Objective Particle Swarm Optimization (MOPSO) algorithm proposed by Coello and Lechuga (2002) in single-reservoir operation to find nondominated solutions. MOPSO results were compared with results of the ε-constraint method as the optimal Pareto-front. Kumar and Reddy (2007) used Particle Swarm Optimization (PSO) algorithm to solve a multipurpose, multireservoir operation problem. The weighting method was used to handle multi-objective problem to the single objective and then the PSO algorithm was used as the optimization tools.

In this paper, the MOPSO algorithm is applied in the operation of a multipurpose reservoir system. Results from the MOPSO algorithm, as the nondominated solutions/Pareto-fronts, are compared with the results of the weighting method.

2. Multi-Objective PSO Algorithm

Particle swarm optimization (PSO) is a swarm intelligence algorithm based on the social behavior of birds. In the real world, the birds' movement toward food/destination is based on the position of each bird in the swarm during the time movement. Thus, each bird moves using its best position and the position of the one which has the minimum distance from the food/destination. In the PSO algorithm, each bird is presented as the particle and a set of the birds (particles) is identified as the swarm. The steps of the PSO algorithm are as follows:

1. Producing the random particles ($X_{N\times D}$) as the initial solutions in which N = the number of particles; and D = the number of decision variables.
2. Calculating the velocity particles ($V_{N\times D}$) by Eq. 1:

$$v_{id}^{t+1} = \alpha\left(w^t.v_{id}^t + c_1.r_1^t\left(Pbest_{id}^t - x_{id}^t\right) + c_1.r_2^t\left(Gbest_d^t - x_{id}^t\right)\right) \quad (1)$$

for $i = 1,2,...,N \qquad d = 1,2,...,D$

in which v_{id}^{t+1} = velocity of *i*th particle for *d*th dimension in (*t+1*)th iteration; α = constriction factor which is a fixed value that controls the velocity movement toward an optimal point; w^t = inertia weight parameter which is calculated by Eq. 2:

$$w^t = w_{Max} - \frac{(w_{Max} - w_{Min}) \times t}{iter_{Max}} \tag{2}$$

This parameter starts from the maximum value (w_{Max}) in the first iteration to the minimum value in the last iteration ($iter_{Max}$); v_{id}^t = velocity of *i*th particle for *d*th dimension in (*t*)th iteration; c_1 , c_2 = cognitive and social parameters which divide the velocity between the best position of the particle and swarm; r_1^t, r_2^t = random numbers in [0,1] with uniform distribution in the (*t*)th iteration; $Pbest_{id}^t$ = best position of the *i*th particle for the *d*th dimension in the (*t*)th iteration; and $Gbest_d^t$ = best position of the swarm for the *d*th dimension in the (*t*)th iteration.

Each particle (bird) moves in decision space by two vectors which are the distance between *Pbest*/*Gbest* and the current position of a particle.

3. Limiting the calculated velocity to the lower (v_{Min}) and upper (v_{Max}) of velocity bounds.

$$v_{\min} \le v_{id}^{t+1} \le v_{\max} \tag{3}$$

4. Updating particles' position using Eq. 4:

$$x_{id}^{t+1} = x_{id}^t + v_{id}^{t+1} \tag{4}$$

The movement toward an optimal point in single-objective PSO (SOPSO) depends on the objective function value. However, the number of objectives is more than one in the MOPSO. Thus, some technique such as multi-swarm can be used. The vector evaluated PSO (VEPSO) is a MOPSO algorithm which links each objective to a swarm. In this algorithm, each particle uses its best potion as the *Pbest* and the best particle of the other swarms as the *Gbest*.

In this paper, the proposed algorithm (Parsopoulos and Vrahatis, 2002) with an external archive is used. All particles are transferred to the archive in each iteration. Nondominated solutions are stored and the others are removed. Thus, the final members of the archive are reported as the Pareto-front. Moreover, in this paper, a technique called warm up is applied to improve the quality of the Pareto-front. This technique allocates a swarm to each objective which leads each swarm to move toward optimal/near-optimal solutions. Then, the resulting solutions are used as the initial swarm in the search process of the MOPSO algorithm.

According to the previous steps, the MOPSO algorithm is based on the stochastic method in the search process. Thus, different Pareto-fronts can be found in the several runs. To compare Pareto-fronts and select the best one, generational distance (*GD*) has been considered as the comparison criterion. *GD* is a metric value proposed by Veldhuizen (1999) in which the average distance between the found nondominated solutions and the optimal Pareto-front, is:

$$GD = \frac{1}{NS}\sqrt{\sum_{i=1}^{NS} d_i^2} \tag{5}$$

where GD = generational distance; NS = number of solutions found; and d_i = the Euclidean distance (in the objective space) between each nondominated solution and the nearest member of the optimal Pareto-front.
In this paper, there is no predefined optimal Pareto-front. Thus, the intersection of the best value of all objective functions is used as the comparative point/optimal Pareto-front.

3. Weighting method

The weighting method is a multi-objective optimization method in which a vector of weights is allocated to the objectives and a multi-objective problem is transferred to a single-objective one.

$$Max./Min.\ \ Z(x) = \sum_{j=1}^{n} w_j . Z_j(x) \tag{6}$$

$$\sum_{j=1}^{n} w_j = 1 \tag{7}$$

where n = number of objectives; w_j = allocated weight to the jth objective; $Z_j(x)$ = jth objective function; and $Z(x)$ = objective function.

To find different points of the Pareto-front, different combinations of weights are used in Eqs. 6-7.

4. Reservoir System Simulation

Application of the MOPSO algorithm is tested in a single-reservoir system with three objectives. Eqs. 8-10 illustrate the maximization of reliability, and the minimization the vulnerability and resiliency of the system with respect to supply and demand as follows:

$$Max.\ \ Z_1 = \frac{\sum_{t=1}^{T} Min.(R_t, D_t)}{\sum_{t=1}^{T} D_t} \tag{8}$$

$$Min.\ \ Z_2 = \frac{N.D}{N.C.D} \tag{9}$$

$$Min.\ \ Z_3 = Max.\left(\frac{D_t - R_t}{D_t}\right) \quad for \quad t = 1,2,\ldots,T \tag{10}$$

where Z_1 = reliability of system; T = number of operational periods; R_t = release at period t; D_t = downstream demand at period t; Z_2 = vulnerability of system; $N.D$ = number of periods in which there is deficit (the value of release is less than

demand); $N.C.D$ = number of periods with continuing deficit; and Z_3 = resiliency of the system.

In the operational model, reliability and resiliency of the system are presented as the quality values, and vulnerability of the system is identified as the quantity value.

The model formulation is constrained by the following relations:

$$S_{t+1} = S_t + Q_t + R_t - Loss_t \tag{11}$$

$$Loss_t = f_1\left(Ev_t, \overline{A_t}\right) \tag{12}$$

$$\overline{A_t} = \left(A_t + A_{t+1}\right)/2 \tag{13}$$

$$A_t = f_2\left(S_t\right) \tag{14}$$

$$S_{Min} \le S_t \le S_{Max} \tag{15}$$

$$S_1 = S_{T+1} \tag{16}$$

in which S_t and S_{t+1} = storage volume at the start of periods t and $t+1$ respectively; Q_t = inflow to the reservoir at period t; $Loss_t$ = volume of losses water from reservoir at period t; Ev_t = evaporation depth of reservoir at period t; $\overline{A_t}$ = average surface of reservoir at period t; A_t and A_{t+1} = water surface of reservoir at the start of periods t and $t+1$, respectively; S_{Min} = minimum storage of reservoir; and S_{Max} = maximum storage of reservoir.

To use the weighing method as the optimization tool in this problem, the objective function is calculated by Eqs. 17-18:

$$Min.\ \ Z(x) = -w_1.Z_1(x) + w_2.Z_2(x) + w_3.Z_3(x) \tag{17}$$

$$\sum_{j=1}^{3} w_j = 1 \tag{18}$$

In this problem, the first objective is maximization of the reliability of the system. To apply all objectives in the minimization form, $Z_1(x)$ is used with the opposite sign.

5. Algorithm Application

To apply the MOPSO algorithm and weighting method, a single-reservoir system is considered. This reservoir is located in the southwest of Iran with a volume of $308.15\times10^6\,m^3$. Monthly releases and initial storage of reservoir have been considered as the decision variables. Thus, the number of decision variables for a five-year operational period is 61.

The weighting method is an optimization tool which solves the introduced model by using nonlinear programming (NLP) and Lingo8 software. To find different points of Pareto-front, 25 weighting vectors have been used and the objective functions are calculated. The Lingo8 software takes lots of time to find a global optimal solution for the proposed problem. To have the same base in different

runs (problem) using each weighting vector, each run is interrupted in the fifth minute of run by using Lingo8. Thus, the time for finding the Pareto-front is 125 (5×25) minutes. Finally, 25 points have been found and just 5 of those points were in nondominated state. The other points which are removed have the worst situation in all objectives (Z_1, Z_2, and $Z3$). The best value for each objective has been calculated by Lingo8 and the comparative point is (0.761, 1.944, 0.500).

To find the best Pareto-front by using the MOPSO algorithm, *GD* criteria is calculated for five different runs. The time of finding the Pareto-front is 125 minutes which is equal to solving model by the weighting method. Table. 1 shows the *GD* criteria and its statistical measures. According to results, the Pareto-front of the fifth run is the best one with the minimum value of *GD*.

Table 1. *GD* criteria and its statistical measures for five runs

Run number					Statistical Parameter				
1	2	3	4	5	Minimum	Average	Maximum	Standard Deviation	Coefficient of Variation
14.481	18.215	13.682	13.423	11.215	11.215	14.203	18.215	2.549	0.179

Fig. 1. shows the best Pareto-front in three and two dimensions.

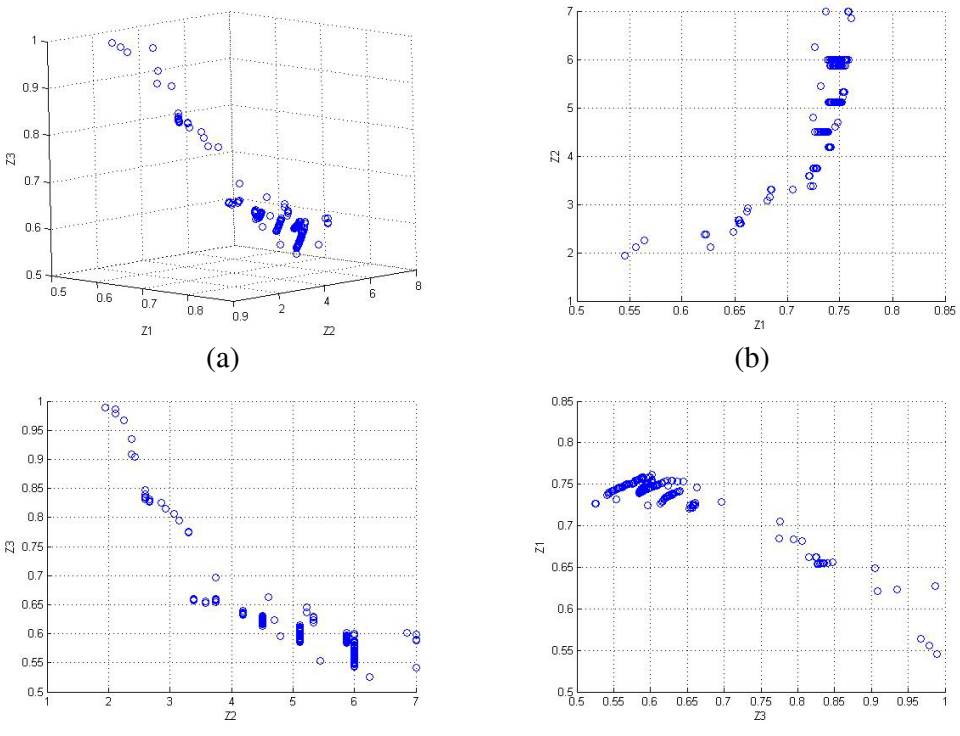

Figure 1. The best Pareto-front: (a) in three dimensions; (b) in two dimensions for the first and second objectives; (c) in two dimensions for the second and third objectives; and (d) in two dimensions for the first and third objectives

According to Fig.1(b), the first objective (Z_1) changes from 0.546 to 0.761. Fig.1(c) shows the best values of the second (Z_2) and third (Z_3) objective are 1.944 and 0.500, and the worst ones are 7.000 and 0.989, respectively. To demonstrate the best objective functions of the best Pareto-front, monthly releases for each of them have been considered in Figs. 2-4.

Figs. 2 and 4 show amounts of release for the best value of Z_1 and Z_3 in the best Pareto-front having a smaller difference from demands. In the first objective (Z_1), the larger value of release in each period, the better value of Z_1. In the third objective (Z_3), to reduce the maximum value of $\left(\left(R_t - D_t\right)/D_t\right)$ in the operational period, the values of release increase in all periods. However, Fig. 3 shows that releases for the best value of the second objective (Z_2) have a lot of fluctuation. In this state, to decrease the number of periods with continuing deficit, the amounts of release have been presented without considering any difference from demands. It means that if there is not enough water to supply demand at a period, the water should be stored in the reservoir and the demand is supplied at the next period.

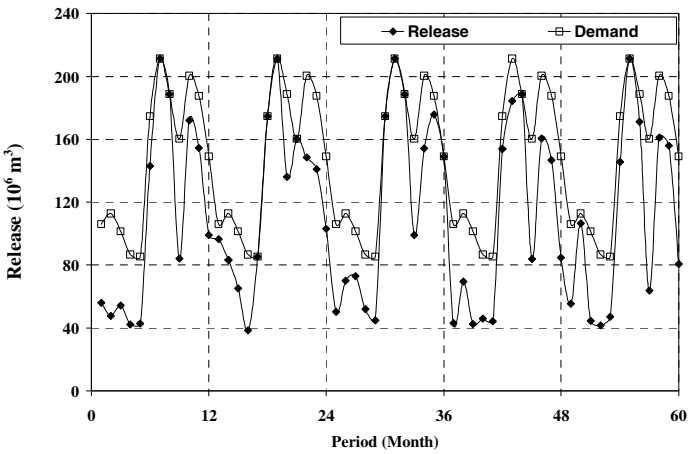

Figure 2. Monthly releases for the best value of Z_1 in the best Pareto-front

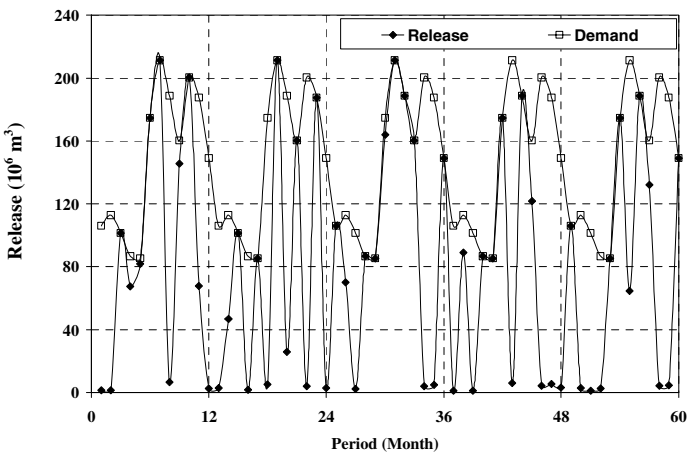

Figure 3. Monthly releases for the best value of Z_2 in the best Pareto-front

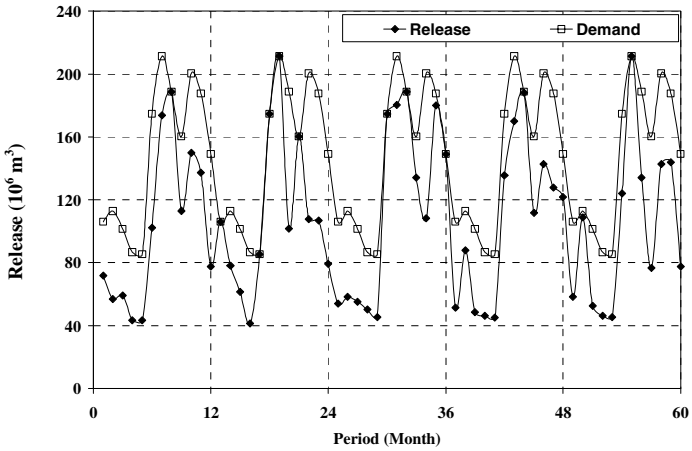

Figure 4. Monthly releases for the best value of Z_3 in the best Pareto-front

To demonstrate the capability of different algorithms, the best values of each objective are presented in Table 2.

Table 2. The best objective functions for different algorithms

Algorithm	Objective Function		
	Z_1	Z_2	Z_3
NLP	0.761	1.944	0.500
Weighting Method	0.728	2.111	0.500
MOPSO	0.754	1.944	0.500

According to results, in the first objective (Z_1), the MOPSO and weighting method are respectively 0.920% and 4.366%, less than the found solution by NLP algorithm. In the second objective (Z_2), the MOPSO algorithm has produced the best value (1.944) but the weighting method has 8.591% difference. In the third objective (Z_3), results of the all algorithms are the same. On the other hand, the MOPSO algorithm in a same time of run (125 minutes) has produced 215 nondominated solutions, whereas the weighting method has produced five nondominated solutions.

Thus, the capability of the MOPSO algorithm to find optimal/near-optimal Pareto-front is more than in the weighting method.

6. Concluding Remarks

In this paper, application of multi-objective particle swarm optimization (MOPSO) algorithm was presented. To show the capability of the MOPSO algorithm, a single-reservoir operation with three objectives (maximization of reliability; minimization vulnerability; and minimization of resiliency of system) was used. Results of the MOPSO algorithm can be presented as a set of nondominated solutions/Pareto-front. The weighting method is another multi-objective optimization tool which is searching for an optimal point by transferring a multi-objective problem to a single-objective one. To compare the results of the weighting method

and MOPSO algorithm, *GD* criteria was used. Results show that the MOPSO can find optimal solutions with a suitable distribution in much less time.

Multi-criteria Decision Making under Uncertainty in Rainfall-Runoff Calibration: A Fuzzy Compromise Programming Approach Based on Alpha Level sets

M. Shafii[1] and F. De Smedt[1]

[1]Department of Hydrology and Hydraulic Engineering, Vrije Universiteit Brussel, Pleinlaan 2, 1050, Elsene, Brussels, Belgium, FAX: (32) 2-629-3022, emails: mshafiih@ub.ac.be, fdesmedt@vub.ac.be

Abstract

This paper involves a methodology developed for multi-criteria decision making and to reduce the number of Pareto optimal solutions. The technique is a Fuzzy Compromise Programming (FCP) coupled to a Genetic Algorithm (GA) applied for a case study on multi-objective rainfall-runoff calibration. The uncertainty associated with probable preferences of decision-makers has also been dealt with by the fuzzy extension principle and alpha-cut levels (i.e. considering the importance of the criteria by triangular fuzzy weights). The problem, therefore, becomes to solve a set of non-linear programming problems using GA, which results in ranking the alternatives based on a distance metrics. The obtained results show that the proposed hybrid FCP-GA approach performs well as a means to sieve among the Pareto optimal parameter sets of the problem. It would also help to choose the most preferable solutions, especially in cases where one is obliged to give a limited number of best solutions.

INTRODUCTION

Calibration of rainfall-runoff (RR) models is a process in which parameter adjustment are made so as to match (as closely as possible) the dynamic behaviour of the RR model to the observed behaviour of the catchment. Because of the multi-objective nature of RR calibration processes, and due to advances in computational power as well as population-based optimization techniques, automatic calibration routines for hydrologic models with multiple objective capabilities are becoming increasingly popular. These approaches have shown to lead to better characterization of complex behaviour of the catchments. Gupta et al. (1998) discussed for the first time the advantages of multiple-objective model calibration and showed that such schemes are applicable and desirable. Subsequently, more research has been focused on multi-objective approaches for calibration of RR models (Yapo et al., 1998; Boyle et al., 2000; Madsen, 2000). There are also an increasing number of recent studies focusing on developing multi-objective calibration strategies for distributed hydrologic models (Madsen, 2003; Ajami et al., 2004; Shafii and De Smedt, 2009).

It should be, though, noted that as more objective functions are included in the calibration, the number of optimal solutions (Pareto-optimal parameter sets, Pareto (1986)) increases and the calibration issue quickly becomes a decision-making problem. In a practical sense, attention is focused towards choosing a suitable

parameter set among the Pareto-optimal solutions. One of the approaches to handle this problem, as proposed by Khu and Madsen (2005), can be the development of a calibration procedure that will result in a small number of preferred solutions. Khu and Madsen (2005) combined an optimization routine, based on multi-objective genetic algorithms (MOEAs), and Pareto preference ordering. In their case, the Pareto-optimal solutions which are also Pareto-optimal in different subspace combinations of the objective functions are preferred.

Another approach that can be applied in this context is Multi-Criteria Decision Making (MCDM). Multi-criteria techniques help in evaluation and ranking of alternatives based on the objective function values associated with each of the alternatives and preference of the various decision-makers. Compromise programming (CP), proposed for the first time by Zeleny (1973), is a MCDM technique which resolves multiple criteria into a commensurable, unitless, distance metric measured from an ideal point (for each alternative). The result is a direct ranking of alternatives, valid for the selected weights and the chosen form of distance measurement, whereby the closest solutions to the ideal point determined by some measure of distance are identified as the most preferable solutions.

Due to different uncertainties associated with MCDM, CP methods need to be combined with an uncertainty assessment routine. Bender and Simonovic (2000) introduced the Fuzzy Compromise Programming (FCP) approach and used it in water resources systems planning. Their proposed method involves the transformation of a distance metric into a fuzzy set by changing all inputs from crisp to fuzzy and applying the fuzzy extension principle. Although some further applications of this technique are reported in decision making for water resources management (Tkach and Simonovic, 1997; Simonovic and Nirupama, 2005), one can hardly find any CP application for RR calibration problem.

Hence, this paper involves two major issues: (i) application of FCP technique to multi-objective rainfall-runoff calibration, i.e. finding the most preferable solution among the Pareto optimal solutions of the problem, and (ii) coupling this method to alpha-cut-level-based extension principle (EP) and evolutionary optimization algorithm to handle the issue of uncertainty. Multi-objective calibration of a distributed hydrological model (WetSpa) on a catchment located in Slovakia forms the case study of this paper. The method is used to sieve through the Pareto-optimal solutions (alternatives) of the problem obtained by a multi-objective genetic algorithm (NSGA-II, Deb, et al., 2002) and select a smaller number of preferred solutions. In this way, alternatives which tend to be closest to the ideal point, as determined by some measure of distance, are called compromise solutions and are preferred. The distance metric is transformed to a fuzzy set by FCP technique through changing all inputs from crisp to fuzzy based on alpha level sets and the fuzzy extension principle. This approach turns out to be a nonlinear programming (NLP) problem which can be solved applying an evolutionary algorithm, in this case Genetic Algorithm (GA). FCP ranks alternatives based on the membership functions of their metrics to select the most suitable parameter set.

This paper is organized as follows. Basic concepts and terminology of multi-criteria decision making analysis are briefly presented in Section 2, followed by the

proposed methodology of this study in Section 3 as a combination of an FCP approach and a GA optimization routine. Section 4 provides the case study addressed in this paper, and the implementation of the FCP technique to solve the problem is discussed in Section 5. Results and discussions are provided in Section 6, and conclusions are presented in Section 7.

MULTI-CRITERIA DECISION MAKING (MCDM) ANALYSIS

MCDM analysis is a discipline aimed at supporting decision makers who are faced with making conflicting evaluations. MCDM aims at highlighting these conflicts and deriving a way to come to a compromise in a transparent process. The general formulation of a multi-criteria decision problem is based on: (a) a set of potential alternatives, (b) a set of objectives or criteria, (c) a number of decision-makers, (d) a preference structure or weights, and (e) a set of performance evaluations of alternatives for each objective. In a mathematical form a multi-objective decision problem can be presented as:

$$\min\left\{ f_1(x), f_2(x),..., f_n(x) \right\} \quad (1)$$

Where $f_i(x), i = 1,2,...,n$ are n different objective functions and x is a set of decision variables such that $x \in X$ while X is a feasible region defined as:

$$X = \left\{ x : x \in R^n, g_i(x) \le 0 \right\} \quad (2)$$

Where R^n is a set of real numbers, and $g_i(x)$ is a set of constraints. Every feasible solution to the problem (1) implies particular values for different objective function. The n-dimensional objective function maps the feasible region in decision space into the feasible region in objective space, defined on the n-dimensional vector space.

For a Multi-criteria optimization problem like the one presented by Eq. (1), it is significant to note that multiple criteria are often non-commensurable and cannot be combined into a single criterion. The criteria usually conflict with each other and any improvement in one can be achieved only at the expense of another. Hence, there is no ‘‘optimal” solution for the Multi-criteria optimization as in case of a single criterion problem. For the solution of problem (1) only a set of non-dominated, Pareto optimal, solutions can be obtained. However, decisions represented by the Pareto set are not uniquely determined (different preferences associated with each of the objectives result in a different Pareto optimal solution). The final decision must include a selection among the set of Pareto optimal solutions, generally considering outranking relationships, distance metrics, and/or utility theory (Bender and Simonovic, 2000). For instance, CP as a Multi-criteria technique, revolves criteria into a unitless, distance metric measured from an ideal point (for each alternative), as discussed in following section.

FUZZY COMPROMISE PROGRAMMING BASED ON ALPHA CUTS

As already mentioned, multi-objective optimization problems deal with decision-making through which more appropriate solutions among Pareto optimal solutions

can be selected. The CP method, proposed by Zeleny (1973), is such an approach. The basic idea of the CP method is to define the scalarized objective function by a metric form, which is non-linear in terms of constitutive criteria. Mathematically, this metric is a sort of evaluation index measuring the minimum distance between the Pareto optimum to be sought and the global unattainable optimal point where all criteria take their optimum value simultaneously. The following mathematical formulation is used to compute the distance metric values (L_j) for a set of n criteria and m alternatives (i.e. in our case Pareto solutions):

$$L_j = \left[\sum_{i=1}^{n} w_i^{\,p} \left| \frac{f_i^* - f_{i,j}}{f_i^* - f_{i,w}} \right|^p \right]^{1/p} \tag{3}$$

where L_j is the distance metric for alternative $j = 1,2,...,m$, f_i^* is the optimal value of the i^{th} criterion, $f_{i,j}$ is the value of the i^{th} criteria for alternative j, $f_{i,w}$ is the worst value of the i^{th} criterion, w_i are weights indicating decision-maker preferences with respect to different criterion, and p is the distance metric exponent ($1 \le p \le \infty$). As it is seen, L_j is directly dependent on p, as well as on the criteria weights the sum of which is assumed to equal unity (i.e. $\sum wi=1$). The CP method of Zeleny (1973) does not consider the uncertainties associated with these judgements of preferences. The combination of a CP technique with fuzzy sets, as an example of a hybrid decision making tool, has been shown to be a proper methodology for uncertainty assessment (Bender and Simonovic, 2000).

The Fuzzy Compromise Programming (FCP) technique developed by Bender and Simonovic (2000) transforms a CP distance metric to a fuzzy set by changing all inputs from crisp to fuzzy through the application of the fuzzy extension principle. This approach can address various uncertainties that are associated with the elements of their case study, i.e. flood management. This paper extends the FCP method of Bender and Simonovic (2000) considering the criteria weights as fuzzy numbers, as well as coupling this technique to a GA to solve the non-linear optimization problem contained in determination of distance metric membership function, as follows.

Assuming a fuzzy definition for the criteria weights (w_i) in Eq. (1), and given an exponent p, the resulting fuzzy distance metrics (L_j) possesses a particular membership function for each alternative. The most commonly used fuzzy numbers have triangular shape membership functions defined as,

$$\mu_{\bar{A}}(x) = \begin{cases} (x-a)/(b-a), & a \le x \le b, \\ (d-x)/(d-b), & b \le x \le d, \\ 0, & otherwise, \end{cases} \tag{4}$$

A triangular fuzzy number is usually denoted as (a, b, d). According to Zadeh's extension principle (Zimmermann, 1991), a fuzzy number/set $\bar{A}$ can also be expressed by its intervals, namely

$$\bar{A} = \bigcup_{\alpha} \alpha A_{\alpha}, \quad 0 < \alpha \le 1 \tag{5}$$

Where

$$A_\alpha = \left\{ x \in X \middle| \mu_{\bar{A}}(x) \geq \alpha \right\} = \left\{ \min\ [x \in X \middle| \mu_{\bar{A}}(x) \geq \alpha],\ \max\ [x \in X \middle| \mu_{\bar{A}}(x) \geq \alpha] \right\} \quad (6)$$

A_α is referred to as α-level sets or α-cuts of the fuzzy number/set $\bar{A}$. Transformation of a distance metric into a fuzzy set is possible by applying the fuzzy extension principle and aforementioned α-level-based method. In this way, choosing the shortest distance to the ideal solution is no longer a straightforward ordering of distance metrics, and it is required to compare fuzzy sets corresponding to different solutions. Let $(w_i)_\alpha = \left[(w_i)_\alpha^L, (w_i)_\alpha^U\right]$ be alpha-level sets of the weights (w_i). The resulting fuzzy distance metric has the following form:

$$\bar{L}_j = \left[\sum_{i=1}^{n} \bar{w}_i^p \left| \frac{f_i^* - \bar{f}_{i,j}}{f_i^* - f_{i,w}} \right|^p \right]^{1/p} \quad (7)$$

Subject to $(w_i)_\alpha^L \leq \bar{w}_i \leq (w_i)_\alpha^U$, where $\bar{L}_j$ and $\bar{w}_i$ are the fuzzified distance metric and criteria weights indicating decision-maker preferences, respectively, of which the latter satisfies $0 \leq w_j \leq 1$, and $\sum w_j = 1$, $i = 1,...,n$ criteria and $j = 1,...,m$ alternatives. Obviously, $\bar{L}_j$ is an interval in this situation, whose lower and upper bounds can be captured by the following pair of fractional programming models:

$$(\bar{L}_j)_\alpha^L = \min \left[\sum_{i=1}^{n} \bar{w}_i^p \left| \frac{f_i^* - \bar{f}_{i,j}}{f_i^* - f_{i,w}} \right|^p \right]^{1/p} \quad (8)$$

$$(\bar{L}_j)_\alpha^L = \max \left[\sum_{i=1}^{n} \bar{w}_i^p \left| \frac{f_i^* - \bar{f}_{i,j}}{f_i^* - f_{i,w}} \right|^p \right]^{1/p} \quad (9)$$

Both subject to $(w_i)_\alpha^L \leq \bar{w}_i \leq (w_i)_\alpha^U$, and $\sum \bar{w}_i = 1$. This is actually a pair of non-linear programming problems that can be solved using appropriate optimization procedures. In this study, a GA optimization procedure is used to search for the optimal values of this distance metric. Given a particular p, different alpha sets $(\bar{L}_i)_\alpha = \left[(L_i)_\alpha^L, (L_i)_\alpha^U\right]$ can be generated by setting different alpha-levels and solving above mentioned optimization problems.

For n alternatives, we have n fuzzy relative closeness values, which are all expressed by their alpha-level sets and are usually no longer triangular. In order to select a best alternative or rank m alternatives, these fuzzy relative closeness values need to be defuzzified. The averaging level cuts (ALC) suggested by Dubois and Parade (1978) is perhaps the simplest defuzzification method based on alpha-level sets and is therefore used in this study. The defuzzified values of $\bar{L}_j$ can be determined by,

$$(L_j)^*_{ALC} = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{(L_j)^L_{\alpha_i} + (L_j)^U_{\alpha_i}}{2}\right) \quad (10)$$

In order to apply this methodology, it is first required to determine the different items of the multi-criteria decision making problem. Initial data requirements include: (a) a set of alternatives, (b) a set of relevant criteria/objective values, (c) the best and the worst criteria values to compute the distance metrics, and (d) fuzzy membership functions for the weights.

CASE STUDY

The case study addressed in this paper is the calibration problem studied by Shafiei and De Smedt (2009) that used a Non-Dominated Sorting Genetic Algorithm (NSGA-II) to calibrate a distributed hydrological model (WetSpa) within a multi-objective formulation for simulation of river discharge in the Hornad catchment, located in Slovakia. Detailed information about the model, the optimization routine, the study area, and the obtained results are provided in Bahremand et al. (2007) and Shafiei and De Smedt (2009). A brief description of the different elements of the problem is provided as follows.

WetSpa is a grid-based distributed hydrologic model to predict peak discharges and hydrographs in a river basin. The WetSpa model potentially involves a large number of model parameters most of which can be assessed from field data. However, some model parameters are of a more conceptual nature and cannot be directly assessed. Hence, these have to be determined through a calibration process. NSGA-II (Deb et al., 2002) is an evolutionary-based population-based multi-objective optimization algorithm used by Shafiei and De Smedt (2009) to calibrate WetSpa. The considered criteria are the model bias (CR_1), the model efficiency to reproduce stream flows, known to be biased for peak flows (CR_2), and a logarithmic transformed model efficiency, giving more emphasize to low-flow values (CR_3). Table 1 provides the mathematical representation of these criteria and the corresponding best and the worst feasible quantities, where Qo_i is the observed discharge at time i, Qs_i the simulated discharge, the bar stands for average, and N is the total number of time steps in the calibration period.

IMPLEMENTATION OF FCP APPROACH BASED ON ALPHA-CUTS

The Pareto optimal front obtained for aforementioned problem includes 27 different parameter sets which are all considered as the calibration outcome alternatives. Table 2 gives the corresponding objective function values. Nonetheless, as already mentioned, it is better to apply a post-processing analysis to reduce the number of the most appropriate solutions. The proposed FCP approach of this paper deals with this issue based on distance metric.

Consideration of the criteria weights as fuzzy numbers takes the uncertainty associated with the preferences of stake-holders into account through the extension principle and alpha-cut levels. The fuzzy weights have a triangular shape (0,1/3,1); notice that the peak is set to 1/3 due to the number of objective functions (i.e. 3). In

order to obtain accurate fuzzy distance metric for each alternative, 11 alpha levels are set for computation, i.e. from 0 to 1with steps of 0.1. For each alpha-cut, the optimization problems determined by (8) and (9) are solved to obtain the extreme values for the distance metric and to build the corresponding membership function. These problems are all solved using GA optimization. As a huge body of literature can be found regarding GA and its concepts, it is not discussed again in this paper.

Table 1. Model evaluation criteria and their range.

Code	Criterion	Description	Best value	Worst value
CR_1	$\left\| 1-\sum_{i=1}^{N} Qs_i \Big/ \sum_{i=1}^{N} Qo_i \right\|$	Model bias for evaluating the ability of reproducing the observed streamflow volume	0	1
CR_2	$1-\frac{\sum_{i=1}^{N}(Qs_i - Qo_i)^2}{\sum_{i=1}^{N}(Qo_i - \overline{Qo})^2}$	Model efficiency for evaluating the ability of the model to reproduce all streamflows	1	0
CR_3	$1-\frac{\sum_{i=1}^{N}[\ln(Qs_i)-\ln(Qo_i)]^2}{\sum_{i=1}^{N}[\ln(Qo_i)-\overline{\ln(Q_0)}]^2}$	Model efficiency for evaluating the ability of the model to reproduce low flows	1	0

RESULTS AND DISCUSSION

The results obtained through application of our FCP approach to above mentioned problem include the quantification of the fuzzy distance metrics and corresponding

ranking of the Pareto optimal solutions. Given different values between 2 and 5 for *p* in Eq. (8), extreme values of the distance metric along different alpha-cut levels were calculated. The defuzzified values computed by Eq. (10) and the corresponding ranking of alternatives were subsequently determined as shown in Table 3. Moreover, the corresponding membership functions of the different alternatives in case of *p=2* are illustrated in Figure. 1.

As it is observed for *p=2*, the solution No. 9 is shown to be superior to all other parameter sets. Likewise, solution No. 8 is more desirable when *p* is 3, 4, and 5. Hence, these solutions can be considered as the best compromise and, hence, the most preferable parameter sets. Obviously, as the results of our proposed hybrid FCP-GA methodology are obtained through consideration of different criteria importance weights, all preferences of future stake-holders would be probably covered. In other words, if we would be obliged to give only a limited number of optimal parameter sets, solutions No. 8 and No. 9 would be the most preferable choices.

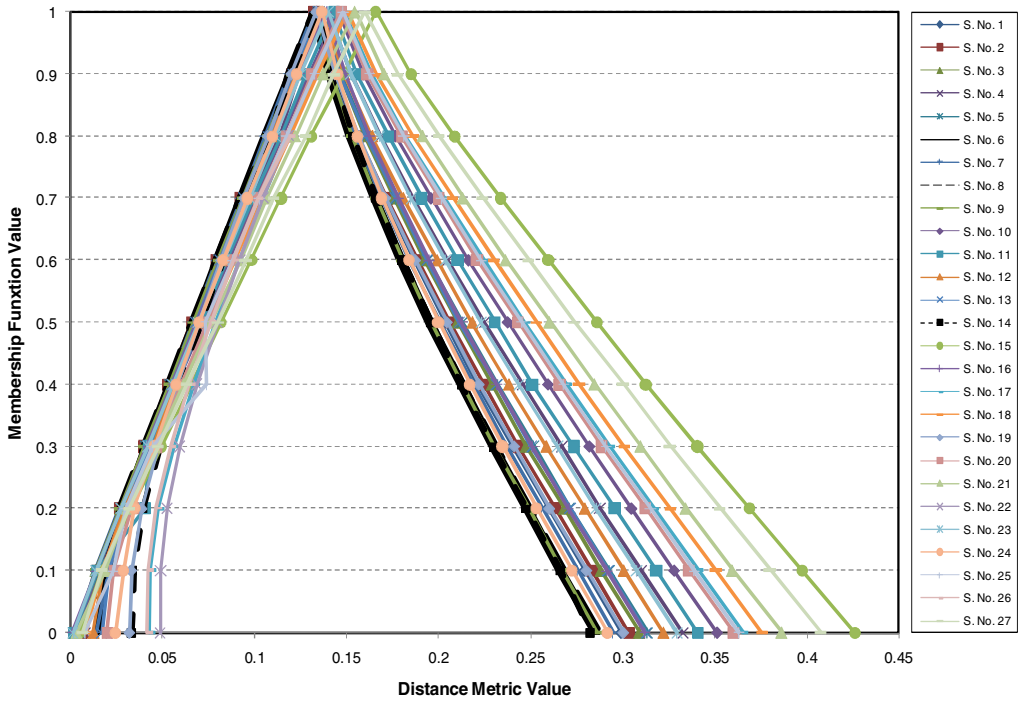

Figure. 1. Distance metric membership functions for different solutions (*p=2*).

CONCLUSIONS

This paper presents an application of an FCP approach coupled to a GA optimization routine to Multi-criteria decision making in a multi-objective rainfall-runoff calibration problem. The goal is to find the most preferable solutions among the Pareto optimal solutions of the problem. The uncertainty associated with probable preferences of decision-makers has been taken into account through the fuzzy extension principle and alpha-cut levels. The technique deals with selecting the most preferred solutions that are closest to the ideal point, as determined by some measure

of distance. Considering the importance of the criteria by triangular fuzzy weights, the distance metric is also a fuzzy number which can be evaluated along different alpha-cuts. The extreme values of distance metric membership function for each alpha-cut are determined by GA solving a pair of NLP problems. Finally, the alternatives can be ranked based on a simple defuzzification of the distance measure.

The obtained results show that the proposed methodology performs well as a means to sieve among the Pareto optimal solutions of the multi-objective optimization problem and to choose the most preferable solutions. In case one is obliged to give a limited number of "best" solutions, application of our hybrid FCP-GA approach would be promising.

ABSTRACT

The present paper discusses the applicability of Multiobjective Differential Evolution (MODE) and single objective Differential Evolution (DE) to a case study of Mahi Bajaj Sagar Project, Rajasthan, India. Three objectives, namely, net benefits, agricultural production and labour employment are analyzed in the multiobjective framework using MODE. Four variations (strategies) of Differential Evolution, namely, DE/rand/1/bin, DE/rand/1/exp, DE/best/1/bin and DE/best/1/exp are explored. Population size, crossover and mutation probabilities and number of generations are the parameters that are required as input to MODE. In order to have a better insight on the performance of the strategies, DE in single objective framework is also employed with the same four strategies for all the three objectives with the above settings. In addition, a comparative analysis is also made for all the four strategies in both single and multiobjective framework.

INTRODUCTION

Water resources for irrigation in many countries are facing acute shortage due to increasing demand from irrigation, municipal, industrial etc. This makes irrigation planning, that involves cropping pattern, storage, release and water allocation policies, rather more complex. In addition, the problem becomes more complex when multiobjective planning is necessitated for the given situation. However, most of the traditional multiobjective optimization methods such as weightage and constraint method require huge computational requirements that lead to complexity while analyzing the solution (Deb, 2001). This is mainly due to the limitation of the methods to generate one solution at a time. This requires efficient solution methodologies that can handle irrigation planning in multiobjective framework in a systematic and sustainable way (Janga Reddy and Nagesh Kumar, 2007).

In the present study evolutionary algorithm, namely Differential Evolution both in single objective and multiobjective framework is employed for a case study of Mahi Bajaj Sagar Project (MBSP), Rajasthan, India. Important parameters that affect the planning problem are population size, number of generations, crossover and mutation probabilities and chosen DE strategy. Present paper is divided into

literature review, brief description about MODE algorithm, case study and mathematical modeling, results and discussion followed by conclusions.

LITERATURE REVIEW

Differential Evolution (DE) algorithm was introduced by Storn and Price in 1995 (Price and Storn 1997; Price and Storn, 2009). DE has advantages in terms of its simple structure, efficiency, robustness and use of floating point encoding instead of binary numbers. DE draws its inspiration from evolutionary algorithm in a way that it has random initial population, which is then improved using selection, mutation, and crossover operations. A predefined upper limit for the number of generations or computed function evaluations provides an appropriate stopping criterion.

Lampinen and Storn (2004) explained Differential Evolution with three numerical examples. They performed sensitivity analysis on various parameters such as population size, crossover constant and weighting factor. It is concluded that the method is easy to implement and use, effective, efficient and robust. Ali and Törn (2004) proposed new versions of the Differential Evolution algorithm to improve its efficiency and robustness. They introduced an auxiliary population of *NP* individuals alongside the original population and proposed a rule for calculating the control parameter *F*, automatically. Liu and Lampinen (2005) proposed a version of DE, where the mutation control parameter and the crossover control parameter are adaptive.

Ranjithan (2005) stressed on the role of evolutionary computation in environmental, water resources systems analysis and discussed the various methods in brief, namely, Simulated Annealing, Tabu Search, Genetic Algorithm, Evolutionary Strategies, Particle Swarm technique and Ant Colony Optimization. He concluded that new areas that shape the direction of a beneficial integration of evolutionary computation into environmental and water resources systems are essential. Vasan and Raju (2007) employed Differential Evolution for single objective, namely, net benefits for the case study of Mahi Bajaj Sagar Project, India in irrigation planning scenario. Janga Reddy and Nagesh Kumar (2007) presented Multiobjective Differential Evolution (MODE) with an application to a case study of Hirakud Reservoir, Orissa with two objectives. The developed algorithm is first tested on a few bench-mark test problems with standard performance measures by comparing them with non dominated Sorting Genetic Algorithm-II.

The following are the inferences from the literature review (1) most studies involve only two objectives and the number of constraints and variables involved are limited (2) Very little work has been reported in the field of irrigation planning in multiobjective evolutionary algorithm framework involving three objectives with extensive sensitivity analysis.

MODE ALGORITHM

MODE methodology can be summarized in the following steps:

1. Input the required DE parameters. Generate the initial population P randomly within the limits of each decision variable.
2. Evaluate the initial population P and perform mutation and crossover to create new children vectors from all the members of the population, i.e., for each parent vector.
3. Evaluate each children vector. Determine the nondominated set by merging the children and parent population according to fast sort algorithm.
4. To maintain the uniformly spread pareto optimal front, select the vectors to next generation based on non domination rank and crowding distance (Deb et al., 2002).

MATLAB code for NSGA-II, developed by Seshadri (2008), has been suitably modified for the working of MODE. Penalty function approach is employed in the present study to handle the constraints. More information on Differential Evolution and Multiobjective Differential Evolution are available in Price and Storn (2009), Janga Reddy and Nagesh Kumar (2007).

CASE STUDY

The Mahi Bajaj Sagar Project (MBSP) is situated near a village Borkhera about 16 km northeast of Banswara town in southern part of Rajasthan state. The project includes a dam, Kagdi pick up weir, a system of canals and two hydroelectric power houses, *PH 1* located near Banswara with installed capacity of 2x25 MW, and *PH 2* near Lilvani village with installed capacity of 2x45 MW. Gross and live storage capacity of the reservoir is 2180.39 Mm^3 (here $Mm^3=10^6$ m^3) and 1829.27 Mm^3 respectively. Culturable Command Area (CCA) of the project is 80,000 ha. Out of this, already 57,531 ha has been opened for irrigation (MBSP Report on Status June 2002 at a Glance, 2002; Vasan and Raju, 2007). The MBSP has three main canal systems namely, Left Main Canal (LMC), Right Main Canal (RMC) and Bhungra Canal (BC). The mathematical modelling of the irrigation planning problem of MBSP command area is explained below. Three conflicting objectives (Raju and Nagesh Kumar, 1999) namely, maximization of net benefits, agricultural production and labour employment are considered.

Mathematical Modeling

Objective 1

The objective of the model is that annual net benefits (*BE*) from planning region under different crops after meeting the costs of seeds, fertilizer, labour, surface water, ground water and plant protection are to be maximized. Mathematically it can be expressed as

$$Max \quad BE = \sum_{il=1}^{12} B_{il}.A_{il} + \sum_{ir=1}^{12} B_{ir}.A_{lr} + \sum_{ib=1}^{12} B_{ib}.A_{lb} - P_{GW} \sum_{t=1}^{12} GW_t$$

where *il* = Crop index for Left Main Canal [1=maize, 2=paddy, 3=cotton, 4=pulses, 5=sugarcane, 6=zaid crop, 7=wheat, 8=barley, 9=gram, 10=barseen, 11=mustard, 12=fruits and vegetables], *ir* = Crop index for Right Main Canal [1=maize, 2=paddy, 3=cotton, 4=pulses, 5=sugarcane, 6=zaid crop, 7=wheat, 8=barley, 9=gram, 10=barseen, 11=mustard, 12=fruits and vegetables], *ib* = Crop

index for Bhungra Canal [1=maize, 2=paddy, 3=cotton, 4=pulses, 5=sugarcane, 6=zaid crop, 7=wheat, 8=barley, 9=gram, 10=barseen, 11=mustard, 12=fruits and vegetables], *t*=Time index (1=January, ... 12=December). *BE* = Net benefits from the whole planning region (Rs.); B_{il}, B_{ir}, B_{ib} =Net benefits from $il^{th}, ir^{th}, ib^{th}$ crop including ground water cost (Rs./ha); A_{il}, A_{ir}, A_{ib} = Area of crop $il^{th}, ir^{th}, ib^{th}$ grown in the command area of LMC, RMC and BC (ha); P_{GW} =Ground water cost (Rs./Mm^3); GW_t =Monthly ground water withdrawal (Mm^3). Here Rs. indicates Indian Rupees.

Objective 2
Agricultural production (PR) of all the crops, for the whole planning area, is to be maximized and can be expressed as

$$PR = \sum_{il=1}^{12} Y_{il}.A_{il} + \sum_{ir=1}^{12} Y_{ir}.A_{lr} + \sum_{ib=1}^{12} Y_{ib}.A_{lb}$$

Where *PR* = Agricultural production (Tons); Y_{il}, Y_{ir}, Y_{ib} = Yield of the crop *il, ir* and ib respectively (Tons / ha).

Objective 3
Labour employment for each crop i, for the whole year for the whole planning area is to be maximized and can expressed as

$$LM = \sum_{il=1}^{12} L_{il}.A_{il} + \sum_{ir=1}^{12} L_{ir}.A_{lr} + \sum_{ib=1}^{12} L_{ib}.A_{lb}$$

where *LM* = Labour requirement for whole planning horizon (Man-Days); L_{il}, L_{ir}, L_{ib} = Labour requirement for crop *il*, *ir* and *ib* respectively in month t (Man-Days) per hectare.

The model is subjected to the constraints such as continuity equation for reservoir storage; crop area restrictions; water releases from the reservoir; storage capacity restriction of reservoir; canal capacity restrictions; monthly releases for hydropower production; crop diversification; monthly ground water pumping restriction (Vasan, 2005).

RESULTS AND DISCUSSION

MODE algorithm is validated using test examples (Deb, 2001) and is then applied to case study of MBSP. Inflow levels of seventy five percent dependability are considered for the planning problem. The model is validated for culturable command area that is opened for irrigation (57, 531 ha) and proposed (80,000 ha) as per phase 1. Accordingly, all the lower and upper bounds were determined for the decision variables. The model includes 67 constraints and 121 variables.

MODE is run for 500 generations with population size of 100, crossover and mutation probability as 0.9 and 0.1 respectively. Figure 1, Figure 2, Figure 3 and Figure 4 presents the result for DE/rand/1/bin, DE/rand/1/exp, DE/best/1/bin and

DE/best/1/exp respectively. It can be observed from Figure 1 and Figure 2 that the pareto optimal curve is fairly continuous while Figure 3 shows that the strategy DE/best/1/bin is converging to a point. Figure 4 shows a discontinuous pareto optimal front and that also with fairly low values of fitness functions. The annual net benefits are varying from Rs.1.134 x 10^9 to Rs.1.1355 x 10^9;agricultural production from 2.62 x 10^6 to 2.645 x 10^6 tonnes and labour employment from 4.96x 10^6 to 4.985 x 10^6 Man-days for strategy DE/rand/1/bin. It is inferred that there is reasonably good variation. The annual net benefits are varying from Rs.9.1 x 10^8 to Rs.9.25 x 10^8;agricultural production from 1 x 10^6 to 1.3 x 10^6 tonnes and labour employment from 3.25x 10^6 to 3.5 x 10^6 Man-days for strategy DE/rand/1/exp. Although the variation is more when compared to DE/rand/1/bin but the fitness function values are very low for all the three objectives. It was inferred that the former strategy is superior to the latter. There is no variation in all the three objective functions in terms of their values for strategy DE/best/1/bin, thus inferring that the strategy is not able to maintain diversity and is not suitable for the problem. Similarly the last strategy DE/best/1/exp is not able to maintain diversity as well as the preferred optimal values when compared to the DE/rand/1/bin. Thus it can be easily inferred that for the chosen case study, strategy DE/rand/1/bin is suitable than the other three.

The annual net benefits, agricultural production and labour employment for all the four strategies namely DE/rand/1/bin, DE/rand/1/exp, DE/best/1/bin and DE/best/1/exp are compared for both MODE and DE scenarios in Table 1. It is observed from Table 1 (MODE result) that values shown for MODE are for 1st member of 1st front having an infinite crowding distance value; however the results of DE are computed after running the algorithm for each individual objective. The table shows that the strategy DE/rand/1/bin has outperformed all the other strategies in terms of all the three objective function values. But in the case of DE strategy DE/best/1/exp is performing the best among the four strategies. However, the values for DE/best/1/bin are very close to that of DE/best/1/exp.

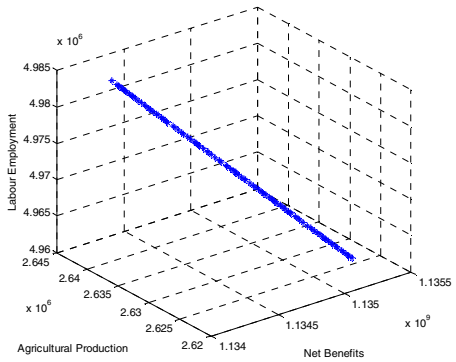

Figure 1. Pareto-optimal front (fitness function) after 500 generations (DE/rand/1/bin) for MODE

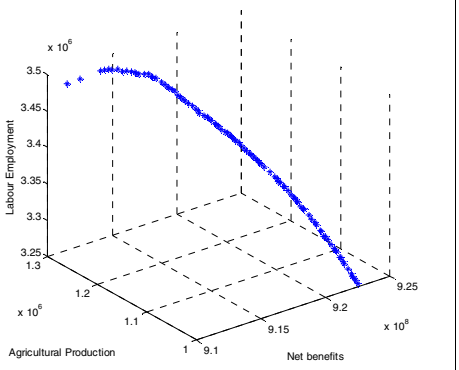

Figure 2. Pareto-optimal front (fitness function) after 500 generations (DE/rand/1/exp) for MODE

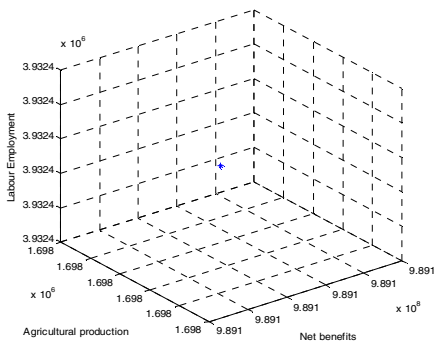

Figure 3. Pareto-optimal front (fitness function) after 500 generations (DE/best/1/bin) for MODE

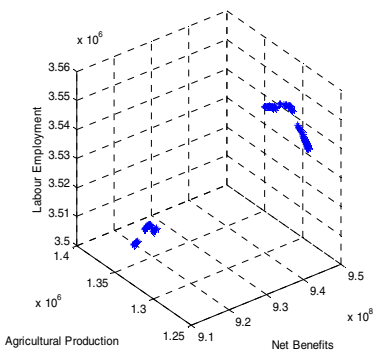

Figure 4. Pareto-optimal front (fitness function) after 500 generations (DE/best/1/exp) for MODE

Table 1: Comparison of objective function values for MODE and DE for all the four strategies

Strategy	Scenario	Objective 1 Net Benefits	Objective 2 Agricultural Production	Objective 3 Labour Employment
DE/rand/1/bin	MODE	$1.172 * 10^9$	$2.789 * 10^6$	$5.109 * 10^6$
	DE	$1.195 * 10^9$	$2.986 * 10^6$	$5.249 * 10^6$
DE/rand/1/exp	MODE	$9.68 * 10^8$	$1.38 * 10^6$	$3.5 * 10^6$
	DE	$1.192 * 10^9$	$3.05 * 10^6$	$5.305\ 10^6$
DE/best/1/bin	MODE	$9.997 * 10^8$	$1.786 * 10^6$	$4.035 * 10^6$
	DE	$1.201 * 10^9$	$3.09 * 10^6$	$5.324 * 10^6$
DE/best/1/exp	MODE	$9.78 * 10^8$	$1.32 * 10^6$	$3.67 * 10^6$
	DE	$1.195 * 10^9$	$3.14 * 10^6$	$5.313 * 10^6$

In single objective environment, out of the three objectives, the maximum value for two namely, net benefits and labour employment, are shown by strategy DE/best/1/bin whilst for the third objective agricultural production maximum value is shown by DE/best/1/exp and also the values for both the strategies are almost same.

While comparing the strategies for MODE and DE for performance analysis, an entirely conflicting situation is observed. In MODE "rand" strategies are performing better while in DE "best" strategies are performed better. There is no clear pattern while comparing strategies on "bin" or "exp" criterion in MODE scenario while in case of DE "exp" strategies are far better than "bin" strategies. However, it is inferred from the analysis made in the present paper that the "best" strategies are performing better in case of DE because in case of single objective optimization maintaining the diversity is not required. On the other hand it is required to find only one optimal solution which is further facilitated by preserving the best member of the generation and then using that particular member for crossover and mutation to develop the new population. This will

eventually help in reaching to the optimum much faster and the search for the member will be concentrated in particular objective space as compared to "rand" strategies where a random member is used for mutation and crossover. But when these "best" strategies are applied to MODE scenario, they do not possess the property of maintaining the diversity and thus finally converge to a point rather than searching for the optimal front in a rather larger objective space; however "rand" strategy keep searching the solution in whole objective space and thus result in a rather continuous pareto front. Also the algorithm developed uses crowding distance and distributing the whole population in number of fronts which support the "rand" strategies more for the same reasons mentioned above. Also in case of DE "rand" strategies values of objective function are constantly improving and are trying to reach further to optimal values thus stating the need to increase the number of generations as compared to almost stable values for "best" strategies. In this regard, more studies are in progress to analyze the strategies with more number of parameter settings and various inflow scenarios.

CONCLUSIONS

Multiobjective Differential Evolution and Differential Evolution is applied for a case study of Mahi Bajaj Sagar Project (MBSP) and following conclusions are drawn based on chosen set of parameters and case study:

1. DE/rand/1/bin generated better pareto-optimal curve as compared to that of DE/rand/1/exp, DE/best/1/bin and DE/best/1/exp when MODE scenario is considered.
2. It is observed that "best" strategies have performed better as compared to "rand" strategies in the case of single objective optimization.
3. It is also observed that "exp" strategies have performed slightly better in the case of DE when compared to "bin" strategies.

It is inferred that MODE with DE/rand/1/bin can be used as an efficient multiobjective optimization solver and also any of the strategies mentioned can be used for single objective optimization given enough number of generations to converge the value.

ABSTRACT

The hydroelectric short term planning is quite challenging in order to respect all the operational restrictions concerned with hydropower generation. A detailed simulation model combining multipurpose constraints and object-oriented software design is presented for short term decision support. The object-oriented design permits a mathematical structure that divides the decisions tasks from the regular hydroelectric computation. The main operational policy allows users to validate a hydro generation schedule towards an inflow forecasting. In other words, the simulator can accept hydro generation as data input and convert it to water flow variables (turbines discharge and spillage), using the inflow forecast and the initial reservoirs storage. The water balance equation, hydro generation and efficiency calculation modules are synchronized with the state-of-the-art of multireservoir operation. As an important result, this simulator can automatically correct the input data of the operational policy, saving substantially time into decision-making process. A test problem on 94-reservoir from Brazilian Integrated Hydropower Generation System was simulated over an hourly one-week horizon with fine performance, evidencing the simulation model capabilities against large scale hydropower operation problem.

SIMULATION MODEL

In reservoir management practices, a simulation model can be used as a valuable planning tool to evaluate the impact of changes to the system's configuration or operational objectives. The desired generation or release scheduling can be checked towards inflow forecasting in order to satisfy the entire set of operational constraints feasibility. At the real time operation stage, a simulation tool can be used to quickly check operational alternatives due to emergency events or planning and real-time incongruence. In post-operation studies, a simulator can be applied as data consolidation tool in exhaustive inspection of recorded trajectories feasibility (Hidalgo et al., 2009).

Inserted in a computer-aided scenario, Yeh (1985) cites simulation as a modeling technique that is used to approximate the behavior of a system on the computer, representing all the characteristic of the system by a mathematical description. Wurbs (1993) provided extensive list of simulation computer models for reservoir system analysis. Using the classification presented by Wurbs, the model here presented can be classified as a conventional simulation model in the sense that no formal optimization or mathematical programming algorithms are

used. However, it will be shown that the data structure for hydro plants joint operation is based on network flow modeling resources and this design can hold a detailed hydroelectric mathematical model.

The simulation of multipurpose reservoir operation is also presented. Fontane (1997) provided a relevant reservoir operations planning model through fuzzy and dynamic programming to deal with imprecise objectives. This model guides the multipurpose implementation of the present simulation model.

This research work aims to present a simulation model that implements such resources and capabilities variety. The mathematical model and software design are detailed presented with emphasis on practical application for further researches become able to reproduce these results. The authors believe that any kind of optimization model for reservoir operation has limitations (Labadie, 2004). Also, it is hard to see comparison studies among different models and their results. In this sense, different operational policies can be checked in a detailed simulation model, with a particular object-oriented design, to address performance analyses and to evaluate distance between model results and real problem aspects.

A test study on 94-reservoir Brazilian hydro plants is presented as demonstration of simulation model capabilities and computational performance. The user interface is outlined to present useful software resources for multireservoir operation analysis. The concluding section discusses design and implementation experience and future development.

Reservoir Model

The reservoir operation has limits and constraints associated to the maximum and minimum water levels, as described in Figure 1. For reservoirs with hydroelectric powerhouses, the minimum level takes into account the minimum head that permits generation. The z^c level represents the dam crest elevation.

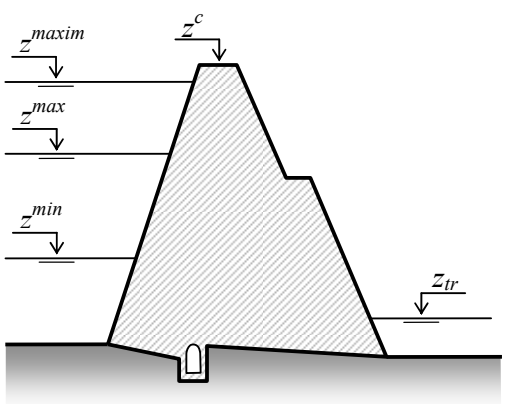

Figure 1. Reservoir operational water levels.

Over the maximum operational level, there is a *maximorum* level related to the dam security purpose. The simulation model presented here has a particular computation module that automatically deals with reservoir constraints under emergency situations, as will be described into the software's design section.

Hydroelectric Model

The simulation model has detailed representation of hydro plants, focused on a complete set of operation constraints and nonlinear equations. In Figure 2 is shown an arrangement of main operational variables. This paper uses the SI units

standard for convenience of Brazilian hydro plants data presentation, although modeling resources are presented for other standards and general application.

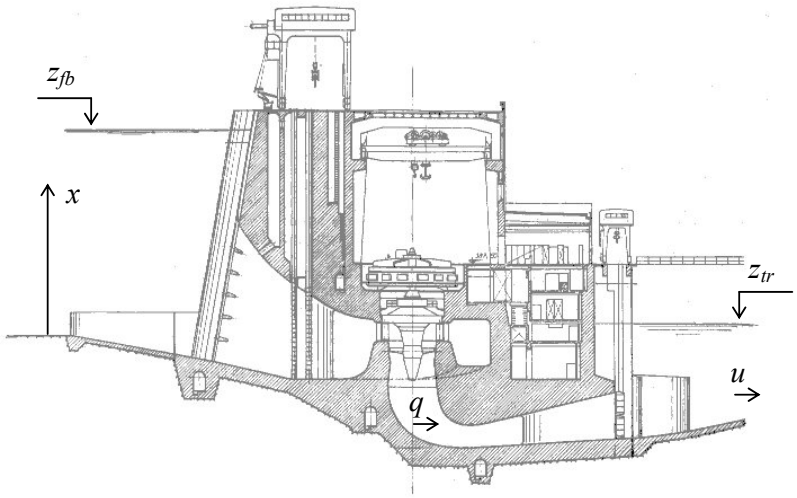

Figure 2. Hydro plant's main variables arrangement.

Hydroelectric power availability is direct related to the potential energy created by a dam, i.e. it depends on the difference between upstream and downstream water levels. Therefore the gross head is directly calculated as:

$$h_g = z_{fb}(x) - z_{tr}(u) \tag{1}$$

where:

h_g is the gross head (m).
x is the water storage in the reservoir of the plant (10^6 m³ or hm³).
u is the total water release (outflow), that is, the sum of the discharge q and the spillage s (m³/s).
$z_{fb}(x)$ is the forebay elevation (m) as a function of the water storage x.
$z_{tr}(u)$ is the tailrace elevation (m) as a function of the water release u.

The forebay and tailrace equations could be expressed as any function of reservoir storage and total outflow, respectively. In the case of Brazilian hydroelectric plants, those functions are commonly represented by polynomials.

There are also losses from the potential energy due to friction of flow through raceways, racks and gateways (Mead, 1908). These losses can be estimated as a quadratic function of turbine discharges, as expressed in Equation (2). Therefore, the penstock head losses are measured in length units.

$$h_{pl} = c.q^2 \tag{2}$$

where:

h_{pl} is the penstock head losses (m).
c is a hydraulic loss parameter (s²/m⁵).
q is the total turbines water discharge (m³/s).

After the head and losses description, the kernel of hydro plant operation is the hydropower production function. This model details the hydro production as shown in Equation (3).

$$p = k.\eta_T.\eta_G.(h_g - h_{pl}).q \quad (3)$$

where:

- p is the instantaneous power obtained in the conversion process of the hydraulic potential energy to electric energy (MW).
- k is the gravity constant, multiplied by the water specific weight and divided by 10^6. This constant manages the power output in MW. Its value is 0.00981 (MW/(m³/s)/m). This constant can also embed unit transformation factors.
- η_T is the efficiency parameter of the turbine in the conversion process of the potential energy to mechanical energy.
- η_G is the efficiency parameter of the generator in the conversion process of the mechanical energy to electrical energy.

The turbine efficiency can be expressed as function of head and hydro power. Some machinery projects have head and discharge as basic input data for efficiency computation. This simulation model accepts any combination from gross or net head and power or discharge. Due to its shape, this function is also known as the efficiency's *hill curve* and an example could be noted in Figure 3a. Also, efficiency contour lines are commonly part of turbines project (Figure 3b).

The turbine and generator mechanic set has operational limits expressed as functions of gross or net water head. The maximum hydro power limit depends on head in two stages (Figure 3b): a) for head smaller than h^{ef} , the power is direct proportional to the head, since it is limited by hydraulic available energy; b) when head is bigger than h^{ef} , the power transferred to the turbine-generator's shaft can damage the equipment, so valves or wicket gates gearing are necessary to keep the output power constant and beneath the electrical damage limit. The h^{ef} head is called *effective head*. A minimum hydro power limit can be imposed and expressed as a function of water head as well (Figure 3b).

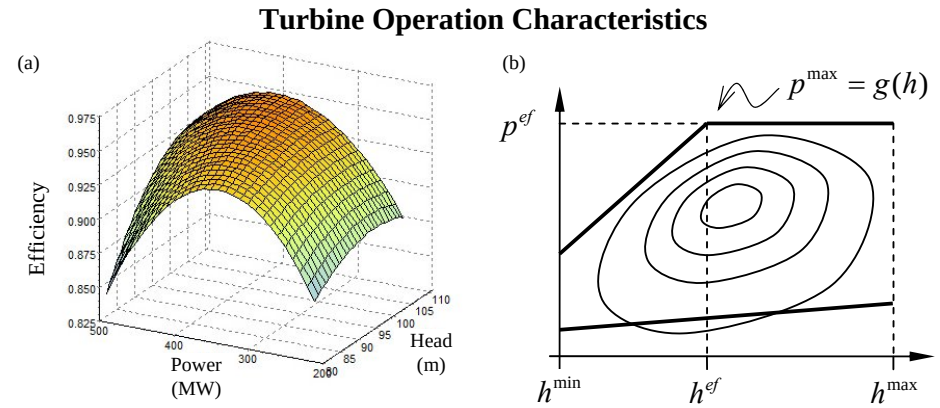

Figure 3. Example of the turbine efficiency function - hill curve - and maximum and minimum power productions functions.

The maximum spill capacity s^{max} can be expressed as a function of reservoir water level z_{fb}. Depending on gates existence, two spillway operations are possible: controlled and uncontrolled. In Figures 4a and 4b are shown examples of these functions, respectively. The term s^{prj} is related to the capacity projected to the spillway. The forebay z^{sc} is the water level on the spillway crest.

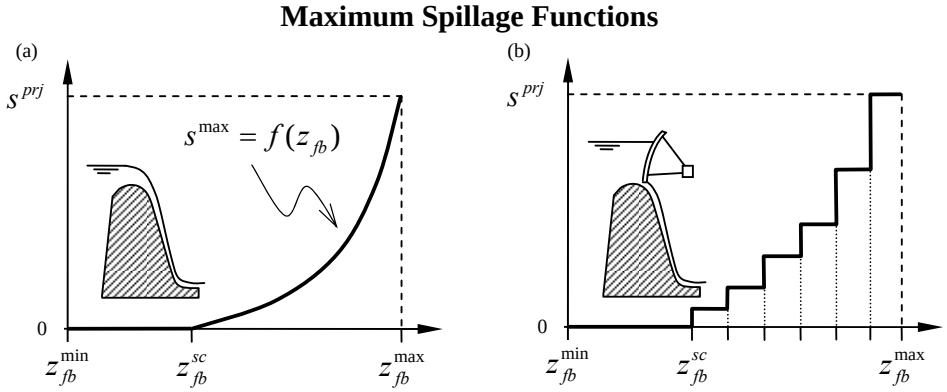

Figure 4. Uncontrolled and controlled maximum spill functions.

As can be seen, the simulation model has a detailed reservoir and hydro power operation representation. In next section, it will be shown the multireservoir model and the adopted implementation structure and design.

Multireservoir Simulation

This section presents a network flow formulation for the multireservoir simulation problem as a temporally expanded arborescence (Rosenthal, 1981). In Figure 5 are shown the hydro elements represented by the simulation model. The model assumes that the exogenous inflows y to the reservoir system are deterministic or provided by inflow forecasting models. Reservoirs could be simple water storage as node number 3 or could have powerhouses working as hydro plants. Special river stream flow control stations can be simulated as well (node 7). Diversions structures, as channels and tunnels, are able to be simulated, as illustrated by the linked-reservoir 3 and 4 example. The practical 94-reservoirs study present later is a bigger replication of the hydro elements example shown in Figure 5. Also, this study simulates two real diversion structures from Brazilian hydroelectric system: the Pereira Barreto's channel that links the Ilha Solteira and Três Irmãos reservoirs located in Paraná River basin and a diversion tunnel linking the reservoirs Jordão and Segredo in Iguaçu River basin. These water diversions are governed by the communicating vessels hydraulic rules.

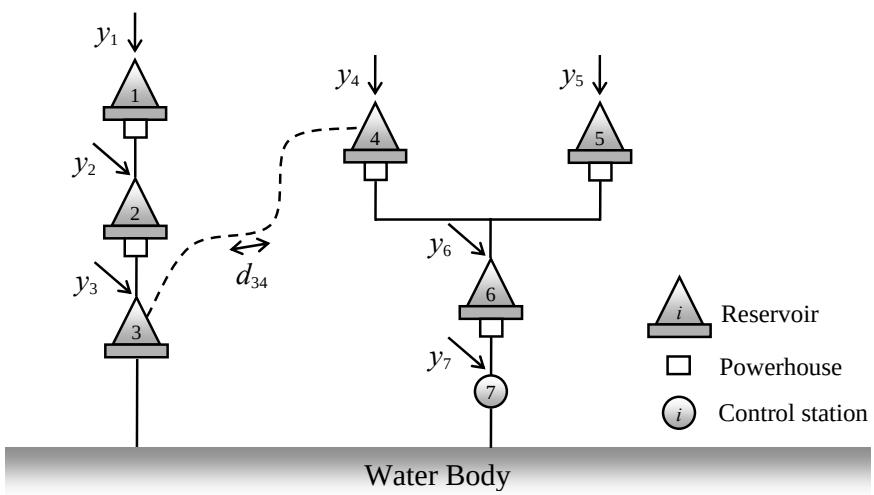

Figure 5. Hydro elements available for multireservoir simulation.

Rosenthal's representation, since a deterministic network flow optimization model, imposes that no reservoir has more than one other reservoir directly downstream from it. This constraint is quite true for all 94-reservoir Brazilian hydropower system. However, the diversion variable was created to overcome this restriction, since a simulation model has more space for structural expansions. The second imposition was related to the routing effect between adjacent reservoirs. This restriction was overcome with adaptations in the expanded arborescence structure, as shown in Figure 6.

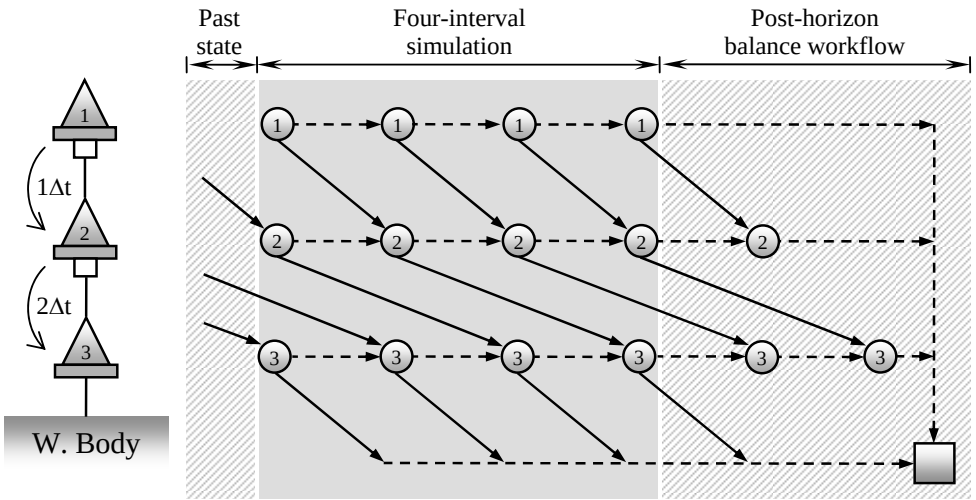

Figure 6. Three-reservoir and four-interval hydro system as a temporally expanded arborescence with routing effect representation.

In the routing effect representation illustrated in Figure 6, solid arrows represent releases and broken-line arrows represent storages transported between time intervals. These storage arcs form the temporally expanded network structure from the arborescence. Note that two additional arc-node sets are necessary to complete the structure: left represents the recent past releases before the first simulation time interval; and right are the post-horizon arcs and nodes, without release arcs, that are necessary to complete and maintain mass balance.

The reservoir mass balance equation (4) is very detailed in terms of multipurpose constraints.

$$x_{i,t} = x_{i,t-1} + \left(y_{i,t} + \sum_{k \in \Omega_i} f(u_{k,t-tr}) - \left(q_{i,t} + s_{i,t} + ev_{i,t} + mu_{i,t} + d_{i,t} \right) \right) . f_{uc} \qquad (4)$$

where:

- i,t are plant and time indexes, respectively. There are N reservoirs and T intervals. The storage variables x are indexed as time instants (initial t-1 and final t). The flow variables are averages during the time interval.
- y is the reservoir inflow (m³/s).
- Ω is the direct upstream reservoirs index set. With the tr time lag, the sum of upstream releases represents the routing effect computation.
- s is the spillage flow (m³/s).
- ev is the reservoir evaporation calculated as a water flow (m³/s). It takes into account the reservoir area at the average volume $(x_t + x_{t-1})/2$, leading to an iterative calculus.

mu represents the reservoir multiple-uses expressed as water flows (m^3/s). As example, irrigation and water supply associated with one reservoir could be simulated with this variable.

d represents the water diversions from reservoir *i*, also expressed as water flow (m^3/s). The diversion can be reach another reservoir, river or an external hydro element not present into the study configuration.

f_{uc} is the unit conversion factor between flow and storage variables.

As a powerful modeling resource, the unit conversion factor f_{uc} embeds into the simulation model the ability of dealing with any kind of time interval. This model can compute studies with monthly, daily, hourly, half hour or even any combination that composes a mixed interval horizon. Considering Brazilian general units hm^3 for storage and m^3/s for streamflows, this factor became:

$$f_{uc} = \frac{\Delta t}{10^6} \tag{5}$$

The multireservoir model ends with the operational constraints related to storage, minimum and maximum releases, maximum discharge as a function of gross head and maximum spill as a function of reservoir storage level.

$$x_{i,t}^{\min} \le x_{i,t} \le x_{i,t}^{\max} \tag{6}$$

$$u_{i,t}^{\min} \le u_{i,t} \le u_{i,t}^{\max} \tag{7}$$

$$p_i^{\min}(h) \le p_{i,t} \le p_i^{\max}(h) \tag{8}$$

$$q_{i,t} \le q_{i,t}^{\max}(h) \tag{9}$$

$$s_{i,t} \le s_i^{\max}(z_{fb}) \tag{10}$$

It is important to note that constraints (6) to (10) have interval indexing for multipurpose constraints representation, as presented in next subsection.

Multipurpose Constraints

Typically, reservoir multipurposes may include a combination of requisites like hydroelectric power generation, water supply for irrigation, domestic and industrial use, water quality improvement, flood control, wildlife and environment maintenance, navigation and recreation (Yeh and Becker, 1982).

The hydroelectric purpose was described in previous subsections. Through multiple-use *mu* and water diversion *d* variables from Equation (4) it is possible to simulate water supply and irrigation purposes. A seasonal minimum water level or storage may be imposed to guarantee water supply impounding, navigation and recreation purposes as well. The releases constraints from Equation (7) permit simulating fish-wildlife maintenance and navigation operational limits. Flood control is generally achieved by maintaining reserve storage in each of the many reservoirs as an anticipation control procedure on high-flow periods. This can be achieved with temporary upper bound storage limits, but smaller than the reservoir maximum, as expressed in Equation (6).

SOFTWARE DESIGN

This section is dedicated on the use of object-oriented modeling as a powerful approach for designing a multireservoir simulator. Slobodan et al. (1997)

present object-oriented design as a successful modeling tool to the Egyptian water resources planning. The natural object-oriented partition between policy commitment and data permits the construction of "what-if" search scenarios in an easier level to the decision-making process. Another interesting object-oriented experience is detailed presented by Belkhouche (1999) and can be used as a guide to object-oriented design of database and software resources to water quality systems. Also, Horstmann (1997) provides a didactical introduction to object-oriented software development.

The present simulation model was implemented using the object-oriented software design. As expected, the software was built using classes to represent all multireservoir simulation aspects. There are classes to represent the hydro plants main components and the network flow elements. Also, there are extra classes to support the software organization, such as horizon description and database connectors and data providers. The whole class diagram is omitted for article's length convenience. However, some important details from the object-oriented design are shown to guide further researches.

Data Structures

The key step for a computational implementation of the simulation model is to interpret the mass balance equation (4) as a network flow node (Rosenthal, 1981). The node flow equilibrium has equivalence with the mass balance using canalized arcs to represent operational constraints, as presented in Figure 7. The *tr* time delay represents the routing effect of upstream releases.

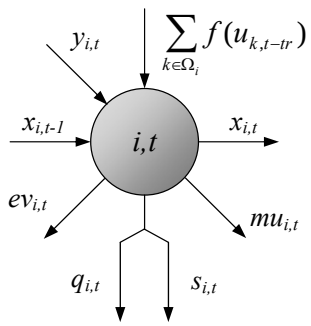

Figure 7. Mass balance equation equivalence with a network node.

The whole network nodes can be simple stored as a bi-dimensional matrix M_{NxT} representing the operation variables from the reservoir *i* during the time interval *t*. Other data structures using node's linked lists can be used as well, but a rectangular matrix provides good performance and reasonable size storage. The arcs are implemented as links between nodes and stored as nodes properties.

Object-Oriented Design

The simulation model uses an object-oriented resource called *polymorphism* to reach a mathematical structure that splits the decisions tasks from the hydroelectric computing tasks in different software components. As a direct result, the simulation model accepts different operational policies, keeping apart the hydro computational kernel composed by the operational restrictions, water balance equation, power generation and efficiency functions. A simulation algorithm flowchart is shown in Figure 8 in order to illustrate the polymorphic composition of the operational policy and the hydro computational kernel. Note

that hydro kernel has a special resource to correct decisions that can lead the reservoir to an infeasible state.

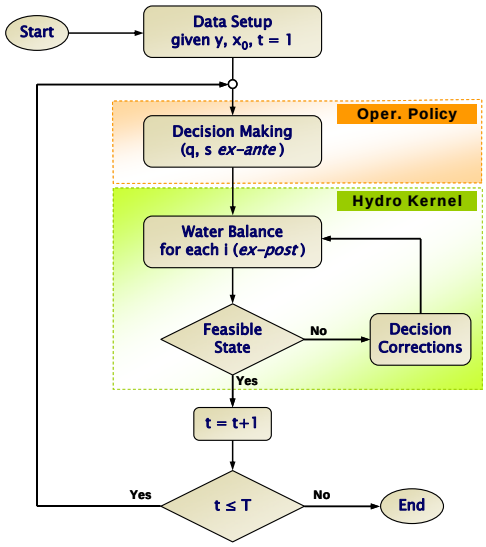

Figure 8. Simulation algorithm with object-oriented polymorphism applied to partition of operational policy and the hydro computational kernel.

The polymorphism concept has many definitions but to this simulation model it will means that *the same operation may behave differently on different classes* (Horstmann, 1997). In other words, the polymorphism will be used to promote a partition between operation policy and hydroelectric and reservoir computations. This object-oriented concept permits that the resultant simulation software to have an expandable and adaptable collection of operation policies.

Operational Policies

The operation policy object is responsible to determine the reservoir total water release. In case of powerhouse existence, the amount of turbines discharge is also necessary. Mathematically, the operational policy can be expressed as a function f_p of the available policy variables from Equation (4):

$$[q_{i,t}, s_{i,t}] = f_p(x_{i,t-1}, x^*_{i,t}, y_{i,t}, \sum_{k \in \Omega_i} f(u_{k,t-tr}), ev^*_{i,t}, mu_{i,t}, d^*_{i,t}) \qquad (11)$$

where the * denotes variables that are not directly available for policy analyses and may be estimated. For example, the final storage at interval t and evaporation can be estimate in function of the release determined by the operational policy. Any external operational policy that has in its results the release and spillage variables can be simulated with this model.

From this polymorphic structure, a particular operational policy was implemented to transform hydro generation dispatch, composed by generation goals and turbines unit commitment, into the discharge and spillage decisions variables. The generation-release transformation is based on iterative and detailed procedure over the hydro production equation (3), where the power is given and the release and spillage are calculated recursively. This policy aims to check generation scheduling towards an inflow forecasting, given the initial reservoir storage states and keeping the hydroelectric kernel intact. As one can see, this polymorphic design can accomplish other types of policies, including the decision results from optimization models (Wurbs, 1993).

CASE STUDY

This section briefly shows a test on 94-reservoir Brazilian hydro plants that demonstrates the simulator capabilities and performance. The generation system has 75.944 MW as installed capacity and a one-week horizon generation scheduling was checked in terms of hydroelectric constraints feasibility.

Simulation Study Main Characteristics		
Reservoirs	94	
Basin/Rivers	8/33	
Drainage area	2,621,243	km²
Installed capacity	75,944	MW
Diversion structures	2	
Control stations	2	
Horizon	7	days
Intervals	168	hours

Figure 9. The 94-reservoir map from Brazilian Integrated Hydropower Generation System and its main characteristics.

The test checks, for each reservoir, an hourly one-week horizon generation scheduling towards a daily inflow forecasting provided by a external hydrologic model. All the variables trajectories (see section about multireservoir model) are available in singular tabs as charts or grid presentation. In Figure 10 are outlined the software and user interface for study's data input and result analyses. The left frame is a study navigator resource that shows studies in a tree view items organization. The data and results access are provided by tabs switch.

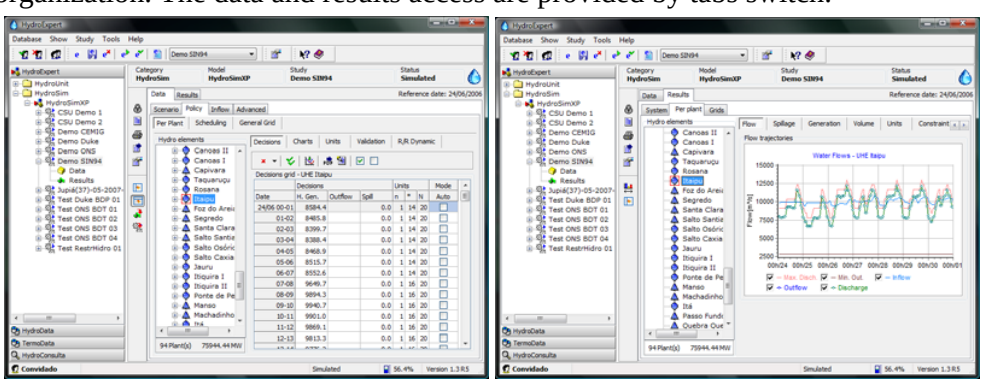

Figure 10. Simulation software and its user interface.

The test was run in computer with a 3.0 GHz Pentium IV processor and 2 GB of RAM. The 94-reservoir and 168-hour horizon study takes 2.4 seconds in average to be simulated. As one can note, this is a relevant computational performance for a simulation model with the operational policy that converts generation goals into release and spillage trajectories with auto constraint feasibility checking.

CONCLUSION

It was presented a multireservoir simulation system with detailed hydroelectric modeling and multipurpose constraints. The software is based on network flow with canalized arcs as data structure to represent multireservoir joint

operation. Two simple but powerful model resources were presented to permit general simulation application: unit conversion factor on hydropower production function and multi and mixed time intervals factor on mass balance equation. Due to the object-oriented design, the operational policies and hydro computational kernel were divided in different software components. With this design it is possible to check different and external operational policies in a detailed simulation model. Also is suitable to address performance analyses and evaluating the distance between computer-aided model results and real problem aspects.

A test study on 94-reservoir Brazilian hydro plants with a one-week horizon generation scheduling was checked toward an inflow forecasting with focus on the operational constraints feasibility. It is distinguished the simulation model performance in terms of reservoir operation accuracy and computational consumed time. The mathematical model and software design were presented with emphasis on practical application for further researches become able to reproduce these results.

ABSTRACT

Studies investigating the chaotic nature of hydrologic processes commonly employ the correlation dimension method. Although this method is generally reliable, it may also have some limitations, influenced by a host of factors. One such factor is the delay time for reconstruction of the phase-space to represent the underlying dynamics. There is also an increasing realization that fixing the delay time window rather than just the delay time itself may be more appropriate. An attempt is made in this study to test the C-C method towards fixing the delay time window and assessing the nonlinear and chaotic dynamic characteristics of hydrologic time series. Three data sets are studied: daily flow from St. Johns River, Florida; biweekly volume from the Great Salk Lake; and daily rainfall from Seoul. The results from this method are also compared with those obtained using the autocorrelation function method.

INTRODUCTION

In recent years, studies investigating the nonlinear deterministic nature of hydrologic processes have gained momentum [see Sivakumar (2000) for a review]. Such studies have employed a host of methods for identification and prediction, including correlation dimension, Lyapunov exponents, false nearest neighbors, and local approximation. Among these, the correlation dimension method has been most widely used, and the presence of a low correlation dimension has generally been treated as an indicator of nonlinear determinism. Regardless of the method, a necessary first step is the reconstruction of the observed data in a multi-dimensional

space for representation of the system dynamics. This multi-dimensional phase-space reconstruction often involves the 'rearrangement' of a single-variable time series that reliably represents the system. Among the many available methods, the method of delays (e.g. Takens, 1981) is the most commonly used one. According to this method, using its history and an appropriate delay time, a single-variable series $\{x_i\}$where $i = 1, 2, ..., N$, can be reconstructed in an m-dimensional phase space, as follows:

$$\vec{x}_i = (x_i, x_{i+1}, \ldots, x_{i+(m-1)t}), \vec{x}_i \in R^m \quad (1)$$

where t is the index lag. If the sampling time is τ_s, then the delay time is $\tau_d = t\tau_s$.

It is clear that the delay time τ_d is a crucial parameter to reliably represent the 'attractor' of the underlying dynamics. However, the effectiveness of implementation of Takens' theorem is not limited by the delay time, because the theorem is based on the assumption that the time series is infinite and noise-free and that any arbitrary delay time would be reliable. This, however, is not the case in real data (which are always finite, often short, and contaminated with noise), for which an appropriate delay time is necessary because only an optimum selection of τ_d gives the best separation of neighboring trajectories within the minimum embedding phase-space.

Many researchers have addressed the delay time selection and proposed different methods, popular among which are: autocorrelation function (ACF), mutual information (MI), and correlation integral (CI). In the ACF method, τ_d is chosen as the lag time (or index lag) at which the ACF first crosses the zero line (Holzfuss and Mayer-Kress, 1986) or attains a certain value (0.1 or 0.5). In the MI method, τ_d is chosen to coincide with the first (local) minimum of the mutual information (Frazer and Swinney, 1986). In the CI method, the first minimum of the logarithm of the generalized correlation integral is considered to provide a proper choice of τ_d (Liebert and Schuster, 1989). Each of these methods has its own advantages and disadvantages and none provides a definitive guideline for choosing the delay time.

A reliable alternative to address the delay time selection is to try to fix the delay time window $\tau_w = \tau (m - 1)$, since τ_w is the one that is of actual interest to represent the dynamics. One such attempt was made by Martinerie et al. (l992), who compared the delay time window and the delay times estimated using the ACF and MI methods but did not observe a consistent agreement between them. This is because, τ_w is basically the optimal time for representing the independence of the data, whereas the ACF and MI methods determine only the first local optimal times in their estimation of τ_d. Kim et al. (l998) showed (through analysis of synthetic time series) that, with an increase in the embedding dimension m, the correlation dimension

converges more rapidly for the case of τ_w held fixed than for the case of τ_d held fixed (especially so for small data sets). Based on this distinction between τ_d and τ_w, Kim et al. (l999) developed a new technique to estimate both τ_d and τ_w. This technique, called the C-C method [see below], uses the BDS (Brock-Dechert-Scheinkman) statistic (Brock et al., 1991, 1996), which has its base on the correlation integral for testing nonlinearity in a time series. The main difference between the BDS method and the C-C method is as follows. The BDS method uses the statistic $S(m,N,r) = C(m,N,r) - C^m(1,N,r)$, where $C(m,N,r)$ is the correlation integral [see Eq.(2) below for details], whereas the C-C method uses the statistic $S(m,N,r,t) = C(m,N,r,t) - C^m(1,N,r,t)$, involving an additional parameter in the form of the index lag t. The study by Kim et al. (1999) reveals that preliminary results of the application of C-C method for determination of delay window τ_w are reliable.

Encouraged by these results, an attempt is made in the present study to estimate the general dependence of hydrologic time series using the C-C method, and hence to assess their nonlinear deterministic characteristics. To this effect, three hydrologic time series are studied: (1) daily flow from St. Johns River near Cocoa, Florida; (2) biweekly volume from the Great Salt Lake; and (3) daily rainfall from Seoul. Interpretations regarding nonlinear determinism in these series are made based on the results for the artificial time series reported by Kim et al. (1998, 1999).

MEASURE OF NONLINEAR DEPENDENCE

Correlation integral and BDS statistic. After the attractor has been reconstructed in the phase-space [Eq. (1)], quantitative characteristic measures or invariants of the system can be determined. The correlation dimension method (Grassberger and Procaccia, l983) is arguably the most basic method for estimation of these invariants and for identification of chaotic behavior. The correlation integral or function with index lag t, which is used in this method for distinguishing between chaotic and stochastic systems, is given by (Kim et al., 1998):

$$C(m,N,r,t) = \frac{2}{M(M-1)} \sum \Theta(r - \|\bar{x}_i - \bar{x}_j\|), \qquad r > 0 \qquad (2)$$

where $\Theta(a) = 0$, if $a < 0$,

$\Theta(a) = 1$, if $a \geq 0$,

N is the size of the data set, $M = N - (m-1)t$ is the number of embedded vectors (or points) in the m-dimensional space, $\| \ \|$ denotes the sup-norm, and Θ(a) is the Heaviside step function. The function $C(m,N,r,t)$ measures the fraction of the pairs of

points $\vec{x}_i$, i = 1,2,…,M, whose sup-norm separation is no greater than r. If the limit of $C(m,N,r,t)$ for N $\rightarrow \infty$ exists for each r, then the fraction of all vector points that are within r of each other is given by $C(m,N,r,t) = \lim_{N\to\infty} C(m,N,r,t)$, and the correlation dimension is given by $D_2(m,t) = \lim_{r\to 0}[\log C(m,r,t)/\log r]$. However, since N remains finite (often small) in real situations, r cannot go to zero. Therefore, a linear 'scaling region' in the log $C(m,N,r,t)$ vs. log r plot is identified for estimation of correlation dimension $D_2(m,t)$; i.e. the slope of the scaling region.

Brock et al. (l991, 1996) used the BDS statistic to test for the presence of nonlinearity in time series. More specifically, the BDS statistic was used to reject the null hypothesis that the data are independent and identically distributed (iid). Under this null hypothesis, the BDS statistic for $m > 1$ is defined as:

$$BDS(m,M,r) = \frac{\sqrt{M}}{\sigma}[C(m,M,r) - C^m(1,M,r)] \tag{3}$$

and the statistic converges to a standard normal distribution as M $\rightarrow \infty$. The asymptotic variance $\sigma^2(m,M,r)$ of the BDS statistic can be estimated as:

$$\sigma^2(m,M,r) = 4\{m(m-1)C^{2(m-1)}(K-C^2) + K^m - C^{2m} + 2\sum_{i=1}^{m-1}[C^{2i}(K^{m-i} - C^{2(m-i)} - mC^{2(m-i)},(K-C^2)]\}, \tag{4}$$

$$C(m,M,r) = \frac{2}{M(M-1)}\sum_{1\le i\le j\le M}\Theta(r - \|\bar{x}_i - \bar{x}_j\|), \tag{5}$$

$$K(m,M,r) = \frac{6}{M(M-1)(M-2)}\sum_{1\le i\le j\le k\le M}[\Theta(r - \|\bar{x}_i - \bar{x}_j\|)\Theta(r - \|\bar{x}_j - \bar{x}_k\|)], \tag{6}$$

Since the BDS statistic originates from the statistical properties of the correlation integral, it measures the statistical significance of the correlation dimension estimation. Although the statistic cannot be used to distinguish between a nonlinear deterministic system and a nonlinear stochastic system, it is still a powerful tool for distinguishing between a linear stochastic (random) time series and a time series generated by a chaotic or nonlinear stochastic process.

The C-C method. The present study is particularly concerned with the properties of the statistic $S(m,N,r,t) = C(m,N,r,t) - C^m(1,N,r,t)$, proposed by Kim et al. (1998). According to Brock et al. (l991), if a stochastic process $\{x_i\}$ is *iid*, it can be shown that $C(m,r) = C^m(1,r)$ for all m and r; i.e. the correlation integral behaves much like the characteristic function of a serial string. This led Kim et al. (1998) to interpret the

statistic $S(m,N,r,t)$ as the serial correlation of a nonlinear series. The statistic can thus be regarded as a dimensionless measure of nonlinear dependence, and can also be used to determine an appropriate index lag t. In other words, for fixed m, N, and r, the $S(m,N,r,t)$ versus t plot is a nonlinear analog of the ACF versus t plot.

In order to study the nonlinear dependence (and eliminate the spurious temporal correlations), the time series $\{x_i\}$, $i = 1,2,\ldots,N$, is first subdivided into t disjoint time series of size N/t, and the statistic $S(m,N,r,t)$ is then computed from these t disjoint time series. The procedure is as follows. For $t = 1$, there exists only a single time series $\{x_1, x_2,\ldots,x_N\}$, and the statistic $S(m,N,r,t)$ is given by:

$$S(m,N,r,1) = C_1(m,N,r,1) - C_1^m(1,N,r,1) \tag{7}$$

For $t = 2$, two disjoint time series $\{x_1, x_2,\ldots,x_{N-1}\}$ and $\{x_2, x_4,\ldots,x_N\}$ are obtained, each of length $N/2$, and $S(m,N,r,t)$ is given by the average of the two as:

$$S(m,N,r,2) = \frac{1}{2}\{[C_1(m,N/2,r,2) - C_1^m(1,N/2,r,2)] + C_2(m,N/2,r,2)] - C_2^m(1,N/2,r,2)]\} \tag{8}$$

In general, for a given t, the statistic is given by:

$$S(m,N,r,t) = \frac{1}{t}\sum_{s=1}^{t}[C_s(m,N/t,r,t) - C_s^m(1,N/t,r,t)] \tag{9}$$

Finally, for $N \to \infty$, the statistic becomes

$$S(m,r,t) = \frac{1}{t}\sum_{s=1}[C_s(m,r,t) - C_s^m(1,r,t)], \qquad m = 2,3... \tag{10}$$

For fixed m and t, $S(m,r,t)$ will be identically equal to zero for all r, provided the data is *iid* and $N \to \infty$. However, since real series are always finite (and often serially correlated), $S(m,r,t) \neq 0$. Consequently, the locally optimal times may be either the zero crossings of $S(m,r,t)$ or the times at which $S(m,r,t)$ shows the least variation with r, as such only indicates a nearly uniform distribution of points. To account for this, several representative values r_j are selected, and the quantity $\Delta S(m,t)$ defined as:

$$\Delta S(m,t) = \max\{S(m,r_j,t)\} - \min\{S(m,r_j,t)\} \tag{11}$$

which is a measure of the variation of $S(m,r,t)$ with r. The locally optimal times t are thus the zero crossings of $S(m,r,t)$ and the minima of $\Delta S(m,t)$. The delay time τ_d will then correspond to the first of these locally optimal times.

Determination of the nonlinear dependence of a finite time series using the statistic $S(m,N,r,t)$ requires some kind of criteria for appropriate selection of m and r. In general, neither m nor r should be too large; the role of the sample size N is also

important. For a fixed value of N, since the data become very sparse for large values of m, $C(m,N,r,t)$ will become vanishingly small. Also, when r exceeds the size of the attractor (since most pairs of points are within r), $C(m,N,r,t)$ will attain saturation. According to Broke et al. (1991), results are better for m ranging between 2 and 5 and r between $\sigma/2$ and 2σ; and also $N \geq 500$ provide good approximations.

Brock et al. (l991) investigated the BDS statistic for time series generated from six asymptotic distributions in order to determine the appropriate values of m and r. They studied three different sample sizes (with N = 100, 500, and 1000) of time series generated through Monte Carlo simulation from the following asymptotic distributions: standard normal, student-t with three degrees of freedom, double exponential, Chi-square with four degrees of freedom, uniform distribution, and bimodal mixture of normals. Their analyses revealed that the results were better when m ranged between 2 and 5 and r between $\sigma/2$ and 2σ. All the asymptotic distributions were also well approximated by finite time series with $N \geq 500$. In light of these, Kim et al. (1998) selected four different values of r in the range $\sigma/2 \leq r \leq 2\sigma$ as representative values, with $r_1 = (0.5)\sigma$, $r_2 = (1.0)\sigma$, $r_3 = (1.5)\sigma$, and $r_4 = (2.0)$. They examined the averages of the quantities in Eqs. (10) and (11), which are given by:

$$\overline{S}(t) = \frac{1}{16}\sum_{m=2}^{5}\sum_{j=1}^{4} S(m, r_j, t) \tag{12}$$

$$\Delta\overline{S}(t) = \frac{1}{4}\sum_{m=2}^{5} \Delta S(m,t) \tag{13}$$

The first zero crossing of $\overline{S}(t)$ or the first local minimum of $\Delta\overline{S}(t)$ for selecting the first locally optimal time data independence were found, which also provided the delay time $\tau_d = t\tau_s$, with τ_s being the sampling time. The optimal time was found from the index lag t for which $\overline{S}(t)$ and $\Delta\overline{S}(t)$ were both closest to zero. If equal importance to these two quantities are assigned, then the minimum of the quantity

$$S_{cor}(t) = \Delta\overline{S}(t) + \left|\overline{S}(t)\right|, \tag{14}$$

can simply be found, which will provide the delay time window $\tau_w = t\tau_s$.

APPLICATIONS TO HYDROLOGIC TIME SERIES

In the persent study, the C-C method is applied to three hydrologic time series to measure their general dependence and assess nonlinear characteristics: daily flow

from St. Johns River, Florida (1979-1988); biweekly volume from the Great Salt Lake (1847-1992); and daily rainfall from Seoul (1987-1996). Figure 1 shows variations of these series. Since the ACF method is widely used in nonlinear dynamic and chaos studies, results from the C-C are also compared with those obtained from the ACF method. The ACF analysis is presented first.

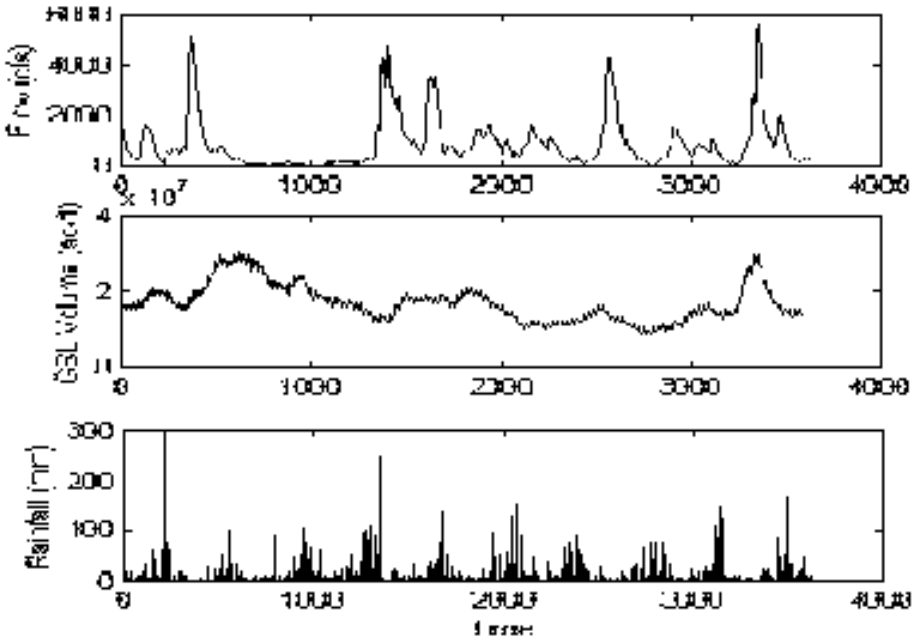

Figure 1 Time series plots: (a) daily streamflow from the St. Johns River; (b) biweekly volume from the GSL; and (c) daily rainfall from Seoul

Delay time estimation using ACF method. As for the selection of τ_d, the guidelines are: if the ACF decays exponentially with index lag t, then τ_d is taken as the index lag at which the ACF drops to 1/e; otherwise, τ_d is chosen as the index lag at which the ACF first crosses the zero line or its first local minimum, whichever occurs first. The ACFs for the flow and lake volume exhibit temporal persistence, while for the rainfall it fluctuates about zero [Figures not shown]. These observations indicate that the flow and lake volume are not random, but the rainfall is probably random. The τ_d values for these three series are 51 (days), 14 (biweeks), and 3 (days), respectively.

Delay time and delay window estimation using the C-C method. In the C-C method, the nonlinear dependence is measured using the statistic $S(m,N,r,t)$. As N is fixed for a given series, this statistic reduces to $S(m,r,t)$, and thus can be estimated with appropriate selection of only the parameters m and r, for a given t. Following the guidelines provided by Kim et al. (1998), four different (representative) values of r in

the range $\sigma/2 \le r \le 2\sigma$ are selected, with $r_1 = (0.5)\sigma$, $r_2 = (1.0)\sigma$, $r_3 = (1.5)\sigma$, and $r_4 = (2.0)\sigma$. Similarly, four different values of m are used, with $m = 2$, 3, 4, and 5. Figure 2 presents the $S(m,r,t)$ estimates obtained for the daily flow from the St. Johns River. It is clear that, for a given m, the index lag t at which the statistic $S(m,r,t)$ first crosses the zero line (τ_d) is different for the four different values of r. The average of these four values is $\tau_d = 89\,\tau_s$. Similarly, τ_d for the biweekly GSL volume is found to be $\tau_d = 11\,\tau_s$, and that for daily rainfall from Seoul is $\tau_d = 3\,\tau_s$ [Figures not shown].

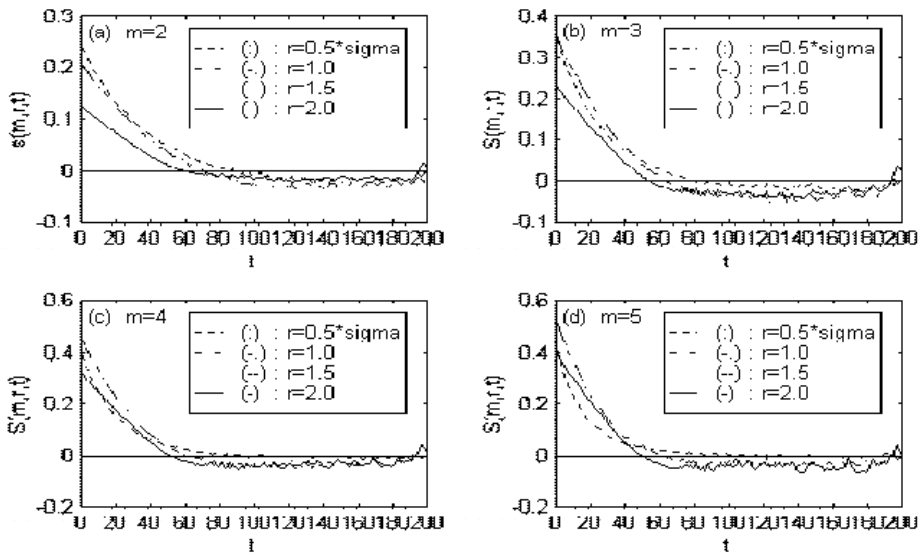

Figure 2 Results from the C-C method to flow series from the St. Johns River. The statistic $S(m,r,t)$ for: (a) $m = 1$; (b) $m = 2$; (c) $m = 3$; (d) $m = 4$

Figure 3 presents further results from the C-C analysis of the daily flow from the St. Johns River: (a) $\Delta S(m,t)$ for m = 2, 3, 4, and 5; (b) $\overline{S}(t)$ and $\Delta\overline{S}(t)$; and (c) $S_{cor}(t)$. The τ_w value is found to be $\tau_w = 194\,\tau_s$. The τ_w values for the GSL volume and the daily rainfall from Seoul are $\tau_w = 223\,\tau_s$ and $\tau_w = 48\,\tau_s$ [Figures not shown].

Comparison of results from ACF and C-C methods. For the daily flow from the St. Johns River and also for the biweekly GSL volume, the τ_d values from the two methods are different: 51 (days) and 14 (weeks) from the ACF method, whereas 89 (days) and 11 (weeks) from the C-C method. However, for the daily rainfall from Seoul, both the methods yield the same value, with $\tau_d = 3$ (days). These results seem

to indicate that: (1) both the methods perform equally well when the time series is the outcome of a linear stochastic process; and (2) the C-C method performs better than the ACF method when the time series is the outcome of a nonlinear process. The fact that the biweekly GSL volume has been shown to exhibit nonlinear deterministic behavior (e.g., Abarbanel and Lall, 1996), the present results are confirmation on the inadequacy of the ACF method for τ_d selection in nonlinear time series.

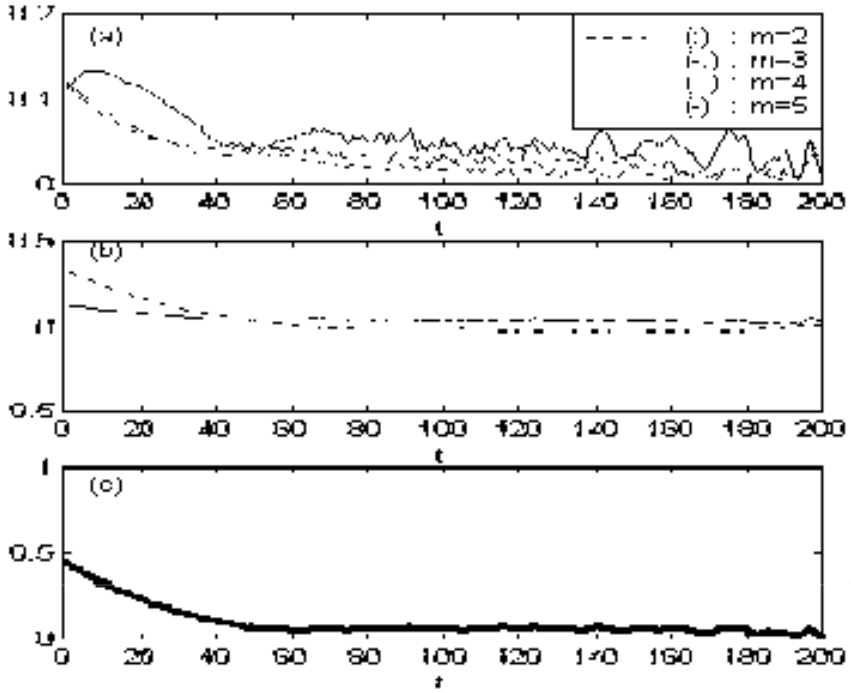

Figure 3 Results from the C-C method to the daily flow series from the St. Johns River: (a) $\Delta S(m,t)$ **; (b) (-):** $\overline{S}(t)$ **and (--):** $\Delta\overline{S}(t)$ **; and (c)** $S_{cor}(t)$

CONCLUSION

This study tested the effectiveness of the C-C method, proposed by Kim et al. (1998), for the selection of delay time and delay window for phase-space reconstruction of hydrologic data. Three hydrologic time series were studied: (a) daily flow from the St. Johns River, Florida; (b) biweekly volume of the GSL; and (c) daily rainfall from Seoul, Korea. The results indicate the ability of the C-C method to represent the general dependence of these series, against only the linear dependence represented by the autocorrelation function method. The results also suggest presence of nonlinear determinism in the daily flow from the St. Johns River and the biweekly GSL volume, while the nature of the daily rainfall in Seoul seem to be linear stochastic.

ABSTRACT

A study of the influences of Paleo Pacific Ocean Sea Surface Temperature (SST) variability and water-year Upper Colorado River Basin (UCRB) reconstructed streamflow is presented. Reconstructed streamflow data is available from several sources in the UCRB. The proxy records (streamflow) are derived from tree ring chronologies and these streamflow reconstructions provide an effective way to analyze patterns of variability (including drought) over a period of time extending beyond any instrumental record in UCRB.

Yearly proxy and coral based Pacific Ocean SST reconstructions, consisting of five by five degree cells, are available from 1590 to 1990. The range selected for the study is from Latitude 20^{o} South to 60^{o} North and 120^{o} East to 80^{o} West and 40^{o} West to 2^{o} West. A "lag" analysis is performed such that the SST dataset is for the year prior to the streamflow dataset. Additionally, epochal variability of climate signals [e.g., El Niño-Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO)] will be examined to determine if ENSO or PDO has strengthened (or weakened) over time.

The Singular Value Decomposition (SVD) statistical method has been identified as the preferable statistical method to identify coupled relationships between two, spatial-temporal fields. While SVD has been applied to SSTs and various hydrologic variables (e.g., Palmer Drought Severity Index – PDSI, precipitation, streamflow), this represents the first such application to reconstructed (paleo) datasets. The use of SVD with Pacific Ocean SSTs eliminates any spatial bias as to which SST region (or regions) may impact streamflow. This will assist in the identification of a SST region (or regions) that may not be represented in existing Pacific Ocean climate variability (e.g., ENSO, PDO) and could display the impacts of climate change.

INTRODUCTION

Numerous investigations have evaluated oceanic-atmospheric variability and continental U.S. hydrologic (e.g., snowpack, streamflow and precipitation) response [*Hunter et al., 2006; Tootle et al.*, 2005; *Gershunov*, 1998]. These studies show strong sub-continental impacts linked to particular phases (e.g. cold or warm) of

Pacific Ocean climate variability [e.g., El Niño-Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO)]. However, a limitation of these studies was that they focused on pre-defined (e.g., ENSO, PDO) regions of climate variability and the resulting hydrologic response to phases (e.g., warm or cold) of these climate signals. An alternative to evaluating known climate signals is to utilize entire regions of sea surface temperature variability. *Bretherton et al.* [1992] concluded that Singular Value Decomposition (SVD) was simple to use and preferable for general use while *Wallace et al.* [1992] found that SVD isolates the most important modes of variability. SVD has been utilized to evaluate SST and hydrologic variability [*Tootle and Piechota*, 2006; *Rajagaopalan et al.*, 2000; *Wang and Ting*, 2000]. However, a limitation of these and the previous climate signal studies is that they utilize (only) instrumental records of hydrologic response. Therefore, only one to three phases of the interdecadal (PDO) signal can be evaluated.

The proposed research represents the first time application of SVD to reconstructed Pacific Ocean SSTs and reconstructed UCRB streamflow. Initially, a "testing or verification" period is used such that three Pacific Ocean SST datasets (instrumental, tree-based and coral-based) and instrumental streamflow are evaluated. Since instrumental SSTs and instrumental streamflow have been utilized in past research efforts, this will allow for the comparison of the results between the instrumental SST dataset and the reconstructed SST datasets. Next, the period of record is extended and tree-based reconstructed Pacific Ocean SSTs and UCRB reconstructed streamflow is used. Finally, for the extended period of record, epochal (approximately 100 year periods) periods are evaluated to determine variability in SSTs and streamflow regions.

DATA

The available datasets used include instrumental and reconstructed streamflow, and instrumental and reconstructed (tree-ring based and coral based) Pacific Ocean SSTs.

Instrumental Streamflow Data

Data from unimpaired UCRB streamflow stations (Figure 1) were obtained from the U.S. Geological Survey (USGS) National Water Information System (NWIS). The average monthly streamflow rate in cfs were summed and converted into water-year streamflow volumes using appropriate conversions.

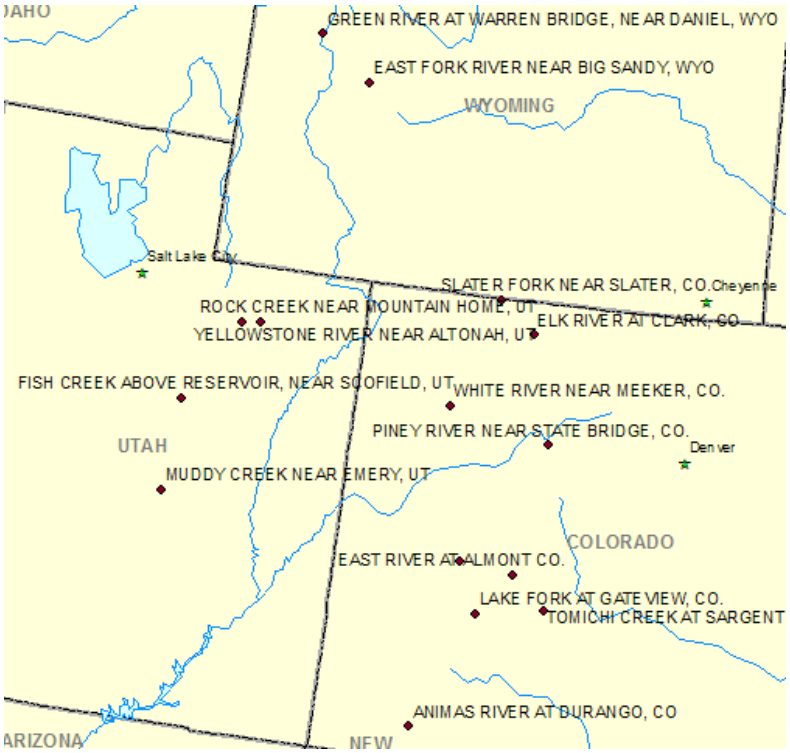

Figure 1: Location Map of UCRB instrumental streamflow gages.

Reconstructed Streamflow Data

Reconstructed water-year streamflow volumes for the UCRB were obtained from several sources including *Woodhouse, et al.* [2006] and *Barnett et al.* [2009] (Figure 2).

Figure 2: Location Map of UCRB reconstructed streamflow gages.

Instrumental Pacific Ocean SST Data

Instrumental Pacific Ocean SST data was obtained from the National Climatic Data Center website (http://www.cdc.noaa.gov/cdc/data.noaa.ersst.html). This dataset consists of monthly average values at a resolution of 2° by 2°. Average yearly values for each grid cell were determined and used in the current research.

Reconstructed (Tree-ring and Coral) Pacific Ocean SST Data

The reconstructed (Tree-ring and Coral) Pacific Ocean SST datasets, at a resolution of 5° by 5°, were obtained from the World Data Center for Paleoclimatology Climate reconstructions website (ftp://ftp.ncdc.noaa.gov/pub/data/paleo/coral/east_pacific/sst_evans2002). The yearly values represent the water-year (Oct to Sep).

Instrumental and Reconstructed ENSO and PDO Indices

The instrumental and reconstructed ENSO and PDO indices were obtained from the Working Group on Surface Pressure website (http://www.cdc.noaa.gov/Pressure/Timeseries), the NCAR Climate and Dynamics website (http://www.cgd.ucar.edu/cas/catalog/climind/TNI_N34/) and the JIASO website (http://jisao.washington.edu/pdo/PDO.latest).

METHODOLOGY

Singular Value Decomposition (SVD)

SVD is a powerful statistical tool for identifying coupled relationships between two, spatial-temporal fields. While *Bretherton et al.* [1992] provide a detailed discussion of the theory of SVD, a brief description of SVD as applied in this study, is provided. Initially, a matrix of standardized SST anomalies and a matrix of standardized water year streamflow anomalies were developed. The time dimension of each matrix must be equal while the spatial component (i.e., the number of SST cells and the number of streamflow stations) can vary in dimension. The cross-covariance matrix was then computed for the two spatio-temporal matrices and SVD was applied to the cross-covariance matrix and "teleconnection" information regarding the relationship between the two was obtained.

The resulting SVD of each cross-covariance matrix created two matrices of singular vectors and one matrix of singular values. The singular values were ordered such that the first singular value (1st mode) was greater than the second singular value and so on. *Bretherton et al.* [1992] defines the squared covariance fraction (SCF) as a useful measurement for comparing the relative importance of modes in the decomposition. Each singular value was squared and divided by the sum of all the squared singular values to produce a fraction (or percentage) of squared covariance for each mode. In applying SVD, the SCF is somewhat analogous to the percent of explained variance (by components) when applying PCA.

Finally, the two matrices of singular vectors were examined, generally referred to as the left (i.e., SST) matrix and the right (i.e., streamflow) matrix. The first column of the left matrix (1st mode) was projected onto the standardized SST anomalies matrix and the first column of the right matrix (1st mode) was projected onto the standardized

streamflow anomalies matrix. This resulted in the 1st temporal expansion series (TES) of the left and right fields, respectively. The left heterogeneous correlation field (for the 1st mode) was determined by correlating the SST values of the left matrix with 1st temporal expansion series of the right field and the right heterogeneous correlation field (for the 1st mode) was determined by correlating the streamflow values of the right matrix with the 1st temporal expansion series of the left field. The left temporal expansion series have a physical meaning since they represent SST variability that may not already be included in existing SST indices and could represent a new index of SST variability.

Utilizing an approach similar to *Tootle et al.* [2008], *Rajagopalan et al.* [2000] and *Uvo et al.* [1998], maps displaying significant (90%) correlation values for streamflow regions were reported while contour maps (displaying all correlation values) were provided for the Pacific Ocean SSTs. If the Pacific Ocean SST and streamflow significant regions have the same sign, then they behave similarly [i.e., higher (lower) SST temperatures result in higher (lower) streamflow] while opposite signs result in opposite behavior [i.e., lower (higher) SST temperatures result in higher (lower) steamflow]. Please note, the "switching" of the signs is inherent to SVD and the importance of the results is the positive/negative relationships between SSTs regions and streamflow stations, as displayed by the figures. For each analysis, the previous year SSTs are used with the current water-year streamflow and (only) the 1st mode of variability is reported.

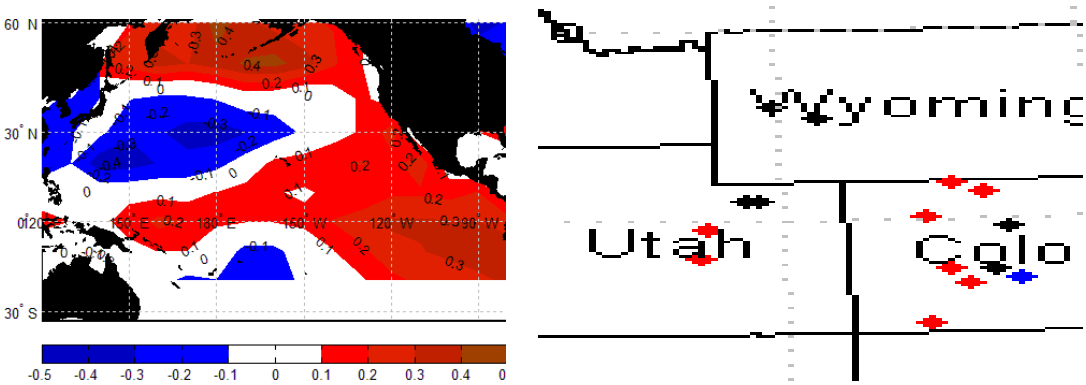
Proposed Research Approach

Verification of Instrumental, Tree-ring based and Coral based Pacific Ocean SST datasets with Instrumental Streamflow

The first analysis compares the SVD results of instrumental Pacific Ocean SSTs and instrumental streamflow to tree-ring based and coral based Pacific Ocean SSTs and instrumental streamflow. Instrumental records typically have less uncertainty than records developed from biological factors. Also, instrumental SST and instrumental streamflow datasets have been previously evaluated in past research efforts and will provide a "benchmark" for comparison to the tree-ring and coral based SST datasets. Therefore, the same period of record (1950 – 1989 for SSTs and 1951-1990 for streamflow) was selected.

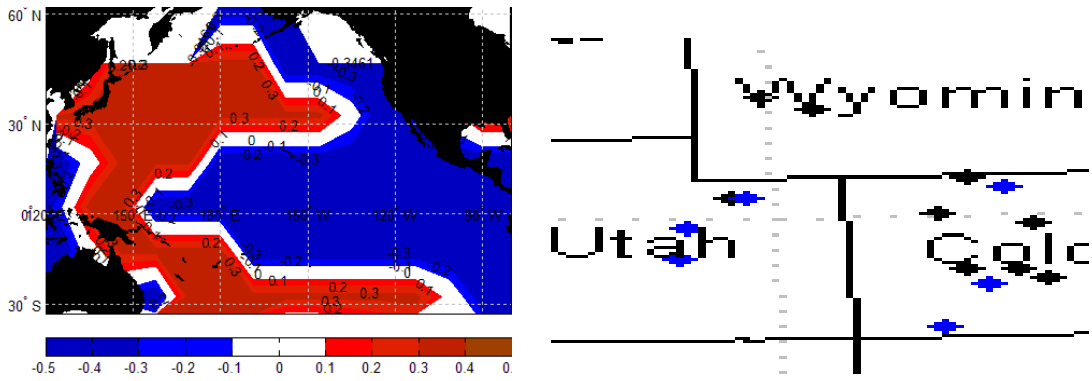
Evaluation of Tree-ring based Pacific Ocean SSTs and Reconstructed Streamflow (Entire Record 1615 – 1989 for SSTs and 1616 – 1990 for Streamflow)

After the verification step, the previous year Pacific Ocean SSTs and the current water-year streamflow were evaluated for the entire period of record.



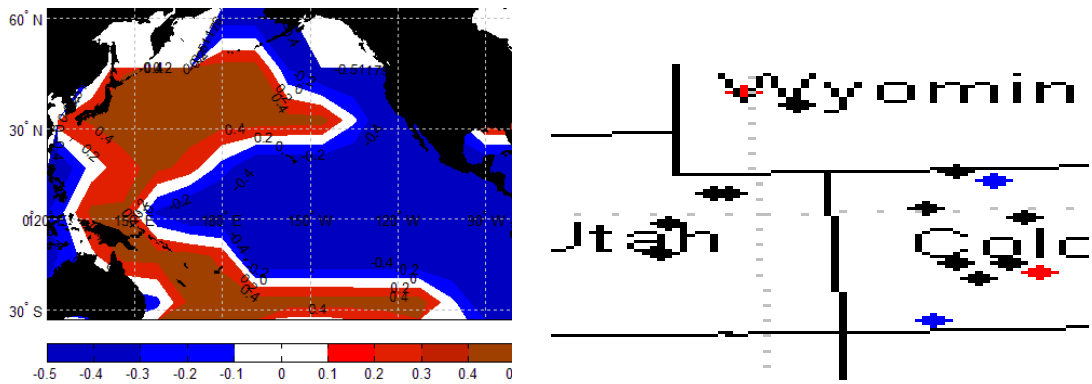
Evaluation of Tree-ring based Pacific Ocean SSTs and Reconstructed Streamflow (Epochal Analysis 1700 – 1799 for SSTs and 1701 – 1800 for Streamflow; 1800 – 1899 for SSTs and 1801 – 1900 for Streamflow; 1900 – 1989 for SSTs and 1901 – 1900 for Streamflow)

The final analysis divides the entire period of record dataset into three, 100-year periods. Each period (epoch) is evaluated to determine if climate signals have varied over time.



RESULTS

Verification of Instrumental, Tree-ring based and Coral based Pacific Ocean SST datasets with Instrumental Streamflow



When comparing the three Pacific Ocean SST datasets with instrumental streamflow for the same period of record, similar spatial Pacific Ocean SST patterns were observed (Figure 3). First, the instrumental SSTs (Figure 3a) display a well defined equatorial region (i.e., ENSO) and a region south of Alaska (i.e., PDO). Both of these "red" regions display positive correlation values. When observing the streamflow stations, approximately eight "red" (positive correlation) stations were significant in Utah and Colorado. The "black" stations are not significant while one "blue" station was identified. This displays the "classic" southwestern U.S. ENSO signal in which increased (decreased) equatorial SSTs results in increased (decreased) streamflow. The tree-ring based reconstructed SSTs (Figure 3b) display a similar ENSO pattern ("blue" or negatively correlated region) and six "blue" (negative correlation) stations are identified in Utah and Colorado. As previously stated, the "switching" of signs is inherent in SVD and the same relationship [increased (decreased) SSTs results in increased (decreased) streamflow] was maintained. Perhaps the most interesting result was the coral-based reconstructed SSTs (Figure 3c). While a similar spatial pattern was displayed for the SSTs, only two stations (blue) were identified with a "positive" relationship to ENSO. It appears that the coral-based reconstructed SSTs do not "capture" SST variability (i.e., more uncertainty and "noise" in the dataset) when compared to the instrumental and tree-based SST datasets. Additionally, both the reconstructed SST datasets have a larger grid size (5 degree) when compared to the instrumental dataset (2 degree).

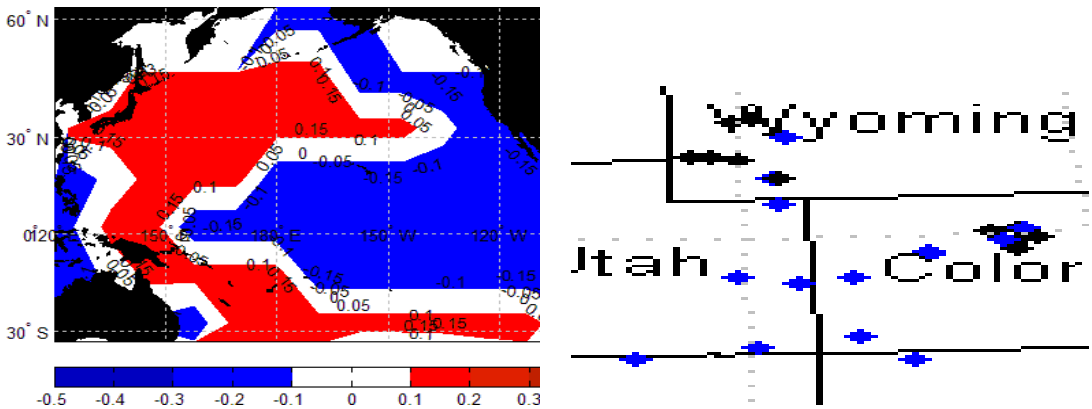
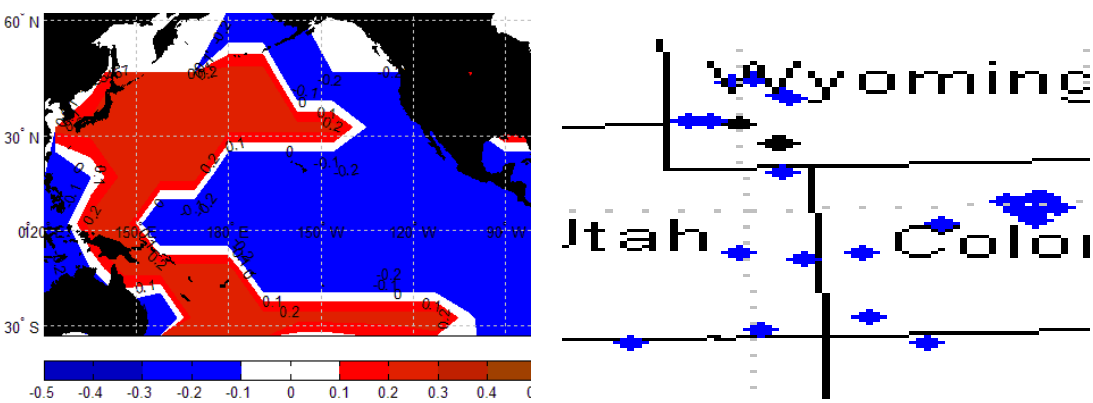
(b)

(c)

Figure 3: Results of SVD analysis (1st mode) of Pacific Ocean SSTs (a) instrumental (b) tree-ring based (c) coral based and instrumental streamflow.

Evaluation of Tree-ring based Pacific Ocean SSTs and Streamflow (Entire Record)
When evaluating the tree-based SSTs and reconstructed streamflow for the entire period of record, a similar spatial SST pattern in addition to a similar spatial streamflow station pattern was observed (Figure 4). It appears that equatorial SSTs (i.e., ENSO) are the primary climatic driver of UCRB streamflow. However, it appears the signal weakens as you move north into the basin (i.e., Green River Basin of Wyoming). Also, there is a consistent "opposite sign" (red) spatial SST pattern southeast of Japan that consistently shows up in this and past research efforts. This pattern may well influence streamflow variability, in addition to ENSO. Interestingly, the "PDO like" SST region is not well defined in any of the reconstructed SST patterns (Figures 3b & 3c and Figure 4). This may be attributed to the larger grid size.





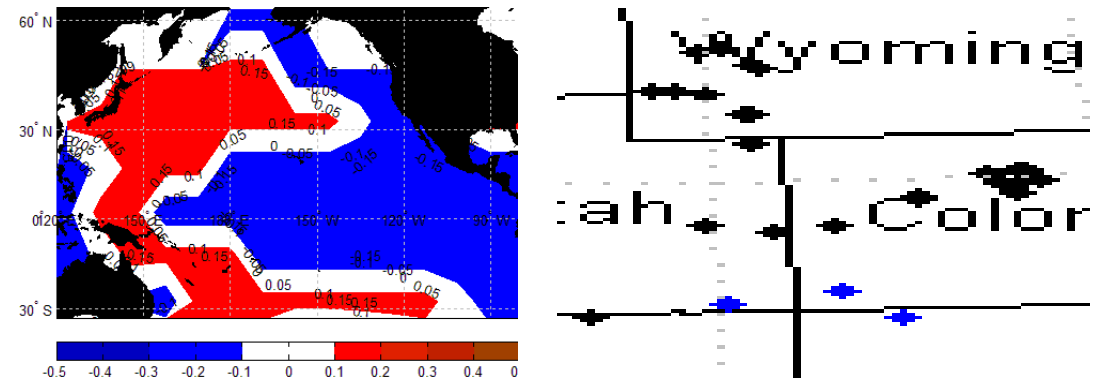


Figure 4: Results of SVD analysis (1st mode) of tree-ring based Pacific Ocean SSTs and reconstructed streamflow.

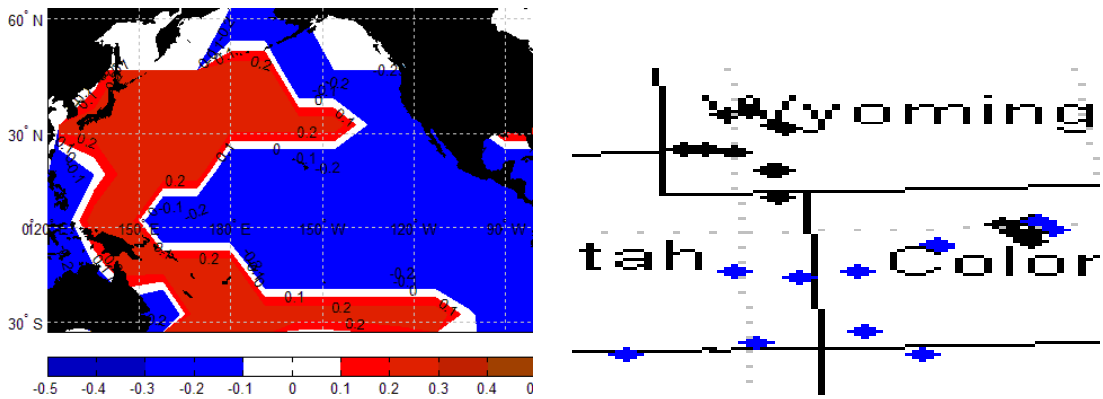
Evaluation of Tree-ring based Pacific Ocean SSTs and Streamflow (Epochal Analysis)



The epochal analysis provided some interesting results (Figure 5). The 1700's (Figure 5a) results in almost all streamflow stations being significant while the opposite occurs for the 1800's (Figure 5b). The 1900's (Figure 5c) closely matches the previous analysis (Figure 3b), which, given the similar time periods, confirms those results. A closer evaluation shows that the ENSO-like SST pattern in the 1700's has a stronger correlation value when compared to the pattern in the 1800's. Perhaps a stronger, more defined ENSO-like signal was present during that epoch, which resulted in a stronger streamflow response throughout the UCRB.

Figure 5: Results of SVD analysis (1st mode) of tree-ring based Pacific Ocean SSTs and reconstructed streamflow (a) 1700-1799 (b) 1800-1899 (c) 1900-1989.

CONCLUSIONS & FUTURE WORK

ENSO appears to be the dominant signal in UCRB streamflow, based on the consistent ENSO-like equatorial SST pattern present in the current research. However, it appears the strength of this signal varies over time which results in UCRB streamflow variability. Future research will evaluate ENSO (and PDO) signal strength during the various epochal periods. Additionally, rather than selecting "arbitrary" 100-year epochal periods, periods may be selected based on cycles of the PDO (25 to 50 years). Also, an important next step in these research efforts is to attempt to relate droughts (or mega-droughts) with these cycles and to determine if ENSO (and PDO) signal strength is changing (strengthening or weakening) and if this change is related to climate change.

Planning for Climate Change

John A. Kliem, PE

Abstract

Climate change is upon us. Models used to predict climate change lack the granularity to allow communities to be accurately predicting the impacts of climate change. Federal Funding of Climate change research can barely keep pace with inflation much less provide the research required for local communities to develop climate change plans. Local governments need to develop a strategy to resource the modeling of climate change for their community. Regions could band together to source the modeling or solicit help from their congressional representatives. Next, leaders need to develop an action plan that addresses possible impacts to the community's industrial base or other natural resources.

Introduction

The world's climate is changing and the vast majority of the world is unprepared to handle the effects of these changes. Our Federal government has taken only modest steps to ensure our country is prepared for climate change. These measures include the creation of an interagency structure of Federal Agencies formed to synthesis and coordinate government climate change research and modest investments were made into modeling climate change. The results of this research, while beneficial at the global and national level, falls short of providing information needed by local governments to assess and make action plans to be ready for the effects of climate change. Local government leaders must assume a larger role in planning for climate change to include developing strategies for resourcing and executing climate change action plans for their communities.

Climate Change Research and Development Funding

Government spending on Research and Development (R&D) for climate change is limited and lacks the focus to get the results required for local leaders. According to the American Association of the Advancement of Sciences, overall federally funded R&D declined during fiscal year 2008. Total Federal investment in R&D increased only 1.2 percent and below the inflation rate (AAAS, 2008). The Department of Energy (DOE), Office of Science, The National Science Foundation (NSF) and the National Institute of Standards and Technology (NIST) budgets were cut to fund continued medical research, Energy R&D, and environmental research that including climate change research (AAAS, 2008). The increase in Environmental R&D and climate change

research only resulted in a rise of four percent to $2.1 billion (AAAS, 2008). The Climate Change research Agencies benefiting from this small increase include the U.S. Geological Survey (USGS), the National Aeronautics and Space Administration (NASA), and the National Oceanic and Atmospheric Administration (AAAS, 2008).

The Budget for fiscal year 2009 is not complete most agencies maintained their 2008 funding levels under the continuing resolution passed by Congress this includes the agencies involved in climate change research. Even if the Democratic Congress and President Obama's administration managed to increase funding for Climate change sciences, it is doubtful in the amount of time remaining in this fiscal year that the government will be able to develop a climate change strategy that will have an effect on local governments.

Climate Modeling Efforts

The Climate Change Science Program created in 2002 coordinate's climate change research within the federal government. This program cuts across executive agencies and assimilates research within the U.S. Global Change Research Program that was established under the Global Change Research Act of 1990 and the Climate Change Research Initiative created by President Bush in 2001 (Bodman; et al, 2007). The Climate Change Science Program orchestrates research on climate and global change amongst 13 Federal Agencies and Departments (Bodman; et al, 2007). Topics within climate that are studied include atmospheric composition, climate variability and change, the global water cycle, land use and land cover effects, the global carbon cycle, ecosystems, and human contributions and responses to environmental change (Bodman; et al, 2007). The Climate Change Science Program ensures unity of effort amongst all the agencies by ensuring a consistent approach to modeling and measurements keeping all agencies focused on the same climate change research and development objectives (Bodman; et al, 2007).

Climate change modeling requires a vast infrastructure of satellites, ocean buoys and land based temperature gauges. These instruments upload measurements of a variety of atmospheric parameters such as green house gasses, temperature and air particulates to super computers loaded with historical climate measurements. This data is the processed through a number of physical, chemical and climate science algorithms (Glass, 2008). One of the more popular climate models is used by NASA's Goddard Space Flight Center along with other government agencies and research institutions created four super computer simulations that simultaneously model the ocean, atmosphere, land surface and sea ice. These simulations comprise the Earth System Modeling Framework this climate model will allow scientists to make climate change projections into the next century (Gutro, 2005). Earth Systems Modeling Framework has unified the climate modeling community making it easier to share data and eliminates the expense of each agency need to develop their own model or coupling software (Gutro, 2005).

Future models being developed will allow climatologists to simulate reactions in the atmosphere. One of these models is a Carbon Cycle model to predict the transport and fate of carbon within our climate. Additionally, two models are being simultaneously developed to look at chemistry in the troposphere and stratosphere.

These models will be coupled to allow better prediction of impacts to air quality and water quality which would then be tied to human health (Glass, 2008).

These Climate models are enabling scientists to make important climate impact predictions on an international or global level as reported in the Climate Change Science Program's annual report. These results have been widely reported and include observations that higher latitudes are experiencing shorter winters and longer summers. Measurements and Modeling indicate that the seasonal changes are the result of human activity vice climate variability (U.S. Fed News Service, 2007). The output of climate models like the one described above makes as reported by David Talbot in *Technology Review* is that these climate predictions are for a large grid square of about 150 kilometers by 190 kilometers (Talbot, 2007). This causes problems since weather patterns can be created by urban centers or mountain ranges within the grid skewing the results. Researchers are working to "nest" regional climate models into larger global climate models to give results more clarity (Talbot, 2007). The creation of regional "nested" models is a new research area that the Federal Government has not focused on to date.

Planning

State and local governments need to start now to develop a strategy for the creation of an action plan for climate change preparedness. We still do not understand all of the potential impacts to climate change and local governments cannot afford to wait for the federal government to push out actionable information for local government leaders. The first step should be to determine potential vulnerabilities within their community. Paying particular attention to major community components that could be impacted by significant changes in the climate. For example, Louisiana and Texas would be impacted by climate change with an increase in size and severity of hurricanes affecting the petro-chemical industry. Local leaders need to develop specific plans to ensure the survival of the region's economic base as well as their communities. Likewise we need to understand and plan for climate change impacts affecting an infrastructure or economic base that is essential to our national security like the example mentioned above. Additionally, local leaders need to also study the impact of climate change on major resources like water.

Resourcing the Plan

There are some reports of Federal Grants being awarded to local communities to implement climate change planning at the local level. These efforts are largely hit or miss and we certainly lack a national strategy for the development of climate change mitigation plans. Notably, the National Science Foundation in fiscal year 2007 and 2008 awarded ten grants to researchers to investigate climate change issues involving urban areas and coastal barrier islands (Dybus, 2008). This is a small but necessary step to encourage and develop the research infrastructure to be prepared to take on a larger role in climate change planning and development. The Federal Government will most likely continue to make modest investments in the short term but will likely lack the emphasis

or focus to lead the comprehensive development of a national strategy for the development of climate change planning.

Industry will not take the lead in planning for climate change. It is difficult for individual industries to take the initiative and begin planning for the impacts of climate change that may not be felt for a few decades. Much of our countries industrial base is developing business plans to positively affect their balance sheet in the next quarter much less planning for the long term future.

This leaves our local leaders to develop ways to resource their climate changing efforts. Some state governments have already taken the initiative to develop and issue climate change planning grants. For example, Aspen, Colorado invested $145,000 to develop climate predictions for their own town (Talbot, 2007). At the end of the spectrum the state of California is investing $4 million in a regional climate model (Talbot, 2007). These local or regional plans will allow local governments to begin detailed planning to mitigate the forecasted climate change (Talbot, 2007). However, most communities will not be able to resource climate change planning efforts on their own. They will need to build a partnership base with other local governments along with state and federal governments. In some cases it may be appropriate to issue a carbon tax or carbon trading program to generate funds for climate change planning. A tax on fuel consumption is another option that would elevate the cost of fuel but local government could remove the tax if the cost of fuel were to rise again. Local governments could also work with the Department of Homeland Security if they can relate local climate change to national security. This could be an effective way of getting a Federal partner to investigate local climate change impacts. The key partner to the local leader to developing a resourcing strategy will be state and federal representatives. It is essential that elected leaders understand that Federal Climate Change research lacks the granularity to allow for local planning and what the potential impacts of lack of planning would be to their state or district. Without their help it is doubtful that the local leader will get the momentum and assistance required to fully develop the plan.

Strategy implications

Local planning efforts need to take the long view. What will the future of climate change bring? It is possible that certain communities may identify the loss of an economic base such as a fishery or a tourist attraction. Through early planning local leaders can take steps to mitigate these losses and even encourage the development of industry that would not be impacted by climate change. It would be a monumental undertaking for a region to shift to a different economic base and will take a great deal of time. This is why local governments cannot afford to wait to begin climate change planning efforts. In most cases it will take decades to implement climate change practices.

It is very likely that local climate change models will identify zoning issues within communities. For example, local climate change models may identify regions that will be more likely to be impacted by flooding. These communities located in climate change impacted zones should be identified early. Assistance will have to be provided in some cases to encourage relocation. Property taxes could also be used to drive a change

in zoning. Effective land use plans would have to be developed for impacted areas. Viable land re-use plans could include space for parks or environmental mitigation zones.

Conclusion

Federal government funding for climate change sciences has been lack luster. Existing climate change models lack the granularity required for local planning and mitigation. Communities need to act now to develop local climate change plans. Communities should identify possible impacts of climate change based on current climate change modeling efforts. Since, local climate change models are expensive local leaders will need to find partners or some fund source through taxation to create their plan. Possible strategic partners with communities could be local industry, state officials, the Department of Homeland Security (if local climate change poses a threat to national security). Once a plan is developed and the climate change impact is identified leaders need to take the long view in implementing the plan taking necessary steps to rezone land and or shift economic bases as required. Planning for climate change will not be easy. However, current climate change predictions indicate radical shifts in climate over the coming decades and it will take communities at least that long to get ready.

Abstract

In many cases, streamflow persistence (month-to-month or season-to-season correlation) can be used in place of climate forecasts to provide useful forecast information to water managers. In this study, an ordinal polytomous logistic regression model is proposed to generate tercile probability stream flow forecasts (i.e., probability of low, medium, and high categories) based on persistence for the Lower Colorado River system in central Texas. Forecast performance is evaluated by cross-validation using the Brier skill score (BSS) and the Ranked probability skill score (RPSS). The results show that stream flow persistence can provide significant forecast skill during the winter and spring seasons, when water allocation decisions are being made for the coming summer growing season.

Introduction

Reliable streamflow forecasts with lead times of one season can have a significant effect on the performance of reservoir operation policies and operation efficiency (Karamouz, et al, 2004). In recent years, much effort has been made to develop mid- to long-term hydroclimatic and streamflow forecasting models for major rivers in the United States. For example, the NOAA Climate Prediction Center issues seasonal forecasts of temperature, precipitation, and soil moisture, as well as a drought outlook, for the entire U.S. In the western U.S., the USDA Natural Resources Conservation Service forecasts streamflows in the first half of the year based on observed snowpack conditions. At many stream gage locations throughout the U.S., the National Weather Service provides probabilistic seasonal flow forecasts through a procedure known as Ensemble Streamflow Prediction, or ESP (Day, 1985; Smith et al., 1992). Traditionally, each of the meteorology traces has been assumed to represent an equally likely scenario for the future; recently, methods have been developed to condition the probabilities of the historical meteorological traces based on seasonal climate forecasts (e.g., Croley 2000). On a global scale, the NOAA/Columbia University International Research Institute for Climate and Society (IRI) is one institution that issues seasonal forecasts of temperature and precipitation.

Significant progress has been made in understanding the influence of large-scale ocean-atmospheric patterns, such as El Niño–Southern Oscillation (ENSO), Pacific Decadal Oscillation (PDO), the North Atlantic Oscillation (NAO), and Atlantic Multidecadal Oscillation (AMO), on regional climate anomalies around world. Recent studies have shown that incorporation of large-scale ocean-atmospheric patterns can improve the ability to forecast streamflow in long lead time (Hamlet and Lettenmaier, 1999; Sharma, 2000; Tootle, et al, 2006). At least three previous studies have identified teleconnections for central Texas. Piechota and Dracup (1996) found strong correlation between the Southern Oscillation Index (SOI) and the Palmer Drought Severity Index (PDSI), indicating the potential of improved climate forecasts, up to a year in

advance, for the region. However, a strong relationship between SOI and streamflow was not found. One possible reason for this is that PDSI is a mathematical function of temperature and precipitation and provides a general indication of drought, whereas streamflow tends to integrate climatic processes over interseasonal time scales, and this seasonal averaging may limit forecast accuracy. For instance, streamflow is a function of both surface runoff and groundwater discharge, and groundwater recharge and discharge processes often exhibit lag times markedly longer than those of rainfall-runoff processes. Furthermore, groundwater basins seldom align directly with surface watersheds, which may confound statistical analyses of climate and streamflow variables measured at specific gage locations.

In another study, Rajagopalan et al. (2000) found correlation between summer PDSI and winter Pacific Ocean sea surface temperature anomalies. However, they also found epochal variations in this correlation, with the period of 1963-1995 showing weaker teleconnections than the period 1895-1962. Of course, without a means of predicting these epochal shifts in teleconnections, such variation tends to confound statistical forecasting methods based on the entire historical record. It is widely hypothesized that interdecadal North Pacific variability modulates ENSO-precipitation teleconnections (e.g., Gershunov and Barnett, 1998), but Rajagopalan et al. (2000) were not able to conclude that either NAO or PDO has any effect on ENSO-precipitation teleconnections in central Texas.

Finally, Tootle et al. (2005) completed a study of the influence of interdecadal, decadal, and interannual oceanic-atmospheric influences on streamflow in the United States. Unimpaired streamflow was identified for 639 stations for the period 1951–2002, and the phases (cold/negative or warm/positive) of ENSO, PDO, NAO, and AMO were identified for the year prior to the streamflow year (i.e., long lead time). Statistical significance testing of streamflow, based on the interdecadal, decadal, and interannual oceanic-atmospheric phase (warm/positive or cold/negative), indicated no spatially coherent teleconnections for central Texas. Although this study focused on a specific annual period (October-September) and forecast lead time, it provides an indication that long-lead climate forecasts may not be useful to water managers in this region.

Streamflow forecasts may be either deterministic or probabilistic, but probabilistic methods are often preferable for water management because they can provide more information about uncertainty. Categorical streamflow forecasts are common, providing the probabilities of flow being in each of a number of categories (e.g., low, medium, high). Probabilities of each category could be generated directly or indirectly. Piechota et al. (1998) proposed linear discriminant analysis to produce the probabilities of each category of streamflow directly. This method involves nonparametric kernel density estimation of the probability density function for each flow category. Regonda et al. (2006) employed logistic regression to directly predict the probability of streamflow above a given threshold. They applied this approach to categorical forecasts of the spring (April-June) streamflow at six locations in the Gunnison River Basin. However, this approach treats the response variable as binary, i.e., 1 if streamflow value exceeds a given threshold and zero otherwise. A drawback of this approach for multiple categories is that the logistic regression needs to be repeated multiple times to obtain the probability corresponding to each category threshold, and sum of probabilities is not guaranteed equal to 1.

In this paper, a statistical method called polytomous logistic regression for ordinal response (Kutner et al. 2004) is proposed to generate tercile probability forecasts (monthly to seasonal lead times) for the Highland Lakes system in central Texas. Because large-scale climate signals do not demonstrate great potential for skillful forecasts, hydrologic persistence will be examined as only predictor variable. In many cases, streamflow persistence (month-to-month or season-to-season correlation) is strong enough to provide useful forecast skill. The performance of forecasts is evaluated by cross-validation using the Brier skill score (BSS) and the ranked probability skill score (RPSS).

Case study

The Lower Colorado River Authority (LCRA) operates the Highland Lakes system in central Texas, a series of six lakes on the watershed of the Lower Colorado River. As a water conservation and reclamation district, the LCRA provides water supply and flood control to a 33-county area, including the City of Austin and several rice irrigation districts along the Texas Gulf Coast (see Figure 1). In addition, the LCRA produces wholesale power for a 53-county service area and provides water resources for lake recreation activities and in-stream flow maintenance. To meet rapidly growing demands, reservoir inflow forecasts with seasonal lead times would be very beneficial; however, hydrologic forecasts are not used by the LCRA for a number of reasons, including high seasonal and annual variability of stream flow, the absence of easily measured hydrologic indicators such as snowpack, and a lack of experience with probabilistic planning methods.

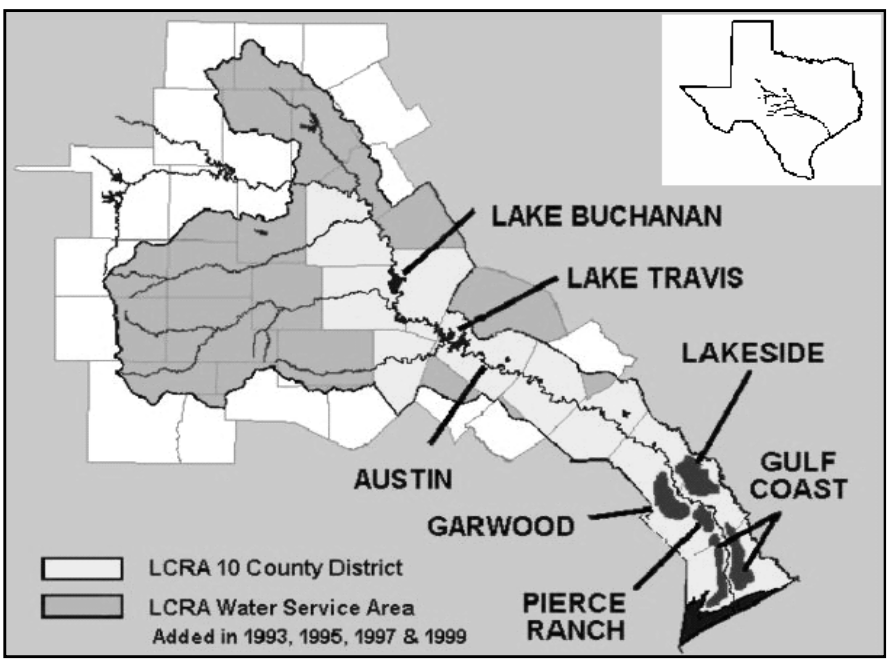

Figure 1. Lower Colorado River Authority District

The data used in the analyses come from two sources: 1) aggregate Highland Lakes inflows based on USGS gage measurements and adjustments made by LCRA staff to account for inflows from ungaged areas; and 2) unregulated flows downstream of the Highland Lakes, as determined by the Texas Water Availability Model (WAM). A total of 57 years of monthly flow data covering from 1950 to 2006 are used in this study. For most of the analyses, the raw flow data are normalized through a two-step process—first a logarithmic transformation, then conversion to a standardized anomaly by subtraction of the mean (of the log values) and division of the standard deviation (of the log values). While this transforms the data so that the statistical assumption of normality is more valid, it should be noted that the correlation coefficients are then inflated (due to the log-transform), and thus an effort is made to illustrate the results in terms of the raw flow data.

Estimates of monthly reservoir inflows may be based on measured flows at three USGS gage sites—Colorado River near San Saba, Pedernales River near Johnson City, and Llano River near Llano. LCRA staff have adjusted these flows to account for ungaged portions of the drainage area, as well as precipitation falling directly onto the lakes. Figure 2 shows the monthly autocorrelations of this time series, ranging from a high of nearly 0.8 for February and March flows to a low of -0.02 for July and August flows. Figure 3 shows seasonal correlations, which again peak in the winter season with a correlation coefficient of 0.66. The correlation coefficient that is significant at the $p = 0.05$ level is 0.20. It may be surprising that the seasonal correlation between OND and JFM flows is higher than the average of monthly correlation coefficients during this period. One reason for this may be that averaging over a three-month period reduces the "noise" that results from individual storm events which have a significant effect on monthly flow totals.

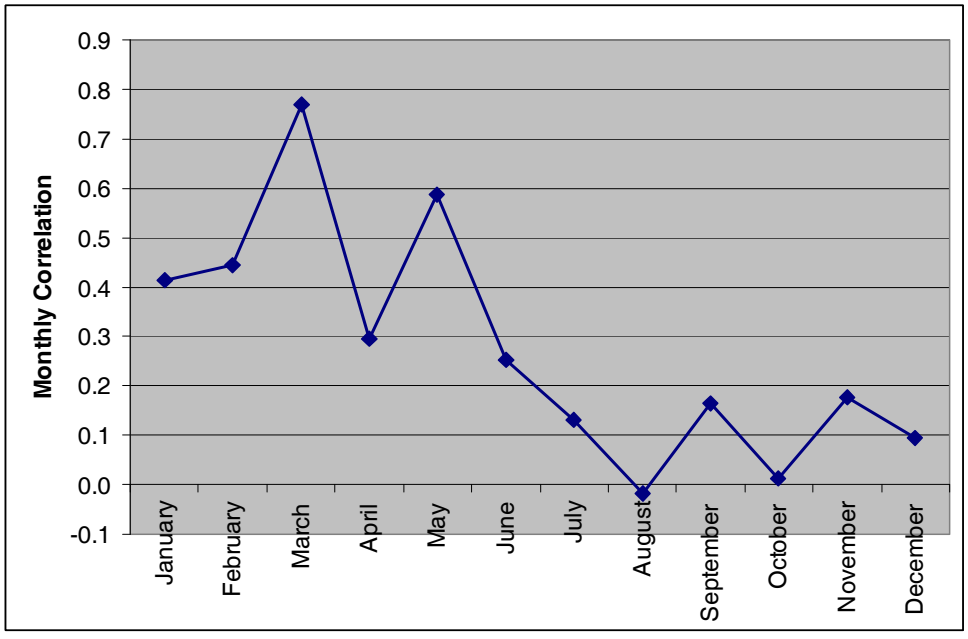

Figure 2. Monthly autocorrelations for aggregate inflows to the Highland Lakes. Correlation coefficients are computed using raw flow data.

Methodology

Logistic regression is most frequently used to model the relationship between a binary response variable and a set of predictor variables. If the response variable has more than two levels, logistic regression can still be employed by means of a polytomous or multicategory logistic regression model (Kutner et al., 2004). The goal of this study is to develop a framework for developing categorical forecasts of streamflows. The polytomous logistic regression method is used to produce tercile probability forecasts (below normal, normal, and above normal categories). Since these categories may be treated as ordered, and the ordinal polytomous logistic regression model may be more effective, yielding a more parsimonious model with easily interpreted results. The basic principle is described below.

In general, a linear logistic regression with a binary response variable Y, logit(p) can be expressed as a function of one (simple linear logistic regression) or more than one predictor variables (multiple linear logistic regression) as follows:

$$\text{logit}(p) = \log(p/(1-p)) = \beta_0 + \beta_1 x_1 + \cdots\cdots \beta_k x_k \qquad (1)$$

where $p = \Pr(Y = 1)$ denotes the probability of success. The parameters β_j are usually estimated using maximum likelihood theory.

In the binary logistic case, logit(p) compares the probability of a category-1 response (success) to the probability of a category-2 response (failure). For a response variable with J categories, it is necessary to develop J - 1 logistic regression models. One category will be chosen as the baseline or reference category, and then all other categories will be compared to it. The choice of reference category is arbitrary. Frequently the last category is chosen.

Using category J to denote the reference category, only J - 1 logits need to be developed. For a nominal response, the jth logit expression for the ith observation is given as:

$$\log\left[\frac{p_{ij}}{p_{iJ}}\right] = X_i^T \beta_j \qquad \text{for} \quad j = 1, 2, \ldots J-1 \tag{2}$$

where $\beta_j = \left[\beta_{0j} \quad \beta_{1j} \quad \cdots \quad \beta_{kj}\right]^T$ and $X_i = \left[1 \quad X_{i1} \quad \cdots \quad X_{ik}\right]^T$

(Note that vectors β_j are different for each category j.)

If multiple response categories are treated as ordered, the logistic regression model could be reduced to J - 1 cumulative logits as follows:

$$\log\left[\frac{p(Y_i \le j)}{1-p(Y_i \le j)}\right] = \alpha_j + X_i^T \beta \qquad \text{for} \quad j = 1, 2, \ldots J-1 \tag{3}$$

The difference between the ordinal response logits and the nominal response logits is that each of the J - 1 parameter vectors β_j is unique for the nominal case; for ordinal response, the slope coefficient vector β is identical for each of the J - 1 cumulative logits, and only the intercepts α_i differ. Finally, the cumulative probabilities $p(Y_i \le j)$ for the ordinal logistic regression model is given as follows:

$$p(Y_i \le j) = \frac{\exp(\alpha_i + X_i^T \beta)}{1+\exp(\alpha_i + X_i^T \beta)} \qquad \text{for} \quad j = 1, 2, \ldots J-1 \tag{4}$$

The maximum likelihood method is used to estimate the unknown parameters. The package VGAM developed by Yee in R (http://www.r-project.org) was used to develop the ordinal polytomous logistic regression model.

Forecast verification

Forecast verification aims to evaluate the agreement between forecasts and observations (Katz and Murphy, 1997; Stephenson, 2003). The Brier skill score (BSS) and the ranked probability skill score (RPSS) are common statistics used to measure the improvement in the accuracy of multicategory probability forecasts over a naïve forecasting method such as climatology.

The Brier skill score (BSS) (Dogget, 1998) is defined as

$$BSS = 1 - BS / BSC \tag{5}$$

where BS is the Brier score, and is defined as

$$BS = (1/n)\Sigma(f_i - l(\text{obs}_i))^2 \tag{6}$$

where f_i is the forecast probability of event i occurring; $l(\text{obs}_i)$ is an indicator variable (1 if event in category i occurs, else 0); n is the number of events; and BSC is the climatologically expected

value of *BS*, and is defined as $BSC = P_i * (1 - P_i)$, where P_i is the climatological probability of the event. The Brier score is often applied to events that exceed a given threshold, but it can also be applied to categorical events. In this study, we consider three tercile categories, i.e., below normal, normal and above normal. Accordingly, $BSC = (1/3)*(1-1/3) = 0.222$ for each category. A perfect forecast has a value of BSS of 1; positive values between zero and one indicate forecast performance better than climatology, and negative values indicate forecast performance worse than climatology.

The ranked probability score (*RPS*) evaluates the sum of the squared differences in the cumulative probability space, so that

$$RPS = \frac{1}{K-1}\sum_{m=1}^{K}\left[\left(\sum_{k=1}^{m} f_k\right) - \left(\sum_{k=1}^{m} o_K\right)\right]^2 \tag{7}$$

where K is the number of forecast categories (below normal, normal and above normal), f_k is the forecast probability for the k^{th} point, and o_k equals zero or one to indicate whether or not the observed flow is in the k^{th} category. The use of *RPS* results in higher penalties for forecasts farther away from actual outcomes, rather than scoring based on only hit and miss. The *RPS* can assume a number between zero and one, with a perfect forecast scoring zero. The *RPSS* then measures the relative improvement of using a forecast over climatology alone, and is given by

$$RPSS = \frac{\overline{RPS} - \overline{RPS}_{climatology}}{o - \overline{RPS}_{climatology}} = 1 - \frac{\overline{RPS}}{\overline{RPS}_{climatology}} \tag{8}$$

The probabilities of streamflow in each category in the climatology forecast (i.e., prior probabilities) are the same and equal 1/3 due to the definition of the flow regimes. Thus, the *RPS* values of the three categories (below normal, normal and above normal) in the climatology forecast are 0.278, 0.111 and 0.278, respectively. A perfect *RPSS* is 1, and negative scores indicate that forecasts performed worse than climatology.

Results

The polytomous logistic regression model for ordinal response described above was applied for forecasting flows in the Highland Lakes system in central Texas. In the model, streamflow persistence (month-to-month, month-to-season or season-to-season correlation) was used as potential predictor variable. The probabilities of three tercile categories of streamflow with one month or one season lead time were predicted. For example, the winter (JFM) streamflow was forecasted based on the previous fall (OND(-1)) streamflow (one season lead time). The January streamflow was predicted using the previous December streamflow (one month lead time), and so on. Performance metrics are based on the leave-one-out cross-validation method, which selects a single data point of the sample for validation and the remaining data points for training data until each data point in the sample is used once as the validation data.

A summary of the results for reservoir inflow forecasts is presented in Tables 1 and 2. Table 1 shows the regression coefficients of streamflow persistence with different lead times, along with the corresponding Wald test p-values. The hypothesis in the Wald test is:

$$H_0: \beta_k = 0 : \ H_a: \ \beta_k \neq 0 \quad \text{for } k = 1, \ldots. 5. \tag{9}$$

Wald test p-values are all much less than 0.05, indicating that the regression coefficients are statistically significant at the 0.05 level and corresponding predictor (streamflow with one to three months lead time) should be retained in the model. Table 2 presents the values of BSS and RPSS, which are consistence with the above analysis. The BSS values show that winter (JFM) streamflow forecast with one month and one season lead times have 19.7% and 31.6% improvement over the climatology, respectively. Monthly streamflow forecasts with one month lead time during winter have an average 37.8% improvement over the climatology. The RPSS values indicate that forecasts have 16.7% and 29.3% improvement over climatology for one month and one season lead times, respectively. According to the RPSS values, the monthly streamflow forecasts with one month lead during winter period have a 34.9% improvement over climatology, on average.

Summary

This work aimed to improve the long-term (from monthly to seasonal) streamflow forecasts for the Highland Lakes system in central Texas. A direct and effective method for producing the probabilistic categorical streamflow forecast using ordinal polytomous logistic regression is presented, with hydrological persistence (month-to-month, month-to-season and season-to-season) examined as the basis for streamflow forecasts. Results indicate that persistence is a very useful predictor for monthly and seasonal streamflow forecasts during winter period. The Brier Skill Score (BSS) and Ranked Probability Skill Score (RPSS), in particular, indicate a significant improvement over climatology. The method presented here is fully transferable to other regions where significant hydrologic persistence exists.

This method is also applicable for other predictors, including large-scale climate signals such as ENSO, PDO, NAO and AMO. These will be investigated in future work for their potential to

improve long-term (seasonal or annual) streamflow prediction. To this end, a higher order polytomous logistic regression model, called polynomial logistic regression, may be developed to incorporate the large-scale climate signals and their interactions into the forecast model.

Acknowledgment

Adjusted flow data and helpful advice was provided by Ron Anderson of the Lower Colorado River Authority.

Providing a Physical Basis for Statistical Homogeneity in Regional Frequency Analyses

Fredline Ilorme[1] and Veronica W. Griffis[2]

Abstract

To estimate the magnitude and frequency of flood flows at ungauged sites, space is traded for time using a regional frequency analysis. This requires the delineation of homogeneous regions in which the flood regime is sufficiently similar to allow the spatial transfer of information to ungauged sites. However, the ability to do so with adequate precision is hindered by our limited knowledge of the physical properties and mechanisms that produce flood flows. In addition, the actual delineation of regions is highly dependent on the similarity measures and classification techniques employed. It is generally accepted that similarity in the flood regime is indicated by similarity in basin characteristics, and thus these basin characteristics can be used to delineate regions and to classify ungauged sites. However, recent evidence suggests this is not the case. The objective of this research is to evaluate whether or not regions which are statistically homogeneous are also physically homogeneous. Preliminary results using data for 480 sites in the Southeastern U.S. are presented in this paper. Multivariate statistical methods were employed to delineate regions based on physical basin characteristics and at-site flood statistics. The delineated regions were then assessed from both a physical and statistical viewpoint.

Introduction

Accurate estimates of flood quantiles are necessary for floodplain definition and management, and for the design of water-use and water-control projects, as well as transportation infrastructure such as bridges and roads. Obtaining such estimates, however, is problematic because of the uncertainty in estimates based on individual station records shorter than the return period of interest, and is even more troublesome when the site of interest is ungauged. To compensate for limited or unavailable data, one solution is to trade space for time using a regional frequency analysis, wherein the characterization of flood flows at sites of interest is derived using information pooled from nearby hydrologically similar gauged sites (NRC 1988). Common approaches are the Index Flood procedure (e.g. Dalrymple 1960; Hosking and Wallis 1988, 1997; Stedinger and Lu 1995; Kjeldsen and Rosberg 2002), and regional regression procedures, such as weighted and generalized least squares regression (e.g. Tasker and Stedinger 1989; Tasker et al. 1996; Madsen and Rosberg 1997; Eng et al. 2007ab; Griffis and Stedinger 2007).

An important component of regional flood frequency analysis is the delineation of homogeneous regions (or groups of sites) in which the flood regime is deemed sufficiently similar to allow the spatial transfer of information to ungauged sites (see for example, Stedinger and Lu 1995, and citations therein). The flood regime includes the magnitude, timing, duration, frequency, and inter-annual variability of flood events. It is generally assumed that the flood regime, or hydrologic response, is similar at sites with comparable basin characteristics (e.g. physiographic characteristics and meteorologic inputs). More recent studies have observed, however, that similar hydrologic response is not guaranteed simply by similar basin characteristics because of complex interactions among those characteristics (Zrinji and Burn 1994; Burn 1997; Burn et al. 1997).

Regional quantile models and flood frequency analyses in general are based on superficial relationships between flood quantiles and physiographic characteristics (Potter 1987; Gupta et al. 1994). These models are hindered by our limited knowledge of the physical properties and mechanisms producing flood flows. Typically only log-log and log-linear relationships between flood quantiles and basin characteristics are employed, and in most cases only drainage area is determined to be useful for estimating flood quantiles at ungauged sites (Eng et al. 2007b; Griffis and Stedinger 2007). More complex relationships and interactions between basin characteristics are generally not considered because the current understanding of hydrology is not advanced enough to know if such a model is reasonable (Eng et al. 2007b; Griffis and Stedinger 2007). Thus, models of flood quantiles and other statistics at ungauged sites can be improved by increasing our knowledge of what basin characteristics, or interactions among basin characteristics, predominantly contribute to flood flows.

For regional regression analyses, regions are often formed as a matter of convenience, such as using state boundaries. In regards to index flood procedures, the delineation of homogeneous regions involves three major steps: (1) selection of an appropriate set of attributes; (2) application of a statistical classification technique; and (3) tests of the homogeneity of delineated regions. A variety of attributes and classification techniques have been employed in the hydrologic literature (for example, GREHYS 1996a; Burn 1997; Burn et al. 1997; Hosking and Wallis 1997; Chiang et al. 2002a,b; Isik and Singh 2008). The delineated regions are dependent on the choice of similarity measures and the classification technique employed (see for example, GREHYS 19961b; Castellarin et al. 2001).

Burn (1997) and Burn et al. (1997) observe that the selection of appropriate catchment similarity measures is complicated by the need to employ measurable features that are indicative of hydrologic response, and allow classification of an ungauged site within a delineated region, as well as the development of a regional quantile estimator for use at ungauged sites. Thus, similarity measures derived from the observed flood series, such as at-site flood statistics and measures related to the timing and seasonality of flood peaks, should not be employed. Use of at-site flood statistics as similarity measures is also not appropriate because subsequent tests to verify the homogeneity of delineated regions are based on the same statistics (Burn

1990, 1997). As a result, the delineated regions may appear homogeneous, but would be inefficient for developing regional quantile estimators.

Further, current techniques for delineating regions do not guarantee statistical homogeneity in terms of the probability distributions representing annual maximum flood series and the subsequent quantile relations. These methods also only superficially provide homogeneity from a physical viewpoint. Rao and Srinivas (2006) observe that regions identified using a variety of clustering algorithms are generally not statistically homogeneous; however, the regions do tend to align with geographical features and soil characteristics. Potentially more informative sets of similarity measures which include the composite effects on flood quantiles due to complex interactions among the basin characteristics have yet to be considered.

The primary objective of this research is to determine if regions which are statistically homogeneous are also homogeneous from a physical viewpoint. In the context of this research, a statistically homogeneous region is defined as one in which the flood response at gauging stations are deemed sufficiently similar on the basis of statistics of the at-site flood distribution. Physically homogeneous regions are those in which the physical basin characteristics are reasonably similar. Preliminary results for 480 sites in the Southeastern United States are presented below.

Study Area and Data Employed

The study area considered in this paper is defined by the watershed spanning the Southeastern United States (Alabama, Tennessee, Florida, Georgia, South Carolina, North Carolina and Virgina). A total of 480 unimpaired U.S. Geological Survey (USGS) gauging stations were considered in this analysis (see Figure 1). These sites were identified using the Hydro-Climatic Data Network (Slack et al. 1993). Annual maximum peak streamflow data were collected for each gauging station from the USGS website (http://nwis.waterdata.usgs.gov/usa/nwis/peak). Summary statistics for the flood series are presented in Table 1 by state.

Table 1: Number of sites per state and record length statistics

State	Number of sites	Minimum record length	Maximum record length	Average record length
Alabama	25	25	77	49
Florida	19	27	81	50
Georgia	169	25	115	43
N. Carolina	118	19	111	55
S. Carolina	38	26	79	51
Tennessee	64	16	131	47
Virginia	47	25	108	53

A number of basin characteristics are considered in this study. For each site, Gruber and Stedinger (2007) provided data on the following ten characteristics: drainage area (A), main channel slope (S_{Ch}), main basin slope (S_B), basin shape (Sh)

computed as a ratio of the main channel length squared to the drainage area, mean basin elevation (E), mean annual precipitation (Pr), percent impervious surface (Imp), percent forest cover (F), average soil drainage index (SI) as a measure of soil moisture, and average hydrologic soil index (Inf) as a measure of infiltration.

Methodology

The methodology employed to evaluate the statistical and physical homogeneity of delineated regions will include five main steps:

1. Delineate statistically homogeneous regions based on at-site flood statistics.
2. Assess the similarity of basin characteristics (i.e. physical homogeneity) within the statistically homogeneous regions delineated in step (1).
3. Assess the dissimilarity of basin characteristics among the statistically homogeneous regions delineated in step (1).
4. Delineate regions on the basis of observable basin characteristics.
5. Assess the statistical homogeneity of the physically homogeneous regions delineated in step (4).

These steps are described in more detail below.

Statistically homogeneous regions in which the flood regime is sufficiently similar from site to site could be delineated on the basis of at-site flood statistics such as the 100-year event (Q_{100}), L-moments, or a measure of the seasonality of flood peaks. The preliminary results presented in this paper consider regions delineated based on the Coefficient of L-Variation (L-CV). Use of the L-CV is advantageous as it is a distribution free measure of the shape of the at-site distribution (Hosking and Wallis 1997).

Regions will be delineated using the Ward clustering algorithm (Johnson and Wichern 2002, pp. 690-692). Each delineated region will be evaluated to determine if criteria for statistical homogeneity have been met. These criteria indicate whether or not the sites in a region have similar probability distributions representing the observed annual maximum flood series. For regional flood frequency analysis, Hosking and Wallis (1997) compare sample L-moments among sites as a means of region validation. In particular, they propose a set of H-statistics, which measure the average distance from the individual site statistics (L-moments and L-moment ratios) to the regional average values. If a region is not deemed sufficiently homogeneous, then the sites therein will be scrutinized further to see if particular sites are influencing the results using a discordancy measure (Hosking and Wallis 1997).

The physical homogeneity of each statistically homogeneous region will be assessed using techniques such as cluster analysis (CA) and principal component analysis (PCA). These techniques will assist in identifying common basin characteristics within a delineated region. For each statistically homogeneous region, CA and PCA will be applied to the ten basin characteristics listed above.

Alternatively, the dissimilarities in the basin characteristics in different statistically homogeneous regions will be identified using canonical correlation

analysis (CCA). In general, CCA results in a series of discriminant functions (or canonical variates) which separate the groups (or delineated regions) as much as possible. The discriminant functions are formed for optimal combinations of variables, such that the first discriminant function provides the most information pertaining to the differences between groups; subsequent discriminant functions provide successively less information pertaining to the differences. In addition, the discriminant functions are orthogonal such that their individual contributions to our understanding of the differences between groups do not overlap. The first few discriminant functions resulting from the CCA should reveal the primary physical differences between the delineated regions. The extent to which the basin characteristics of sites identified as discordant differ from the remaining sites will also be investigated.

In addition, regions will be delineated on the basis of the ten basin characteristics using the Ward clustering algorithm. The statistical homogeneity of these physically homogenous regions with then be assessed using the H-statistics and discordancy measure of Hosking and Wallis (1997).

Preliminary Results

Using the ward clustering algorithm, six statistically homogeneous regions were delineated on the basis of the L-CV and sis physically homogeneous regions were delineated on the basis of the ten basin characteristics under consideration. The resulting regions are illustrated in Figures 1 and 2 for the L-CV and the basin characteristics, respectively. The number of regions delineated in each case was optimized according to the pseudo F-test which maximizes the differences between the regions (Fovell and Fovell, 1993). Although it is difficult to discern any patterns in the delineated regions, a quick comparison of the two figures indicates that regions delineated using physical basin characteristics are not consistent with those delineated based on the L-CV.

Tables 2 and 3 provide the mean and standard deviation of the basin characteristics and the L-CV for the regions illustrated in Figures 1 and 2, respectively. Overall, the results in Table 2 reveal that there is very little difference between the statistically homogeneous regions in terms of the basin shape (Sh), mean annual precipitation (Pr), percent impervious surface (Imp), percent forest cover (F), average soil drainage index (SI), and average hydrologic soil index (Inf). This suggests that these basin characteristics do not contribute significantly to the hydrologic regime of annual maximum flood series. The differences among the statistically homogeneous regions in terms of the remaining basin characteristics are unclear because the standard deviation of each characteristic is quite large relative to the mean. However, the average of the drainage area (A), main basin slope (S_B), and mean basin elevation (E) tends to be inversely related to the magnitude of the L-CV.

Fewer observations can be made based on the results in Table 3 for regions delineated based on watershed characteristics. Overall, there is very little difference between the delineated regions in terms of the basin characteristics basin shape (Sh), mean annual precipitation (Pr), average soil drainage index (SI), and average hydrologic soil index (Inf). Thus, these characteristics are not responsible for the clustering of sites. However, it is unclear which of the remaining characteristics governed the clustering. Simple two-sample t-tests performed on a pairwise basis suggest significant differences between the delineated regions in terms of the average values of the main channel slope (S_{Ch}), main basin length (S_B), percent impervious surface (Imp), and percent forest cover (F). The use of multivariate statistical techniques in future analyses should reveal more conclusive results.

Summary

The significance of this research lies in the fact that more accurate estimators of quantiles and the associated flood risk are needed at ungauged sites and sites with limited data. To this end, available data must be used more efficiently, and our understanding of the underlying relationships between basin characteristics and the flood regime must be improved. As a start in the movement to address this issue, this research will ultimately assess the value of using physical basin characteristics to delineate regions which are sufficiently statistically homogeneous for the transfer of information to data limited and ungauged sites.

Preliminary results indicate that basin characteristics such as the drainage area, main basin slope, and mean basin elevation tend to be inversely related to the magnitude of the L-CV. Thus, these basin characteristics may serve as appropriate attributes for use in delineating regions which are statistically homogeneous.

Admittedly, the results presented herein do not provide much insight as to how the basin characteristics differ among the statistically homogeneous regions. More definitive results are expected from future analyses using multivariate statistical methods such as cluster analysis, principal component analysis, and canonical correlation analysis as outlined in the Methodology section above.

Future work will also include an assessment of the impact on quantile estimates due to differences in region delineation resulting from the use of at-site flood statistics such as the L-CV for clustering versus physical basin characteristics. In addition, the same methodology will be applied to the U.S. portion of the Great Lakes basin in order to consider a wider range of geographic locales and potentially a wider variety of flood generating mechanisms (e.g., snowpack).

ABSTRACT

Our environment is changing rapidly in many regions of the world, with often-significant implications for current and future water resources. Disturbances to the current environmental system include land cover change, and the increasing impacts of a changing climate. The potential of developing successful strategies to respond to these changes lies in our capacity to anticipate their impact. One important question in this context is the potential change to streamflow characteristics at the watershed scale. However, most watersheds in the US and elsewhere are ungauged, leading to large uncertainty in our hydrological predictions to establish benchmarks, which are often the basis for the development of water resources management strategies. How can we obtain a reliable and continuous spatio-temporal picture of regional environmental status, trends and long-term projections to identify information gaps – and thus monitoring needs – and likely hot spots and hot moments where for example critical ecosystem thresholds are exceeded or will be exceeded in the future? This paper presents a methodology to formalize regional information on streamflow characteristics using a Mixture of Gaussians approach, which provides constraints on continuous watershed simulations. US examples show how this approach leads to reduced uncertainty in continuous streamflow predictions for water management in ungauged basins and in terms of potential change impacts.

INTRODUCTION

"*The United States is facing unprecedented environmental changes, but decision makers do not have the information they need to understand and respond to these changes in a timely fashion*" (Heinz Center, 2008; see also The White House, 2008). Stresses to the environment include land cover change (DeWalle et al., 2000; Poff et al., 2006a;b), and the increasing impacts of changing climate (U.S. Climate Change Science Program, 2008). The potential of developing successful strategies to deal with these changes lies in our capacity to anticipate their impact (Clark et al., 2001; U.S. Government Accountability Office, 2007). Watersheds collect, store and release incoming precipitation and thus provide important freshwater (watershed)

services for aquatic ecosystems and for people (Wagener et al., 2008; see also Brauman et al., 2007). Headwaters (Poff et al., 2006a;b) are increasingly recognized for their importance in controlling ecological and water quality functions throughout river basins (Lowe and Likens, 2005). Headwaters contain over 50% of the total strength length in the US – excluding Alaska (Nadeau and Rains, 2007), and a much higher percentage in certain regions, for example in most of the Eastern US. They are however severely under-represented in operational gauging (Freeman et al., 2007), where nearly 95% of smaller streams are poorly characterized with less than 3% of all gauges (Poff et al., 2006a;b). At the same time, processes and ecosystem habitats in headwaters are particularly sensitive to atmospheric and terrestrial disturbances (Buttle and Meatcalf, 2000). The National Research Council (NRC, 2004) stresses that the lack of gauges in small streams requires research into better modeling tools for streamflow simulations across hydroclimatic and geologic settings. "… *for the majority of streams that support aquatic life, a systematic understanding is lacking on water quality, habitat, biota, specific discharge*, …" (Bishop et al., 2008). How can we obtain a continuous spatio-temporal picture of regional environmental status, trends and long-term projections? Since "… *protecting the long-term ecological integrity and ecosystem services of natural systems, whether aquatic or terrestrial, cannot succeed without a foundation of intact and functional headwaters*" (Lowe and Likens, 2005). The maintenance of these services will require significant advances in our understanding and in our ability to predict natural system response patterns and their controls (Palmer et al., 2004). We need to address the "… *increasingly evident need for regional-scale interdisciplinary investigations that integrate observations, data and information systems, process studies, and models with the process detail and spatial resolution necessary to advance scientific understanding of ecosystem processes and the impacts of multiple interlinked environmental stresses*" (NCAR, 2002).

Models of watershed hydrology are the tools used to quantify our state of knowledge about the underlying system and to predict future watershed behavior. The unavoidable uncertainty present provides an indicator of the state of our science (Beven, 2006), and quantifies our degree of confidence for decision-making (Reckhow, 1994). In gauged watersheds, conditioning the model on available observations of the response variable can reduce uncertainty. In ungauged watersheds, model application has so far meant reducing the uncertainty on *a priori* parameter estimates (Atkinson et al., 2003; Koren et al., 2003) or on regionalized parameter sets (Lamb, 2000; Bloeschl, 2005). Both approaches still result in significant uncertainties (McIntyre et al., 2005) and are ultimately limited by our current lack of ability to observe bulk hydraulic properties of the environment at the model element scale (Wagener and Wheater, 2006; Beven, 2001), even if the model is physically-based (Parkin et al., 1996). "*Given the increasingly widespread usage of watershed models for solving environmental problems, the regionalization of watershed models may be one of the most challenging and fundamental problems within the entire field of hydrology*" (Vogel, 2006). However, current streamflow predictions are uncertain if local observations of the watershed response are not available for model calibration (Sivapalan et al., 2003), as is the case for most headwater streams (Freeman et al., 2007), a situation that is even worse in the global

context where existing monitoring networks are declining (Stockstad, 1999). Thus significantly limiting the possible assessment of conditions and trends in ecosystem services (e.g. Millennium Ecosystem Assessment (MEA, 2005)), and for water resources applications especially in those regions of the world where resources for hazard mitigation and adaptation are extremely poor (GRDC, 2004; Widen-Nillson et al., 2007). Advancement in this area is most likely to come from the synthesis of state-of-the-art observations, models and theory (Kirchner, 2006; Bloeschl, 2006).

Our ability to predict the hydrologic response behavior of watersheds is crucial for operational applications such as flood and drought prediction, and it is evidence of our degree of understanding (or lack thereof) of hydrologic systems. In this paper we discuss a new approach to derive continuous ensemble predictions in ungauged basins. Watersheds form a landscape element (at various scales) that integrates all aspects of the hydrological cycle within a defined area that can be studied, quantified and acted upon. The hydrologic response (e.g. streamflow) is depending on the functions that a specific watershed exerts on the precipitation it collects. Those functions include the partitioning of water into different pathways at the land surface, the storage of water (in fluid or solid form) in different stores with different residence times, and the release of water through different pathways for example as streamflow or evaporation (Wagener et al., 2007). The watershed also transmits water between hillslopes, the riparian zone and the river network; and it acts as a conveyance system for mass and energy (Brutsaert, 2005). These functional characteristics of watershed are reflected in the observed response behavior, i.e. the response provides a signature of the specific functional behavior of a watershed. Being able to link functional behavior and signatures, and being able to predict the functional behavior based on knowledge of physical watershed characteristics and the regional climatic regime would provide a significant advancement to the current state of hydrologic science. Winter (2001) for example suggests that *"... areas having similar land slopes, surficial geology, and climate will result in similar hydrologic flow paths regardless of the geographic location of the site"*. Such behavioral characteristics or signatures typically include characteristics of streamflow, but could also be extended to evaporation, groundwater dynamics, soil moisture dynamics, snow cover, distributions of residence time and water age, isotopic composition, concentrations of chemicals such as chloride and nitrate (Sivapalan 2005). In this paper we discuss how such regional relationships can be established and used in an optimization framework to reduce the uncertainty in predictions in ungauged basins. We close with a brief discussion of how such a prediction in ungauged basins (PUB) framework can be linked with the concept of watershed services to explicitly address water resource management issues.

CONDITIONING WATERSHED MODELS ON REGIONAL CONSTRAINTS

As identified above, a problem common to all watershed models is that they require some degree of parameter calibration to achieve reliable predictions, i.e. a process in which the model parameters are adjusted (manually or automatically) until observed and simulated watershed responses match as closely as possible. This calibration step is by definition not possible if the watershed is ungauged or went through significant

changes, e.g. land use. As discussed, two main approaches have been used to compensate this lack of calibration – estimation of parameters directly from local physical characteristics or through regional equations. Reducing the uncertainty on predictions in ungauged basins from which both approaches suffer is a current focal point of the hydrologic community (Sivapalan et al., 2003).

An alternative to the derivation of *a priori* model parameter estimates from physical watershed characteristics lies in the regionalization of streamflow signatures. Prior studies have found that the correlation between streamflow signatures and physical watershed characteristics is often significantly higher than between model parameters and watershed characteristics (e.g. Poff et al., 2006a;b; Yadav et al., 2007). Although the correlation between streamflow and watershed characteristics does not directly provide predictions of the continuous streamflow hydrograph, regionalized flow signatures provide dynamic aspects of the watershed system that can be used to constrain hydrologic model predictions, even if they are only known with some degree of uncertainty. Yadav et al. (2007) revised the regionalization of flow characteristics by including estimates of uncertainty in the regression equations. Uncertainty ranges, in addition to the expected values of flow characteristics, are valuable sources of information for constraining a model and thus for creating ensemble predictions at ungauged locations. Yadav et al. (2007) showed in a pilot study using 30 UK watersheds how this regionalized information can be used to constrain ensemble predictions of any model at ungauged sites. Dominant controlling characteristics were found to be climate (wetness index), topography (slope), and hydrogeology. Main streamflow signatures were high pulse count (defined as how many times the flow exceeded three-times the mean flow per year), runoff ratio (the long term ratio of streamflow to precipitation), and the slope of the flow duration curve (between the 33rd and 66th percentiles). Streamflow ensembles from *a priori* (unconstrained) feasible parameter sets produced very uncertain predictions at ungauged locations. This uncertainty was significantly reduced when ensemble members that conflicted with the regionalized flow signatures (i.e. the constraints) were rejected. The work of Yadav et al. (2008) provides an avenue to assimilate regional information to reduce the uncertainty in continuous predictions of streamflow at ungauged locations, and could possibly be used to assess the impact of change (Wagener, 2007).

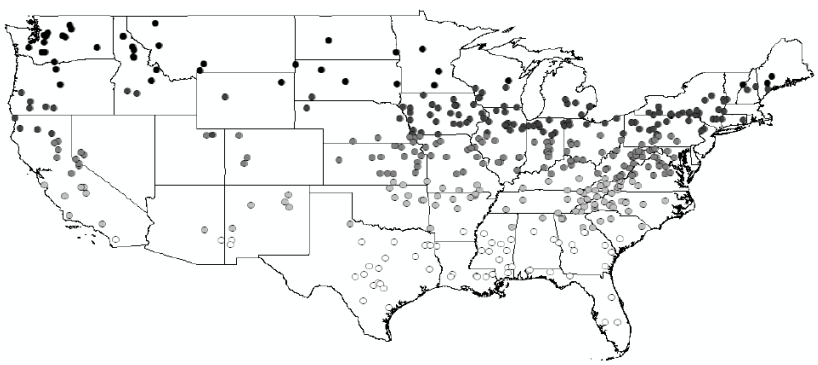

Figure 1. Over 400 watersheds with daily hydro-meteorological data were used to derive the joint PDF shown in Figure 2.

Recently, we started working on replacing the regression based definition of regional constraints with a Mixtures of Gaussian approach (Wojcik et al., 2006). Gaussian Mixture Models (GMMs) are linear combinations of Gaussian densities and provide a nonparametric approach to deriving PDFs. Combared to regression analysis, GMMs do not require potentially restrictive assumptions about the PDF underlying the data (e.g. Gaussian). Rather, they can approximate any continuous density to any precision while adapting even to complex geometries (McLachlan and Peel, 2000). A preliminary result of this approach to derive regional PDFs is shown in Figure 2.

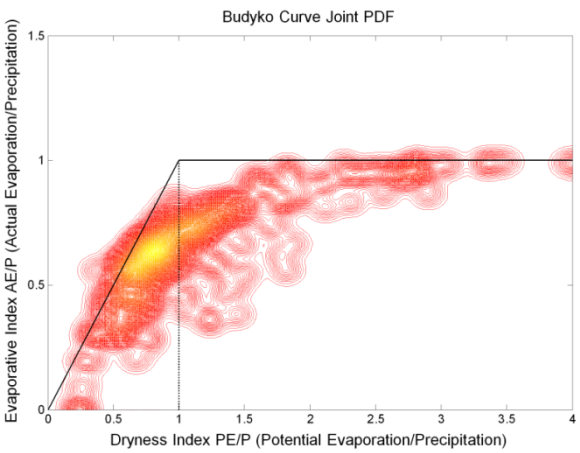

Figure 2. Preliminary result showing a joint probability density function (PDF) of evaporative and dryness indices derived using Mixtures of Gaussians. This graph is often referred to as Budyko curve (Budyko, 1974). The PDF is based on an analysis of over 400 watersheds distributed across the US (MOPEX database). Conditional PDFs of the evaporative index in ungauged watersheds can be derived from knowledge of long-term precipitation and potential evaporation of the specific location. Knowledge of the evaporative index provides an estimate of the expected long-term runoff ratio (a signature) of the ungauged location, and thus a constraint on the watershed yield.

However, the search for parameter sets providing simulations that fall within the regional behavioral signature space has proven to be very cumbersome in many cases (Zhang et al., 2008). At the same time, there have been decades of research into developing powerful global optimization algorithms (Wagener and Gupta, 2005) that, as yet, are unused in ungauged circumstances. Zhang et al. (2008) recently suggested a solution to this problem by introducing a novel multiobjective framework for identifying behavioral parameter ensembles for ungauged basins using suites of regionalized hydrologic signatures, i.e. constraints (Figure 3). The new formulation enables, for the first time, the use of multiobjective optimization algorithms for the identification of model ensembles (i.e. parameter sets within a selected model structure) for predictions in ungauged basins. In this approach, the behavioral signature space is assumed to be spherical. The objective is to find solutions (i.e. parameter sets that produce signatures consistent with the constraints) that fill the sphere, since all solutions on the inside are considered equally likely (in this

formulation). A trade-off is created by defining objective functions that search for solutions close to the centre of the sphere and close to the edge. Application of the new formulation to the 30 watersheds of Yadav et al. (2007) in a three constraints problem, and a comparison of the results with the previously used Monte Carlo approach demonstrated that the new formulation significantly advances our ability to reduce the uncertainty of PUB. The high efficiency and robustness of the ε-NSGAII (the multiobjective Genetic Algorithm used in their study, for details see Tang et al., 2006) in finding behavioral parameter sets indicates that (1) more complex (incl. distributed) hydrologic model decision spaces can be searched using the multi-objective PUB framework presented in this study, and (2) an increasing number of hydrologic indices can be tested for constraining ensemble predictions for ungauged basins. Zhang et al. (2008) demonstrate that PUB can be viewed as a new class of multiobjective search problems. Reformulating the PUB problem as a multiobjective search for behavioral model parameter sets, generalizes our ability to test a wide range and number of hydrologic signatures to maximize our use of the information available in streamflow datasets. The PUB problem formulation contributed in their study can be easily adapted to solve larger, more computationally demanding model identification problems. This will have particular value for future studies seeking to develop high fidelity, probabilistic scenarios for environmental change under uncertainty (Wagener, 2007).

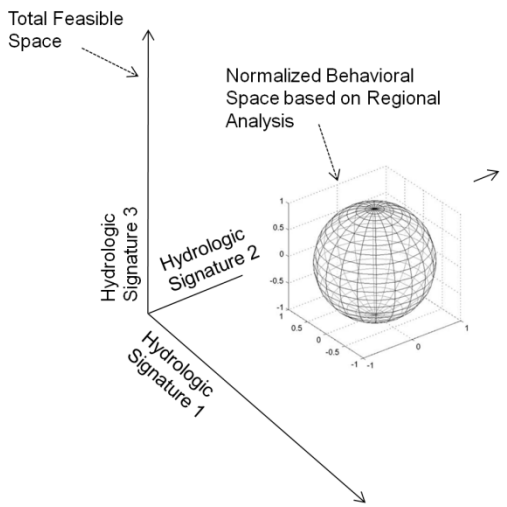

Figure 3. Conceptual representation of a three constraint (signature) search space including the behavioral solutions' sphere as defined by Zhang et al. (2008).

CONCLUSIONS AND OUTLOOK

In conclusion, it is important to look towards how this discussion on PUB can ultimately advance our ability to better use models in support of water management for water security of humans and ecosystems from water scarcity or excess. While hydrologic signatures describe hydrologically relevant characteristics of the watershed response, it is crucial to explicitly include the implication of the values of

different streamflow characteristics for humans and ecosystems. Such an inclusion would explicitly define the societal relevance of watershed behavior. We can distinguish positive and negative implications of watershed functions for humans and ecosystems. Benefits received by humans supplied by resources and processes of natural ecosystems have become known as ecosystem services (e.g. Daily, 1997). Here, we are concerned with the positive impacts or benefits received by nature (ecosystems) and humans from resources and processes supplied by watersheds, and will therefore refer to these as ***watershed services*** (Wagener et al., 2008). The PUB approach discussed, based on physical characteristics, climatic characteristics and signatures, can provide significant advances to our ability to predict the continuous streamflow response of ungauged basins. These ensembles predictions subsequently enable us to extract any (streamflow related) indicator that relates to watershed services (or disservices) provided to humans or ecosystems.

ABSTRACT

The San Joaquin River is a prominent and important feature of California's Central Valley. Historically, spring runoff from Sierra streams would spread over a valley floor covered by marshes and seasonal wetlands. In 1942, Reclamation completed construction of Friant Dam, ceasing flow to some portions of the river and ultimately led to the extirpation of salmon runs in the San Joaquin. In 1988, a coalition of environmental groups challenged renewal of long-term water service contracts to the CVP Friant Division contractors. On September 13, 2006, after more than 18 years of litigation, all litigants signed onto a Stipulation of Settlement.

A significant challenge to the implementation of the Settlement will be creating an adaptive management plan for a river which has not provided a connected ecosystem in over fifty years. The monitoring plan discussed in this paper is being developed to assist in the adaptive management of the Settlement.

INTRODUCTION

The San Joaquin River is a prominent and important feature of California's Central Valley. Originating in Sierra Nevada Mountains, the San Joaquin conveys high mountain snowmelt to the valley floor before turning north and becoming the second largest river in California and the backbone of a multiple-river system draining the southern half of the Central Valley. The river's water feeds the Sacramento-San Joaquin Delta and ultimately flows to the Pacific Ocean under the Golden Gate Bridge in San Francisco Bay.

Historically, spring runoff from Sierra streams would spread over a valley floor covered by marshes and seasonal wetlands. These marshes would slowly drain to the Delta, providing rich habitat that supported numerous aquatic and wildlife species, including Chinook salmon. Over the past two centuries, water resource development has dramatically transformed the San Joaquin River. In the late 1880s, the valley lowlands were drained for agriculture, and a series of diversion dams and canals was constructed to support small farms. Over time, hydroelectric development harnessed power in upper portions of the San Joaquin watershed, further modifying the river.

In 1942, Reclamation completed construction of Friant Dam, thereby diverting a substantial amount of the San Joaquin River for agriculture. Today, over 1

million acres of highly productive farmlands along the eastern portion of the San Joaquin Valley rely upon Friant Dam for irrigation. Operation of the dam ceased flow to some portions of the river and ultimately led to the extirpation of salmon runs in the San Joaquin River above its confluence with the Merced River.

OVERVIEW OF THE SETTLEMENT

In 1988, a coalition of environmental groups led by the Natural Resources Defense Council (NRDC), filed a lawsuit challenging the renewal of long-term water service contracts between the United States and the Central Valley Project (CVP) Friant Division contractors, *NRDC et al. v. Kirk Rodgers et al*. On September 13, 2006, after more than 18 years of litigation, NRDC, Friant Water Users Authority (FWUA), and the U.S. Departments of the Interior and Commerce agreed on terms and conditions for a Stipulation of Settlement which was subsequently approved by the U.S. Eastern District Court of California (Court) on October 23, 2006. The Settlement establishes two goals:

- **Restoration Goal –** To restore and maintain fish populations in "good condition" in the mainstem San Joaquin River below Friant Dam to the confluence of the Merced River, including naturally reproducing and self-sustaining populations of salmon and other fish.
- **Water Management Goal –** To reduce or avoid adverse water supply impacts on all of the Friant Division long-term contractors that may result from the Interim Flows and Restoration Flows provided for in the Settlement.

To achieve the Restoration Goal, the Settlement establishes releases of water from Friant Dam and flow targets to the confluence of the Merced River. Additionally, the Settlement calls for a combination of channel and structural modifications along the San Joaquin River below Friant Dam and the reintroduction of Chinook salmon.

To achieve the Restoration Goal, the Settlement establishes releases of water from Friant Dam and flow targets to the confluence of the Merced River. Additionally, the Settlement calls for a combination of channel and structural modifications along the San Joaquin River below Friant Dam and the reintroduction of Chinook salmon.

The activities undertaken to implement the Water Management Goal revolve around water supply arrangements and strategies, and thus fall outside the scope of this paper.

THE SAN JOAQUIN RIVER RESTORATION PROGRAM

The San Joaquin River Restoration Program, SJRRP consists of a multi-agency interdisciplinary team with a co-located office in Sacramento, CA. State and Federal agencies, led by the U.S. Bureau of Reclamation (Reclamation) formed the SJRRP to implement the Stipulation of Settlement. Implementing Agencies are Reclamation, U.S. Fish and Wildlife Service (USFWS), National Marine Fisheries Service (NMFS), California Department of Water Resources (DWR), California Department of Fish and Game (DFG), and California Environmental Protection Agency (CalEPA).

The Settlement includes a detailed timeline for developing and implementing SJRRP actions, as shown Table 1-1.

Table 1-1. Key Settlement and SJRRP Milestones.

Date	Milestone
September 2009	Complete program-level NEPA, NHPA, ESA, CEQA reviews
October 2009	Initiate Interim Flows and Monitoring Program
September 2010	USFWS submits a completed permit application to NMFS for reintroduction of spring-run Chinook salmon
April 2012	NMFS issues a decision on the permit application for reintroduction of spring-run Chinook salmon
December 2012	Reintroduce spring-run and fall-run Chinook salmon
December 2013	Complete Phase 1 improvements Secretary of the Interior, in consultation with the Settling Parties, develops operational guidelines
January 2014	Initiate full Restoration Flows
December 2016	Complete Phase 2 improvements
December 2024	Secretary of Commerce reports to Congress on the progress made in reintroducing spring-run and fall-run Chinook and discusses plans for future implementation of the Settlement
December 2025	Review and revise Restoration Flows, if necessary
January – July 2026	Any party to the Settlement may file a motion to request an increase, decrease, or material change in the quantity and/or timing of the Restoration Flows

Key:
CEQA = California Environmental Quality Act
ESA = Federal Endangered Species Act
NEPA = National Environmental Policy Act
NHPA = National Historic Preservation Act
NMFS = National Marine Fisheries Services
USFWS = U.S. Fish and Wildlife Service

Federal Role in Implementing Settlement

The Settlement identifies the Department of the Interior, through Reclamation, as the lead Federal agency responsible for implementation and the lead National Environmental Policy Act (NEPA) agency in preparing a Program Environmental Impact Statement / Report (PEIS/R). USFWS is the lead Federal agency responsible for reintroduction of spring-run and fall-run Chinook salmon. The Settlement also identifies the Secretary of the U.S. Department of Commerce, through NMFS, as a necessary participant for the reintroduction of spring-run Chinook salmon. Implementation will require federal authorization from the U.S. Congress.

State Role in Implementing Settlement

The Settlement also calls for participation by the State of California (State) through the Natural Resources Agency's DWR and DFG, and through CalEPA. DWR will assist in the Settlement identified physical improvements including flood protection, levee relocation, and modifications to and maintenance of channel facilities. DFG will provide technical assistance on the release of flows and the reintroduction and monitoring of fish, and planning, designing, and constructing facilities to provide fish passage. DWR is the lead California Environmental Quality Act (CEQA) agency in preparing a PEIS/R.

PURPOSE, NEED AND OBJECTIVES OF THE SJRRP

The purpose of the SJRPP is to implement the Settlement. The need for action is to establish changes to the operation of Friant Dam to support achievement of the Restoration Goal, while reducing or avoiding adverse impacts to water deliveries to the Friant Division long-term contractors. The Implementing Agencies identified several objectives that need to be met to successfully achieve the purpose of the SJRRP, including: Release Interim and Restoration flows from Friant Dam, Implementation of channel and structure modifications, Reintroduciton of spring-run and fall-run Chinook salmon, and Development and implementation of monitoring and management plans to incorporate adaptive management into implementation of the Settlement.

Geography of the SJRRP

Much of the restoration effort focuses on a 150-mile reach of the San Joaquin River between Friant Dam and its confluence with the Merced River. This stretch defines the SJRRP's Restoration Area. A significant challenge to the Restoration effort will be redesigning the existing Restoration Area, which contains several physically and operationally distinct reaches, into something which provides a naturally self-sustaining population of salmon. Figure 1 and the following descriptions provide context for the fragmented state of the Restoration Area, today.

Reach 1 begins at Friant Dam and ends at Gravelly Ford, about 39 miles downstream from Friant Dam. An average of about 117,000 acre-feet of water per year is released from Friant Dam for riparian water users. This is the only reach with existing gravel and a river gradient suitable for Chinook salmon spawning. Gravel mining has left many pits, some connected to the river, within the historic floodplain. Reach 1 has become heavily incised since completion of Friant Dam.

Reach 2 meanders across the alluvial fan of the San Joaquin River between Gravelly Ford and Mendota Dam. The channel for Reach 2 and downstream reaches primarily has a sand bed. Sand moving downstream from Reach 1 affects channel capacity in Reach 2.

Except during times of floods, water passing Gravelly Ford typically infiltrates before reaching the Chowchilla Bypass Bifurcation Structure, and therefore, Reach 2B normally does not convey water. Many of the levees in Reach 2

seep water into adjacent fields during flood events. Portions of Reach 2A have become heavily incised since completion of Friant Dam.

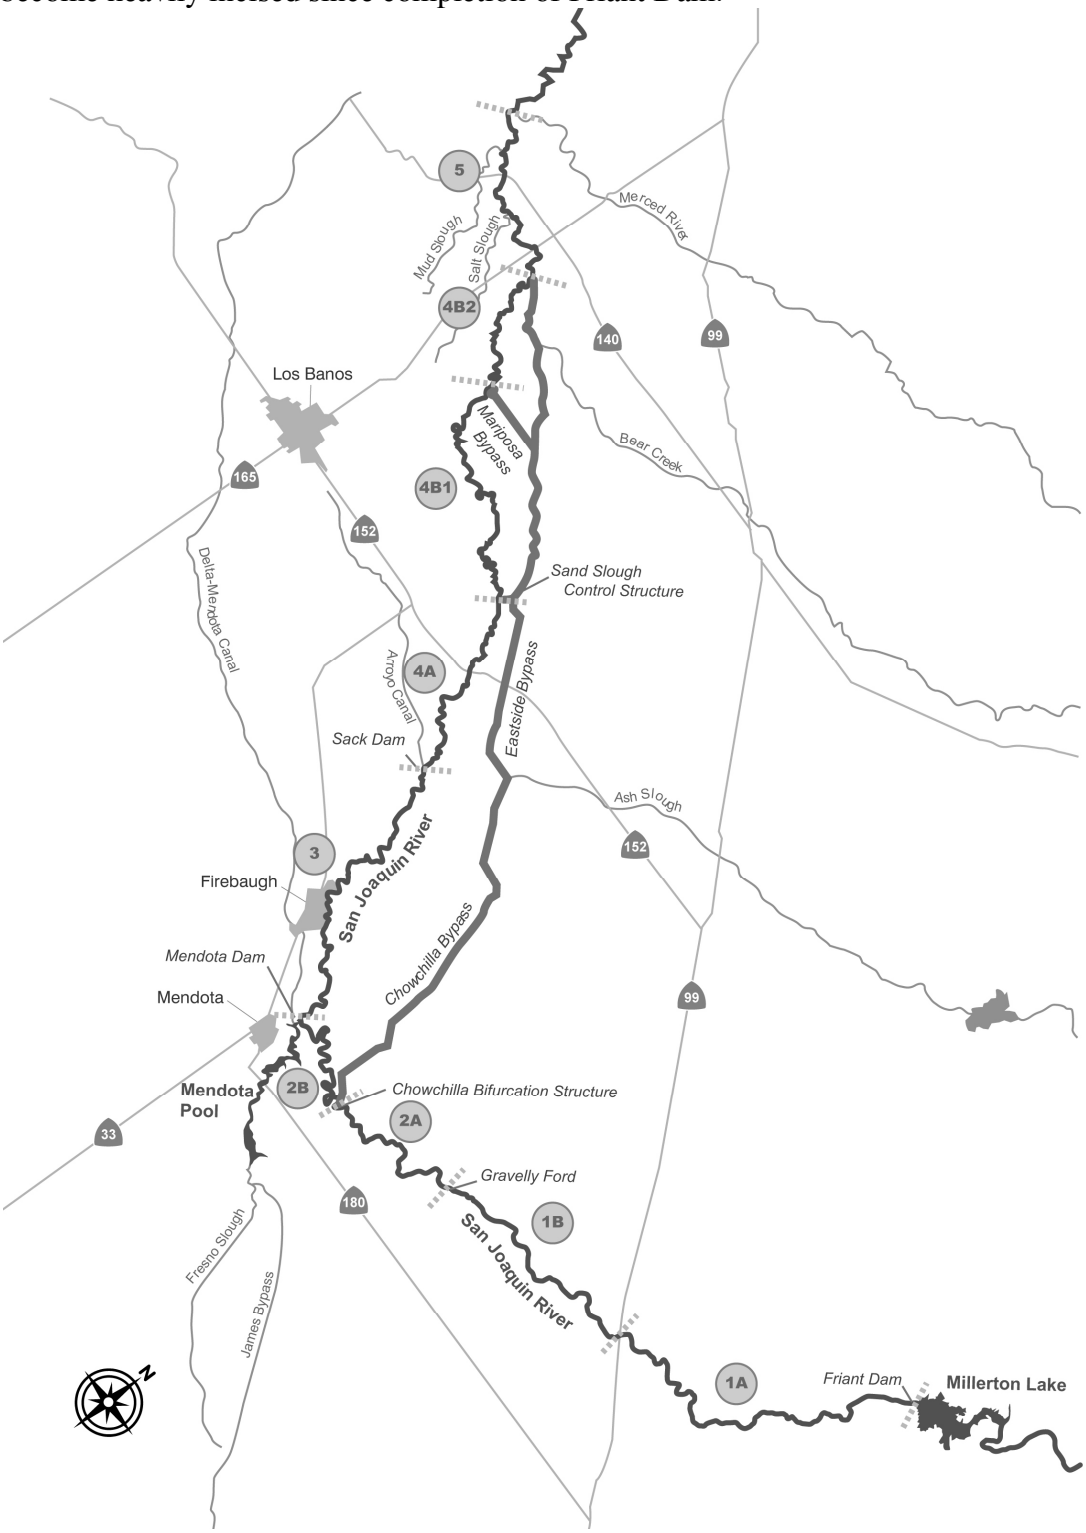

Figure 1 – Reaches of the San Joaquin River within the Restoration Area.

Reach 3 conveys flows of up to 800 cfs for water deliveries from the Delta-Mendota Canal (DMC), through the mainstem San Joaquin River, and to Sack Dam for diversion to Arroyo Canal. For most of its length, this reach is bounded on both sides by irrigation canals.

Reach 4 has been divided into several sub-reaches, but overall extends from Sack Dam to the confluence with Bear Creek and the Eastside Bypass. Except for times of high flows, Reach 4A only carries seepage water from Sack Dam and from adjacent agricultural areas. At the downstream end of Reach 4A, any water in the channel flows into the Eastside Bypass through Sand Slough. Reach 4B1 has not carried flow in many years, and channel capacity has been greatly reduced by vegetation, road crossings, and other obstructions. Although Reach 4B1 was designed to carry 1,500 cfs, portions of Reach 4B1 may have a flow capacity of less than 20 cfs. Downstream from the Mariposa Bypass, Reach 4B2 has greater capacity than Reach 4B1 and regularly conveys agricultural return flows and runoff.

Reach 5 includes levees that are part of the Federal/State flood control project for the San Joaquin River. Reach 5 is bounded on the west bank by Federal/State levees downstream to the Salt Slough confluence and on the east bank to the Merced River confluence. Reach 5 has become incised since completion of Friant Dam.

Chowchilla, Eastside, and Mariposa bypasses were designed to conveys water during high-water conditions to prevent flooding. Currently, water at the downstream end of Reach 4A flows to the bypasses rather than into Reach 4B. Many of the levees along the bypasses seep water into adjacent fields during flood events. During floods, sand from Reach 2 is conveyed into the bypass.

The Eastside Bypass extends from Ash Slough to the head of Reach 5. The Eastside Bypass receives flows from the Chowchilla Bypass, Sand Slough, the Chowchilla River, the Mariposa Bypass, and Deadman, Owens and Bear creeks.

Management Plan Structure

The Restoration Area has changed dramatically since the completion of Friant Dam, and the conditions which the Settlement provides for restoration of salmon runs to the San Joaquin River are considerably different than what may have existed 200 years ago. As a result, Restoration will be guided by adaptation to information collected by several management plans.

Settlement stipulates the restoration Spring-run Chinook salmon, and monitoring of releases to do so. Additional monitoring requirements will be needed for flood control, and the avoidance of seepage impacts to third parties and biological conditions within the river. Seepage impacts result when the Restoration Flows raise groundwater tables in adjacent farm lands. These complex physical and biological monitoring efforts have been divided among management plans for Flow, Seepage, Vegetation, Sediment and Fisheries.

The management plans group actions by timeframe, decisions, and subject matter. Implementation of the various plans will be coordinated by the multi-agency SJRRP office. The SJRRP uses a simplified structure for each management plan. The following outline presents the common components of each management plan:

- **Objectives**: description of desired outcomes
- **Thresholds**: measurement which indicates an outcome or initiates an action.
- **Monitoring**: network of instrumentation, sampling schedule, and reporting.
- **Short-term Actions**: responses to reduce or avoid immediate impacts.
- **Long-term Institutional and Structural Modifications**: policy documents, construction, or mitigation activities to increase operation flexibility where goals cannot be reached.

Experimentation will play a key role in implementation of the Restoration Program. The SJRRP management plans do not prescribe how the program will adapt and change. Changes to Program implementation are expected to come from the review and recommendation of the SJRRP workgroups with representatives from all implementing agencies.

Monitoring Programs

Monitoring objectives contribute toward known needs for meeting the Restoration and Water Management goals, and in avoiding adverse impacts to Third Parties. A physical monitoring plan has been drafted for measuring flow, water quality, groundwater and seepage, sediment transport and morphology, and vegetation growth resulting from implementation of Interim Flows and Restoration Flows. A Fisheries Management Plan (FMP) includes objectives in monitoring for fisheries benefits. New information and changing objectives through time may result in alteration to the monitoring plan. This paper describes the long-term monitoring efforts. Implementation may require numerous studies with shorter-term objectives beyond the scope of this document.

Flow Monitoring

The Settlement requires that flows be measured at six locations between Friant Dam and the Merced River (e.g., Friant Dam release, Gravelly Ford, below the Chowchilla Bifurcation Structure, below Sack Dam, Top of Reach 4B, and Merced River confluence). A combination of existing gages, retrofitted gages, and newly constructed gages will be used to satisfy the requirement.

Water Quality Monitoring

Adverse impacts to water quality may limit the operation of the SJRRP. Water quality monitoring is planned for 10 locations along the San Joaquin River (e.g., Friant Dam, below Friant Dam, Gravelly Ford, below the Chowchilla Bifurcation Structure, Mendota, below Sack Dam, top of Reach 4B, Fremont Ford Bridge, Hills Ferry, and Crows Landing). The SJRRP will coordinate with water quality data being collected for the Central Valley Project Baseline Water Quality Monitoring Program (full Title 22 organic and inorganic compounds, plus bacterial) and Grassland Bypass Project (nitrate, ammonia, total kjeldahl nitrogen, total phosphate, and ortho phosphate). Other water quality parameters to be measured include: electrical conductivity (salinity), temperature, pH, dissolved oxygen, turbidity, and chlorophyll. Future efforts will include a list of short term monitoring.

Groundwater and Seepage Monitoring

Monitoring of seepage includes combining data from surface water discharges, diversions, groundwater conditions, and groundwater extractions in the vicinity of the San Joaquin River. Monitoring of groundwater levels, streamflow, river stage, land use, and geophysical data provide information to understand surface–ground- water interactions by capturing the variability in groundwater levels. Monitoring of groundwater levels and river stage will help to determine whether seepage losses increase and result in impacts to areas with productive lands. To meet river losses and bank seepage monitoring requirements, a series of monitoring wells will be used to measure groundwater levels along selected transects through the San Joaquin River. A total of 144 new groundwater wells are planned, including: nine in Reach 1A, twenty-one in Reach 1B, thirty-four along six transects in Reach 2A, seven along one transect in Reach 2B, nineteen along three transects in Reach 3, eighteen along three transects in Reach 4A, eighteen along three transects in Reach 4B, eighteen along three transects in Reach 5.

Sediment Monitoring

Adverse impacts of sediment displacement may limit the operation of the program to meet the Restoration Goal of a self-sustaining Chinook salmon population. The sediment impacts include reduced channel capacity due to deposition, and infrastructure risk due to systemic scour. Maintenance of habitat also depends on sediment transport rates. Suspended and bed load sampling is planned at twelve locations, including: three sites in Reach 1A, one in Reach 1B, one in Reach 2A, two in Reach 2B, one in Reach 3, one in Reach 4A, two in Reach 4B, and one in Reach 5.

Measurements of bank erosion and river bed profile is planned at areas of high mobility and includes surveyed transects.

Vegetation Monitoring

Vegetation monitoring seeks to establish habitat conducive to fish and avoid the spread of invasive species. A component of the Restoration Flows includes a volume of water for shaping to recruit native willow and cottonwood species. Vegetation monitoring includes observing seed dispersal to determine the likely timing. Transects to monitor seedling establishment will identify the risk of desiccation. Regular aerial flights will record the growth of vegetation and potential encroachment on flood conveyance capacity.

FISHERIES MONITORING PROGRAM

Monitoring is a critical component in the adaptive management process and will be used to assess the performance in terms of meeting the Restoration Goal. The monitoring and evaluation methods were developed to assess the performance of the SJRRP through monitoring in accordance with guidance developed by the CALFED Performances Measures Report, Phase 1 (CALFED 2007). The FMP identifies three types of monitoring needs, each useful at a separate stage of the Adaptive Management Approach. Limiting factor monitoring and assessment is a necessary precursor to the development of potential actions, and is used to verify the

prioritization of limiting factors and goals of the conceptual models. This type of monitoring also is useful to fill important life history information gaps, which are in turn useful for the development of quantitative models. Action-specific monitoring is used to determine the effectiveness of all types of restoration actions to identify the success of actions and incorporate new information into the SJRRP Adaptive Management Approach. Program-level monitoring is designed to measure the success of the program in meeting the Restoration Goal. Program-level monitoring is generally at the fisheries population-level, and consists of the measurement of elements such as escapement levels, viability values, and genetic fitness.

Table 2 summarizes monitoring activities and objectives from the FMP.

Table 2. Summary of the SJRRP Fisheries Monitoring Elements.

Monitoring Element	Performance Measure
Migration timing for Chinook salmon	Temporal and spatial occurrence of adult and juvenile fish
Adult Chinook salmon escapement	Number of spawning Chinook salmon
Egg survival and emergence	Early life history survival (e.g., egg survival, number of fry per redd)
Chinook salmon juvenile recruitment	Number of outmigrating smolts
Fish health	Fish body condition and survival rate
Genetic fitness	Genetic diversity and effective population size
Food supply	Maximized growth rates and accelerated smoltification
Predation	Egg, juvenile and adult Chinook salmon predation rates
Harvest	Impact of harvest on salmonid populations
Straying	Number of adult Chinook salmon that stray into false migration diversions
Entrainment	Number of juvenile Chinook salmon entrained in diversions
Juvenile stranding	Stranding rate
Migration and passage of other fish	Passage for other fish at structures
Individual, community and population condition	Fish community condition
Streamflow	Meet at least minimum passage requirements for adult Chinook salmon; Number of successful outmigrants; Holding pool habitat capacity and quality; Depth, velocity and flow conditions during spawning; Spawning gravel quality and quantity in Reach 1
Gravel recruitment	Spawning habitat quality and quantity in Reach 1
Holding pool habitat	Holding pool capacity and quality
Water temperature	Maintain sufficient water temperature for adult passage Maintain sufficient water temperature for juvenile and adult

	salmonids to meet the Restoration Goal
Water quality	Maintain suitable water quality to meet the Restoration Goal
Instream habitat, floodplain inundation, and riparian vegetation	Floodplain inundation frequency and accessibility for Chinook salmon and other fish; Instream habitat and riparian vegetation quality

Next Steps

The Stipulation of Settlement provides a framework to return flows and fish to the San Joaquin River but left considerable flexibility in implementation. Restoration will require rebuilding a substantial portion of the river while learning how to operate a new system within the confines of agency authority. A dramatic change from historical conditions and limited information will require innovative solutions which develop and improve through time. Monitoring provides information to support operational decisions and hypotheses on how to make the most of available water for river restoration while providing water supply to the rich agricultural lands of the Southern Central Valley, CA. The Program maintains a web site for public information at www.restoresjr.net. The monitoring program begins with the first release of flows in October 2009.

ABSTRACT

The Austin Clean Water Program (ACWP or Program) was created in 2001 to assist the City of Austin in meeting the terms of a USEPA Administrative Order that required the City to address its overflow problems by 2009. With a database of more than two thousand defects and overflows, it was not immediately obvious how the City should proceed. The City and the Program were under significant time constraints with less than eight years available to establish a course of action and then design and build the needed improvements. This paper describes the decision making process used to identify the improvements included in the program. A flow down approach was employed to systematically identify the system deficiencies and associated remedies that were likely to accomplish the objectives of the Program. The final Program now consists of one hundred collection system rehabilitation, repair or replacement projects with a total cost of 350 million dollars.

BACKGROUND

Austin Texas is the 16th largest city in the United States with a 2000 census population of 656,562 and an estimated 2007 population of 743,074. The city is situated along the Colorado River at the boundary between the Texas coastal plain and the Edwards Plateau formed by the Balcones Escarpment. The Austin Water Utility provides water and wastewater services to the City of Austin and a few adjacent communities and independent systems. The city's first wastewater treatment facility was built in 1917 on the banks of the Lower Colorado River. The facility used a tank for the settling of wastewater solids. In 1937, the tank system was replaced by the Govalle Wastewater Treatment Plant, a revolutionary facility utilizing a relatively new treatment process using activated sludge. As the City grew, the sanitary sewer system evolved along the natural gravity paths that followed the different creeks. As was common practice early in building sanitary sewers, many were located within the creek beds.

Today, the city's sewersheds are delineated along the 47 different watershed boundaries. The Govalle plant was recently taken off line and there are two newer, major wastewater treatment plants in operation; the South Austin Regional and
